subcutaneous tissue by extensions (retinacula cutis). The deepest sweat coils (► [Chaps. 27, “Infrared Densitometry for In Vitro Tape Strip-ping: Quantification of Porcine Corneocytes,”](#) and ► [1, “The Human Skin: An Overview”](#)) and the bulbs of the terminal hairs in anagen phase are located in subcutaneous protrusions into the dermis. In some parts of the body, the subcutaneous tissue contains a thin layer of muscle, the subcutaneous muscle or panniculus carnosus. In humans, this muscle is only present in the neck and testis, while in most mammals this subcutaneous muscle covers most of the trunk. In humans (and also in pigs), there is one of more thin membranous layers (stratum membranosum) within the subcutaneous tissue that in some parts of the body separates subcutaneous tissue into two distinct zones: a fatty superficial layer (Camper’s fascia) and a thinner, more membranous deeper layer (Scarpa’s fascia).

There is some debate on the correct nomenclature of the membranous layers within subcutaneous tissue, with some referring to it as “subcutaneous fascia,” while others have argued that this term should be used to designate the entire subcutaneous tissue and the membranous layer (s) designated as a “membranous layer(s) within the subcutaneous fascia” (Abu-Hijleh et al. [2006](#); Benjamin [2009](#); Lancerotto et al. [2011](#)).

The loose structure of subcutaneous tissue makes it a path for blood and lymphatic vessels and nerves going to or coming from distant body sites; their course is short on the trunk and the cephalic areas and long on the limbs because of the elongation and deformation of the metameres during intrauterine limb growth. Additionally, the subcutaneous tissue holds a specific nervous structure, the Pacinian corpuscle, which acts as a mechanical pressure detector, as well as free nerve ending, especially in the part of subcutaneous tissue adjacent to perimuscular fasciae (Corey et al. [2011](#); Hoheisel et al. [2011](#); Tesarz et al. [2011](#)). Finally it contains the subcutaneous adipose tissue which is an organ in itself.

Subcutaneous tissue is much more compliant than both dermis and perimuscular fasciae (Iatrdis et al. [2003](#)). Since it is situated between

these less compliant structures, subcutaneous tissue is responsible for much of the deformation, or strain, that develops within non-muscle soft tissues as a result of externally or internally generated mechanical forces.

1.2 Interstitial Pressure

The interstitial pressure in the absence of mechanical stress has been studied in animals using a capsule with holes which has been inserted in the subcutaneous tissue and left in place until the end of the traumatic inflammation. Within the capsule, the pressure is negative and approximates 6 Torr (1 Torr = 1 mmHg (in honor of Torricelli)) (Brace and Guyton [1979](#)). There is recent evidence that connective tissue fibroblasts actively participate in regulating interstitial fluid pressure and transcapillary fluid flow. A defining characteristic of areolar connective tissue is its loose collagen mesh filled with polyanionic glycosaminoglycans that bind large quantities of water. Reed et al. demonstrated that tension exerted by fibroblasts via integrins onto the collagen network restrains the loose matrix from excessively swelling by preventing osmotically active glycosaminoglycans from becoming maximally hydrated. One can thus think of areolar connective tissue as a meshwork with pores partially occupied by cells (fibroblasts) that hold on to the sides of the pores, keeping the mesh within a certain average pore size that prevents swelling (Reed and Rubin [2010](#); Wiig et al. [2003](#)). During acute inflammation, loss of integrin-mediated cell-matrix tension results in a rapid drop in interstitial fluid pressure (becoming much more negative), causing a large rise in transcapillary fluid flux and the formation of edema.

1.3 Molecular Transfer Function

Insofar as blood capillaries run through the subcutaneous interstitium, exchanges and molecular transfers can occur. They are passive and regulated by the diffusion laws (Fick’s laws). The

following formula applies to the passage from the blood capillaries toward the interstitial tissue:

$$J = K_f(P - p) - (\pi_d - \pi)$$

where J (moles $\text{cm}^{-2} \text{h}^{-1}$) is the flow, P and p are the perfusion and oncotic pressures in the capillary, and π_d and π the electrostatic and osmotic pressures in the ground substance. These exchanges apply especially to water and small molecules. However the capillary wall is not completely impermeable to proteins, resulting in a slow and continuous flow of large molecules into the interstitial tissue where the concentration in proteins reaches a quarter to three quarters of the plasmatic concentration (Renkin and Crone 1996). These proteins are first captured by the lymphatic capillaries and then drained toward the central veins (40–72-h cycle) (Renkin and Crone 1996). In case of edema, the distance over which metabolic exchanges have to be made is increased, which favors the occurrence of decubitus ulcers.

1.4 Shape Preservation

One of the major functions of the connective tissues is to preserve the overall shape of soft tissues (Scott 1975). The same applies to the subcutaneous connective tissue, which keeps the skin closely round the relief of the muscles and underlying bones. This function is secured by the gel nature of the ground substance and its hydration. In case of extracellular dehydration, the subcutis turgor decreases and loses its elasticity: the lower recovery of skin when it is raised is a sign frequently used in medicine. During aging the GAGs content decreases, inducing the laxity of the tissue.

1.5 Mechanical Function

The “looseness” of subcutaneous tissue allows the skin to be lifted up and moved laterally. Where the subcutis is absent (e.g., in a grafted area), the skin

cannot be moved and is very fragile on friction. Limb movements also need skin sliding over joints and consequently subcutaneous shear. The looseness of areolar connective tissue layers within subcutaneous tissue also allows for some amount of “internal” gliding relative to stiffer adjacent membranous fascia layers (such as the subcutaneous membranous fascia layer mentioned above and perimuscular fasciae). In humans and animals, shear strain between subcutaneous connective tissue layers can be measured with ultrasound elastography.

Until recently, the stiffness of connective tissue was thought to be determined by the material properties of the extracellular matrix. It is now apparent that, at least in rodents, fibroblasts within “loose” areolar connective tissue play an active role in regulating the tension of the tissue. When the tissue is stretched, fibroblasts expand by actively remodeling their cytoskeleton (Langevin et al. 2005). This change in fibroblast shape is accompanied by the extracellular release of ATP and results in a drop in tissue tension (Langevin et al. 2011, 2013b). Whether similar tension regulation also occurs in humans remains unknown but could be important for adjusting interstitial fluid pressure and transcapillary fluid flow and prevent swelling when the tissue is stretched during body movements (Langevin et al. 2013a).

The deformability of subcutaneous tissue is anisotropic as moving the skin is easier in a specific direction. On the other hand, the filling of the subcutis by adipose tissue contributes to skin being permanently stretched. On the body sites subjected to high or prolonged external pressures, the adipose tissue forms a cushion which distributes the force on a larger area. Physiological body pressure sites (soles, buttocks) are provided with a thick fat (or muscular) mattress. The loss of adipose layer on the metatarsal heads is associated with thickened stratum corneum and callus formation. Subcutaneous fat-deprived people are prone to decubitus ulcers and pressure sores (type 1 pressure sore). However overweight people also are likely to develop such wounds. A lower mechanical resistance of subcutaneous tissue to shearing forces facilitates excessive sliding

of skin over bones when in semirecumbent position and results in endothelial damage of vessels crossing the fascia and their further occlusion and thrombosis. This is the most current mechanism of type 2 decubitus ulcers (Exton-Smith 1983).

2 The Subcutaneous Adipose Tissue

Humans, as aquatic mammals, are endowed with a subcutaneous adipose layer over their whole body (Vague et al. 1974), even in conditions of great thinness. Subcutaneous fat is absent on a few areas only: the eyelids, nose, ear pinna, and male genitalia. This adipose layer is in general thicker in females. It is one of the two components of the total fat mass, the other one being the deep adipose tissue. In addition to the well-developed cells, both contain a fraction of immature adipocytes that may grow upon endocrine stimuli and lead to obesity. The subsequent metabolic problems apply especially to deep adipose tissue.

2.1 White Adipose Tissue: Morphology

Adipocytes are voluminous cells (Table 1) compacted in lobules separated by thin connective tissue septa where run vessels and nerves. Each lobule has its own arteriole (Sudan and Payan 1974). The cells, round or deformed by mutual pressure, have a more or less regular diameter (about 50 µm). They harbor an enormous single

lipidic vesicle devoid of membrane (Sudan and Payan 1974) and on the periphery a pushed away thin ring of 0.2–0.3-µm-thick cytoplasm containing a flattened nucleus. The adipocyte is surrounded by a regular and continuous basal membrane and a loose connective tissue (interstitium). The latter is made not of bundles but of isolated collagen fibers. It contains, very close to the cells, vessels without pericytes and an amyelinic nerve network. Neither naked axons nor contact with adipocyte membrane is found. Some fibroblasts, mast cells, and macrophages are visible (Sudan and Payan 1974), as well as a few adipoblasts, which are oblong cells with abundant cytoplasm and one or several small lipidic vacuoles. Adipogenesis is still possible in adults (Sudan and Payan 1974).

Adipocyte volume, as measured with Sjostrom and Bjorntrop’s technique (Sjostrom et al. 1971), is usually larger in the subcutaneous tissue than around internal organs. It also shows a great variation according to body sites and sex (Fried and Kral 1987), being larger on the hips than on the shoulders in females and children and generally smaller in males (Table 1). Weight loss induced by sport reduces the adipocytes size, not their number.

2.2 Body Fat Mass and Subcutaneous Fat

Body fat mass decreases in males after the age of 13, whereas in females it still increases until adulthood (Table 2) and then keeps higher than in males over the whole life span (Table 3). In both

Table 1 Adipocytes mean volume (nl) (mean ± 2 sem) (Vague et al. 1984)

	Males		n	Females		n

70–91	0.46 ± 0.09	0.46 ± 0.09	13	0.53 ± 0.06	0.59 ± 0.06	22

sexes, it increases with age up to the 60s. Until the age of 15, in both sexes, fat is predominant on the lower part of the body. The same applies in women until the age of 50, at which time the fat increases in the upper part of the body, together with the body fat mass. In males, from puberty to old age, the fat is mostly located in the upper part of the body (Rebuffé-Scrive 1988; Vague et al. 1984; Table 4). This distribution is also found in obese subjects who are classified in two main categories: gynoid type if the subcutaneous fat accumulation is found mainly on the hips and thighs and android type if it is located preferentially on the upper part of the trunk and the abdomen. Android type obesity is associated with visceral deposits and an increased risk of arterial

occlusive disease. Chubby cheeks are positively correlated with visceral obesity (Levine et al. 1998), as shown by computed tomography, but not with the subcutaneous fat thickness.

2.3 Energetic Function

The adipose tissue's main function is to serve as the most important energy store of the organism. In normal conditions, it represents 10 % of the body weight or 40 days of energy expenditures, stored in the lipidic vesicle in the form of triglycerides (Black and Cunliffe 1998). In spite of histological appearance, the adipose tissue is very active: its metabolic rate is identical to that of the kidney, half that of the liver (Jungermann and Barth 1996).

After a meal, the chylomicrons of the circulating VLDL are hydrolyzed by the lipoprotein-lipase at the endothelial surface of the capillaries, and their fatty acids are captured by adipocytes, where, in the endoplasmic reticulum, they are transformed into triglyceride. Insulin stimulates fatty acids and glucose capture, together with fatty acids and triglyceride synthesis within the cell.

Releasing energy from adipose tissue consists in triglyceride hydrolysis into fatty acids by triglyceride-lipase (within the adipocyte endoplasmic reticulum), an event triggered by

Table 2 Fraction of fat tissue in body weight (%), as measured from content in triglycerides (France 1970–1980) (mean \pm 2 sem) (Vague et al. 1984)

Age group	Male	n	Female	n

glucagon and catecholamines. Oxidation by the peripheral tissues of these fatty acids may represent 80 % of the basal consumption of oxygen. Inside the adipocyte, lipolysis is facilitated by activation of β receptors (formation of cyclic AMP) (Mauriege et al. 1988), the contrary occurring when α receptors are activated. Cyclic AMP is destroyed by phosphodiesterase, but the latter is inhibited by theophylline (1.3 dimethylxanthine), hence the use of this product and caffeine (1.3,7 trimethylxanthine) as lipolytic. However the intensity of the response varies with body sites and sex; it depends on the relative proportion of β and α receptors. α_2 receptors outnumber β receptors in the subcutaneous adipocytes, whereas they are found in similar quantities in the omental adipocytes (Mauriege et al. 1987). In females, the subcutaneous adipocytes of the gluteal and femoral areas have more α than β receptors and are larger than in males (Richelsen 1986). The lipoprotein-lipase activity is also higher (Fried and Kral 1987). It would be increased in situ by estrogen or progesterone injection (Rebuffé-Scrive 1987; Rebuffé-Scrive et al. 1985).

In addition to the release of fatty acids, other lipids, and metabolites, adipose tissue secretes several hundreds of identified bioactive factors (adipokines) including leptin, adiponectin, apelin, and vaspin that influence local adipogenesis, immune cell migration into adipose tissue, and adipocyte metabolism and function, as well as regulate metabolic processes in the brain, liver, muscle, vasculature, heart, and pancreatic β -cells

(Cao 2014). Leptin (LPT), a 167-amino-acid protein, is secreted by adipocytes as soon as the lipid supply is sufficient. LPT inhibits the hypothalamic center for hunger and reduces the synthesis and release of the neuropeptide Y, which increases food intake, reduces thermogenesis, and increases insulin blood level. In short, LPT regulates the feeding habits, the metabolic level, the autonomous nervous system control, and the energetic equilibrium. LPT blood level is a reflection of body fat mass. For a similar BMI, it is much higher in women (testosterone would inhibit LPT synthesis and secretion). In obese subjects, the efficiency of the LPT is reduced and hyperleptinemia is observed. A lipid-rich diet would facilitate the resistance to LPT (Friedman 2000).

Adipoblasts can differentiate into adipocytes and therefore increase the fat mass when they mature. This transformation would require the action of plasminogen, after the fibronectin matrix which surrounds the adipoblast has been degraded by the plasma kallikrein (Selvarajan et al. 2001).

Although visceral adipose tissue was for decades considered a major culprit in development of the metabolic syndrome, recent evidence indicates that subcutaneous adipose tissue, especially on the trunk, also can be involved in the development of insulin resistance. Decreased adipocyte differentiation leading to adipocyte hypertrophy and spillover of free fatty acids can lead to local inflammation as well as ectopic fat deposition in other tissues such as liver and pancreas (Patel and Abate 2013).

2.4 Thermal Function

The subcutaneous adipose tissue contributes to the thermal insulation of the organism. The fatty areas (gluteus, outer sides of the arms, and thighs in children and women) are usually the coldest ones. The thermal inertia of fat is low: $22\text{--}32 \cdot 10^{-5} \text{ cal}^2 \cdot \text{cm}^{-4} \cdot \text{C}^{-2} \cdot \text{s}^{-1}$, whereas that of the skin without subcutis is higher than $90 \text{ cal}^2 \cdot \text{cm}^{-4} \cdot \text{C}^{-2} \cdot \text{s}^{-1}$ (Houdas and Guieu 1977). This property is most useful to protect the inner organs (the core) in hot as well as cold environment, a

situation that should have been endured by many primitive humans.

2.5 Aesthetic Function

The body distribution of the subcutaneous adipose tissue is an essential component of the male and female morphology: predominance on shoulders and thorax in males and hips and buttocks in females. In the latter, the relief of the limb muscles is lightly marked, as it is masked by the adipose tissue. On the face, adipose tissue reduction preceding skin hyperlaxity is often the first sign of aging: in cases of obesity, the chubby cheeks maintain a barely wrinkled aspect on the face longer. Filling is a technique used in cosmetic surgery to compensate for a reduced adipose tissue. In infants under a year, the subcutaneous adipose tissue thickness, especially in the face and limbs, gives the child a typical morphology. It is likely to be an energy reserve before the start of a period where growth, standing, and exercise will be simultaneously acted.

2.6 Brown Fat

Brown fat has long been known for its thermogenic functions in hibernating animals. The morphology of their adipocytes is very specific because of the multilocular distribution of the adipose vesicles (Lever and Schaumburg-Lever 1983). It was, until recently, thought to be vestigial in humans and present mainly in fetus and newborns. However, the role of brown and “beige” fat is now being reexamined with the new understanding and knowledge that adipocytes within white adipose tissue can be induced to become thermogenic, especially after cold exposure (Lee et al. 2014; Peirce et al. 2014).

2.7 Conclusion

The subcutis is an area of the body that has received comparatively little attention, compared

with the skin and underlying muscles. The anatomical continuity between the subcutaneous connective tissues, especially the membranous layers, and the fasciae enveloping muscles, is recently being appreciated from the points of view of biomechanics and sensory perception. There is no doubt that further incorporation of subcutaneous tissue into our understanding of the cutaneous, adipose, and musculoskeletal systems will inform our understanding of whole-body physiology.

Keywords

Adipomuscular ratio • Adipose tissue • Bioelectrical impedance analysis (BIA) • Body mass index (BMI) • Connective subcutaneous tissue • Dual X-ray absorptiometry (DXA) • Fat Mass Distribution • Guyton's technique • Subcutis oxygen partial pressure • Skinfold thickness • Waist circumference • Waist–hip ratio

The subcutis (or hypodermis) harbors two types of tissue: the loose connective tissue, where blood, lymphatic vessels, and nerves find a path to muscles, bones, and skin (often at a distance as far as limbs are concerned); and the subcutaneous adipose tissue. Their physiology is different (see ► [Chap. 41, “Dermis Connective tissue histopathology”](#)) but their metrology often uses the same techniques.

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

1 Metrology of the Adipose Tissue**1.1 Global Assessment**

Adipose tissue is the energy reservoir of the organism. It provides for the basal metabolic rate and the additional energy needs whenever they are not entirely fulfilled by the diet. Hence the importance of its measurement or even approximate assessment.

In healthy adults, the fat mass amounts to 10–15 % of the body weight in men, 15–25 %

in women. In both sexes it increases with age. This tissue is distributed in two distinct areas: the deep or visceral fat and the subcutaneous fat. Although there are many differences according to ethnic types, the visceral fat is especially developed within the mesentery, retroperitoneal area, and intermuscular spaces. The subcutaneous fat is present at all body sites (see ► Chap. 41, “Dermis Connective tissue histopathology”), although it is mostly developed in specific areas that vary with age and sex. Its development is not necessarily connected with that of the visceral fat, even in obese patients. Accordingly, obesity cannot be assessed by subcutaneous fat only (Rudolf et al. 2001). However, it seems that the buccal adipose tissue (buccal fat pad) may be a marker of visceral fat (Levine et al. 1996).

For the last 60 years, several methods have been devised to assess body fat. The first uses the difference in density between fat (0.90 g/cm^3) and nonfat tissue (1.10 g/cm^3) to calculate the proportion of the body weight that is lean mass and fat mass by underwater weighing (hydrodensitometry) (Behnke et al. 1942). Two other methods are based on calculating the lean mass and deducing the fat mass by subtraction from the body weight (Wahner and Fogelman 1994). Lean mass is assessed either through measurement of total body potassium counting (by ^{40}K low-level counting) assumed to be a body weight constant fraction (60 mmol/kg in females, 66 mmol/kg in males), or through total body water measurement by heavy water (a nonradioactive isotope) dilution, also assumed to be a body weight constant fraction (73.2 %). These methods are now used only by research laboratories and will not be described here.

Today two techniques are widely used for assessing the global fat mass: a simple and rather inexpensive one, the bioelectrical impedance assessment, and a more sophisticated and expensive one, dual X-ray absorptiometry (DXA).

1.1.1 Dual X-Ray Absorptiometry

Dual X-ray absorptiometry (DXA) is mainly used to quantify bone density, especially in osteoporosis, and has superseded dual photon absorptiometry (DPA) using the ^{153}Gd

radionuclide source, but based on the same rationale. It uses X-ray with two energy levels (either 38 and 67 keV, or 40 and 100 keV). While propagating, the X-ray energy decreases depending on its initial level and on the composition of the traversed tissues. It is thus possible first to assess body mineral content (BMC) from the calcium-rich (bone) mass assumed to be a constant fraction (approximately 37 %) of the mineral component. Further on, the (non-mineral) soft tissue mass is partitioned into fat and (water-equivalent) lean body mass by a calibration procedure based on the attenuation of the soft tissue outside the bone (Wahner and Fogelman 1994). The composition of soft tissue is given by the R value, which is the ratio of beam attenuation at the lower energy relative to that at the higher energy. However, the raw data must be adjusted for body size. Accordingly, the following equation has been proposed for Caucasian females (based on $n=203$, aged 47.7 ± 12.9 years):

$$\begin{aligned} \text{Total body fat (kg)} &= 25.25 - 0.35 \text{ height (cm)} \\ &\quad + 0.84 \text{ weight (kg)} \\ &\quad + 0.056 \text{ age (y)} \end{aligned}$$

In the same paper, other equations are proposed for lean mass, muscle mass, bone mineral content, for trunk, leg fat, etc. and also for black females (Aloia et al. 1999).

The technique comprises a series of transverse (front-to-back) scans made from head to toe at 1-cm intervals, the total scan time lying between 10 and 20 min. The intraindividual variation coefficient is below 5 %, even in obese subjects. The radiation dose is 12 μSv (sievert) for a spine investigation, and 0.6 μSv for total body scan (for a simple chest roentgenogram irradiation is 2–5 μSv) (The International Committee for Radiation Protection maximum authorized dose is 50,000 $\mu\text{Sv}/\text{year}$. It will be lowered to 100,000 μSv over 5 years.).

It is possible to divide the total body scan into regional measurements (e.g., arms, legs, trunk, and head) and calculate the fat mass in each of these areas (Aloia et al. 1999; Mazess et al. 1990) (Table 1). Accordingly, the method can be used

Table 1 Fat and nonfat components in soft tissue of three body regions as found by DXA. Mean±SD; *n* = 6 males and 6 females. (Modified from Mazess et al. 1990)

Region	Fat tissue (g) males	Females	Lean tissue (g) males	Females
Arms	887±138	1,566±142	6,595±253	3,665±169
Legs	4,118±430	7,791±374	22,181±360	15,887±428
Trunk	4,274±459	7,072±436	26,237±530	17,504±499

for assessing the fat mass distribution (see Sect. 1.2) or the degree of fatness of a lower limb (e.g., in the follow-up of thigh cellulitis). However, it cannot give the tissue composition of a single transverse scan because X-scanning is only anterior-posterior.

Commercial instruments have their own software and calibration system and usually give slightly different results:

1.1.2 Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA), a recently renewed method, is currently used by practitioners and nutritionists. It is a measurement of body water through its ability to conduct electric current. Impedance is extrapolated through a circular regression between reactance and resistance, the former being related to cell membranes and the latter to water conductivity. Total water (about two-thirds of body weight) is assessed by impedance at 1 MHz, and extracellular water by impedance at 5 kHz (Boulier et al. 1992). Water is located only within the lean mass, and its part depends on body size, sex, and age. From measurements in healthy subjects, predictive equations have been devised using height, weight, and age in various combinations (Hendel et al. 1996; Stolarczvk et al. 1997; Segal et al. 1988), which can compute the lean mass from the assessed total body impedance (Segal et al. (1988) have proposed four equations, each of them specific to a group: obese women (>30 %

body fat), nonobese women (<30 % body fat), obese men (>20 % body fat), and nonobese men (<20 % body fat). For obviously nonobese female and male subjects, the Segal BIA average method can be used safely for their classification in low-fatness groups, thus avoiding lengthy measurements (Stolarczvk et al. 1997)). Finally, the fat mass is obtained by subtracting lean mass from body weight.

Most current devices use only 50 kHz and leg-to-leg BIA (Utter et al. 1999) (Biometer, Spengler Electronic, 94230 Cachan, France; TBF 521, Tanita Corporation of America, Inc, Arlington Heights, IL, USA). The battery-operated device resembles a portable scale where anterior feet and heel sites are separated and make up both scales and electrodes. The patient stands immobile on the device, and the weight first, then the fat mass are displayed on the connected computer. Other devices use several frequencies (5, 50, 100, 1000 kHz) and in addition assess total intracellular and extracellular body water (Analycor XF, Spengler Electronic, 94230 Cachan, France). The 1-MHz electrodes should by-pass the stratum corneum and consequently are thin needles to be inserted into the dermis or subcutis. In both cases, a chart is provided by the manufacturer, which makes it possible to position the obtained value relative to the normal range.

BIA has several advantages: low cost and portable devices, short duration of the assessment (less than 5 min), noninvasiveness (0.5 mA), and safety (battery operated). Like DXA, it estimates the total body fat and fat-free mass, and regional parameters. However, the measurement is indirect, based on assumptions relative to the body and lean mass water contents. It may not be valid for edematous or dehydrated people. In obese

patients, BIA is said to overestimate the lean mass relative to hydrodensitometry or DXA, mostly in tall people (Hendel et al. 1996; Carella et al. 1997).

1.1.3 Assessment of Fat Mass Normality: Body Mass Index

The body mass index (BMI) characterizes the body fatness, hence it is not the measurement of the body fat mass but an estimate of its normality. It is widely used in spite of being an approximation. $BMI = \text{weight (kg)} / (\text{body height})^2 \text{ (m}^2\text{)}$

Thinness	<18.5
Normal	18.5–24.9

The World Health Organization classification of the BMI (kg/m^2) for adults under 60 years is the following (World Health Organization 1997):

Overweight	25.0–29.9
Obesity	≥ 30.0
Class I	30.0–34.9: moderate or common obesity
Class II	35.0–39.5: severe obesity
Class III	≥ 40.0 : massive obesity

In men and women over the age of 35, the normal BMI is between 21 and 25. After the age of 65 it goes up to 29 in women (Jungermann and Barth 1996). The higher musculoskeletal mass in black women may lead to misclassification as obese if their BMI lies between 18 and 30. In such cases, composition values for mineral, fat, and muscle mass should preferably be obtained from DXA and adjusted for ethnic background. In children, obesity is stated if the weight exceeds 20 % of the ideal weight in relation to size, but a more precise normal range often depends on the country and nutritional habits. In France, BMI tables from birth to 87 years have been constructed (Rolland-Cachera et al. 1991). For children in the USA, the Center for Disease Control (Centre for Disease Control 2000) published BMI curves in June 2000, which apply to age brackets between 2 and 20. The same year, the International Obesity Task Force (IOTF) (Cole et al. 2000) established a new definition for obesity for worldwide use: children having a BMI

above the centile 1 ($25 \text{ kg}/\text{m}^2$) are considered obese.

1.2 Fat Mass Distribution

The DXA method is quite appropriate for the assessment of fat distribution over the body through quantification of regional fat masses, especially trunk and upper or lower limbs. Again, the raw values should be adjusted for height and race (see Sect. 1.1.1). However, easier to handle and inexpensive measurements are also available in clinical practice.

1.2.1 Waist–Hip Ratio

The waist–hip ratio (WHR) is the ratio between the waist circumference (at umbilical level) and the hip circumference (the largest one). It is of great value in case of obesity. Android obesity cut-offs for males are, $WHR > 1.0$, and for females, $WHR > 0.85$ (Black and Cunliffe 1998), and for the 40–49-year age group, > 0.95 and > 0.80 , respectively (Bray 1990). Android distribution is associated with a metabolic and cardiovascular risk associated with excess visceral fat.

1.2.2 Waist Circumference

According to some (Despres et al. 1991), waist circumference is more highly correlated with visceral abdominal fat than WHR. But its normal range varies with geographical regions and countries. For Caucasians, the upper limit of normality is 100 cm in men, 88 cm in women.

1.2.3 Adipomuscular Ratio

The adipomuscular ratio (AMR) is obtained by measuring, either at the upper arm or the thigh, the ratio of mean skinfold thickness (from four circumferential points: medial, lateral, anterior, posterior) to the limb perimeter (at the same site) (Vague et al. 1969, 1984). In females and males before the age of 15, this ratio is always higher in the thigh than in the upper arm. Normal values in a Caucasian population (France, 1960–1970) are quoted in ► Chap. 53, “Skin Capillaroscopy,”

Table 53.4. Using the ARM is somewhat outdated because DXA, impedance measurement, and computed tomography provide the same type of information with much better precision. Nevertheless, it can be still useful when modern equipment is not available.

1.3 Subcutaneous Fat Layer Thickness

1.3.1 Skinfold Thickness

The advantage of this old method is that it requires only a small and portable device, modified pinchers exerting constant pressure (Harpden Skinfold Caliper, Holtain Skinfold Caliper, Lange Caliper, etc.). The measurement must be done quickly (1–2 s) because under sustained pressure the fold thickness gradually decreases.

The measurement should be taken at four different sites, then calculate the sum (Σ 4SKF) (Lohman et al. 1988) ((1) triceps: a vertical fold measured on the midline of the posterior aspect of the upper arm, over the triceps muscle, at a point midway between the acromion and olecranon processes (elbow extended and relaxed); (2) biceps: a vertical fold on the anterior midline of the upper arm over the belly of the biceps muscle at the level of the triceps site; (3) subscapular: a diagonal fold just inferior to the inferior angle of the scapula; (4) suprailiac: a diagonal fold measured on the midaxillary line, immediately superior to the iliac crest (Lohman et al. 1988)).

To measure the subcutis thickness, it is essential to take two measurements on the same area:

first that of the big fold including both skin and subcutis, then that of the skin alone (a very thin superficial fold); the latter value is then deducted from the former. This precaution is not mentioned in most published results: it was probably considered that the skin thickness was negligible compared to that of the adipose panicle, or that this measurement was of no use for the comparative studies of several anatomical sites. However, the skin thickness measured in this way can exceed 2 mm. Comparisons with ultrasound measurement have confirmed that the dermis thickness cannot be disregarded. Accordingly, ultrasound measurements are preferable whenever possible.

Normal values in shoulders and hips (reference sites to measure obesity) are between 5 and 10 mm (Table 2). Great variation is observed with body sites. The tricipital skinfold (upper arm) alone would seem less sensitive than BMI to detect overweight (Rudolf et al. 2001).

1.3.2 Photograding of Mechanically Accentuated Macrorelief

In order to assess the efficiency of anticellulite treatments quantitatively, a skinfold-derived measurement technique of the subcutis has recently been developed (Perin et al. 2000). In this condition, subcutaneous nodules are found under palpation. The proposed technique consists in lifting the area of interest (about 20 cm²) using springs deeply pinching the skin on each side, and thus making the nodules bulge. A photograph under oblique light (30°) is then taken. It is quantified by comparison with a seven-degree photographic scale.

Table 2 Subcutaneous fat thickness (mm): mean \pm 2 SEM of skinfold (averaged circumferential measures at the same level: lateral, anterior, medial, posterior) (From Vague et al. 1984)

Age group (years)	Males upper arm	Hip	<i>n</i>	Females upper arm	Hip	<i>n</i>
5–9	5.4 \pm 0.7	14.8 \pm 1.8	17	6.7 \pm 0.8	18.4 \pm 2.2	9
10–14	5.5 \pm 0.6	16.3 \pm 1.9	24	8.3 \pm 1.0	26.4 \pm 3.2	17
15–19	5.8 \pm 0.6	10.0 \pm 1.2	22	10.9 \pm 1.2	30.5 \pm 3.8	25
20–29	6.3 \pm 0.7	9.7 \pm 1.1	42	10.9 \pm 1.3	31.3 \pm 3.5	53
30–39	6.2 \pm 0.7	8.6 \pm 1.0	22	10.4 \pm 1.2	31.5 \pm 3.9	21
40–49	6.3 \pm 0.7	9.1 \pm 1.1	27	10.6 \pm 1.2	31.6 \pm 4.0	20
50–69	6.4 \pm 0.9	9.4 \pm 1.0	13	11.1 \pm 1.4	29.1 \pm 4.1	14
70–91	5.8 \pm 0.8	8.3 \pm 1.0	13	9.1 \pm 1.1	13.3 \pm 1.8	22

1.3.3 Ultrasound Imaging

For subcutis imaging, the devices should use ultrasound frequencies between 2 and 10 MHz, which give resolutions of a few hundred micrometers and investigate depths over several millimeters. These frequencies achieve the best compromise between spatial resolution, which increases with frequency, and focusing depth, which decreases with frequency. To study adipose tissue, linear scanning probes are generally used. In practice, 7.5-, 10-, and 13-MHz frequencies give axial resolutions at best of 300, 150, and 120 μm , respectively, for exploration depths of 110, 50, and 20 mm, respectively (Fig. 1). The probe contact area is 3–5 cm^2 , the image displaying rate 10–50 images/s, and 128–512 echo lines on the image.

Adipose tissue imaging is easy and fast. Marked contrasts at the cutis-subcutis and subcutis-muscle interfaces allow easy observation and measure of tissue thickness (Fig. 2). The thigh subcutis thickness in normal women is between 20 mm and 60 mm, but may reach several hundred millimeters in obese subjects (Perin et al. 2000; Diridollou 2000; Schnebert et al. 1999; Pittet et al. 1996). Accordingly, on this particular site, 7.5–10-MHz frequencies provide the best compromise between a good axial resolution (150–300 μm) and an exploration depth up to 11 cm. Images of the same thigh area obtained at 7.5, 10, 13, and 20 MHz in the same subject

(Fig. 3a–d) illustrate the choice of frequency in relation to the requested information (cutis or subcutis thickness, observation of retinacula cutis or of connective bundles). Ultrasound imaging is sensitive enough to measure the fat tissue thickness variation in relation to the menstrual cycle (Perin et al. 2000; Pittet et al. 1996, 1997) and to assess the efficiency of anticellulite products (Schnebert et al. 1999; Armengol et al. 1992). The methodology must be rigorous, paying particular attention to subject's position, probe position, control of probe pressure on the skin, site marking. Several measurements should be taken per image.

A study on 20 women aged 18–35 years (weight 58.2 ± 6 kg) carried out by two operators (only one was experienced) showed that: (a) the subcutis thickness was 37.2 ± 7.2 mm, (b) the reproducibility was 1–5 % depending on the operator's expertise, and (c) the correlation coefficient between operators was 0.985 (Diridollou 2000).

The subcutaneous fat thickness on the abdomen (in front of the rectus muscle) and on the back (infrascapular region) in seven newborn babies (Petersen et al. 1995) measured using a 15-MHz A-mode ultrasound device is presented in Table 3.

A technique commonly used to measure skin thickness (Einsenheiss et al. 1998), 20-MHz B-mode imaging, rarely visualizes the deeper part of the subcutis owing to ultrasound

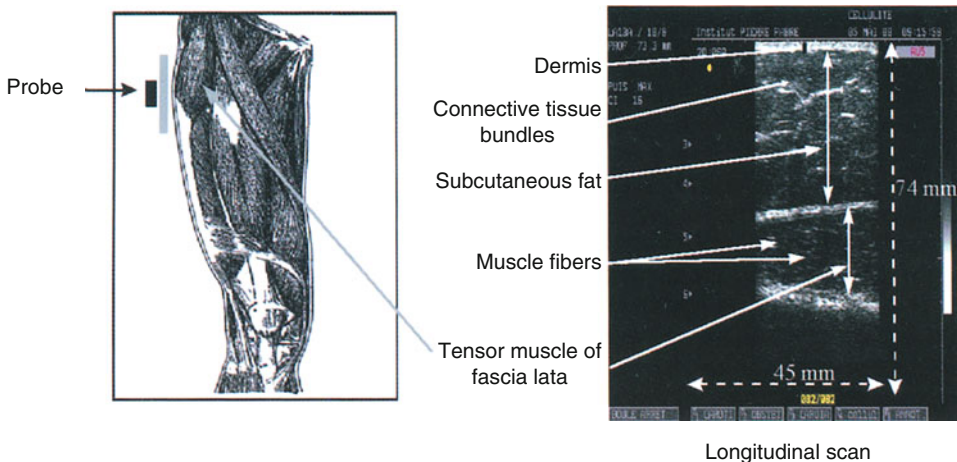

Fig. 1 A 7.5–10-MHz B-scan of the thigh, upper part lateral aspect. AU 5 (Esaote, Genoa, Italy) with a linear applicator

Fig. 2 A 10-MHz B-scan of the abdomen. Subcutis thickness: 26 mm. AU 5 (Esaote, Genoa, Italy) with a linear applicator

attenuation. However, it can be used to study the dermis-hypodermis interface, which is marked by anchoring dermal extensions within the hypodermis (retinacula cutis). Through summation of 28 images taken on a 482-mm² skin surface area (ultrasound C-mode imaging), the decrease in the actual-to-plane ratio interface area following treatment by massage in a case of cellulitis was demonstrated (Lucassen et al. 1997).

In conclusion, ultrasound imaging has the advantages of simplicity, rapidity, non-invasiveness, reliability, and reproducibility when associated with sound methodology. Its limitation is the substantial role of the operator's experience. The operator must pay particular attention to precise selection and marking out the investigated site, which is essential in repeat investigations.

1.3.4 Computed Tomography

Computed tomography (CT), an X-ray investigation method based on the analysis of reconstituted cross-sectional images, provides direct visualization and measurement of deep organs or structures. Its principle is X-ray differential transmission depending on the density,

atomic composition, and thickness of the tissues they pass through. Serial measurements of absorption density, through various angles of incidence, provide a set of profiles from which a cross-sectional image is reconstituted. Equipment is available mainly in hospitals. Measurements more and more sensitive with time: helix scanner scans are 0.5 mm apart. From several cross-sections, images in any other incident angle can be computed. A CT single cross-section at umbilical level irradiates 1 μ Sv, but usually several adjacent cross-sections are necessary, and there is always substantial overlap between cross-sections, so that the total irradiation can come close to 100 μ Sv.

Although CT is not perfectly adapted to the study of soft tissues, the subcutis fat can, nevertheless, be studied because its density is lower than that of the skin and muscle (Enzi et al. 1986). Both cutis-subcutis and subcutis-muscle interfaces can easily be visualized and the subcutis thickness measured (Figs. 4 and 5). Computed tomography also provides a reliable measurement of the oral adipose tissue (Levine et al. 1996) and, at the lumbar level (L2-L3 interval), of the abdominal and subcutaneous fat (Jensen

Fig. 3 (a–d) B-scan of the same area of the thigh, upper part lateral aspect. (a) 7.5 MHz. (b) 10 MHz. (c) 13 MHz. AU 5 (Esaote, Genoa, Italy). (d) 20 MHz Dermcup 2020 (2 MT, Labège, France)

Table 3 Neonate subcutis thickness (mm) ($n=7$), ultrasound A mode (From Petersen et al. 1995)

Body weight (g)	Abdomen	Back
1,095	0.65±0.07	0.77±0.10
1,810	0.78±0.13	0.95±0.13
1,940	1.52±0.20	1.53±0.16
2,900	1.67±0.17	1.87±0.19
3,390	1.80±0.16	1.74±0.23
3,890	1.95±0.31	1.84±0.27
4,750	2.90±0.22	2.45±0.24

et al. 1995). In a study of healthy subjects, the adipose tissue cross-sectional area was 8–20 cm² (cheeks), 16–100 cm² (visceral fat), and 20–150 cm² (subcutaneous fat).

The main advantage of CT is to provide cross-sectional images of any part of the body, thereby visualization and measurement of the subcutaneous fat thickness or amount at any site. The spatial resolution is about 1 mm. Rapidity and independence from the operator are clear advantages. Drawbacks include the use of X-ray (for a single cross-section at umbilical level irradiation is 0.01 Gy) and the expensive equipment available only in hospitals.

1.3.5 Nuclear Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) comes from nuclear magnetic resonance (NMR), which was developed in 1946 by Bloch and Purcell and was

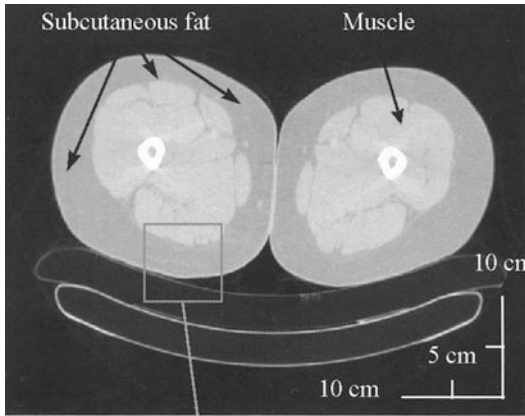

Fig. 4 Computed tomography cross-section of both thighs (Courtesy of Prof. Joffre, Radiology Department, Rangueil University Hospital, Toulouse, France)

Fig. 5 Computed tomography of the thigh. Part of cross-section with fat enhancement (Courtesy of Prof. Joffre, Radiology Department, Rangueil University Hospital, Toulouse, France)

first used in chemistry. In the early 1980s, a major step forward was made in medical imaging with two types of investigation: magnetic resonance imaging (MRI), which shows body cross-sectional images, and magnetic resonance spectrometry (MRS). Both applications are based on the tissue atom nucleus magnetic moments interacting with magnetic fields. Hydrogen atom nuclei are concerned in imaging, those of hydrogen and phosphor-31 in spectroscopy. The nuclear spins, when placed in an intense magnetic field, divert and line up with the field axis. They are then excited by a radio-frequency wave, which turns them perpendicularly to this axis (through a resonance phenomenon). When excitation stops, the spins gradually recover their basal position (nuclear relaxation). Two types of magnetic interaction are described, characterized by the longitudinal (T1) and transverse (T2) relaxation times. After treatment of this basic signal, information is given either as a spectrum (MRS) or an image (MRI).

From the MRI-generated signals, it is possible to reconstitute a cross-sectional image of any part of the body. Hydrogen is a major component of water and lipids. This accounts for the better performance of MRI as compared to CT in visualizing soft tissues and mostly adipose tissue. Fat is easily detected through its intense T1 signal, giving a bright area on the image. This makes it

possible to directly measure the thickness of the adipose layer (Figs. 6 and 7) and even to distinguish the connective tissue septa (Fig. 8). Nonfat nonbone tissues give a mid-intensity T1 or T2 signal and appear as grey areas (Fig. 8). Resolution is in the range of 70 μm to 1 mm, for investigation depths of a few millimeters to several centimeters, respectively. High resolutions are obtained by adding a special coil (see ► Chap. 41, “Dermis Connective Tissue Histopathology”). Furthermore, from the measurement of the relaxation times, MRI obtains data on lipid and water content of adipose tissue (Brix et al. 1993; Saiag et al. 1994; Krug et al. 1998; Richard et al. 1991, 1993; Lopez et al. 1997; Idy Peretti et al. 1998; Querleux et al. 1994, 1998, 2000; Franconi et al. 1995; Wright et al. 1998; Harada et al. 1994; Fowler et al. 1990; Schreiner et al. 1996).

The advantage of the method is the high-resolution images that give a precise measurement of adipose tissue thickness and distribution on cross-sections, without an operator’s direct intervention. Providing an image of tissue composition is a specific output, particularly useful for the determination of subcutis water and lipid contents.

Querleux et al. (2002) studied the anatomy and physiology of subcutaneous adipose tissue

Fig. 6 MRI cross-section of lower abdomen. T1 relaxation (Courtesy of Prof. Joffre, Radiology Department, Rangueil University Hospital, Toulouse, France)

Fig. 7 MRI cross-section of the thigh. T1 relaxation (Courtesy of Prof. Joffre, Radiology Department, Rangueil University Hospital, Toulouse, France)

in relation to sex and the presence of cellulite. The topography of the dermal-hypodermal junction and the three-dimensional architecture of the subcutaneous fibrous septae were investigated using high spatial resolution. In addition, water and lipid fractions within fat lobules were quantified using proton spectroscopy. A study involving 21 women with cellulite was undertaken, and the results compared to 20 women with no cellulite and 23 men. The data showed deeper indentations of adipose tissue into the dermis, increased dermal thickness, and an increase in thickness of the

deeper layer of subcutaneous adipose tissue. However, no change in water content or modification of unsaturated and saturated lipid fractions on a adipose tissue were observed in women with cellulite.

In conclusion, MRI is the most powerful tool for soft tissue imaging and quantification, especially fat tissue. It also provides cross-sections of any part of the body and from any angle. These advantages make it unique and irreplaceable. The drawback is the technical expense and complexity: MRI is meant for medical purposes and is available only in large hospitals (Fig. 9). It requires specifically trained staff and implies a long and stressful examination for volunteers. It is therefore a method reserved for research or exceptional circumstances.

2 Conclusion

Many methods are available today to investigate body fat. Choosing the appropriate ones depends on the objective of the measurement.

To demonstrate overweight or obesity and its type, BMI followed by WC and WHR are helpful and in current use. Quantification is provided by either DXA or BIA. For patient follow-up, the latter is preferable to DXA because of the risks associated with repeat X-ray irradiation. In children, the use of the CDC chart in the USA and the IOTF chart in

Fig. 8 MRI with additional surface coil. Cross-section of the thigh. T1 relaxation (Courtesy of Prof. Joffre, Radiology Department, Ranguel University Hospital, Toulouse, France)

Fig. 9 MRI total body device with additional surface coil for skin and subcutis imaging (Courtesy of Prof. Joffre, Radiology Department, Ranguel University Hospital, Toulouse, France)

other countries should be associated with BMI. BIA is easy to handle and safe, but is an indirect method based on prediction equations and consequently bears some risk of uncertainty. DXA cannot be used repeatedly.

To measure the subcutaneous adipose tissue thickness on a particular site, ultrasound imaging at 10 MHz is the best technique. The measure of skinfold thickness, or its pinching variant is a good substitute when ultrasound equipment is lacking. CT and MRI should be only used for research.

3 Special Parameters of Connective Subcutaneous Tissue

3.1 Tissue Internal Pressure

With a simple experimental device, Merlen (1967) found that the pressure required to introduce a liquid into the forearm subcutis was between 1 and 15 Torr. The device consisted of a needle

sealed at its extremity, with several holes bored on its sides, that is connected to a syringe via a glass container (whose purpose is to attenuate the increasing pressure rate from syringe action). Between the needle and the container (tap 1) and between the container and the syringe (tap 2), two 3-outlet taps are inserted to communicate with atmospheric pressure. A manometer is placed in a by-pass between tap 1 and the container. Measurement follows several sequential steps. (1) The syringe is filled with saline in slight excess and the liquid level on the tube is marked with ink. (2) Tap 1 is turned off and the needle is introduced into the subcutis. (3) Taps 1 and 2 are opened to the outside: the manometer shows zero (the saline is at atmospheric pressure). (4) Tap 2 is turned off and the minimum amount of air necessary to push the saline level in the tube is injected (i.e., to inject a small amount of saline into the subcutis). (5) Tap 1 is turned off and the pressure indicated on the manometer is noted.

In Guyton's technique (Brace and Guyton 1979), a capsule connected to a venous pressure transducer

is inserted into the subcutis for several days. The experiment was made in animals. In contrast with Merlen's data, a negative pressure was recorded. Its possible meaning is discussed in ► Chap. 66, "Subcutaneous Tissue Histophysiology," Sect. 1.2.

3.2 Subcutis Oxygen Partial Pressure

Subcutis oxygen partial pressure can be useful in diseases involving the subcutis, especially leg ulcers whatever their etiology, as well as in cosmetic and reconstructive surgery. However, it does not seem to be widely used.

The oxygen pressure in the subcutis can be monitored by introducing a microcatheter containing a Clark-type polarographic electrode (Revoxode) and a pH 7.4 electrolyte solution. The measurement is automated (LICOX cmp, GMS 24247 Kiel-Mielkendorf Germany, email: gmsmb@aol.com). In situ temperature and blood flow (laser Doppler) can be simultaneously recorded.

Another technique uses the oxygen-induced fluorescence extinction (Oxylite). It also provides subcutis oxygen partial pressure monitoring and simultaneous blood flow and temperature measurement (Oxford Optronix Ltd, Oxford, UK, e-mail: sales@oxford-optronix.com).

3.3 Mechanical Behavior

Subcutis mechanical function has a double purpose: first to allow the overlying skin to move as a whole, both horizontally and vertically, and second to attenuate and/or disperse the spells of external pressure. Although sound devices are commercially available that can apply forces able to make the skin move in every direction, and measure the displacement, apparently no data are available on the subcutis elastic or viscous resistance. However, some studies have investigated the subcutis behavior under compression, mainly aimed at assessing edema: the magnitude of mechanical impedance decreased with increased frequency (maximum at low

frequencies of 10–30 Hz). It decreased with the degree of pitting edema but increased in case of hard, nonpitting edema. These variations in the subcutis water content paralleled those of in vitro water content of gels (Mridha and Ödman 1985). The same authors proposed a method to assess both the degree of edema and the edematous fluid viscosity. Using a disc 17 mm in diameter, the skin is depressed abruptly (26 mm s^{-1}) down to 4 mm, and the exerted force versus time is recorded for 30 s while the depression is maintained (Mridha and Ödman 1986). As the liquid flows out of the compressed area the force decreases. Using the curve of per cent decrease versus time assesses the volume of expelled liquid, according to the formula:

$$V_t = 0.9 (1 - F_t/F_{t=0})$$

where V_t is the volume (ml) expelled at time t , F_t and $F_{t=0}$ are the forces at times t and zero, and 0.9 is the pressure head area multiplied by the indentation depth.

In normal tissue, two force decreasing rates were observed, a high, then a lower one, as in current relaxation experiments, indicating two types of viscosity. In pitting edema, a third and higher decreasing rate was found initially, due to the edematous fluid outflow. This simple method has the advantage of obviating the measurement of the tissue's elastic resistance.

1 Introduction

The subcutaneous tissue, also called hypodermis, is composed of an extensive network of fatty lobules separated by thin fibrovascular septa. It helps with thermoregulation, provides an energy store, and serves as a cushion to protect internal organs (Ebling et al. 1992). This mesodermic layer presents its own pathology and also may be affected by abnormalities that lie in the neighboring layers or structures.

The use of sonography for studying subcutaneous tissue has been growing in the last few decades due to the development of multichannel machines with high and variable frequency probes that currently range from 7 to 22 MHz (Wortsman 2012a). Importantly, these probes present high definition for studying both superficial and deep structures and can unveil both morphology and blood flow in real time.

2 Technical Considerations

The requisites for observing subcutaneous tissue ideally are an adequate equipment (ideally, multichannel high-definition ultrasound machine with variable frequency probes that go from 7 to 22 MHz) and a trained sonographer with knowledge of both dermatologic pathology and ultrasound imaging (Wortsman 2012b).

The sonographic technique for exploring subcutaneous tissue is the same as was described for examining localized lesions of the skin (Wortsman and Wortsman 2010). A copious amount of gel is applied over the skin surface, and the probe is gently located on the lesional area. Virtually no compression of the subcutaneous tissue is performed, and the tissue is explored in its most natural form, preventing the collapse of slow flow vessels. Grayscale, color, and/or power Doppler images of the lesional area in at least two perpendicular axes are made. These color and power Doppler sequences allow the detection of the blood flow patterns. Then, 3D reconstructions of grayscale and/or power Doppler images can be performed to improve presentation and understanding of the pathology. These reconstructions are performed by doing a 5–8 s sweep in the region of interest.

3 Normal Anatomy

Subcutaneous tissue appears on sonography as a hypoechoic layer mostly composed of hypoechoic fatty lobules separated by hyperechoic linear

fibrous septa (Wortsman et al. 2006; Fig. 1). Slow flow thin arterial and venous vessels are detected within this layer. The thickness of the subcutaneous tissue varies according to the corporal region. Thus, it may easily reach ≥ 1 cm in the abdominal wall or hips; however, it may be thin and measure <0.1 cm in the dorsum of the hands of a child.

On top of the subcutaneous tissue, there is a hyperechoic band that corresponds to the dermis. Beneath the subcutaneous tissue, other layers such as the hypoechoic fibrillar structure of the muscle layer or the hyperechoic fibrillar pattern of the tendons are detected.

4 Sonographic Measurements in the Subcutaneous Tissue

The current equipment allows us to measure directly from the machine the distance in all axes (cm), the area (cm^2) or volume (cm^3), and the peak systolic velocity of the vessels (cm/s). It is also possible to measure the resistive index of the arterial vessels (i.e., peak velocity systole – end velocity diastole/peak velocity systole), although this latter vascularity data is rarely used in the subcutaneous tissue, being more frequently used for assessing stenosis in the large arteries.

It is also possible to qualify the changes in the echotexture patterns in case of abnormalities. For example, under inflammatory conditions, the echogenicity of the fatty lobules in the

Fig. 1 Normal sonographic appearance of the subcutaneous tissue (transverse views). (a) Grayscale ultrasound shows the hypoechoic fatty lobules and the hyperechoic

fibrous septa of the subcutaneous tissue. (b) 3D reconstruction (5–8 s sweep)

subcutaneous tissue usually increases (hyperechogenicity-white), and there may be anechoic fluid (black) within the septa. In the case of tumors, hypoechoic (gray) nodules that frequently show less echogenicity (dark) compared with the surrounding subcutaneous tissue can be found.

Vascularity patterns can also be qualified and compared with the non-lesional region. These can be defined as hypervascular or hypovascular areas.

5 Pathology

5.1 Inflammatory Conditions

5.1.1 Edema and Fluid Collections

The presence of interstitial edema in the subcutaneous tissue diffusely increases the echogenicity of the fatty lobules, and they also show blurry borders. Fluid collections such as seromas or hematomas appear as anechoic or hypoechoic commonly compressible structures that sometimes can show echoes (debris) or septa and usually decrease in size over time (Ryu et al. 2011).

5.1.2 Panniculitis

This condition implies the presence of inflammatory cellular infiltrates that usually involve both

the fatty lobules and the septa. According to the main affected component, panniculitides can be separated in septal or lobular (Requena and Yus 2001; Requena and Sánchez 2001). On sonography the involvement of the lobules shows as hyperechogenicity in the fatty tissue, and the effects on the septa present as hypoechogenicity and thickening of the septal structures. Moreover, increased regional blood flow may be detected with color or power Doppler (Fig. 2). Inflammatory subcutaneous conditions with fat necrosis show as hyperechoic areas with anechoic pseudocystic structures that correspond to liquefaction sites in the fatty tissue (Ester et al. 2009).

5.1.3 Lymph Nodes

These are oval-shaped solid structures that belong to the immune system. They are composed of an outer capsule, mainly cellular, and an inner medulla with prominent ducts and sinuses. An external fibrous capsule surrounds the cellular capsule with the exception of the vascular hilum region. They are distributed in well-known anatomical regions, and they usually can become palpable under inflammatory or tumoral conditions. They show on sonography as oval-shaped structures with hypoechoic rim (cortex) and hyperechoic center (medulla). On color Doppler the vascular hilum is usually detected in one of the aspects containing

Fig. 2 Lobular panniculitis (transverse views, right cheek). **(a)** Grayscale ultrasound shows hyperechoic focal area (*) that involves the fatty lobules of the subcutaneous

tissue. **(b)** Power Doppler ultrasound demonstrates increased vascularity within the affected subcutaneous region

Fig. 3 Lymph nodes (grayscale ultrasounds; (a) and (b): transverse views; (c): longitudinal view). (a) Normal lymph node: well-defined, oval-shaped structure with hypoechoic cortex and hyperechoic medulla. (b) Inflammatory lymph node: enlarged oval-shaped structure that

conserves the cortex-medulla echostructure. Notice the increased thickness of the cortex. (c) Metastatic lymph nodes: oval and round-shaped structures (*) that lose the hyperechoic medulla

low-flow arterial and venous vessels. Benign lymph nodes frequently conserve their oval shape and cortical and medullar echostructure. In contrast, malignant lymph nodes tend to show an oval or rounded shape and lose their hyperechoic center, therefore appearing as fully hypoechoic and sometimes with anechoic regions (Dudea et al. 2012; Fig. 3).

5.2 Tumors

There are multiple types of tumors that primarily or secondarily can affect the subcutaneous tissue.

We will focus on causes of involvement that may be part of the common differential diagnoses in daily dermatological practice.

5.2.1 Benign

Cystic

Epidermal Cysts

These frequent dermatologic lesions are composed of stratified squamous epithelium with a granular layer and are commonly located in both the dermis and subcutaneous tissue. On sonography, they show up differently according to the

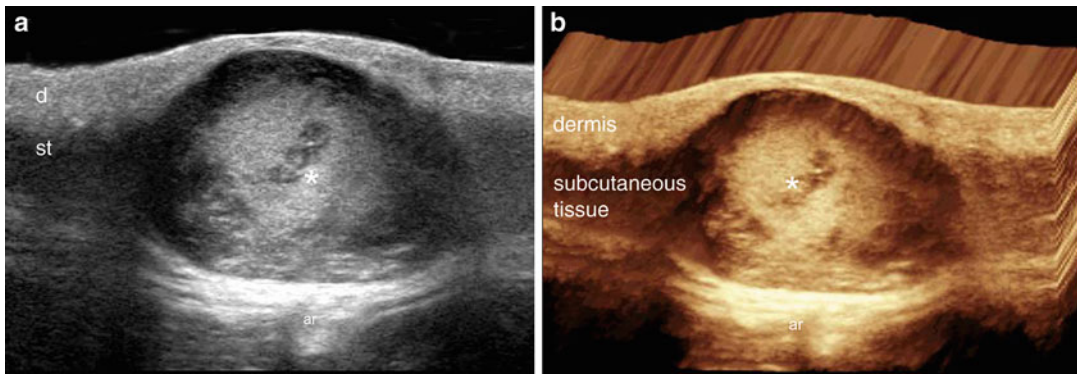

Fig. 4 Epidermal cyst (longitudinal views, lumbar region). (a) Grayscale ultrasound shows a well-defined, oval-shaped hypoechoic structure (*) with posterior acoustic reinforcement

artifact. (b) 3D reconstruction of the lesion (5–8 s sweep). Abbreviations: *d* dermis, *st* subcutaneous tissue, *ar* posterior acoustic reinforcement artifact

integrity of their walls and the presence of inflammation. Intact cysts present as well-defined, oval- or round-shaped, anechoic or hypoechoic structures that elicit a posterior reinforcement artifact typically seen in fluid-filled lesions (Fig. 4). Under inflammation the cysts become enlarged, and the keratinous material is mixed with inflammatory components which increase the echogenicity of the content and the peripheral blood flow. When the cysts are completely ruptured, they tend to show as an ill-defined, irregular, and hypoechoic structure that usually conserves the posterior reinforcement artifact and can show prominent peripheral vascularity. Occasionally, an anechoic connecting tract is observed between the cyst and the subepidermal region (Wortsman 2012a, b; Yuan et al. 2012).

Pilonidal Cysts

These are pseudocystic lesions commonly founded in the intergluteal area and composed of a nest of keratin and hair tract fragments. On sonography they appear as oval-shaped hypoechoic structures located in the dermis and subcutaneous tissue. Frequently, hyperechoic linear hair fragments are detected within the cysts (Fig. 5). Under inflammation pilonidal cysts may show increased peripheral vascularity with low-flow arterial and venous vessels. Hypoechoic tracts connecting to the base of the hair follicles are common findings. Sonography may also

demonstrate the axis and branches of the cyst which may support surgical planning (Wortsman 2012a, b; Solivetti et al. 2012; Mentis et al. 2009).

Vascular Tumors

Hemangiomas

These are the most common soft tissue tumors in infancy. They present an abnormal growth of endothelial cells. Commonly they involve the dermis and subcutaneous tissue. Hemangiomas tend to show a fast postnatal growth, followed by a slow involution period. On sonography, the appearance varies according to the phase of the hemangioma. In the initial proliferative phase, they present as hypoechoic hypervascular solid masses with prominent arterial and venous vessels and occasionally arteriovenous shunts. During the partial involution phase, hemangiomas show mixed echogenicity with hypoechoic and hyperechoic areas (Fig. 6). The blood flow tends to sequentially decrease over time. In the total involution phase, hemangiomas show as hyperechoic and hypovascular masses. Sonography can detect both subcutaneous and deeper layers or organ involvement (Wortsman 2012a, b; Dubois et al. 1998; Paltiel et al. 2000).

Vascular Malformations

These are errors of morphogenesis and are composed by an abnormal amount of vascular

Fig. 5 Pilonidal cyst. Grayscale ultrasound (longitudinal view, intergluteal region) demonstrates 8.02 cm long dermal and subcutaneous hypoechoic structure (*, between

markers) with hyperechoic lines that correspond to hair fragments (*arrows*). Abbreviations: *d* dermis, *st* subcutaneous tissue

Fig. 6 Hemangioma (dorsal region). (a) Grayscale ultrasound (transverse view) shows an ill-defined, mixed echogenicity structure with hypoechoic (*) and hyperechoic (o) areas that involves the dermis and

subcutaneous tissue. (b) Color Doppler ultrasound (longitudinal view) demonstrates prominent vascularity (colors) within the lesion

channels with normal endothelium. Usually they tend to grow in proportion with the child's growth. According to the type of channel, they can be classified into arterial, venous, lymphatic, or capillary. Also they can be separated according to the degree of vascularity into high (arterial or arteriovenous) or low (venous, lymphatic, or capillary) blood flow. There are also some mixed forms of vascular malformations. On sonography, they appear as nests of anechoic tubular or tortuous channels,

hyperechoic islets, or anechoic pseudocystic structures. Spectral curve analysis can show the type of blood flow within the vascular tracts (arterial or venous) (Fig. 7). Additionally, sonography can rule out the presence of thrombus within the vessels which appears as hyperechoic content within these channels. In venous vascular malformations, hyperechoic calcium deposits, also called phleboliths, may be found (Wortsman 2012a, b; Paltiel et al. 2000).

Fig. 7 High-flow arterial vascular malformation (transverse views, lobe of the left ear pinna). (a) Grayscale ultrasound demonstrates several anechoic tubular ducts and pseudocystic structures (*) in the subcutaneous tissue.

(b) Color Doppler with spectral curve analysis shows high arterial flow (peak systolic velocity: 57.6 cm/s). (c) 3D power Doppler reconstruction demonstrates increased vascularity within the lesion (*)

Solid

Lipomatous Tumors

These are the most common soft tissue tumors and present as a proliferation of adipose cells that may be mixed with fibrous (fibrolipoma) or vascular (angioliipoma) tissue. Lipomas show a variable appearance on ultrasound according to the proportion of the histological components. Thus, fibrolipomas or simple lipomas tend to present as well-defined, oval-shaped hypoechoic solid subcutaneous masses that follow the axis of the skin layers (Fig. 8). Hyperechoic fibrous septa are commonly detected within the structure. In contrast angioliipomas tend to show as well-defined, round or oval-shaped hyperechoic structures in the subcutaneous tissue. Lipomas are usually hypovascular, and the finding of prominent vascularity within these lesions may give rise to the suspicion of atypical or malignant transformation (Wortsman 2012a, b; Fornage and Tassin 1991; Kuwano et al. 2009; Lee et al. 2011).

Hair Matrix-Derived Tumors

Pilomatrixomas

These hair matrix-derived tumors, also called epitheliomas of Malherbe, are most common in children and young adults. They are composed of a nest of lobules with basaloid and ghost cells, eosinophilic keratinous debris, and calcifications. Pilomatrixomas are surrounded by a fibrous pseudocapsule of connective tissue, and these tumors commonly involve the dermis and subcutaneous tissue. On sonography they show a wide range of appearances, the most common being the target type (hypoechoic rim and hyperechoic center) (Fig. 9). Other forms of presentation include the cystic type (anechoic and hypoechoic areas) and the completely calcified type (hyperechoic with posterior acoustic shadowing). In up to 80 % of the cases, hyperechoic calcium deposits are detectable within the tumors. Occasionally, pilomatrixomas can show prominent vascularity on color Doppler ultrasound (Hwang et al. 2005; Choo et al. 2010; Wortsman et al. 2010).

Fig. 8 Lipoma. Grayscale ultrasound (transverse view, right flank of the abdominal wall) shows 6.12 cm long \times 1.03 cm wide, well-defined, oval-shaped hypoechoic mass (*) in the subcutaneous tissue

Fig. 9 Pilomatrixoma (longitudinal views, anterior aspect of the left leg). (a) Grayscale and (b) 3D reconstruction ultrasounds show dermal and subcutaneous, target-type structure with an hypoechoic rim (r) and hyperechoic

center (*). Notice the hyperechoic spots (*arrowheads*) that correspond to calcium deposits. Abbreviations: *d* dermis, *st* subcutaneous tissue

5.2.2 Malignant

Melanoma Metastasis

On sonography, a locoregional staging of melanoma can be performed. Thus, secondary satellite (<2 cm from the primary lesion), in-transit metastasis (≥ 2 cm from the primary lesion), and lymph node metastasis can be detected. These metastases commonly involve the subcutaneous

tissue and show as hypoechoic solid nodules that may present prominent vascularity (Fig. 10). Metastatic lymph nodes lose their hyperechoic center and show as round or oval-shaped hypoechoic structures. Commonly, anechoic areas due to hypercellularity (not necrosis) and tortuous and irregular vessels within the lymph nodes are observed (Gupta et al. 2011; Catalano et al. 2011).

Fig. 10 In-transit metastasis of melanoma. Grayscale ultrasound (longitudinal view, posteromedial aspect of the left thigh) shows two well-defined, oval-shaped hypoechoic structures (*) in the subcutaneous tissue. Notice the increased echogenicity of the surrounding subcutaneous tissue secondary to regional edema

Fig. 11 Dermatofibrosarcoma protuberans. Grayscale ultrasound (longitudinal view, left arm) shows a 4.14 cm long \times 0.7 cm depth, mixed echogenicity lesion (between

markers) with hypoechoic (*) and hyperechoic pseudopodia-like (o) projections. Abbreviations: *d* dermis, *st* subcutaneous tissue

Dermatofibrosarcoma Protuberans

This locally aggressive cutaneous fibroblastic tumor mainly involves the trunk and proximal extremities of young and middle-aged adults. On histology, it shows a proliferation of spindle cells with elongated nuclei, with little or no pleomorphism. This malignant tumor commonly affects the dermis and subcutaneous tissue; however, it may

also involve deeper layers. On sonography, the most common form of presentation is an ill-defined heterogeneous solid tumor with hypoechoic and hyperechoic areas that present lobulated borders with pseudopodia-like projections following a horizontal axis (Fig. 11). Slow flow vessels are frequently detected within the tumor (Oliveira-Soares et al. 2002; Shin et al. 2008).

Fig. 12 Calcinosis. Grayscale ultrasound (longitudinal view, left flank of the abdominal wall) demonstrates hyperechoic spots (*) with posterior acoustic shadowing artifact. Abbreviations: *d* dermis, *st* subcutaneous tissue

Fig. 13 Foreign body. Grayscale ultrasound (transverse view, dorsum of the right index finger) shows two hyperechoic linear fragments (*arrows*) that correspond to glass fragments and elicit posterior reverberation artifact (*r*). Abbreviations: *d* dermis, *st* subcutaneous tissue

5.3 Endogenous Material

5.3.1 Calcifications

Subcutaneous calcium deposits can be detected in several conditions such as inflammatory connective tissue diseases (e.g., secondary calcinosis) or associated with vascular malformations (phleboliths). The presence of gross heterotopic mature lamellar bone deposits in the subcutaneous tissue is named panniculitis ossificans (Wollina et al. 2009; Müller et al. 2010). The differentiation between isolated immature and mature lamellar bone is usually performed on histology. On sonography, calcium deposits appear as hyperechoic spots, and large-size calcium deposits commonly present a posterior acoustic shadowing artifact (Fig. 12).

5.4 Exogenous Material

5.4.1 Foreign Bodies

These are exogenous components usually accidentally embedded in the subcutaneous tissue. They can be separated according to their nature in organic (e.g., splinters of wood or thorns) or inert (e.g., fragments of glass and metal). On sonography they show as well-defined laminar or bilaminar hyperechoic structures surrounded by hypoechoic granulomatous tissue. Glass or metal fragments commonly produce a posterior reverberation artifact (Fig. 13). Ultrasound may support both the diagnosis and percutaneous extraction of the foreign structure (Wortsman 2012a; Bradley 2012).

Fig. 14 Silicone oil. 3D reconstruction (transverse view, glabellar area, 5–8 s sweep) shows two hyperechoic deposits (*) in the dermis and subcutaneous tissue with posterior reverberation artifact. Abbreviations: *d* dermis, *st* subcutaneous tissue, *b* bony margin of the skull

5.4.2 Fillers

These compounds are used for cosmetic purposes and can be separated according to their characteristics into degradable, such as hyaluronic acid, and nondegradable, such as silicone oil, polymethyl methacrylate, calcium hydroxyapatite, and polyacrylamide. On sonography, these deposits are commonly found in the subcutaneous tissue and show different sonographic appearances. Thus, hyaluronic acid presents as small round or oval-shaped anechoic pseudocysts that decrease in size over time (3–6 months), usually becoming undetectable or barely detectable after 6 months. Silicone oil is not FDA approved but may be used off-label in some countries. It shows as hyperechoic deposits with posterior acoustic reverberation artifacts (Fig. 14). Polymethyl methacrylate appears as multiple bright hyperechoic dots that elicit a mini comet-tail artifact (small posterior reverberation artifact). Calcium hydroxyapatite presents as hyperechoic deposits with posterior acoustic shadowing artifacts. Polyacrylamide shows as well-defined medium- or large-size anechoic pseudocystic structures with increased echogenicity of the surrounding subcutaneous tissue. The latter polyacrylamide deposits have been reported to not modify their appearance for at least 18 months (Wortsman et al. 2012; Wortsman and Wortsman 2011, 2012).

6 Conclusion

Sonography can show with high definition the anatomical characteristics of a wide range of dermatologic and non-dermatologic conditions that affect the subcutaneous tissue. It allows measurement of the abnormalities in all axes in real time, demonstrating their vascularity patterns and giving a noninvasive insight into the pathophysiology of the subcutaneous entities.

1 Introduction

Cellulite is characterized by dimpled or puckered skin of the buttocks and posterior and lateral thighs. This condition has also been described as resembling an orange peel and cottage cheese or as having mattress-like appearance (Hexsel et al. 2010a; Hexsel and Soirefmann 2011) (Fig. 1).

Published studies suggest that approximately 85 % of postadolescent women have some degree of cellulite (Draelos and Marenus 1997; Harvard Women's Health Watch Cellulite meltdown 1998). In men, this condition is very rare as the result of differences in the connective tissue (Hexsel et al. 2010a).

According to Scherwitz and Braun-Falco (Khan et al. 2010), it was Alquier and Paviot who first described cellulite, in 1920, as a noninflammatory, complex cellular dystrophy of the mesenchymal tissue, where defects in water

Fig. 1 Depressed lesions of cellulite on the buttocks and upper thighs, with mattress-like appearance

metabolism led to saturation of adjacent tissues by interstitial liquids as a result of traumatic, topical infectious, or glandular stimuli.

Synonyms of cellulite include adiposis edematosa, incipient cellulite or status protusus cutis, full-blown cellulite or dermopanniculosis deformans, nodular liposclerosis, gynoid lipodystrophy, and edematofibrosclerotic panniculopathy (Khan et al. 2010).

2 Definition

Cellulite is defined as a localized metabolic disorder of subcutaneous tissue that provokes an alteration in the female body shape. It presents as a modification of skin topography evident by skin dimpling and nodularity. This

condition occurs mainly in women on the pelvic region, lower limbs, and abdomen (Khan et al. 2010).

Cellulite usually presents after puberty and tends to be chronic (Hexsel et al. 2009a). While it is a common clinical condition affecting the majority of women of all countries and cultures, it is thought of as a female secondary sex characteristic (Khan et al. 2010; Hexsel et al. 2009a). Cellulite is rarely found in men (Hexsel et al. 2009a).

Differences in subcutaneous tissue architecture between men and women may explain the female sex predominance of this condition (Nürnberg and Müller 1978). Cellulite appears to be the result of localized adipose deposits and edema within the subcutaneous tissue. In women, bands of connective tissue are oriented longitudinally, from deep fascia to the dermis. These bands are the fibrous septae that segregate fat into channels. As the fat layer expands, it occurs herniation of subcutaneous fat within fibrous connective tissue, leading to a puckered appearance of the skin (Khan et al. 2010; Querleux et al. 2002; Piérard et al. 2000). The criss-crossing pattern of the connective tissue in the thighs and buttocks of men, which holds the fat layer, prevents the projection of the adipose tissue on the skin surface (Querleux et al. 2002; Piérard et al. 2000).

Different morphological patterns may be seen in cellulite patients. The skin surface alterations are mainly lower than the normal adjacent skin, but raised areas can also be seen. Depressed lesions occur because of the presence of fibrous septa that pull the skin surface down, and raised areas are the projection of underlying fat to the skin surface (Hexsel 2001).

Results of the magnetic resonance imaging analysis showed that cellulite depressions on the buttocks were significantly associated with the presence of underlying thick fibrous septa. It was found that all fibrous septa in the examined areas were perpendicular to the skin surface, and most of them were ramified (Hexsel and Soirefmann 2011; Hexsel et al. 2009b).

With aging and consequent increased laxity of the skin, the depressed lesions became more evident, as well as more linear or oval, following the skin lines and giving the skin a draped appearance (Hexsel et al. 2009b).

Regarding the importance of body weight, cellulite is not specific to overweight females, but added weight may cause enlargement of the fat lobules, further protrusion into the dermis, and exacerbation of this condition (Smalls et al. 2005).

3 Evaluation

The evaluation of a patient with cellulite may be done most of the times on clinical examination and sometimes using image exams.

Patients with cellulite should be evaluated in standing position with relaxed muscles, in order to correctly identify depressions of cellulite that are clearly apparent, independently of pinch test or muscular contraction (Hexsel and Mazzuco 2000). A pinch test can be done to make the lesions more evident (Fig. 2).

Digital photographs should always be taken before and after treatments. It is very important that these photographs follow the same standards, including light patterns, position, and camera settings (Figs. 3a-d) (Hexsel et al. 2001).

Gherardini et al. published a study that described the proper lighting, equipment, and backgrounds necessary to achieve standardization in photography for body contour surgery. General principles for clinical photography were reviewed, and the authors presented some consistent recommendations for photographic documentation of skin “textural” changes and “cellulite,” allowing comparison of results and techniques (Gherardini et al. 1997). Khavkin et al. also highlighted the fact that standardized, high-quality images can be achieved by using proper equipment, lighting, and patient positioning (Khavkin and Ellis 2011). Persichetti et al. defined guidelines for accurate image capture in different anatomic areas, in order to obtain

Fig. 2 Pinching the skin or pressing the affected areas can make cellulite lesions more evident

reasonable standardization, consistency, and reproducibility. The authors highlighted some important items (Persichetti et al. 2007), such as the following:

1. Background: The background must be an even, nonreflecting, monochromatic surface. A white or light blue drape can be held behind the patient by an assistant. Patient must be positioned 50–90 cm from the background.
2. Camera Settings: Single-lens reflex camera (SLR) digital camera is excellent for photographing, and it has a fixed focal length of 35–70 mm that guarantees an undistorted image, considering that the focal length of the human eye is 50 mm.
3. Position: The patient must be positioned at a distance from the camera, which varies the extent of the anatomic site to be included in

Fig. 3a-d A series of pictures of the same patient, in the same studio with the same lightning, but different camera settings

the picture. Generally, it is advisable to maintain the camera more than 1 m away from the patient, taking advantage of the zoom. The zoom is a type of lens that allows the operator to vary the focus, and only the optical zoom should be used when it is necessary to capture details (Persichetti et al. 2007).

4. Illumination: An adequate illumination must guarantee optimal definition of anatomic details and must be reproducible. In a photograph studio, lights are fixed which is certainly advantageous. Therefore, it is important to follow these items: two lamps at 45° with respect to the patient on a plane parallel to the frontal one. One of these lights should be in a sagittal plane, perpendicular to the frontal one, aiming downward. The other light should be behind the patient, on a plane parallel to the frontal one, aiming forward. This second lamp is placed at a distance 30–60 cm from the background. A “cold light” is always preferable (Persichetti et al. 2007). Other authors also highlight that an adequate illumination of the exam room with a light source in a downward position is helpful to visualize cellulite depressed lesions (Hexsel and Mazzuco 2000; Hexsel et al. 2010b).

There are a few devices in the market that were designed for photographic documentation of cellulite. These include the Vectra XT1[®] and IntelliStudio[®] systems, both from Canfield Scientific, Inc (USA). The Vectra XT1 is a three-dimensional camera system, with ultra high-resolution color image capture to produce a razor sharp definition of the smallest details. IntelliStudio[®] is a photo studio that makes consistent clinical quality photography, with fast and easy positioning to get the right view pre-op, and again to match it in the post-op session.

Recently, image exams may be indicated for cellulite adjunctive evaluation. The image exams may be used for research purposes or for special study of an individual case.

Ultrasound can be used to study the thickness and the quality of the connective tissue. This device may also be used to visualize the edematous component of cellulite (Biefeldt et al. 2008). Ultrasound imaging of the skin affected by cellulite reveals thinning of the dermis with subcutaneous fat pushing upward, which translates into the rumpled skin known as cellulite (Draeos 2005). Another study using a 20 MHz ultrasound shows that the frequency

of adipose protrusions into the dermis correlates with visual cellulite severity (Biefeldt et al. 2008).

Magnetic resonance imaging (MRI) allows visualization of specific changes in subcutaneous architecture caused by cellulite. This technique is able to show clearly images of the skin fat layers beneath the dermis and down to the level of muscles as well as to quantify herniations of adipose tissue into the dermis. Therefore, it is a good method to evaluate cellulite in clinical trials (Biefeldt et al. 2008) and also to determine anatomical features of cellulite (Hexsel et al. 2009b) (Fig. 4).

Laser Doppler flowmetry (LDF) is an optical technique used to evaluate the skin microcirculation which provides information on blood flow and erythema. The radiation is reflected by the skin and converted to electrical signal, which is proportional to the flux of erythrocytes of the blood flow. Therefore, it consists in a reliable

method to estimate cutaneous microcirculation (Biefeldt et al. 2008).

Thermography is an effective technique to evaluate local skin temperature, and it is based on the detection of infrared radiation emitted by skin. Areas affected by cellulite present less local skin blood flow, consequently presenting lower temperatures (Biefeldt et al. 2008).

Newly, a thermal infrared camera was proposed as a reproducible method to assess the severity of cellulite. The conclusion of the study pointed out that the thermal camera can be used to reliably document the changes in the skin temperature that are related to the presence and the severity of cellulite (Nkengne et al. 2013). Further studies using image and thermal devices are necessary in order to improve the complementary evaluating and knowledge of this condition.

Patients should be classified regarding their degree of cellulite. This is important to determine the more appropriate treatment and to monitor treatment improvement. Two classifications of cellulite are currently used. The first is made on clinical basis (Table 1) (Hexsel and Mazzuco 2000).

Fig. 4 MRI image of the buttock showing a skin marker on a depressed lesion of cellulite and its correspondent fibrous septa. MRI can be also used to study fat tissue in areas with cellulite

Table 1 Classification of cellulite based on clinical criteria (Nünberger and Müller 1978)

Grade or stage	Clinical characteristics
0 (zero)	There is no alteration to the skin surface
I	The skin of the affected area is smooth while the subject is standing or lying, but the alterations to the skin surface can be seen by pinching the skin or with muscle contraction
II	The orange skin or mattress appearance is evident when standing, without the use of any manipulation (skin pinching or muscle contraction)
III	The alterations described in grade or stage II are present together with raised areas and nodules

Table 2 Hexsel and Dal’Forno and Hexsel e Cellulite Severity Scale (CSS) (Hexsel et al. 2009a)

(A) Number of evident depressions
This item refers to the total number of evident depressions by visual inspection in the area to be examined. The scores are expressed as:
ZERO = None/no depressions
1. A small amount: 1–4 depressions are visible
2. A moderate amount: 5–9 depressions are visible
3. A large amount: 10 or more depressions are visible
(B) Depth of depressions
This item evaluates the depth of depressions by visual inspection of the affected areas; comparison to the pictures of CSS is recommended
ZERO = No depressions
1. Superficial depressions
2. Medium depth depressions
3. Deep depressions
(C) Morphological appearance of skin surface alterations
Item C assesses the different morphological patterns of skin surface alterations; comparison with the pictures of CSS is recommended
ZERO = No raised areas
1. “Orange peel” appearance
2. “Cottage cheese” appearance
3. “Mattress” appearance
(D) Grade of laxity, flaccidity, or sagging skin
Laxity, flaccidity, or sagging skin confers the affected skin a draped appearance. This effect aggravates the appearance of cellulite. Item D assesses the grade of flaccidity, and comparison to the pictures of CSS is recommended
ZERO = Absence of laxity, flaccidity, or sagging skin
1. Slight draped appearance
2. Moderate draped appearance
3. Severe draped appearance
(E) First cellulite classification described by Nürnberger and Müller (1978)
This item incorporates the first classification of cellulite, shown in Table 1. Patients should be evaluated in the standing position with relaxed gluteus muscles. However, if the patient has no evident depressions, they should be asked to contract their gluteus muscles or the <i>pinch test</i> should be applied (by pinching the skin between the thumb and index finger) in order to differentiate between scores zero and 1
ZERO = Zero grade
1. First grade
2. Second grade
3. Third grade

Table 3 New classification of cellulite based on the results of scores of Cellulite Severity Scale

Points	New classification of cellulite
1–5	Mild
6–10	Moderate
11–15	Severe

Although this classification is useful, it does not attend to important additional morphologic aspects of cellulite (i.e., laxity) and is not the ideal for assessing treatment response. Hexsel, Dal’Forno, and Hexsel published a new cellulite classification (Hexsel et al. 2009a), based on a new scale in which important clinical and morphological aspects of cellulite are assessed. The scale is called *Hexsel and Dal’Forno* and Cellulite Severity Scale (Hexsel et al. 2009a) and is shown in Table 2. It is an alpha-photonic scale that grades cellulite on basis of five items: (A) number of evident depressed lesions, (B) depth of depressions, (C) morphologic appearance of skin surface alterations, (D) grade of flaccidity or sagging skin, and (E) cellulite classification by Nürnberger and Müller. Each of these items is graded from zero to three. The sum of these scores will lead to a new classification of the cellulite as mild, moderate, or severe, as shown in Table 3.

The publication of *Hexsel and Dal’Forno* and *Hexsel* Cellulite Severity Scale (Hexsel et al. 2009a) was of great value in the evaluation of cellulite patients, since this new classification included different aspects of cellulite lesions and additional morphologic characteristics (i.e., laxity) (Fig. 5).

1 Basic Concepts

Anthropometry is defined as “measurement of the human body and its dimensions.” Surface anthropometry involves measurements of body mass, stature, skeletal breadths, limb lengths, circumferences and skinfold thicknesses that are used, either as raw data or predicted values, to describe concepts such as absolute and body frame size, body composition, and body surface area (Stewart and Eston 2007). Anthropometry is a multidisciplinary science and has revelations with other sciences such as anatomy, physiology, medicine, and nutrition. Historically, the main concern in surface anthropometry has been the standardization of measurements. During the past 50 years, several researchers and organizations attempt to achieve universal recognition and provide international standards in anthropometry (Lohman et al. 1988; Norton and Olds 1996). This chapter is based on the latest standards of the International Society for the Advancement of Kinanthropometry (ISAK) (ISAK 2011), and its purpose is to present key principles, methods, and equipment for measuring the most commonly used anthropometric variables.

2 Standard Equipment

Stadiometer: (e.g., Holtain, SECA) mounted on wall or stand with sliding headboard and accurate to 1 mm. The stadiometer should be checked every month or after measuring 30 subjects, against a standard height.

Weighing scales: portable beam balance machine, calibrated in kilograms and tenths of kilograms (150 kg) (e.g., SECA). The electronic digital scales is becoming more general and is of the same accuracy.

Skinfold calipers: Harpenden or Slim Guide Skinfold Calipers calibrated to $10 \text{ g}\cdot\text{mm}^{-2}$, scale to 80 mm, which can be read to 0.1 mm and 0.5 mm, respectively. Holtain calipers have similar quality and can be used with equal precision.

Anthropometric tape: metal, with a stub extending 6–10 cm beyond the zero line (blank area). The Lufkin W606PM and its modified version Rosscraft anthropometric tape and CESCORF anthropometric tape are the preferred instrument for performing girth techniques. All can be read to 0.1 cm.

Segmentometer: a flexible metal tape with rigid sliding branches for identifying lengths and landmark locations (Rosscraft), read to 1 mm.

Bone calipers: Tommy 2, Tommy 3, and Bonimeter 1 are good examples of bone calipers with extended branches and round pressure plates 15 mm in diameter.

3 Standard Methodology

3.1 Common Prerequisites

There are some important considerations for surface anthropometry measurements:

- Subjects require appropriate information in advance, and informed written consent should be obtained.
- Ensure that the physical space is large enough ($3 \times 3 \text{ m}$) and illuminated to allow the measurer moving freely, considering personal space (front space of the body of subject) and privacy of the subject.

- Subjects should be recovered from previous exercise, fully hydrated, and voided.
- Subjects should be asked to present themselves in minimal clothing. Swimsuits (two-piece suits for female subjects) are recommended.
- Cultural differences may preclude the acquisition of some or all measurements in some subjects. Measurement of females or children by male measures requires particular sensitivity and the individual's entitlement to a chaperone. It is always advisable to have another adult (preferably female) present in such circumstances.

3.2 Stature

Stature is measured to 1 mm without any footwear. The subject stands with head level, looking straight ahead, and the heels together. The subject inspires for measurement, and the recorder brings down the headboard to compress the hair.

3.3 Body Mass

Body mass is measured to 100 g. Clothing is also an issue, and the type and amount of clothing must be standardized. Body mass changes at various times of the day as a result of meal and beverage consumption, urination, defecation, and dehydration, or water loss. Therefore, a standard time (e.g., early in the morning, 12 h after any food and after voiding) is recommended.

3.4 Skinfolds

Skinfolds are the most commonly measured anthropometric sites in surface anthropometry. They are very good representative of level of fatness and subcutaneous fat storage in the body. To measure them, measurer needs to landmark at first. In fact, accurately landmarking is one of the vital aspects of good anthropometric measurement. A sound knowledge of surface anatomy is essential. Skeletal landmarks are the reference

points and must be located in the same procedure to guarantee reproducible measurements. Skinfold locations are marked with a cross, with two lines intersecting at right angles. A longer line shows the orientation of the skinfold, and the shorter one defines the finger and thumb placement. Bony edges are commonly marked with a short (0.5 cm) line, while points (e.g., the inferior tip of the scapula) are marked with a dot, from which linear measurements are made. A description of very common landmarks is summarized in Table 1.

Measurements of skinfold thicknesses should be made on the *right* side of the body. Skin of the subject should be dry, nongreasy, and healthy. The skinfold is raised by the left hand, which is positioned so that the thumb points downward and the back of the hand is in full view of the measurer. The fold is grasped firmly in the appropriate orientation, following the natural lines of the skin (*Langer's lines*), and raised far enough (but no further) so the fold has parallel sides. The measurer should use the thumb and index finger of the left hand to raise a fold that contains a double layer of both adipose tissue and skin. In order to eliminate muscle, good palpation technique guarantees a

double layer of both adipose tissue and skin. The caliper jaws are applied 1 cm away from the thumb and index finger (fold), at a depth of mid-fingernail. It is important to hold the fold throughout the measurement procedure (Fig. 1).

The calipers are held perpendicular to the skinfold, the spring pressure is released, and the measurement value recorded after 2 s. The calipers are removed before the skinfold is released. Common skinfold sites are described in Table 2.

3.5 Girths

A cross-handed technique is the standard procedure with the stub held in the left hand and the housing in the right hand. The girth measurements are measured with tape at right angles to the long axis of a bone or body segment. The measurer, from the right side of the subject, passes the stub around the body segment, grasped by the right hand, and then passed back to the left hand which pulls it to the appropriate tension. The cross-handed technique is simply a matter of reaching across with the left hand and gripping the stub with the thumb and index finger while the right hand holds the housing. There should be no visible indentation of the skin at the measurement.

Table 1 Skeletal landmarks and the related skinfolds

Landmarks	Description
Mid-acromiale-radiale	<i>Midpoint level between the most lateral point in the superior border of the acromion process in the midway between the anterior and posterior border of the deltoid muscle (acromiale) and the point at the most upper and lateral border of the head of the radius bone (radiale) (triceps skinfold and biceps skinfold)</i>
Subscapularis	<i>The bottom tip the inferior angle of the scapula bone (subscapular skinfold)</i>
Iliocristale	<i>The most lateral point on the iliac crest on the ilioaxilla line (iliac crest Skinfold)</i>
Iliospinale	<i>The most inferior point or bottom tip of the anterior superior iliac spine (ASIS) (supraspinale skinfold)</i>
Omphalion	<i>The midpoint of the navel or umbilicus (abdominal skinfold)</i>

Fig. 1 A triceps skinfold measurement illustrating appropriate technique

Description of some common girth measurements are summarized in Table 3.

3.6 Breadth

Bony breadths are very important variables in surface anthropometry. They have been used in estimation of body size, body shape, and growth

studies. For measurement purposes, the bone calipers lie on the backs of the hand while the thumbs rest against the inside edge of the caliper jaws and the extended index fingers positioned along the outer surface of the jaws. After finding the correct bony landmarks, the measurement is made with the calipers in place, with the pressure maintained along the index fingers. Description of some common girth measurements are summarized in Table 4.

Table 2 Skinfold measurements (location and orientation)

Skinfold	Location and orientation
Triceps	On the posterior aspect of the upper arm in the level of mid-acromiale-radiale (vertical)
Subscapular	Two cm lateral and inferior to the subscapulare (oblique)
Biceps	On the anterior aspect of the upper arm in the level of mid-acromiale-radiale (vertical)
Iliac crest	Immediately superior to iliospinale (horizontal)
Supraspinale	The intersection of iliocristale and iliospinale landmarks (oblique)
Abdominal	5 cm at right lateral of the omphalion (umbilicus) (vertical)
Front thigh	Midpoint of the perpendicular distance between the inguinal crease at the midline of the thigh and the midpoint of the posterior border of the patella when seated with the knee flexed to 90° (vertical)
Medial calf	The most medial aspect of the calf, at the level of maximum girth, with subject standing and weight evenly distributed (vertical)

4 Practical Usage

4.1 Body Mass Index (BMI)

The body mass index (BMI) is the ratio of body mass to stature squared: $BMI(kg/m^2) = BM(kg)/stature(m)^2$. In epidemiological studies, body mass index (BMI) is used as a crude index of overweight and obesity. ACSM (2014) recommends using BMI to evaluate obesity ($BMI \geq 30 kg/m^2$) as a risk factor for coronary heart disease. Table 5 describes the classification of BMI.

4.2 Waist-to-Hip Ratio (WHR)

The waist-to-hip ratio (WHR) compares the girths of the waist to that of the hip. It is an indicator of body fat distribution (i.e., the apple or pear shape of body) or as a measure of general health. A high WHR has been recognized as a risk factor for chronic disease. This technique is simple to administer and requires only an anthropometric tape. In some cases, WHR may be a better

Table 3 Girth measurements (location and subject position)

Girth	Location	Subject position
Waist	Narrowest circumference between lowest rib border and pelvis	Arms folded or abducted
Hip	Greatest posterior protuberance of buttocks	Relaxed, feet together
Upper arm – relaxed	Mid-acromiale-radiale	Arm abducted slightly, elbow extended
Upper arm – flexed and tensed	Maximum in tensed state	Arm raised, elbow flexed at 45°
Calf	Maximum	Weight equally distributed

predictor of mortality than BMI. However, because it is a circumference ratio, it does not provide an indication of percent body fat. Standards for WHR values are shown in Table 6.

4.3 Percent of Body Fat (PBF)

The skinfold thicknesses have good correlation ($r = 0.7-0.9$) with the results of criterion

Table 4 Breadth measurements (location and subject position)

Breadth	Location	Subject position
Humerus	The distance between the medial and lateral epicondyles of the humerus	Subject in standing position, right arm raised horizontally, and elbow flexed at right angle to the upper arm
Femur	The distance between the medial and lateral epicondyles of the femur	Subject seated and knee is bent at right angle

Table 5 Classification of body mass index (BMI)

Classification	BMI value
Underweight	<18.5
Normal weight	18.5–24.9
Overweight	25–29.9
Obesity	30–39.9
Morbid obesity	>40

American College of Sports Medicine (2014)

Table 6 Norms of waist-to-hip ratio (WHR)

	Age	Low risk	Moderate risk	High risk	Very high risk
Male	20–29	<0.83	0.83–0.88	0.89–0.94	>0.94
	30–39	<0.84	0.84–0.91	0.92–0.96	>0.96
	40–49	<0.88	0.88–0.95	0.96–1.00	>1.00
	50–59	<0.90	0.90–0.96	0.97–1.02	>1.02
	60–69	<0.91	0.91–0.98	0.99–1.03	>1.03
Female	20–29	<0.71	0.71–0.77	0.78–0.82	>0.82
	30–39	<0.72	0.72–0.78	0.79–0.84	>0.84
	40–49	<0.73	0.73–0.79	0.80–0.87	>0.87
	50–59	<0.74	0.74–0.81	0.82–0.88	>0.88
	60–69	<0.76	0.76–0.83	0.84–0.90	>0.90

Heyward and Gibson (2014)

techniques such as hydrodensitometry. The principle behind skinfold measurements is that the amount of subcutaneous fat is proportional to the total amount of body fat. It is assumed that nearly one-third of the total fat is located subcutaneously. This led to the proliferation of hundreds of regression equations to predict body fat. A list of the famous regression equations estimating percent of body fat is described by various resources (Norton and Olds 1996; Lohman et al. 1988). These equations can typically be divided into generalized equations and specific equations. Regression equations used to convert sum of skinfolds to percent body fat should consider some variables such as gender, age, and race for greatest accuracy. Norms of PBF values for women and men by age are summarized in Tables 7 and 8, respectively.

4.4 Body Frame Size

Measures of frame size are supplemental to height and help to have a better estimation of the bone or body width. Body frame size as an important concept in the assessment and evaluation of body weight can increase the validation of the height-weight tables. Direct measurement of frame size is not possible. There is general agreement that measures used as substitutes for frame size should be distributed normally within a population, be highly correlated with lean body mass, and not be correlated with fat. Many sites have been proposed for the estimate of frame size:

Table 7 Norms of percent of body fat (PBF) for women

	Age					
	20–29	30–39	40–49	50–59	60–69	70–79
Very lean	11.0–14.0	11.2–14.3	12.1–15.2	13.9–16.9	13.9–17.7	11.7–16.4
Excellent	15.0–17.0	15.5–17.5	16.8–19.5	19.1–22.3	20.2–23.3	18.3–22.5

Heyward and Gibson (2014)

- Bi-trochanteric breadth
- Ratio of height to wrist girth

Comparison and evaluation of these methods are hindered by differences in the study samples of factors that are potentially related to frame size and may confound the data. These include age, gender, and ethnicity. There are no reference standards for any of these measures except elbow breadth. In fact, the elbow breadth is currently the best measure for frame size for most applications because it has been validated, has reference values, and is relatively simple and practical to measure. Reference data for humerus breadth is described in Table 9.

1 Introduction

The follicle is composed in its distal part by the bulb, which is formed by the hair matrix and papilla, and in its side wall, from the bottom up, by the bulge, which contains “follicular germ cells” and is the insertion site of the smooth erector muscle of the hair, the sebaceous glands, and the apocrine sweat gland. In the germinal compartment, bulb matrix cells are found and multiply due to the activation by the bulge cells, forming well-differentiated structures that correspond to the hair shaft and inner root sheath. Between the undifferentiated matrix cells and the differentiated cells, there is a limit, which is known as “Auber’s line.” The central part corresponds to the hair shaft and has three concentric layers from inside to outside: cortex, medulla, and hair cuticle or “epidermicule.” The inner root sheath (IRS) also has three vertical layers known as the sheath’s cuticle, Huxley’s layer, and Henle’s layer (outward, respectively). Between the IRS and outer root sheath (ORS), there is a single-cell layer known as the “companion layer” (CL). The ORS comes from the epithelium and, together with bulge stem cells, has great value in the

epithelialization of wounds. The ORS accompanies the hair follicle to the area between the erector muscle insertion and sebaceous gland, known as “Straile’s area,” where the temporary structures disintegrate (Fig. 1). Outside the ORS, there is a fibrous connective tissue sheath which

forms the basal follicular membrane called “vitreous membrane” and a conjunctive sac in which the neurovascular structures are located. There are two follicle matrix areas: the hair bulb, with matrix cells around the dermal papilla, and the bulge matrix cells in the lower part of this structure. Follicular cycles are initiated by the “activation of the cells of the bulge.”

The “hair growth cycles” are established from the time the child is born. While growing, the hair follicles are in the *anagen phase*, and when they are resting, they are in the *telogen phase*. The transition between these two states is the *catagen phase*. We call the stage in which the hair follicles eliminate the hair shaft in the telogen phase from its interior, remaining empty, the *exogen phase*. And the *kenogen phase* is the presence of “empty follicles” as a result of failure in telogen hair replacement by anagen hairs in early-onset alopecia. Anagen follicles are surrounded by dense plexus of arterioles and capillaries originating from the branches of the dermal plexus or directly from musculocutaneous arteries. Follicular innervation is different depending on whether it deals with terminal hair follicles or vellus hairs. Some myelinated nerves run parallel to the permanent part of the follicle, and other finer nerves form a network as a sock or bag surrounding the rest of the follicle. A cluster of parallel myelinated nerve fibers forming a stockade or “palisade” can be seen near the follicle canal and some of these nerves branch in the vicinity of their distal terminals, resulting in bulging, reminiscent of tines of a fork. The nerves are better organized around vellus hair follicles (Fig. 2a, 2b) than in the large terminal hair follicles, allowing their consideration as a “follicular tactile organ” (Holbrook 1983).

Fig. 1 Lower part of the follicle. In the bulb (*B*), the undifferentiated matrix cells (*Ma*) are arranged in a line as they ascend toward the keratogenous area (*K*) where the cortical cells (*Co*) are keratinized. The bulb contains the dermal papilla (*P*). Immediately above the matrix cells, a line known as Auber’s line (*AL*) separates the permanent structures of transitory structures. The melanocytes (*Mc*) are arranged on the roof of the dermal papilla. Hair is composed by medullar cells located in the center. Note that the medulla is discontinuous. Surrounded the medulla are the hair cortex and epidermicule or hair cuticle (*hc*). The outer (*ORS*) and inner root sheath (*IRS*) with their three different layers (Henle’s layer (*he*), Huxley’s layer (*hx*), and the cuticle of the inner root sheath (*cir*)) can be followed easily until the level of the bulb, where they are separated by dark spinous cells (*sp*) that are the cells of the companion’s layer. The connective tissue sheath (*CT*) is continued with the dermal papilla and is separated by a thick vitreous membrane (*VM*) which in its internal part can be confused with the basal membrane

2 Follicular Formation: Embryology

Hair grows early and vigorously in the skin of human fetus. The hair follicle is differentiated toward the end of the second month (Holbrook 1983; Billingham 1958), first in the eyebrows, upper lip and chin, and then on the scalp and face. Around the fourth and fifth month, follicles

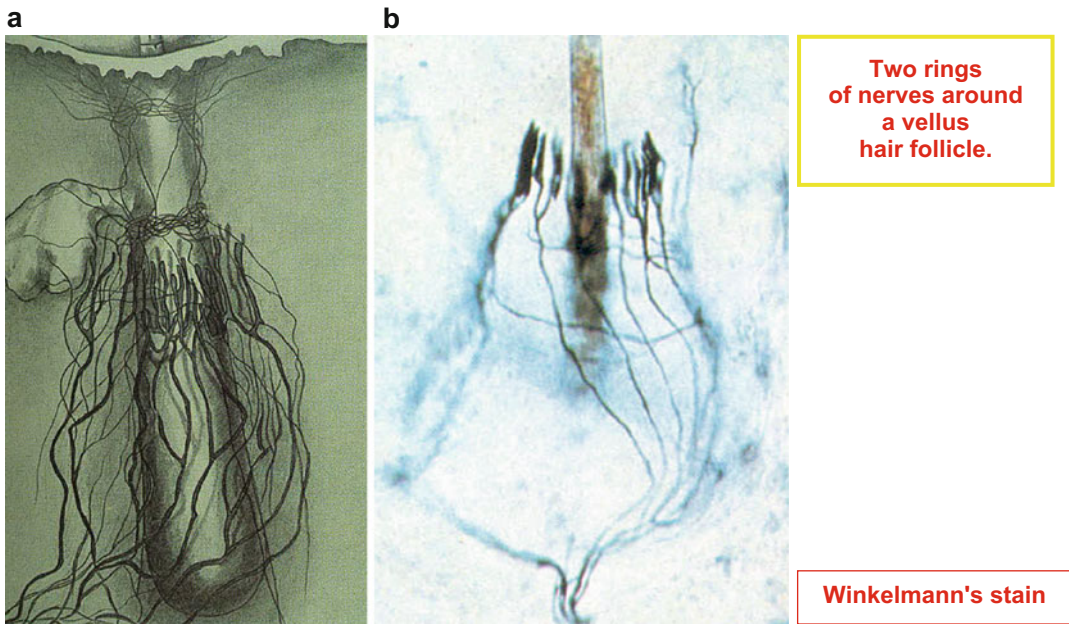

Fig. 2 (a) Nerves well organized around a vellus hair follicle. Schedule of the two rings of nerves around a vellus hair follicle forming a well-structured sensory nerve

ending. (b) Myelinated nerves around a vellus hair follicle. Stained with Winkelmann's silver technique

are formed by the rest of the body and continue to form until the end of the pregnancy. Hair follicles are initiated along the hairlines, with a distribution that is generally similar in all people, and later, they are developed in the spaces between these lines, as the fetal body surface expands. According to available data, no new hair follicles are formed after birth because when we are born, we have all the hair follicles of the future (Billingham 1958).

During fetal life, the hairs grow to a certain length in the anagen phase, and then the follicles enter catagen and telogen phases. After a short rest period, the hair grows again, entering the anagen phase and substituting the telogen hair by a new hair (Montagna et al. 1992). In the embryony life, this process may occur two or more times on the head and face and less frequently elsewhere (Montagna et al. 1992).

Differentiation of hair follicles in the human fetus begins by the presence of a cluster of cells. These cell aggregates, known as “primitive hair germ,” cause a small bulging on the underside of the epidermis. As soon as the cells of the primitive

hair germ become recognizable, mesenchymal cells in the dermis crowd underneath, they are signaling the appearance of the dermal papilla of that hair follicle. Both clusters penetrate obliquely in the dermis and result in the lower portion of the bulb, follicular papilla, and temporary structures and in the upper portion, the bulge where erector muscle is inserted, and sebaceous gland and apocrine gland.

2.1 Advances in Knowledge of the Differentiation of the Follicles in the Fetus

2.1.1 Knowledge Up to 1980

As Montagna and Camacho (2013) pointed out, the differentiation of hair follicles in the human fetus begins by the presence of a cell cluster in the basal layer of the still relatively undifferentiated, bilayered periderm which is the future epidermis. These cells of the epidermis basal layer are condensed and their small and basophilic nuclei are elongated and arranged perpendicular to the skin (Fig. 3a). These cell clusters, known as “primitive

hair germ,” “bud,” or “placode,” produce a small bulge in the lower surface of the periderm and one may observe how below of this “bud” the mesenchymal cells of the dermis are accumulated, indicating the appearance of the dermal papilla of each hair follicle. The two cell groups, the basal cells of the hair germ and the mesenchymal cells of the papilla future, become more apparent, and begin to penetrate obliquely in the dermis pushed by a column of epithelial cells adopting a “club-shaped structure” (Fig. 3b).

The “club-shaped” column is claviform and has an anteroposterior tilt. This structure shows large columnar cells arranged radially in the periphery, while the central cells are aligned longitudinally. This is the “primordial follicle” completely constituted. The distal portion of the primordial follicle adopts a truncated appearance with which it pushes toward the interior of the dermis to the papillary mesenchymal cells (Fig. 3c). The claviform column begins to split their distal portion where they will collect the papillary mesenchymal cells. On the back side of the epithelial column, two protuberances grow: the lower one, at first the larger one although later it is reduced, corresponds to the insertion area of the erector muscle which corresponds to the bulge, and the upper one corresponds to the primordial sebaceous glands (Fig. 3d). At this early stage, it can be determined that cells of the middle of the sebaceous protuberance have a foamy cytoplasm, thus constituting the earliest synthesis and lipid accumulation. Also in this phase, the presence of the connective tissue is verified, and some mesenchymal cells that are grouped linearly under the sebaceous gland and positioned toward the bulge consisting of the outline of the future erector muscle. The follicle begins to split its truncated distal portion in order to grow around the dermal papillary cells, although it remains attached by a narrow pedicle to a group of cells that continues with the conjunctive peribulbar sheath. At first, pigmented melanocytes can be observed around the bulb, but, later, only in the upper portion above the dermal papilla. Most cells in the lower portion of the bulb are not differentiated and constitute the proliferating follicular matrix. The first follicle

differentiation occurs in the inner root sheath, whose cells, which surround the dermal papilla, are longitudinally aligned, acquire trichohyalin granules, and later form the lining of the hair. When the primordial follicle is almost formed, it is found that the bulb has included the papilla and also undifferentiated matrix cells are observed on the basal membrane of the bulb, and the two side swellings which are the adhesion area of the erector muscle and sebaceous gland (Fig. 3d). Between 15 and 20 weeks above both swellings, a third protuberance or bulge to be the rudiment of apocrine sweat gland begins to be observed. And when the primordial follicle is already fully formed, on the inclined side portion, from bottom to top, the three swellings are observed, and in the center, one may observe how cortical cells begin to be differentiated, reaching the isthmus and infundibulum and constituting, along with the cells of the inner root sheath, the intraepidermal follicular canal. There will also appear the first hair shafts that will only possess cortical cells but will not have medulla or pigment (Fig. 4; Holbrook 1983; Montagna 1981; Hashimoto 1978; Montagna et al. 1985a).

2.1.2 Recent Knowledge on the Differentiation of the Follicles in Fetuses

As mentioned above, at the end of the second and beginning of the third month, primordial hair follicles, also called primitive hair follicles, may already be seen on the head, specifically in the area of the eyebrows or ciliary regions, interciliary upper lip, and chin. Shortly afterward, follicles appear on the forehead and scalp, and in the fourth to fifth month, they appear in the rest of the integument (Billingham 1958; Montagna et al. 1992; Pinkus 1910; Pinkus 1927; Koelliker 1850; Pinkus 1958; Montagna et al. 1967, 1974; Camacho et al. 2013).

The development of follicles is dyssynchronous in the body, being able to find fully formed follicles and others in various stages of differentiation in the same corporal regions. As the skin expands, primary or “secondary” follicles emerge among those already existing, and it is even possible to observe how other secondary or “tertiary” follicles

Fig. 3 (a) Placode. Basal epithelial cells with vertical alignment to the surface. Mesenchymal cells, the forerunner of the dermal papilla, are beginning to gather at the base of the bud. (b) The hair germ is well defined, and the dermal papilla cells are more clearly delineated at the base of the dimpled column of cells. (c) Primordial follicle. The cells in the core of the epithelial column are aligned perpendicularly and have begun to manufacture the keratin of the inner sheath. On the lateral wall, a primordial sebaceous gland is developing. (d) Primordial follicle is well developed. The bulb has included the dermal papilla. The follicular layers are well differentiated, and a hair is being formed in the center. In the lateral wall, two swellings are demonstrated, lower the bulge and upper the anlagen on a sebaceous gland. The erector muscle can be seen on the bulge

immediately emerge adjacent to those already formed to constitute groups of three or more follicles that are known today as “follicular units.” Next to them, eccrine sweat glands can be observed. To observe the arrangement of the primary, secondary, or even tertiary follicles, “separate skin preparations” are used between the epidermis and dermis. If we destroy the dermis and hypodermis, the bulbs and follicles are observed heading to the epidermis, and when the epidermis is destroyed, one may observe the follicular ostium of these groups of follicles coming from the dermis.

Holbrook (1983) reminded us in his magnificent work, and in the photos presented in the second edition of Montagna and Camacho (2013; Fig. 5a–5d), that the small swelling on the lower surface of the epidermis, called “primitive hair

germs,” is CD10 positive (Poblet and Jiménez 2008) and the mesenchymal cells of the dermis accumulating underneath, indicating the appearance of the dermal papilla of each hair follicle, are CD34 positive (Poblet and Jiménez 2008).

The fact that both CD10 and CD34 are observed in the placode and in the accumulation of matrix cells of the papilla, respectively, of follicles in the anagen phase suggests that these proteins have a role in the initial stages of follicular formation. This is confirmed by the fact that CD10 is also expressed in the matrix cells, inner root sheath, and conjunctive sheath of the follicles in the anagen phase but disappears in catagen and is impossible to detect in telogen follicles. Through immunostaining with CD34, it is possible to verify it in the outer root sheath of the follicles in the

Fig. 4 Completely formed embryonic follicle. In the posterior part, one can see a superior bulge which corresponds to the outline of the sebaceous gland (*S*) and a lower protuberance which is the bulge (*B*). The arrow is pointing to the “hair cone” in whose tip only the inner root sheath is seen (Courtesy Dr. K. Holbrook. From Montagna and Camacho 1997)

anagen phase but not in fetal follicles which, we recall, is where it is expressed in the papillary cells, or in the catagen or telogen stages.

When the rudiment of the sebaceous gland becomes visible (Montagna et al. 2013), mesenchymal cells near the follicle are extended and aligned toward the posterior edge of the follicle. These primitive erector muscles extend toward the “bulge.” At this time, the primary follicle is a keratinized solid epithelial structure (Langbein and Schweizer 2005; Schweizer et al. 2007; Langbein et al. 2013) surrounded by a mesenchymal sheath. Later, the smooth and primitive muscle cells are extended and their thickness increased.

2.1.3 Molecular Mechanisms Regulating Hair Follicle Development

Although it is not the purpose of this chapter to address all of the molecular mechanisms required for hair follicle formation, we will refer to the magnificent paper of Sarah E. Millar (2002),

published in 2002 in the *Journal of Investigative Dermatology*, in which she commented on the “signals,” known up to that time, that are emitted into the skin of mice and chicks during the embryogenesis phase between skin cells and the overlying epidermal cells that, although not completely superimposing the human cells, explain how the placode and hair germ formation begins, passing through the “club-shaped column” stage until the final formation. Without a doubt, today we know of many more “signals” of inhibition or promotion.

The first signal that the dermal cells are being accumulated under the epithelial cells in order to form the “primitive hair germ” (Figs. 3a and 5a) is induced by β -catenin, although the fibroblasts could also influence, at least it happens this way in the follicular neogenesis in adult skin (Collins et al. 2012). In any case, it is not clear that a key molecule for transferring the power of a signal (in this case, β -catenin would be a transducer of the Wnt signal) is going to be acting in this phase alone (Collins et al. 2012). What is clear is that in the initial development phase of the hair follicle, the first epidermal signals, located in the placode, can be promoters (Wnt, β -catenin (Myung et al. 2013; Ahn et al. 2013), factor linked to the increase in lymphocytes-1 [LEF1] (Wang et al. 2012), fibroblasts growth factor and FGF receptor genes [FGF/FGFR2-IIIB], MSX1, MSX2, ectodysplasin/ectodysplasin receptor [EDA/EDAR], NOGGIN, and DELTA-1/NOTCH) as well as inhibitors-repressors acting on cells that surround the placode (BMP2, BMP4, DELTA-1/NOTCH1). However, knowing that Wnt/ β -catenin activation is required for the anagen phase (Myung et al. 2013), we still do not know what the source of production is. Therefore, from all of the above, it should be highlighted that it is certain that the first signal that initiates follicle development is Wnt, but it is not yet known if it comes from the epithelium or from the dermis (Fu and Hsu 2012). It has also been recently shown that the neurotrophin receptor p75 (p75NTR) is expressed in fibroblasts that later develop the dermal papilla and, although its role is not known, the authors suggest that it would act

Fig. 5 Primitive hair germ developing in the basal layer of the periderm. Mesenchymal cells are gathering in the base of the germ (a). More advanced stage of the hair germ development in which one can clearly see the mesenchymal cells which make up the beginning of dermal papilla (b). Primitive elongated hair germ growing perpendicularly to periderm. On the *left* hand side, a protuberance can be observed. The base of the germ has a “clavate” shape. The arrow is signaling a condensation of mesenchymatous cells which represent the cells of the early dermal papilla (c). The primitive hair follicle growing around the future dermal papilla (d) (Courtesy Dr. K.Holbrook. From Montagna and Camacho 1997)

as a receptor which would negatively control the hair follicle through various routes.

Later, when the epithelial germ begins to be constituted, with the presence of the placode that pushes the papillary cells, Wnt would act as an epithelial signal and PDGF-A and Shh (Sonic hedgehog) as signals for the formation of the dermal papilla (Cui et al. 2011; Figs. 3b and 5b). Later on, in the club-shaped column phase, when the column increases and pushes the papillary cells, there is a second dermal signal caused by HGF/MET (Lindner et al. 2000), probably by ACT β /FS and SOX18, and three signals for the proliferation of follicular epithelium (SHH), for polarity of the cells in the follicle (probably Wnt and Shh), and for the follicle (TGF α /EGFR and ETS2). Finally, the differentiation of the root sheaths begins. Until 2002, it was not known which was the signal for the differentiation of the inner sheath. The differentiation of the outer sheath is done by external NOTCH1, BMP2, BMP4, Wnt3, LEF1, NOVO1, HOXC13, and WHN and probably by MSX1 and MSG2.

Woo et al. (2012) reported that Shh regulates growth dermal follicular maturation maintaining the dermal papilla and also leads Noggin follicle morphogenesis. Finally, once the follicle is formed, the hair needs to come out. The matrix metalloproteinases are involved in the creation of the ductus from which the hair will protrude, especially metalloproteinase 9 (MMP-9); however, it is still unclear if other MMPs such as MMP-2 may modulate the effects of MMP-9, nor is it clear whether, as occurs with other cell types, the expression of MMP-9 is regulated by the Wnt, TGF- β /BMP, HGF, and EGF signaling pathway (Sharov et al. 2011). Recently, Cadau et al. (2013) have identified four new Wnt-related genes which could be involved in hair follicle initiation, two activators Wnt-2 and Zic-1, and two inhibitors, Dkk-2 and Dact-1. Nevertheless, this chapter does not attempt in any way to clarify each and every one of the signals the follicle receives for its formation; we only want to state that its development has a molecular mechanism which is increasingly better known, from which we will probably obtain therapies for the future (Li et al. 2013).

3 Hair Follicle Anatomy

As noted in the introduction, the follicle has in its distal portion the bulb which is composed by the hair matrix and the papilla. Downward on the lateral wall of the follicle, we have the sebaceous gland, the apocrine sweat gland, and the insertion of the smooth erector muscle by the Nagel elastic tendon. This tendon is comprised of elauninic and oxytalanic elastic fibers. The “bulge” is located in the area of insertion of the erector muscle, which forms an obtuse angle and contains “follicular germ cells” that will result in a new follicle after each catagen period (Lavker and Sun 1983; Cotsarelis et al. 1990).

The bulb matrix cells, which are found in the germinal compartment, multiply forming well-differentiated structures that correspond to the hair, inner root sheath (IRS), and another single-cell layer known as the companion layer. Among the not differentiated and the differentiated matrices, there is a limit, which was known as “critical level of Auber” and today is simply referred as “Auber’s line” (Fig. 1).

The central part, which corresponds to the hair, has three concentric layers from inside outward: medulla, cortex, and hair cuticle or “epidermicule.” The inner root sheath (IRS) consists of three vertical layers: cuticle of the sheath, which adheres like a zipper to the hair cuticle, Huxley’s layer, and Henle’s layer. Huxley’s and Henle’s layers are rich in trichohyalin granules, similar to the keratohyalin of the epidermis, but not in melanin (Langbein and Schweizer 2005; Schweizer et al. 2007; Langbein and Schweizer 2013). Huxley’s layer has some cells with lateral projections of a “wing” type, for which reason they have been called “winged cells”, which cross Henle’s layer to reach the companion layer (CL) which is a single-cell layer that lies between the IRS and the ORS (Camacho Martínez 2009).

The outer root sheath (ORS) or “trichilemmal” is the outer epithelial layer of the follicle. It proliferates downward from the epithelium to the bulb and surrounds the two structures derived from the matrix cells. The ORS consists of a single-cell layer when it is around the hair bulb, but above the bulb, it gradually stratifies, and

farther above, it shows a seamless transition with the protuberance and the isthmus. This complete stratified ORS has an outer layer of palisade cells (ORSe) and two other layers, medium and internal (ORSm, ORSi), of the same cobblestone morphology or shape differences without signs of differentiation or keratinization (Fig. 6).

The ORS accompanies the hair to the follicle area between the insertion of the erector muscle and sebaceous gland, known as “Straile’s area,” where it disintegrates.

From this area, there only remains outside the ORS, which accompanies the follicle to the epidermis from which it comes, and while the follicle is in the dermis, it is also surrounded by a fibrous sheath of connective tissue that forms the basal follicular membrane, called “vitreous membrane,” and by a conjunctive sac in which is found neurovascular structures (Rothnagel and Roop 1995).

In between the ORS and the IRS, there is a vertical structure of a single-cell layer called “companion layer” (CL) which accompanies the ORSi from the lower portion of the bulb to the upper part of the isthmus. The CL cells contain a clearly asymmetric cluster of bundles of intermediate filaments of compact keratin toward the center of the hair follicle known as “Hoepke circular filaments.” The CL was considered by Pinkus (1910) as the innermost layer of the ORS but today is known to

be an independent follicular structure (Montagna and Camacho 2013; Langbein and Schweizer 2013; Camacho Martínez 2009). In the edition of the book by Montagna and Camacho (1997), Montagna pointed out in reference to the 6D figure “Observe the large melanocytes and prickly dark cells (Sp), described for the first time, that separate the inner root sheath (IRS) from the external (ORS)” (Fig. 7; Montagna and Camacho 1997). He was describing the development of companion layer from the matrix cells of the bulb (Camacho Martínez 2009). In 1995, Rothnagel and Roop reminded the existence of companion layer between Hurler layer and ORS (Rothnagel and Roop 1995), and Winter et al. in 1998 the novel human type II cytokeratin, K6hf, specifically expressed in the companion layer (Winter et al. 1998).

When the follicle enters catagen phase, the bulb matrix cells together with the matrix cells of the papilla form the “secondary germ” and ascend until being situated near germ cells of the bulge.

After passing the resting phase, immediate physical interaction or “activation of bulge cells” occurs, thus beginning a new cycle of follicular growth. When the secondary germ moves toward the bulge, it leaves behind him, in the form of a tail or “serpentine” shape, a fibrous structure filled with remnants of fibrous connective sheaths of the follicle, vessels, and nerves (Forslind 2000; Fig. 8).

3.1 The Importance of the Companion Layer

Having described in the introduction the general structure of the pilosebaceous follicle, we need to make a few comments on the most recently known follicular layer. I refer to the companion layer (CL).

Today, there is no doubt that the CL is a single-cell layer, very fragile, ranging from the germ cells of the bulb (Fig. 7) to the isthmus and just below the entrance of the sebaceous gland duct in the follicle canal. The fragility of the CL is what justifies that the pulling of the hairs breaks this layer in the lower portion of the follicle. This happens because the CL cells are asymmetrical and have few desmosomal connections with ORS

Fig. 7 The cells of the matrix and of the outer root sheath (ORS) are aimed upward. Note the large melanocytes (*M*) and also some dark spinous cells (*Sp*), which separate the inner root sheath (*IR*) from the outer root sheath (ORS). These dark cells are the companion layer's cells that are produced in the bulb. One can also see the dermal papilla (*P*), the connective tissue sheath (*CT*), and a thin basal membrane (*BM*) inside the vitreous membrane (*GM*). Fibroblasts (*F*) can be seen in the connective tissue sheath

cells, although, as noted above, they are closely related to the cells of Henle's layer by means of desmosomes and a circular network of intermediate filaments, called "belt or circular fibril."

The importance of the CL is that this single-cell layer next to the inner root sheath guides and holds the hair toward its outlet. In order to perform its function, it forms a block with the outer part of the inner root sheath cells, thanks to the winged cells coming from Huxley's layer. These cells, upon being introduced between the cells of Henle's layer and coming into contact with the companion layer by means of projections of intermediate filaments and/or desmosomes, form an IRS-CL block which will subsequently join the ORS, possibly allowing intercommunication of all the follicular layers. This phenomenon will ensure greater rigidity of all follicular layers, especially Henle's layer, and even the exchange of nutrients (Lindberg and Forslund 2004). The end of the companion layer occurs within the isthmus, slightly below the inlet of the sebaceous duct in the hair channel (Montagna and Camacho 2013).

4 Hairs

"Hairs" are keratinized skin elements with structural, mechanical, and physicochemical properties that are out of the ordinary. The cells that constitute them trap air bubbles, for which reason they float on water. It consists of three strata that, from the inside outward, are the medulla, cortex, and cuticle of the hair.

The hairs are produced in the follicles and each follicle can be influenced by endocrine-metabolic factors, especially hormones, being responsible of the changes from the puberty that justify the hair differences with the age. For example, in the scalp or in the face of a man, the hairs are transformed into vellus hair during senescence (Fig. 9) and the vellus hairs of areas hormone dependent are transformed into terminal hair during puberty. What really happens in these cycles is that the follicles "miniaturize" or increase in thickness, respectively. The follicles of the terminal hair penetrate the dermis to a depth of 3.6 mm, while the follicles of the vellus

Fig. 8 Hair growth stages. Each stage is shown in cross section. On the left, there is an follicle “in anagen”; in the middle, there is a follicle “in catagen”; and on the right, there is a follicle “in telogen.” This diagram notes the different parts of the follicle: dermal papilla (*P*), bulge (*B*), club hair (*CH*), and epithelial capsule (*EC*). In the figure, we can see the fibrous structure filled with remnants of fibrous connective sheaths of the follicle, vessels, and nerves

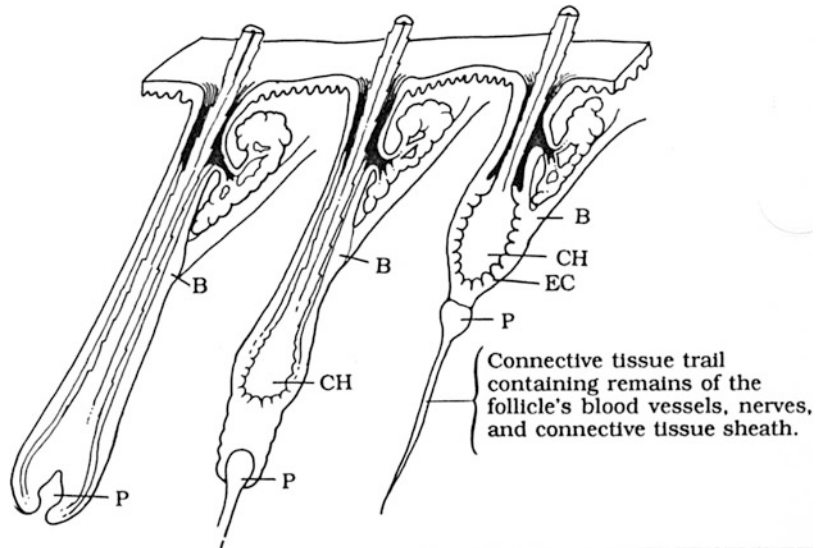

Fig. 9 In successive growth cycles, a transformation occurs on the scalp, from hair to vellus hair. Really, what happens in these cycles is that follicles “miniaturize”

hairs only penetrate the dermis to a depth of approximately 0.5 mm.

In the center of the hair shaft is the *medulla*, which in humans may be continuous, discontinuous, fragmented, or even nonexistent. The medulla is formed from a hemispherical structure, called pre-medulla, which is formed by the cells around the papilla above Auber’s line (Fig. 1). In humans, the medulla is only found, consistently, in the pubic hair since in the scalp hair, its presence depends on population factors (Forslind

2000; Lindberg and Forslind 2004) and the body hair does not have medulla. However, the hair of the beard of males has a medulla composed of irregularly arranged but horizontal cells that are full of multiple keratohyalin granules and tend to form vesicles and air-filled spaces that act as insulators.

Surrounding the medulla is the *cortex*, comprised by elongated and keratinized cells containing varying amounts of pigment. It is the more compact structure of the hair shaft

composed of elongated, spindle-shaped cells loaded with bundles of intermediate keratin filaments. It originates in the matrix of the hair next to the cell compartment of the lower germ cells, below Auber's line, and extends from the upper portion of the bulb to the keratogenous zone which is the area where their cells are keratinized and no longer present nuclei, an area known as "Adamson's fringe" (Montagna 1981).

At the outermost portion of each hair is the *cuticle*, which is the protective layer of the hair shaft and which is formed by cells that are very large, thin, flat, scalelike, pigmented, intertwined, and oriented obliquely like shingles on a roof, with the free ends facing upward toward the end of the hair. The cells of the cuticle hold the hair and anchor it into the follicle, fixing it to the corresponding cuticular cells of the inner root sheath, which are directed downward (Fig. 10). Cuticle cells, of the hair as well as of the inner root sheath, are differentiated immediately above the bulb of hair follicles, where the cells of the cuticle begin to be keratinized in the pre-keratogenous

area while the cells of the outer root sheath are keratinized at a higher level.

Each hair is unique in that its "structure" is different from one segment to another (Fig. 11). Even the hairs formed in the "same" follicle may have very different structures. One must bear in mind that the hairs that emerge subsequently are not formed by the same follicle since each follicle is destroyed during the catagen phase.

The *hair* has an intrafollicular portion known as the "root" and an outer portion, the "shaft." The keratinoblasts of the matrix, among which are found melanocytes, multiply rapidly and are keratinized, but, contrary to what takes place in the surface epidermis, there is no granular stratum, for which reason this abrupt keratinization is complete within 1 mm above the apex of the papilla. From the inside out, the hair is composed of the medulla, cortex, and cuticle or epidermicule, with only the first two being melanized.

Despite observations to the contrary, there exists the same amount of hair on the body of a woman as on that of a man, with the difference being that the body hairs of women are smaller. Among the many factors responsible for the growth of hair on the human body are specific body areas, heredity, hormones, sex, race (Hamilton 1958), and age. The hairs are keratinous fibers and can be thick or thin, long or short, and straight, wavy, or curly. In cross section, curly hair looks like ribbons; the rest are mostly oval or ovoid.

The hairs are generated in the follicles. The two major categories of hair, "terminal hair" and "vellus hair", refer to its size. Felix Pinkus (Pinkus 1927) included the "intermediate-sized" hair which is between the cited two. Although there is the idea that all the hairs are the same among the different living species, one must remember that other mammals have other types of hair; this does not merit further comment.

The majority of the "terminal hairs" and "intermediate hairs" are thick, rigid, usually pigmented, and medullated; those on the scalp, eyebrows, eyelashes, beard, mustache, and axilla and pubic areas and on the limbs are terminal hairs.

The "vellus hairs" are generally without pigmentation and/or invisible. Those that can be seen are, in principle, short, without pigmentation, soft,

Fig. 10 SEM of a hair follicle. The edges of the cuticular cells of the hair (C) are smooth and aimed upward. The smaller cells aimed downward (CI) are cuticular cells of the inner root sheath. The cuticle cells attach the hair to the inside of the follicle (Courtesy Dr. D.Knutson. From Montagna and Camacho 1997 (Montagna and Camacho 1967))

Fig. 11 SEM of hairs from the surface of chest of four men. It is impossible to differentiate these hairs only on the basis of their aspect (From Montagna and Camacho 1997)

Fig. 12 SEM image of the surface of the tragus of a male patient. One can see numerous vellus hairs which are not visible to the naked eye, rounding one terminal hair

and very thin; however, blond hairs that grow on the forearms, cheeks, and around the periphery of the areola of the breast can be short or very long. The majority of the areas of the human body apparently devoid of hairs, such as the forehead, eyelids, “prematurely” bald scalp, ears, and other areas erroneously called hairless (*hairless* = *skin without hair*), have numerous vellus hairs that can be seen very well with scanning electron microscopy (SEM) (Fig. 12) with follicles that are visible on histological skin preparations of “separated skin” when viewed with low-intensity light microscopy.

The “intermediate-sized hairs” may be 1 cm, more or less, and are found mostly on the limbs, abdomen, and thorax of hirsute Caucasian men.

The intermediate hairs are not as large and long as terminal hairs, and most remain at the same size and appearance throughout the lifetime. Actually, in the elderly, intermediate-sized hairs of the beard, mustache, and other body areas tend to become thicker.

Human hair color goes from black to white, including red. This different color possibility is due to the variable number and distribution of melanosomes which produce melanin. The melanosomes are distributed in the form of rounded black points on cortical cells (Fig. 13). Most hairs contain eumelanin, a pigment that depending on its quantity produces black, dark brown, brown, light brown, blond hair color, in that order, while red hairs contain the same amount of eumelanin and pheomelanin (Ito and Wakamatsu 2011). The configuration of the hair surface can cause light to be scattered in different directions, which contributes to color and gloss.

As for hair growth, all body hair grows to the envisaged “length” that is characteristic of each area of the body and each individual. All hairs are replaced periodically by others of the same size and length. This means that the hair follicles have controlled growth and rest periods known as *hair growth cycles*. We are not immediately aware of these growth cycles because human hair growth is asynchronous, while it is synchronous (synchronous growth means that every hair on any skin area is in the same growth phase) in mice, lagomorphs, and others. Thus, in humans, neighboring hairs, even those that emerge through the same

Fig. 13 Melanosomes like *rounded black dots*, distributed over the cortical cells

orifice, may be in different phases of the cycle. Growth periods become less frequent in the elderly in which the periods of inactivity (*telogen*) are longer.

Most hairs “emerge” on the skin surface following characteristic patterns (Perkins et al. 1967) according to the body area and species. In human skin, particularly in older people, the patterns are difficult to identify. Hairs grow inclined from the head to the distal portions of the limbs, that is, arms and legs, but on the face, crown, dorsal-sacral region, abdomen, and certain areas, hairs grow following a spiral pattern.

The number of hairs, the patterns that emerge, the “density of distribution” on the body, and their growth rates (Saitoh et al. 1967) are similar in men and women, with the size of each hair that each follicle produces being the only real difference between the sexes. After the age of 50, the hair density generally decreases in both sexes, even in adults who show no signs of baldness on the scalp.

The “growth” of the majority of the hairs is approximately 0.4 mm per day (Saitoh et al. 1967). Barman et al. (1965) believe that in both sexes, the hair grows faster between 16 and

46 years of age. Puche et al. (1971) have observed that the density decreases in the axilla hair at a rate of about 0.31 hairs per year and Pecoraro believed that the rate of hair growth in humans is characteristic for each zone (Orentreich 1967). Some authors have calculated the percentage of terminal hair in respect to the vellus hair on each sex and in different parts of the adult human body; however, these data have no real value, as most of vellus hairs are not visible to the simple visual inspection, only being visible with SEM. Even so, of the 100,000–150,000 terminal hairs that are said to be growing on the scalp, around 10,000–15,000 are renewed every year, or what is the same, 35 per day (Randall 2004; Bradfield 1974). Although we know all these details, we must remember that the growth rate of other follicles varies depending on the age, health, and internal and external environmental conditions (Montagna et al. 1992).

In general, it is said that hair grows faster in women than in men (Orentreich 1967). Leaving apart the diurnal variations, and sex and age of individuals, Japanese researchers have estimated that human hair grows about 0.5 mm per day in the region of the crown of the head and 0.4 mm in the temples. The “lashes” that emerge in the anterior edge of the ciliary portion of the eyelid margin are more numerous and longer in the upper eyelid since in it, there are about 100–150 eyelashes, while on the lower eyelid, there are 70–75, and they are arranged in a single row but at different levels, so if any of the adjacent eyelashes, one or two, are lost, it will not leave a visible space (Cotsarelis et al. 1990). They grow for 30–45 days, after which they rest for 105 days. At the base of the eyelashes, there are modified sweat glands known as Moll glands and other sebaceous glands known as ciliary glands that secrete a sebaceous material like the Meibomian glands, which are about 20–30 sebaceous glands which are found in the posterior lip. This sebaceous material of the ciliary glands along with the Meibomian glands constitutes the rheum. The “eyebrow hairs,” structures that measure about 5.5 cm and which are located between the forehead and eyelid, separated by the glabellar area, have a follicular cycle of 112 days and there are typically about 600 per eyebrow, approximately

100 per cm². The “beard hairs,” the coarsest of the body, grow about 0.3 mm per day, and if they are not cut, they can grow up to 30 cm or more. With age, many unpigmented vellus hairs growing on the pinna, tragus, and antitragus, inside and around the external auricular orifice, on the surface of the nose, and into the nostrils of men can become intermediate or terminal hairs (Puche et al. 1971). Postmenopausal women often have visible hair in any place, but especially in the mustache area, along the side of the upper lip, on the chin area and jaw regions. The “*pubic hair*” usually, but not always, is curled or twisted on its axis and can reach 16 cm although it will be shorter or longer in some individuals; pubic hair coarseness is also an individual characteristic. In older people, pubic hair is usually almost straight, thinner, and longer than in young people. The pubic hair grows primarily in an area that outlines an inverted triangle in both men and women. Many people wrongly believe that pubic hair of men grows in a rhomboid shape, with the vertex of the major axis directed toward the navel. In reality, some Caucasian men have coarse hair that grows on the abdomen, tending to accumulate in the midline, but these hairs should not be confused with pubic hair. The “axillary hair,” like the pubic hair, is also curly on its axis in young people, and it is said to be coarser in men than in women. As with the pubic hair, the axillary hairs become straight and thin with increasing age. Axillary hairs almost disappear in many older people both men and women.

5 Some Physiological Aspects of Hair

Human fetuses begin to show primordial follicles on the eyebrows, upper lip, and chin at the end of the second and beginning of the third month. These areas are the “hairlines” that have a similar distribution in each person. Later, follicles appear on the forehead and scalp, and from the 4th–5th month in the rest of the body. As the skin expands, primary and secondary follicles emerge between those already existing, forming groups of three or more.

The hair follicles of human scalp have completed two or more cycles of growth in utero whose sequences are the same as in postnatal life. Therefore, hairs are observed in *vernix caseosa*.

5.1 Hair Growth

Although the hair growth will be explained in another later chapter, it is necessary to describe the “follicular cycle” with three stages, the growth or “anagen” stage, the quiescent or rest or “telogen” stage, and the transition stage from anagen to telogen or “catagen.” We adopt the term “anagen,” and consequently “catagen” and “telogen,” because the basic term is “anagenesis,” which means “regeneration of destroyed parts from those conserved” (Fig. 14).

In the introduction, we noted that after the three stages of the cycle, there is an early anagen stage. This mechanism is not so simple since there are six stages of anagen (anagens I–VI) and two large parts in the cycle: proanagen and metanagen (Camacho et al. 2013).

5.1.1 Proanagen

This includes the first five stages of the anagen. In anagen I, cells of the papilla increase in size and increase RNA synthesis (Fig. 15a). At the same time, the secondary germ cells, probably induced by the cells of the bulge, were in turn activated or stimulated by the dermal papilla (“activation swelling” hypothesis) (Cotsarelis et al. 1990), beginning in depth growth (Figs. 15b). In anagen II, the secondary germ grows into the depths adopting a truncated pyramidal form that pitches toward the interior of the dermis to the papillary mesenchymal cells (Fig. 15c) and immediately after surrounds the papilla (Fig. 15d), starting the formation of hair and inner root sheath. In anagen III, the maximum follicular length is reached. At this stage, the bulb increases in size and tends to include all of the papilla, the dendritic melanocytes begin the formation of melanin, and hair may already be observed, although it is still short and surrounded by the inner root sheath (Fig. 15e). The anagen IV stage is characterized

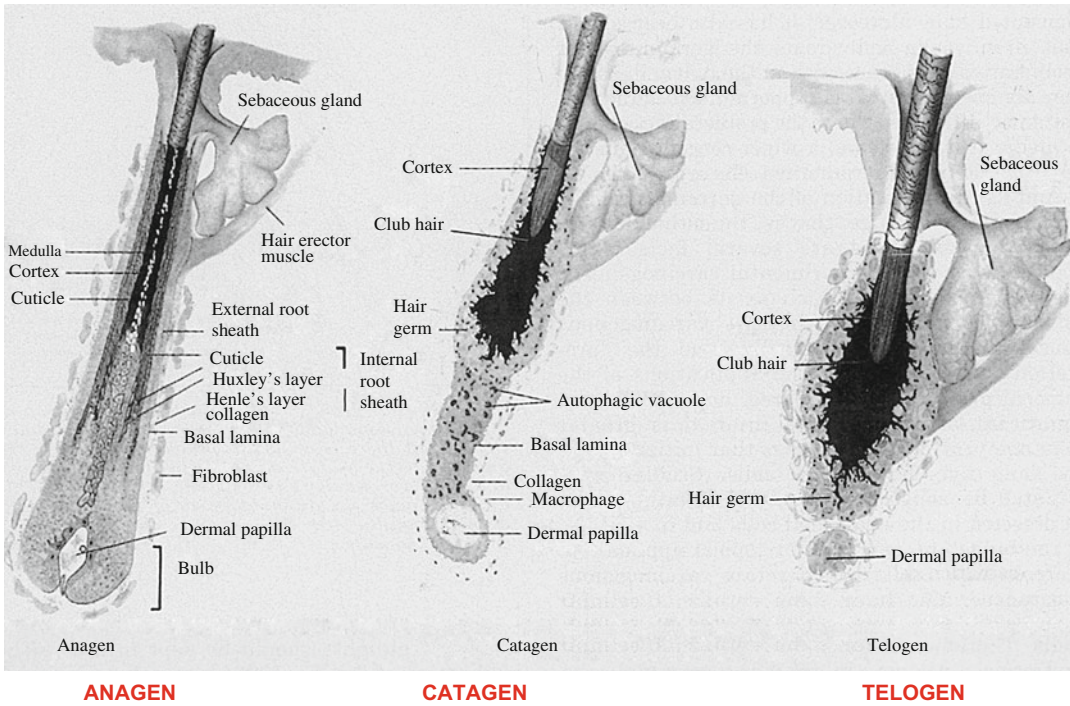

Fig. 14 Hair growth cycles. On the *left*, there is an active follicle “in anagen”; in the *middle*, there is a follicle “in catagen”; and on the *right*, there is a follicle “in telogen.”

Only the *lower* part labeled as transient is reabsorbed during catagen

by evident hair growth with the distal end at the level of the sebaceous gland. Furthermore, dermal papilla cells undergo proliferation and temporary decondensation, probably in response to a signal from the matrix. In anagen V, the distal end of the hair is at the level of the follicular ostium.

final phase of anagen V, even within the proanagen stage and a prior step to metanagen. If there is hair in anagen inside, then the follicle is empty or in the “kenogen” phase, which is the true resting phase when the follicle is inactive. It is also known as “latent phase.” Reduction in the duration of anagen with the extension of the ketogen occurs primarily in males with androgenetic alopecia.

5.1.2 Metanagen

This encompasses from anagen VI, the stage in which the hair emerges in the skin surface, to the next rest stage, naturally including the catagen stage.

5.2 Cyclic Follicular Activity

The activity varies according by the region and even in the same area. The cycle is typical of each follicle and is independent of the others. The anagen/telogen relationship expresses the cycle of each hair (Montagna et al. 1967; Camacho et al. 2013; Montagna 1988). The total number of hair follicles on the human body is estimated at about five million.

5.1.3 New Terms That Are Part of the Follicular Cycle

The terms “exogen” or “teloptosis” and “ketogen” have been introduced recently. We are going to explain them. When hair is in the telogen phase, it is eliminated constituting the “teloptosis” or “exogen” phase and the one that is inside the follicle in anagen should appear, corresponding to the

Hair follicles have a rate of mitotic activity in 12 h, usually during the night and during sleep.

Fig. 15 Proanagen. (a) Finishes the telogen phase, the papilla cells of the secondary germ begin to increase in size and increase RNA synthesis. (b) At the same time, the matricial bulb cells of secondary germ also begin in depth growth. (c) In anagen II, the secondary germ grows into the depths adopting a truncated form that pushes toward the interior of the dermis to the papillary mesenchymal cells.

(d) Immediately after surrounds the papilla, beginning the formation of hair and inner root sheath. (e) In anagen III, the maximum follicular length is reached. At this stage, the bulb increases in size and tends to include all of the papilla, the dendritic melanocytes begin the formation of melanin, and hair may already be observed, although still short and surrounded by the inner root sheath

Only the hair of the beard and forearms has a higher growth rate during the day.

The anagen phase is different depending on the hair type. Thus, the hair has an anagen phase of 2–6 years, that is, 3 years on average. As the telogen lasts 3–6 months and the catagen around 3 weeks, the “rule of three” (3 years-3 weeks-3 months) is used to define the duration of a follicular cycle of the scalp. However, the anagen stage is shorter in terminal hair of other regions; for example, the body has stages with periods of similar duration that reach

a maximum of 6 months: that of the arms, 13 weeks of anagen and another period of telogen; and that of the legs, 20 weeks for both phases (Sayag and Aquilina 1989). Others have chronological differences in their cycles such as the beard, which has a 1-year anagen stage and a telogen stage of 10 weeks: that of the hands, a 10-week anagen stage and 7-week telogen stage (Camacho 1987); the pubic region with an anagen stage of 45 weeks and a telogen stage of 50 weeks; and the upper lip with an anagen stage of 12 weeks and a telogen stage of

6 weeks (Sayag and Aquilina 1989). Eyelashes have an anagen stage of 30 days, catagen stage of 15 days, and a telogen stage of 106 days (De Villez 1986).

In a normal scalp, one will observe 85–80 % of follicles in anagen, 13 % in telogen, and 1 % in catagen, which signifies that, since there are around 100,000–150,000 hairs, daily it has to shed 35–100 hairs, being this number higher after washing because this eliminates some that would not have been removed spontaneously (Camacho 1987). Without considering washing, the amount of hair left every day on the pillow, clothing, or combing varies between 31.9 and 37.6, considering that whenever more than 50 hairs are shed each day, the possible pathological cause should be investigated (Stroud 1987).

The percentages of cycle stage are different depending on the area; therefore, the number of telogen hairs is lower, in both sexes, in parietal and occipital regions than in frontal and crown areas. In the latest two regions, the telogen percentage is 17 %, being different in men and women because in the men, it is 18.22 %, while in women, it is 16.48 %, which explains the differences of frontal hair growth which is denser and lower in women than in men.

And to end this section, we must recall that the cycle of each follicle varies according to the region and even in the same area, with even the way of appearing is different since some come out surrounded by debris and others clean. In summary, each hair has its own characteristics that differentiate them from the adjacent hairs and, furthermore, there may be hair in different body areas with identical morphology (Montagna et al. 1967; Camacho et al. 2013; Montagna 1988; Uno and Montagna 1988).

These differences, or characteristics of each hair, have been studied closely in the areas with terminal hairs or unwanted vellus that are desired to be eliminated, especially in women. For that reason, we will not comment here the percentage in the anagen phase or the duration of the telogen phase of the vellus of the chest and abdomen that many men, called “metrosexuals,” remove. In the beard area, 70 % of the hairs are in the anagen phase and the telogen phase lasts 10 weeks; the

mustache area has 65 % of hairs in anagen and the telogen phase lasts 6 weeks; in the axilla, 30 % of the vellus are in anagen and the telogen usually lasts about 3 months; on the arms 20 % of hairs are in the anagen phase and telogen phase lasts about 18 weeks, and on the legs and thighs, there are also 20 % of the hairs in the anagen phase with the telogen phase lasting 24 weeks (Wanitphakdeedecha and Alster 2008; Table 1).

One datum that is known all over the world but until now no one knew why it occurs is that “the growth rate of gray-white hair is significantly higher than the black hair.” In the study of the expression of genes of keratins and their associated proteins, it has been demonstrated that they are overstimulated to twice their activity in active growth of white-gray hair, compared with black-pigmented hair (Choi et al. 2011). The structure, follicular cycle, and pigmentation of eyelashes have been well studied by Bernard’s team (Thibaut et al. 2010).

5.3 Hair Growth Pace After Being Pulled Out

This is a question asked by many patients after trichogram and after shaving the scalp. The new hair takes about 129 days to appear in the vertex, about 117 in the temporal regions, and about 92 days on the cheeks.

5.4 Hair Thickness

The volume or diameter of the hairs is related to the matrix/bulb. To check the hair diameter, one observes under graduated microscope 0.025 mm divisions. The diameter of the hair increases in the first 3 or 4 years of life, and it is somewhat less over the next 6 years and increases little from 12 years. The diameter of a *terminal hair* of the scalp of an adult is about 70 μm (60–84 μm) (Fig. 16). We speak of thick hair when its diameter is 0.1 mm, of an *intermediate hair* when it is about 0.05 mm, and thin hair when the diameter is approximately 0.025 mm (Olsen 1999). In older people, hair diameter is reduced, while in a young adult (21 years old) the percentage of hairs

Table 1 Hair growth cycle in different areas of the body

	% Telogen	% Anagen	Telogen duration	Follicular density	Follicular depth
				(No. fol./cm ²)	
Scalp	10–15	85	3 months	350	3–5 mm
Eyebrows	85–95	5–15	3–4 months	100	1.1–1.4 mm.
Eyelashes	60–70	0–40	3.5 months	^a	1.9–2.2 mm
Mustache	35	65	6 weeks	500	1–2.5 mm
Beard	30	70	10 weeks	500	2–4 mm
Axilla	70	30	3 months	65	3.5–4.5 mm
Trunk	^b	^b	10 weeks	70	2–4.5 mm
Pubic area	65–81	19–35	12 weeks	70	3.5–4.5 mm
Arms	72–86	14–28	2–4 months	80	^c
Legs	62–88	12–38	3–6 months	60	2.5–4 mm
Thighs	64–83	17–36	2–3 months	60	2.5–4 mm

^aThere are 420 eyelashes between the two lids: on the upper lid, 100–150 measuring 8–10 mm and on the lower lid, 70–75 measuring 6–8 mm

^bDifferences between chest, abdomen, back, and lumbar regions

^cNo studies were found, probably due to lack of interest. It seems that the depth of the follicles in the dermis is different between males and females

Fig. 16 SEM micrograph of a normal hair fiber. Note the increasing irregularity of the free cuticular edges (left to right). White bar 1 mm

according to thickness is 72.1 % thick, 18.8 % intermediate, and 10 % thin. This phenomenon occurs in all regions and is independent of follicular density. It is important, however, to remember that there is a direct relationship between the growth phase and thickness of the hair; therefore, 84 % of thick hairs are in the anagen phase, only 4 % in catagen and 12 % in the telogen phase.

Apart from the terminal hairs, there are vellus and intermediate hairs. The *vellus* are short, thin, and hypopigmented and have a diameter less than

0.03 mm, that is, like the thin terminal hairs. And before, we indicated that *intermediate hairs* have a thickness of about 0.05 mm (Sperling 1991). Besides this difference in thickness between vellus, terminal hairs, and intermediate hairs, there is also a difference between pigmented and nonpigmented terminal hairs, because the white or gray hair has greater thickness than the pigmented hair (Gayoso et al. 1982).

As about the “shape,” the cross section of the hair during the first 2 years of life is round, later becoming oval. By about age 3, it has an oval surface area of about 0.25 mm² and gradually widens to reach 0.40 mm² at 17 years of age (Fig. 17). Therefore, from that moment, the terminal hair has a major axis and a minor axis (Hutchinson and Thompson 1997). Eyebrows and eyelashes are flat and curved. Follicular depth of the eyebrows in the dermis is from 1.02 to 1.20, and the eyelashes of 1.8–2.2 mm (Thibaut et al. 2010). The pubic vellus are twisted on their axis.

As we have indicated, the hair has an elliptical shape, but as it grows, that is to say, become separated from the scalp, it presents variations. Thus, it has been observed that the hair in full anagen phase, which is usually about 6–8 cm from the scalp, is when it presents its larger diameter but from that point, there are variations of the major transverse axis which is reduced by up to

Fig. 17 Cross section of normal Caucasian hair with a discontinuous medulla (*center*). The cut through the fiber caused a disorder of the cortex material when the compression forces of the cutting edges were released (*bottom of fiber*). *White bar* 0.1 mm

20 %, and its elliptical shape is reduced by approximately 13 %, while the minor transverse axis is unchanged. These changes, which are due to intrafollicular mechanisms, are responsible for the fact that as the hair grows in the anagen phase, it becomes thinner and round (Messenger 2011; Montagna et al. 1985b).

5.5 Hair Length or “Linear Growth”

This is related to the duration of the anagen phase. The *scalp hairs* grow from 0.37 to 0.50 mm per day, specifically about 0.5 mm per day in the region of the crown and 0.4 mm in the temporal region. The growth of hairs from other areas is different: the hairs of the *beard* grow about 0.27 mm per day; those of the *chest*, 0.44 mm; those of the *axilla*, 0.36 mm; those of the *thighs*, 0.29 mm; those of the *pubic area*, 0.40 mm; those of the *eyebrows*, 0.16 mm; those of the *back*, 0.13 mm; and those of the *forehead*, 0.03 mm.

The daily growth of hair in children has not been studied in depth. It is known that while the vertex is around 0.05 mm/day in the occipital and parietal regions, it is 0.30–0.35 mm/day in the parietal region. The hair growth on the thighs is 0.13–0.20 mm/day, a proportion that is usually maintained in adults.

With regard to the maximum hair growth, we know that the eyebrows measure about 1 cm (Montagna et al. 1985b) and the hair on the forehead varies between 1.5 and 2.2 mm, that of the chest between 3.4 and 5.1 mm, and that of the back between 4.9 and 6.4 mm. The beard hair in males can reach up to 30 cm, the pubic vellus up to 6 cm, and that of the axilla varies between 1 and 6 cm. We also know that the axillary and pubic vellus begins at puberty and has its greatest diameter around age 25 and declined thereafter (Messenger 2011).

5.6 Gender Differences

And in relation with gender differences, we know that the scalp hair diameter of the women increases from the age of 22 having its point of greatest diameter at 30 years of age and decreasing from that time (Messenger 2011). The eyebrows and nose hairs, those of the ears and even the beard, in women begin to grow later and also increase later remaining the same throughout their life except for the beard which grows in the elderly (Messenger 2011). For the other types of hair, we already accepted that there is the same amount of follicles and hair on the body of women as on men despite the appearance of “hairy” skin in males.

The implantation of frontal hairline is different in men and in women. In women, the hairline is more anterior (Fig. 18a), sometimes occupying almost the entire forehead and occasionally adopting a pyramidal form (Fig. 18b). Although there are differences between the values of the frontal hairline of Spanish and American women (Ceballos et al. 2013; Nusbaum and Fuentesfria 2009) and the shape of the foreheads of Korean women (Jung et al. 2011), we cannot fail to mention that the measurements are made taking into account the average distances between a center front point known as “widow’s peak” two “lateral protrusions” at about 4 cm and two other points at the temples at 4 cm too (Fig. 19, red line). The widow’s peak measures 1.83 in width and 0.80 in height (Fig. 19, angulated red line). The forehead height is measured between the lowest point of the

Fig. 18 (a) Normal frontal implantation hairline in woman. (b) Although it is lower than in men, occasionally, it can be very low occupying almost the entire forehead, at time adopting pyramidal form

Fig. 19 Values of the frontal hairline of Spanish women. **a** Measures of the widow's peak: 1.83 wide – 0.80 high. **b** blue Measure from lowest point widow's peak to the glabellar midpoint: 5.54 cm. **c** Measure from the frontal midpoint to the lateral protrusions: *right*, 3.74 cm; *left*, 3.97 cm. **d** Distance between lateral protrusion and temporal points: *right*, 3.78 cm; *left*, 3.51 cm

d. Lateral protrusion - temporal point:
Right: 3.78
Left: 3.51

widow's peak and glabellar midpoint, that in Spanish women, the middle is of 5.54 cm (Fig. 19, blue line). In addition, the outline of the temporal regions or receding hairlines must be assessed as triangular, concave (which are the known triangular or concave "receding hairlines," respectively), convex, or straight. The five forehead patterns of the Korean surgeons are round, M-shaped, rectangular, bell shaped, and triangular (Jung et al. 2011). In woman, the density of the mid-forehead line decreases with age from 293 ± 61.3 hairs per cm^2 at age 35 to 211 ± 55.1 hairs per cm^2 when she is 70 years old (Olsen 1999; Messenger 2011).

The rhythm and manner of growth are also different according to sex and area. Thus, the beard hair only tends to grow in the male with the exception of some individuals in whom it reaches a considerable length; in general, it only grows to 30 cm. Pubic vellus, which is curved and twisted around its axis and measures approximately 60 mm in length, is thinner, hypopigmented, and longer in the elderly. Also, pubic vellus grows differently in men than in women, considering it a secondary sexual characteristic because while in women it should be distributed in the shape of an inverted triangle on the

mons Venus, in the male, the distribution is rhomboidal with the greatest axis over the *linea alba* (Montagna et al. 1985b).

Even the scalp hair has a different growth rhythm for men and women, as in 10 days the average growth in males is 3.70 mm while in females it is 3.39 mm.

5.7 Racial Variations

There are also racial variations. For example, the black and oriental races have less body hair than whites. Moreover, the growth of the beard in Caucasian males is also much greater than in the Japanese. The only places lacking hairs are the palms, soles, dorsal surface of the last phalanx of the fingers, nipples, penis, clitoris, and inner surface of the vulva (Gayoso et al. 1982).

There are also variations regarding the direction of the hair: (a) Mongoloid and Caucasian hairs (Fig. 20a) are straight because the follicles are oriented vertically to the skin surface; (b) the hair of blacks are spirals, like wool, although with greater texture (Fig. 20b) because the follicles are curved and the lower portion is placed in an almost horizontal position to the skin surface (Blume et al. 1991); (c) the hair of Australasian

aboriginals is wavy; and (d) the hair of white Caucasians can be of any shape, like above, including wooly hair spiral or, more commonly, straight hairs which tend to bend as the follicle makes an acute angle with the skin surface.

And writing about racial variations, there is a subject which is worth considering here. Caucasians may have straight or curly hair (Fig. 21a, 21b), and it may be blond (Fig. 22a), red (Fig. 22b), or black (Fig. 22c). Straight hairs are produced by follicles with a round lumen, while the curly hair come from follicles with an elliptical or oval lumen (Lindelöf et al. 1988). Moreover, both Caucasian males as well as females show a tendency to have body hair, which makes this one of the major racial differences since while Caucasian women may be hirsute, those of other races do not tend to be so (Montagna et al. 1985b).

5.8 Variations Chronological

With respect to the age, hair grows faster between 16 and 46 years, clearly decreasing after 50 years of age.

The percentages in anagen, catagen, and telogen hairs during fetal life and in the first

Fig. 20 Variations regarding the direction of the hairs: (a) Mongoloid and Caucasian hair is straight whereas (b) Negroid hair is spiral shaped

Fig. 22 *Hair color (a) A woman with straight blonde hair. (b) A woman with red curly hair (c) A woman with straight black hair*

weeks after birth are totally different from those of adults because the cycles in the fetus are very short. Around the fifth month of intrauterine life, all the hairs are in anagen phase, although the follicles are small and produce very thin hairs. In another 8–10 weeks, that is, at about the seventh month of prenatal life, the majority of the follicles of the frontal and parietal regions pass to the telogen phase, beginning in the frontal region, and a week later in the parietal area. These cycles are very short, lasting about 8 weeks, beginning a new anagen cycle in these two regions about 5–6 weeks before birth. For this reason, at the

moment of birth, there is a superposition of cycles according to areas because while the scalp hairs of the frontal and parietal areas are already in a new follicular anagen cycle, those of the occipital area are still in the first. The percentages of scalp hairs in catagen and telogen phases at the time of birth are 31.6 % of the frontal region, 26.1 % of the parietal region, and 16.1 % of the occipital region. After birth, the follicles of the temporal and occipital areas quickly become telogenic, with approximately 100 % of them being in this phase between the 10th and 16th weeks while only 50 % of those on the frontal region are telogenic. Around the

32nd to 40th weeks, the percentage of anagen hairs stabilize throughout the scalp. This percentage of 100 % of scalp hair in the telogen phase in the occipital region toward the tenth week justifies the presence of occipital alopecia in children who sleep in the supine position due to the friction with the pillow (Janniger and Bryngil 1993).

Children between 3 and 11 years of age have 90 % of their hairs in the anagen phase, with this percentage being higher in the occipital region, and in the crown than in the frontal, and parietal areas.

Research has been carried out in American children between 14 and 18 years of age on the hair density in different parts of the body, observing that the vellus that first appears is the pubic hair which is complete at age 16. Next emerges axillary vellus which at 14 years it is 40 %, at 16 years it is 97 %, and it is complete at 18 years of age. This is followed by the anterior surface of the legs, anterior surface of the thighs, forehead, abdomen, buttocks, cheeks, lumbar region, and arms (Table 2).

In adults over 50 years of age, a number of variations can be observed: (a) there is a lower hair density and a greater range of dispersion; (b) the hair density of women is less than that of men; (c) the growth rhythm is also less at this age; (d) both on the scalp and in other body regions the

number of thick hairs is higher in older people than in those under 46 years of age; and (e) the proportion of scalp hairs in the telogen phase is greater, although there are differences according to age, such as males between 60 and 83 years show a lower proportion of scalp hairs in the telogen phase than those between 50 and 59 years (Barman et al. 1969).

5.9 Follicular Density

“Follicular density on the scalp” refers to the “number of follicles per cm² of surface,” which varies clearly according to the age (Table 3). In newborns, there is nearly almost double the number of follicles than between the ages of 20 and 30 years and about three times more than in 80–90 years. In addition, one must remember that bald people undergo a “miniaturization” of the follicles, which is because they also have a lower follicular density. The follicular density is not very different in both sexes.

An important aspect to note is that “speaking of follicular density is not the same as speaking of hair density” because, usually, the number of hairs that emerges is much smaller than the number of “follicular units” existing in the area. The follicular unit usually consists of four to five follicles, sometimes more, but with a common erector muscle. There are follicular units with low hair density that produce only one or two scalp hairs and others of high hair density containing three to five hairs (Messenger 2011). Prepubertal children,

Table 2 Percentage of hair growth in three ages of American children

Area	14 years	16 years	18 years
Pubic region	97	100	100

80–90 years	435
Bald	
45–70 years	330
70–85 years	280

i.e., 3–9 years, have crown hair density of 250 hairs/cm² and 170–205 hairs/cm² in the parietal and occipital areas. Boys have a slightly higher scalp hair density than girls.

Studying scalp hair density in the parietal region of a group of women and two subgroups of men with a mean age of 60.5 years for men and 63.4 for women, it was found that the average density was 163.8 ± 12.6 (87–330) hairs/cm², with the group of women being 147 ± 10.4 (87–215) hairs/cm², the subgroup of men between the ages of 54 and 59 years being 178 ± 13.4 (104–330) hairs/cm², and the subgroup of men between ages of 60 and 83 years being 161 ± 13.6 (90–270) hairs/cm², with the density in the total groups of males being 168.5 ± 13.4 hairs/cm² (Messenger 2011).

In a recent study, it was shown that the hair density decreases with age (Barman et al. 1969), but another more current study, in which a group of males with or without androgenetic alopecia, aged between 25 and 32 years, except one who was 49, were followed up for 8–14 years, showed a reduction not only of hair density but also of the follicular activity. This is due to the fact that aging causes the growth cycles to be shorter, while the quiescent periods are lengthened, which leads to there being fewer active follicles and thus fewer and thinner hairs per unit area (Courtois et al. 1995).

For the study of follicular density on the scalp, the use of TrichoScan has been evaluated positively, among other reasons because it always is done in the same area and at the same distance. However, in order to know the hair density in other areas, such as the beard, the measurements of follicular density must be based on other measures. Wan et al. (2011) used transparent templates with a diameter of 2.5 cm which were placed on four or five areas of the treated beard, observing that the hair density grew in each of them after having been 2 days without shaving the area. Controls were performed in 2–4 weeks with a Nikon D70S machine at a distance of 30 cm. The overall assessment that resulted depended on a previously created scale in which areas with complete alopecia were evaluated as 0, while a score of 1 had very little repopulation, 2 had little repopulation, 3 moderately dense, 4 dense, and

5 very dense. An area with a count of 195.0 hairs was considered as moderately dense and with 237.2 hairs as dense ($P = 0.003$). While this type of counting may be valid, it has the limitations of not being able to get a tattoo in the area to take samples always in the same area and not using devices capable of taking the picture in the same projection and distance, so the results may be variable. However, it is an inexpensive method that uses an inexpensive material.

5.10 Seasonal Changes in Hair Growth

In many mammals, hair growth throughout the year is related to the length of daylight and to a lesser proportion to the existing temperature. The follicle interprets these environmental changes as if they were consequence of alterations of the pituitary and hypothalamic hormones, which in turn regulate the levels of many circulating hormones including the gonadal, thyroid, and corticosteroid hormones, which are well known that alter the mammalian follicular activity. Prolactin is involved in the seasonal changes of red deer, mink, and goat (Randall 2004).

Although the human hair growth is different from mammals, it also undergoes changes with the seasons. The scalp hair of Caucasians, both men and women, have an annual cycle with the highest loss in the autumn, while the percentage of scalp hairs in anagen at the beginning of spring is 90 % and in the summer 80 %; therefore, there are also people who notice the beginning of the falling hair season in summer.

And just as in mammals, there is greater hair loss in relation to the amount of daylight; it was found that men who work in closed places have increased hair loss when they are exposed to the sun for a much time in the long days of summer.

Hair growth of the beard and thighs has also been associated with winter or summer seasons. It has been observed that, while in winter it grows much slower, in summer it may even increase by 50 % in the beard and, although the percentage is not known, thigh hair grows faster in men than in women. These changes seem to be related with an

increase in the androgens that is found in the summer.

Hair • Healthy • Scalp • Ethnic • Trichoglyphs • Whorl • Biofilm • Weathering

Even healthy hair seems easy to define, trying to state clearly frontiers between healthy and non-healthy remains more than difficult. This is notably because of variations between ethnical origins and modifications correlated to age or sex. For these reasons, specific parameters need to be well known before being categorized as *normal (healthy)* or *pathologic*.

1 Functions of Healthy Hairs

Hair functions are essential: as a protection barrier seems obvious (mechanical, thermal regulation, UV radiations), body hair loss along the evolution of the human race could have participated at human domination upon other animals. Hairs are of course also the reflection of customs and trends in societies, who now, can we say, roughly aspire to more scalp hair and less body hair. The role of the hair as a sexual differentiation (and dimorphism) – for animals and humans – and attraction, its meaning within religions, its significance in mythology, the symbolism related to shaving imposed as punishment or renunciation, and the psychological impact of losing loosing all the hair

due to chemotherapy or Alopecia Totalis testify to its importance.

2 The Healthy Hair Follicle

Each hair follicle on the body, according to each anatomical region, presents structure, shape, length, cycle, and orientation (angle implantation) specificities. As a common practical example, acquired kinky hair on the scalp can be a sign of becoming a “non-healthy” witness of androgenetic alopecia.

Three types of pilosebaceous follicles can be individualized: the “terminal follicle,” on scalp and hairy areas, with voluminous hair and gland, the “vellus follicles” (on the limbs and lower part of the trunk) with both small components (hair length <1 cm, diameter <30 μm), and “sebaceous follicles” where the hair is of vellus type and the gland is voluminous found exclusively on the hairless seborrhic areas (head, shoulders, thorax).

Concerning the scalp, figures considered to be “normal” for healthy hairs are 100,000–150,000 hairs on the head (one-tenth of body hair), 200–300 per cm^2 , which correspond for a hair-style made of 20 cm length a total of 6 m^2 flat. The so-called *average* hair growth is 0.35–0.44 mm per day during the anagen phase which lasts from 1 to 7 years. We know the hair is divided into follicular units (FU): composed of three to five hairs, sebaceous glands, arrector muscles, and more often a single ostium. Terminal/vellus hair ratio is 7:1. The average diameter of a terminal hair varies from 0.07 to 0.09 mm and for a vellus, by definition, is less than 0.03 mm.

3 Healthy Hair Follicles: Differences and Limits

3.1 Ethnical Differences

In fact the number and the diameter of the hair are different according to the ethnic origin (Sperling 1999; Lee et al. 2002; Franbourg et al. 2003; Blume-Peytavi et al. 2008; Table 1, Fig. 1). The

Table 1 Hair differences according to ethnic origins

Type	Average diameter (μm)	Number of hair
Blond (orig. European)	40–80	130,000
Brown hair to black (orig. European)	50–90	110,000
Red haired (orig. European)	50–90	90,000
African Americans	60–100	90,000
Asian (Korea)	80–120	90,000

Fig. 1 A healthy hair whorl

transversal section of the hair also varies: European hair appears elliptical, Asian (Mongoloid) circular, and African highly elliptical (sometimes “kidney-like” shape). These features lead to differences in form (straight, curly, kinky), in flexibility, but in this way make resistance differences (lowered on hair of black skin compared to the white skin and a fortiori from the Asian).

Sebum is most important in African subjects, so the flora of the scalp is hereby amended. The hair growth is reduced ($256 \pm 44 \mu\text{m}/\text{day}$ on black skin compared to $396 \pm 55 \mu\text{m}/\text{day}$ on white skin). The average age of onset of hair whitening is different according to the ethnical origin (mid 30s for white skin, late 30s for Asian and medium quarantine for black skin). Whitening appears with a classical order: temples, vertex, rest of the scalp, beard, and body.

More details concerning ethnic hair, metrology, strength, and permeability of hairs will be presented in ► [Chaps. 75, “Clinical Assessment of the Scalp and Hair,”](#) and ► [76, “Scalp Sebaceous Function Assessment”](#)).

3.2 Sexual Differences

In females hairs grow faster (Birch et al. 2001; Messenger 2011). During pregnancy the anagen stage is prolonged, but the menstrual cycle does not seem to affect the hair growth cycle.

3.3 Seasonal Influence

From the month of July, telogen counts are higher, inducing increased shedding in September–October.

3.4 Age-Related Differences

These modifications during life are also notable, for the size or the number of hair which changes. Concerning the scalp hair, reduction of the anagen phase, the diameter of hair however is increased in women between the ages of 22 and 30–35 to reduce then (Messenger 2011). Modification of body hair along life is evident: from the lanugo to the onset of puberty pilosity and later for men hair on trunk and later again increased thick hairs on eyebrows, ears, nostrils. The thickness of the scalp also changes (Garn et al. 1954) (4.8 mm at the age of, 5.6 mm at 40–69 years, and probably more for black people), but also the arrangement of the hair (including the loss of the temporal line during puberty). The amount of sebum is lower in the second childhood before puberty and also in women after age 60 or 70. If the involution of the hair or hair senescence (reduction of phase anagen, increase of the lag phase, decrease in density, and moderate reduction in size) is to be regarded as a natural phenomenon, it remains difficult to define precisely the limits from androgenetic alopecia.

4 Organization of Scalp Hair

The pattern of hair disposition on the scalp is divided into trichoglyphs, with a whorl, least clockwise in 88.9% of the cases. Difficult to see on black skin, this whorl is unique in 95 % of cases, and in the remaining 5 %, there are two, or even three, very rarely more (a publication (Ruiz-Maldonado 2002) lists 14 whorls on a child). The whorl is usually located in front of the posterior fontanelle. It was noted on the right side in 40.4 %, median in 44.3 %, and left in 15.3 % (Samlaska et al. 1989). Its mode of occurrence is still discussed.

5 Flora of Healthy Hair Follicles

A so-called “healthy scalp” contains, in addition to bacteria dominated by *Propionibacterium acnes* – which could be organized in biofilms in the under part of hair follicles (Matard et al. 2012) – fungi and especially *Malassezia*, but also viruses and parasites (*Demodex folliculorum*). This flora remains poorly known; it enters the constitution of the microbiome, of the virobiome, of the mycobiome, and what might be termed parasitobiome.

6 Healthy Appearance of the Hair

The cuticle gives the hair a smooth contact, and the hair’s shiny appearance is also a witness of its health. It enables the hair to reach a substantial length in addition to the term of the anagen phase. Altered by external aggressions (sun exposure, inadequate care as repeated oxidation bleaching, exaggerated combing) responsible for what is named “weathering,” the hair loses its shine especially on the distal part and tends to fracture.

Bruno A. Bernard

Keywords

Growth Cycle • Human Hair Follicle • Hypoxia • Pigmentation Unit • Stem Cells

Human hair fiber is produced by a unique and complex organ, the hair follicle. Starting the third month of human embryogenesis, epithelio-mesenchymal interactions result in the formation of 100,000–150,000 follicles, whose spatial distribution at the surface of the scalp is controlled by a process called reaction-diffusion. The hair follicle adopts a concentric structure, each compartment being characterized by distinct and specific differentiation programs.

One remarkable feature of human hair follicle stems from its dynamics, the hair growth cycle, which involves successive phases of growth (anagen), involution (catagen), and rest (telogen), with an average duration of 3 years, 3 weeks, and 3 months, respectively. A side phase, termed “exogen,” has been described, independent of the rest of the hair cycle, and during which the club fiber is actively released (Stenn 2005; Higgins et al. 2009) without direct consequence on anagen initiation (Higgins et al. 2009). Following hair loss,

a latency period is observed in 80 % of hair cycles (Courtois et al. 1994), between hair shedding in exogen (Higgins et al. 2009) and the onset of a new anagen hair. The duration of this period, called kenogen (Rebora and Guarrera 2002), varies from 2 to 5 months on average (Courtois et al. 1994). At the end of the telogen-kenogen phase, a neomorphogenetic process takes place which results in the formation of a new hair follicle. We recently named this transitory phase the neogen phase (Bernard 2012).

As described, the hair cycle looks as regular as a clock, and an oscillator control has been looked for, but without success (Paus et al. 1999). In fact, we have demonstrated that human hair follicles do not adopt such a regular cyclic behavior. Each follicle has an autonomous and independent behavior, the transition from one phase to the next occurring after time intervals given stochastically by a lognormal distribution characterized by a mean and a variance (Halloy et al. 2000, 2002). From this analysis, it can be concluded that instead of a cyclical behavior with an intrinsic automaton, a bistable steady state controls human hair follicle behavior, which under a stochastic

L'Oréal Research and Innovation, Clichy, France
e-mail: bbernard@rd.loreal.com

way jumps from the dormant to the active steady state and vice versa (Bernard 2012) (Fig. 1). This autonomous switching between two quasi-steady states, involving bistability and excitability, was recently mathematically modeled (Al-Nuaimi et al. 2012). This unique behavior guarantees the permanence of hairs at the scalp surface.

A number of factors were reported to positively or negatively modulate hair growth (Paus and Foitzik 2004). The positive effects of IGF-1 on hair growth were described as early as 1994 (Philpott et al. 1994) and attributed to IGF-1 secretion by dermal papilla (Itami and Inui 2005). More recently, the beneficial effects of IGF-1 were linked to the induction of platelet-derived growth factors A and B and by an apoptosis-preventing increase in Bcl2/Bax ratio (Ahn et al. 2012). Of note, 1,763 MHz radio frequency induces an increased IGF-1 synthesis in dermal papilla and stimulates human hair growth in vitro (Yoon et al. 2011).

Although the molecular mechanisms and molecular actors controlling the phase transitions have been extensively studied and characterized (Sennett and Rendl 2012), telogen phase was considered as a quiescent phase until recently. New data demonstrate that it is not that quiescent. Indeed, during this phase, the follicle is under the influence of factors that would repress the onset of a new follicle and factors that would trigger it (Plikus 2012). A strong expression of “bone morphogenic protein” (BMP) (Botchkarev et al. 2001) and “fibroblast growth factor-18” (FGF-18) (Kimura-Ueki et al. 2012) defines a refractory period, during which the neogen onset is prevented. The progressive increase in the production of BMP antagonist noggin, Wnt/Fzz/b-catenin pathway activators, and TGF- β 2 (Higgins et al. 2009; Oshimori and Fuchs 2012) will reach a critical threshold shifting the telogen follicle to a competency status, receptive to FGF-7, secreted by the nearby dermal papilla (Greco et al. 2009)

Fig. 1 New representation of the hair follicle behavior, with an active steady state (ASS) of fiber production (anagen) and a dormant steady state (DSS) (telogen/

kenogen), interspaced by short-lasting phases of neomorphogenesis (neogen) and regression (catagen). Three successive periods ($n, n + 1, n + 2$) are represented

and ultimately triggering the onset of the neogen phase.

The hair follicle cycle is controlled by a number of factors (Paus and Foitzik 2004; Sennett and Rendl 2012), some of them stimulating anagen and others triggering catagen or maintaining telogen. For example, calcitonin gene-related peptide (CGRP) neuropeptide (Samuelov et al. 2012) and vanilloid-receptor-1 agonist capsaicin (Bodo et al. 2005) both induce premature catagen, while thymic peptides differentially modulate follicle growth. Indeed, if thymulin (TYL) increases hair growth rate, both thymosin α 1 and thymosin β 4 (TB4) slightly decrease hair shaft production. Moreover, TYL prolongs anagen while TB4 shortens it (Meier et al. 2012).

With regard to the hormonal control of hair growth, both androgens and estrogens modulate hair growth and cycling. It was already known that both TGF- β 1 and TGF- β 2 were androgen inducible in dermal papilla and behaved as anagen-to-catagen inducers (Inui and Itami 2011). Recent data have shown that dihydrotestosterone (DHT), the active form of testosterone, also induces IL-6 production by dermal papilla, which functions as an inhibitory paracrine mediator that inhibits hair shaft growth by suppressing matrix cell proliferation (Kwack et al. 2012a). DHT also induces DKK-1 production by dermal papilla cells, which in turn promotes catagen progression by suppressing Wnt/ β -catenin signaling and inducing apoptosis in follicular keratinocytes (Kwack et al. 2012b). Altogether, these results position DHT as a major inducer of catagen. However, as androgens also inhibit the dermal papilla Wnt/ β -catenin signaling pathway involved in hair follicle stem cell differentiation and onset of hair regeneration (Leiros et al. 2012), they must also be considered as neogen inhibitors. With respect to estrogens, they lead to reversible hair cycle retardation through inducing premature catagen by upregulating TGF- β 2 and maintaining telogen by upregulating BMP4 (Hu et al. 2012).

Besides androgens and estrogens, prostaglandins now emerge as key modulators of hair growth. Human hair follicle is indeed endowed with a complete endogenous prostaglandin metabolism (Colombe et al. 2007; Michelet et al. 2008) and

expresses an intricate network of prostaglandin receptors, including the GPR44 (PGD2) receptor (Colombe et al. 2008). While both latanoprost, a PGF $_2\alpha$ analog, and bimatoprost, a prostamide-related F $_2\alpha$ analog, stimulate hair growth (Khidhir et al. 2013), PGD2 was recently shown to inhibit hair growth through its binding to GPR44 receptor (Garza et al. 2012). Of note, PGD2 synthesis is increased in alopecic areas (Garza et al. 2012). These results suggest that hair growth is under a subtle balance between positive influence of PGE $_2$ et PGF $_2\alpha$ (Sasaki et al. 2005) and negative influence of PGD2.

Altogether, the above results demonstrate that hair growth is tightly regulated by growth factors, cytokines, neuropeptides, hormones, and environmental cues. However, the existence of anagen, catagen, telogen, and neogen phases underlines a unique feature of hair follicle that hair growth is not a continual process and hair follicle must be cyclically renewed. Hair follicle renewal requires transient activation of local reservoirs of stem cells. Seminal work in mice localized a reservoir of slow-cycling, epithelial stem cells in the bulge, a distinct segment of the outer root sheath (ORS) of mouse follicles (Cotsarelis et al. 1990). It is now known that the follicle is endowed with numerous stem cell reservoirs and that these reservoirs express different markers and seem to have different functions (Jaks et al. 2010). With respect to human hair follicles, early work suggested the existence of at least two pools of pluripotent cells (Lenoir et al. 1988). In accordance with these findings, high β 1-integrin (CD29) expression was observed in sections of both the upper and lower ORS (Commo and Bernard 1997). In addition, K19 labeling clearly identified two groups of putative stem cells in the hair follicle (Commo et al. 2000). The upper and lower reservoirs of K19+ cells are not, however, identical and can be distinguished by differential expression of K15 and CD200, more highly expressed in the upper reservoir, and CD271, CD29, and CD34, more highly expressed in the lower reservoir (Inoue et al. 2009). This differential epitope mapping appears being not restricted to the ORS since the connective tissue sheath (CTS) in conjunction with these two reservoirs

also harbors distinct compartments. For example, one chondroitin sulfate epitope (4C3-CS) is specific for the upper CTS, while another chondroitin sulfate epitope (7D4-CS) and N-sulfated glucosamine-rich heparan sulfate epitope (HepSS-1) are only observed in the lower CTS (Malgouries et al. 2008). In summary, the human hair follicle can be characterized by the presence of at least two epithelial stem cell reservoirs that interact with specific microenvironments. Both reservoirs fuse during catagen and telogen phases and then separate again in early neogen and anagen (Commo et al. 2000). We recently demonstrated that the lower reservoir stem cells expressed hypoxia-specific markers, namely, carbonic anhydrase IX and GLUT-1 glucose transporter (Rathman-Josserand et al. 2013), highlighting the fact that the upper and lower stem cell reservoirs were subjected to very different microenvironments. As hypoxia is believed to promote an undifferentiated state in several stem and precursor cell populations (Mohyeldin et al. 2010), we propose that hypoxia signaling in suboptimal conditions would help maintain hair follicle stem cell functionality and hence prevent alopecia or at least favor neogenesis.

All above results underline the complexity of the regulatory networks which control human hair cycle and its successive phases of growth, involution, rest, and regeneration. Of note, the hair pigmentation unit responsible for hair pigmentation also undergoes cyclical alterations. In fact, a fully active follicle contains two melanocyte populations, one located on top of dermal papilla, the pigmentation unit, and one located in the basal layer of the upper outer root sheath, in the permanent part of the follicle (Commo and Bernard 2000). The former contains constitutively active melanocytes which produce melanin throughout anagen and transfer pigment-loaded melanosomes to the nearby cortical cells, whereas the latter is now considered as a reservoir for quiescent melanocyte progenitors/stem cells (Commo and Bernard 2000). During catagen, the pigmentation unit almost entirely disappears through a massive apoptotic process, whereas the melanocyte progenitors/stem cell reservoir remains unaffected and detectable during telogen (Commo and Bernard

2000). At the neogen onset, a subset of melanocyte progenitors is recruited, migrates down to the nascent bulb, and transiently amplifies to regenerate a fully functional pigmentation unit. This melanocyte behavior is another example of the unique cell dynamics and tissue choreography which characterize the human hair follicle growth cycle.

1 Sebaceous Glands

Sebaceous glands are multilobular structures which invaginate the dermis. At the periphery of glands, there are epithelial cells surrounded by a basement membrane. Generally, the duct of each gland is connected to a hair follicle and forms a pilosebaceous unit. The sebaceous glands may also exist without an apparent attachment to the hair follicle or, like on the forehead, may be connected to a vellus hair (Kligman and Shelley 1958).

Majority of sebaceous glands, together with hair itself, are a principal part of a pilosebaceous unit (Smith and Thiboutot 2008). Pilosebaceous unit differentiation occurs between months 2 and 4 of gestation. A complex signaling pathway between dermal mesenchymal cells and embryonic epidermis takes place and induces formation of dermal papilla which initiates the final differentiation of pilosebaceous unit (Tóth et al. 2011). Differentiation of pilosebaceous unit depends upon Sox9 signaling (Nowak et al. 2008). Differentiating toward hair follicle or toward sebaceous lineage depends on the presence or inhibition of β -catenin. Indian hedgehog signaling stimulates further sebaceous differentiation (Allen et al. 2003; Han et al. 2006; Niemann

et al. 2003). There are some other proteins/genes involved in embryonic development of sebaceous glands or their homeostasis. They include a protein expressed on stem cells called B lymphocyte-induced maturation protein 1 (Blimp 1) transcription factor and c-myc (Horsley et al. 2006; Schneider and Paus 2010; Schneider et al. 2009).

In the neonates, the cell organization of sebaceous acini consists of undifferentiated, differentiating, and differentiated, mature sebocytes (Tosti 1974). In adults, sebaceous glands can be divided into three zones: peripheral zone, maturation zone, and central necrosis zone of differentiated sebocytes (Schneider and Paus 2010; Thody and Shuster 1989). The number of glands is nearly constant throughout life, while their size can increase and their turnover speed slows down with aging (Fenske and Lober 1986; Zouboulis and Boschnakow 2001; Plewig and Kligman 1978).

Sebaceous glands are composed of sebocytes and sebum is the product of sebaceous glands. Sebocytes are formed from indifferent germinal cells in epithelium in the periphery of the glands. Newly formed cells migrate toward the center of the gland as the gland matures (Clarys and Barel 1995). Lipid synthesis and discharge in sebocytes last for more than a week (Plewig and Kligman 1978). Sebum is a species-specific mixture made of relatively nonpolar lipids (Nikkari 1974) including squalene, wax esters, cholesterol esters, triglycerides, and possibly some free cholesterol (Thody and Shuster 1989; Nikkari 1974; Ramasastry et al. 1970).

2 Sebaceous Glands and Hair Follicles

The hair follicle can be divided into various sections. The upper part of hair follicle up to the sebaceous duct is the infundibulum. In this region due to the absence of a tight attachment between hair shaft and the skin, the shaft can move. Sebaceous gland secretions fill the gap between the shaft and skin (Schaefer and Lademann 2001). Below the sebaceous duct is the isthmus. It

continues up to the area of attachment of arrector pili muscle to the hair follicle. From the isthmus upward, the hair follicle does not disintegrate during follicle growth. At the location of attachment of arrector pili muscle, there is a bulge area which is a hair growth regulator (Viragh and Meuli 1995). The lower follicle starts below the bulge area, and here there is a keratogenous zone. Keratinization is an important process for hair growth and might be playing a role in the transporting processes. The sebaceous gland duct acts as a border in terms of keratinization: below the opening of sebaceous gland duct, the outer root sheath cells have little keratinization, if any, while above the sebaceous gland duct, outer root sheath cells are keratinized and are more similar to the cells of epidermis. Bulb is the lowest part of hair follicle and the location of matrix cells, the basement membrane, and the papilla. They are also hair growth regulators (Hashimoto and Shibazaki 1976). Below the bulge area and from outside to the center, the following layers can be observed: the outer root sheath, the inner root sheath and the Henle layer, the Huxley layer, and the cuticle (outermost layer of hair shaft). The hair shaft includes the cuticle, cortex, and medulla (Hashimoto and Shibazaki 1976; Bertolino et al. 1993).

Sebaceous glands can act as a target for topical application of drugs based on the fact that there is a direct connection between the follicular duct and the sebaceous gland (Agarwal et al. 2000).

Sebaceous glands of the scalp are important to maintain hair, and their absence can be associated with scarring alopecia (Schneider and Paus 2010; Sundberg et al. 2000). Hair follicles of pilosebaceous unit are categorized into vellus hair and terminal hair. Vellus hair reaches into the dermis, while the terminal hair goes deeper and into the subcutaneous fat layer. The highest density of hair follicles is on the scalp region (Sperling 1991). Sebaceous gland density is high on the scalp and the skin of the forehead. There are no sebaceous glands in the palms and soles; on the other body parts, they do exist more or less (Smith and Thiboutot 2008; Elias 1983).

3 Sebaceous Glands of the Scalp

Human scalp has the highest hair follicle density throughout the body (200 hairs per cm^2). It also has a dense and specific microflora. In addition, it produces a large amount of sebum (casual level of $150 \mu\text{g}/\text{cm}^2$) (Pouradier et al. 2013). After using shampoo or local degreasing, scalp recoating restarts immediately and will complete within a couple of hours; proximal hair shafts on the scalp start recoating much later, and complete recoating can take 3 days (Pierard 1987). Sebum casual level is maximum on the forehead and on the scalp (Pierard 1987; Greene et al. 1970). A casual level of less than $50 \mu\text{g}/\text{cm}^2$ is considered as hyperseborrhea. Hyperseborrhea (oily skin) refers to oversecretion of sebaceous glands in which the casual level can reach high levels of $500 \mu\text{g}/\text{cm}^2$ and commonly affects areas rich in sebaceous glands such as the scalp. Both greater sebum production and a higher sebaceous gland density contribute to hyperseborrhea (Pierard 1987). It is a predisposing factor for seborrheic dermatitis (Smith and Thiboutot 2008).

A significant difference between the scalp and forehead in terms of sebum excretion was reported in early 1980s. This cannot be only justified by the density of sebaceous glands on the scalp and forehead because both have the same range of sebaceous gland density (400–900 per cm^2). The scalp has a slower refatting rate probably due to the fact that there are differences in follicular reservoir, the reservoir of lipid contained within the pilosebaceous unit (Kligman and Shelley 1958; Saint-Léger and Levegue 1982). The thin vellus hair on the scalp would increase the effective volume which is available for a lipid reservoir. The ratio between excretion and secretion kinetics differs between scalp and forehead regions due to the existence of hair follicles (Saint-Léger and Levegue 1982).

The scalp is a region with two characteristics: it is rich in sebum due to the abundance of sebaceous glands, and it is sensitive to androgens (Saint-Léger and Levegue 1982; Piérard-Franchimont and Piérard 1988). Each day, grams

of sebum are delivered to the scalp and hair surfaces (Saint-Léger 2005). Sebaceous gland product is a nutrient for scalp biocenosis (Piérard-Franchimont et al. 2006). Sebum excretion rate in the scalps of people with androgenetic alopecia has been reported to be higher (Piérard-Franchimont and Piérard 1988) or equal (Maibach et al. 1968) than controls. Maibach et al. showed that the casual sebum level of the scalp in bald men is not higher than controls and suggested that the hairs normally act as a wick for disposing serum and in bald men this mechanism is not operative so sebum spreads on the skin and produces the oily appearance of bald scalp (Maibach et al. 1968). Sebaceous glands of bald scalp have been reported to have greater binding affinity for androgens compared to these glands in hairy scalp (Sawaya et al. 1989). Sebaceous glands of people suffering from androgenetic alopecia have shown increased levels of glutathione S-transferase activity and reactive oxygen species compared to normal hairy scalp sebaceous glands (Giralt et al. 1996).

Systemic hormonal status significantly affects the secretion of sebaceous glands, and therefore, the function of these glands changes with aging (Piérard-Franchimont and Piérard 2005). A recent study showed no significant difference in casual sebum level on the scalp with aging. On the forehead, on the other hand, the function of sebaceous glands showed a plateau phase at the 30s and then slowly decreased thereafter with a more prominent reduction from menopause (Nazzaro-Porro et al. 1979; Man et al. 2009).

It has been suggested that the scalp is not very reliable for assessment of sebaceous gland excretion due to the fact that sebaceous gland production and sebum behavior may be affected by several external factors such as scales, dandruff, migration along the hair shafts, etc. (Pouradier et al. 2013).

The biologic activity of sebaceous gland is regulated through interaction of different ligands with receptors on sebocyte surface such as androgen and estrogen receptors, PPARs and liver X

receptor (LXR) (Hong et al. 2008; Russel et al. 2007), neuropeptide receptors, and retinoid and vitamin D receptors (Schmuth et al. 2007; Zouboulis 2000, 2004). The interaction between the ligand and the receptor leads to activation of several pathways including differentiation, proliferation, lipogenesis, metabolism of hormones, and release of chemokines and cytokines (Zouboulis and Schagen 2008).

4 Factors Influencing the Functions of Sebocytes

- Bacterial stimuli such as *Propionibacterium acnes* and lipopolysaccharide (LPS) can affect Toll-like receptors 2, 4, and 6 and possibly increase β -defensins, cathelicidin, tumor necrosis factor- α (TNF- α), interleukin-8 (IL-8), and interleukin-1 α (IL-1 α) (Tóth et al. 2011; Lee et al. 2008a, 2009; Nagy et al. 2006; Oeff et al. 2006).
- Acid arachidonic might increase lipid synthesis, apoptosis, and differentiation and also increase interleukin-6 (IL-6), IL-8, leukotriene B4 (LTB4). Its potential target is not clearly known; it might be a protein kinase or peroxisome proliferator-activated receptors (PPARs) (Alestas et al. 2006; Tóth et al. 2009; Wrobel et al. 2003).
- Linoleic acid acts on PPARs and increases lipid synthesis, differentiation, and testosterone to 5- α -dihydrotestosterone (5- α -DHT) conversion (Chen et al. 2003; Rosenfield et al. 1998, 1999).
- Testosterone and 5- α -DHT act on androgen receptor and increase proliferation in the presence of cofactors such as PPAR agonists. They also increase lipid synthesis and differentiation (Rosenfield et al. 1998, 1999; Choudhry et al. 1992; Fritsch et al. 2001; Pelletier and Ren 2004).
- Estrogen binds to estrogen receptors α and β and might decrease sebogenesis, while progesterone binds to its receptor and its role is not well defined (Pelletier and Ren 2004; Deplewski and Rosenfield 2000; Guy et al. 1996).
- Corticosteroids have a permissive effect and also increase proliferation and decrease lipogenesis. Their receptor is not clear (Chen et al. 2006; Solminski et al. 1995; Zouboulis et al. 1998).
- Vitamin D3 binds to vitamin D receptor (VDR) and decreases IL-6 and IL-8 and also increases cathelicidin. It can increase or decrease proliferation based on the speed of proliferation and also can decrease lipid synthesis (Lee et al. 2008a; Kramer et al. 2009).
- Growth hormone binds to growth hormone receptor (GHR) and increases differentiation without having an effect on proliferation (Deplewski and Rosenfield 1999; Lobie et al. 1990).
- Insulin-like growth factor I (IGF-I) binds to IGF-I-1 receptor and increases proliferation and has a minor effect on differentiation. It also increases lipogenesis (Deplewski and Rosenfield 1999; Makrantonaki et al. 2008).
- Insulin binds to insulin receptor and increases proliferation and differentiation and also has a supportive role for 5 α -DHT, GH, and IGF-I (Deplewski and Rosenfield 1999).
- Epidermal growth factor (EGF) binds to EGF receptor and increases proliferation while decreasing differentiation (Guy et al. 1996).
- Fibroblast growth factor 7 (FGF-7) binds to FGF receptor 2b and increases acne formation. Also knockout mice without the receptor undergo sebaceous gland atrophy (Grose et al. 2007; Zouboulis et al. 2002).
- IL-1 β increases IL-8 while its receptor has not been described in sebocytes (Melnik et al. 2009).
- β -Endorphin binds μ opioid receptor and increases lipid synthesis, increases differentiation, and decreases proliferation (Melnik et al. 2009).
- Corticotropin-releasing hormone (CRH) binds to CRH receptors 1 and 2 and increases lipid synthesis, increases expression of 3- β -hydroxysteroid dehydrogenase/ Δ 5-4 isomerase, and increases differentiation while decreasing proliferation. It also increases IL-6 and IL-8 (Melnik et al. 2009; Krause et al. 2007; Slominski et al. 2004).

- α -Melanocyte-stimulating hormone (α -MSH or melanocortin) binds to melanocortin receptors 1 and 5 and increases differentiation and lipid synthesis while decreasing IL-8 (Bohm 2009; Bohm et al. 2002; Thiboutot et al. 2000).
- Adrenocorticotropin hormone (ACTH) binds to melanocortin receptor 2 and increases differentiation and lipid synthesis (Guo et al. 2010; Zhang et al. 2003).
- Substance P causes increase in IL-6, IL-8, TNF- α , and PPAR γ lipid synthesis and also size of sebaceous glands and differentiation. Its receptor on sebocytes has not been described so far (Lee et al. 2008b; Toyoda and Morohashi 2001).
- Endocannabinoids bind to cannabinoid receptor 2 and increase differentiation, lipid synthesis, and apoptosis (Tóth et al. 2011; Dobrosi et al. 2008).
- Capsaicin binds to transient receptor potential vanilloid 1 (TRPV1) and retinoid X receptors (RXRs) and causes decrease in lipid synthesis and differentiation and also a decrease in IL-1 β . It increases proliferation (TRPV1 specific) and necrosis (in large doses and is TRPV1 independent) (Tóth et al. 2009).

Won-Soo Lee

Keywords

Hair density • Pattern of hair loss • Hair-loss classification • Basic and specific classification (BASP) • Ethnic differences • Familiar factors

The key factor of clinical assessment of scalp hair is to evaluate the density of hair and pattern of hair loss, if it exists. To achieve this goal, various classification methods have been proposed for describing hair density and pattern of hair loss. Pattern hair loss (PHL) typically present with the progressive thinning and shortening of hair in affected areas.

Various classification methods have been proposed for describing PHL. The first systematic classification of PHL was established by Hamilton (1951) in 1951. He sub-classified the patterns of baldness based on frontoparietal and frontal recession and vertex thinning and then evaluated a large group of men and women for the presence of specific patterns of hair loss from the prenatal period through the tenth decade of life. In 1975, Norwood (1975) refined Hamilton's classification by emphasizing temporofrontal or vertex-only subcategories of hair loss into seven

types with a type A variant and reported the incidence of male pattern baldness at various ages in white adult male subjects. An additional pattern (type II vertex) to the Hamilton-Norwood classification system was introduced in the clinical trial of finasteride in male PHL (MPHL) (Kaufman et al. 1998). In 1992, Savin (1992) introduced a classification of MPHL based entirely on a pictorial depiction of hair density as derived from mid-line scalp part width. Olsen (2003) first proposed assigning separate designations (temporal, frontal, mid, and vertex) to the areas of the scalp that bald at different rates in different individuals with MPHL. Olsen (Olsen et al. 2003) also proposed an individualized classification system that assigned a density scale to each of these designated scalp areas in any given patient, which was further refined in a later publication. Subjects thus classified would have a TFMV classification (e.g., T3F2M0V3) (Olsen et al. 2003). In 1977, Ludwig (1977) presented quite a different picture of hair loss in women from that described by Hamilton (1951). He emphasized preservation of the frontal fringe despite progressive centrifugal loss over the top of the scalp and arbitrarily designated three gradations of hair loss. Olsen (1994) and Olsen et al. (2003) proposed that frontal

accentuation (or the “Christmas tree” pattern) be considered another pattern of hair loss in women, which helps to distinguish PHL from other potential hair-loss mimics in women.

Although the several aforementioned classification methods of PHL have been suggested, these classifications have some limitations (Lee et al. 2007). The Norwood-Hamilton classification is too detailed and is less stepwise in its description, making it difficult to memorize for common use. It also does not list some peculiar types of baldness, such as FPHL (Lee et al. 2007). Additionally, many women with MPHL cannot be classified using the Ludwig classification system (Olsen 2003; Olsen et al. 2003). In addition, for most of these classification systems, the clinicians must use distinct methodologies for each gender in order to correctly classify the pattern (Lee et al. 2007).

Lee et al. (2007) devised a new classification system named the basic and specific (BASP) classification, which is comprehensive and systematic regardless of race or gender.

This new classification of PHL was designed based on the pattern of hair loss, including the shape of the anterior hairline and the density of hair on the frontal and vertex areas. The basic types represent the shape of the anterior hairline, and the specific types represent the density of hair on specific areas, which are frontal and vertex. The shape of the anterior hairline is divided into four types: L, M, C, and U. In contrast to the basic types, the specific types may be selectively included when necessary. According to patterns observed at specific areas, there are two specific types: F and V. The final type is decided by the combination of the basic and specific type. One of the basic types must be selected, and the specific type may be selected if it exists. Each of the various types is subdivided into three or four subtypes, according to its severity (Lee et al. 2007).

During the balding process, the recession of the anterior hairline, represented with the basic type classification, relatively corresponds with the thinning of hair on the crown and vertex. However, because the degree of recession might be out of accordance with the density of hair in many individuals, the separation of both characteristics

is important for proper classification. Furthermore, the combination of two features of PHL is better suited to more thorough description of the baldness phenotypes (Lee et al. 2007).

A total of 2,213 Korean subjects, comprised of 1,768 males and 445 females, were classified according to the BASP classification (Lee et al. 2007). For both sexes, the majority of patients enrolled in the study were in the third and fourth decades of life (65.1 % of males and 56.68 % of females). In males, the older as well as the younger group were more likely to have little recession of the frontal hairline (classified as type M1-2) and diffuse thinning over the top of the scalp (type F1-2). The women in the study developed typical female PHL. In men, regardless of age, 1,434 of the 1,768 males were classified as type M, accounting for 81.1 % of cases. Among the subtypes and according to the severity of baldness, the majority of subjects below 50 years of age were classified as type M1, whereas most subjects over the age of 50 were classified as type M2. The incidence of type L (9.3 %) tended to decrease with age, but those of types C (5.8 %) and U (3.8 %) tended to increase. In women, type L showed the highest frequency in all age groups, accounting for 210 (47.2 %) of 445 female subjects. Regardless of age, types M, C, and U were the next most common in order, observed in 121 women (27.2 %), 111 women (25.0 %), and 3 women (0.6 %) of the 445 subjects, respectively. Type C0 was the second most common subtype in female subjects between the second and fourth decade of life, and its incidence decreased with age. In men, type F, which is identical to FPHL in the Ludwig classification, was observed in 42.4 % (749/1,768) of male subjects, and type V was observed in 19.8 % (350/1,768). The grades of both types increased slightly with age. In women, type F was observed in 70.6 % (314/445) of female subjects with PHL (Lee et al. 2007).

Although the Norwood-Hamilton classification is the most commonly used classification worldwide, it can only be used in MPHL, and there are several types of male hair pattern that could not be described by this classification (Lee et al. 2007). Some previous studies were performed to estimate the reliability of the

Norwood-Hamilton classification and the result was unsatisfactory, even in the hands of expert appraisers (Taylor et al. 2004; Guarrera et al. 2009; Littman and White 2005). Hong et al. (2013) compared the reliability of the BASP and Norwood-Hamilton classifications. In terms of repeatability, the Norwood-Hamilton classification showed the lowest match rate in repeatability. Also, the intergroup reproducibility was higher with the BASP classification. In conclusion, the BASP classification not only classifies all kinds of hair-loss patterns regardless of sex or race, but also has better reproducibility and repeatability than the Norwood-Hamilton classification (Hong et al. 2013).

There are also racial differences in the density of hair and patterns of hair loss in different ethnic groups. In a previous study, FPHL was observed in 11.1 % of Korean males with PHL (Paik et al. 2001). In a Chinese study, MPHL was found in 13 of 108 (12 %) women with PHL, all of whom were over 50 years of age (Xu et al. 2009). In an Indian study, although it was possible to classify 80 % of cases of PHL and II (28 %) and III (15 %) were the most common types of PHL, 27 patients of 150 male subjects (18 %) did not fit into specific patterns according to the Norwood-Hamilton classification¹⁶. In addition, the type “a” variant was noted in 20 % of patients, clearly indicating the limitations of the existing classifications. There is considerable overlap in types IV, V, and VI in the Norwood classification, with the “a” variants further confusing the picture (Sehgal et al. 2007).

Family history plays an important role in the hair density and pattern of hair loss, which is believed to be influenced by genetic factors. However, the exact mode of inheritance has not been well characterized. A recent study by Lee et al. (2011) using the BASP classification revealed that familial factors affecting the morphology of PHL differ between males and females and for each BASP subtype. Parental influences on anterior hairline shape in men were predominantly from the paternal side, whereas these effects were less notable in women. In patients without family histories of PHL, a higher frequency of early-onset PHL than late-onset PHL

was identified in men but not in women. Basic types of hair loss had a higher degree of heritability from the paternal side of the family, regardless of the specific type. This study provides detailed information indicating that each hair-loss pattern according to the BASP classification has different familial factors (Lee et al. 2011).

Scalp • Hair follicle • Sebum • Skin surface lipid • Measurement

Scalp has the highest density of hair follicles (200 hair/cm²) and main sebum production (casual level of 150 µg/cm²) (Agache 2000). The skin of the scalp is commonly exposed to many topical agents such as drugs, hair care, and cosmetic products. In normal conditions, numerous hairs make scalp an invisible region for instrumental measurements. Due to this limitation, there is a lack of information about the function of the stratum corneum (SC) of scalp skin including sebaceous gland function (O'goshi et al. 2000).

Three different types of pilosebaceous follicles are recognized which include terminal hair follicle, vellus hair follicle, and sebaceous follicle. This classification is based on the volume of the sebaceous glands and the size of the connected hairs. The largest sebaceous glands are present at the skin of scalp. Terminal hair follicles are present on the scalp and beard region in men where the hair shaft is thick, and the sebaceous gland size is medium to large (Uhoda et al. 2005; Pierard-Franchimont et al. 2010).

On the scalp, sebum appears partly as discrete droplets emerging from follicular outlets and partly as a surface coating. The droplets are unevenly spread on the hair (Pierard-Franchimont et al. 2010).

Scalp and skin sebum amounts must be distinguished. Estimating the amount of scalp sebum needs a miniature sampling method, and in some methods hair must be shaved 24–30 h before measurement. The amount of sebum is conveniently measured *in vivo* using photometric assessment and lipid-sensitive tapes (i.e., Sebumeter[®]) (Pierard-Franchimont et al. 2010; Pierard et al. 2000).

1 What Can Be Assessed?

Similar to the assessment of skin surface sebum (see ► Chap. 21, “[Dermoscopy: Basic Knowledge of an Innovative Imaging Tool](#)”), the composition of skin surface lipid (SSL), the quantitative parameters of sebum excretion, and glandular parameters (density and activity of sebaceous glands) can be measured on the skin surface of scalp. The only difference is in terms of sampling and preparing the scalp skin before beginning the assessments.

2 Methods of Collecting Scalp Sebum

2.1 Solvents

For collecting SSL from hairy skin (scalp and beard region in men), the best method is to rinse the hair with a solvent (e.g., ether). The rinse is filtered by using Whatman paper to separate the hairs and squames and then evaporated. The solvents most commonly used are shown in Table 21.1 of ► Chap. 21, “[Dermoscopy: Basic Knowledge of an Innovative Imaging Tool](#).” It seems that the most convenient and effective solvent is ether.

Unfortunately in this method, there is no control of the amount of sebum collected from follicular reservoirs which may have an influence on the results. On the other hand, the application of these solvents can alter the physiology and structure of the SC; hence this method is no more recommended for assessing the amount of SSLs (Pierard et al. 2000).

2.2 Photometric Methods and Lipid-Sensitive Tapes

2.2.1 Sebutape

The Sebutape[©] (CuDerm, Corp., Dallas, Texas) consists of a hydrophobic polymeric white film (Kligman et al. 1986) and is used to measure the sebum secretion (Dobrev 2007; Clarys and Barel 1996) and evaluate the distribution of skin pores (Pierard 1986; Nordstrom et al. 1986). There are innumerable, tiny air cavities, and the surface is coated with a lipid-porous adhesive which enables the tape to be sealed to the skin during the period of collection. The film absorbs the sebum originating from the follicular openings. As sebum reaches the skin surface, it is rapidly absorbed in to the film. As the air within the microcavities is displaced by sebum, the lipid-filled cavities become transparent to light. The output from each follicle forms a sharply defined spot; the size corresponds to the volume of the droplet. Sebum absorption by Sebutape is slow and perhaps incomplete because of the barrier of the glue (Saint-Leger and Cohen 1985).

For assessment of scalp sebaceous gland function, first the skin surface of scalp is ordinarily prepared by shaving 24–30 h in advance, and at the time of measurement, the surface is washed with soap and water to remove debris and lipids (Perkins et al. 2002). According to Beach et al., Sebutape samples can be collected before and 15 min after towel drying hair that is shampooed and conditioned (Beach et al. 2012). For greater accuracy, complete defatting can be obtained by wiping with a gauze pad soaked in hexane. The film is placed on the surface for 1–3 h and then a computer image analysis is conducted. In the places where the sebaceous secretion has been absorbed, the film becomes transparent. Thanks to the placing of the film on the dark background, we can receive the pore patterns (Clarys and Barel 1995). Lipids which are examined with this method can be also extracted and then analyzed with thin-layer chromatography (Nordstrom et al. 1986; Sisalli et al. 2006).

The self-adhesive application of the Sebutape omits the difficult procedures encountered in the other methods (► Chap. 21, “[Dermoscopy: Basic](#)”).

Knowledge of an Innovative Imaging Tool”). Moreover, the area under investigation is covered during the procedure, resulting in a more standardized collection. The Sebutape requires a shorter collection time, as most of the parameters can be determined after 1 h of collection and also, most of the evaluation methods can be carried out on the same principles as Sebutape: kinetic color measurement during the collection period, image analysis after the collection period, and quantitative and qualitative analysis after extraction of the lipids from the tape.

2.2.2 Sebufix F16

The Sebufix instrument is also commonly used. Here, similar to the Sebutape[®], a polymer film is used to measure the activity of the sebaceous glands. For scalp application, the hairs in the area (1 cm²) should be shaved before measurement. The film is image analyzed with a UV-light video camera (Visioscan VC 98[®] or Visioscope[®] PC 35, C + K Electronic, Cologne) device (Dobrev 2007). The Sebufix is thus very similar to the Sebutape; the only difference is the fact that in the case of the Sebutape, the film is placed on the selected area for 1–3 h and in the Sebufix for 30 s (Clarys and Barel 1996). Therefore, the Sebufix allows for measuring sebum secretion within a shorter period of time.

The method is not really quantitative because the relation between the surface of a spot and the quantity of sebum it contains is not known and several spots can rapidly coalesce. Accordingly, it cannot measure the CL, but it may provide an estimate of the refatting rate (► Chap. 21, “Dermoscopy: Basic Knowledge of an Innovative Imaging Tool”). It can display the distribution of the active sebaceous glands and the individual refatting rate of each gland (Saint-Leger and Cohen 1985).

2.2.3 Sebumeter SM 815 (Cassette)

This device facilitates objective measurement of sebum from the skin surface areas and can be used to determine the level of sebum on the skin surface or the rate of its secretion (Knaggs et al. n.d.; Tagami 2003; Schaefer and Kuhn-Bussius 1970; Bergler-Czop and Brzezińska-Wcisło 2010; Biro

et al. 2003). It cannot, however, determine the state of the sebaceous glands (Son et al. 2008). The Sebumeter is a simple device, easy to operate, which can be used to make an objective classification of dry, normal, or oily skin (Nouveau-Richard et al. 2007; Youn et al. 2005; Kim et al. 2006) as well as to evaluate “the biological age” of the skin (Jacobsen et al. 1985; Marrakchi and Maibach 2007; Firooz et al. 2012). The measurement is based on grease-spot photometry. The Sebumeter cassette contains a mat synthetic tape, 0.1 mm thick. A special tape becomes transparent in contact with the sebum on the skin surface of scalp. For sebum determination, the measuring head of the cassette is inserted into the aperture of the device, where the transparency is measured by a light source sending light through the tape which is reflected by a little mirror behind the tape. A photocell measures the transparency. The light transmission represents the sebum content on the surface of the measuring area and is displayed in units from 0 to 350. The assessment should be measured 48 h after shampooing (Pouradier et al. 2013). The probe is applied once to the measuring area for 30 s which is controlled by a clock set in the device. The measuring head of the cassette exposes a 64 mm² measuring section of the tape. For a measurement, the tape is moved forward by a trigger at the side of the cassette to expose a new section of tape. The used tape is rewound inside the cassette. The accuracy of this device is about ±5 %. It would be the best choice for assessment of SSLs on hairy skin and scalp skin because there is no need to shave the hairs.

The applications of Sebumeter include (Firooz et al. 2007; Davari et al. 2008; Seirafi et al. 2009; Davoudi et al. 2010):

1. To study the effectiveness of hair and skin cosmetic products
2. To study sebaceous gland activity in different diseases
3. To assess the effectiveness of different kinds of treatment on skin diseases

Compared with Sebutape, the Sebumeter is more user friendly, and there is no need to clean the probe at each assessment and shave the scalp

hair before measurement for preparing. Thanks to its integrity, reproducibility, commercial availability, easy handling and operating, short measuring time, and numerical values, the Sebumeter is now used in most of the sebum evaluation studies (Yong et al. 2002; Ambroisine et al. 2007; Lee et al. 2006; Cheng et al. 2007, 2009; Stinco et al. 2007; Akhtar et al. 2010).

1 Introduction

This chapter will focus on the basic principles involved in human hair evaluation and more specifically in hair growth measurement. Historically, evaluation was rather subjective, and it took about 30,000 years before eventual categorical classification systems and clinical scoring together with objective follow-up methods became available (Fig. 1 adapted from Van Neste 2008). Although subjective approaches were classically considered to be sufficient to run the routine activities of a dermatology practice, more and more hair clinics were established, and these categorical classifications do not stand the process of scientific

Belgium
e-mail: info@skinterface.be

investigation. There are some reports showing poor concordance and weak repeatability even with trained clinicians (personal unpublished observations and others; Guarrera et al. 2009).

During the last 25 years of the previous century, we thought that the time would come where more precise observation, understanding, and exchange of information between the practitioner and the patient could be required. In the early days of hair science (1960s and 1970s; reviewed in Van Neste 2002; Dawber and Van Neste 1995), all measurements were made *in vivo* (capillary tubes or stereomicroscopy observations), and numbers were published but no documentation allowed us to check a source file or an objective record. What was really observed and measured? How come institutions like the FDA (USA) ever accepted *in vivo* hair counts made by untrained and/or unexperienced investigators, whether doctors or nurses, and took those fancy numbers as evidence during hair regrowth trials in the 1980s and 1990s? As no images can be retrieved, no one will never be able to check, and this is but one of the weaker aspects of these observer-dependent methods.

Based on repeat close-up photography, the seminal work of Saitoh (Saitoh et al. 1970) opened up avenues for further technological progress after the 1970s. Photographic methods available until the late 1990s were gradually replaced in the early twenty-first century after the advent of microcomputers and charge-coupled devices (CCD) in digital cameras. These made imaging technology accessible to a larger community.

However, progress in hair clinics remains slow as it depends on a basic understanding of what is required to generate meaningful numbers as they relate to hair growth measurement. We refer the interested reader to other publications (Van Neste 2005, 2006a, 2013) where a number of basic points were illustrated and some prerequisites were proposed for this purpose.

Those who are acquainted with growth of hair and hair follicle cycling may easily skip the very short resume on basics and proceed to the next sections.

2 Basics About Hair Structure in Relation with Global and Analytical Imaging Procedures

Here, we shall briefly review some basics about hair follicle structure and function. Basics are necessary to understand why fine-tuning of technical aspects of hair imaging remains a prerequisite. Scalp hair is an appropriate example to introduce the concept of global and analytical methods while “zooming” into the field of hair (Fig. 2). Scalp hair appears as a stable mass of hair. It actually represents the cumulative end result of discrete changes of individual hair follicle dynamics: hair shedding and its continuous replacement by regrowing hair that results in global maintenance. The key to the appropriate assessment of a patient complaining about hair shedding or hair loss and recovering an appropriate amount of hair or achieving hair maintenance lays first in a thorough understanding of the hair cycle (for a review, see Stenn and Paus 2001).

In the past, we proposed a very simplified explanatory scheme for one single hair follicle (Fig. 3). On the scalp there are about over 100,000 follicles. Importantly, not all follicles are active at the same time: some produce hair while others are resting and clearly empty or dormant. After completion of this resting phase which includes telogen–exogen transition, the club hair is processed for its programmed release. Exogen phase resolves with the shedding of the old hair fibre. What is left over in the scalp is the old exogen follicle from where eventually a new hair follicle will derive and a new hair might become visible. Each follicle appears to function independently from its neighbours, i.e., the process of scalp hair growth is normally not synchronized. However, follicles in a certain field may express a common phenotype after exposure to some compounds, i.e., sex hormones or drug treatments. Some scalp areas, in genetically predisposed individuals, will show a phenotype of defective hair replacement, i.e., patterned balding (Figs. 1 and 2). In other areas (axillae, face, chest,

Fig. 1 Scalp hair patterning: 30,000 years from qualitative observation to quantitative dynamic measurements. Patterns of scalp hair in younger-looking and more aged subjects appeared already on the walls of caves in pre-historical times (a) (Modified after Van Neste 2008). They do not differ from the more recent cartoons inspired from the Hamilton–Norwood classification (b). A scientific observer will soon recognize that it is very difficult to squeeze the spectrum of patterns displayed by a group of 30 males, i.e., real patients (c), and ascribe the right man in the right place within these simplified classification

schemes. In the *lower panel*, we show the results of a subgroup of patients who received placebo-containing pills during a 5-year period. We graphically estimated the time required for 50 % of the subjects to be considered as worsened compared to baseline (*arrow* derived from the intersection of regression *lines*). It would take about 9 months on placebo to have a reduced hair count (*blue line* and *arrow*) and 3 years with global imaging (*magenta line* and *arrow*), while a clinical investigator/observer (*yellow line*) would not detect worsening with progressive hair loss in 50 % of the subjects after 5 years on placebo!

Fig. 2 Global imaging and CE-PTG-EC in Caucasian male pattern hair loss. On the global view (*left*), we show the region of interest (ROI; *white outline*) where we performed a contrast-enhanced phototrichogram with exogen collection (CE-PTG-EC). *Baseline* image (*t0*) shows that all hair is clipped very short in the ROI. All hair fibers are well contrasted against the background. Forty-eight hours later, a new image is taken (*t2*) after extracting the exogen hair. In the *lower panels*, two enlarged fields of *t0* and *t2* highlight the presence of exogen hair. These hairs are underscored as

thin (*red* in *t0a*) and thick (*blue* in *t0b*) hair at *t0*. The underscored targets show that these exogen hairs are no longer visible in the images taken at *t2* (*t2a* and *t2b*). Because exogen are entrapped in a matrix, the exogen hair can be examined under the stereomicroscope, and hair shedding of calibrated hair can be described as numbers per unit area. On the *right panel*, the same subject is shown with a grid superimposed on the image; each *square* can be rated individually for scalp coverage scoring (SCS) as will be detailed later

genital skin, etc.), other “patterns” will be expressed: the very thin hair follicles will now grow longer and coarser hair, and such hair usually grows during limited periods of time and is retained as telogen hair for prolonged periods of time as compared to the scalp hair. As such the clinical appearance of “hairiness” depends as much on the number of hair follicles as on systemic factors responsible for regional modulation of the hair follicle activity and duration of each of its cycle phases in particular.

3 From Global Photography to Analytical Evaluation of Hair Growth

There is not a single technical modality that will encompass with a sufficient degree of precision the many dimensions of hair (Sinclair et al. 2003; Van Neste et al. 2003a). At the one end of the spectrum is the clinical observation. Hair patterning has been classified but more recently documentation has been improved with global imaging. Such images document and illustrate files submitted to the health authorities or eventually to individual patients. At the other end one

finds a number of more detailed imaging procedures and some of these will be reviewed.

3.1 Global Imaging

Standardization of global photography has been a significant step forward in scalp hair documentation not only by creating a permanent record but also more specifically by defining the conditions to prepare the scalp in order to prevent “photographic cures” for hair problems (Canfield 1996) as documented in Figs. 4 and 5.

Processing and rating of global images were initially intended to be performed as follows: the image taken before treatment is placed on the left while another image taken under similar conditions after the subject has taken or applied a drug for a given period of time is placed on the right. The expert views paired images and rate changes (right vs left or after vs before) on a seven-point scale ranging from greatly decreased (−3) to no change (0) and up to greatly increased (+3) (Kaufman 2002). Other techniques are based on scalp coverage scores (SCS; Van Neste et al. 2003b) where the observed scalp is divided into arbitrary subunit areas as shown in Figs. 1c, 2, 5, and 6.

Each field that is outlined can be scored individually (value of coverage between 0 and 5). Adjacent fields can be grouped and the mean value, i. e., a scalp coverage scoring (SCS), generates valuable quantification. This can be measured under randomization with blinding as to treatment and to time (Van Neste et al. 2003a, 2006). Trained experts' data can be traced in both the paired examination of global views (Google: FDA NDA 21-812/000, 2005) or with the SCS system (Van Neste et al. 2003b, 2006). The experience acquired during the last two decades clearly shows that analysis of standardized global images is more objective in the appreciation of hair growth effects after drug treatment as compared with subjective evaluations made by investigators or by patients. Nevertheless, global imaging requires a long period of time for detecting deterioration of the scalp condition (Fig. 1); this period of time may eventually result in the irreversible loss of a clinically significant number of follicular units (Van Neste 2008).

Global images require a high degree of standardization, and all the preparatory procedures remain key as the same holds true for its use in vivo. A simple "error in the lightning" or angle or distance between head and camera (Fig. 4) or even a different haircut or a hair dye session can have dramatic effects. As it modifies our interpretation in terms of therapeutic response, it potentially "ruins" a clinical file during a clinical study on a hair growth promoter!

Global viewing, even when highly standardized procedures are being used, does not resolve the question of hair cycling changes, but it remains clinically inspiring in terms of efficacy assessment. It is also an easy way to communicate between clinicians and patients. Stating it very simply: one is not in a position to infer from global imaging that hair grows faster or that hair fibers are thicker or that cycling is improved or a combination thereof!

Besides objective documentation and the risk of erroneous interpretation, we illustrate also the challenge faced by subjectivity: it is a daily experience that patients report their satisfaction or lack of it with our therapeutic proposals. In Fig. 5, we show

two typical cases with a discrepancy between subjective and objective appreciation of efficacy. There was a great biological and clinically significant improvement in a pessimist patient as compared with a clear-cut biological and clinical worsening in an optimist patient! These psychological dimensions, i.e., satisfaction with oneself, are usually misinterpreted or underestimated during discussions with health authorities (FDA, EU or national health authorities). The wrong interpretation recurrently sounds like accurate technology is useless because the patient "can not appreciate the effect" or the consumer "can not perceive it." From a historical perspective, we evolved during the last 25 years from fancy in vivo hair counts to more precise noninvasive technologies that help us stay away from trichoquackery. In other words, one must be aware that subjective impressions of the patient and the clinician are influenced by far too many uncontrolled factors that are encompassed as "placebo" effect. We maintain that a combination of well-standardized global images together with a thoroughly validated analytical technology can get rid of all and any irrelevant or extraneous factors of variation, i.e., those influenced by subjectivity. The psychosocial aspects and influences on perception and satisfaction are usually put in the fore by companies, and these subjective, error-prone, aspects are not taken into account in this chapter.

3.2 Analytical Methods

3.2.1 A Brief Historical Review: What Did We Learn with the Conventional PTG?

The basic principle of the phototrichogram (PTG) consists of taking a close-up photograph of a certain area of the scalp. The hair is cut very close in preparation for the first photograph, followed by repeat photographic documentation after a certain period of time. This period of time should be long enough to allow the growth of a hair segment (time window which is usually between 24 and 72 h) but not too long in order to prevent outgrowth or too much overlapping of growing hair. The growth is then evaluated by comparing the two pictures. Hairs that have

Fig. 3 Hair cycle. The hair growth phase (anagen) during which hair is visible at the skin surface and growing are shown in (A) while the apparent resting phase of the hair cycle (telogen) together with initiation of hair regrowth from the new follicle is shown in (B). (A) From growth to rest. The same hair follicle is represented at various times at the very end of the growth phase (day *a* to day *i*). At the skin surface, there is normal pigmented hair production with the constant daily hair production (measurable elongation *L1* and *L2* between days *a*–*b* and days *b*–*c*; notice that *L1* roughly equals *L2*). Then, in the depth of the hair follicle, the pigmentation of the newly synthesized hair shaft is gradually decreased (day *c*) as shown by the shaded area at the bottom of the hair fiber. This early event heralds the regression of the impermanent portion of the hair follicle and is followed by terminal differentiation of cells in the proliferation compartment (day *d*). This is associated with apoptosis and indicates the earliest morphological steps of the catagen phase. It will inevitably propel the follicle into telogen with the typical club hair formation. The shrinking dermal papilla (day *d*) begins an ascending movement together with the hair shaft (days *d*–*i*; estimated 21 days). This characterizes the catagen phase with an apparent elongation of the hair fiber (*I*) that reflects the outward migration of the hair shaft (*L3* is much smaller than the daily growth rate *L1* or *L2*). This can clearly be measured as slowing down of hair elongation rate and

terminates with no growth during a while (see later). What is left after disappearance of the epithelial cells from the impermanent portion of the hair follicle are basement membranes followed by dermal connective tissue usually referred to as streamers or stelae shown as dark remnants at the bottom of the diagrams (days *f*–*i*). The true resting stage begins when catagen is completed, i.e., when the dermal papilla abuts to the bottom of the permanent portion of the hair follicle. Would there be no physical interaction between dermal papilla and the bulge, there would be no reactivation of stem cells now densely packed within this area. As a consequence, the next hair cycle (see B) would be definitely compromised. As of now no hair growth is observed at the surface (days *g*–*i*). (B) From rest to growth. During this stage, shown in the lower panel, one notices no elongation of hair fiber as it is seen at the skin surface (days *a*–*e*) but significant changes occur in the deeper parts of the hair follicle. The dermal papilla expands and attracts epithelial cells from the bulge (stem cell zone) in a downward movement (days *a*–*b*). To create space, previously deposited materials have to be digested (days *a*–*c*). The epithelial cells then start differentiation in an orderly fashion starting with the inner root sheath (forming the initial cone in *b* and then a funnel in *c*). The mirror image of the cuticle of the inner root sheath reflects on and contains the tip of the hair cuticle. In the very center of the newly formed hair shaft, one finds the tip of the newly

grown are in anagen phase and those, which have not, are in telogen phase.

In 1989, we devised scalp immersion photography (Van Neste et al. 1989) or proxigraphy (Van Neste et al. 1992) and listed a number of problems related to the fiber, its association with the follicular opening, and the scalp skin in the background and immediate surroundings. All these difficulties will be recapitulated at the end of the chapter, and one will be able to understand the progress made during the last 20 years. Then, the term “epiluminescence microscopy” took over. It is of note that image magnification (up to 200 times or more) does not correspond exactly to the optical equipment contained in instruments known as microscopes. In short, epiluminescence microscopy became the accepted denomination for examination under special lighting with high magnification.

The next step was to evaluate the limit of detection comparatively with another more invasive method (Rushton et al. 1993). As some uncertainties were detected, we considered with great care the discrepancies and devised contrast-enhanced (CE) phototrichogram (CE-PTG) as a further improvement (Blume et al. 1991; Van Neste 2001). The CE-PTG became almost equal in terms of resolution as transverse microscopy on serial sections made on scalp biopsies, while, at that time, only a few sections were considered as the gold standard (Headington 1982; Headington

and Novak 1984; Whiting 1990, 1993, 1998; Headington 1993). So far, the CE-PTG remains the only noninvasive method that has documented all transitions of thick and thinning follicles from anagen to catagen to telogen phases on a follicular basis (Van Neste 2001).

3.2.2 What Can We Learn to Measure with the CE-PTG and Are There Possibly Further Improvements?

The assessment is made on one or a number of predefined scalp sites considered representative of the condition. After feeding the computer with source images and after a human intervention, preferably with the help of a trained and calibrated technician, the data that can be generated from a PTG are total number of hair present in a certain area (i.e. hair density (n/cm^2)), percentage of hair in the growth phase (anagen %), linear hair growth rate (LHGR; $\mu m/day$), and hair thickness (μm), and the latest developments added a split-up according to thickness of growing and resting hair together with the transition from telogen to exogen.

Thickness can be measured on hair clippings, on scalp biopsies, and on scalp hair photographs. It may seem trivial to state that the hair diameter evaluation is more precise with the microscope as the 3D movement allows measures to reflect diameter whenever the fiber section is not circular. Interestingly, the hair section remains almost

Fig. 3 (continued) formed less or yet unpigmented hair cortex (days *c–e*). The resting hair remains in the hair follicle for approximately 1–3 months (days *a–e*), and then a detachment process transforms the old telogen follicle into exogen where the release of the exogen hair can now take place either immediately (day *f*) or after a while during which it may stick in the follicle before being shed (days *f–g*). The shiny root end of the shed hair is the club. Before, during, or after hair shedding, there may be replacement by a new gradually thicker and more pigmented hair shaft (period *e–g*). Indeed, under physiological conditions, the follicle may proceed immediately or only after some lag time with new hair production (from *b* to *g*; up to 90 days). In conditions like androgenetic alopecia after shedding, the old follicle may remain empty for a longer period of time as a lag phase has been reported before the new regrowing hair follicle initiates a new hair

cycle with a visible hair fiber at the scalp surface. Note that a prolonged adhesion to the epithelial structures may increase intrafollicular stasis of exogen hair: this turns into trichostasis due to abnormal accumulation of nonadherent or loosely attached elements. Also exogen does not always result in immediate recycling, and there may be a much longer interval before regrowth is recorded at the scalp surface. At the earliest visible stages, i.e., when the new anagen follicle is again deeply set into the dermis, one notices at the scalp surface a thin usually nonpigmented hair tip that is seen first (day *h*). This is soon followed by a thicker, more pigmented, and faster growing hair fiber (day *i*). All hair cycle transitions can now be recorded in vivo with noninvasive technologies. This sequence of course depends on the many systemic, regional, and local regulatory factors controlling the hair follicle activity during its replacement

Fig. 4 Problems of standardization of global imaging in three subjects with male pattern hair loss (MPHL): Black African female (*upper panel*) and two Caucasian male (*middle and lower panels*) and in a series of images taken from an experimental model. In clinical cases, baseline view of the top of the head is shown on the *left panels* before treatment (*m0*). After 12, 24, or 36 months of treatment (*m12*, *m24*, and *m36*, respectively), images unravel some technical errors. These make interpretation hazardous in the absence of analytical data. The reader is invited to compare the color of the background (*left and right*) and the range of “objective” color patches (objective rulers included in the *lower part* of each image). These

circular when the fiber is thinner than or equal to $40\ \mu\text{m}$ (Rushton 1988) independently of ethnic background.

Finally, the number of hair sprouting from one opening is another source of difficulty that has also been addressed recently. As the production of different hair follicles composing a single follicular unit is randomized, i.e., not synchronized, it may be difficult to formally trace “hair thinning” during the succession of individual hair follicle cycles! In addition, the complexity will even increase in scalp imaging in case an observer wishes to evaluate the susceptibility of each individual follicle to the follicular regression and eventually its progression towards organ deletion.

3.2.3 Technological Requirements

Before discussing in greater detail the practicalities for performing hair growth analysis and the data so generated, it is useful to recapitulate some difficulties that every investigator will encounter, sooner or later, as he becomes exposed to a new technology.

Fig. 4 (continued) objective color rulers are fixed onto the front panel fixed of the stereotactic device. These are recorded in all our pictures and clearly document differences in light exposure. One should now focus on hair length and style as well as on the position of the head in the stereotactic device: these are but a few of the many factors of variation such that improper (like in these three cases) or even appropriate global imaging documentation should in any case be supported by analytical data before interpretation is being provided in terms of improvement or worsening (see also Fig. 5). In the Caucasian proband, while changes in hair style suggest impressive differences, the same number of hair was present though growth fraction was improved after treatment. The influences of distance and angle on global perception were subject to image analysis in a model (shown in the *lowest panels*). Standardized pieces of green cloth with a known size were fixed in specific fields on a model. Those sites correspond to a number of anatomical fields known by clinicians as frontal, parietal, and vertex that are located, respectively, on anterior scalp, top of the head, and between top and posterior scalp. Images were taken with the model positioned at various angles (range from 75° to 135°). The measured surfaces in the two-dimensional images of the standard patches ranged from 6 % to 224 % of the value that was measured on the images taken at 90° (second image starting from the *left*)

Fig. 5 Standardized global scalp imaging in male pattern hair loss testing topical treatment vs placebo, in combination with finasteride. In this study, a double-dummy placebo controlled protocol was used for the topical lotions while all subjects received an oral medication (finasteride 1 mg/day). They were assigned randomly to either minoxidil topical solution 5 % (MTS5%, once a day) or a control solution (containing ethanol–water and propylene glycol in the same proportions as the vehicle of the active MTS5%). The compliance was checked on counting the pills and weighing bottles containing lotion at monthly visits and with dairies. Compliance exceeded 98 %. Examine first the two images in the *top panel*. As compared with baseline (*m0*), changes in scalp coverage scoring (SCS) at month 3 were impressive in favor of MTS5%. The biological response of the scalp follicle target (*dot*) showed a 26 % increase of thick anagen hair per cm^2 (thick = hair fiber thickness over $40 \mu\text{m}$). The scalp coverage scores (SCS) in the mid scalp and vertex area were 4.2 ± 0.8 at baseline and 4.7 ± 0.4 at m3. The mean difference 0.5 represents a 12 % increase in the SCS. Interestingly, we probed the level of subjective satisfaction in terms of change from

baseline using a hair questionnaire exploring five items. In this individual, the rate of global satisfaction with changes from baseline was 56 %, which is rather low. Examine now the two images in the *lower panel*. In the subject treated with the control solution, the SCS (baseline 4.1 ± 0.7 vs m3: 3.8 ± 0.9) indicated objective worsening of the condition from the “blinded as to treatment” investigators’ perspective who performed the SCS test in vivo. There was a 7.3 % global worsening (SCS method). This keeps in line with a 20 % decrease of the thick anagen hair count per cm^2 (growing hair with a thickness $>40 \mu\text{m}$ in the target area, *dot*). This patient, using the same hair questionnaire, rated 72 % satisfaction in terms of global response of his scalp condition. Hence, we can mathematically estimate that the subject shown in the *top panels* is disappointed by an efficient treatment, who is considered as a pessimist, while the one shown in the *bottom panel* has a great degree of satisfaction while objectively worse and he could be considered as an optimist! The latter typifies the patient or consumer that makes trichoquakery “WORKS” supporting the useless hair procedures and hair restoration claims made by cosmetic products!

In order to keep analytical technology in the field of clinical relevance and within an acceptable range of variability, we suggested that a “clinically representative” field containing around 100 hair fibers would be acceptable (Van Neste 1993). There is no magic value to the number 100, but this means that a “5 hair detection

error” still keeps variability lower than 5 %. We also stated that the analysis would be valuable only if “exhaustive” sampling took place. This means that all and any hair whatever its growth stage and whatever its thickness should be taken into account (Van Neste 1993, 2001). We would also like to add “whatever the nature of the

background skin” as a medical field technology should be compatible with all types of scalp encountered in the hair clinic. Since this was published, extensive quality control studies were conducted internally, and all criteria set forth in the context of validation (Bircher et al. 1994) were appropriately met by the CE-PTG technology including the collection of exogen hair (CE-PTG-EC) (Van Neste et al. 2007).

We can communicate the conclusion of this audit (Hugh Rushton, personal communication): “All files were revised independently by an external audit” who reported that “the Accuracy, Sensitivity, Reproducibility, Repeatability of the CE-PTG method including the results obtained with and without the exogen collection method were checked in detail and the methods for acquiring images through to editing the results were found to be appropriate and well documented.” The variation for those parameters was found to be less than 3 % (Van Neste, 2015) and we realize that discussing all the statistical details is beyond the scope of this chapter.

Hence, we feel comfortable by the combination of a global and an analytical method to evaluate our patients (Fig. 6), while at the same time we keep in line with others (Pierard et al. 2004) and advise making a scalp biopsy for diagnostic

purposes. Also making biopsies was a critical step to compare the invasive scalp biopsy approach with serial sectioning (i.e., exhaustive sampling) and performing the paired stereological analysis of individual hair follicles in order to validate the noninvasive procedures (Van Neste 2001). However, we think that making repeat scalp biopsies should be considered inappropriate for hair growth monitoring purposes. Indeed from a typical 4 mm diameter scalp biopsy specimen, one samples around 15 follicular units or less providing about 40 follicles (Headington 1982; Whiting 1990). This means that a one hair error represents a 2.5 % error, and as density decreases like in male pattern hair loss (MPHL), then the risk of variability increases. Also, it should be clear that one does not really measure the pharmacodynamic response of the individual hair follicles essentially because of the destructive nature of the sampling method. Hence, a statistical evaluation on different before and after samples is being made while even sampling itself may be subject to bias (personal communication at the Society for Investigative Dermatology, unpublished data).

Finally, the use of small destructive sampling methods and statistical evaluations led to the speculative interpretation that finasteride taken by man with MPHL would be able to revert affected

Fig. 6 Combined global viewing and CE-PTG-EC. The top of the head of three young male subjects complaining of hair shedding (A, B, C) is shown with a parting in the middle (*left panel*) and hair combed as spokes of a wheel (*right panel*). These views suggest an increasing visibility of scalp through the hair as one proceeds from subject A to C, especially when parting the scalp hair. However, there is no typical Hamilton–Norwood pattern. Therefore, we classify these subjects as preclinical and mild hair thinning. For

each individual, phototrichograms are displayed. From *left to right* we show the baseline image (t_0), 48 h later (t_2), and the processed image ready for CE-PTG-EC analysis. The computer-assisted image analysis on the latter generates the detailed data shown in Table 1. These data confirm abnormal hair follicle performance as compared with male controls (data shown in Tables 2 and 3). Patients were diagnosed as preclinical or early stages of MPHL, and they were given medical treatment

Fig. 7 Small fields of the scalp at selected time periods during the 48-month follow-up CE-PTG-EC study. The study of hair cycling with CE-PTG (we show only those images taken 48 h after clipping where the longer fibers represent anagen hair and the shorter ones telogen hair). While CE-PTG was made at monthly intervals, we do show only those months as numbered in the *upper left corner*. Months 1, 2, 3 (first *top panel*), 9, 10, and 11 (second row) belong to the “before treatment period.” The *lower panels* (three bottom rows) show the same

area from month 34 to 48 while volunteer was on oral finasteride treatment (1 mg/day from month 24–48). Individual hair fibers are numbered from 1 to 8, and their thickness and progression through the hair cycle can be appreciated objectively. The images point to the fact that more than one follicle opens into one orifice. When three or more hair fibers are creating a dynamic but complex field, it is almost impossible to secure a proper follow-up of individual hair follicle cycling

follicles producing vellus-like hair in one cycle into the production of terminal hair follicles (Whiting et al. 2003). However, direct evidence is lacking and this hypothesis remains unproven as reported elsewhere in detail (Van Neste 2006b; Van Neste et al. 2016), and source documentation is shown again herein (Fig. 7).

3.2.4 Advantages of Noninvasive Techniques over a Scalp Biopsy for the Study of Hair Cycling

While estimates of the cycling process as well as the duration of the lag phase remain a painstaking

task, some effort has been made in this field (Courtois et al. 1994). The complexity of this investigative field has been somehow underestimated, and as more than one hair can grow from a single follicular opening and that hair cycles within a follicular unit are not synchronized, it is clear that accuracy cannot be certified, and it requires a great deal of caution to use the existing published figures without knowing all the uncertainties.

Biodynamics of the hair follicle is extremely active, and we now realize that some biological variability should appear when long-term studies

are launched. Furthermore, hair density or the number of hair per unit area is usually reported as number/cm² as it reflects the number of functionally active follicular units whether growing (anagen) or not (telogen). Because this is the highest number that can be generated, it will also probably vary the least. Under physiological conditions, i.e., the long duration of anagen phase, short telogen duration and exogen initiation will produce long and clearly visible hair at the scalp surface which may change dramatically in some hair disorders leading to hair loss and balding.

Under steady-state conditions, the percentage of anagen follicles properly reflects the time during which hair follicles are engaged in active growth. Now that we have some idea about the complexity of the field, let us review briefly how we got there starting with the classical phototrichogram and a number of variants where hair fiber thickness has been included either as it is measured under the microscope, on images, or with computer-assisted image analysis.

With a few notable exceptions, we may state that the thicker the fiber, the longer the duration of anagen. Hair has been classified into terminal, intermediate, and miniaturized, but there is no absolute consensus on the definition of the latter categories (sometimes less than 40 or less than 30 μm thickness). We suggest to pursue refined research work in that direction and to establish criteria for describing individual follicular performance rather than statistics such as average hair thicknesses or even worse cumulative hair thickness. The latter exposes the clinician to further confusion as it is a composite index of hair count + hair thickness. This means that it reflects the number of more or less frequently present hair shafts, i.e., duration of anagen combined with thickness. Besides other weaknesses of the system used for this particular composite index (see later), the cumulative hair thickness is often mistakenly translated by clinicians (Riedel-Baima and Riedel 2009) who subsequently interpret these data and use descriptive terms that are not relevant to the performance of individual hair follicles.

Many based their assumptions on the thickness of hair fibers, but we argue that there has not been enough attention in the past devoted to the

combined analysis of variables such as growth rate, natural pigmentation (Van Neste 2004), and other factors such as scalp location in healthy controls and in functional disturbances.

Indeed in the earliest preclinical stages of MPHL in man, there was obvious shortening of the anagen phase detectable with this sensitive method (Van Neste 2013, 2006c) in the absence of clinically massive or obvious hair miniaturization. This preclinical stage evolves into patterning, i.e., the full-blown phenotype associated with a further shortening of the growth phase along with reduction in hair diameter (Van Neste et al. 2003a; Courtois et al. 1994, 1995, 1996; Tsuji et al. 1994; Ishino et al. 1997; Rushton 1999). The structural follicular regression process is associated with functional changes (shorter anagen duration, prolonged empty phase, and slower growth rates (Van Neste 2015 and Van Neste and Rushton 2015)) finally resulting in production of clinically non-visible hair (Van Neste 2002; Dawber and Van Neste 1995).

Similar findings from transversal studies were keeping in line with a gradual regression of follicular performances in males (Tsuji et al. 1994; Courtois et al. 1995, 1996; Ishino et al. 1997; Rushton 1999) while the process might follow a different pathway in females (Van Neste and Rushton 1997; Ueki et al. 2003; Van Neste 2006d).

Contrary to the thinnest hair with a circular section, thicker Caucasian hair may become elliptical. In Africans the hair flattens even more and some reports indicate differences in growth characteristics from Caucasians (Loussouarn 2001). However, data from patients and controls were not separated such that some confusion remains. As yet, we are not aware of any published data on the value of hair thickness evaluation on scalp photographs of properly selected Black African healthy controls and affected subjects. From the technological point of view, CE-PTG is again able to measure all and any hair including the nonpigmented and finest ones even against a pigmented skin background (Fig. 8). The same comment holds true for other body sites where curly and flattened hairs are the rule rather than the exception.

Fig. 8 Contrast-enhanced phototrichogram with exogen collection (CE-PTG-EC) in Black African scalp. The method we developed for Caucasian scalp performs exhaustive visualization and detects all and any hair even on Black African scalp, as shown here. A first image is taken immediately after clipping (t_0) and a second one is made 48 h later (t_2). There is a very low density of hair and very little growth as appears in the analysis of the combination $t_0 + t_2$. The region of interest (ROI) – as outlined in the latter panel – appears enlarged in the two views of t_0 and t_2 (two extreme right panels). Two distinct compartments can be analyzed in the enlarged ROI: the interfollicular epidermis and the hair follicle dynamics. The interfollicular epidermis shows the typical pigmented network in a honeycomb pattern with brighter spots. The pigment contained in the epithelium that outlines the

acrofundibulum of the hair follicle generates a slightly accentuated pigmented ring. The interfollicular scalp displays numerous small pale spots, usually less than 100 μm in diameter. These reflect acrosyringia or openings of sweat glands and should not be mistakenly interpreted as scarring alopecia. Besides the empty follicle (blue outline at t_0), several hair types have been dot-mapped: nanohair that are not in the exogen stage (red dots) can either look isolated or appear amidst a follicular unit along with thicker hair. Cycling is easily observed on the thicker hair (magenta dots). These are split up into resting or telogen hair or anagen as they stay the same length or not at t_0 and t_2 . The latter can be pigmented (green dot) or nonpigmented (blue dots). African scalp (and many other scalp conditions) cannot be analyzed by the commercially available automated hair analysis programs

Taken together, we found a significant correlation between paired microscopic measurements and thickness evaluation on Caucasian scalp hair photographs in the range of $<20 \mu\text{m}$ to $>100 \mu\text{m}$ thick hair fibers (less than 1–3 % variation depending on the parameters in a test using qualified technicians; Van Neste 2014) so reducing methodological errors of other approaches (Leroy and Van Neste 2002), and it would be worth some effort to pursue our research related to our earlier findings that there is a correlation between thickness and linear growth rates (Van Neste et al. 1991). We believe that there is still a lot to be learned like changes in the growth rate during aging (Ueki et al. 2003; Van Neste 2006d) and other phenomena associated with hair loss including but not limited to androgen-driven patterned hair loss, especially during clinical trials (Rushton et al. 2011). Once again, the human intervention and manual processing should be strictly controlled highlighting the difficulties encountered on the path of scientific and medical progress in the field of measuring hair follicle activity (Rushton et al. 2011).

When the photographic camera is replaced by a video or CCD camera equipped with specific

lenses, other variants of PTG recording are obtained.

In fact, early reports in Orientals and Caucasians were published based on the assumption that the natural contrast between hair and scalp seems favorable enough for the application of any imaging method. While the low figures of hair density could possibly be in relation with ethnicity (Hayashi et al. 1991), more studies will be required after validation of these methods not using extra contrast enhancement (CE). As shown earlier (Blume et al. 1991; Leroy and Van Neste 2002) the use of CE is advisable in all cases and especially when balding is present or during aging. More recently, the use of epiluminescence and computer applications for textile fiber analysis was integrated into hair recognition. Such a system has been proposed (Hoffmann 2001) initially with a major source of variability (area less than 0.25 cm^2) because the number of hair so analyzed is definitely less than 100 and dropping below statistically acceptable population sample size (Van Neste 1993). The recent increased size of the scalp area has solved that very point, but others remain to be clarified as will be discussed later in this chapter. Furthermore, automated systems generate consistent

numbers without securing that all hairs in the field were detected. Various commercial brands have been proposed such as TrichoScan[®] (Hoffmann 2001), the French CapilliCARE (data in file), the Russian system by TrichoScience (V. Tkachev, personal communication), and the Korean system (Kang et al. 2009). The two latter brands announced a fully automated system in the early days of development. Soon, they had to realize that full automation is less reliable and decided to involve human observers during the image processing. So the dream of an easy and fast method vanishes as it was, is, and will probably remain for a period of time – a time-consuming procedure.

Because it seems so fast and user-friendly, some clinicians eventually labeled the CE-PTG as an “obsolete technique” (Camacho-Martinez 2009). While TrichoScan[®] might appear as the most convenient method, more and more in-depth investigations end up with a better identification of unidentified sources of discrepancies. While evidence about errors can be traced in the earliest publications (Hoffmann 2001; Hoffmann and Van Neste 2006) and is now well established by us and others in scalp hair (Van Neste and Trüeb 2006, 2008; Saraogi and Dhurat 2010; Tajima et al. 2007; Lopez et al. 2011), promoters and clinicians behave like believers and continue to advocate its use (Camacho and Montagna 2013) albeit more evidence has been published on discrepancies in the same textbooks (Van Neste 2013). More studies will be required in order to get a consensus about the evidence-based source studies. The fact that the TrichoScan[®] method has been noticed as acceptable by a committee of experts does not mean that those experts did some auditing or methodological evaluation in view of qualification or validation of this technique (Pierard et al. 2004). Accordingly the committee stated in the absence of experimental evidence that such imaging technologies “provide insight into the complexities of hair cycling and shedding.” The non-substantiated comments by such committee should be considered as nonrelevant to the domain of sciences.

We advise everyone who uses the TrichoScan[®] method to search for a number of hair visible in the source images that could not be detected or were erroneously interpreted by the analyzer and ask themselves whether the discrepancies are of any clinical significance, because such errors cannot be rejected by those who developed the computerized automated system (Hoffmann and Van Neste 2006). Therefore, since convenience and speed of action have become a trendy way of considering progress in the field of science, some time should be spent at providing sound information about the limits of the automated method of hair measurement.

While the method analyzes only a limited number of clinical situations and even when all clinical conditions are suitable for the computer, it does not generate all data that may be of interest to the observer in terms of diagnosis, prognosis, progression from miniaturization, and reversible inhibition towards organ deletion or any other clinically relevant information.

In high-density hair like the scalp especially in the thinning process (Van Neste 2013) and low-density hair where good natural contrast between skin and hair is documented, the quantitative evaluation is likewise error-prone such as that of the TrichoScan[®]. As illustrated in Fig. 9, all sources of variation with CE-PTG-EC coupled with computer-assisted image analysis after manual processing (CAIAMP) can easily be traced vs “pseudo-counts” by the automated analysis.

Such scientific observations confirm an academic opinion expressed some years ago by independent clinical observers (Chamberlain and Dawber 2003): “the potential of computer-assisted technology in this field is yet to be maximized and the currently available tools are less than ideal.”

3.2.5 Future Trends in Computerized Methods

More than two decades ago, we listed the different problems arising when automated computer-assisted image analysis (ACAIA) came into the scope of hair growth measurement and we would like to add an updated comment (Van Neste 1989). Some problems have been solved. Accurate

Fig. 9 Low density as a model to understand what is meant by “variability.” In biological evaluation, there is always some degree of variability. For the sake of demonstration on very low density, we tested hair counting in body sites with good natural contrast between skin and hair (Van Neste, 2014). Images were obtained from the same site before hair dye (*left*), immediately after hair dye (*middle*), and after clipping (*right*). Thick hair ($\geq 30 \mu\text{m}$) and thin hair ($< 30 \mu\text{m}$) counts were obtained with our CE-PTG-EC technique with computer-assisted analysis after manual processing. Dot mapping was color-coded in the image on the *left* (thick = red dot; thin = green dot), and topography of the dots was maintained from *left* to *right*. The thin hair on the *left* had a thickness of $25 \mu\text{m}$. After the

hair dye, the cuticula becomes visible and adds some μm to the detected width which becomes $> 30 \mu\text{m}$ (*middle* and *right* panels). Therefore, from *left* to *right*, we found 21, 22, and 28 thick hairs. The change from 21 to 22 is explained by the only thin hair that was found on the *left* panel. How to explain a shift from 22 to 28? Due to a small shift (*right* panel), one thick hair was found outside the target area (*black dot*). At the same time seven thick hairs entered into the field (*white dots and arrows*). In comparison, the same images were analyzed with TrichoScan[®]. From *left* to *right*, the automated software described 6.5, 7.5, and 4.5 thin hairs and 53, 78.5, and 103 thick hairs. These are major unexplained variations related to measurement errors that cannot be accepted as real hair counts!

analysis still requires expert human intervention during the sampling and processing of images (Figs. 6, 7, 8, 9, and 10). To date we are easily coping with the three dimensions involved in hair, and we are mastering the requirements in terms of enlargement factor or pixel size, immersion, and polarized light. We also wiped out the problem of backscattering of light and other problems linked to presence of sebum droplets, sweat, and scales. More recent developments helped us to clear the scene from any other loosely attached elements such as exogen hair. Increasing contrast between scalp and hair allow us to express data in a single-case observation or to perform accurate time-course studies of hair growth changes using highly standardized operating and monitoring procedures. As an example of the technological resolving power, we discussed recently on hair pigmentation during aging and how it might affect the outcome of a clinical trial. Initially non-visible hair under conventional PTG may become visible for drug effects such as increased pigmentation, initiation of short-lived but thick anagen hair, etc. The spectrum of follicular bio-responses is

actually underestimated and requires sophisticated investigations.

As usual, when facing new technologies, clinicians occasionally express their fears about new information generated by these up-to-date technologies, for example, take into account the fact that thin hair is becoming visible (Olsen 2003) even though thinning remains underestimated with automated tools and remains hard to confess as illustrated elsewhere (see Fig. 2 in Hoffmann and Van Neste 2006). More recently (Van Neste and Rushton 2013), we provided evidence from data appearing in published papers rated as “high quality” that FDA-approved technologies for hair counting might be confounded by topical agents: undetected hair present at baseline would become visible at later stages because of a modification of the biophysical properties of skin and hair by the vehicle, i.e., nondrug-related effects resulting in high increases of hair counts or not only thin hair that is becoming visible (Olsen 2003)!

This clearly illustrates that our message did not come completely through and we hope today’s statement will become a landmark:

Fig. 10 Within 1 month, weekly follow-up of scalp with CE-PTG-EC showing all hair cycle transitions. Interestingly, a simple statement like “good natural contrast between skin and hair” can be measured as reflected by no change in hair counts after the hair dye (*left and middle panels*). A scalp field was monitored at weekly intervals during 1 month. Each week, there were duplicate visits for the CE-PTG-EC; top row shows image taken immediately after clipping (from *left to right*: day 0, 0+7, 0+14, 0+21, and 0+28) and bottom row shows the same 2 days later without clipping (0 + 2, etc.). Individually numbered hair fibers can easily be followed over time as images are compared *left top, left bottom*, and then *top +7*, which is again immediately after clipping and so on. Hair 1:

Continuously growing anagen. Hair 2 (with *arrow*): The minimal elongation reflects no-growth stage, i.e., end catagen–telogen (day 0 up to day 0 + 14). Between day 14 and day 2 + 14, the fiber was collected as exogen. The tip of the very thin fiber shows up at day 0 + 28 indicating new anagen that grows further on day 2 + 28. Hair 3: Thick catagen hair (day 0–day 2 and probably day 0 + 7 and day 2 + 7) that stays in telogen all over time after day 9. Hair 4: Earliest stage of anagen showing up at the scalp surface at some time between day 0 and day 2. The thickness increases in a few weeks. Rapidly growing fine tips at the surface reflect intense proliferation in deeply seated root of a thick hair follicle (revisit images from *right to left*)

Table 1 Analytical data generated with computer-assisted image analysis of CE-PTG-EC

	A	B	C
Thick hair density	215*	274	167***
Thick anagen hair %	66**	75*	57***
Thin hair %	18	17	26***
Nanohair	41***	39***	86***
Exogen hair	3	2	11**

Whenever data from the three subjects shown in Fig. 6 reach the limits or differ slightly, moderately, or severely from controls (unpublished data; Tables 2 and 3), numbers are marked, respectively, as *, **, or ***

Thick hair displays a width over 40 μm and is shown as thick hair density (n/cm²) with percent of growing hair (thick anagen %). The lower limit or reduced % of thick anagen as compared to controls indicates in all three cases a shortening of the duration of anagen

Thinner hair expressed as a proportion of the total (sum of thick and thin hair counts; data not shown) indicates that subject C is most severely affected. He may represent a later step in the process of decreased hair follicle performance as thick hair numbers and thick anagen % are already much lower than subjects A or B

In all three subjects, there is a tremendous increase of nanohair whose width is less than 20 μm. We consider this as an early marker of the preclinical stages of male pattern hair loss even when a “normal” number of thick hair is still present (subject B)

Taken together, lowered hair density and anagen % with increased % thinning and a high number of nanohair and exogen hair in subject C confirm that he is the worst affected one of the three. We speculate that irreversible functional damage or organ deletion might follow if the condition continues to progress without treatment

Table 2 Normal values in male and female controls with CE-PTG-EC (usual criteria)

♂♀	∂ nano	∂ total	∂ thick	∂ thin	∂ exogen
Mean	6	295	241	54	2
St. dev.	5	50	41	22	2
P5	0	211	171	22	0
P95	17	370	301	89	7
♂	∂ nano	∂ total	∂ thick	∂ thin	∂ exogen
Mean	6	285	240	44	3
St. dev.	5	59	47	20	3
P5	0	198	172	20	0
P95	18	389	323	83	9
♀	∂ nano	∂ total	∂ thick	∂ thin	∂ exogen
Mean	6	309	242	67	2
St. dev.	5	30	33	18	2
P5	1	256	189	44	0
P95	17	351	293	96	5

Normal hair values were evaluated on the top of the head during four repeat observations (two during summer and two during winter) in young volunteers (16–20 years) who did not complain of hair shedding or hair loss

The table details values of the more familiar criteria like density (n/cm^2) that we split up according to hair fiber thickness: total hair ($\partial \geq 20 \mu m$), thin hair ($20 < \partial < 40 \mu m$), and thick hair ($\partial \geq 40 \mu m$) as well as nanohair ($\partial < 20 \mu m$) that were not included in the other hair counts due to uncertainties

The statistics like mean and standard deviation are shown together with “extreme normal limits” of CE-PTG-EC data (either P5 or P95) as a group and separately for male and female

Table 3 Normal values in male and female controls with CE-PTG-EC (less usual criteria)

♂♀	∂ anagen	% anagen	Thick as % of total	∂ thick anagen	Thick % anagen	Thin as % of total	∂ thin anagen	Thin % anagen
Mean	248	84 %	82 %	214	89 %	18 %	33	60 %
St. dev.	42	9 %	7 %	35	8 %	7 %	19	19 %
P5	174	68 %	73 %	151	75 %	9 %	9	32 %
P95	302	96 %	91 %	261	99 %	27 %	72	89 %
♂	∂ anagen	% anagen	Thick as % of total	∂ thick anagen	Thick % anagen	Thin as % of total	∂ thin anagen	Thin % anagen
Mean	230	82 %	85 %	207	87 %	15 %	23	54 %
St. dev.	44	9 %	5 %	38	8 %	5 %	11	17 %
P5	160	67 %	75 %	147	74 %	8 %	9	29 %
P95	296	95 %	92 %	265	98 %	25 %	42	83 %
♀	∂ anagen	% anagen	Thick as % of total	∂ thick anagen	Thick % anagen	Thin as % of total	∂ thin anagen	Thin % anagen
Mean	271	88 %	78 %	224	93 %	22 %	47	69 %
St. dev.	26	7 %	6 %	27	7 %	6 %	18	17 %
P5	230	73 %	67 %	182	78 %	15 %	25	43 %
P95	305	96 %	85 %	257	99 %	33 %	82	91 %

This table details more statistics on less usual criteria such as absolute densities (∂ = density; n/cm^2) of anagen hair and its %, the proportion of thick (% of total hair count shown in Table 1), density of thick anagen hair, and proportion of growing hair in the thick hair subpopulation (thick % anagen) and the proportion of thin (% of total hair count shown in Table 1), density of thin anagen hair, and proportion of growing hair in the thin hair subpopulation (thin % anagen)

The statistics like mean and standard deviation are shown together with “extreme normal limits” of CE-PTG-EC data (either P5 or P95) as a group and separately for male and female

1. Contrast enhancement makes not only thin hair more visible but also thick less pigmented hair more visible.
2. All and any hair in any patient whatever his/her genetic condition or background must be measured and taken into account.

Why is this necessary? This is necessary because of the following: first, in order to establish a proper description in the context of a diagnostic procedure; second, in order to know whether a miniaturized hair has any potential meaning or is just useless as a potential site for drug action; third in order to know what a normal scalp functioning program represents (data in Tables 2 and 3 help to clarify the status of patients shown in Fig. 5 and Table 1); and fourth, to get rid of nondrug-related effects. The illusion of efficacy must be tracked whatever the substrate of measurement (hair in our case!) with a scientific method! Anything else should be considered as dogmatic statements, erroneous interpretations, or speculative issues contributing to maintaining hair science and technology in the marshlands of trichoquackery.

The future will tell whether the work done during the last decade will definitely bring such systems closer to the status of medically acceptable as diagnostic, prognostic, and therapeutic monitoring tools.

4 Conclusion

A bold statement would be to say that the assessment of hair loss requires some experience and a lot of technological effort in order to grasp all the variables involved in hair measurement. There was a time when some colleagues argued that measurement methods were not necessary as the patient could tell when hair is growing or not. It is obvious that this is untrue as soon as one enters the continuum of the hair replacement process especially when some hair is still present. Such a statement also looks outdated when one acknowledges the importance of the placebo effect. Indeed, subjective evaluation may reach 60 % or more satisfaction while significantly decreased hair counts clearly document the

natural worsening of the condition (Kaufman 2002). Our experience points to the fact that a combination of a highly sensitive and precise analytical approach together with a global calibrated method seems advisable in the context of kinetic monitoring of hair growth and hair loss in the hair clinic in general, and this is warmly recommended in the context of efficacy analysis of new (and recognized!) compounds in future clinical trials.

In vivo reflectance confocal microscopy • Non-invasive diagnosis • Non-invasive therapeutical follow-up • Scalp • Alopecias • Inflammatory diseases • Skin tumors

1 Introduction

Scalp diseases frequently need microscopical support for diagnosis because of the peculiar anatomical site and the complexity of the differential diagnosis between different inflammatory skin disorders and tumors.

Skin biopsies of the scalp areas could be needed in order to select the appropriate therapeutical approach. However, histopathology confirmation is generally difficult because of inadequate sampling (too superficial, limited by the pain, bleeding and sometimes not detailed).

Optical histology of the scalp usually requires horizontal cut, especially for alopecia examination, in order to better evaluate the adnexal structures epithelium. Dermoscopy of the scalp is commonly used as a valid support to the clinical diagnosis and patient management, but presents several limits because it lacks microscopical detailed information needed especially for inflammatory diseases and therapeutical follow-up.

In order to solve the problem, in vivo reflectance confocal microscopy (RCM) is a noninvasive, high-resolution imaging technique that already demonstrated its usefulness for the

diagnosis, therapeutical follow-up, and management of inflammatory disorders and neoplastic lesions. RCM offers the clinicians the possibility of a real-time, noninvasive microscopical examination of the tissue with very high lateral resolution, giving cellular details.

2 The In Vivo Reflectance Confocal Microscopy Technique

RCM Vivascope 1500 (Lucid Technologies, Henrietta, NY, U.S.A.) and Vivascope 3000 are the commercially, in vivo confocal microscopes that can be used in the clinical routine. Both the systems operate with a diode Class 3A laser (European version), at a wavelength of 830 nm, with power <35 mW at tissue level. A 30×0.9 numerical aperture (NA) water immersion objective lens is used. Contrast is provided by differences in the refractive index due to molecule and organelle size present in the cell's cytoplasm as well as the extracellular microstructures within the tissue (Rajadhyaksha et al. 1995; Marghoob and Halpern 2005). Throughout RCM examination of pathological skin, single microscopic changes affecting the different skin layers are visualized with a new, direct point of view. Horizontal mosaics (VivaBlock), composed of a collection of single RCM frames, ranging from 2 to 8 mm can be performed with Vivascope 1500 version, and vertical "microtomographic" skin analyses (VivaStack) can be performed during examination in both versions of the system.

On the scalp, different from the Vivascope 1500, Vivascope 3000, thanks to its ergonomic design, doesn't need to be connected by an adhesive window to the skin avoiding hair cutting and reducing artifacts. Video series can be performed for analyzing and recording dynamic processes such as blood flow in dermal vessels. Vertical VivaStack software imaging (a sequence of images captured from the same area going down stepwise 5 ml for every image) is used for the evaluation of adnexal structures from the ostium to the maximum depth.

3 RCM of the Scalp

Using RCM on the scalp, all the different skin layers can be evaluated disclosing microscopical details as hair shafts, adnexal infundibular epithelium (focusing on the opening), and stroma.

In literature, RCM has been already demonstrated to be able to identify both microscopical features characterizing specific inflammatory process with high grade of correspondence and correlation to optical histology (Ardigò et al. 2011a, b). More recently in vivo RCM has been used for the evaluation and management of inflammatory skin diseases involving the scalp showing a high potential in the diagnosis (Rudnicka et al. 2008) as well as in therapeutical management (Agozzino et al. 2011).

As demonstrated for melanocytic and non-melanocytic tumors affecting the skin, RCM provides similar diagnostic information also for the lesions involving the scalp.

In inflammatory scalp diseases, RCM has been demonstrated to be useful for clinical-microscopical correlation supporting the diagnosis (Moscarella et al. 2012; Ardigò et al. 2007, 2009). Moreover, it can be of great value in choosing the best biopsy site in order to obtain microscopic diagnostic criteria. It can be considered as an intermediate step between trichoscopy and horizontal histology getting information about adnexal structure distribution and density, hair shaft integrity and size, localization and semi-quantification of inflammatory cells in different epidermal layers, dermal scarring, and vascularization.

A major limit of RCM of the scalp is the depth of imaging confined to the upper dermis without the possibility of visualizing the reticular dermis, hair follicle, glands, and distinguishing sub-type of leukocytes. Moreover, when the adhesive window of the Vivascope 1500 has to be connected to the scalp the presence of hair cause artifacts (hair bubble, obscuration of the tissue below, etc.); in this case the handheld confocal device named Vivascope 3000 is preferred as it doesn't need to be attached to the skin for confocal imaging. Handheld version gives the possibility of a larger field of tissue visualization during the same

clinical session without hair cutting (Rajadhyaksha et al. 1999), but lacks the possibility of a total lesion mapping for an overview of the process.

3.1 RCM of the Normal Scalp

In non-affected scalp, RCM lets the visualization of the terminal hair shaft structures with high definition of the medulla, visible as a strongly bright structure, the shaft, and cuticle. Also the infundibular epithelium and the openings of the follicle and glands can be evaluated.

3.2 RCM of the Hair Shaft

Consequently, in cases of diseases affecting exclusively the hair shaft (i.e., uncombable hair syndrome, pili torti, trichothiodystrophy), RCM discloses diagnostic clues as the alteration of hair in terms of medulla thickness and uniformity of the cuticula (Rudnicka et al. 2008) or the involvement of the adnexal epithelium in case of exocentric inflammatory processes (LPP, LED, AGA, etc.) (Agozzino et al. 2011).

3.3 RCM of Nonscarring Alopecia

Throughout RCM of the scalp, it is possible to evaluate major and distinctive microscopic criteria as the presence of inflammatory cells with adnexotropism and presence or absence of the scar tissue (sclerosis of the upper dermis). In non-scarring alopecias (i.e., alopecia areata), those features are absent. In specific, in alopecia areata, dermoscopic structures as yellow dots can be observed with RCM and correlated with dermoscopy disclosing their microscopical correspondence (Ardigò et al. 2011b).

Similarly, in androgenetic alopecia, preliminary data confirms that a more detailed distribution and evaluation of the degree of the miniaturization of follicle can be seen using RCM. In particular RCM lets the visualization of

miniaturized follicle differently nonvisible at dermoscopy. Moreover, RCM discloses the presence of inflammatory cell infiltration and dilated vessels involving epithelial structure where miniaturized hair follicle is present disclosing the inflammatory component of androgenetic alopecia with consequent therapeutical implications.

3.4 RCM of Scarring Alopecia

RCM for cicatricial alopecia has been tested prevalently in discoid lupus erythematosus (DLE), lichen planopilaris (LPP), and its variant defining the real power of this technique in differential diagnosis with noncicatricial alopecias. Biopsy sampling and therapeutical follow-up can be done with RCM in the case of the suspect of cicatricial alopecia.

The main confocal feature seen in scarring alopecias is represented by the dermal sclerosis of the upper dermis. The inflammatory process is focused around and inside the adnexal epithelium, in the epidermis, and inflammatory obscuration of the dermoepidermal junction (interface dermatitis) can be observed (Fig. 1). Throughout the RCM follow-up, useful microscopical criteria for the treatment management can be identified (Agozzino et al. 2011): in responsive cases, reduction of epidermal and dermal inflammation and disappearance of inflammatory cells around adnexal structures can easily be observed with RCM.

3.5 RCM of Common Inflammatory Diseases

Starting from the previous experience on inflammatory conditions involving the skin, diseases like psoriasis (Ardigò et al. 2009), contact dermatitis (Ardigò et al. 2012), and other inflammatory processes, RCM can be applied on the scalp. In details, it has been demonstrated that RCM lets the identification of the most common and distinctive microscopical criteria useful for the differentiation between spongiotic dermatitis and

Fig. 1 (a, b) Clinical and dermoscopic pictures of LPP showing multiple violaceous papules located on the nuchal region; (c) RCM mosaic image at the level of DEJ. Papillary rims obscured by inflammatory cells infiltrate disclosing the focal interface changes (*yellow circles*) and inflammatory involvement of adnexal structures; (d) RCM single frame of inflammatory cells infiltrate, focused around adnexal structure, composed of numerous brightly refractile, plump, oval to polygonal cells corresponding to

melanophages (*red arrows*); (e) RCM close-up around the adnexal epithelium showing inflammatory cell infiltrate composed of melanophages (*red arrows*) and small, less refractile, roundish cells corresponding probably to lymphocytes (*yellow arrows*); (f) RCM image at the level of the upper dermis showing dermal sclerosis associated with obscuration of follicular ostia for the increased and thickened number of dermal fibers

hyperkeratotic process. In this way, it is possible to discriminate allergic and irritant contact dermatitis, from psoriasis or seborrheic dermatitis involving the scalp areas.

In contact dermatitis, moderate to severe spongiosis reaching vesicle formation associated with dilated dermal vessels can be visualized by RCM as dark areas (due to the presence of nonretractile water into the tissue) in comparison to the surrounding epidermis associated with the presence of cellular bright elements corresponding to inflammatory cells. Differently, in psoriasis, using RCM, thickening of the stratum corneum with parakeratosis, thickening of the

epidermis (evaluated using vertical tomographic analysis of the tissue – Vertical VivaStack) with papillomatosis, and presence of vertically oriented vessels filling the dermal papillae can be visualized (Ardigò et al. 2009) (Fig. 2). Thick and parakeratotic stratum corneum with thick epidermis is a microscopical feature common between psoriasis and seborrheic dermatitis, but the second is associated with medium to severe epidermal spongiosis and dermal inflammation. Moreover, in seborrheic dermatitis, inflammation is seen to be associated with the presence of horizontally orientated, enlarged vessels in the upper dermis (not published observation).

Fig. 2 (a, b) Clinical and dermoscopic images of psoriasis; (c) RCM single frame at the level of the stratum corneum showing presence of refractile nucleated structures corresponding to the paracomification (*red square*) and Munro abscesses (*green square*); (d) RCM Vivablock

mosaic at the level of DEJ shows an increased number and density of dermal papillae (papillomatosis); (e) RCM close-up of papillomatosis shows dilated dermal papillae with thin interpapillary spaces, inside the papillae dilated vessels are visible

The possibility of real-time microscopical confirmation of the clinical diagnosis of inflammatory diseases ranging from contact dermatitis to psoriasis gives the clinician the possibility of a better selection of treatment and a more precise management of patient with scalp diseases.

3.6 RCM of Skin Tumors of the Scalp

The spread experience on RCM on both benign and malignant skin tumors can be easily transferred to the scalp trying to avoid or at least to limit the number of unnecessary biopsies of benign lesions in such a bleeding and painful anatomical area. Moreover, melanocytic and epithelial tumors can be mapped in order to define the extension of the lesion and limit the margins of the

excision preserving healthy tissue in an area where reconstruction and/or flaps are difficult procedures.

Confocal microscopy distinctive features of the nevi (i.e., preserved skin structure with junctional proliferation of normally structured melanocytes and/or regular nest size and distribution in the upper dermis) or melanoma (i.e., up migrated or round, dendritic atypical melanocytes, disarranged epidermis and dermis, inflammatory cells) involving the scalp are substantially the same as the once seen in lesions arising in other anatomical sites (Pellacani et al. 2012; Pupelli et al. 2013) (Fig. 3). Same happened for all the most common malignant epithelial tumors (i.e., basal cell carcinoma, squamous cell carcinoma) and for seborrheic keratosis (Guitera et al. 2012).

Fig. 3 (a) Dermoscopic image of a pigmented lesion located on the scalp and diagnosed as melanoma; (b) RCM mosaic at the level of granulosum spinosum layer shows at scanning, the presence of atypical cells, to note the presence of areas of artifacts due to the limit of the

blocks on the scalp because of the presence of hairs; (c, d) RCM close-up of the previous Block disclose the presence of multiple large cells with bright cytoplasm and dark nucleus with clearly visible dendrites connected to the cells corresponding to dendritic pagetoid cells (red arrows)

The main limit for the RCM examination on the scalp is represented by the presence of hair and the convexity of the scalp limiting the attachment of the adhesive windows and determining artifacts. A valid solution is represented by the use of the handheld confocal microscope that lets the examination of 1 mm large spots and permits to scans handily all the “front” of the lesion.

4 Conclusions

In conclusion, in addition to the possibility of clinical-dermoscopic-confocal correlation for the diagnosis, mapping, and management of

scalp melanocytic as well as non-melanocytic tumors, RCM seems to be particularly useful for inflammatory scalp diseases as already proven for the skin lesions. If RCM differentiation of psoriasis versus seborrheic dermatitis can be useful for a better management of patients, probably, the most interesting application of RCM on the scalp is alopecias due to its high sensitivity and sensibility in differential diagnosis between cicatricial and noncicatricial alopecias. Moreover, the therapeutical follow-up of scarring alopecias using dermoscopy in association with RCM has been demonstrated to be much more precise than using only dermoscopy, thanks to the possibility of a “quasi” histological examination of tissue.

Alopecia areata • Androgenetic alopecia • Androgenic alopecia • Dermoscopy • Dermatoscopy • Female pattern hair loss • Follicular unit • Hair • Hair shaft thickness • Trichoscopy • Lupus • Telogen effluvium

The term “trichoscopy” refers to dermoscopy of hair and scalp (Rudnicka et al. 2008, 2012). The method allows to visualize growing hair shafts and scalp skin at multifold magnification (Fig. 1). The usual in-office working magnification of a hand-held dermoscope is 10–20-fold, but a magnification of 70-fold or more may be achieved with a digital dermoscope (videodermoscope).

Among the dermoscopes, there are devices which require immersion fluid and dermoscopes which use polarized light to cancel out reflections from the stratum corneum. Polarized light dermoscopes may have a contact or noncontact lens. Devices, which combine contact and noncontact attributes (hybrid dermoscopes), are also available. The choice of a particular device is a matter of individual preference. They do not differ significantly by their usefulness for performing trichoscopy.

Trichoscopy is based on analysis of main structures, which may be visualized with a dermoscope. These structures may be divided into four big groups: (1) hair shafts, (2) hair follicle openings (dots), (3) perifollicular epidermis, and (4) blood vessels.

Fig. 2 Measuring hair shaft thickness in trichoscopy performed with a digital dermoscope

1 Hair Shafts

Most hairs viewed by trichoscopy are normal terminal hairs. They are over 55 μm thick, uniform in thickness and color (Fig. 2) (Rakowska 2009; Vogt et al. 2008). Hair shaft thickness may be roughly estimated with a handheld dermoscope (thin, intermediate, thick). Many videodermoscopes possess software allowing detailed

assessment of hair shaft thickness in micrometers. Precise measurement of hair shaft thickness is not essential for diagnosis, but may be useful for monitoring treatment efficacy and in clinical trials (Olszewska and Rudnicka 2005). In such cases hair may be measured according to the method by Rakowska et al. (Rakowska 2009), which is based on evaluation of average thickness of about 20 hair shafts, separately in the frontal area,

parietal area, and the occipital area. This distinction is of particular importance in evaluation of treatment efficacy in female and male androgenetic alopecia.

Up to about 10 % of normal human scalp hairs are vellus hairs, defined as hypopigmented, nonmedullated hairs which are less than 30 μm in thickness and less than 2–3 mm in length (Rakowska 2009; Vogt et al. 2008). An increased proportion of vellus hairs is characteristic for male and female androgenetic alopecia, where vellus hairs replace terminal hairs in the process of hair follicle miniaturization (Inui et al. 2009; Van Neste 2006). High percentage of vellus and intermediate hairs contributes to high hair shaft thickness heterogeneity, a hallmark of androgenetic alopecia (Inui et al. 2009; Rakowska et al. 2009). New, healthy, regrowing hairs are also short and thin, but they differ from vellus hairs by their upright position, firm appearance, and pointed end.

Various hair shaft structure defects may be identified by trichoscopy. A classification of hair shaft abnormalities observed in trichoscopy was recently suggested in a publication by Rudnicka et al. (2012). This classification distinguishes fractured hairs, narrowings, nodular structures, curls and twists, bands, and short hairs ≤ 1 cm.

An important measurable parameter in trichoscopy is the number of hairs emerging

from one follicular unit (Fig. 3). Usually two to three hairs emerge from one follicular unit. Occasionally, four emerging hairs may be found, but this is more common in patients with dark skin phototypes, than in Caucasians. The percentage of follicular units with only one emerging hair shaft is usually less than 30 % in healthy individuals. The number of hair shafts emerging from one follicular unit is decreased in various types of hairs loss, especially in telogen effluvium and androgenetic alopecia. Successful therapy results in a significant increase of the percentage of follicular units with two or three hairs and in an increase of the average number of hairs per follicular unit. For monitoring treatment efficacy, it is advisable to calculate the average number of hairs per follicular unit separately for the frontal area, the parietal area, and the occipital area (Rakowska 2009). Usually, the average number is calculated based on results obtained in four fields of view of a dermoscope.

The number of hairs in one follicular unit is increased in tufted folliculitis. These may be small tufts, of five to seven hairs. Small tufts may be observed in inflammatory diseases, such as tinea capitis or lichen planopilaris. Big tufts of ten or more hairs result from merging few follicular units and are characteristic of folliculitis decalvans. The big tufts are usually walled by a wide, hyperkeratotic, scaly hair follicle opening.

Fig. 3 A decreased number of hair shafts per follicular unit may be an indicator of hair loss. In such cases follicular units with one (a) and two hairs (b) predominate. In a healthy person, most units contain three hairs (c)

2 Hair Follicle Openings

The term “dots” refers to hair follicle openings seen from the perspective of a dermoscope. Black dots are residues of pigmented hairs broken or destroyed at scalp level. Yellow dots are follicular infundibula with keratotic material and/or sebum. Fibrotic white dots represent fibrosis in areas of selective follicular destruction. Pinpoint white dots are observed in patients with dark skin phototypes. They correspond to empty hair follicles or to the epidermal portion of eccrine sweat ducts. Red dots were described in discoid lupus erythematosus. Pink to pink-brown dots are a characteristic finding in the eyebrow area of patients with frontal fibrosing alopecia (Rudnicka et al. 2012; Ross et al. 2006).

The number of “dots” may be calculated per field of view of a dermoscope and used for monitoring treatment efficacy. For example, the average number of black dots per field of view is considered a marker of disease activity in alopecia areata (Inui et al. 2008).

3 Perifollicular Epidermis

Perifollicular and interfollicular skin surface provides significant information, which may facilitate diagnosis in hair and scalp diseases. It is one of the measurable parameters in the presence of perifollicular brown color (“peripilar sign”), which is believed to correspond to the presence of lymphocytic infiltrates (Deloche et al. 2004; Wallace and de Berker 2010). This finding is common in androgenic alopecia (Inui 2011) and telogen effluvium and may be seen in up to 10 % of hair follicle openings in healthy individuals (Rakowska 2009). The peripilar sign disappears with successful therapy of hair loss.

Epidermal scaling is a common finding in various inflammatory scalp diseases and in healthy individuals. The intensity of scaling may be assessed by trichoscopy and graded in a semi-quantitative manner from 0 (for no scaling) to 4 (severe scaling).

In conclusion, trichoscopy is a novel method of noninvasive skin imaging that may be applied for diagnosing hair and scalp diseases as well as for quantitative evaluation and monitoring of hair loss.

4 Blood Vessels

Trichoscopy of normal scalp shows multiple thin arborizing vessels in the occipital area and pinpoint vessels in the frontal area (Rakowska 2009). Abnormalities in thickness and structure of blood vessels may provide clues for the diagnosis of several inflammatory scalp diseases, such as psoriasis, discoid lupus erythematosus, or dissecting cellulitis (Rudnicka et al. 2012).

1 Introduction

Hair disorders are common diseases, frequently observed in dermatology. Alopecia has an important psychological impact on patients suffering from it. Therefore, the management of the patient must be complete and reassuring. The examination should be composed of a complete history taking, clinical and trichoscopic examinations, blood tests, trichogram, and sometimes biopsies.

The trichogram or hair pluck test is a semi-invasive, qualitative, and quantitative method which expresses the number and the proportion of hairs in the different phases of the hair cycle. The procedure is easy to perform and reliable and consists of a microscopic evaluation of plucked hairs in order to determine their cycle phases: anagen, catagen, or telogen and thus assess the dynamic phenomenon of hair cycle. Van Scott et al. introduced the trichogram in 1957, and in

the middle of 1960s, Barman and Pecoraro described several trichometric features and established normal values.

The sampling is already a part of the treatment, because the patient is less anxious and feels understood. Indeed, the sampling process is as important as the test result.

The trichogram allows also the assessment of hair shaft and diameter and also its anomalies.

This technique is employed for diagnosis, prognosis, and treatment monitoring of hair disorders but provides also the hair growth assessment in clinical trials in medical and cosmetic fields.

2 The Plucking Procedure

2.1 Material

The material is not expensive and easily available (Fig. 1):

- Forceps with rubber-protected jaws
- Adhesive tape or mounting medium, glass slides, and cover slips
- A pair of scissors
- Microscope (magnification 10 \times , 20 \times , and 40 \times) or microfilm reader (48 \times)

Fig. 1 Materials for the trichogram: microfilm reader, glass slides, cover slips, mounting medium, tape, scissors, forceps with rubber-protected jaws, and micrometric slide

2.2 Procedure

It is recommended to do the trichogram on an unwashed and untreated scalp for 5 days. In fact, no mechanical actions must be done: washing, brushing, and drying in a period of 5 days before the trichogram. Indeed, mechanical actions may eliminate telogen hairs and consequently reduce their number during the plucking which may lead to an artificial reduction of telogen rate leading to false results.

Selecting the plucking zone depends on the clinical status. In diffuse alopecia, a central part of the affected area and also non-affected area, as a control, should be sampled. For example, in androgenic alopecia (AGA), the first point is 2 cm behind the frontal line and 2 cm from the midline, and the second zone should be on the occipital region, 2 cm besides *protuberantia occipitalis externa*. In focal alopecia, the first point would be at the border of the lesion and the second on the contralateral, clinically unaffected side.

Trichoscopic examination may be, firstly, performed to determine the more relevant area to pluck.

- A bundle of about 30 hairs is carefully ranged. Plucking more hairs is frequently used, but it is difficult to pluck when it is painful and represents an important amount of hairs (Dhurat and Saraogi 2009). According to our experience, 30 hairs represent a reliable quantity to provide enough information.
- The lock of hairs is tightly plucked with the forceps as close as possible to the scalp, in order to avoid dystrophic and broken hairs and to pluck miniaturized hairs as well.
- One hand maintains the scalp stretched, while the other hand pulls rapidly with a unique ample movement in the direction of their emergence (Fig. 2). Plucking very curly, African, or short hairs is more difficult and may be done one by one with tweezers.
- A vigorous massage of the area, just after the sampling, relieves the discomfort caused by the sampling.

Fig. 2 Plucking procedure

- Hairs are arranged side by side on a glass slide and taped with transparent adhesive tape. It is also possible to use mounting medium used in microscopy like Eukitt[®] or Corbit-Balsam and cover slips. The mounting medium contains a preservative that is more expensive and may form air bubbles. It is permanent, and the procedure is longer because it needs a drying time. It is recommended not to cut taped hairs to assess their lengths and diameters in order to distinguish regrowing hairs from miniaturized hairs.
- Bulbs are examined at low magnification with a light microscope or on a screen of a microfilm reader. The latter allows an immediate global visualization of the entire sample on a wider screen and makes the count easier. Moreover, the screen is more useful to show and explain the shedding process to the patient.
- The sampling can be preserved and examined several weeks after sampling since the bulbs retain their morphology. Results and slides should be archived for patient follow-up.

3 Information Collected

The hair plucking procedure and analysis need a short training in order to obtain reliable and reproducible results. Indeed, if the trichogram is carried out inappropriately, many dystrophic and broken hairs are obtained and make the interpretation impossible.

The main objective of the trichogram is to evaluate hair roots, but the microscopic evaluation allows also the assessment of diameter and shaft morphology.

Cycle phasing and counting of the fair and white hairs (canities) are more difficult due to the absence of pigmentation.

3.1 Hair Root Assessment

3.1.1 Morphological Characteristics of Hair Roots During the Different Hair Cycle Phases

Anagen, the Growth Phase

The anagen root presents a darkish keratogenous zone, with the presence of melanin in matrix (Fig. 3a–c). A double translucent epithelial sheath can be presented and intact or partially present or sometimes absent (naked anagen).

Different patterns of anagen hair roots can be observed on the trichogram according to the different anagen stages. Trained examiner may be able to differentiate anagen stages; nevertheless, it needs a long training. However, the inter- and intraindividual variety of the time duration of these stages does not have a real clinical interest.

In early stage, hair roots are widest at their proximal end and narrow on the distal part (trapezoidal shape). In late stage, hair roots have a diameter more uniform throughout (rectangular shape).

Often an angulation of root and/or shaft can be observed.

The diameter of anagen hairs of children and fair or red-hair adults is lower, and the medulla is sometimes absent, making the distinction between hair cycle phase more complicated.

Catagen, the Regressing Phase Mediated by Apoptosis Phase

Catagen hairs are rare, less than 2 %, and sometimes difficult to distinguish from telogen (Fig. 4). The diameter of catagen hair root is smaller; sheaths persist but are shorter and narrower than those in anagen phase.

Fig. 3 Anagen hairs: (a) Anagen hair naked, (b) anagen hair with sheath and rectangle root, and (c) anagen hair with sheath and trapezoidal root

Early catagen hairs show an equal diameter throughout and a slight keratinized tip.

Late catagen hairs have a club-shaped tip, less keratinized (the future telogen), and ended by a “tail” corresponding to an epithelial cord remnant joining the papilla.

A high proportion of catagen hairs inform about the alopecia progress.

Telogen, the Quiescent Phase

Telogen hairs have a typical club-shaped root, have a thickening of the proximal end, and keratinized, mostly transparent but partly pigmented (“swab” shape) (Fig. 5). Although they have no internal or external root sheath, their club-shaped roots are surrounded by an epithelial sac, sometimes absent. The presence of this epithelial sheath indicate strong binding, suggesting early telogen, whereas the absence of an epithelial sheath indicates loose binding accompanied with hair shedding (Piérard-Franchimont and Piérard 2001).

Fig. 4 Catagen hairs

No angulations are observed on telogen hairs.

3.1.2 Other Morphological Features Observed

Dystrophic Hairs

In the literature, the terms “dystrophic” and “dysplastic” hair roots are rather confusing and sometimes be used in place of each other (Fig. 6). Basically, these two terms refer to an abnormal anagen hair with shaft and/or root defect. To avoid misunderstanding and confusion with other diseases, we suggest to use the unique term of “dystrophic hair.”

This impairment may be an artifact due to the plucking procedure (too slow epilation) or a real disease such as keratinization impairment in “loose anagen hair syndrome” or the inflammatory aggression of bulb and papilla in “alopecia areata” and “psoriasis.” However, dystrophic hairs can also be observed in healthy scalp (approximately less than 5 %).

A dystrophic hair may be characterized by several patterns:

- Absence of sheaths.
- Decreased matrix diameter; dystrophic hairs are thinner.

Fig. 5 (a) Telogen hair surrounded by an epithelial sac. (b) Telogen hair naked

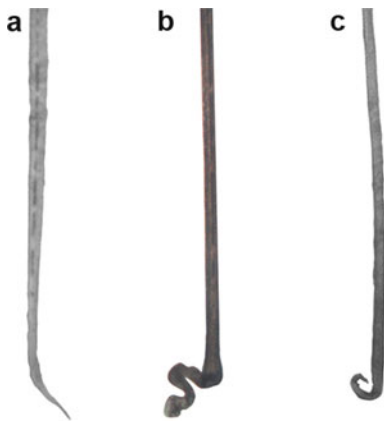

Fig. 6 Dystrophic hairs: (a) Dystrophic naked hair with a tapered root, (b) dystrophic hair with “wavy” shaft, and (c) dystrophic naked hair with a hook-shaped root

- Marked hair shaft constriction.
- Rupture of the hair around the upper third of the papilla leading to a tapered root.
- Lower end of the hair shaft is usually wavy.

Fig. 7 Broken hair

- Deformation of the bulb which looks distended, stretched, and colorless.
- Often hair roots show $>20^\circ$ angulation: “hooked hair.”

Broken Hairs

Usually they correspond to anagen hair shafts that break off due to the fragility of the hair or an inadequate plucking technique (Fig. 7). The shaft presents a cutoff section excluding the root.

It seems necessary to count them as the healthy anagen hairs because this indicates their strong adherence to the scalp. However, fragility may be the clue of a pathology or deficiency; therefore, a pull test should be associated. If the number of broken hairs is lower than 10 % and the pull test is negative, they will be counted as anagen hairs. Beyond 10 %, the trichogram is not interpretable.

Artifacts

- Pseudomonilethrix, described by Bentley-Phillips et al. in 1973 (Bentley-Phillips and Bayles 1973), corresponds to a hair shaft abnormality characterized by globular swelling (“nodes”) or irregular flattened areas with a larger diameter than normal shaft (Fig. 8). These abnormalities occur in brittle or pathologic hairs but also in normal hairs. In fact, pseudomonilethrix represents an artifact

Fig. 8 Pseudomonilethrix induced manually by the plucking procedure. *Blue arrows* represent globular swelling (“nodes”)

induced by a traumatic process of preparing the hair for microscopic examination (forceps or pressure on the glass slide or tape) rather than a pathologic hair shaft defect (Ferrando et al. 1990). This artifact could be misinterpreted and confused with congenital hair shaft defect including monilethrix, trichorrhexis nodosa, trichorrhexis invaginata, pili torti, or wooly hair. This artifact could be avoided by using rubber-armed forceps to gently plucked hairs and taping on the slide with low pressure.

- Impairments of the hair shaft can occur if the tweezers do not close tightly enough and slip along the shaft (Fig. 9).

3.2 Hair Diameter Assessment

3.2.1 Androgenic Alopecia

Besides the root assessment, the hair shaft diameter can be also evaluated with the trichogram. During hair growth, the new anagen hairs have

their definitive diameter; thus, a thinner hair indicates an impact of androgens which reduce the cycle phase duration and consequently decrease the length and diameter of hairs. When the diversity of hair shaft diameter is high, this phenomenon, called miniaturization, is a hallmark of AGA. It has been suggested that if in trichoscopy miniaturization is more than 20 % of the entire scalp, it is highly diagnostic of AGA. In the other hand, the presence of more than 10 % in the frontal area by itself is also highly suggestive for this diagnosis (Miteva and Tosti 2012).

To measure the diameter of plucked hair shaft with precision, a micrometric scale like a micrometric calibration slide for microscope objective can be used.

A normal terminal hair is 50 μm (blond hairs) to 120 μm thick (Asiatic hairs). Miniaturized hair is defined as fine, short, and unpigmented hair with a diameter less than 40 μm (Rushton et al. 1983).

Although the trichogram allows a qualitative measurement of the miniaturization, it provides

Fig. 9 Impairment of the hair shaft induced by tweezers

only a semi-quantitative indication. Indeed, some miniaturized hairs are too thin to be plucked so the quantification will be neither exhaustive nor accurate. Nevertheless, if the number of miniaturized hair counted in the trichogram is higher than 20 %, it means that there are at least 20 % of miniaturized hairs on the scalp and makes the diagnosis of AGA.

3.2.2 Deficiency

The trichogram may also emphasize some severe nutritional deficiency. During severe diet, protein deficiency (kwashiorkor), or severe digestive diseases with malabsorption, the hair shaft diameter and melanin ratio may decrease brutally leading to thinner and brighter hairs. In the case of intermittent deficiency, the diameter may vary throughout the shaft with alteration from low to normal diameter. The clinical presentation, called flag sign, corresponds to a sequential band of light and

dark color along individual hair fibers due to an intermittent protein deficiency.

3.3 Hair Shaft Assessment

The hair length may be correlated with the hair shaft diameter which is the reason that may distinguish the difference between regrowing hair and miniaturized hair. In the case of regrowing hairs after telogen effluvium, the short hair with normal diameter (50–120 μm) can be observed, while in miniaturized hairs, the short hair with poor diameter (<40 μm) and pigmentation can be observable which is a hallmark of AGA.

Moreover, hair length is a time indicator and it can be used as a witness for calculating the onset of pathology. Knowing the speed of hair growth, which is about 1.3 cm per month, it is possible to estimate the onset of a telogen effluvium and find the triggering factors by measuring the length of regrowth anagen hairs (2–4 months retrospectively).

Finally, trichogram is a microscopic examination which, accordingly, may detect shaft abnormalities and make the diagnosis of congenital hair shaft defect including monilethrix, trichorrhexis nodosa, trichorrhexis invaginata, pili torti, wooly hair, etc.

4 Results

1. An overview of trichogram results in normal condition (Hillmann and Blume-Peytavi 2009; Agache et al. 2004; Peereboom-Wynia et al. 1993; Martinez and Montagna 1997; Blume-Peytavi 2008) and in the context of common scalp diseases (Galliker and Trüeb 2012; Rakowska et al. 2009; Tosti et al. 1997; Trüeb 2009; Bleiker 2005; Paus et al. 2013; Cantatore-Francis and Orlow 2009; Dhurat and Deshpande 2010; Lachapelle and Pierard 1977; Oranje et al. 1986; Stanimirović et al. 1998) are presented in Table 1.

Table 1 Trichogram characteristics of different hair conditions of Caucasians' scalps taking into account inter- and intraindividual, seasons, gender, and phototype variations. In gray, normal values; –, lower than the normal value; =, equal to the normal value; +, higher than the normal value, a. In this study, Pecoraro et al. included catagen hairs in the telogen group

Conditions	Assessed sites	Anagen (%)	Telogen (%)	Catagen (%)	Broken (%)	Dystrophic (%)	Specific characteristics
Normal Adult (Hillmann and Blume-Peytavi 2009; Agache et al. 2004; Peereboom-Wynia et al. 1993; Martinez and Montagna 1997; Blume-Peytavi 2008)	The entire scalp	70–90	10–20	<2	<10	<5	The rate of dystrophic anagen can occasionally reach higher in children, adolescents and adults with thin hairs

Catagen hairs					[<2 %]
Broken hairs					[<10 %]
Miniaturized hairs					[<10%] >20%: AGA [10-20%]: Abnormal
Ratio Anagen/Telogen		N/A		N/A	[>5] [4-5]: Dubious <4: Abnormal

Conclusion:

2. Example of a collection sheet (Table 2)

On healthy scalp, the anagen/telogen ratio is stable and more than 5. An anagen/telogen ratio lower than 5 is abnormal but does not provide any additional data. For example, in telogen effluvium, the telogen percentage is not correlated with severity of hair loss (Guarrera et al. 1997).

3. Physiological variations

The distribution of cycle phases on the scalp is heterogeneous and depends on inter and intraindividual variations:

(a) Scalp location

In both genders, the number of telogen hairs is higher on frontal and vertex regions than on parietal and occipital regions.

(b) *Gender*

In the entire scalp, the number of hairs in a telogen phase is higher in males than in females (Barman et al. 1965).

(c) *Age* (Table 1)

Basically, on newborns' scalp, the anagen phase predominates (65–90 %), but catagen hairs are more frequently observed in newborns than in adults. The telogen phase is most predominant in the frontal region, and the catagen occurs most frequently in the parietal regions than others (Pecoraro et al. 1964a).

In childhood before puberty, generally 90 % or more of hairs are in the anagen phase. Moreover, the number of hairs in telogen phase is lower than in adults. Finally, the proportion of telogen hairs in the frontal and parietal regions is higher than in occipital region (Pecoraro et al. 1964b).

In adulthood, hairs are mostly in the anagen phase; nevertheless, the number of hairs in telogen phase increases with age in each scalp regions (Barman et al. 1965). Moreover, the number of miniaturized hairs increases with age due to the effects of androgens and the progressive physiological degeneration of the dermal papilla which accelerate the hair cycle.

(d) *Seasons*

During summer the percentage of telogen hairs increases, while the percentage of anagen decreases which explains the autumnal hair shedding. The same phenomenon occurs in spring but less remarkable. The telogen rate is the lowest in late winter (Kahn et al. 2009; Kunz et al. 2009).

Thanks to its reproducibility, the trichogram is also used in the routine disease follow-up and in clinical trials as a primary endpoint as well.

This semi-invasive, rapid, objective, and inexpensive microscopic evaluation provides reliable information about hair root, hair shaft, and hair viability.

Although trichogram was widely used routinely for decades, nowadays many dermatologists discontinued this examination due to the lack of knowledge in the interpretation. Indeed, although the procedure is simple, it needs a short training and good experience in the plucking procedure as well as in interpretation to benefit the advantages of this technique.

1 Introduction

Various methods are available for evaluation of a patient complaining of hair loss. Those methods can be invasive, semi-invasive, or noninvasive (Dhurat and Saraogi 2009).

Scalp biopsy is an invasive method.

Semi-invasive methods are pull test, trichogram, or unit area trichogram.

Noninvasive methods include efficacy questionnaire, quality of life questionnaire, daily hair count, standardized wash test, 60 s hair comb test, hair weight, hair diameter measurement, global photographic assessment, dermoscopy, videomicroscopy, photographic hair count, and phototrichogram.

The phototrichogram (PTG) is a safe, noninvasive, and reproducible method that allows in vivo study of the hair cycle. PTG is able to quantify a lot of hair growth parameters including hair density. Hair loss and hair thinning are the main complaints in clinical hair diseases. Even if the diagnosis of androgenic alopecia is clinical, clinical assessment of the hair density is not easy

P. Reygagne (✉)
Centre de Santé Sabouraud, Hôpital Saint Louis, Paris,
France
e-mail: p.reygagne@centresabouraud.fr

especially at the beginning when hair density is nearly normal, and we need a sensitive tool to measure hair loss and hair density and to monitor effect of treatments on alopecia. The phototrichogram is based on the following principle: after shaving a target area of the scalp, it's possible to distinguish growing hairs in anagen phase which lengthen by about 0.35 mm a day and the resting hairs in telogen phase. As a trichogram, PTG is able to quantify percentage of anagen and telogen hair. And as a macrophotography of a selected area (global hair count) (Canfield 1996), or as a unit area phototrichogram (Rushton et al. 1983), or as a scalp biopsy (Whiting et al. 1999), PTG is able to quantify density of hair. Furthermore PTG can measure hair growth speed and hair diameter, and it's possible to check carefully and to control all those values on stored photographs.

For those reasons PTG is nowadays the gold standard for noninvasive hair growth measurement in hair research and in clinical studies or for a patient's follow-up assessment during treatment of none scarring or scarring alopecia. Most of the time PTG is combined in clinical studies with a cosmetic assessment included a questionnaire and global photographs.

2 History

The PTG was described for the first time by Satoh in 1970, on scalp and body hair of three Japanese men studied over a period of 2 years (Saitoh et al. 1970). Fiquet and Courtois were the first to propose PTG to access hair growth, severity of alopecia, and evolution after anti-hair loss treatments (Fiquet and Courtois 1979; Courtois

et al. 1982). Then Bouhanna and Guarrera improved the methodology (Bouhanna 1982, 1984; Guarrera and Ciulla 1986) and Bouhanna invented in 1988 a variant, the tractiophototrichogram (Bouhanna 1988). The advantage of the tractiophototrichogram is to avoid the second visit necessary for a classical PTG: you choose the area of interest; you pull all the hairs of this area firmly between thumb and forefinger to eliminate telogen hair. You count the number of eliminated telogen hair and after you take a picture to count the remaining anagen hair. The main problem is that the traction is not standardized and investigator dependent, and now the tractiophototrichogram is not in use anymore. In 1991 Blume used the PTG for visual and manual vellus hair count, and vellus hairs, generally colorless, were dyed (Table 1) (Blume et al. 1991). Classical PTG even on the scalp is limited by the contrast between hair and scalp color. This contrast is poor in the case of fair or white hair and in the case of AGA because of the miniaturization process: vellus hairs are thinner and lighter than terminal hair. In 1992 Van Neste introduced the application of an immersion oil (scalp immersion photographic method) (Van Neste et al. 1992); and in 2001 he added hair dye to proposed the contrast-enhanced PTG (CE-PTG) (Van Neste 2001). With an increase of contrast and resolution, thanks to the use of immersion oil and hair dyer, CE-PTG is nowadays the most sensitive methodology specially in case of fair hair or AGA. A comparative evaluation of scalp hair by PTG and unit area trichogram analysis showed comparable results in the same subjects for anagen hairs (Rushton et al. 1993), and CE-PTG is as sensitive as transverse sectioning of scalp biopsies for detecting hair and percentage of anagen and telogen hairs (Van Neste 2001).

Table 1 Phototrichogram results for vellus hair follicles in healthy subjects (Blume et al. 1991)

Localization	Density	% Anagen	Rate of growth
Facial hair females (forehead)	448/cm ²	48	0.037 mm/day
Thorax hair females (back)	93/cm ²	31	0.15 mm/day
Thorax hair females (chest)	53/cm ²	42	0.11 mm/day
Facial hair males (forehead)	429/cm ²	49	0.025 mm/day
Thorax hair males (back)	77/cm ²	32	0.12 mm/day
Thorax hair males (chest)	61/cm ²	35	0.11 mm/day

The CE-PTG is the best tool to access hair regrowth in clinical research, but CE-PTG without automatic analysis is time consuming and difficult to perform in clinical practice. For this reason some authors developed automatic hair counts and analysis, easier to use in clinical practice. First attempts to automate the process began in 1986 (Pelfini and Calligaro 1986; Hayashi et al. 1991) and then continued with Dominique Van Neste who was the most well-known pioneer of this new method (Van Neste et al. 1989, 1992).

3 Methodology: CE-PTG

We are going to describe the CE-PTG which is in 2014 the best method to access hair growth and hair loss. The CE-PTG is used to detect and quantify early changes of decreased hair density, diameter, or growth in diffuse alopecia or in androgenetic alopecia (AGA). This method is usually used for scalp hairs but analysis of body hairs is also possible.

First of all the area of interest must be chosen in an active area. In the case of AGA, it could be the vertex or an anterior or lateral area close to the vertex in a transitional area of hair loss. It's possible to choose an anterior area along the receding hairline but it's more visible. It's always better for cosmetic reason to avoid the parting. In the case of scarring alopecia, you must choose an area along the border of an inflammatory patch.

On day 0 a scalp area of interest of about 1 cm^2 is delineated with a standardized plastic template applied on the selected area. All hairs of this area are combed through this template with the help of a little curved hook or a pointed scissor and shaved with a surgical curved scissor or a hairliner or better a mini haircut (Wella® or Ermilia®) (Photo 1, 2, and 3). The length must be the same for all the hairs of the area, and short hair shafts should remain visible (about 0,5 mm), and that's difficult with a scissor and easier with a mini haircut. Adhesive tape can delimited the target area shaved to avoid the crossing of outside hair (Photo 4). It is very important to remove carefully all clipped hair with an adhesive strip or with pulsed hair to avoid their count in the target. A magnifying glass can help to check the area is definitely clean. A brown or best a black dyer is used to dye hairs of the target area to enhance the contrast between hair and scalp before the photography. This is always necessary in the case of blond, gray, or white hair; it is not essential in the case of very dark hair, but vellus hairs are always more visible if they are dying. After 10–15 min, the area is cleaned with an antiseptic alcoholic solution. You must choose a time of application, according to the hair and the used dyer, long enough to dye the hair but not too long to don't dye the scalp. Usually more than 15 min would unintentionally dye the scalp and less than 10 min resulted in uncompleted staining of hair.

Photo 1 Hair liner

The photography is taken with a macrocamera or a video camera (Photo 5) under fixed distance, fixed magnification, and fixed light conditions. It's possible to use different devices: Canfield camera (Photo 6) or medical Nikkor lenses, Canon or FotoFinder medicam (Photo 7), etc. Image quality is better with the scalp immersion

Photo 2 Mini hair cut

proxigraphy method: the camera device includes a glass slide at fixed distance, and by pressing the glass slide on the scalp, you flatten the scalp and the hairs. The scalp is photographed under the glass slide with a drop of immersion oil between the glass slide and the scalp (Photo 8). This increases the resolution of the images. A hydroalcoholic antiseptic solution can also be used, and with a hydroalcoholic solution or with water, it's easier to avoid bullous formation around follicles between the glass and the scalp.

On day 2–3, the second photography is taken without shaving the hair but after hair dyer and with the same methodology. The most difficult is to photograph exactly the same area, and for that you can use semipermanent dot tattoo or a nevus or an angioma. In the case of tattoo, you can use one tattoo in the center of a circle if your target area is a circle. In this case it's better to don't use a black tattoo which could mask few hairs on the photographs. A red tattoo is better. If your target area is a square, you can use black or dark brown color at two opposite corners of the square just outside of the target for hair counting. In France the only brand of tattoo with a CE approval for medical tattooing is Biochromaderm® (Laboratoires Biotic Phoccea). If there is no nevus and no angioma and if the patient doesn't agree for a tattoo, you can exactly measure the distance between the

Photo 3 Shaving of the selected area

Photo 4 Adhesive tape delimitate the target area

Photo 5 Achievement of the photo

area and the nose and between the area and left and right ears. After you must check exactly the follicular location of few typical follicular units on previous photography, but it's very difficult and time consuming and the use of a dot tattoo is easier and guaranties the analysis of the same area to insure reproducibility over a long period of time in clinical studies (Courtois et al. 1995).

An interval of 2 days between the first and the second photography of the PTG is enough to see and measure elongation of hair. It's important in case of linear hair growth hair measurement to respect the same hour in the day for both photographies. An interval of 3 days can measure a more precise elongation of hair but if

interval is longer, hairs are too long, and because of many crossings or overlap of hairs, hair counts and interpretation of picture are more difficult. Some hair can be forgotten or otherwise counted twice.

Results (Photo 9): comparing the first and the second photographies with the help of manual marking of hairs on images allows to measure number of hair, anagen hair, telogen hair, hair elongation, hair diameter, terminal hair (with a diameter $>40 \mu\text{m}$), and vellus hair (with a diameter $<40 \mu\text{m}$). The detection limit is depending on the resolution, quality, and magnificence of the photographs. Usually hairs under $5 \mu\text{m}$ of diameter are not visible.

Photo 6 Candfield camera

Photo 8 A drop of immersion oil

Phototrichogram before and after 12 weeks of a cosmetic topical treatment

	Total Hair count	Hair Density (1/cm ²)	Anagen hairs (%)	Telogen hairs (%)
Week 0	113	201	74,3 %	25,7 %
Week 12	123	218,8	85,5 %	14,5 %

Photo 9 Phototrichogram assessment before and after a topical treatment

- Elongation of hair indicates an anagen hair.
- No elongation or missing hair on the second photo indicates a telogen hair.

Evaluation parameters:

- Total number of hair in the target area (H)
- Total density of hair (H/cm²)
- Number of terminal hair (TH)
- Density of terminal hair (TH/cm²)
- Number of vellus hair (V)
- Density of vellus hair (V/cm²)
- Percentage of terminal hair (TH/H) × 100 %
- Percentage of vellus hair (V/H) × 100 %
- Terminal-to-vellus ratio (H/V)
- Total number of anagen hair (A)
- Total anagen hair density (A/cm²)

- Total number of telogen hair (T)
- Total telogen hair density (T/cm²)
- Percentage of anagen hair (A/H) × 100 %
- Percentage of telogen hair (T/H) × 100 %
- Anagen-to-telogen ratio (A/T)
- Length (mm)
- Linear hair growth rate (LHGR; mm/day)

The LHGR is the length of hair on the second photo minus the length of hair on the first photo, divided by the interval of time between the two photos in days.

The best parameters correlated to the hair volume and the cosmetic improvement are:

- Total density of hair
- Total density of terminal hair

Percentage of anagen hair, percentage of terminal hair, and LHGR can be considered.

The worst parameter is the A/T ratio: variations are very important, and an increase of this parameter is possible without increase of anagen hair density, with a decrease of telogen hair density, and with a decrease of total density of hair, without cosmetic improvement and with a worsening of the alopecia.

3.1 Advantages of PTG

- Reproducible procedure
- No hair plucking and no painful, noninvasive method
- Information on density (as for macrophotography alone)
- Information on % of anagen and telogen hair (as for trichogram)
- Information on hair diameter
- Possibility to survey over many years the evolution of exactly the same groups of hair on the same precise area of the scalp (Courtois et al. 1995)
- Storing pictures to control results

3.2 Inconvenience of PTG

- No visualization of hair shafts.
- Need of two visit for the patient with 2 or 3 days of interval.
- Need to shave the target area.
- Manual hair count is time consuming.
- Manual count is investigator dependent.
- Automated PTG Is Expensive
- Detection of hair is dependent on the magnification and the sensibility of the photographic procedure.
- Tattoos (0.2–0.5 mm) can remain many years if red or brown and all the life if black.

In clinical studies CE-PTG is usually combined with a global photographic assessment for

evaluating quantitative improvement with the CE-PTG and cosmetic improvement induced by treatment with the global photographic assessment.

4 Automated PTG

Conventional manual hair counts on photographs of CE-PTG are accurate but laborious and very time consuming, and results are investigator dependent even for the same photographs.

First attempts to automate the counts of PTG began in 1986 (Pelfini and Calligaro 1986; Hayashi et al. 1991; Van Neste et al. 1989, 1992).

In 1996, L’Oreal proposed an automatic system count, but this has not been available for the public (Chatenay et al. 1996).

The Folliscope™ version 2.8 (LeadM Corp, Seoul, South Korea) is a semiautomated tool using videodermoscopy of scalp and software to help the manual count (Photo 10). The Folliscope uses a light and small video camera, easily portable with a port-USB connection. The 100-fold lens magnification allows measuring easily hair thickness. Hair thickness is measured by mouse point dragging from one side to the other side of the hair shaft (Photo 11). The 50-fold lens is used to access hair density, but the hair count is not fully automated, so this count can change with different investigator and target area is too small for accurate PTG. Accurate results needs to analyze three locations in each chosen area for hair count and five to ten hairs for thickness or hair diameter (Lee et al. 2012).

In 2001 (Hoffman 2001) Hoffman described a fully automated method for the measurement of CE-PTG parameters, thanks to a new software named TrichoScan®. His method combines epiluminescence videomicroscopy with automatic digital analysis. The first version was able to count total number of hair, number of telogen and anagen hair, percentage of telogen or anagen hair, hair growth rate, and anagen/telogen ratio,

inside a circle target area of 0.642 cm^2 , with a good intraclass correlation within the same TrichoScan operator and for different TrichoScan operator (Hoffman 2001).

TrichoScan is able to demonstrate in a small group of 12 men with AGA a significant increase in total number of hair after 3 and 6 months of treatment with finasteride 1 mg/day (+17 % at month 3, $p = 0.055$ and +20 % at month 6, $p = 0.021$) (Hoffman 2003). Furthermore in the same group, increase of hair thickness was +11 % at month 3 ($p = 0.034$) and +18 % at month 6 ($p = 0.006$) (Hoffman 2003). Also TrichoScan allows to demonstrate significant increase of hair density, cumulative hair thickness, and terminal hair count in a small group of 10 women and 21 men with AGA after 6 months of treatment with 5 % topical minoxidil (Hoffmann and Van Neste 2005).

For few authors TrichoScan seems no better than the clinical observation or no better than the modified wash test to diagnosis telogen effluvium (Guarrera et al. 2013). But it's difficult to conclude that without a gold standard assessment. The TrichoScan has been validated to measure severity and evolution of hair growth in

androgenetic alopecia (Gassmueller et al. 2009). This new tool obtains quickly reproducible results with a smaller margin of operator error than the hair manual count (Gassmueller et al. 2009). TrichoScan is not a good tool for alopecia areata. Hair is a tricky material for automated computer-assisted analysis and in Indian population (Saraogi and Dhurat 2010), and in some other cases, TrichoScan can overestimate the number of telogen hair by erroneous fragmentation of hair stands and underestimate the vellus hair percentage specially vellus hair under $10 \mu\text{m}$ of diameter (Van Neste and Trüeb 2006), but those errors are reproducible and vellus hairs under $10 \mu\text{m}$ of diameter are with no cosmetic value. For those reason TrichoScan is a good tool for big clinical studies.

The last available version is TrichoScan Professional Version 3 (Photo 12). TrichoScan 3 is able to count total number of hair, vellus hair ($<40 \mu\text{m}$), terminal hair, anagen and telogen hair, and in a research version hair diameter and cumulative hair thickness. The detection limit of the software is between 5 and $10 \mu\text{m}$. TrichoScan can quantify more important miniaturization of hair diameter in the crown area than in the

Photo 12 TrichoScan 3 Screenshot results

occipital one in women with AGA, and in this way it can help to make a good surgical decision for micrographs (Riedel-Baima and Riedel 2009).

TrichoScan is very popular in Germany and Italy and TrichoScan[®] is used for clinical practice and for clinical studies.

TrichoScan can access hair growth and length of the growing hairs after hair removal on the body (Kuck et al. 2012) or on the face (Hoffman 2008) or demonstrate an increased telogen/anagen ratio in patients with scalp psoriasis (Kasumagić-Halilović et al. 2010).

Technical procedures are the same than for classical CE-PTG, but accurate results need a better image quality than for a manual count. The software is able to count as hair dirty area, remnants of the hair dye, melanocytic nevi, or dark tattoo. It's very important to clean carefully the scalp to avoid remnant of coloration on the scalp and to avoid dot tattoo inside the target area,

except if the tattoo is slightly red because the red color will not interfere with the automatic hair count. For a good quality image suitable for analysis and to avoid air bubbles between the scalp and the slide of the camera, it's important to use for immersion a hydroalcoholic lotion or water. It's better to avoid oil for this immersion. The software measures length of hairs on the second picture. There is a standard limit of 0.63 mm with the TrichoScan 3 and shorter hairs are counted as telogen and longer as anagen. The target area is a circle of 0.526 mm². The circle is the best figure to minimize the perimeter/surface ratio. This is important to reduce hair count errors along the limits of the target area. TrichoScan will analyze the same area before and after treatment. It is quicker than a visual count and this software allows different technicians without a great experience to get accurate and reproducible results. Fotofinder Trichoscale is a new software wich

Table 2 Hair density assessment with PTG in healthy population, depending on the methodology, age, sex, and ethnicity

Author	Methodology	Patients	Hair density/cm ²
Birch 2001 (UK)	Visual counting	Healthy women 35 years old	Mild scalp density 293
D'Amico 2001 (Italy)	Phototrichogram using videomicroscopy	20 healthy women	Vertex density 300 ± 20
Ueki 2003 (Japan)	Phototrichogram	31 healthy women	120
Nakazawa 2006 (Japan)	Phototrichogram	Healthy women 30 years old	230
		Healthy women 60 years old	199
Aktan 2007 (Turkish)	Visual counting	31 healthy women 35 years old	Mild scalp density 212.8 ± 32.9
	TrichoScan	31 healthy women 35 years old	Mild scalp density 141.7/cm ² ± 21.6
Kim 2013 (Korea)	Folliscope PT 2.8	683 healthy women	123–165
		674 healthy men	126–171

allows to determine follicular units, percentage of vellus hair, hair diameters and cumulative thickness.

5 Normal Results

According to the ethnicity, the total number of scalp hair follicles varies from 150,000 to 90,000.

Results of phototrichogram are depending on the methodology, age, pathology, and origin of the studied population. For example, European scalp hair density is more important than Asian scalp hair density, but thicker hair is more important in Asian population with or without AGA (Lee et al. 2012). With PTG frontal and occipital density are lower in Asian women with untreated AGA (114 and 118 hair/cm²) compared to European women (127 and 140 hairs/cm²).

Hair density in healthy women ranges from 175 to 450 hairs/cm² (Aktan et al. 2007). Results of normal total hair density with PTG are reported in Table 2 (Birch et al. 2001; D'Amico et al. 2001; Ueki et al. 2003; Nakazawa et al. 2006, Aktan et al. 2007; Kim et al. 2013).

Due to individual differences, some overlap in hair density and in percentage of telogen hair exists between normal population and males or females with hair loss (Kim et al. 2013).

Wash test • Pull test • Noninvasive methods

1 Introduction

Hair loss is a common complaint in both genders and often entails psychological distresses which may be severe. Hence, the problem needs to be approached thoroughly, and this requires using a quantitative, possibly noninvasive, assessment. Useful noninvasive methods are the pull test and the modified wash test (MWT).

2 The Pull Test

The pull test should be tried first in any patient complaining of hair loss. The method requires that the patient is examined when his/her hair has not been washed recently and, in fact, a 5-day abstinence from the last shampooing is recommended. Unfortunately, the large majority of patients seeking advice in the office are so kind as to come with their hair shampooed the very same morning. In such a condition, the pull test is useless, unless the hair shedding is massive.

Two different procedures (Camacho and Montagna 1997) come under the same title: in the first one, a cluster of 40–50 hairs is grasped between two fingers, while two fingers of the other hand apply a steady traction (Figs. 1 and 2). This procedure serves essentially to test the fragility of the

Fig. 1 Pull test. Two hands grasp a cluster of 40–50 hairs, while the other one applies a steady traction on the hair shafts

Fig. 2 Sabouraud's maneuver. Only one hand sinks into the hairs and applies a gentle traction

hair shaft. In the second procedure, once called *Sabouraud's maneuver*, the widen fingers of one hand are sunk into the hairs (if they are long enough) and apply a gentle traction. The hairs retained between the fingers are counted. In both procedures four different areas of the scalp should be tested: the right and left parietals and the frontal and occipital areas.

Normally, only telogen hairs are shed and, in the adults, their number does not exceed four to five for the whole scalp. Collecting more than eight to ten hairs suggests the diagnosis of telogen effluvium (TE). When the hands are full of hairs, the diagnosis of alopecia areata incognita (AAI) should be surmised. In androgenetic alopecia (AGA), the total hair number is in between four and ten. The presence of dystrophic hairs suggests active alopecia areata and AAI. In cicatricial alopecias and in pemphigus, some anagen hairs are extracted with their outer sheaths (Delmonte et al. 2000). In the loose anagen syndrome (LAS), many hairs are extracted and, if observed under a low magnification microscopy, lack the outer sheath and their cuticles are ruffled. To diagnose LAS at least 70 % of the hairs should show these features (Tosti and Piraccini 2002).

The pull test is a rough method and their reliability is low mainly because of the variable strength of traction, but, if performed correctly, is a good indicator of the severity of hair loss.

In physiology, the pull test performed on 60 healthy children (4–10 years old) established that the normal mean loss was 1.77 ± 1.57 (Rebora et al. 2016).

3 The Wash Test (Modified)

MWT is a simple noninvasive method, designed for the office, that permits the diagnosis and the assessment of the severity of hair loss (Rebora et al. 2005).

The method is based on the fact that in TE only terminal hairs are shed, while also miniaturized hairs or vellus hairs are lost in AGA. According to Rushton, vellus hairs are shorter than 3 cm and thinner than $40 \mu\text{m}$ (Rushton 1993). For sake of easiness, only the length of the shed hairs is measured.

After 5 days of abstention from shampooing, the patients wash and rinse their hair in a sink with the draining hole covered by a gauze and collect all hairs remaining in the gauze. The patients should not comb their hairs before or during the shampoo and should not use hair conditioner after the shampoo. The hairs shed when the patient,

after soaping and rinsing, brushes and dries the hair are not considered. The collected hairs are let dry and put in a paper envelop. The examiner counts the number of all collected hairs and the percentage of the vellus hairs. Studying the hair roots under a microscope may provide additional information, namely, the presence and the prevalence of exogen and/or dystrophic roots (Rebora et al. 2014; Quercetani et al. 2011). The latter, associated with a global number exceeding 350, is diagnostic of AAI.

Fig. 3 Modified wash test. The four different results obtained with the modified wash test. AGA, TE, AGA +TE, and normality or remitting TE. The columns indicate the total number of shed hairs; the line indicates the percentages of vellus hairs collected with the shampooing

Fig. 4 The wash test in children. The “normal” shedding as found in a group of prepubertal children of both genders

The results suggest four possible diagnoses (Fig. 3): more than 100 shed hairs with less than 10 % vellus indicates TE, less than 100 hairs with more than 10 % vellus suggests AGA, more than 100 hairs with more than 10 % vellus suggests the association of AGA+ TE, and less than 100 hairs with less than 10 % vellus reflects normality or a remitting TE. Actually, a statistical analysis suggested that the cutoff value is 91 instead of 100 (Guarrera et al. 2011).

In physiology, the wash test performed well in an attempt to establish the “normal” shedding (Rampini et al. 1999). In a group of prepubertal children of both genders, free from five alpha reductase and therefore of AGA, we were able to verify that “normally” they shed 10.68 ± 3.01 hairs, a number that steadily increases up to 11 years when puberty is approaching (Fig. 4). This finding ruled out the arbitrary figure of 100 hairs that would be allegedly shed daily in “normal” subjects.

MWT is a reliable and reproducible method. In a study of ours (Guarrera et al. 2011), the interclass correlation coefficient, which is a measure of the level of reproducibility among measures (reliability), proved to be almost perfect in a group of patients with AGA for both total hair count and vellus hairs percentage (0.96 and 0.85, respectively) and in normal and TE groups of patients for the vellus hair percentage (0.88 and 0.84, respectively). Good reliability was found in all other cases, but in the total hair count of normal subjects in which it was only moderate (0.43). In addition, sensitivity and specificity, as assessed using the receiver

operating characteristic (ROC) curves, ranged from 81 % to 100 % (p : 0.0045–0.001), except for the vellus hair percentage of TE patients in which they were low (64.3 % and 50 %, respectively) and for the total hair count of AGA patients in which sensitivity was low (50 %).

MWT has a number of advantages. First, it easily permits AGA and TE to be diagnosed precisely with a simple noninvasive and cheap procedure. Other methods, like phototrichogram or computer-aided dermoscopy, are either time-consuming or more expensive. In addition, they fail to detect dystrophic hairs whenever they are haphazardly scattered all over the scalp as in AAI. A comparison with TrichoScan[®] (Guarrera et al. 2013) revealed that MWT was better ($k = 0.32$ vs. 0.22) especially, as expected, at detecting TE. Second, it distinguishes the association AGA+TE which other methods cannot diagnose. Third, it permits to recognize people who claim to lose hairs but in fact do not. More important, it provides a quantitative assessment of the severity of both TE (the global number of the shed terminal hairs) and AGA (the percentage of vellus hairs) and to decide, in case of the association AGA+TE, which of the two disorders is the most important and should be treated first. Lastly, MWT consents patients in treatment to be followed-up and the efficacy of the treatment to be verified. If the patients with TE are instructed to count at least all shed hairs at home, they can perform the duty nicely over time providing invaluable information about the state of their disorder.

Drawbacks consist in the difficulty in convincing young patients to abstain from shampooing for 5 days, in testing people with curly hairs which entangle during shampooing yielding underestimated results and in testing young

male patients with hairs shorter than 4 cm. A possible major source of bias is the risk that the patients comb their hair immediately before washing them or that they vary each time the modality of shampooing. It is sufficient, however, to recommend to collect their shampooed hairs in the morning before any other toilet care.

1 Background

Polarized light microscopy is a contrast-enhancing technique that is designed to observe and photograph specimens that are visible primarily due to their optically anisotropic character (Weaver 2003). The technique is based on the rule of reflection and transmission which states that the angle of reflection is equal to the angle of incidence for any particular light ray irradiating a smooth, reflective surface. When the surface is irregular and a broad beam of light is used, then we get diffuse reflection. When the surface is polished and we use a narrow beam of light, then we get specular reflection, and this reflected light can be polarized (McCrone et al. 1978; Carlton 2011).

In a polarizing microscope, there are two polarizing filters known as polarizer and analyzer. Only light oscillating in one direction is allowed to pass through them. A polarizer is placed in the light path before the specimen; an analyzer is positioned in the optical pathway between the objective rear aperture and the observation tubes or camera port.

Fig. 1 Polarized light microscopy in differential diagnosis of hair shaft abnormalities. (a) This picture shows hair shaft with irregular contour, but it is difficult to differentiate if this is caused by hair shaft twist along the long axis or if this is nodosity (light microscopy, $\times 10$); (b) polarized

light microscopy shows that the hair shaft seen in picture a has few twists along the long axis, and the diagnosis in this case is pili torti ($\times 10$); (c) polarized light microscopy allows to observe details of the hair inner structures ($\times 20$)

When the vibration azimuths of both filters are positioned at right angles to each other, the polarizer and analyzer are said to be crossed, with no light passing through the system and a dark view field present in the eyepieces. When the filters are positioned perpendicularly to one another, the image contrast arose, and the specimen details can be observed on a dark background.

2 Polarized Light Microscopy in Hair Analysis

As compared to light microscopy, the examination of hair shafts under polarized light provides more varied and very bright hues to the hair inner

structures. It is a result of cortex fibrillar nature and interference phenomenon.

The main indication for polarized light microscopy is congenital and acquired hair shaft abnormalities because differentiation between nodosities, narrowings, and twist (Fig. 1a, b, c) of hair shafts or even changes in hair color is easy in this technique (Valente et al. 2006; Itin and Fistarol 2005).

The role of polarized light microscopy is crucial in the diagnosis of trichothiodystrophy (Rakowska et al. 2008). Trichothiodystrophy, or sulfur-deficient brittle hair, identifies a group of rare and complex neuroectodermal disorders with remarkable clinical heterogeneity (Morice-Picard et al. 2009). Clinical features of patients

Fig. 2 Polarized light in trichothiodystrophy. (a) Light microscopy shows hair shaft with an irregular, undulating contour ($\times 40$); (b) the same hair shaft seen in polarized light shows striking alternating bright and dark bands referred to as “tiger tail” banding. This is crucial for diagnosis of trichothiodystrophy ($\times 40$); (c) the diagnosis of trichothiodystrophy can be set if almost all hairs seen under polarized light revealed tiger tail banding ($\times 10$)

with TTD vary widely in nature and severity, and the single common feature in all patients is the fragile hair (Liang et al. 2005). With polarizing microscopy, using crossed polarizers, hair shafts show a distinctive hair feature: striking alternating bright and dark bands, often referred to as “tiger tail” banding (Fig. 2b, c) (Itin and Pittelkow 1991). Light microscopy shows hair shafts with an irregular, undulating contour (Sperling and DiGiovanna 2003). The bright and dark bands seen with polarized light correspond to the undulating orientation of the cortical fibers in TTD patients (Fig. 2a). The diagnosis of TTD cannot be made on the basis of seeing a few

hairs that appear to have alternating bright and dark bands; rather all hair should show the tiger tail pattern and all should have an undulating irregular contour (Fig. 2a, b).

The structural abnormality that causes the interrupted transverse bright lines along the hair shafts is not completely understood. An X-ray microanalysis revealed alternating content of sulfur along the long axis of the hair (Itin et al. 2001). The X-ray analysis results also showed that calcium was absent in tracts corresponding to dark bands, whereas it was normally present in light bands (Richetta et al. 2001). The amino acid analysis of the hair shows the notably low cysteine content (less than half of normal content because of major reduction in synthesis of high-sulfur matrix proteins) that parallels the low total sulfur content (Itin et al. 2001).

1 Introduction

The heterogeneous structure of the surface of hair, with its innate variability of morphology due to its biological origin, is at the base of the interaction with the external agents, from natural (UV, brushing) to cosmetic treatments (dyeing, bleaching, etc.). Consequently, the knowledge of the surface of hair (or skin and nails) is essential to develop innovative and functional cosmetic products (Zviak 1986).

The structure of the cosmetic substrate impairs its intrinsic mechanical and physicochemical properties that are manifested at the macroscale in many different ways. Hair fibers, for instance, although considered to have an exceptional resistance are affected by continuous exposure to sunlight, weathering its properties. In addition most of the cosmetic treatments try to improve or repair the intrinsic properties of hair which eventually reflects in enhanced mechanical and tribological behavior.

Hair is roughly a cylindrical fiber of ~50–100 μm diameter. The overall number of hairs covering a normal human head is comprised between 120,000–150,000, which leads to a significant surface area (typically ~6 m^2 for ~20 cm-long hairs).

In cosmetics, hairstyle, hair perception, and hair manageability depend on numerous parameters: geometry of the fibers (length, diameter, ellipticity, degree of curl), topography of the implantation, and in particular fiber-to-fiber interactions. The combinations of all these parameters result in extremely different cosmetic properties.

The cuticle forms the outer surface of hair. It has an overlapping scalelike (approximately 50 μm across by 0.5 μm thick) structure protecting the cortex and oriented from the root to the tip of the fiber to produce a series of scale edges on the outer surface of each hair. The final structure of the outermost layer of the cuticle (epicuticle) is of special interest: the surface properties of hair depend on the physicochemical properties of this layer.

The most recent findings have shown that the epicuticle membrane of hair fibers contains highly cross-linked protein ($\sim 75\%$) and fatty acids ($\sim 25\%$). Among these adsorbed fatty acids, the 18-methyleicosanoic acid (18-MEA) is the most abundant 50% w/w (Yorimoto and Naito 1994), appears to be covalently grafted on the outer surface (constitutes the outer β -layer) via covalent thioester linkages to the protein (Wertz and Downings 1988; Evans and Lanczki 1997), and is considered to play an important role in the physicochemical and tribological properties of hair.

Based on these observations, a model is used to explain the fine molecular structure of the hair surface (Negri et al. 1996) depicting a highly ordered monolayer of 18-MEA grafted to the proteins of the epicuticle that would explain the excellent tribological properties of natural hair in ambient conditions (Breakspear et al. 2005; Huson et al. 2008).

It is not clear how these various chemical regions contribute to the overall interactions (noncontact forces like van der Waals and electrostatics and in contact as friction and adhesion) between the fibers, which determine the dynamic as well as the static behavior of the hair in both water and dry states. Inter-fiber interaction is the basis of an individual's everyday perception of the state of their hair, and it is therefore not unexpected that its comprehension is of interest to the

hair care and cosmetic industry (Bouillon and Wilkinson 2005; Robbins 2001). Still, the means by which a complex multifiber system may adopt different three-dimensional shapes, or how a system of hundreds of thousands of fibers interact among each other while in motion, are questions for the physics community and go beyond a purely cosmetic interest and extend to other fields, ranging from textiles (Mizuno et al. 2006; Huang et al. 2009) to character animation in the cinema and entertainment industries (Ward et al. 2007).

The surface of hair consists of scales laid out like roof tiles. This structure results in anisotropy during interactions; hair fibers exhibit macroscopically what is known as "differential friction effect," i.e., friction is different when sliding "root to tip" versus "tip to root." The friction coefficient is higher when sliding takes place from the hair end to the root ("against the scales"). Generally, a relatively characteristic stick-slip phenomenon is also observed (LaTorre and Bhushan 2006).

Technologies like atomic force microscopy (AFM) can be of great importance for the development of cosmetic products, as well as for understanding their mode of action. These methods can provide essential information about the structure of the surface, its properties, and their evolution after an applied treatment due in particular at the possibility to interact with them locally, right at the structure of interest.

For example, by conventional AFM the properties of the outermost layers of hair, and in particular the effect of a (18-MEA), have been often studied. The presence of this layer can be easily detected by observing an increase of adhesion and friction of a SiN tip when this layer was not present (e.g., this may happen in certain pathologies or on bleached hair).

2 Crossed Fiber Atomic Force Microscopy

To have access to the interaction between fibers, we use the AFM in crossed fiber mode to measure both the forces in contact (friction and adhesion) and the noncontact forces in both air medium and

Fig. 1 A representation of the crossed human hair fiber system used in the AFM. The nominal lengths of the *upper* and *lower* hair segments are typically 60 and 500 μm , respectively. The hair diameter ranged from 53 to 94 μm

aqueous medium. These latter forces consist of the van der Waals interaction and charge interactions and in addition to providing fundamental information about the nature of the hair surface are also interactions that should be taken into account to understand and predict the behavior of any multifiber system especially in a humid or aqueous environment (Fig. 1).

The AFM cantilevers used were silicon and tipless (NSC12, MikroMasch, Estonia) with a specified normal spring constant of 0.65 N/m. Etched tungsten wires attached to a micromanipulator (Eppendorf) were used to position the glue and the fiber pieces, respectively, on an AFM cantilever under a stereomicroscope. Fig. 2a shows a scanning electron micrograph of a hair fiber which has been trimmed using a focused ion beam, FIB (Volkert and Minor 2007), to alleviate this issue. If the hair fiber on the AFM cantilever is long, then it will also bend and deform under normal and lateral forces, and there is no way of reliably obtaining the effective spring constant. Secondly the AFM cantilever actually sits at about 12° to the surface. Therefore, if the hair

protrudes too far beyond the cantilever, it may potentially strike the substrate before the hair-hair contact is made and preclude force measurement. The outer (left hand) cut is that performed with the FIB, and it is apparent that this edge is finer than the inner cut which was performed with ordinary clippers.

The experimental technique allows the separation between the two fibers to be controlled with nm resolution and both the normal force and friction between hair fibers to be determined with a resolution of nN. The crossed cylindrical geometry is equivalent to that of a sphere interacting with a flat surface.

The force and friction experiments were performed using an atomic force microscope (Nanoscope IIIa, PicoForce, Veeco) according to protocols described in an IUPAC report (Ralston et al. 2005). Briefly, each AFM experiment started by acquiring two normal force curves at a constant scan rate of 400 nm/s. Afterwards, friction measurements were run at sliding velocities varying between 4 and 20 $\mu\text{m/s}$ with scan size of 10 μm . These rates, relatively slow, represent well the random small dynamic deviations from a static equilibrium shape that occur in a hair assembly and are experimentally convenient. An initially low applied load was gradually increased to the maximum value (typically 100–120 nN) and then reduced again until the surfaces spontaneously separated. These latter experimental parameters *are* relevant for the interactions experienced by hair in daily life. The relatively large scan size was chosen to ensure that the probe would cross a cuticle edge at least once while sliding (the distance between cuticle edges is around 5 μm as can be seen in Fig. 2).

For the measurements performed in liquid, the hair fibers were exposed to each surfactant solution for approximately 15 min before force and friction measurements. The surfactant was tetradecyl trimethylammonium bromide (TTAB) ($\geq 99\%$, Sigma-Aldrich, Germany). A small amount of background electrolyte (1 mM NaCl, 99.99%, Merck, Germany) was used for the aqueous systems, which is a standard practice in surface force measurement since it limits the thickness of any electrical double layer to a

Fig. 2 (a) SEM image of the hair probe attached to a cantilever. The fiber has been truncated with an FIB to reduce overhang and minimize the effect of the fiber on the mechanical response of the FM cantilever. The FIB cut is considerably smoother than the conventional cut. In this example the “root” direction of the fiber is to the right. (b) Diagram of the crossed hair fiber system viewed from *above*. θ is the angle between tips of the two hair fiber cuts and defines the sliding angle. *Inset*: SEM image of hair probe attached to cantilever. The outer (*left-hand*) cut is that performed with the FIB and it is finer than the inner cut (*right hand*) performed with ordinary scissors

convenient experimental range and renders the fitting of the force curves much simpler (Ducker et al. 1991; Israelachvili and Adams 1978). To simplify, we refer to the solutions *not* containing surfactant as “water.”

For studying the angle dependence of friction, the lower fiber was rotated relative to the hair probe manually to achieve different relative sliding angles. Irrespective of the angle of the lower fiber to the cantilever, the movement of the lower surface was normal to the long axis of the cantilever/upper fiber (see Fig. 2b). Measurements were performed at low humidity (25–30 %) and

high humidity (70–75 %) levels, controlled by potassium chloride-saturated aqueous solution (Rockland 1960). The normal and torsional signal of the cantilever changed in response to the humid environment due to expansion of the hair arising from moisture gain (Robbins 2001). Hence experiments were not performed until after the signal had stabilized (typically 3 h).

If the shape of a probe is not perfectly cylindrical or if the probe is not precisely mounted at the center of the cantilever, the normal load applied to the probe in fact *twists* the cantilever *even in the absence of sliding*. For hair probes (which have a large diameter compared to the cantilever width), this induced torsion can be large. Thus, to be able to isolate directional effects in sliding friction and to get independent friction coefficients for the two sliding directions, we developed a method to accurately account for the asymmetry-induced twist (see reference Mizuno et al. 2010).

3 Interaction Forces Between Hair Fibers

Figure 3 shows the forces on approach and the effect of surfactant addition to the solution for the case of native hair. It is possible to observe a repulsive force at longer range from overlap of the electrical double layers (Verwey and Overbeek 1999) associated with a negative electrical charge at the surface (arising primarily from dissociation of polar proteinaceous moieties (Robbins 2001)). At shorter range, below about 15 nm, an attractive force component is observed before a final elastic/steric compression of the surfaces into a rigid compliance. This attractive component appears to be slightly too long ranged to be solely due to dispersion forces (van der Waals or Lifshitz interaction) and may also reflect the inherent hydrophobicity of the native hair caused by the palisade layer of fatty acids (see the inset in Fig. 3). A continuous, tightly packed lipid layer with the alkyl chains presented to the aqueous phase is expected to display hydrophobic behavior, and forces between such surfaces are known to be attractive

Fig. 3 Normal force curves for native hair measured in 1 mM NaCl in the presence of TTAB solutions. (\square) no surfactant, (\blacktriangle) 1 CMC, and (\circ) 10 CMC. The CMC of TTAB at 1 mM NaCl is 3.2 mM. κ^{-1} is 9.6 nm for the water, 4.7 nm for the 1 CMC solution, and 2.6 nm for the 10 CMC solution. The fitted surface potentials are -42 mV for water and $+33$ mV for 10 CMC. The surface potential

for 1 cmc is constrained to a value of $+50$ mV, and the ensuing effective radius is $1.0 \mu\text{m}$ (see text). The Debye length has been constrained to the calculated value from the solution conditions, except for the 10 cmc case where the calculation is dependent on knowledge of the degree of dissociation of the micelles

(Carambassis et al. 1998; Tyrrell and Attard 2001; Stevens et al. 2005), though the range of this force is highly variable depending on the specific surface involved, and various mechanisms have been proposed (Christenson and Claesson 2001; Meyer et al. 2006; Eriksson and Henriksson 2007). There is however broad consensus (Eriksson et al. 1989) that at short range (of the order of that observed here), this force is related to the unfavorable water structure associated with the hydrocarbon-water interface (Tyrode et al. 2005; Hore et al. 2008).

From this force data, fitting of DLVO allows determination of both a surface potential and effective surface charge. For that we need to know the local effective radius of interaction (certainly considerably smaller than the mean of the fiber radii $\sim 40 \mu\text{m}$). We used an internal reference based on the layer of surfactant that remains between the surfaces in contact (Atkin et al. 2003; Rutland and Parker 1994; Stiernstedt et al. 2005; Koopal et al. 2005). In effect, the surface potential of TTAB is well known between surfaces of well-characterized radius. Consequently the radius can be *estimated* by scaling

the *measured force* to fit the *expected double-layer interaction*. The potential of a TTAB surface has previously been obtained (Stiernstedt et al. 2005) and is expected to be of the order of $+50$ mV. In each experiment employing a different pair of hairs, the double-layer force in 1 cmc solution was scaled to fit this value and resulted in effective radii of curvature between 1.0 and $1.5 \mu\text{m}$. The surface potentials obtained from fitting the curves with DLVO theory (Chan et al. 1980) are thus -42 mV (native hair in solution), $+50$ mV at 1 cmc (constrained), and $+33$ mV at 10 cmc. The native hair surface is well known to be negatively charged, and the zeta potential of hair has been reported to be around -12 mV at pH 5.5 (Jachowicz and Berthiaume 1989). As expected zeta potential is lower because it is measured further from the charged surface (Giesbers et al. 2002) and averaged over the hair surface, rather than a local measurement at the cuticle edge. At 10 cmc the lower potential reflects the higher electrolyte concentration associated with the counterions and may well also reflect heterogeneity associated with a loss of hydrophobicity due to lipid removal.

Fig. 4 Normal force curves of bleached hair measured in 1 mM NaCl aqueous solution with corresponding DLVO fits (*solid and dashed line*). The curve is the average of ten individual measurements and normalized by the effective radius, R_{eff} . The Debye length, κ^{-1} , was 9.6 nm and was not a fitting parameter. The *solid line* is the constant charge limit and the *dashed line* is the constant potential limit. A somewhat arbitrary Hamaker constant of 5×10^{-21} J was employed based on the Hamaker constant in air ($\sim 4.4 \times$

10^{-20} J), calculated from the Lifshitz-van der Waals surface energy component of H_2O_2 treated hair fiber⁵¹. (No attractive component is visible in the interaction, and no adhesion was observed.) A surface potential of -55 mV was estimated from the DLVO fits. The *inset* is a schematic of the native hair surfaces facing each other in crossed fiber configuration. The outer surface consists predominantly of lipids, the majority of which are 18-methyleicosanoic acid (18-MEA) covalently bonded to the underlying protein

Figure 4 shows the forces in aqueous solution between two bleached hair fibers. The effect of this treatment is a reduction in the hydrophobicity of the protective outer layer which is provided by a palisade layer of lipid molecules, schematically shown in the inset (Huson et al. 2008; Breakspear et al. 2005; Jones and Rivett 1997; Swift 1999).

The double-layer potential obtained from fitting DLVO theory to the data returns a surface potential of -55 mV and surface charge $0.49 \mu\text{C}/\text{cm}^2$ which is larger than for the case of native hair shown in Fig. 3. The larger value in the case of the bleached hair is consistent with the exposure of a larger amount of charge-bearing protein, ordinarily protected by the lipid layer. In addition the attractive force of 3.1 ± 1.1 mN/m observed in the native hair case and ascribed to the more hydrophobic nature of the surface is not observed in this case.

Force measurement is rendered more difficult in air because of the formation of static charges, and the curves reflect a long-ranged attraction

characteristic of a Coulombic interaction which is illustrated in Fig. 5. This implies that after the initial contact, charge transfer occurs from one hair fiber to the other. In this case the force is negative, indicating a uniformly *attractive* force. As the solid line demonstrates, the form of the force is consistent with a Coulombic interaction. The force is so long ranged (in the Figure measured up to 800 nm long) that the cuticle height starts to influence the appearance of the force. The inset to the figure nonetheless shows that at very short separations, a steeply attractive van der Waals force takes over from the electrostatic force. Using a similar radius of $\sim 1\text{--}1.5 \mu\text{m}$ leads to a Hamaker constant for the system of 2×10^{-20} J. This value is slightly lower than that predicted from contact angles (Molina et al. 2001), but is of the right order of magnitude.

When two hair fibers interact *in vivo*, they do so in a much more humid environment which would discharge the static electricity. We note that in extremely dry conditions, where the

Fig. 5 The long-ranged attractive interaction in air. The effective radius is $1.0 \mu\text{m}$ obtained as described in text. The *solid line* fits the functional form of the Coulomb attraction to the data, and the apparent zero separation of the Coulomb interaction is offset by 250 nm to the apparent zero of separation for the force measurement. (This corresponds to about 50 % of the cuticle height.) *Inset*: the short-ranged

part of the interaction where the van der Waals interaction dominates the interaction below approximately 7 nm and the surfaces jump into contact due to a spring instability. The *solid line* in the *inset* corresponds to the theoretical van der Waals interaction assuming a Hamaker constant of $2 \times 10^{-20} \text{ J}$

humidity in the hair itself is also reduced, static electricity is commonly observed, for example, during brushing. (In this case of course, the interaction is repulsive between the hairs as the charge transfer occurs between the hair and the brush and the hairs have the same charge sign.) Opposite charging in a symmetric system is somewhat unexpected, but in fact this phenomenon is rather well documented for hair, where the heterogeneity of the surfaces renders this possible if the cuticle edges (which tend to have a higher density of polar, ionizable material) are implicated in the contact (Robbins 2001).

4 Friction of Natural Fibers: Effect of Sliding Angle

The friction force measured by AFM is obtained from the cantilever torsion and the ensuing lateral photodiode response as the hair probe slides over the lower haircut in a reciprocating way.

The friction coefficients obtained for both native and bleached hair (70 % RH) are shown

in Figs. 6 and 7. In the case of native hair (Fig. 6), there appears to be only very slight, if any, dependence of μ_{against} and μ_{along} on the sliding angle. Figure 6b shows how $\Delta\mu$ ($\mu_{\text{against}} - \mu_{\text{along}}$) varies with sliding angle; for 74 % of the measurements, $\Delta\mu$ is within the range of ± 0.05 . This indicates that while in most cases $\Delta\mu$ is positive (i.e., sliding against the cuticle direction involves higher friction), the directional effect is negligible for native hair at almost all angles. The apparent absence of directional effects, the large radius in comparison to cuticle height, means that mechanical interlock of the cuticles (the origin of directional effects) is only feasible for certain angles and conditions.

For bleached hair however, a very different behavior was observed. μ_{against} was systematically larger than μ_{along} (Fig. 7a) indicating that the directional effect and mechanical interlocking are significant with weathered hair. Furthermore, there appears to be a strong angular dependence of this effect (Fig. 7b). We thus speculate that two mechanisms are involved in this phenomenon: (a) at all sliding angles, $\Delta\mu$ is enhanced due to lifted, ragged cuticles (LaTorre and Bhushan

Fig. 6 Friction coefficient of native hair at different sliding angles at high RH (a) and difference in friction coefficients against versus along the cuticle (b). The average μ_{against} and μ_{along} are 0.11 and 0.10, respectively

2006), and (b) variation of $\Delta\mu$ with sliding angle is associated with the probability of antiparallel cuticle-cuticle interaction.

From geometrical considerations the highest probability that two cuticles both meet and interlock during sliding is at 45° and 135° , and the lowest probability is at 90° . In Figure 7b, which shows $\Delta\mu$ for bleached hair, it is possible to interpret two peaks on either side of a minimum as expected from the above treatment. The experimental maxima are found at roughly 70° and 130° and the minimum at around 100° . The angle of 130° is close to the predicted angle of the highest probability, but 70° is rather different from the

other predicted maximum for reasons that remain unclear. We can only conclude from that particular result that mechanical interlocking is not the primary cause of directional hysteresis. Damaged/lifted cuticles merely have to be involved in the sliding contact, and the extra friction sliding against the cuticle direction may well be due to deformation (“bending back”) of the cuticle. With undamaged hair the cuticle lies “flush” with the fiber so that bending back is unlikely.

Finally we reiterate that the AFM technique developed here for angular dependence measurement always provides movement at right angles to the cantilever mounted probe. Thus the movement

Fig. 7 Friction coefficient of treated hair at different sliding angles at high RH (a) and difference in friction coefficients when shearing against versus along the cuticle (b). The average μ_{against} and μ_{along} are 0.42 and 0.20, respectively, for bleached hair

is not axial with the lower fiber. This geometry is essentially a constraint of the AFM device, but in fact is more representative of the type of moving contact typically formed by two hair fibers. The antiparallel arrangement is an extremely unlikely conformation on, for example, a head of hair, but in the case of wool fibers in textiles, it is expected.

5 Conclusions

Both the contact and noncontact forces between hair fibers at nanoscale contacts, with high resolution of both the force and separation, can be

measured. The action of well-characterized cationic surfactants alters the range and magnitude of these forces. Despite the relatively complex chemical structure of hair, the novel fiber-fiber probe technique shows the interactions to depend on the following classical forces – van der Waals and Poisson-Boltzmann in liquid and Coulombic and van der Waals attraction in air.

The friction coefficient of native hair is relatively independent of sliding angle and the directional effect is not clearly observed. On the other hand, bleached hair exhibits a clear directional effect at most sliding angles due to higher surface roughness, and this is a periodic function of the

angle. This finding is related to the likely cuticle-surface or cuticle-cuticle interaction between two hair fibers, and it is clear that cuticle lifting and serration (a result of oxidative damage) is a necessary requirement for directional effects between hair fibers to be observed. The directional effect has a symmetrical distribution with sliding angle, i.e., when sliding one cuticle against the other, it does not appear to matter whether cuticles are aligned parallel or antiparallel on the counter surface. This implies that frictional hysteresis may in fact be due to deformation (bending) of single lifted cuticle edges rather than mechanical interlocking of the cuticles as has previously been surmised.

Quantitative analysis of friction at various sliding angles can now be applied to other fiber systems. This is particularly useful to understand properties of fiber assemblies whose fibers interact at various angles, for example, polyester fibers, the inter-fiber friction of which determines mechanical strength of the array. Finally this kind of information will be essential for predicting the dynamic behavior of multifiber assemblies.

1 Anatomy

The nail which grows throughout the life is a transparent, semihard, oblong tablet with a long longitudinal axis in the hands, transverse in the feet (De Berker et al. 2007).

Its upper side is smooth and glossy. The nail plate sinks at an acute angle into a large deep groove, practically parallel to the cutaneous surface, the nail cul-de-sac (or posterior or proximal groove) (Fig. 1). The lateral nail grooves complete the bezel of the nail. They are lined by the lateral folds. The visible part of the nail ends with a free edge, which owes its whitish color to the underlying presence of air. The onychodermal (onychocorneal) band presents at the distal margin of the nail bed a contrasting hue in comparison with the rest of the nail bed. Normally, this a transverse band of 1–1.5 mm of a deeper pink (Caucasian) or brown (Afro-Caribbean). Its color or presence may vary with disease or pressure which influences the vascular supply. It represents the fast barrier to penetration of materials beyond the nail plate (Sonnex et al. 1991). The nail bed's dorsal surface is characterized by longitudinal

Fig. 1 Nail diagrams

ridges, and a complementary set of ridges is also found on the underside of the nail plate (though not at its free edge), which has led to the nail plate being described as led on rails as it grows out and to the suggestion that the ridges contribute to adhesion between the nail plate and the nail bed.

The proximal nail fold (or dorsal or PNF) is an expansion of the epidermis of the dorsal aspect of the distal phalanx. Its ventral part constitutes the roof of the proximal nail groove, which covers, on approximately 0.5 cm, the thinned base of the nail that is loosely stuck to the matrix. The cuticle, which ends the fold, adheres strongly to the upper side of the plate and seals the virtual space that opens onto the nail cul-de-sac. The inner side of the lateral folds is also lined with a stratified epithelium and produces a soft keratin that does not flake off but tends to persist as a thin and rough membrane overflowing on the neighboring surface of the nail. Because of the lateral folds that it connects, the proximal nail fold provides a continuous anatomical path for the spreading of pathological processes.

The nail matrix covers the floor of the cul-de-sac and rises on the posterior quarter of the roof of the proximal nail groove, the anterior three-quarters of which constitute the eponychium. The deep side of the matrix rests on the terminal osseous phalanx and forms a crescent with posteroinferior concavity. On the big toes, both ends of the crescent are located on a plane lower than that of the fingers. This anatomical layout explains the appearance of spicules when the matrix horns are incompletely excised in the radical treatment of a growing nail. The lunula, opaque white, with an anterior arc-shaped edge, corresponds to the distal and visible portion of the matrix. Particularly noticeable on the thumbs, it may be absent or covered by the cuticle on the other fingers. The proximal portion of the matrix produces the upper third of the nail plate, its distal part the lower two-thirds.

The thickness of the nail (0.50–0.75 mm in the fingers, up to 1 mm in the toes) is proportional to the length of the matrix. As a consequence, the thickness of the tablet depends on the global

number of germinative cells. However, the thickness seems to be increased in manual workers. Usually, the thinning of the nail plate can proceed from a diminution of the length of the matrix (transverse biopsy), a matrix compression, in which case this thinning will be limited to a nail segment, a stopping or a reduction of the cellular divisions of the matrix (responsible for Beau lines).

Ahead of the lunula, the pinkish area seen by transparency corresponds to the nail bed: the absence of fatty tissue puts the mesenchyme directly in contact with the bone. Contrary to the matrix epithelium, the epithelium of the bed adheres to the ventral part of the nail plate after a surgical nail avulsion. It shows the dermal papillae of the nail bed arranged in longitudinal parallel furrows resembling corrugated iron, in transverse section. They follow the longitudinal crests of the ventral aspect of the nail plate.

The hyponychium which contains the solenohorn corresponds to the area where the nail plate loosens from the underlying tissue. A condition where forward extension of the hyponychium anchoring to the undersurface of the nail plate and obliterating the distal groove is called ventral pterygium (collagenoses, causalgia, etc.). Its horny substance accumulates physiologically in the distal groove, an arc-shaped furrow with anterior convexity. The distal groove marks the most distal boundary between the nail unit and the fingertip.

Entheses are the sites of insertion of tendons ligaments or joint capsules to bone. Entheses consist of both soft tissue (tendon ligament and their fibrocartilages) and hard tissue (calcified fibrocartilage, adjacent bone, and trabecular network) components. In many sites, the enthesis is more than simply a focal attachment joint and it is intimately associated anatomically and functionally with the synovium forming a distinct organ referred to as the synovio-entheseal complex.

The circulation of the nail apparatus is supplied by two digital arteries that course along the digits and give off branches to the distal and proximal arches.

The sensory nerves to the dorsum of the distal phalanx of the three middle fingers are derived from fine, oblique, dorsal branches of the volar collateral nerves. Longitudinal branches of the dorsal collateral nerves supply the terminal phalanx of the fifth digit and the thumb.

Histology recognizes nail matrix and nail bed that have no granular layer in contrast to the upper ventral aspect of the proximal nail fold and the hyponychium.

The functions of the nail unit are manifold. Equivalent to claws and hooves in other mammals, the nail allows one to manipulate objects, enhances the sensation of fine touch, protects the delicate tips of fingers and toes against trauma, and is used for scratching and grooming. But among its multiple functions, the nail provides counter pressure to the pulp that is essential to the tactile sensation involving the fingers and to the prevention of hypertrophy of the nail bed and the distal pulp.

Nail biting, which severely compromises the beauty of nails, is known to serve several needs, including providing a sense of relief as well as alleviating boredom (Williams et al. 2007). Finally, the nail unit is in some respects comparable to a hair follicle sectioned longitudinally and laid on its side.

2 Hardness

Excellent biophysical studies by Forslind et al. (1980) explain the hardness of the nails by the ultrastructural organization of the keratin fibrils, the main bulk of which are oriented perpendicular to the growth axes of the nail and parallel to its surface. They appear birefringent under polarized microscopy. The study of the diffraction of the nail fragments exposed to X-rays supports the concept of the fibril arrangement that provides for the torsional rigidity of the nail plate and a high breaking strength.

The keratin fibers are stabilized by the disulfur bridges of the cystine molecules and by the double

transverse and longitudinal convexity of the plate. This double curvature prevents lateral buckling. The transverse curvature is due to the shape of the terminal osseous phalanx and the existence of a dorsal strip of connective tissue, the bundles of which settle on its lateral edges. The longitudinal curvature could be due to a difference in growth rate between the cells in the nail plate and/or a pressure forming the curvature growing faster than the lower. Hardness is also due to the adherence of the cells to each other, their connection, and their typical architectural layout in two layers in the nail plate. The superficial layer is made of small cells (2.2 μm), a discretely indented cellular membrane, and regular intercellular spaces presenting ampullar dilatations between cells. The lower part is made of larger cells (5.5 μm), the cellular membrane of which has an anfractuous contour and intercellular spaces containing anchoring knots. Finally, an intracellular envelope, the marginal strip, gradually forms on the internal part of the cellular membrane. The continuous intercellular junctions (tight junctions) explain the good quality of cell interaction and the rigidity of the dorsal nail. The cellular surface is proportionally greater than the volume because the edges of the cells of the underlying layer overlap each other. As a consequence, the properties of this area, stemming from the distal part of the matrix, are more plastic than those observed in the superficial part of the tablet, which is hard and breakable. Different aggressions (e.g., detergents) will contribute to its cleavage. The cutting capacity of the plate is also a result of these two layers.

3 Nail Plate pH

The pH of the nail plate surface was around 5, with toenails having a significantly higher pH than fingernails. Immediately after hand washing, the nail surface pH increased significantly, from pH 5.1 ± 0.4 to 5.3 ± 0.5 . However, this was not sustained with time, and the pH returned to prewashing levels within 20 min. Gender had an influence on unwashed, but not washed, nail plate pH. The pH of the nail plate interior was lower than that of its surface (Murdan et al. 2011).

4 Penetration and Function as a Barrier

It seems obvious that the barrier function is of great practical interest when using medicine through the nails. Burch and Winsor (1946) used a simple gravimetric method to measure the diffusion of water through the nails postmortem and on various cutaneous areas. The rate of diffusion through the nails was similar to that observed in palms and soles.

Spruit (1971) measured out the nail loss in vapor *in vivo* by letting nitrogen pass through the tablet and measuring the water carried by the gas. There was a constant inversely proportional ratio in the nail between the vapor loss and the thickness of the nail.

Walters et al. (1983) brought forward information on the permeability coefficients in the nail for water, methanol, and ethanol *in vitro*. They also showed that the nail was less permeable to *n*-alkanols when hydrophobia was increased and that polar compounds could easily go through the nail keratin.

The penetration is increased even more when the solubility of the product in the carrier is improved, which is achieved by decreasing its pH. Baran (2000) showed that some antifungal products, in particular, could go through the nail barrier and act as transungual delivery systems. Hemidy et al. (1994) suggested a new simulation model, the sheep hoof, in order to study the topical penetration of antifungal products into hard keratin *in vitro*. A good work on drug delivery to the nail following topical application has been published (Murthy and Maibach 2013).

5 Transmission of Radiation

Nails can transmit light. In the study by Gammeltoft and Wulf (1980) nails of normal thickness transmit about 30 % of Bucky rays (12 kV) compared to 80 % of X-rays at 29 kV: Bucky therapy is therefore inefficient when pathological nails are thick, whereas 60 % of X-rays at 29 kV are likely to go through them.

Parker and Diffey (1983) showed that the nail plate acts like a sunscreen that imposes strong limits to the transmission of UVB (280–315 nm), but allows wavelengths over 330 nm only to go through. According to Baran and Juhlin (1987, 2002), 3–20 % of radiation between 313 and 500 nm pass through a normal nail, whereas their penetration through a psoriatic nail is lower than 4 %.

6 Tactile Sensibility on the Finger Nail

Tactile discrimination and threshold values over the nail plates and finger pulps were measured on 300 digits in 30 healthy subjects with a mean age of 23 years. Subjects with cosmetic nail modifications, injuries, neurological deficits, dermatological conditions, or history of upper limb surgery were excluded. Equivalence testing was conducted to look for clinical equivalence between values obtained at both sites.

The mean static 2-point discrimination, moving 2-point discrimination, and threshold value over the human nail were 6.7 mm, 2.4 mm, and 0.06 g, respectively. The corresponding values for the finger pulp were 2.4 mm, 2.2 mm, and 0.01 g, respectively. The static 2-point discrimination and threshold values were superior for the finger pulp, whereas moving 2-point discrimination values at both sites were clinically equivalent. This study suggests that tactile discrimination and threshold levels can be measured over the nail plate and that moving 2-point discrimination values are clinically equivalent to those obtained on the corresponding pulp. This highlights the importance of the nail plate in the sensory function of the fingertip. The normative data from this study may be useful in establishing the impact of nail injury and the contribution of the nail to the overall function of the hand (Seah et al. 2013).

1 Nail Plate

The metrology of the nail plate encompasses routine techniques as well as more sophisticated and even experimental ones. Often the examination of only a nail clipping may be of great interest.

1.1 Linear Nail Growth

Nail growth derives from the nail matrix and can be assessed at tissue level or macroscopically in terms of nail length, mass, or thickness (Moffitt and de Berker 2000). In Dawber's technique, (1970) a T-shaped scratch is made on the

R. Baran (✉)
Nail Disease Center, Cannes, France
e-mail: baran.r@wanadoo.fr

fungernails at a distance X (approximately 3 mm) from the proximal nail fold (PNF). After a period of approximately 1 month, the scratch will have moved and its distance to the proximal nail fold will have grown to Y. Daily nail growth is calculated as $(Y-X)/\text{number of days}$. Measurement is made with a dermoscope with integral scale. All patients are asked not to push back their cuticles during the period of the study. Toenails are estimated to grow around 1 mm/month. Orentreich et al. (1979) measured the linear nail growth in dogs by cutting a shallow groove in the proximal nail with a piece of hacksaw blade. A screw set two-pointed caliper marked the distance from the groove to the proximal skin fold of the nail. The distance between the points of the caliper was then measured to the nearest 0.1 mm with a micrometer built into a magnifying glass. Measurements at 4-week intervals were made on nails 2, 3, and 4 of the right front paw. The average outgrowth was divided by the elapsed time in weeks for the rate of linear nail growth in millimeters per week. Orentreich measured circadian and temperature effects on the linear nail growth rate in humans with a split-image range finder adapted to a trinocular microscope. With this instrumentation, measurements of nail growth were made over intervals as short as 15 min. Heikkila et al. (1996) measured nail growth by making indentations on the nail surface and then measuring the change in the volume of these grooves as they reached the free edge. There was a reduction in volume of 30–50 %, which was taken as evidence of a contribution of the nail bed to the nail plate. However, this interpretation is less believable than the possibility that the nail is losing cells from the surface, and histology of grooves in a similar study shows that this is likely to be the case (de Berker and Forslind 2004). Yaemsiri et al. (2009) recorded distance and time between the two measurements. Average fingernail growth rate was faster than that of toenails (3.47 vs. 1.62 mm/month, $P < 0.01$). Nail growth rates have increased compared with previous estimates conducted decades ago. Toenail clippings may reflect a long exposure time frame given the relatively slow growth rate.

A transverse scratch at the convex apogee of the lunula is the easiest technique and subsequent measurements are made with reference to the lunula. The introduction of magnified photographs, before and after comparison of these photographs, has increased the precisions of these methods. As the lunula is not always visible in all digits (it becomes progressively more concealed beneath the PNF in the more lateral digits) and is rarely seen in toes (to measure growth in digits with no apparent lunula), the PNF must be used as a substitute. As a measure of total matrix activity, estimation of linear nail growth could be misleading. Hamilton et al. (1955) sought to measure volume by the following equation:

$$\begin{aligned} & \text{thickness(mm)} \times \text{breadth(mm)} \\ & \times \text{length grown per day} \\ & = \text{volume.} \end{aligned}$$

In some diseases, this may alter the impression of reduced nail growth – where a nail that is thickened has a low longitudinal growth rate but is still producing the same mass of nail. For example, in yellow nail syndrome, “the nail that grows half as fast grows twice as thick” (Moffitt and de Berker 2000).

1.2 A Normal Nail Grows Out Straight

Kligman (1961) explains why a nail grows out instead of up, and this is because its base is covered by the proximal nail fold (PNF). This is wrong (Baran 1981). The so-called proof of Kligman explanting the nail matrix placed in the forearm and which grew a perpendicular pillar of keratin to the axis of the matrix explant ignores a rule empirically known in genetics: One cannot conceive a normal nail atop an anomalous ungual phalanx, because there is a “bone-dependent nail formation” (Baran and Juhlin 1986). Recent molecular and knockout studies support this theory showing that mesenchymal condensation forming the distal phalanx occurs at the time of

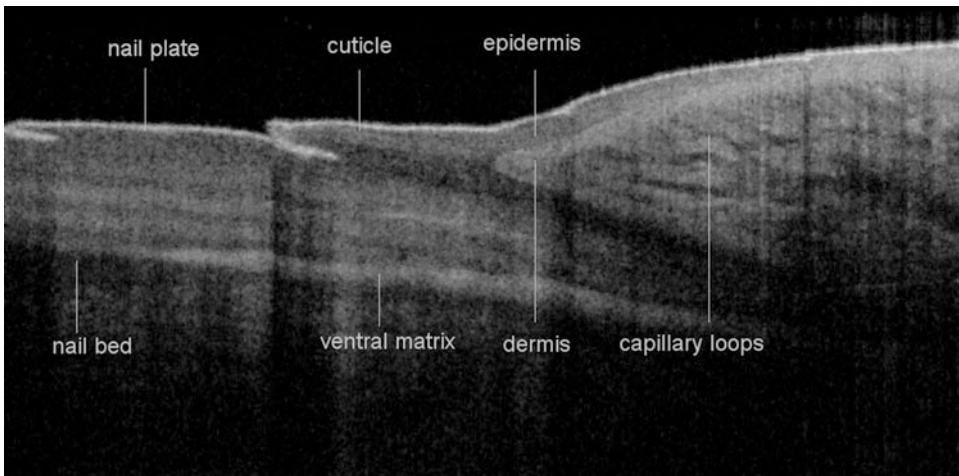

Fig. 1 Optical coherence tomography. Normal nail

the epidermal thickening and formation of the nail fold (Seitz and Hamm 2005). To provide additional support to the absence of the role of the PNF which has no effect on the direction of the nail growth, I have cut the PNF of several fingers presenting with recalcitrant chronic paronychia without any secondary change in the direction of the nail growth. Moreover Jamieson (1893) has reported on a patient with congenital aplasia of the PNF and the nail grew out instead of up. Finally, K. Hashimoto (Hashimoto et al. 1966) has clearly demonstrated that in early embryonic life, the nail was formed by the dorsal, apical, and ventral matrices and that all the matrix cells were oriented in a central-distal direction. The programmed process maintains itself throughout adult life.

1.3 Thickness

The simplest way to measure the nail thickness at its free border is to use a caliper.

Finlay et al. (Finlay 1988) used a handheld electronic micrometer (Moore and Wright Ltd, Sheffield, UK), which measures with an accuracy of ± 2 μm .

For the other parts of the nail *in vivo*, the most readily available method is the 20/25-MHz ultrasound imaging, keeping in mind that the

ultrasound speed in the nail plate is about $3,100 \text{ ms}^{-1}$ (only $1,600 \text{ ms}^{-1}$ in viable skin). Accordingly, nail thickness displayed by current skin imaging devices should be corrected.

In standard optical coherence tomography (OCT), the nail plate appears as a layered structure containing a varying number of horizontal homogenous bands of varying intensity and thickness (Fig. 1).

Polarization sensitive OCT (PS-OCT) images of the nail plate also show a layered structure. The refractive index of the nail was 1.47 ± 0.09 ; OCT and PS-OCT had low coefficients of variation, 6.31 and 6.53, respectively, compared with other methods: high-frequency ultrasound 12.70 and calipers 14.03 (Mogensen et al. 2007).

1.4 Roughness

Although the nail plate surface relief can be measured directly *in vivo*, replicas are useful, because they suppress the inevitable trembling due to heart beats and can be done in the doctor's office with further treatment in a specialized center. They may be analyzed by either computerized image analysis or optical profilometry and related techniques. Longitudinal ridges are made of small rectilinear projections extending from the PNF as far as the free edge of the nail or they may

stop short. They may be interrupted at regular intervals, giving rise to a beaded or sausages like appearance (For technical detail, see ► [Chap. 5, "Skin Color and Pigmentation,"](#) 1st ed.).

Optical profilometry has permitted a study of acquired nail beading in patients receiving intermittent itraconazole and has shown that it could be an indicator of faster nail growth (De Doncker and Piérard 1994). In addition, optical profilometry and laser techniques can quantify other nail surface alterations such as trachyonychia, pitting, and grooves (Nikkels-Tassoudji et al. 1995; Piérard and Piérard-Franchimont 1996a).

Piérard et al. (Piérard and Piérard-Franchimont 1996b) have also measured the changes in nail surface contours during 3 mg/kg per day cyclosporin A therapy, a new objective technique used to assess the efficacy of a drug.

1.5 Color

Changes in the color of the nail plate are due to changes in the bulk or at the surface of the nail or in the underlying tissues, which are then seen through the translucent nail plate. Exogenous as well as endogenous factors can affect all or part of the nail plate. The pattern of discoloration can indicate the cause: If discoloration follows the shape of the proximal nail fold and grows out with the nail, it is caused by a topical application of agents. On the contrary, if discoloration corresponds to the shape of the lunula, its origin is systemic.

Nail pigmentation can be best measured by spectrophotometry, which determines whether the discoloration originates from melanin or not (for principle and technical details, see ► [Chaps. 4, "The Skin Surface Ecosystem: A Presentation,"](#) and ► 44, ["In Vivo Magnetic Resonance Imaging of the Skin,"](#) 1st ed.). The epithelium of the matrix contains melanocytes and Langerhans cells. Melanocytes are about 200/mm² in number (about 1150/mm² in the epidermis). Most of them are dormant and do not produce pigment. However, in dark-skinned subjects longitudinal melanonychia

can be observed. Melanocytes are rare (47/mm²) or may be absent (Perrin et al. 1997).

1.6 Physical Properties of Nails

The five important nail properties include (Schoon 2005):

1. Strength, the ability to resist breaking under a heavy load
2. Hardness measuring a surface's resistance to be scratching or denting
3. Flexibility which allows a substance to bend
4. Toughness, a balance of strength and flexibility
5. Wear resistance that is the ability to resist abrasion or rubbing

Numerous authors have devised more or less complicated machines in order to measure some of these properties. However, to our knowledge, there is at present no commercially available instrument able to perform these measurements. Accordingly, technical details can be found in the quoted articles. Before doing any experiment, it must be remembered that the main factor influencing these properties is the water content of the nail.

Young et al. (1965) used nail specimens of rectangular cross-section produced by gently sanding the edges of the fingernail clippings with fine emery paper. They were tested as simply supported beams of rectangular cross-section on a span of 0.33 cm. A testing machine devoid of inertia and equipped with a strain-gage-type dynamometer was used for loading the specimen. The full scale loading range was 2 kg or less, and the speed of moving gear was 0.05 cm/min. The load was supplied through a bar having a radius of 0.013 cm.

The Knoop indenter is an instrument that measures hardness by measuring depth of indentation of a fixed load on a constant area. Knoop hardness of fingernails requires specimens suitably prepared for testing if meaningful reproducible hardness numbers are to be obtained. The purpose of

the Newman and Young study was to establish the order of magnitude of the indentation hardness of fingernails. Human nail specimens were subjected to spherical ball indentation statically. The hardness number found was 9 kg/mm² (88.3 MPa). Interferometric studies have revealed that the indents are not spherical in shape: Their central portion is either flat or slightly elevated. These studies reveal that the human nail has a tremendous capacity of recovery when deformed by mechanical operation. The relaxation time of internal stress is quite long so that recovery continues for a long period, about 1 h.

Maloney and Paquette (Maloney et al. 1977) developed and tested a miniature apparatus for measuring the physical properties of fingernails. Included were a device for cutting test specimens; a template for preparing tensile bar samples; an apparatus for performing flexural, tensile, and tearing tests; and finally a device for determining impact absorption (ballistometry). The ranges of fingernail physical properties were as follows: flexural strength, 4,928 lb/in² (33,8 kPa) to 17,653 lb/in² (122 kPa); tensile strength, 4,464 lb/in² (30,8 kPa) to 17,081 lb/in² (118 kPa); tearing resistance 274.3–672.2 lb/in (48 10³–118 10³ N/m); and impact absorption (rebound ratio) 0.4632–0.7273. Maloney and Paquette demonstrated differences related to age, sex, and digit.

Finlay et al. (1980) developed the nail flexometer to determine the effect of various materials on nail flexibility. It repeatedly flexed longitudinal nail sections up to 90° and recorded the number of bendings required to fracture each section. Immersion in water or a phospholipid-water preparation greatly increased the flexibility of untreated and lipid extracted nails; immersion in mineral oil did not. Nail flexibility was directly related to the duration of immersion in water.

In an attempt to quantify the main physical properties of nails, Baden measured (Baden 1970) the velocity of sound in nail plate, for assessing elasticity, water-binding capacity, and the rate at which water diffuses through it. Interestingly, measurement of the modulus of

nail elasticity gave values similar to those of hair and suggested that connections between cells contributed to the strength of nail tissue.

Nail exhibits viscous flow for the property of withstanding breaking and buckling, but rigidity or stiffness would be more appropriate. Measuring the effective elastic modulus of nail, they found $E = 1.21 \pm 0.07$ (SEM) GPa and stressed the importance of water content on nail physical properties.

The measurement of the physical properties of nails was addressed by Vargiolu et al. (1999) using an indentation method and the Vickers indenter (pyramidal in shape). Recording the plot of resisting force versus depth of indentation during loading (maximum applied: 0.12 N) and unloading phases made it possible to calculate nail hardness (ratio of force to imprint area) and Young's modulus E (initial tangent of the unloading phase). They found $E = 1.6, 4.7,$ and 5.6 GPa at 20 months, 27 years, and 65 years of age, respectively.

1.7 Fluorescence of Nail Under Wood's Light

Wood's light examination can be rapidly and easily performed *in vivo*. Normal nails exhibit a whitish fluorescence. A yellow fluorescence of the lunulae (Hendricks 1980) and the nails (Dopuglas 1963; Zaun and Dill-Müller 1999) has been observed in patients taking oral tetracycline and a red fluorescence when taking demethylchlortetracycline (Kierland et al. 1946).

Interestingly, quinacrine hydrochloride also results in yellow-green nail fluorescence. This technique can be helpful in distinguishing these drug-induced nail pigmentations from other causes of yellow nails.

1.8 In Vitro Nail Examination with Polarized Light

Polarized light can be helpful in the examination of the underside of nails. A light microscope

identifies the longitudinal ridge plate (Apolinar and Rowe 1980).

In true leukonychia, the nail structure under polarized light appears disrupted due to disorganization of the keratin fibrils (Baran and Achten 1969).

2 Capillaroscopy of the Proximal Nail Fold

Proximal nail fold capillaroscopy is a simple, *in vivo*, noninvasive, and reliable technique used to evaluate superficial microvascular structures (Vaudaine 2012).

The capillaroscope is composed of an optical microscope with a $\times 50$ to $\times 200$ magnification and a cold light source in order to avoid vasodilation.

The microvascular structures of the proximal nail fold and the vessels are not seen from above and have a peculiar arrangement of vascular loops parallel to the skin surface.

Skin is “prepared” with an ointment of cedar oil or liquid petrolatum in order to obtain a better transparency of the epidermal structures. Second, third, fourth, and fifth fingernails of both hands are consecutively examined.

Some authors have suggested the use of a dermoscope (or an ophthalmoscope) to perform a capillaroscopic examination of the proximal nail fold. The lower magnification permits visualization of megacapillaries but is insufficient to explore other components of the bloodstream in detail.

Useful information can be obtained by an overall examination of the vascular structures. Capillary loops physiologically have a hairpin shape and are arranged in two parallel longitudinal rows in the proximal nail fold. Usually 12–18 loops are found per millimeter. Proximally, the subpapillary veins can be observed with a disposition perpendicular to the capillary loops.

Different patterns can also be observed in places without any pathological significance: glomerular aspect, elongated and tortuous loops. Pathological changes include ramified vessels,

elongated loops, mega capillaries, parallelism disruption, and microaneurysms.

With the highest magnification, the bloodstream can be observed: a continuous stream or an intermittent one with flow stops, which irregularly occur over time.

Vasomotricity can be subjectively evaluated by detailed observation of a vascular field. It is found very active in idiopathic Raynaud phenomenon and decreased in acrocyanosis. In lupus erythematosus, vasomotricity rapidly and intensively changes over time and within the same capillary loop.

Examination of the background also yields useful information. Physiologically, the color of the background is pinkish but can be orange in cases of venous stasis. Dark epidermal pigmentation can impair the visibility of the capillaries.

A pericapillary halo can be observed in inflammatory conditions or in cases of vascular stasis.

Hazy aspects can be observed in scleroderma. Hemorrhages are observed in cases of evolutive microangiopathy. In this instance, the typical aspect of a pearl necklace permits the differential diagnosis with trauma-induced hemorrhages with a blotch aspect.

It is possible to measure capillary blood cell velocity, dynamic capillary blood pressure, and transcapillary diffusion of fluorescent tracers in human skin. Vital capillaroscopy is successfully used to study the microcirculation of human skin capillaries. Capillary videomicroscopy at the proximal nail fold in connection with a local cold exposure test is a method with clinical applicability in vasospastic disease (For details and technical information on capillaroscopy, see ► Chap. 40, “A Pharmaceutical Approach of Transcutaneous Oxygen Therapies,” 1st ed.).

3 Nail Plate and Nail Bed

3.1 Transillumination

Transillumination is useful to distinguish between intrinsic nail plate chromonychia and surface changes (Goldman 1962; Ekin et al. 1997)

Fig. 2 Normal nail sonography (Courtesy of Ximena Wortsman, Chile)

- Transillumination is the least expensive technique. The patient is taken into a dark room. It is possible to transilluminate a digit by shining a strong penlight beam upward through the pulp or to use a fiber-optic probe directed at the border adjacent to a cystic tumor, the light being directed into the dorsum of the distal interphalangeal joint.
- Transillumination is helpful in identifying the cystic nature of the lesions, especially when they are not characteristic locations or deep in the tissue. It also identifies multiple lobes when present.
- Transillumination may be used for diagnosis of subungual glomus tumors. Because it has a different color on the transillumination test, the tumor can be localized and its size easily estimated.

3.2 Digital Thermography

Digital thermography (Passareti et al. 1988) is highly sensitive in glomus tumors; it shows a light circumscribed circular zone in the digit (For technical and theoretical discussion, see ► Chap. 38, “In Vivo Confocal Microscopy in Clinical Dermatology,” 1st ed.).

3.3 Ultrasonography

Ideally, a compact linear and variable-frequency probe that works in the range of frequencies from

7 to 18 Mhz is used for performing the examination. The nail unit comprises three main areas: the nail plate, the subungual, and the paronychia tissues. The dorsal and ventral plates present a bilaminar hyperechoic structure (two parallel lines) separated by an almost virtual hypoechoic tissue (interplate space) (Fig. 2). Low-velocity arterial and venous vessels are usually detectable within the nail bed (color Doppler with spectral curve analysis) (Fig. 3). The distal insertion of the lateral bands of the extensor tendon in the distal phalanx shows a fibrillar hyperechoic pattern, typical of the tendinous structures and lastly the bony margin of the distal phalanx shows a continuous hyperechoic line following the contour of the cortex of the bone that is only interrupted by the anechogenicity of the distal interphalangeal joint space that contains a virtual amount of fluid and cartilage.

Finlay et al. (1987) measured human fingernail thickness in vivo using an adapted electronic micrometer and ultrasound transmission time was measured both distally and proximally. Distal ultrasound nail transmission time correlated well with micrometer measurements. Distal nail transmission time was 8.8 % less than proximal transmission time (See also ► Chap. 20, “Skin Friction Coefficient”).

Jemec and Gniadeska (1999) used high-frequency ultrasound to conduct longitudinal studies of psoriatic nail changes during therapy.

The exact location of a glomus tumor is easy to detect if there is discoloration of the nail.

Fig. 3 Ultrasonography with color Doppler (Courtesy of Ximena Wortsman, Chile)

However, there are cases in which the tumor is difficult to locate. Ultrasonography (US) might be useful for detecting glomus tumor before surgery. Echograms give clear echoic shadows of subungual tumors (Wortsman and Jemec 2013).

The sonographic aspect of mucoid pseudocyst includes a poorly echogenic round mass or simple thickening of the subungual space, and these features do not distinguish it from glomus tumors or angioma.

A 30-MHz frequency high-resolution B-mode was applied to normal and damaged nails, and the echograms confirmed the diagnostic value to the nail plate deformity (Hirai and Fumiiri 1995).

Ultrasonography imaging with high-frequency transducers is useful in both the diagnosis and the preoperative three-dimensional localization of glomus tumors. The diagnosis should be made on the combination of as appropriate clinical setting and the demonstration of a local, hypoechoic mass.

Differential sonographic diagnosis should include implantation, mucoid pseudocyst, and angiomas. Hematomas beneath the nail plate may be particularly misleading.

The sensitivity of this investigative method depends on the instrument used and on the experience of the operator. Limitations of detection with ultrasonography are related to the resolution of the sonographic transducer. Commercially

available devices, working at 20 MHz, use an aqueous gel as a coupling milieu between probe and skin. This may hydrate the nail and make it swell. Accordingly, any examination should be of very short duration if aimed at dimensional or structural investigation. On the other hand, the nail thickness is calculated from the time the US beam goes down and returns, and current devices are set to the US speed in viable tissue ($=1,600 \text{ m s}^{-1}$), whereas it is much higher in nails ($=3,100 \text{ m s}^{-1}$ in dorsal nail and $=2,100 \text{ m s}^{-1}$ in ventral nail). Therefore, a correct ultrasound measurement of nail thickness must take this into account; otherwise the nail would be found erroneously thin.

The specificity of sonography is low, so its diagnostic value is limited. However, it should be used as a first choice, because it is inexpensive and provides the possibility of defining the lesion in nearly 50 % of cases.

US and clinical findings show good correlation for the assessment of the nail in psoriatic disease. The demonstration of subungual extensor tendon enthesopathy in both psoriasis and psoriatic arthritis (PsA) supports the importance of enthesopathy in nail disease pathogenesis whether or not clinical arthritis is present (Aydin et al. 2012). In addition, Aydin et al. (2013a) used ultrasonography with power Doppler to test the hypothesis that subclinical enthesopathy in

PsA was associated with an inflammatory or vascular phenotype compared to that seen in psoriasis. Their study shows that the ultrasound appearances of subclinical enthesitis in psoriasis differ from the subclinical enthesitis in PsA, with PsA patients having more power Doppler. This is suggestive of a more inflammatory or vascular process in PsA and offers potentially novel insights into the progression from skin to joint disease in psoriasis.

3.4 Optical Coherence Tomography

Optical coherence tomography (OCT) is an optical analogue of US, using infrared light instead of acoustic waves. The reflection of the light waves (Piérard 1993; Corcuff and Levêque 1993; Kaufman et al. 1995; Hongcharu et al. 2000) from the tissue is measured and processed in order to improve the signal-to-noise ratio and transfer to a computer generating an OCT image. The axial resolution is determined by the bandwidth of the light source, which is 1–2 mm in general, limiting its use to very superficial tissues.

It has also been widely investigated in dermatology, particularly in nonmelanoma skin cancers. For nail disease, it was suggested to be useful as a diagnostic tool in onychomycosis. Additionally, comparison of high-resolution US and OCT indicated the benefits of OCT such as a better ability to differentiate morphological details and nail thickness. OCT may be regarded as an optical analogue of US providing of better resolution but inferior penetration (Fig. 1).

OCT is compatible with both physical findings and with US in patients with symptomatic nail disease in psoriasis. Surprisingly, the diffuse nail dystrophy shown on clinical photographs was associated with a relative normality of superficial nail but OCT abnormalities at the nail plate anchorage to the underlying skin. The validation of the use of OCT in measuring the thickness of the nail plate in comparison to US has already been demonstrated. This suggests that OCT may have the potential to provide quantitative data regarding psoriatic nails and may be a more accurate and

objective outcome measure, potentially suitable as a surrogate outcome measure in interventional trials. OCT detected subtle abnormalities in 12 clinically normal nails and in 41 nails with normal US findings (Aydin et al. 2013b).

3.5 Reflectance Confocal Microscopy

Reflectance confocal microscopy (RCM) is an emerging technique which, by a real-time confocal microscope, uses reflected light to optically section living tissue at various depths, to examine and image layers of the nail unit without stains in vivo (Cinotti et al. 2014). Due to the fact that both the light and the microscope objective are focused at the same specific focal plane, objects and structures above and below this plane do not interfere with the formed image. RCM gives horizontal images of the analyzed tissue with resolution at a cellular level and without alteration of the tissue surface. Skin and nails are ideal locations to be explored by RCM because they are easily accessible sites. The depth to which the confocal microscope can optically penetrate is limited by the light penetration into the tissue and by the reflectivity of the observed structures and corresponds to 200–300 µm for skin tissue.

The unique properties of RCM make it possible to explore the capillary nailfold and the nails extending to the deeper layers of the nail plate and nail bed.

RCM is able to display single corneocytes and the integrity of their borders. The nail plate can be scanned from the surface to the lower part adjacent to the underlying nail bed. Three different layers can be differentiated by RCM, according to the intensity of the reflection. The superficial layer shows a brighter reflection, followed by a zone with a poorer signal, followed again by a brighter zone in the deepest part.

Two main applications interest the dermatologist:

1. Confocal microscopy and onychomycosis

Hongcharu et al. (2000) first reported the possible application of in vivo RCM for the

diagnosis of onychomycosis. RCM produces high-resolution images and has the great advantage of being noninvasive. Nails can therefore be imaged in their native state at high resolution and contrast without fixing, sectioning, or staining. Hongcharu et al. correlated RCM findings with the results from routine KOH preparations. RCM is faster and more accurate than the conventional microscope used with KOH preparations in the diagnosis of onychomycosis.

As attempts to document fungal infection by KOH preparations and fungal culture are sometimes unsatisfactory, RCM is an additional tool that can be used in these cases.

2. Confocal microscopy and melanonychia

Recent studies showed that the proximal nail fold could be reclined during nail biopsy procedure in order to better visualize nail matrix pigmentation and to perform intraoperative dermoscopy and RCM.

In most cases, the images obtained both by *ex vivo* and *in vivo* RCM were reliable enough to make the diagnosis and the slight loss of quality, sometimes observed *in vivo* because of subtle movements, did not have any impact on the diagnostic value of the observed features. Intraoperative RCM revealed sufficiently atypical cytological and architectural features to accurately suggest the correct final diagnosis of melanoma. A good correlation between RCM and histopathology was found: Subungual melanoma was diagnosed intraoperatively in seven out of eight cases that proved to be melanomas by histological examination (Debarbieux et al. 2012).

The authors suggest that RCM is a promising tool for the intraoperative diagnosis of melanonychia because it combines the advantages of dermoscopy (noninvasive examination of the whole interested area without alteration of the epithelial surface) and histopathology (resolution at a cellular level). RCM offers a good contrast between melanocytes and adjacent structures. It permits the visualization of architectural and cytological features of the melanocytic proliferation. *Ex vivo* examination can be used either alone or as a

complementary technique if the data provided by *in vivo* examination are not diagnostic.

3.6 In Vitro Dual Flow Cytometry

Dual flow cytometry after labeling fungal proteins with fluorescein isothiocyanate (FITC, Sigma Chemical Company) and fungal DNA with propidium iodide (PI, Sigma Chemical Company) was performed by Arrese et al. (1995) following a variant of Miller and Quarles' method. This technique was found between culture data, revealing a single fungus and positivity of fungal filaments with monoclonal antibodies. The dual dye combination of FITC and PI yielded strong detectable fluorescence of fungi.

3.7 Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an effective method of locating tumors, particularly where there is diagnostic difficulty. It can be used in a range of periungual neoplasms, although it is most useful when the tumor contrasts with surrounding tissues with respect to density, fluid, or fat content (Drape et al. 1995; Goettmann et al. 1994).

The most marked example of this is with mucoid cysts, but even normal soft tissues can be differentiated and an *in vivo* anatomical assessment made using MRI. This can be a useful means of identifying the inflammatory changes of psoriatic arthritis where it has consequences for the soft tissue element of the nail unit and consequently affects nail growth and appearance and remains the gold standard for glomus tumors of the nail unit.

MRI detects tumors only 1 mm wide; defines their tissue characteristics; determines their site, which facilitates surgical management.

T₁-weighted sequence allows morphological evaluation of lesional contour and anatomical extension.

T₂-weighted sequence defines tissue characterization from signal intensity emitted by the tumor.

Gadolinium assesses the vascularization of the tumors and may highlight the lesional contours.

The signals obtained in the various sequences are characteristic and can differentiate the most common tumors encountered in the nail region.

Drapé et al. have shown that high-resolution sagittal magnetic resonance images depict an oval area in the dermis beneath the nail matrix that gives a particular signal. This study defines the MRI characteristics of this area and examines its correlation with the lunula. A high-resolution surface gradient coil, especially designed for skin imaging was used on a 1.5 T magnetic resonance unit. The subnail matrix (SNM) areas of 12 subjects had a significantly longer T2 relaxation time and a higher enhancement ratio after injection of gadolinium than did the nail bed dermis. The length of the SNM area distal to the free edge of the proximal nail fold was highly correlated with the length of the lunula ($R = 0.98$) in 30 fingers and 10 toes. The total length of the SNM area was somewhat correlated with the nail thickness ($R = 0.86$) in 30 fingers. The histology and microvascularization of the subungual tissue in 21 fingers showed that this SNM area had specific features: The area was composed of loose connective tissue without bundles, and the reticular and subdermal vascular networks had large regular meshes in this oval area. The lunula is shown to be linked to a well-defined area in the underlying dermis with a specific histology and microvascularization (Drapé et al. 1996).

3.8 Synchrotron X-ray Microdiffraction Structure of Human Nail

Three layers from the outer to the inner side of the human nail were observed by synchrotron X-ray microdiffraction. These are associated with the histological dorsal, intermediate, and ventral plates. The hair-like type α -keratin filaments are only present in the intermediate layer and are perfectly oriented perpendicularly to the growth axis in the nail plate. Keratin filaments of stratum corneum type, found in the dorsal and ventral cells, are oriented in two privileged directions: parallel and perpendicular to the growth axis. This “sandwich” structure in the corneocytes and the strong intercellular junctions gives the nail

high mechanical rigidity and hardness. Lipid bilayers parallel to the nail surface fill certain ampullar dilations of the dorsal plate and intercellular spaces in the ventral plate. The use of X-ray microdiffraction shows that onychomycosis disrupts the keratin structure, probably during the synthesis phase (Garson et al. 2000).

3.9 Tribological Characteristics of the Nail Surface

Abrasion, micro-induction, and sclerometry are used to investigate the reactions of the nail surface. In particular, sclerometry simulates, by a scraping technique, the effects of wear and tear on its surface. This later leads to deformities of the surface and to an appreciable removal of material. These insults produce deterioration in the morphological, mechanical, and optical properties and, thereby, the loss of the principal functions of the nail (Vargiolu et al. 1999). Simulation of the worn nail by abrasion or sclerometry facilitates the study of wear, which is the prime target of cosmetic application such as nail hardeners and surface striae and nail varnishes (resistance to wear).

3.10 Bone Scintigraphy

The value of bone scintigraphy in refining the diagnostic accuracy of enthesoarticular involvement was demonstrated in a study of patients with early psoriatic arthropathy (Namey and Rosenthal 1976).

High-resolution [^{18}F] fluoride positron emission tomography of the distal interphalangeal joint in psoriatic arthritis is an exploratory study suggesting diffuse increased bone metabolism involving the entire distal phalanx periosteum and entheses (Tan et al. 2013).

4 Nail Clipping

Nail Clipping is a common procedure used in forensic analysis. However, it has been used to evaluate titanium which has been found in

patients affected by yellow nail syndrome and leading to the removal of dental implants followed by the cure of this condition (Berglund and Carlmark 2011).

1 Part I: Nail Growth Evaluation

Nail evaluations have been documented in the literature as early as 1684. However, the modern-day measuring technique dates back to 1939 by Gilchrist and Buxton in their pivotal study of nail growth. They utilized a fixed groove in the nail compared to another reference point and then measured the change over a set period of time. Subsequent studies remained similar to this original technique, although with some modifications to reference points and use of magnification and photography to increase accuracy. Figure 1 shows the reference points commonly used in nail measurements.

Robert Boyle, a physicist, was given credit for being the first to publish on nail growth in his paper that appeared in 1684 (Boyle 1684; Heller 1927). In 1871, Weir Mitchell published on the transverse serrations and the slow growth of the nails on the paralyzed hand of a 56-year-old woman under his care for a stroke. He then had the idea to stain the nails with nitric acid in men with hemiplegia to study the growth of their nails (Fritsch 1981). Nail growth has been quantitated in the literature as early as 1929, when Halban and Spitzer measured it by the distance a stain on the nail advanced from the cuticle (Halban 1928). In

Fig. 1 Reference points for nail growth measurements

1930, Voit quantitated nail growth by measuring the weight of fingernail and toenail clippings of three subjects (Voit 1930). In 1937, Basler published on using a special “biomicrometer” to measure nail growth hourly. He measured the progression of a distance between two brass strips, one cemented to the nail and the other cemented to the skin and overlapping the nail. He also used a microscope to increase the accuracy of these measurements, but commented that this was difficult due to slight movements of the finger (Basler 1937).

The modern-day measuring technique dates back to 1939, when Gilchrist and Buxton studied nail growth in undergraduates and elementary school children in Oxford. Over the years, this method has been modified, but still remains similar to the original method described. These methods utilize an imprint of a fixed reference mark on the nail and then measuring the change in position compared to a fixed structure separate from the nail after a certain time period. Gilchrist and Buxton made a transverse scratch with a small file, described as that used for opening glass ampules, approximately 2 mm from the central point of the most distal margin of the lunula. Measurements were made with a magnifier fitted with a micrometer scale, and they were able to make measurements as small as 0.1 mm. They recorded measurements approximately once per month as the transverse scratch moved distally and thus calculated the daily growth rate of the nail. They commented that the margin of the lunula as a landmark was sharp enough for the

thumb, the index, and middle fingernails, but the ring and fifth fingers were not as distinct. They also noted that the lunula might not be visible in all people, making measurements impossible. They advised that if the eponychium was obscuring the lunula, Vaseline could be rubbed over the nail (Gilchrist and Dudley Buxton 1939). While using the lunula as a fixed point has been used in many large-scale studies, one shortcoming of this reference point is that it may be blurred when using high magnification (Dawber and Baran 1987).

In 1953, Bean published on a 10-year study of the growth of his left thumbnail. He commented in this paper, referring to the previous work on the subject, that nail measurements could be made in three different ways: first, marking the nail with an indelible stain such as nitric acid; second, scoring the nail with a sharp instrument; and third, weighing or measuring clippings from the nail. He chose to make a transverse marking on the nail plate on the first of the month where the nail emerged from the cuticle and repeated this process every month. He then recorded the number of days needed for this mark to grow from this reference point to the site of separation of the nail plate from its bed. To make this mark, he first used a razor blade and later used a sharp file commonly employed to open small glass vials, as Gilchrist and Buxton described. The linear growth rate was then recalculated each year and assigned to the starting month. This technique gave average growth rates over periods of approximately 120 days. Therefore, it was appropriate for studies

lasting a few months, but not appropriate for measuring growth over periods of less than a month. It should be noted that the disadvantages of using the cuticle as reference point are that it may be damaged due to hydration, dehydration, friction, and manicuring. Furthermore, it may be hard to see or even absent in some individuals (Dawber and Baran 1987). He also showed that weights of fingernail clippings are subject to large errors because of wearing away of the nail. In addition, weight measurements are not considered accurate for short-term measurements of nail growth because it may take 5 months for changes in thickness to grow out to the point that they can be measured (Bean 1953).

Slight variations have been made to the original method described by Gilchrist and Buxton. In 1955, Hillman, like the previous authors, made the transverse mark at the convex margin of the lunula and made measurements using the lunula as a reference point. However, to increase the accuracy of the measurements, he also employed electrocardiogram-type calipers and a blocked steel ruler. He made measurements every 2–8 weeks, with an average interval of 46 days (Hillman 1955).

Later, Babcock improved nail growth measurements by taking magnified photographs over time and comparing the photographs. This allowed for optical enlargement of the distance to be measured, as well as the ability to thoroughly analyze permanent records at a later point in time. The author also commented on the difficulty of choosing a reference point for the measurements. He stated that the cuticle should not be used because it can easily be manipulated and moved. He said the same was true of the point of separation of the nail plate from its bed. He also believed that the lunula was not a good choice because as noted previously, it may not be visible on all digits. In addition, the lunula is not sharp when magnified and is blurred on photographs. Due to the shortcomings of the previous methods, he tested three reference points, namely, the phalanx bone, the skin near the nail, and the lunula. His methods were innovative, but would not pass the institutional review boards of today. He marked the nail with a deep scratch, which was then filled with

bismuth amalgam. This made it radiopaque and allowed comparison with the underlying bony reference points on x-ray. A follow-up x-ray, after refilling the scratch with amalgam, allowed growth estimation. He also took enlarged photographs ($6.4\times$) on the same day and took an average of five individual readings made with calipers. He concluded that using the lunula as a reference point along with positive transparencies was more precise for measuring growth of nails than lunula photograph or skin photograph methods. He concluded that there was no significant difference between the rate of nail growth measured by x-ray and photographs, the latter being easier to perform (Babcock 1955). This technique was modified only slightly by Sibinga who used a different optical system to magnify the photographs as high as 35-fold. This made it possible to measure nail growth daily and conduct studies of nail growth over a period as short as a month (Sibinga 1959).

In 1958, Geoghegan et al. published on nail growth in 49 naval personnel. The authors made a transverse mark at the margin of the lunula of the first and third fingernails of each hand and made weekly measurements over 2–6-week periods. They used a Beck Luminex magnifier with a scale calibrated to tenths of a millimeter (Geoghegan et al. 1958).

Four years later, Morton used a modified form of Babcock's technique to measure nail growth. He drilled small index holes (0.0135 in.) into the thumbnail using a twist drill in a thumb chuck. The holes were superficial and did not penetrate through the nail plate. These holes were then filled with black wax. The lens used to photograph the nails was $2.5\times$ and the resulting negatives were then enlarged to a total magnification of $10\times$. Skin creases were used as reference points. The nails were photographed once per week for a total of 12 weeks. Because Morton concluded that his technique was not sufficient to study the effects of therapy on onychomycosis, he performed a 5-month study using time-lapse cinematography. He required the patient to come to the hospital twice daily, every day, including holidays and weekends for 5 months. He used a plaster cast of the patient's hand for standardization and a

micrometer cursor that coincided with the spacing of two small holes drilled into the nail (Morton 1962).

In 1963, Bean published a 20-year study of his own nail growth, which was a continuation of his previous studies. He modified his original technique from the 10-year study with a tattoo on the proximal nail fold adjacent to the cuticle as a reference point. He tattooed his skin to make a permanent reference mark in the case that his cuticle advanced or receded (Bean 1963). He also started to use magnified photographs. He used the same technique as he continued the study as a 25-year study of his left thumbnail (Bean 1968).

In 1970, Dawber modified the original method used by Gilchrist and Buxton by using a different reference point (Dawber 1970a). He made a T-shaped scratch 3 mm from the cuticle and measured the change after a period of 27–35 days (mean 32 days) using the cuticle as the reference point. Measurements were made with an 8× magnifier calibrated with a linear scale accurate to 0.1 mm. All patients were asked to avoid pushing back their cuticles during the study. Measurement from the base of the nail to the lunula in the midline of the nail was made on the thumbs of all patients with visible lunulas.

In Bean's 30-year nail study, he continued to use a small file to make a transverse groove in the nail just at the edge of the free margin of the cuticle. He added to the measuring techniques he mentioned in his previous papers that the nail could be marked with the juice from the walnut hull or little holes could be punched or drilled into the nail. He also noted that during certain phases of the study, he took detailed photographs of the nail, in order to take measurements of the nail over short periods of time. The camera was fixed on a rack and the thumb was inserted into a wooden frame to make more precise measurements (Bean 1974).

Orentreich et al., in 1979, studied the effect of aging on linear growth. The authors used a glass slide to make a transverse groove just distal to the lunula of the nail plate. They used a glass reticule calibrated to 0.1 mm intervals, built into a magnifying glass, to measure the distances from the

transverse groove proximally to the distal edge of the hyponychium and from the transverse groove distally to the distal emergence of the nail plate from the nail bed. To obtain linear growth in mm per week, these two measurements were obtained at set intervals, and their average was divided by time elapsed in weeks. To make measurements in intervals as short as 15 min, they used a split-image range finder adapted to a trinocular microscope and could make measurements with an accuracy of 0.01 μm (Orentreich et al. 1979).

In Bean's 35-year study of nail growth, published in 1980, he noted that nail polish could also be used to mark the nail, but he still preferred to use a file to make a transverse groove in the nail because it was the most simple. He continued to use the same technique of making an indentation on the first of the month and measuring until the mark advanced to the free margin of the nail (Bean 1980).

A summary of nail growth measurement methods by date and with modifications is shown in Table 1. Figure 2 shows a schematic of the techniques commonly used to measure nail growth.

Nail growth measurements can also be utilized to determine drug effectiveness in onychomycosis with several variations from the methods described above. This is based upon the concept that antifungal drugs act clinically as barriers to the invasion of the fungus toward the proximal nail plate and that a normal nail plate should be produced after an effective dose of the antifungal medication is given. In addition, the nail grows out distally; however, the fungus grows in the opposite direction to nail growth. In one study, the authors marked the nail plate superficially with a scalpel parallel to the onychomycotic border, in the midline of the nail. The groove was filled with ink and distance measured from this point to the proximal nail fold. The barrier effect of the medication was then measured at monthly intervals. If the dose of the medication is effective, then the onychomycotic area will not invade proximal to the mark, and the amount of new nail plate will be reflective of normal nail plate production. If, however, the onychomycotic area invades

Table 1 Summary of nail growth measurement methods

Authors	Reference point	Notes
Gilchrist and Buxton (1939)	2 mm from distal point of lunula	Lunula not clear in 4th and 5th fingers, blurred with magnification
Bean (1953)	Cuticle	Cuticle may be damaged due to hydration, dehydration, friction, and manicuring. May be hard to see or absent in some individuals
Hillman (1955)	Convex margin of lunula	Used calipers to increase accuracy
Babcock (1955)	Lunula	Magnified photographs 6.4×
Sibinga (1959)	Lunula	Magnified photographs 35×

Dawber method, 1970

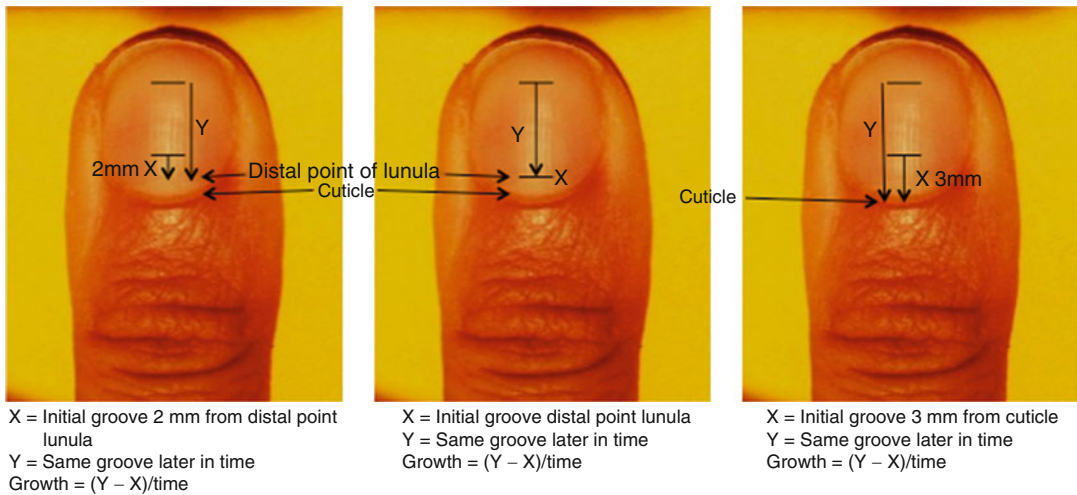

Fig. 2 Schematic for commonly used nail growth measurements

proximal to the transverse groove, then the medication is not effective at that dose. A new transverse groove can be made and evaluated monthly as the dose of the medication is increased (Zaias and Drachman 1983).

In 2002, Sawhney published a study on the effect of high altitude on nail growth, involving 22 healthy highlander troops and 6 lowlander troops. He employed the method described previously by Dawber, as he made a T-shaped cut on

the nail plate of the right index finger in each subject with a blade, 3–4 mm away from the proximal nail fold. The baseline reading and the subsequent reading after 2–3 months were taken using a vernier caliper and the proximal nail fold as reference point (Sawhney 2002).

Some authors overcame the concern over variation in the non-nail plate reference point by using two reference points. This has been performed by making a scratch or a mark with a

CO₂ laser at the uppermost midpoint of the lunula and measuring the distance to the distal limit of the nail plate attachment, visible through the nail plate. Subsequent measurements are made from both the lunula and the edge of nail plate attachment. Their sum should always be equal as a way of verifying the method (Yu et al. 2004).

In 2010, Yaemsiri et al. published a study on the growth rate of fingernails and toenails in healthy American young adults. This study differed from previous studies in that measurements were made without the aid of photographs or magnification and were done by the patients. Twenty-two subjects marked their nails adjacent to the proximal nail fold with the 4-1/2 in. sapphire nail file provided. They recorded the date and the distance from the proximal nail fold to the mark using a 6-in. stainless steel ruler provided. One to 3 months later, participants repeated this measurement. Nail growth rate was calculated based on recorded distance and time between the two measurements. The standard error using this technique ranged from 0.07 to 0.12 mm per month (Yaemsiri et al. 2010).

Optical profilometry has been cited as an alternative way to study nail growth. This technique utilizes surface imaging of the nail to measure nail surface irregularities and does not require using marks or scratches on the nail plate. This technique has been reported by De Doncker and Piérard in a study of nail growth during itraconazole therapy. Nail beading was correlated with faster matrix turnover. It should be noted that only nail clippings and not entire in vivo nail plates were assessed (Doncker and Pierard 1994).

While the methods described all involve measurement of linear growth, Hamilton et al. attempted to measure volumetric growth using the equation, volume = thickness (mm) · breadth (mm) · length grown per day (mm). The authors measured thickness of the nail using micrometer calipers in the midline of clippings from the free edge of the nail. They specifically used the proximal portion of the clippings rather than the distal portion was since the latter is known to undergo crumbling or wearing away (Bean 1953). They repeated this measurement in three places, namely, the midline, the lateral edge,

and the midway between the midline and the lateral edge. They noted that no significant error was introduced if the measurement was 1.0 mm from the midline in children or 3.0 mm in adults. They also noted that both humidity and dryness did not affect measurements of thickness. The calipers were fitted with a release mechanism to prevent compression of the nail. Prior to measurement, magnification of 5× was used and debris was scraped from the undersurface of the clippings using a sharp razor blade. Needlepoint calipers were used to measure the greatest breadth of the nail in the subjects. The authors noted that due to the mediolateral curvature of the nail, this value did not represent the true width of the nail. To measure length, they made an incision on the surface of the nail plate and recorded the distance it moved over a period of 6 weeks. They magnified the nail 2× and used needlepoint calipers. They used the cuticle as the reference point (Hamilton et al. 1955).

In an attempt to determine whether only the nail matrix forms the nail plate or whether there is also a contribution of the nail bed, Johnson et al. measured volumetric growth with respect to linear growth, irrespective of time. The authors used cadaveric avulsed nails and measured the thickness at three different points in the nail using either screw-gauge micrometer or vernier calipers. They calculated the thickness of each sample from the mean of three measurements. They also calculated the mass in three parts of the nail plate by calculating the surface area of each sample by tracing onto paper, weighing it on a balance, and then calculating mass as dry weight/unit area (Johnson et al. 1991).

2 Part II: Factors Affecting Nail Growth

2.1 Introduction

The nail unit is metabolically and mitotically active throughout life. The germinative layers of the nail matrix undergo DNA synthesis, divide, and differentiate to produce the nail plate without a quiescent phase. Normal growth arises from the

germinative nail matrix with a small contribution from its nail bed and proceeds linearly (Hillman 1955; Johnson et al. 1991; Baran 1981; Fleckman 1997; De Berker et al. 1996). Nail growth rates in the literature vary within a small range, and the average growth rate is 3 mm per month for fingernails and 1 mm per month for toenails (Hillman 1955; Geyer et al. 2004). Therefore, it typically takes 4–6 months for a fingernail to completely grow out and between 12 and 18 months for a toenail to completely grow out (Cohen and Scher 1992). A recent publication found a growth rate of 3.47 mm/month for fingernails and 1.62 mm/month for toenails in healthy young adults. The authors concluded that the longitudinal growth has increased over time. However, it should be noted that in this study, the subjects, rather than the physicians, took the measurements so the data may not be directly comparable to earlier studies (Yaemsiri et al. 2010).

The proliferative capacity of the nail matrix cells determines the nail growth rate. However the longitudinal growth rate can be affected by physiology, the environment, certain disease states, trauma, and treatments as shown in Table 2. It should be noted that detailed growth kinetics have been performed for some, but not all of these factors and variables. Some of the published work is based upon observations in one patient or small case series. In addition, some of the studies have shown conflicting data, which is indicated in the table and elaborated on in the text. The effect of these variables on nail growth is medically important, because some factors can be modified and medications prescribed to change the rate of nail growth. While altering the rate of nail growth by itself may not cure an abnormal nail, when used as an adjunct with other treatments, it may provide a more rapid and complete cure (Geyer et al. 2004). For instance, by decreasing the nail growth rate of psoriatic nails, which grow faster than normal, may lead to improvement in the abnormal nails in combination with psoriasis treatments (Dawber 1970b; Farber and Nall 1992). On the other hand, to treat nails affected by onychomycosis, which may grow more slowly than normal (Elewski 1998; Cohen et al. 1982; Tosti and Piraccini 2003), augmenting longitudinal nail growth in

combination with antifungal drugs may lead to a better cure rate (Evans 2001; Baran and Hay 2001).

2.2 Physiology and Nail Growth

A decrease in nail growth with age was first suggested by Voit, who studied the nails of three subjects of different ages (Voit 1930). Bean studied his left thumbnail over a period of 35 years and observed a small but consistent decrease in nail growth rate as he became older. Notably, when he started the study at age 32, the nail growth rate was 3.69 mm per month, and at the end of the study at age 67, his nail growth rate was 2.85 mm/month (Bean 1953, 1963, 1968, 1974, 1980). Hillman and Hamilton et al. both confirmed the finding of decreased nail growth with age (Hillman 1955; Hamilton et al. 1955). Dawber found a decrease in nail growth with age both in normal subjects and in those with nail psoriasis (Dawber 1970a). It should be noted that Clark and Buxton and Gilchrist and Buxton in two different studies did not observe a variation in fingernail growth with age; however, they had a narrow span of younger years represented in their studies (Gilchrist and Dudley Buxton 1939; LeGros Clark and Buxton 1938). In addition, Edwards and Schott saw no effect of age on the growth of toenails (Edwards and Schott 1937).

The data on the difference in nail growth rates between men and women is controversial, but most studies have found that there is no statistically significant difference in rates between the sexes. For example, Clark and Buxton and Gilchrist and Buxton in two different reports did not observe any variation in nail growth with sex (Gilchrist and Dudley Buxton 1939; LeGros Clark and Buxton 1938). Similar results were seen by both Voit and Head and Sherren (Voit 1930; Head and Sherren 1908). In addition, Hamilton et al. found that nails in males grew faster than nails in females only in the 15–19-year-old age group. In other age groups, the results were not statistically significant (Hamilton et al. 1955). Dawber also did not observe any statistical significant difference in nail growth between men and

Table 2 Factors influencing longitudinal nail growth rates

Faster	Slower	No change	Notes
Physiology			
Younger individuals	Older individuals		A small number of conflicting studies show no difference
		Men and women	One conflicting report
Pregnancy	Postpartum	Maternal weight at conception, maternal weight gain during pregnancy, parity, duration of gestation, length of labor, maternal smoking habits	
		Birth order, age of mother at time of birth	
		Puberty	
		Within family	
Third fingernail	1st and 5th fingernails		Nutrition – conflicting reports, no consensus
			Right hand, left hand, handedness – conflicting reports, no consensus
		Height, weight	
		Nail thickness	
Nail plate length			
Environment			
Day	Night		Season, weather – conflicting results, no consensus
Trauma			
Nail biting			
Nail avulsion			
		Smoking Moderate stress	
	Paralysis, immobilization in splint or cast		Reversed with regaining of function in limb, massage
Disease states and nail conditions			
	Acute severe illnesses	Acute minor illnesses	Some conflicting data
A-V shunts	Cardiovascular disease		
Increased circulation	Decreased circulation		
Hyperthyroidism	Hypothyroidism		
		Family history cancer, hypertension, coronary artery disease, diabetes mellitus

women (Dawber 1970a). Hillman, on the other hand, found in his study that the mean nail growth rate for men was higher than that of women (Hillman 1955).

Halban and Spitzer showed that during pregnancy, nail growth rates are one fourth to one third higher than normal (Halban 1928). Hillman supported this earlier study by showing that during pregnancy, nails grow faster. He also showed that the nails grow even faster at later stages of

pregnancy. Furthermore, he observed a decrease in nail growth rates postpartum. He found that nail growth rate was unaffected by maternal weight at conception, maternal weight gain during pregnancy, parity, duration of gestation, and length of labor. Maternal smoking habits had no effect on nail growth rates (Hillman 1960). In a separate study, he also found that birth order and age of the mother at time of birth had no effect on nail growth (Hillman 1955).

One study showed that there is also no change in nail growth rate with pubertal development. In this study, the authors took into account axillary hair, rate of growth of axillary hair or beard, and the incidence and severity of acne (Hamilton et al. 1955).

In a small number of subjects, in two independent studies, it was shown that there are familial patterns of nail growth. For example, Hamilton et al. found that both male and female siblings had growth rates that were similar to the rest of the family (Hamilton et al. 1955). Hillman also showed the rate of fingernail growth in a set of identical twins and a set of fraternal twins was similar between those siblings (Hillman 1955).

Clark and Buxton showed that nails on the longer fingers grew more rapidly than the shorter fingers (LeGros Clark and Buxton 1938). Hillman confirmed this finding, in that he observed the fingernail on the third fingernail grew faster than the others (Hillman 1955). This was confirmed once again by Hamilton et al., in their studies of Japanese subjects (Hamilton et al. 1955). Dawber also agreed that that middle fingernail grew more rapidly than the other nails (Dawber 1970a).

The connection between nutrition and nail growth is controversial. For example, more rapid growth of nails has been associated with better nutritional status in one study (Gilchrist and Dudley Buxton 1939). However, it should be noted that at the time the relevant study was performed, nutritional status was based on general physical appearance as opposed to clinical signs of specific nutrient deficiencies (Hillman 1960). Similarly, it was also observed that during periods of starvation, (Ivanowsky 1923) and malnutrition conditions, such as kwashiorkor and marasmus (Fitzpatrick et al. 1971), nail growth is slowed. Hamilton also mentions unpublished studies on rodents, in which nail growth is slowed with starvation (Hamilton et al. 1955). In contrast, in another study, nutritional status, as estimated by the thickness of skinfolds measured with calipers, had no effect on linear nail growth (Hamilton et al. 1955). In addition, a study was also done on ten newborn infants who were hospitalized, to evaluate the requirements of essential amino acids. For brief periods of time, single amino

acids were removed from their diets, and weight gain either decreased or halted. It was found that omitting these amino acids from the diet had no effect on nail growth (Sibinga 1959). Finally, the effect of calorie restriction on nail growth was also studied in seven obese adults who were on 600/day calorie diets over 1–2 months. It was found that diet had no effect on nail growth rates (Sibinga 1959).

There is disagreement on the data for the influence of the right and left hands and handedness on nail growth rates. Some studies did not show consistent differences in growth between different hands and also showed that handedness had no effect on nail growth (Hillman 1955; LeGros Clark and Buxton 1938). However, Dawber found that on average the nails on the right hand grew faster than the nails on the left hand (Dawber 1970a).

Numerous studies have substantiated the finding that height has no effect on nail growth (Hillman 1955, 1960; Hamilton et al. 1955). Some studies have also shown that weight has no influence on nail growth rates (Hillman 1955; Hamilton et al. 1955; Hewitt and Hillman 1966). Weight gain or loss does not affect growth kinetics (Hillman 1955). Additionally, nail thickness and nail plate length do not affect the linear growth rate of the nail (Hamilton et al. 1955).

2.3 Environment and Nail Growth

Basler showed that nail growth was faster during the day than at night (Basler 1937). It has been hypothesized that this difference is due to diurnal variations in blood pressure, with lower blood pressure at night (Riddle 1908).

The effect of seasonal variation on nail growth rates is controversial. Some studies have emphasized that seasons affected the growth rate of nails, with nails growing faster in warmer weather and slower in colder weather (Gilchrist and Dudley Buxton 1939; LeGros Clark and Buxton 1938). Another report supported this association in a study of 49 sailors in the British navy in the temperate waters around Britain and on an Arctic cruise. The authors found that mean daily nail

growth in the Arctic environment was slower than in the temperate region (Geoghegan et al. 1958). Bier hypothesized that nails grow faster in warmer weather due to a relative hyperemia to the nail apparatus as opposed to slower growth in cooler weather with ischemia (Bier 1905). However, several other studies failed to demonstrate any variation of nail growth with season, and two of these studies included men exposed to varying temperatures in Antarctica (Hillman 1955; Bean 1974; Donovan 1977; Gormly and Ledingham 1983).

2.4 Trauma and Nail Growth

Trauma, such as nail biting, has been found to increase the rate of growth of nails in numerous studies (Hillman 1955; Hamilton et al. 1955; LeGros Clark and Buxton 1938). In addition, in patients with onychomycosis who failed traditional treatments, when the nails were avulsed, the fungal load was reduced, and while no formal studies were done, the trauma of the surgery may provide mechanical stimulation for faster regrowth (Zaias 1990).

One study showed that smoking has no effect on nail growth (Hillman 1955). In addition, moderate stress such as that experienced during final exam periods had no influence on nail growth rates (Hillman 1955).

Numerous studies have also shown that immobilization and paralysis cause a temporary slowing of nail growth. This was first reported as early as 1871, when Mitchell observed that the nails on the paralyzed hand of a 56-year-old woman under his care for a stroke grew more slowly than those of the unaffected hand. He subsequently studied the nails of two men with hemiplegia; he saw soon after the acute episode and found that the nails of the paralyzed hand ceased to grow. However, growth returned at its usual rate, abruptly in one man after 12 days and in the other man after 21 days, when they regained function in the limb (Mitchell 1871). This finding was confirmed by Blake, who also observed that nail growth was slowed in the paralyzed side in hemiplegia (Blake 1899). Head and Sherren also observed that nails grow slower in the paralyzed

side. Interestingly, they showed similar results when there is immobilization with a limb or finger fixed in a splint or cast. They found that massage stimulated growth (Head and Sherren 1908).

2.5 Disease States and Nail Conditions and Nail Growth

While there is no change in nail growth with acute minor illnesses (Hillman 1955), most of the data support that acute severe illnesses are associated with a slowing of nail growth (Bean 1953, 1974; Sibinga 1959). Bean reported on two episodes of influenza like cold with severe respiratory infection that were associated with slowing of nail growth (Bean 1974). In addition, with the mumps, there was almost a complete cessation of nail growth (Bean 1953). Sibinga found that in all 23 patients that he studied with the measles, there was a slowing in the nail growth rate. He also found a cessation of nail growth in an adult patient with mumps complicated by orchitis and a premature infant with staphylococcus septicemia (Sibinga 1959). On the other hand, ten children with acute febrile tuberculosis did not have a slowing of nail growth (Sibinga 1959).

Chronic diseases and conditions can also affect nail growth. High-flow vascular states such as arteriovenous shunts, as well as hyperthyroidism, are associated with increased nail growth (Orentreich et al. 1979). Conversely, decreased circulation, congestive heart failure, and hypothyroidism have been reported to cause a decrease in nail growth (Orentreich et al. 1979).

Hillman noted that family history had no effect on nail growth, specifically cancer, hypertension, coronary artery disease, and diabetes mellitus (Hillman 1955).

Dawber reported that psoriatic nails affected by pitting grew faster than clinically normal nails from patients with psoriasis, which in turn grew faster than nails of healthy controls (Dawber 1970a). In addition, Dawber et al. found that nails affected by onycholysis, whether idiopathic or caused by psoriasis, grew faster than clinically unaffected nails in the same patient and faster than normal controls (Dawber et al. 1971).

Other diseases besides psoriasis, in which there is faster nail growth, are pityriasis rubra pilaris and congenital bullous ichthyosiform erythroderma (Samman 1978). It is believed that the nail matrix is hyperproliferative in these diseases (Dawber 1980).

Nail conditions may cause a deceleration or cessation of nail growth. One example is the yellow nail syndrome (YNS), which is characterized by the triad of yellow nails, lymphedema, and respiratory disease. Nail growth is significantly slowed with fingernails reported to grow 0.12–0.27 mm per week (Samman and White 1964), which is three to six times slower than the average nail growth rate (Hillman 1955; Geyer et al. 2004). The decrease in longitudinal growth is usually compensated by increased nail thickness, with the observation that “the nail that grows half as fast grows twice as thick” (Moffitt and de Berker 2000). Another nail condition in which there is slow nail growth is the brittle nail syndrome. It is characterized by dehydration of the nail plate, which may lead to breakage and splitting. Nail plates are often brittle, frayed at the distal edge, and have longitudinal ridging (Scher and Bodian 1991). In addition, lichen planus (LP) may involve nails about 10 % of the time (Samman 1961) and has been reported to result in slowed nail growth (Baran 2000; Tosti et al. 2000). There is inflammation of the nail matrix, which may lead to onychorrhexis, pterygium formation, and scarring. Inflammation of the nail bed may result in permanent dystrophy.

Nail infections can also cause a slowing of longitudinal nail growth. Onychomycosis is the fungal infection of the nails. One study showed that when onychomycosis affects more than half of the total nail plate, the growth rate of the nail is slower than the unaffected toenails (Yu et al. 2004).

2.6 Medications and Nail Growth

Many medications have been shown to accelerate the rate of nail growth. However, it should be

noted that much of the data are not derived from double-blind, placebo controlled trials. In 1992, Shelley and Shelley showed that there was increased nail growth associated with fluconazole therapy (Shelley and Shelley 1992). There were also three independent studies comparing terbinafine with griseofulvin in patients with onychomycosis, all showing a higher overall growth rate with terbinafine as compared to griseofulvin therapy (Haneke et al. 1995; Faergemann et al. 1995; Baran et al. 1997). Two studies have shown increased nail growth rate with itraconazole. In one study, patients with onychomycosis were treated with a pulse regimen of 400 mg daily for 1 week per month, for a total of 3–4 months. The authors calculated an average growth rate was 2.4–2.7 mm per month in the patients treated with itraconazole, while in unaffected individuals the average growth rate was 1.1 mm per month (Doncker and Pierard 1994). There is also a published case report on a patient with YNS treated with pulse itraconazole therapy for 4 months, with an acceleration of growth (Luyten et al. 1996). However, it should be noted that in another report of eight patients with YNS treated with pulse itraconazole therapy for 6 months, there was no increase in nail growth (Tosti et al. 2002). In addition, since there were no control patients with onychomycosis or yellow nail syndromes in these studies, it is not clear whether these antifungals are accelerating nail growth or whether the nail is growing faster because the nail is cured.

There is an isolated case report of a woman treated for Parkinson’s disease with levodopa for 12 months, who had an increase in nail growth on therapy (Miller 1973). There are two published studies on patients taking benoxaprofen who had an increase in nail growth rate (Fenton et al. 1982; Fenton and Wilkinson 1983). There is also an isolated case report of a patient being treated for hypophosphatemic osteomalacia with oral phosphate, calcitriol, and calcium during the time of increased bone turnover, who had increased nail growth (Hogan et al. 1984). Oral contraceptives have also been reported to increase the growth of

nails (Knight 1974). Biotin and cysteine have also been reported to increase nail growth (Piraccini and Tosti 1999). Notably, it has been shown that biotin may reduce nail fragility, while also increasing both the thickness and rate of longitudinal growth (Uyttendaele et al. 2003).

Medications can also decrease the rate of nail growth. The chemotherapeutics likely decrease the mitotic activity of the nail matrix keratinocytes. For example, methotrexate had a marked suppressive effect on nail growth in psoriatic patients (Dawber 1970b). In addition, azathioprine also decreased nail growth in patients with psoriasis, but less so than methotrexate. Interestingly, corticosteroids had no effect on nail growth in patients with psoriasis (Dawber 1970b). However, psoralen in combination with ultraviolet A therapy has been shown to slow nail growth in patients with psoriasis (Landherr et al. 1982).

The data on the effect of retinoids on nail growth is controversial, with some studies suggesting increased nail growth and others showing the opposite effect. For example, animal models show that retinoids increase nail growth (Baran 1986), and a similar finding was reported in humans in two separate studies (Fritsch 1981; Ott 1977). In addition, in a small study of 28 patients, the oral retinoid, etretinate, was shown to increase the nail growth rate in patients with psoriasis over their baseline. On the other hand, etretinate had no effect on nail growth in patients without psoriasis who were being treated with this drug for other reasons (basal cell carcinoma, basal cell nevus syndrome, lichen planus, actinic keratosis, and palmoplantar keratoderma) (Galosi et al. 1985). In other studies, there has been a slower growth of nails during oral retinoid treatment (Baran 1982). For example, in one study of 130 patients taking etretinate, linear nail growth was reduced in roughly half the patients treated (Baran 1986).

Other drugs that have been associated with a decreased nail growth rate are lithium, sulfonamides, gold, zidovudine, cyclosporine, and

heparin (Piraccini and Tosti 1999). It should be noted that detailed growth kinetics were not performed.

1 Introduction

In contrast to the large body of literature on skin pH and its alterations in certain skin disorders (Schmid-Wendtner and Korting 2006; Ali and Yosipovitch 2013; Stefaniak et al. 2013; Fluhr and Bankova 2006) and on nail properties (Gupchup and Zatz 1999; Murdan 2012), there is very little literature on the pH of the nail plate. An understanding of the nail plate pH is however extremely important. It is possible that nail plate pH has a role in the health and antimicrobial defense of the nail unit, in the same way that the acidic nature of the skin is vital to the latter's barrier properties and integrity. In this context, the pH of the nail plate was measured in our laboratory, in volunteers with healthy nails, to determine the baseline (i.e., in health) values (Murdan et al. 2011). The influences of gender, anatomical site (finger/toe), side (left/right), digit (1–5 of fingernails), and washing, on the nail plate pH, were explored. In addition, pH of the nail plate interior was measured.

The nail plate's surface pH was measured potentiometrically using an apparatus (skin pH

The work described in this chapter was supported by the School of Pharmacy, University of London (now UCL School of Pharmacy).

meter PH 905[®], Courage and Khazaka GmbH, Germany) that is commonly used to measure skin pH. A hydrated planar glass electrode connected to a pH meter was placed on the nail plate. It is expected that water-soluble components of the nail plate would be extracted out of the nail plate and into the liquid interface between the nail and the pH-measuring probe. The pH of this solution would then be read by the glass electrode and would give an indication of the pH of the nail plate surface. The pH value thus obtained due to the extraction of only the water-soluble components out of the nail plate should be regarded as an apparent pH and interpreted with caution, as has been suggested for skin pH (Rieger 1989).

Measuring the pH of the nail plate surface using an apparatus originally designed for the skin presents a number of challenges. Unlike the skin, the nail plate is a hard surface, such that it is difficult to create a perfectly good interface between the nail plate and the flat glass probe. Certain nail plates, such as the little fingernails and all the toenails (except for digit 1), are too curved or have too small area, while others are too ridged, to allow measurement. Nevertheless, it was possible to measure the nail plate pH in many nail plates in 37 individuals (16 females and 21 males, aged 22–69 years old) recruited for the study.

2 Measurements

Measurements were performed *in vivo* following ethics approval, in an air-conditioned room where the temperature ranged from 20.1 °C to 25.2 °C (mean 22.8 ± 1.1 °C) and the relative humidity ranged from 22 % to 35 % (mean 28.0 ± 3.4 %). Volunteers rested in the room for 20 min prior to measurement to acclimatize. The pH probe was rinsed with distilled water and applied at right angle to the nail plate with gentle pressure for about 1 min before the pH was read. Multiple readings were taken to ensure the pH had stabilized and the stable pH value was then recorded.

To determine the influence of washing, volunteers washed their hands with tap water and Cussons Carex[®] (sensitive) handwash (whose pH was 4.02) and blotted them dry using paper towels. The pH of the washed nail plates was measured immediately afterward and then at time intervals, to investigate for changes in pH with time. It was found that following washing, the nail plate pH stabilized within 20 min. Subsequently, a larger study was conducted to measure the pH of washed finger- and toenail plates, where the volunteers washed their hands and feet as described above and rested in the room for 20 min prior to measurement.

To determine the pH of the nail plate interior, the thumbnail plates were used. Following acclimatization and an initial pH measurement, the nail plates were tape stripped; an adhesive disk (D-Squame, Cuderm, Dallas, USA) was applied to the nail plate and firmly pressed by the operator for 30 s before being removed. This was repeated a number of times, and the pH of the newly exposed nail plate surface was measured after every ten strips and at the end of the experiment, when the volunteer felt tingling and discomfort at the nail and stripping was stopped. The different volunteers experienced discomfort following different extents of tape stripping. Thus, in the unwashed nails group, the volunteers received a total of either 15 (one volunteer), 20 (one volunteer), 30 (two volunteers), 40 (one volunteer), or 50 (one volunteer) stripings. In the washed nails group, the volunteers received a total of either 15 (one volunteer), 20 (five volunteers), 30 (one volunteer), and 40 (three volunteers) tape stripings. The different tolerances of the volunteers to tape stripping are likely due to interindividual variability in the mechanical properties of the nail plate, such that different amounts of nail cells/layers would be removed by each tape strip. Such interindividual variability reflects results by Tudela et al. who reported variable amounts of nail protein removed in different individuals following 20 tape strips in each volunteer (Tudela et al. 2008).

3 Results and Discussion

3.1 pH of Unwashed Nail Plate Surface

The pH of the nail plate surface was found to be acidic (Table 1). The mean (\pm SD) pH of the surface of unwashed nail plates was 5.0 ± 0.5 , with a minimum of 3.4 and a maximum of 6.3 measured in 157 fingernails and 33 big toenails in 15 males and 13 females. These pH values are expected to be due to the extraction of water-soluble components of the nail plate into the liquid interface between the nail plate and the pH-measuring probe, as well as residual cosmetics such as hand creams and the presence of sweat (which has a pH of 5–7 (Agache and Candas 2004)) and sebum (a large proportion of which is made up of free fatty acids (Agache 2004)) on the nail plate. Low levels of sebum have been measured on the nail plates (Murdan et al. 2012); sweat and sebum may be present on the nails following contact between the skin and nail and/or their flow from the surrounding skin onto the nail plate.

General linear model statistical analysis showed an influence of gender and anatomical site (finger/toe), with nail plate pH being higher in males and in toenails ($p < 0.01$), while side (right/left) had no influence ($p = 0.2$). In addition, no significant differences were found among the pH of the ten fingernails ($p > 0.01$, repeated measures ANOVA using pH values from 15 volunteers where it had been possible to measure all ten fingernails). A lack of difference in nail plate

pH between right and left sides and among the ten fingernails could be due to the similar environments experienced by the right and left hands or feet and by the digits.

It is not known why toenail pH was statistically higher than fingernail pH (Table 1). Toenail plates are thicker, grow at a slower rate compared to fingernails (Fleckman 2005), and allow a smaller transonychia water loss than the fingernails (Murdan et al. 2008). It is interesting, though, to note that the higher toenail pH (compared to fingernail pH) reflects the statistically higher foot skin pH compared to hand skin pH reported in a small cohort of Japanese men (Chikakane and Takahashi 1995). Although the reason for the higher toenail pH is unclear, it may have clinical significance. If the acidic nature of the nail plate does have a role in antimicrobial defense, the lower acidity of toenail plate (compared to the fingernails) might contribute to their greater susceptibility to onychomycosis (fungal infections of the nail). Indeed, a higher incidence of onychomycosis (Midgley et al. 1994), greater recalcitrance to treatment, and the need for longer treatment duration in toenails compared to fingernails are well known (BNF 2012). The higher toenail pH might also favor the production of fungal spores; the latter's production by *Trichophyton rubrum* – one of the most common causes of onychomycosis – was shown in vitro to increase when the medium pH was increased from pH 4.5 to pH 7.5 and to decrease thereafter (Yazdanparast and Barton 2006). A higher toenail pH could favor the presence of fungal spores,

Table 1 Measured pH of unwashed and washed finger- and toenail plate surface in males and females (Reproduced with permission from Murdan et al. 2011)

pH of the nail plate surface				
mean \pm SD				
(Minimum-maximum; N = number of nails in n = number of volunteers)				
Gender	Unwashed nails		Washed and rested nails	
	Fingernails	Toenails	Fingernails	Toenails
Males	5.1 ± 0.5 (3.4–6.1; $N = 87$ in $n = 10$)	5.3 ± 0.4 (4.5–6.3; $N = 20$ in $n = 10$)	5.1 ± 0.5 (3.9–6.4; $N = 125$ in $n = 13$)	5.3 ± 0.7 (4.1–6.9; $N = 20$ in $n = 11$)
Females	4.8 ± 0.4 (3.8–5.7; $N = 70$ in $n = 7$)	5.4 ± 0.5 (4.4–5.8; $N = 13$ in $n = 7$)	5.1 ± 0.6 (3.9–6.5; $N = 79$ in $n = 9$)	5.1 ± 0.6 (4.7–6.9; $N = 13$ in $n = 7$)

which provide a reservoir for fungal infection. The influence of gender on nail plate pH is discussed in the next section.

3.2 pH of Washed Nail Plate Surface

In order to remove the possible influence of extraneous substances such as residual cosmetics on the nail plate pH, nails were washed. Immediately after handwashing and drying, the pH of the fingernail surface increased, from a mean \pm SD of 5.1 ± 0.4 to 5.3 ± 0.5 (paired *t*-test, $p < 0.01$, $N = 140$ fingernails in 14 volunteers). This could be due to the nails being exposed to high pH during washing. Although the liquid cleanser had a pH of 4.02, the pH of the washing solution (cleanser + tap water) would have been much higher, the pH of a 2 %w/w aqueous solution of the cleanser in tap water being measured to be 7.90. The raised nail plate pH was however not sustained with time, as shown in Fig. 1. Within 20 min of washing, the pH had decreased to prewashing levels. The transient increase in the pH of the nail plate surface and subsequent return to prewashing levels reflect the profile of skin pH upon washing (Gfatter et al. 1997; Korting et al. 1987).

Subsequently, a larger study was conducted to measure the pH of washed, dried, and rested (for at least 20 min) finger- and toenail plates. The mean (\pm SD) pH of the surface of washed nail plates was

found to be 5.1 ± 0.6 , with a minimum of 3.9 and a maximum of 6.9 measured in 204 fingernails and 32 big toenails in 13 males and 9 females. The pH of toenail plates was higher than those of fingernail plates (Table 1, general linear model, $p = 0.01$), while right/left side and gender had no influence ($p > 0.2$). As for the unwashed nails, the pH of the ten fingernails did not differ significantly (repeated measures ANOVA, $p = 0.2$, pH of all ten fingernails measured in 15 volunteers).

When the pH of washed and unwashed nails were compared (Table 1), it was found that washing did not significantly influence finger- and toenail plate pH in males (independent *t*-tests ($p \geq 0.5$, Table 1)). In females, however, washed fingernails had a significantly higher pH than unwashed ones ($p < 0.01$), while there was no difference in the pH of their toenails ($p \geq 0.5$). This suggests that washing removed something from the fingernails, such as hand creams. The fact that gender influenced the pH of unwashed nails, but not that of washed ones, indicates that the lower pH in females' unwashed nails was due to an exogenous factor, such as residual hand creams. The use of cosmetics such as moisturizers has been suggested as a potential reason for reported differences in skin pH between males and females and for the conflicting reports on the influence of gender on skin pH (Burry et al. 2001), although a recent systematic study found consistently higher skin (forehead, cheek, neck,

Fig. 1 Change in nail plate surface pH upon washing and subsequently with time. The latter is given as an approximation, rather than a definite value as the time varied slightly for each volunteer and for each nail, depending on the durations of pH measurements (Reproduced with permission from Murdan et al. 2011)

forearm, and hand) pH in females compared to males (Luebberding et al. 2013). Further studies where volunteers refrain from using topical products on the hands and feet and use the same cleansers for washing, for a run-in phase prior to measurement of nail plate pH, could shed more light on the influence of gender on nail plate pH.

3.3 pH of the Nail Plate interior

Tape stripping removes nail plate cells, and the newly exposed nail plate surface appears somewhat “flaky” (Fig. 2) with volunteers complaining of a tingling sensation at the nail once a certain number of strips had been removed. Different volunteers had different numbers of tape stripping performed before they complained of discomfort and before the experiment was stopped; hence, pre-stripping and post-stripping pH for each volunteer were compared to investigate for differences, if any, between the surface and interior nail plate pH. For unwashed nails, a statistically significant difference (paired *t*-test, $p < 0.05$; $N = 12$ thumbnails in six volunteers) was found, with the pH of the nail plate interior (4.1 ± 0.7) being lower than that of its surface (4.7 ± 0.7). For washed nails (20 thumbnails in ten volunteers), the pH of the nail plate interior was also slightly lower (4.8 ± 0.6) than that at its surface which were 5.1 ± 0.5 (before washing) and 5.2 ± 0.7 (after washing and resting).

Fig. 2 The “flaky” appearance of the nail plate surface after tape stripping. This volunteer received a total of 15 tape strips, at which point he felt discomfort and tingling (Reproduced with permission from Murdan et al. 2011)

The lower pH of the nail plate interior could be due to enhanced extraction of acidic, water-soluble nail components during the pH measurement, once the topmost nail layers had been removed by tape stripping. The topmost layer of the nail plate is known to be the least permeable part of the nail plate, and its removal results in increased permeation of chemicals into the nail plate (Kobayashi et al. 1999). Similarly, removal of the topmost nail layer is expected to increase the movement of molecules out of the bulk of the nail plate and into the liquid interface between the nail plate and the pH-measuring probe. A decrease in nail plate pH upon tape stripping reflects the **initial** reduction in skin pH upon tape stripping that has been observed prior to an increase in skin pH upon further tape stripping (Wilhelm et al. 1991; Berardesca et al. 1998; Wagner et al. 2003; Ohman and Vahlquist 1994).

4 Conclusions

The pH of the nail plate surface was measured to be around 5, with toenails having significantly higher pH than fingernails. There was no difference, however, among the ten fingernails or between the two great toenails. Gender influenced the pH of unwashed fingernails – with women having lower pH compared to men – but had no influence on the pH of washed ones, suggesting the influence of an exogenous factor on women’s lower fingernail pH. Washing the nails with a liquid cleanser and tap water transiently increased pH, which subsequently returned to prewashing values within 20 min. Tape stripping the nail plates in order to measure the pH of the nail plate interior revealed a lower pH inside the nail plate compared to its surface.

This study has shown that it is possible to measure the surface pH of nail plates using the Courage and Khazaka skin pH meter, although a long stabilization time is needed, and the small area and high curvature of certain nail plates preclude their measurement.

5 Future Work

The study has established pH values of healthy finger- and toenail plates. Much more needs to be done, to understand the origin and significance of the nail plate acidity and any changes in the diseased state. The influence of factors such as aging, environment, and systemic disease, e.g., diabetes, on the nail plate pH could indicate how these factors predispose one to develop nail diseases such as onychomycosis. Changes, if any, in diseased nails should enable a greater understanding of these diseases and investigations into new prevention and treatment modalities. For example, changes in nail plate pH in onychomycosis, if any, could shed light on factors which influence fungal colonization and infections. Fungi are known to detect and respond to their environmental pH, secreting the appropriate proteolytic enzymes, which allows fungal invasion and subsequent infection (Martinez-Rossi et al. 2012). The dermatophyte, *T. rubrum*, has also been shown to alter the pH of the growth medium to pH values ranging from 8.3 to 8.9, irrespective of the initial medium pH (Ferreira-Nozawa et al. 2003). Whether such a change in nail plate pH occurs in vivo in onychomycotic nails remains to be seen. The difficulties of using the glass electrode of the pH meter were mentioned above. An electrode that is more flexible and smaller in area is needed to enable more accurate measurements on nail plates.

Imaging • Ultrasound • Skin • Nail • Anatomy

The nail is of functional and cosmetic importance and therefore constitutes a sensitive area for most patients. Clinical diagnosis may also pose a challenge, but the usual diagnostic recourse to biopsy is influenced by the risk of subsequent scarring and risk of lasting nail deformities. In addition patients would often prefer noninvasive diagnostics. High-frequency ultrasound imaging is therefore a suitable and generally available technique for nail studies.

1 About Ultrasound

Ultrasonography is real-time noninvasive diagnostic imaging based on a principle of inaudible sound waves that are transmitted through the material examined and the analysis, of the subsequent reflected echoes, which is converted to a two-dimensional visualization of the material. The sound waves are characterized by their amplitude, propagation speed, and frequency. Differences in the reflected sound waves are caused by the different acoustic impedances of different substances changing the amplitude or propagation speed of the sound waves. Generally hard or dry materials and air have higher impedance shown as (hyperechoic) bright areas, whereas fluids have low impedance and are shown as (hypoechoic) dark areas (Wortsman and Jemec 2006; Bitsch et al. 2011).

In standard grayscale mode (B-mode) ultrasound, the frequency is constant. High frequencies generally create high resolution and shallow penetration, whereas low frequencies yield low resolution but deeper penetration.

When analyzing changes in the frequencies of reflected echoes, it is possible to visualize movement of material, most often flow of liquids through Doppler ultrasound. This is often shown as a blue to red color overlay (color Doppler mode) or as monochrome overlay (power Doppler mode) on the B-mode ultrasound visualization. Flow in selected areas of the examined material can be further explored both visually and auditory by using spectral Doppler mode.

A static computer-assisted three-dimensional visualization is also a possibility in many ultrasonographic devices enabling an overview of complex lesions such as the nail apparatus (Bitsch et al. 2011).

2 Technical Features/Handling

Many different ultrasound devices are marketed, and modern equipment is readily available in many hospitals that provide a wide range of capabilities, which include the technical capability to image the skin and the nail. The quality of imaging equipment has generally improved, prices have decreased, and handheld devices are now widely available and affordable.

The ultrasound device is basically a computer connected to specialized transducer containing the piezoelectric crystals. As in personal computers, big processors and screens with high numbers of pixels provide better images. High-frequency transducers usually linear or compact linear probes (hockey stick shaped) are commonly used for studying the skin and nail (Bitsch et al. 2011).

These variable frequency probes range in their upper frequencies between 15 and 22 MHz; however the same probes may also work in lower frequencies that range from 7 to 8 MHz. Therefore the operator may set the parameters of the machine according to the depth of the anatomical

structure under study. This range will suffice in both appropriate depth and high resolution, with higher frequencies being more suitable for the imaging of the nail apparatus.

An abundance of gel should be used to discriminate all the layers of the skin or nail from top to bottom. As opposed to internal organs, a minimum of pressure should be applied to avoid thinning out layers of the skin or closing vasculature.

The digit under examination should be as extended as possible to ensure recognizable landmarks during scanning. Longitudinal and transverse planes should be scanned through. B-mode (grayscale), Doppler color flow, Doppler power flow, and (rarely) Doppler spectral analyses can be relevant regarding the nail (Wortsman and Jemec 2006; Wortsman 2013).

3 Anatomy/Acoustic Properties of the Nail

3.1 Anatomy of the Nail

The anatomy of the nail unit is well described. The surface anatomy consists of the nail plate, the proximal and lateral nail folds, the lateral nail grooves, and the eponychium. The nail plate itself can be described as convex both longitudinally and transversely – with a distal free margin, a hyponychium, a central nail plate, and a proximal lunula. Changes in the nail plate are described in ► [Chap. 92, “Gene Expression and Genetic Evaluation of the Skin.”](#)

Beneath the nail plate is the nail bed. Proximally, underlying the lunula is the nail matrix and nail sinus producing the keratinocytes of which the nail plate consists and further distally the nail bed consists of a thin epidermis overlying a collagenous dermis and the distal phalanx.

The most prominent nerves and vessels in the digits run on the palmar side. Both the neural and arterial supply to the distal phalanx is primarily provided by palmar conduits; however the nail matrix is supplied from the dorsal arterial arcade. Clusters of arteriovenous shunts, glomus bodies, are found in the nail bed (Fleckman 2005).

The entheses of extensor tendons are found adjacent to the nail matrix.

4 Normal Nail Sonography

The different tissues of the nail have different densities and thus different echogenicities. The nail plate has a characteristic bilamellar structure with a central hypoechoic interplate space (Jemec and Serup 1989). See Fig. 1. The speed of sound in the nail plate has been determined at 2459 m/s, compared to the 1580 m/s estimated speed of sound in the skin. It is thought that the

bilamellar structure reflects the water (35 %) distribution in the nail plate, with a dry outer compartment in which the speed of sound is 3103 m/s and a deeper more humid compartment in which the speed of sound is 2125 m/s (Jemec and Serup 1989).

Under the nail bed, it is possible to detect the hyperechoic linear bony margin of the distal phalanx. Proximally to the nail plate and in close proximity to the nail matrix, the insertion of the extensor digitorum tendon on the phalanx can be visualized. Low-velocity blood flow can be detected in the nail bed, usually close to the bony margin of the distal phalanx (Fig. 2). The

Fig. 1 Ultrasonography of normal nail plate (*grayscale*, longitudinal view) showing the different part of the nail unit

Fig. 2 3D power Doppler reconstruction of the nail unit (longitudinal view) demonstrates the vascularity (*red color*) within the nail bed

Table 1 Sonographic nail findings

Pathology	Typical findings
Alopecia areata	In alopecia areata, two thirds of patients have somewhat unspecific nail involvement, which however may precede scalp affection. Most often nail pitting and nail dystrophy are seen similar to nail changes in psoriasis. However, in contrast with psoriasis, usually the nail bed is hypovascular (Wortsman 2013)
Ichthyosis	Often nails are thickened and the hypoechoic thin layer between the dorsal and ventral plates is no longer discernible (Wortsman and Aranibar 2001)
Benign tumors	Glomus tumors – these benign vascular tumors are derived from the neuromyoarterial glomus and clinically present exquisite pain in the nail region. Sonographically, they appear as a hypoechoic well-defined nodule that commonly shows hypervascularity. Scalloping of the bony margin of the distal phalanx is a frequent associated finding (Wortsman and Jemec 2009)
	Onychomatricoma – seen as yellow bands along the nail. Sometimes added convexity can make the nail cone shaped. Often hypoechoic areas with hyperechoic spots or lines of the nail bed and interplate space are seen. The underlying bone is usually unremarkable (Soto et al. 2009)
	Keratoacanthoma – these squamocellular neoplasms can rarely occur in the nail bed. Appears as a well-defined solid mass with a central cystic/anechoic area surrounded by hypoechoic tissue and enhancement artifact. Can affect both nail plate and bony margin. With Doppler the tumor will show hypovascularity (Choi et al. 2007)
	Granuloma – a chronic proliferative inflammatory scarring reaction most often involving periungual tissue, but also nail bed or even matrix. Sonographically hypoechoic lesion without sharp demarcation. Increased nail bed thickness, corrugated upward skewed nail plates (Wortsman et al. 2010b)
	Verrucae – subungual warts are hypoechoic spindle-shaped elements resulting in thickened nail plates (Wortsman et al. 2010c)
Dermatomyositis	A telltale sign in prolonged disease is the calcinosis. Small epidermal fingertip calcium deposits visualized as hyperechoic deposits with pronounced posterior acoustic shadowing (Wortsman 2013)
Malignant tumors	Bowen disease – no early diagnosis is possible in Bowen disease; however in later stages an hypoechoic solid mass that erode the nail plate may be found (Wortsman 2013)
	Malignant melanoma – when arising from the nail matrix, it is typically seen as a dark-pigmented longitudinal stripe involving the lunula and the hyponychium. Early diagnosis by sonography is difficult, because pigments are currently not detected by ultrasound. Nevertheless, hypoechoic ill-defined areas and localized hypervascularity may be found. In later stages, a hypoechoic solid tumor can be seen (Wortsman 2013)
Onychomadesis	Onychomadesis is basically a Beau line with full separation, instead of an indentation. After nail growth arrest onychomadesis is seen. The nail plate separates from the matrix. Typically two unconnected hyperechoic nail plates are seen. Often the distal nail plate is somewhat thickened (Wortsman et al. 2010a)
Psoriasis	Psoriatic nail involvement is linked to psoriatic arthritis and severity of skin disease. Classic findings are thickened nail beds measured by the distance between the nail plate and the phalanx. Thickening of both plates and blurring of the ventral nail plate. In late disease even blurring of dorsal plate is seen as well. Corrugated nail plate can be seen
	Hypervascularity in the nail bed during active disease giving increased Doppler activity (Gutierrez et al. 2009)
Scleroderma	Vascular damage is in focus with nail pathology in scleroderma patients. Thickened nail beds with lower echogenicity and thickened nail plates with loss of interplate space. Commonly the nail bed shows hypovascularity (Wortsman et al. 2011)
SLE	Irregular nail beds and plates and hypovascularity are often seen (Wortsman et al. 2011)
Subungual abscess	Anechoic areas with acoustic enhancement and inflamed and thickened nail beds. Hyperechoic air bubbles may be present. Sinus tracts increasing the risk of joint affection or osteitis can be followed if present (Wortsman 2013)

skin surrounding the nail plate is almost devoid of fat, though in other ways no different from a normal skin sonography (Wortsman and Jemec 2006; Wortsman 2013).

5 Pathology/Applications

Diagnosing ungual, subungual, or periungual pathologies clinically is often difficult as the nail plate naturally prevents closer inspection. Similarly, the use of diagnostic biopsies through the nail or in the periungual area is often painful or unpleasant to the patient and potentially harmful as the nail matrix is easily damaged leaving the patient with a permanent defect in a cosmetically important area.

The convenience and the noninvasive dynamic nature of ultrasound enable the early diagnosis of common nail pathology. The use of this imaging method relies on an interpretation of basic sonographic tissue characteristics:

1. Inflammation: The inflammation causes dilatation of vessels and subsequent edema and possibly abscess formation. The vascular changes are best visualized using color Doppler or power Doppler, which shows hypervascularity and increased flow. Inflammation generally presents as associated hypoechoic areas. In older lesions a reactive thickening of the nail bed will often be seen.
2. Tumors: The sonographic image depends on the density of the tumor. When measuring tumors, using a standard procedure is therefore an advantage. Diagnostically, it is important to know the precise position of the tumor, size, composition, what structures are involved, and if it is hypo- or hypervascularized.
3. Abscess or cysts: Fluid-filled cavities with or without air appear anechoic and show no Doppler activity, but often enhancement artifacts, where underlying tissue appears hyper-reflective.

A summarized review of nail pathologies as identified by ultrasound is given in Table 1.

6 Conclusion

High-frequency ultrasound of the nail can give valuable clues and support early diagnoses and is easy to use. Both rare and more frequent lesions can be diagnosed with ultrasound examination in context of the clinical work-up.

Sonography is not the same as, e.g., histology. It is not as detailed and does not allow the same detail of diagnosis, but it offers an important advantage over histology as it provides functional real-time information about the tissue as well. A prime example of this is the bilamellar images of the nail plate, where sonography reflects hydration which would otherwise not be seen. Similarly, the density and perfusion of tissue are readily available in ultrasound, but not in histology, making it an important imaging method for clinical manifestations in the skin.

The simple and dynamic nature of the sonographic examination and the ready accessibility compared to the, e.g., magnetic resonance imaging are important factors when choosing diagnostic methods. Lastly, sonography can offer a noninvasive window into the physiopathology of nail diseases.

1 ECM and Skin Culture Models

Much of knowledge on fibroblast physiology is based on monolayer culture studies. After few passages of cells grown from a skin biopsy, fibroblasts exhibit their phenotypic and metabolic characteristics. Thus, cultured papillary and reticular fibroblasts exhibit stable differences in the production of some, but not all, extracellular matrix molecules (Sorrell and Caplan 2004) (Table 1).

To study cell-cell and cell-matrix interactions, three-dimensional organotypic cultures are used. Bell et al. (1979) introduced equivalent dermis models, so-called lattices, in which fibroblasts are embedded into different collagen gel systems. Free-floating lattices retract over time as fibroblasts migrate and reorganize the collagenous matrix. Tense lattices develop internal tension as gel retraction is prevented by attachment of the matrix (Viennet et al. 2005). Such models have revealed the importance of fibroblast adherence to the matrix through mechano-sensing integrin signaling (Dallon and Ehrlich 2008). When integrins bind collagen, they transduce a signal which regulates cellular biological functions, such as proliferation, migration, and matrix metabolism. Intracellular signaling cascades such as

Table 1 Expression of extracellular matrix molecules by monolayer cultures of dermal fibroblasts (from Sorrell and Caplan 2004)

Matrix component	Papillary fibroblasts	Reticular fibroblasts
Collagens I and III	Produced – ratio same as for reticular cells	Produced – ratio same as for papillary cells
Collagens V and VI	Produced	Produced
Collagen XII	Produced	Produced
Collagen XIV	Not produced in monolayer culture	Not produced in monolayer culture
Collagen XVI	Produced at high levels	Produced at low levels
Tenascin-C	Produced	Produced
Tenascin-X	Not studied	Not studied
Versican	Produced at low levels	Produced at high levels
Decorin	Produced at high levels	Produced at low levels

transforming growth factor- β (TGF- β), extracellular signal-regulated kinases, p38 mitogen-activated protein kinase, and Wnt/ β -catenin pathway have been implicated in the regulation of ECM production in fibroblasts.

Fibroblasts synthesize matrix metalloproteinases (MMPs), which are responsible for the turnover of collagen and elastic fibers. MMPs are zinc-dependent enzymes involved in the degradation of ECM and in the release and activation of growth factors and cytokines. Their activity is controlled by tissue inhibitors of metalloproteinases (TIMPs), and their production is regulated by a number of factors, including cell/ECM interaction, mechanical force, and the expression of cytokines/growth factors (TGF- β , IL-1, TNF α). According to the MMPs expression profile, it is possible to characterize different subtypes of fibroblasts: oral fibroblasts exhibit increased levels of the active form of MMP-2 as compared to dermal fibroblasts (Stephens et al. 2001). Expression or activation of MMPs differs if fibroblasts are cultured in monolayer or in three-dimensional collagen lattice. MMP activity is significantly induced when keratinocytes and fibroblasts were cocultured. Paracrine interaction between keratinocytes and fibroblasts appears to play an important role in the regulation of collagen metabolism (Tandara and Mustoe 2011).

Gene expression and synthesis of ECM molecules in biological models of the skin can be measured by PCR, zymography, and ELISA.

Due to diverse synthetic functions, fibroblast activities need control. Improper control results in

synthesis of excessive or inadequate products that are reflected in disease processes such as scleroderma, systemic sclerosis, and keloids, but also in wrinkles and premature aging of the skin.

2 ECM in Skin Aging

With aging, fibroblasts lose their proliferative potential, and they show diminished ECM biosynthesis capacity, resulting in dermal atrophy and wrinkle formation. Compared to adjacent skin fibroblasts, wrinkle-cultured fibroblasts show decreased production of type I collagen and increased synthesis of MMP-1 (Fig. 1). In monolayer culture, fibroblasts from old donors, or even in vitro aged fibroblasts, have been shown to express age-specific features. Aged fibroblasts show a decrease in proliferation and type I collagen production and an increase in MMP-1 synthesis compared to young ones (Humbert et al. 2012).

One of the causes of aging is the appearance of the advanced glycosylation end products (AGEs) during life. The glycation reaction results from a nonenzymatic reaction between a sugar and a free amine group of Lys, Arg amino acids in proteins. Therefore, it seems that AGEs modify the expression and the synthesis of ECM molecules. They provoke the activation of fibroblasts; the increase of type III and IV collagens; MMP-1, MMP-2, and MMP-9 production; and the modification of $\alpha 6$ and $\beta 1$ integrin patterns (Pageon et al. 2007; Pageon 2010) (Fig. 2).

Fig. 1 Expression of type I collagen and MMP-1 molecules by monolayer cultures of adjacent skin (*NF*) and wrinkle fibroblasts (*WF*) (Unpublished data)

3 ECM in Wound Healing and Fibrosis

Wound healing is a complex process that involves inflammation, granulation tissue formation, and tissue remodeling, and this is all regulated by a number of cytokines and growth factors. Fibroblasts play a crucial role in wound healing. During this process, fibroblasts proliferate and produce many of the ECM molecules in a TGF- β -dependent manner, and this contributes to the recovery of connective tissue integrity.

The expression by dermal fibroblasts of several genes and the synthesis of proteins involved in skin wound healing were found to be tension inducible (Agha et al. 2011). This is the case of type I and III collagens and procollagen C-proteinase (enzyme required for the formation of insoluble collagen fibers) whose expression is

increased by mechanical tension (Lambert et al. 2001; Kessler et al. 2001). Other ECM components are also induced by mechanical tension such as Tenascin-C, a modulator of cell adhesion, migration, and growth (Chiquet-Ehrismann and Chiquet 2003). As regards the remodeling of ECM, MMP-1, MMP-3, MMP-9, and MMP-13 are upregulated when tensile forces are dissipated (Lambert et al. 2001).

Disruption of either production or degradation of ECM and imbalances between MMPs and TIMPs production can lead to abnormal scarring. Both keloids and hypertrophic scars are cutaneous abnormalities that are characterized by excessive accumulation of connective tissue, especially collagen. When compared with normal fibroblasts, keloid fibroblasts exhibit an altered expression of several molecules implied in all wound healing phases. Cultured keloid fibroblasts showed increased production of type I collagen,

Fig. 2 HES histological staining (**a, b**) and AGE labeling (**c, d**) of skin reconstructed in vitro using untreated collagen (**a, c**) or preglycated collagen (**b, d**). The histological

pictures look similar except that the dermal organization seems to be modified by glycation (bar = 100 μ m) (From Pageon et al. 2007)

fibronectin, MMP-1, MMP-2, MMP-3, MMP-13, MMP-19, and TIMP-1. MMP-8 is decreased (Shih et al. 2010). In addition, increased production of MMPs had a role in the high migratory activity of cultured keloid fibroblasts (Fujiwara et al. 2005).

Systemic scleroderma is a generalized disorder characterized by excessive deposition of ECM. The overproduction of type I, III, and VI collagens by systemic and localized scleroderma fibroblasts has been demonstrated (Krieg et al. 1981). Increased matrix deposition has been shown to be due to enhanced gene transcription and stability of mRNA. In comparison with normal fibroblasts, systemic scleroderma fibroblasts respond differently to their extracellular environment, indicating an altered feedback (Herzhoﬀ et al. 1999).

4 Conclusion

The extracellular matrix is one of the most important regulators of cellular and tissue function in the body. Tightly controlled ECM homeostasis is essential for development, wound healing, and normal organ homeostasis, and dysregulation can result in pathological conditions. Fibroblasts are the major cells in the dermis, and these cells provide tensile strength and elasticity through the production and secretion of various components of ECM, including collagens, elastin, glycoproteins, and proteoglycans. Thus enhancing the activity of fibroblasts, in the context of ECM production, may have beneficial effects on maintenance of skin texture.

Fibroblasts • Mechanical stress • Contractile forces • Dermis • Ulcer legs • Wrinkles • Stretch marks • Photoaging

As well as their primary role in extracellular matrix production, fibroblasts are capable of contraction (Gabbiani et al. 1971; Grinnell 1994; Ryan et al. 1974). The mechanical behavior of the skin in the rest state corresponds with the dermis. External forces applied on the skin are transmitted to the dermis, and internal forces of the dermis affect the epidermal surface. Internal forces are the result of the natural tension of the network of fibers of the dermis and the contractile activity-induced tension of the fibroblasts on fibers. External forces applied on the surface of the skin are the result of compression, tension, and friction forces. Mechanical stress stimulates the proliferation of fibroblasts and modulates their phenotype by inducing the expression of alpha-smooth muscle actin and differentiation into myofibroblasts. Mechanical compression induces apoptosis and regulates the release of cytokines. Previous studies have found that fibroblasts in granulation tissue are myofibroblasts and suggest that they might produce the force of wound

contraction (Darby and Gabbiani 1990; Hirschel et al. 1971; Schurch et al. 1984). An in vitro model that is considered to be an equivalent of the process of wound contraction has already been established. Bell et al. reported that the incorporation of fibroblasts in a collagen gel induces a progressive contraction of the gel, resulting in the formation of a dense collagen disk, called retracted lattice (Fig. 1) (Bell et al. 1979). Fibroblasts reduce their proliferation potential, and three mechanisms seem to be responsible for lattice contraction: cell contraction, cell tractional force related to locomotion, and cell elongation (Dallon and Ehrlich 2008). Contraction is determined by measurements of gel diameter over a period of time. A new device, the Glasbox[®] (Fig. 2), has been developed by Professor Philippe Humbert (Besançon, France), which can measure directly the forces exerted by fibroblasts on the collagen gel (Viennet et al. 2004). The culture model used is a tense lattice in which cells are seeded within a collagen matrix immobilized at its extremities. Contraction is inhibited and lattice formation is associated with the production of internal tension. This model developed is based on a silicon slide, which is fine enough to be

C. Courderot-Masuyer (✉)
Bioexigence, Besançon, France
e-mail: bioexigence@wanadoo.fr

curved by even the weak forces involved in the tense collagen lattice. The slide deformation is measured by strain gauges deposited on its surface. The collagen lattice is attached to the sensor through a grid etched on the silicon stripe. Such tense lattices are more closely related to the skin than retracted lattices in terms of both internal structure and mechanical behavior, because the skin is also permanently under tension. Several

force measurement devices are described in the literature (Campbell et al. 2003; Chapuis et al. 1996; Darby et al. 1991; Eastwood et al. 1994; Kasugai et al. 1990; Kolodney and Wysolmerski 1992). Different cell sources have been studied to test the idea that the ability of fibroblasts to generate contractile forces vary between populations (Delvoye et al. 1986; Gillery et al. 1991; Rayan and Tomasek 1994). Glasbox[®] makes it possible

Fig. 1 Evolution of the diameter of collagen lattices over 10 days of culture

Fig. 2 (a) Schematic diagram of the Glasbox. **(b)** View of the Glasbox. The cell chamber was composed of eight rectangular culture wells in which lattices developed. Two opposite silicon beams hanged down into each well. The lattice was attached to this sensor through a grid directly etched on the lower part of the beams. A strain gauge was deposited at the beam surface and connected to form a Wheatstone bridge. The strain gauges signal output was amplified and then converted and collected by a computer, which included an acquisition card and a specific program for giving directly the forces in real time

to detect differences in contractile forces of fibroblasts from leg venous ulcers, stretch marks, irradiated fibroblasts, and wrinkles when those are compared to surrounding normal “healthy skin.” Fibroblasts from early stretch marks were the richest cells in alpha-smooth muscle actin filaments and generated the highest contractile forces. Their peak contractile force was 26 % greater than normal fibroblasts. There was a 150 % higher level of alpha-smooth muscle actin content in fibroblasts from early stretch marks. On the contrary, there was no significant difference in contraction forces between old stretch mark fibroblasts and normal fibroblasts. Normal fibroblasts do not express alpha-smooth muscle actin. The contractile properties of fibroblasts vary depending of the stage of the disease (Viennet et al. 2005). The device Glasbox[®] makes it possible to know whether an active might have relaxing effects on contractile forces in order to prevent the formation of stretch marks. The evaluation of the mechanical activity of venous ulcer fibroblasts showed that, in comparison with ulcer-edge fibroblasts, the force generation with ulcer-centered fibroblasts was much enhanced, and this is also correlated to the presence of high levels of alpha-smooth muscle actin. So in chronic venous ulcer, the generation of contractile forces and the formation of cytoplasmic actin filaments are not affected (Viennet et al. 2004). The development of contractile forces by fibroblasts after UVA irradiation was also studied using the Glasbox device. Several studies have proven that UVA wavelengths by themselves participate in the long-term clinical effects of photoaging (Lavker et al. 1995). Only UVA reach dermal fibroblasts. In sun-exposed skin and during skin aging, the normal fibrillary pattern of dermal extracellular matrix (ECM) is replaced by nonfunctional ECM, in which the normally divalent collagen cross-links have been replaced by trivalent cross-links, causing thickening and tangling of collagen fibrils (Kligman and Kligman 1986). Advanced glycation end products (AGEs), the products of nonenzymatic glycation and oxidation of proteins and lipids, modify skin elastin especially during UV-induced photoaging

(Mitzutari et al. 1997) and AGEs accumulate on skin elastin and collagen, interfering with normal skin function and structure (Wondrak et al. 2002). Okano et al. postulated that AGEs bind to fibroblast cell membranes, contributing to the progression of skin aging (Okano et al. 2002). The UVA-generated reactive oxygen species are also responsible for the cross-linking of proteins (such as collagen), oxidation of sulfhydryl groups causing disulfide cross-links, oxidative inactivation of certain enzymes causing functional impairment of cells (fibroblasts, keratinocytes, melanocytes, Langerhans cells), and liberation of proteases, collagenase, and elastase (Dalle Cabonare and Pathak 1992). Reduced synthesis of collagen I is a characteristic feature of chronologically aged skin and enhanced by photodamage (Varani et al. 2006). A recent study showed a decrease in contractile forces of fibroblasts after UVA irradiation and secondly the protective and restoring effects of a mixture of silanols on photoaging through the study of its effects on collagen I production and on the alterations of mechanical properties of fibroblasts provoked by UVA irradiation (Figs. 3, 4, and 5) (Robin et al. 2012). Differences in biomechanical behavior and synthesis between normal aged fibroblasts and fibroblasts from the base of wrinkles from the same patient have been shown. Fibroblasts from wrinkles synthesize lower levels of collagen I than normal aged fibroblasts (Jouandeaud et al. 2004). A recent study showed that L-poly lactic acid modified the metabolic state of wrinkle fibroblasts. A restoration of the production of collagen I and the cell migration was noted after 42 days of culture of wrinkle fibroblasts with L-poly lactic acid showing a direct effect of L-poly lactic acid on metabolic properties of wrinkle fibroblasts (Courderot-Masuyer et al. 2012). The device Glasbox also showed that wrinkle fibroblasts developed lower contractile forces than those of normal aged fibroblasts (Fig. 6). Glasbox allows a screening of actives in order to choose the best one used for its anti-wrinkle properties. In conclusion, the quantification of contractile forces of fibroblasts shows discrepancies between

1 Introduction

Skin is the largest organ of the body and performs many functions that support its protective role and survival. It helps us sense our surroundings and provides a barrier to environmental insults. Greater understanding of the mechanisms of skin development and the molecular interactions, within and between skin cells, benefits from large-scale proteomic and genomic technologies. These technologies contribute to increase our knowledge of skin diseases and injuries as well as to evaluate/develop therapeutics to treat them.

For scientist, skin is a very exciting tissue eliciting specific features: its physiology requires constant cell renewal and the involvement of different cell types that ensure simultaneously distinct functions. One may imagine easily the

number of genes expressed to maintain the homeostasis of basic functions in each cell types and the other number of genes, which are involved to respond to injuries or external stimuli.

The difference between a skin cell and other cells is mainly a matter of gene expression. Whereas all cells have the same DNA, their behavior is determined by the proteins, which are synthesized. The instructions to produce those proteins are carried by RNA, and the value of probing RNAs is well recognized to gain insight into the expression differences that define tissues, developmental stages, and diseases.

Today, to get an overview of the transcriptional state of a cell, the so-called transcriptome or cellular RNA content, two options are available: DNA microarrays and RNA-seq.

The transcriptome is dynamic and changes under different circumstances due to different patterns of gene expression. The study of the transcriptome is termed transcriptomics and is based on the evaluation of a change in gene expression that is the translation of information encoded in a gene into protein or RNA structures that are present and operating in the cell. Expressed genes include genes that are transcribed into messenger RNA (mRNA), the key intermediary in gene expression, which translates the DNA's genetic code into the amino acids that make up proteins. Some genes are transcribed into RNAs that are not translated into protein. Among them, transfer and ribosomal RNAs contribute to protein synthesis, and microRNAs (miRNAs), more recently discovered, are small noncoding RNA molecules, which function in transcriptional and posttranscriptional regulation of gene expression. It is noteworthy that, due to other posttranscriptional gene regulation events, there is not necessarily always a strong correlation between the abundance of mRNA and the related proteins. However, RNA quantification is still a useful tool in determining how the transcriptional machinery of the cell is affected in the presence of external signals (e.g., drug treatment) or how cells differ between a healthy state and a diseased state.

2 Technological and Methodological Aspects

2.1 DNA Microarrays

DNA microarrays are a high-throughput screening system based on the properties of nucleic acids such as DNA to interact/hybridize with a complementary strand of either DNA or RNA (Scheda et al. 1995). Microscopic DNA spots are attached to a small 2D surface, usually a glass slide, and each spot contains picomoles of a specific gene sequence. Thus, gene sequences of the whole genome can be represented on an array, and due to miniaturization of the processes, one slide can contain eight arrays allowing the quantification of RNAs issued from different biological samples at one time. Their density can reach roughly 60,000 DNA spots including, for each gene, similar sequences to evaluate the reproducibility as well as different sequences to detect alternative RNA species issued from a same gene (called splicing variants). Through the formation of hydrogen bonds between complementary nucleotide base pairs, each DNA sequence (known as probes) will hybridize a cDNA or cRNA (also called anti-sense RNA) sample (called target) under high-stringency conditions. This sample results from the processing of all RNAs extracted from cells into cDNAs or cRNAs labeled with a fluorophore. Using a laser scanner, the intensity of the emitted fluorescence after probe-target hybridization is detected and quantified to determine relative abundance of all RNAs between different experimental conditions (Fig. 1). Indeed, microarrays use relative quantification in which the intensity of one given DNA spot in one array is compared to the intensity of the same spot in another array. The identity of the DNA spot (the name of the gene from which the short spotted sequence is derived) is known by its position on the array. The process of measuring gene expression is called expression analysis or gene expression profiling.

The result from such analysis is typically a list of selected genes whose expression levels changed during the experiment. It is then up to

Fig. 1 Target generation for DNA microarray hybridization. RNAs are processed into cDNA or cRNA fluorescent molecules. These molecules issued from either “control condition” or “test condition” are then hybridized to spotted DNA/oligonucleotide arrays which are submitted to a laser scanner for quantification of the emitted fluorescence.

Spot *A*: no modulation between the two conditions is detected; spot *B*: expression of the corresponding gene is upregulated in the test condition; spot *C*: expression is downregulated; spot *D*: the absence of signal means that the corresponding gene is not expressed in the cells/tissues

the user to make sense of this list that means to determine the affected biological processes in which the modulated genes are involved.

2.2 RNA-seq

Another kind of transcriptome analysis is performed using the next-generation DNA sequencing (NGS) technology called RNA-seq, in which total RNA is reverse-transcribed into cDNA, converted into a sequencing library, sequenced, and analyzed (reviewed in Wang et al. 2009). NGS is a very high-throughput technique for generating millions of sequences at one time in order to analyze organisms at a genomic level. This allows the researcher to sequence and compare data at a rate previously not possible. In contrast to DNA microarrays that required the knowledge of the genome sequence, NGS will read whatever cDNA is in the sample.

One advantage of RNA-seq over microarrays is that it offers a wider dynamic range than microarrays and generally can pick up less abundant transcripts. Unlike microarrays, which report

relative expression values based on fluorescence intensity, RNA-seq can report those abundances absolutely, because it counts the transcripts that it reads. Finally, RNA-seq can reveal transcript structure and splicing and can even identify novel isoforms, gene fusions, and allele-specific variants. Indeed, the development of such high-throughput sequencing technology has increased the determination of single changes in gene sequences, termed single nucleotide polymorphism (SNP). For instance, SNPs were found to contribute to normal variation in physiological processes such as pigimentary phenotype (reviewed in Rees and Harding 2012) as well as to distinct susceptibilities to cancers such as melanoma (Kunz et al. 2013).

However, the cost of RNA-seq remains, presently, much higher than DNA microarrays and limits its use. In most cases, investigators are not interested in the absolute level of an expression but whether expression changes between two conditions. Thus, when sensitivity is not limiting, the low cost, short turn-around time, exceptional quantitative accuracy, and ease of data generation all make the glass slide microarray an acceptable choice (Peterson 2010).

2.3 Experimental Design

Since the starting biological material from which RNAs will be extracted to perform a gene expression analysis involves cells, it has to keep in mind that cell lines, primary cell cultures, 2D/3D epidermis model, or skin explants might not give similar answers. The absence of cross talks between cells, genetic backgrounds but also anatomical site differences, distinct areas of the same biopsy, and conditions of cultures have strong impacts on gene expression and, as a consequence, on protein contents.

Thus, due to the biological complexity of gene expression, the considerations of experimental design are preliminary of critical importance. It is currently admitted that replication of the biological samples, which includes independent RNA extractions, is essential for drawing conclusions. However, having in mind the cost of an array, the question is, how many replicates should be performed in order to generate statistically relevant data? Moreover, gene expression is a dynamic process, and the number of replicates will be multiplied according to different experimental conditions including kinetics and/or dose responses. In contrast to cells issued from a same batch (cells will be splitted accordingly to the number of experimental conditions required) that should provide similar data, significant differences might appear when using biopsies or cultured skin explants. As we mentioned, these differences are not artifacts and rely mainly on distinct genetic background and physiological status of skin areas among donors. Again, the number of arrays to be performed with RNAs extracted from a cohort (e.g., healthy donors and patients) should be high enough to provide statistical significance.

On the other hand, the use of commercial kits for RNA extraction and the design of commercial microarrays, which contain similar DNA spots all over the array to ensure the homogeneity of the hybridization, reduce considerably the need of technical replicates (two RNA samples obtained from each experimental unit). As reviewed by Lander (Lander 1999), good

scientific questions and high quality of RNA have more impacts on the results than the technology itself.

2.4 Data Normalization

Following microarray hybridization, the resulting data are submitted to image analyses, and background corrections are performed to provide a final expression value for each RNA transcript. Microarray data sets are commonly very large, and analytical precision is influenced by a number of variables. Statistical challenges include taking into account effects of background noise and appropriate normalization of the data. Each commercial microarray platform provides their own tools for normalization based on specific algorithms for image analyses (gridding, spot recognition of the scanned image, removal, or marking of poor-quality and low-density features) and data processing (background subtraction, determination of spot intensities, and intensity ratios). Several consortiums such as the “Microarray Quality Control (MAQC) project” conducted by the US Food and Drug Administration (FDA) and the MGED Society have developed standards and quality control metrics which allow the use of microarray data in drug discovery, clinical practice, and regulatory decision-making.

2.5 Data Analyses

Once normalization is achieved, the question is then, how to extract useful information based on gene lists issued from test and control conditions? A basic tool is provided by clustering procedures, which rely on automatic classification of the data (Hand et al. 2001). One can distinguish between unsupervised and supervised procedures. The great majority of computational methods that have evolved for microarray data analyses can all be referred to three main approaches: “class discovery,” “class comparison,” and “class prediction.” In class discovery,

the objects are not grouped into predefined classes; this approach is therefore “unsupervised.” A clustering algorithm is applied and genes and/or samples are grouped on the basis of similarity across conditions. The method starts with the definition of a distance metric to represent the distance between the genes and the samples in terms of gene expression. The algorithm then groups the objects such that the distance between objects of the same group is minimized while the distance between objects of different groups is maximized. In class comparison studies the classes are defined on the basis of a prior knowledge, independently from the expression profiles. The method is therefore “supervised” and is used to determine if the expression profiles are different between the predefined classes. The typical output of this approach is a list of genes differentially expressed genes between the classes. Commonly used methods to assess the statistical significance of differential expression are *t*-test and ANOVA. The class prediction approach is also “supervised,” as it starts from prior knowledge to group the objects of study (e.g., the biological samples) into different classes. These methods have great potentialities in clinical research, and applications have been described for risk assessment, diagnostic testing, prognostic stratification, and treatment selection (Golub et al. 1999).

Even though several strategies exist to identify genes whose expression is modulated, biologists are more confident with fold change and *t*-statistic, presumably because of their simplicity and interpretability. Obviously, identification of differentially expressed genes relies on fold changes based, for each gene, on a ratio of the intensity values of the “test” condition and those of the control (patients vs. healthy volunteers, treated patients or cells/biopsies vs. untreated controls). Several reports indicate that fold change results in more reproducible gene lists than the *t*-statistics (Witten and Tibshirani 2007) and the choice of the method used to identify modulated genes can greatly affect the set of genes that are identified (Jeffery et al. 2006).

2.6 Functional Interpretation of Microarray Experiments

In most of the cases, several hundreds of genes can be found either upregulated or downregulated. The biological interpretation of the results, which involves translating these data into useful biological knowledge, still remains a challenge. Methods leading to classify genes, according solely to their relationships with biologically relevant terms such as those defined by the Gene Ontology (GO) project, present low performances. Indeed, a classification of the genes based on the enrichment in significant biological terms fails to determine precisely how altogether gene products function within a particular biological process. Moreover, their activities, through posttranscriptional events or distinct interactions with other partners, can be different depending on cell types or tissues. It is therefore important to determine among the modulated genes those whose expression can be regulated by the same transcriptional factors or as products are involved within a given signaling pathway (Fig. 2). Several free or commercial software integrating a combination of interactive and visualization tools have been developed to identify the involvement of the gene products in molecular interactions, pathways, diseases, and processes (reviewed in Kelder et al. (2010), Hedegaard et al. (2009), Benech et al. (2007), Barrey et al. (2009, 2012), Mille-Hamard et al. (2012)). They are mainly based on text mining performed either on curated publications or on an exhaustive list of published abstracts issued from PubMed, a bibliographic database for the biomedical literature provided by the National Center for Biotechnology Information (NCBI). Their efficiency relies on the use of multidimensional correlation matrixes enabling, toward iterative queries, to integrate genes within functional networks in a specific physiologic/pathologic or tissue context (Fig. 3). Highlighting such functional networks issued from gene expression profiling leads to a better understanding of the molecular basis that sustained physiological processes, therapeutic responses, or diseases.

Fig. 2 Screenshot illustrating the correlations found between modulated genes. The software (PredictSearch™) allows the identification of biological terms co-cited with genes (*left* panel) that can be dropped into the working desktop. These terms can be selected according to p-values or the number of publications. Genes or terms, which do not present any relationships with the selected genes (*underlined in red*), are hachured.

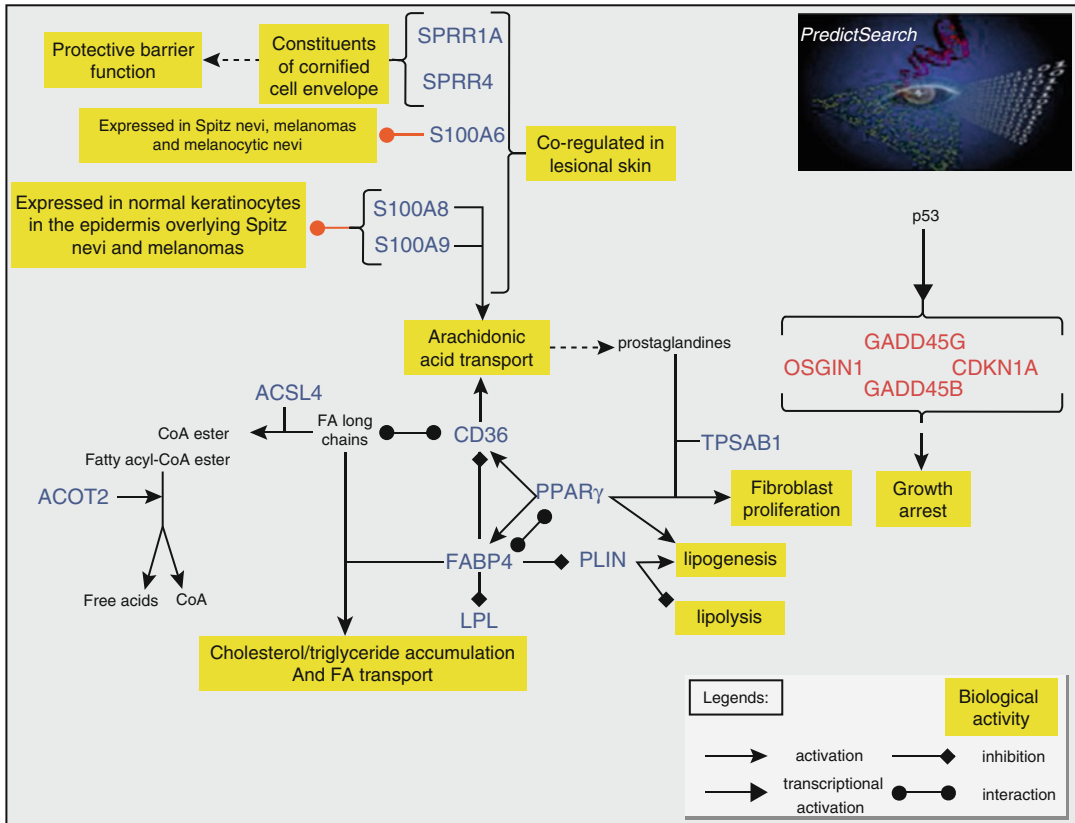

Fig. 3 Schematic representation of a genomic network. The correlation identified through the use of text mining-based computational tools is integrated into functional networks allowing to see how genes work together within

defined biological processes. Genes whose expression is upregulated or downregulated are indicated in blue or in red, respectively

3 Gene Expression Profiling and Psoriasis: A Case Study

Psoriasis is an immune-mediated disease which is associated with a chronic inflammation leading to uncontrolled keratinocyte proliferation and altered differentiation. Several DNA microarray experiments were undertaken to gain a better knowledge of this pathology (Bowcock et al. 2001; Oestreicher et al. 2001; Zhou et al. 2003). For instance, one of these studies (Zhou et al. 2003) found that 1300 genes were differentially expressed between lesional and non-lesional skin. Among them, a significant number of genes were related to immune signaling cascades and some encode chemokines, which had not been described in psoriasis before. The

functions of these chemokines, involved in the regulation of T lymphocyte and dendritic cell trafficking, support the local tissue invasion of inflammatory cells seen in psoriasis. More recently, comparison of different published lists of differentially expressed genes (DEG) has shown apparent inconsistencies based on the number of overlapping genes (Suarez-Farinas et al. 2010). Although all data were issued using the same DNA microarray platform, there are many reasons that could explain such discrepancies. Indeed, distinct array series and laboratory effects should account for the variability found among these studies. However, our own experience suggests that alternative statistical tests and choices of cutoffs contribute mainly for the low overlap between DEG. It is likely that the DEG found in common among the distinct analyses

(Suarez-Farinas et al. 2010) define the hallmarks of the pathology, keratinocyte proliferation, and inflammation. Inflammation is supported by the identification of DEG, known to be upregulated in psoriasis, such as IFN γ (interferon gamma)-regulated genes, genes encoding antimicrobial peptides, and proinflammatory proteins. Current statistical tools to analyze common features among patients lead to smooth the data and result in the loss of key elements, which account for individual differences illustrating the heterogeneity of the pathology. Thus, heterogeneous biological variations existing in psoriatic patients should explain the apparent low reproducibility of DEG detection. Several reports (Shi et al. 2008; Zhang et al. 2008) discussed these issues and concluded to the need of developing novel metrics, in particular for evaluating the reproducibility of data in terms of correlated molecular processes rather than simply counting the overlaps of genes. An intriguing possibility is that non-overlapping DEG would be more informative since they can be markers for patient stratification as well as disease severity.

Ainali et al. have recently investigated the involvement of molecular subtypes that might impact on prognosis or treatment outcomes (Ainali et al. 2012). Transcriptomic analyses of skin samples from inflamed/lesional type (PP) and non-inflamed/non-lesional tissue (PN) of 37 psoriatic patients as well as from 34 normal individuals (NN) were performed. Based on an unsupervised hierarchical clustering, they showed that as it can be expected, NN and PN co-clustered away from PP. Whereas under-expressed genes were related to immune responses and fibrotic processes, overexpressed genes encode proteins involved in keratinocyte proliferation and differentiation. Further analyses distinguished among PP two subgroups whose network clusters were enriched either in Wnt, Notch, TGF-beta, and ErbB signaling pathways or in metabolic and BMP pathways. This indicated that the two lesional psoriatic subgroups possess different functional properties, suggesting different underlying biological processes although they were clinically difficult to distinguish. The authors proposed that these differences might help explain

why some patients have a different disease course and why some respond better to therapy. However, besides the link of each of these pathways with psoriasis, potential relationships among these pathways and their potential global impact in psoriasis were not discussed.

The Wnt signaling pathways are a group of signal transduction pathways, which act either in a paracrine or autocrine manner. The three best characterized Wnt signaling pathways are the canonical Wnt pathway, the noncanonical planar cell polarity pathway, and the noncanonical Wnt/calcium pathway. The difference between them is that a canonical pathway involves the β -catenin while a noncanonical pathway operates independently of it (Rao and Kühl 2010). Wnt signaling plays a critical role in different processes including embryonic development, axis patterning, cell fate specification, cell proliferation, cell migration, and insulin sensitivity (reviewed in Nusse and Varmus). An evidence for altered Wnt signaling in psoriatic skin came from a previous gene expression profiling study showing an overexpression of the RNA encoding Wnt-5a, one member of the Wnt protein family, in biopsies from lesional psoriatic skin (Gudjonsson et al. 2010). The results suggested a shift away from canonical Wnt signaling toward non-canonical pathways driven by interactions between Wnt-5a and its cognate receptors in psoriasis. This shift might be likely related to an impaired homeostatic inhibition of Wnt signaling. The authors proposed that Wnt-5a might have a role in inducing the marked vascular changes in lesional skin, influencing epidermal proliferation, and in the amplification of inflammatory responses.

Interestingly, an intricate functional relationship between Wnt and Notch signaling during the assignment of cells to particular fates has been proposed (Hayward et al. 2008). Both signaling belong to the six major and universal transduction cellular devices providing the basic machinery for cell fate transitions and assignments that underlie embryonic development (reviewed in Martinez Arias and Stewart 2002). It has been suggested that Wnt and Notch signaling could act on alternative pathways to determine

the effectiveness of other signaling pathways that drive the specific fates, with low Notch signaling favoring Wnt signaling and vice versa (Hayward et al. 2008). Taking into account the possible involvement of β -catenin in self-renewal of different types of stem cells (Lowry et al. 2005), a fine-tuning of Wnt and Notch signaling might have a crucial impact in the dysregulation of proliferation/differentiation. In line with this hypothesis, whereas in the skin, Wnt promotes the stem cell fate, Notch promotes the “transit-amplifying” (TA) cell compartment fate (Lowell et al. 2000).

Similarly, it has been shown that Wnt and ErbB signaling crosstalk and transactivate one another in development and cancer (reviewed in Hu and Li 2010). ErbB family, implicated in the development and progression of most common epithelial malignancies, is composed of four members, ErbB1 (also known as EGFR), ErbB2 (HER2), ErbB3 (HER3), and ErbB4 (HER4), which are involved in the autocrine growth pathway (Bièche et al. 2003). ErbB1/EGFR is a cell surface receptor that binds to epidermal growth factor (EGF), transforming growth factor- α (TGFA), amphiregulin (AREG), but also epiregulin (EREG), betacellulin (BTC), and heparin-binding EGF (HB-EGF). In addition to EGFR expression, EGFR ligands such as AREG, HB-EGF, and EREG are known to be overexpressed in psoriasis lesions, and EGFR binding induces receptor dimerization and tyrosine phosphorylation leading to cell proliferation. Recent advances in the knowledge of the EGFR pathway revealed its contribution to distinct immune/inflammatory functions in the epidermis. Indeed, EGFR ligands are involved in a number of immune protective mechanisms through the expression of several antimicrobial peptides (Sørensen et al. 2003), in the induction of leukocyte attractants (Miller et al. 2005), as well as in the regulation of chemokines implicated in the massive recruitment of T cells, monocytes, and immature dendritic cells (Mascia et al. 2003). It has been proposed that the ErbB signaling pathway has to be part of TGFA-ligand-driven amplification circuit during keratinocyte response to skin inflammation (Mascia et al. 2010). Although the most common adverse effect seen with EGFR inhibition therapy

is a pronounced skin inflammatory response (Robert et al. 2005), blockers of the EGFR kinase have been suggested to be potent antipsoriasis agents (Ben-Bassat and Klein 2000). These apparent opposite observations might illustrate the ability of the EGFR-ligand system to act as a link between proliferation and innate and adaptive immune responses and support the two main hypotheses about the process that occurs in the development of the disease. Whereas the first hypothesis considers psoriasis as primarily an alteration leading to excessive growth and skin cell renewal, the second sees the disease as being an immune-mediated disorder. According to the second hypothesis, the excessive cell renewal is secondary to the production of cytokines by T cells, following their activation and migration to the dermis. The recent finding that Th17 cells carrying TCR recognizing epidermal autoantigen induce psoriasis-like inflammation (Nishimoto et al. 2013) together with the presence of different antigens possibly related to the various clinical subtypes of psoriasis (Hagforsen et al. 2007) supports the later hypothesis. It is noteworthy that disturbances in protein degradation processes in the skin can be attributed from the increased expression of genes encoding the components of the ATP/ubiquitin-dependent non-lysosomal proteolytic pathway involved in peptide processing and presentation to T cells (Bowcock et al. 2001).

If the different gene expression studies described here highlight the involvement of converging pathways (Wnt, Notch, and EGFR signaling) in psoriasis, the distinction among causes and consequences remains unclear. This is a recurrent criticism, which is made against DNA microarray technologies, generating somehow a sense of frustration. On one hand, deeper functional analyses should be systematically performed to precise the nature of the relationships existing between the differential expressed genes helping to propose a sequence of the events leading to the pathology. On the other hand, it is likely that performing gene expression comparison between skin biopsies and peripheral blood mononuclear cells from the same patients as well as between a variety of autoimmune diseases should be of particular importance. Indeed, the overall comparison, toward the

identification of correlations, might allow defining the respective contribution of the immune system, the inflammation, and the proliferation/differentiation processes.

4 SNP-Based Genetic Testing and Its Contribution in Dermatology

As mentioned previously, the RNA-seq technology provides not only a quantification of RNA molecules but allows also the sequencing of the RNA transcripts, which leads to the identification of RNA variants and in particular of SNPs. Whereas some SNPs are located in the gene sequence corresponding to the RNA transcripts, they are most commonly found in regions between genes, and therefore such SNPs can be detected only on genomic DNA. Occurring once in every 300 nucleotides on average, which means there are roughly ten million SNPs in a human genome, SNPs are the most common type of genetic variation among people.

Representing a single nucleotide difference, the presence of an SNP does not lead systematically to a change in the amino acid sequence of a protein. In contrast, missense (a change affecting the amino acid) or nonsense (introduction of a stop codon affecting the size of the protein) SNPs might have drastic consequences on the activity of a protein (gain or loss of functions). When SNPs are located within a regulatory region that controls the transcription of a gene, gene expression can be altered.

SNP detection, as part of genetic/DNA testing, is more and more used to predict individual's responses to drugs, susceptibility to environmental factors, and risks of developing particular diseases. However, without genetic consultation, the expanding use of direct-to-consumer (DTC) genetic testing by private companies to determine a person's chance of developing a disease is having an unforeseen consequence. Indeed, people, without showing any symptoms, are facing an exaggerated and inaccurate message about the connection between genetic information and disease risk. In many cases, DNA variants are only

slightly associated with risk, or there is little good evidence to support any association. Moreover, as we have described in psoriasis, the risk to develop diseases depends on complex interactions between genes and lifestyle accounts for much of our susceptibility to diseases. Even diseases caused by a single gene, such as cystic fibrosis, are influenced by other genes that can affect the degree of severity.

In addition to RNA-seq, various analytical methods, including DNA sequencing, are available to discover or to detect SNPs. Several bioinformatics databases exist helping interpretation and analysis or describing associations between polymorphisms and diseases, and genome-wide association studies (GWASs) are commonly used for polygenic diseases such as type 2 diabetes, obesity, and Crohn's disease. GWASs scan DNA from a large panel of patients with a particular disease to look for SNPs. Databases resulting from the Human Genome Project and the International HapMap Project contain the reference human genome and maps of common genetic variation in large populations ([National Institutes of Health](#); International HapMap Consortium 2003). Thus, the potential impact of SNPs can be deduced by determining whether homozygous or heterozygous SNPs are more frequent in the affected patients than in controls from an ethnically similar population.

Different approaches of genetic testing have been undertaken to study dermatological diseases (reviewed in Kwon et al. 2013). In addition to the characterization of several psoriatic susceptibility loci including human leukocyte antigens (HLA) and PSORS (Saneczko et al. 1997; Jullien and Barker 2006; Al Robaee 2010), large-scale GWASs have identified polymorphisms within genes encoding cytokines with functional relevance to psoriasis (Pietrzak et al. 2008). Even though some of these SNPs present a good discriminant power and thus can be used for psoriasis prediction (Fang et al. 2011), they are not necessarily causal markers for the disease.

As for gene expression, GWAS fails to distinguish among causes and effects, and there is a considerable interest in pathway analysis. Several approaches for testing associations with pathways

have been proposed (reviewed in Zhao et al. 2011). Furthermore, RNA-seq technology or combination of gene expression profiling and GWASs should reveal the biological impacts of particular SNPs within patient subgroups. It has been shown that the risk variant in IL12B associates with its increased expression and predisposes to stronger Th1 polarization (Johnston et al. 2013). These effects result from a deviation of the local inflammatory environment toward IL12/IFN γ at the expense of IL-23/IL-17 responses. In a recent report (Swindell et al. 2013), the same group, analyzing expression patterns in psoriatic lesions from 163 patients, has shown that most increased DEG can be explained by keratinocyte activity and inflammatory cell infiltration. They identified subgroups that differ depending on inflammatory cell infiltration and IFN- γ activity. Moreover, the differences allow differentiating between etanercept responders and nonresponders, providing a means to predict treatment outcomes with anti-TNF therapy. It has been proposed that the patient-specific differences rely, at least in part, on the developmental context for each psoriasis lesion, which is likely shaped by an integration of genetic and environmental signals.

5 Conclusion and Perspectives

The progress made in identifying the basic variation present in human brings a number of exciting opportunities and challenges. Gene expression, genotyping of SNPs, and copy number variations have become extremely important to researchers for understanding dermatological disorders and molecular mechanisms. These technologies highlight the variability occurring between individual patients, probably on the basis of their age, ethnicity, sex, genetics, skin types, and environmental influences. Undoubtedly, combined analysis of global gene expression, DNA variation, and functional approaches through the development of computational tools will take advantage of the increasing enrichment of bioinformatics databases. At a nexus in medical history, the challenge is to learn how to use

the acquired repository of information to change the course of disease management. Dermatologists, which have an easy access to biological samples issued from their patients, have to be at the forefront of this history. Indeed, according to the dermatology advances toward personalized medicine, transcriptomic and genetic investigations will be part of the personalized dermatology practice of the near future. As qualified counselors, they would have to warn the public about the possible risks of direct-to-consumer genetic testing proposed on the Internet and the potentially misleading or oversimplified explanations of the results.

Skin surface pH • Glass planar electrode • Workplace measurement • Occupational skin diseases • Stratum corneum

The outer surface of the skin is coated with a co-mixture of aqueous sweat and oily sebum that together help to maintain skin surface pH. Among its functions, skin surface pH promotes maintenance of the skin barrier integrity, regulates epidermal barrier homeostasis, and maintains microbial flora balance (Ali and Yosipovitch 2013). In occupational settings, the skin is potentially exposed (sometimes simultaneously) to various chemical, physical, and mechanical stressors. These exposures may alter the skin surface pH which is problematic for several reasons. First, changes in skin surface pH can expedite the dissolution and/or partitioning of many chemicals thereby increasing their bioaccessibility on the skin (Collins 1957; Hemingway and Molokhia 1987). Secondly, skin surface pH will influence the formation of water soluble complexes between dissolved ions and sweat constituents, which, in turn, influences their interactions with skin proteins and cellular constituents (Stefaniak et al. 2014). Finally, alterations of skin surface pH can impair the barrier properties of the stratum

corneum, thereby making it easier for chemicals to penetrate and enter the body.

Measurement of skin surface pH is usually performed in highly controlled clinical settings (Parra and Paye 2003). However, the ability to measure skin surface pH in nonclinical settings such as the work environment offers many advantages. Importantly, both the amount of contaminant on the skin and the pH of the skin surface can be assessed almost simultaneously, thereby providing a more accurate characterization of the skin barrier condition at the time of exposure (Du Plessis et al. 2013). Knowledge of skin surface pH can also be used to identify opportunities for implementation of control strategies to protect workers, e.g., use of chemical-resistant gloves by workers with acidic skin pH to minimize contaminant dissolution/partitioning. Additionally, the influence of activities such as hand washing with an alkaline soap on skin surface pH can be documented to provide feedback to managers and workers on how specific tasks can change the skin barrier properties. In this chapter, practical guidance for measurement of skin surface pH in nonclinical settings is described. Details of the skin surface acidity and instruments for measurement of skin surface pH are described in ► Chap. 12, “Measurement of Skin Surface Acidity,” respectively.

1 Apparent Skin Surface pH

The universal method for measuring skin surface pH is the glass planar electrode connected to a voltage meter. In chemistry, pH is defined as $-\log[\text{H}^+]$ concentration of a pure aqueous solution. However, the skin surface film is not pure water; rather, it is a mixture of aqueous sweat, sebum lipids, and cellular degradation products (Rippke et al. 2002). As such, the skin surface pH is not a measure of H^+ ion concentration, but is a measure of H^+ ion release from amphiphilic free fatty acid lipids into water that is applied to the skin with the glass planar electrode. More accurately, the pH measured on the skin surface

should be referred to as the *apparent skin surface pH* (Parra and Paye 2003).

2 Factors Influencing Skin Surface pH

Several endogenous, exogenous, and environmental factors relevant to work environments may affect skin surface pH (Table 1). In general, values of skin surface pH vary among anatomical positions (e.g., forehead versus forearm) and within locations (e.g., T- and U-zones of the face) (Ehlers et al. 2001a; Kim et al. 2006; Kleesz et al. 2012; Kobayashi and Tagami 2004; Lee et al. 2013; Luebberding et al. 2013a, b, 2014; Marrakchi and Maibach 2007; Youn et al. 2013; Zlotogorski 1987) though not all investigators have observed differences (Pratchyapruit et al. 2007; Schreml et al. 2012; Treffel et al. 1994). Data on the influence of gender on skin surface pH are not fully understood; some studies report differences between sexes (Ehlers et al. 2001a; Kim et al. 2006; Luebberding et al. 2013a; Youn et al. 2013; Jacobi et al. 2005; Man et al. 2009; Ohman and Vahlquist 1994) but others do not (Zlotogorski 1987; Dikstein and Zlotogorski 1994; Wilhelm et al. 1991). Data are conflicting on the role of ethnicity in skin surface pH (Lee et al. 2013; Berardesca et al. 1998; Grimes et al. 2004; Warrier et al. 1996; Wesley and Maibach 2003). Skin diseases such as atopic dermatitis, urticaria, and irritant contact dermatitis may alter skin surface pH in adults (Cork et al. 2009; Jungersted et al. 2010; Kezic et al. 2012; Knor et al. 2011; Ohman and Vahlquist 1998; Schmid-Wendtner and Korting 2006; Ye et al. 2014). Some studies indicate that skin surface pH varies during the day, with minimal values often observed in the evening or early morning (Ehlers et al. 2001b; Latreille et al. 2004; Le Fur et al. 2001; Yosipovitch et al. 1998), which has implications for shift work. Age influences skin surface pH, with values becoming less acidic after ages 70–95 years (Luebberding et al. 2014; Marrakchi and Maibach 2007; Zlotogorski 1987; Schreml

^a+ = has an influence; ± = inconclusive data

et al. 2012; Man et al. 2009; Wilhelm et al. 1991; Dikstein et al. 1984; Sato et al. 2014); however, these ages are generally outside of normal working years.

Exogenous factors that influence skin surface pH and are frequently encountered in the workplace include hygiene practices (i.e., frequency, use of soaps and detergents), use of topical products (i.e., lotions, barrier creams, and cosmetics) and occlusion (e.g., from use of protective garments). Of high relevance is skin hygiene, which may involve harsh soaps, especially in dirty and greasy workplaces, or frequent hand washings among healthcare workers (Jungbauer et al. 2004; Keegel et al. 2012) and food preparers (Steiner et al. 2011). Alkaline soaps tend to raise skin surface pH, whereas acidic soaps tend to cause only a slight increase or even a lowering of skin surface pH (Duncan et al. 2013; Korting et al. 1987, 1990, 1991; Moldovan and Nanu 2010). The effects of soaps, synthetic detergents, and topical products is often transient with skin pH returning to baseline within 2 h (Duncan et al. 2013; Korting et al. 1987; Moldovan and Nanu 2010) though recovery may

be incomplete up to 12 h after washing (Grunewald et al. 1995; Lambers et al. 2006). Alcohol-based hand rubs used by healthcare workers may lower skin surface pH, though results are inconsistent (Ahmed-Lecheheb et al. 2012). Use of occlusive disposable gloves for just 2 h can increase skin surface pH for up to 4 h after removal (Rippke et al. 2002). Exercise is known to increase skin pH which may be relevant for non-sedentary jobs such as landscapers and construction workers (Luebberding et al. 2013c; Wang et al. 2013).

The influence of season on skin surface pH is unclear (Abe et al. 1980; De Paepe et al. 2009; Galzote et al. 2014), but investigators should be aware of it as a factor, especially when studying outdoor workers.

3 Measurement Protocol for Nonclinical Settings

As described in Sect. 2, many factors encountered in workplace settings can influence skin surface pH. Hence, it is crucial that any protocol

for a workplace study is well designed to enable the specific research question to be answered. This protocol must include clear instructions to participants regarding behaviors that may influence measurement results. To facilitate the development of a study protocol, a checklist that captures many of the considerations for workplace measurement of skin surface pH is provided in ► [Chap. 94, “Biometrology Guidelines for the In Vivo Assessment of Transepidermal Water Loss and Skin Hydration in Nonclinical Settings.”](#)

3.1 Workplace Measurement Considerations

When designing a study protocol, it is crucial to consider real-world limitations that can be encountered in workplace settings. For example, clinical guidelines recommend that skin surface pH measurements should be made 2–3 h after washing with tap water, 5 h after washing with synthetic detergents, and 10 h after washing with alkaline soaps (Parra and Paye 2003). If ointments, body lotions, and other topical products are applied to the measurement location, clinical guidance is to wait 12 h before measurement (John 2006). Realistically, such long lag times are generally not possible during a standard 8 h work shift, particularly among professions that engage in wet work such as healthcare workers and food handlers who frequently wash their hands or cosmetologists who frequently handle lotions, dyes, and other products (Jungbauer et al. 2004; Steiner et al. 2011; Lysdal et al. 2012). Hence, measurements in nonclinical settings should be made before washing or application of ointments and lotions if feasible (e.g., prior to the start of a work shift and before the end of a shift). If measurements cannot be made before washing or application of topical products, the researcher should be aware of the influence of water, soaps, etc. on skin surface pH (Table 1) in data interpretation. Finally, no measurements should be made on skin that is inflamed or adjacent to such areas (Stefaniak et al. 2013).

Use of personal protective garments such as coverall suits and gloves made of highly occlusive material is commonplace in work environments (Jungbauer et al. 2004; Lysdal et al. 2012). Even garments made from natural textiles (e.g., cotton) can be occlusive in work situations. Given that even short-term use of occlusive gloves can lead to elevated skin surface pH for hours after use (Rippke et al. 2002), researchers must observe whether a study participant wore protective garments (gloves, coveralls, elastomeric facepiece respirators, etc.) over an anatomical measurement position and document the event when reporting results.

3.2 Measurement Environment

Ideally, a study participant should be acclimated to the measurement environment for at least 20 min prior to determination of skin surface pH (Parra and Paye 2003). Workplace studies are challenging because measurements are usually made prior to, during, and/or after a worker's shift. Measurements performed before or after a work shift place a burden on the employee who must arrive at work early or stay later, but he or she may not be compensated for their time. Measurements made during a work shift place a burden on employers in terms of lost productivity, staffing reassignments, and paid wages. Hence, it may not be feasible for a worker to acclimate for 20 min plus time for measurements, especially if multiple measurements are to be made throughout a work shift.

In clinical settings, ambient conditions for measurement of skin surface pH are temperature of 20–22 °C and relative humidity of 40–60 % (Parra and Paye 2003). In workplace studies, researchers may not have full control over the ambient temperature and humidity levels where measurements are to be performed because doors and windows may be open (or closed) to cool (or heat) the workspace. As such, for workplace studies every effort should be made to perform measurements at 20–22 °C and relative humidity of 40–60 %; however, if these conditions are not possible, the investigator should control and

characterize the measurement atmosphere as far as reasonably practical and provide a detailed description of the conditions when reporting results.

3.3 Measurement of Skin Surface pH

It is important that the glass planar pH electrode is handled and used in accordance with the manufacturer's instructions. Prior to use, the electrode should be calibrated using at least a two-point calibration with buffers that span the expected skin surface pH values (e.g., pH 4–7) and recalibrated as specified by the manufacturer or verified periodically using standard buffers. The pH electrode and the meter should be equilibrated in the same environment in which measurements will be taken for at least 20 min prior to use (Parra and Paye 2003).

The skin surface at the measurement location should be clean and free of cosmetics and lotions or other topical products. If necessary, the skin can be cleaned using a clean, dry, oil- and lotion-free tissue paper. Water alone can alter pH and should not be used to clean the skin at the measurement location (Lambers et al. 2006). Typically, the electrode surface is moistened with 20 μL of distilled water prior to placing it on the skin (Parra and Paye 2003); however, Lambers et al. (2006) report that water volumes up to 100 μL do not influence measurement results. The pH electrode should be held at a right angle to the skin with gentle pressure to ensure optimal contact (Ehlers et al. 2001b); avoid applying excessive pressure which can affect the volume of liquid at the interface of the electrode and skin (Parra and Paye 2003). Measurements should be recorded when a stable signal (as defined by the instrument manufacturer) is achieved.

Three sequential measurements should be made at the same anatomical position, with a 5 s lag time between measurements, and the results averaged. To reduce any possible effect of electrode contamination on skin pH measurements, it should be rinsed with deionized water periodically (Ehlers et al. 2001b). All measurements at

a given anatomical position should be made before moving to the next position (Stefaniak et al. 2013). If repeat measures of skin surface pH will be made at a given anatomical position (e.g., pre- and post-work shift), record both sets of measurements at the same position to reduce error. Digital photography is useful for documenting the anatomical positions to ensure consistency in measurements. If simultaneous assessment of skin exposure to a contaminant is also a study goal, the area of pH measurement should be as close as possible to the area monitored for skin exposure without confounding the respective measurements. Finally, if other biophysical skin measurements are to be made, Kottner et al. (2014) recommend determination of transepidermal water loss before determination of skin surface pH or stratum corneum hydration to avoid measurement bias.

Measurements obtained by different researchers may introduce variability to the results (because they might use different pressures or probe angles); therefore, the same person should perform all measurements. Report skin pH values with precision of ± 0.1 units. Between measurements, the electrode and meter should be stored in accordance with the manufacturer's instructions.

4 Data Interpretation and Reporting

The factors that influence skin surface pH (Table 1) illustrate the challenges associated with measurements in workplace settings with myriad exposures. Additionally, consensus is lacking in regard to reference values for skin surface pH of normal or diseased skin. As such, reporting absolute values of skin surface pH can be problematic, especially when comparing data among studies. Therefore, measurement results should be reported in relative terms, such as percent change over a work shift. All measurement results for a given set of conditions should be expressed with both a measure of central tendency (e.g., arithmetic mean of three repeat measurements) and variability (i.e., standard deviation or percentiles). If the aim of a study warrants use of a control

group, the volunteers should be matched to workers with respect to relevant endogenous, exogenous, and environmental factors and measurements made in a similar environment with the same instrumentation to ensure consistency in data collection.

A minimum data set should be reported with any study results, including: (1) relevant endogenous (anatomical site, skin health at time of measurement, date, time, etc.), exogenous (skin hygiene, use of topical products, use of occlusive garments at measurement locations, etc.), and environmental (season, geographical location) factors; (2) measurement conditions (acclimation time and conditions for equipment and participants, pH electrode calibration, number of measurements, etc.); (3) measurement results in relative terms (percent change) accompanied by a measure of central tendency and variability; and (4) pertinent deviations from the study protocol and the measurement guidance provided herein.

1 Introduction

The most important functions of the skin are to prevent loss of fluids from within the body to the environment and to prevent entry of xenobiotic substances and infectious agents into the body (Zhai and Maibach 2002; Agache 2004; Proksch et al. 2008). This barrier function resides primarily in the epidermis and consists of a physical and biochemical barrier (Proksch et al. 2008). Corneocytes and lipids of the stratum corneum (SC) form the physical barrier, while the slightly acidic hydro-lipid film on the skin surface serves as a complementary biochemical barrier (Korting et al. 1990; Ohman and Vahlquist 1998). Skin barrier functionality and skin appearance are maintained by the interaction between transepidermal water loss (TEWL), SC hydration, sebum levels on the skin, and skin surface pH (Roskos and Guy 1989; Wilhelm et al. 1991).

TEWL and skin hydration have been widely used as surrogate markers for assessing skin barrier function (Zhai and Maibach 2002; Pirot and Falson 2004; Rogiers 2001; Levin and Maibach 2005; Tupker and Pinnagoda 2006; Rawlings 2006; Darlenski et al. 2009). The most prominent finding is elevated TEWL in a number of skin diseases (e.g., atopic dermatitis, eczema, and psoriasis) and in experimental studies in which solvent and detergents are applied to the skin (Proksch et al. 2008; Darlenski et al. 2009). Furthermore, elevated TEWL values in a disturbed skin barrier are frequently correlated with low hydration of the SC (Proksch et al. 2008).

In occupational environments, damage to the skin and a compromised skin barrier, although not necessarily visible, commonly occur as a result of physical/mechanical and chemical damage. Evidence suggests that a compromised skin barrier may increase dermal penetration and absorption of chemicals and of larger substances (e.g., particulates and proteins), which normally cannot effectively penetrate intact skin (Kezic and Nielsen 2009). Scrubbing, friction, or abrasion may partially or completely remove the SC and thus disrupt the skin barrier by exposing the epidermis to the environment (Fluhr et al. 2008; Kezic and Nielsen 2009). Organic solvents increase skin permeability by extracting and altering the structure of intercellular lipids from the SC, while desmosomes may also be damaged (Kezic and Nielsen 2009). Surfactants (detergents) interact with skin lipids and proteins leading to disorganization of extracellular lipids, reducing corneocyte cohesion and decreasing skin hydration (Kezic and Nielsen 2009; Nielsen 2005). Occlusion created by prolonged wearing of protective clothing, in particular impervious gloves, prevents evaporation of water thereby leading to accumulation of water in intercellular spaces across the SC and swelling of corneocytes (Zhai and Maibach 2002). This swelling disrupts SC lipid bilayers leading to enhanced skin permeation of substances due to the lower diffusion resistance provided. Prolonged contact

with water, i.e., wet work, has a similar effect as that of occlusion on the SC (Kezic and Nielsen 2009).

A number of studies have been published in which changes in skin barrier function in occupational settings have been investigated. The findings of these studies are beyond the scope of this chapter, yet the most notable occupational settings were (contaminants, where applicable, indicated in brackets) (i) metal industry (water-soluble oils and mineral oils) (Coenraads et al. 1986; Goh and Gan 1994; Berndt et al. 1999; Kütting et al. 2010); (ii) health care, in particular nurses (Smit et al. 1994; Hachem et al. 2002); (iii) hairdressers (wet work and chemicals in hair products) (Smit et al. 1994; John et al. 2000; Packham et al. 2005); (iv) rayon manufacturing (carbon disulfide and sulfuric acid) (Chou et al. 2004); (v) manufacturing industry (ultralow humidity) (Chou et al. 2005); (vi) food industry (wet work) (Packham et al. 2005; Bauer et al. 2007); (vii) daycare/nurseries (wet work) (Packham et al. 2005); (viii) construction industry (cement containing chromium) (Chou et al. 2008); and (ix) base metal refineries (sulfuric acid during refining of nickel and cobalt) (Du Plessis et al. 2010, 2013).

Guidelines for the *in vivo* measurement of TEWL and skin hydration in highly controlled clinical settings are well known and widely used (Rogiers 2001; Pinnagoda et al. 1990; Berardesca 1997), and guidelines for the measurement of TEWL, skin hydration, and skin surface pH in nonclinical settings were published recently (Du Plessis et al. 2013; Stefaniak et al. 2013). “Real-life” occupational environments may be more variable and difficult to control, as a result of numerous and often uncontrollable factors, which presents unique measurement challenges not encountered in clinical settings. This chapter presents these published guidelines, as well as amendments since publication thereof, for the *in vivo* measurement of TEWL and skin hydration in nonclinical settings such as the workplace.

2 Instrumentation for Measurement of TEWL and Skin Hydration

TEWL can be measured in vivo by using a closed-chamber or an open-chamber method. The measurement principles of these instruments are described in ► [Chap. 108, “Transepidermal Water Loss”](#), but the reader may also consult Pirot and Falson (2004), Tupker and Pinnagoda (2006), and Imhof et al. (2009, 2014).

The open-chamber measurement method is widely used in clinical and experimental research and is the standard against which newer closed-chamber methods are judged (Imhof et al. 2009; Fluhr and Darlenski 2014; Imhof et al. 2014). However, the open-chamber method has a number of limitations, such as being easily influenced by disturbances in ambient air movement, calibration inconsistencies, angular dependence, temperature dependence, contact pressure dependence, and relatively long measurement times of approximately 30 s (Imhof et al. 2014). In contrast, closed-chamber methods are not influenced by ambient air movements, and the overall measurement time of unventilated-closed chamber instruments is very short (<10 s) (Nuutinen 2006; Imhof et al. 2009), making them useful for measurements in nonclinical settings. Some manufacturers claim that measurement with closed-chamber-type instruments is not affected by the probe angle, but several studies reported an angular dependence (Raynor et al. 2004; Cohen et al. 2009).

The commercially available open-chamber instruments are the DermaLab (Cortex Technology, Hadsund, Denmark), Evaporimeter (ServoMed, Stockholm, Sweden), and Tewameter (Courage and Khazaka, Cologne, Germany). The AquaFlux (Biox Systems Ltd, London, United Kingdom) is a condenser-type closed-chamber instrument, while the AS-CT1 (Asahi Biomed Company Ltd, Yokohama, Japan) and the VapoMeter (Delfin Technologies, Kuopio, Finland) are unventilated closed-chamber

instruments that are commercially available (Du Plessis et al. 2013).

Skin hydration can be measured based on three principles, namely, capacitance, conductance, and impedance (Barel and Clarys 2014). These principles are addressed in ► [Chap. 15, “Measurement of Skin Surface Hydration”](#). Commercially available instruments based on conductance as measurement principle are the Corneometer (Courage and Khazaka, Cologne, Germany) and the MoistureMeter SC (Delfin Technologies, Kuopio, Finland). The ASA-M2 (Asahi Biomed Company Ltd, Yokohama, Japan) and Skicon (ISBS Co Ltd, Hamamatsu, Japan) are based on capacitance as a measurement principle, while the DermaLab Moisture Unit (Cortex Technology, Hadsund, Denmark) and Nova Dermal Phase Meter (Nova Technology Corporation, Portsmouth, NH, USA) are based on impedance as a measurement principle (Du Plessis et al. 2013).

3 Guideline Protocol for Measurement of TEWL and Skin Hydration in Nonclinical Settings

The aim of this protocol is to provide guidelines and best practices for measurement of TEWL and skin hydration in nonclinical settings by recognizing and accounting for, and to the extent possible, eliminating, or minimizing the influences of endogenous-, exogenous-, environmental-, and measurement/instrumentation-related factors (Table 1).

3.1 Informed Consent

Informed consent must be obtained from each participant (worker) in accordance with the human subject policy of the institution(s) governing the study prior to performing any measurements. The informed consent must provide

Table 1 Influence of endogenous-, exogenous-, environmental-, and measurement/instrumentation-related factors on TEWL and skin hydration (Adapted from Du Plessis et al. 2013; Fluhr and Darlenski 2014)

	TEWL	Skin hydration
Endogenous factors		
Age	Yes ^a	Yes
Gender	No	No
Ethnicity	Controversial	Controversial
Anatomical position	Yes	Yes
Skin temperature	Yes	Yes
Sweating	Yes	Yes
Circadian rhythm	Yes	Controversial
Skin health	Yes	Yes
Exogenous factors		
Skin washing and wet work	Yes	Yes
Solvents/surfactants	Yes	Yes
Occlusion	Yes	Controversial
Skin damage	Yes	Yes
Intake of vasoactive substances (drugs, caffeine, nicotine)	Yes	Yes ^b
Environmental and measurement factors		
Air convection/movement	Yes/no ^c	Yes
Ambient temperature	Yes	Yes
Relative humidity	Yes	Yes
Direct light	Yes	
Season	Yes	Yes

^aBaseline TEWL is independent of age among persons in their working years, slightly lower >60 years

^bSmoking only

^cClosed-chamber instruments are not influenced by air convection or movement, while open-chamber instruments are

precise information on the purpose(s) of the study, a description of the procedures to be performed, the participant's responsibilities, risks and benefits of participation, and any other pertinent information relevant to the study.

3.2 Instructions to Participants

After obtaining informed consent, precise instructions should be communicated to participants regarding acceptable and permissible hygiene practices (skin washing), the use of topical products (i.e., cosmetics, lotions, and barrier creams), and ingestion of potential vasoactive substances such as caffeine (including beverages), nicotine (smoking), and/or drugs (medicines) prior to measurements (Rogiers 2001; Brandner et al. 2006; Crowther et al. 2008; Fluhr and Darlenski 2014).

3.3 Instruments

For TEWL measurements in nonclinical settings, such as workplaces, it is highly recommended that a closed-chamber-type instrument be used because this design is not influenced by air movement and has short measuring times, and some are small battery-operated devices making them easily portable (Imhof et al. 2009, 2014). The two most prominent closed-chamber TEWL instruments in literature are the AquaFlux and VapoMeter. They differ in measurement principle, concept, and design with the aforementioned using a condenser-chamber method of measurement in a benchtop, mains-powered design. The VapoMeter uses an unventilated-chamber method of measurement in a small self-contained, battery-powered design. Their performance characteristics, described by Imhof et al. (2014), differ as

well with the AquaFlux having higher accuracy, sensitivity, and repeatability, with speed of measurement (short measurement time, i.e., 7–16 s) and mobility as the main features of the VapoMeter.

If, however, an open-chamber TEWL instrument is to be used in nonclinical settings, the use of a draft shield will help to minimize the effect of air movement on measurements to a great extent.

One manufacturer of an open-chamber-type TEWL instrument recommends measurement of skin temperature prior to measurements as Rogiers (2001) found that a difference between skin temperature and probe temperature influences TEWL values. The TEWL probe heater is set at the skin temperature measured, and the TEWL probe/instrument is heated to a temperature corresponding to that of the skin before making measurements.

In addition, an ambient thermometer and relative humidity (RH) meter are required to record ambient temperature and RH.

3.4 Preparation, Handling, and Storage of Instruments

The instrument should be turned on at least 15–30 min prior to taking measurements in the area in which actual measurements will be taken (Pinnagoda et al. 1990; Tupker and Pinnagoda 2006; Imhof et al. 2009, 2014). If the instruments are to be used intermittently during the day, it should not be switched off between measurements (Tupker and Pinnagoda 2006). However, battery-operated instruments are designed to switch-off automatically after a few minutes of nonuse to prolong battery life. Prior to and during measurements, the TEWL probe, in particular the VapoMeter, should always be handled with an insulated glove as holding the probe causes an increase in the temperature of the probe through heat transfer and subsequently influences TEWL readings (Rogiers 2001; Imhof et al. 2009, 2014; De Paepe et al. 2005).

For hygienic purposes, the probe head must be wiped with an alcohol-soaked tissue after completion of measurements on a study participant in order to prevent possible transfer of infections between participants. Another alternative is the use of single-use disposable shields, which are available from some manufacturers. It should be noted that the use of shields increases the distance between the skin and probe sensors and the use thereof should be reported.

Between uses, the instruments should be cleaned and stored in accordance with the manufacturer's instructions. In general, this implies cleaning of the instrument/probe with a soft tissue or an alcohol-soaked tissue to remove excessive dirt and storage in a clean dry place with temperature and RH resembling that of the usual environment when used (Du Plessis et al. 2013).

3.5 Calibration of Instruments

Only calibrated TEWL and hydration instruments should be used for measurements. Two types of calibration could possibly be performed, namely, manufacturer calibration and prior to use calibration (not applicable to all instruments). Manufacturer calibration requires that the instrument be sent to the manufacturer for calibration at specified predetermined intervals, usually once a year. Biannual or quarterly manufacturer calibration is recommended, if practicable, with very frequent use. Calibration prior to use should be performed at regular intervals as specified by the manufacturer. The procedures of prior to use calibration may vary between manufacturers and should also be done in accordance to the instructions provided by the manufacturer. Due to the simplicity of some calibration procedures, calibration could easily be performed daily. For further quality control purposes, and if practicable, prior to use calibrations could be verified after performing a set number of measurements on a specific day or in between prior to use calibrations (Du Plessis et al. 2013).

Two flux calibration methods, as described in detail by Imhof et al. (2009), are currently in use

for TEWL instruments, namely, the more commonly used wet-cup method (for open- and closed-chamber-type instruments) and a new droplet method (for instruments capable of recording continuous flux, but not unventilated closed-chamber-type instruments).

For skin hydration instruments, a two-point (low- and high-value) *in vitro* calibration check on cellulose and filter pads should be performed prior to use and during periodic verifications of calibration (Du Plessis et al. 2013; Barel and Clarys 2014).

3.6 Measurement of TEWL and/or Skin Hydration

Prior to measurement of TEWL and/or skin hydration, a participant should be acclimated to the measurement environment to avoid errors caused by environmental temperature or sweating. EEMCO's clinical study guidelines recommend an acclimation period of least 15–30 min at an ambient temperature (20–22 °C) and relative humidity (40–60 %) prior to measuring TEWL (Rogiers 2001; Pinnagoda et al. 1990) and at least 20 min for skin hydration (Berardesca 1997). More recently, Fluhr and Darlenski (2014) suggested ambient temperatures as low as 18 °C, but not exceeding 21 °C for TEWL measurements with an acclimation period of 20–30 min. Barel and Clarys (2014) state a constant ambient temperature of 20–21 °C as ideal for skin hydration measurements.

In the workplace, it may not always be possible for a worker to leave their shift long enough to acclimate for 20–30 min plus time for measurements. Workers may also be unwilling to have measurements performed in their own time (before, during, or after a shift) because of personal reasons. An acclimation period as long as practicably possible, but preferably at least 20 min, is recommended. In nonclinical settings, such as workplaces, the environmental conditions recommended for clinical studies may not be readily achievable. In experiences gained from past workplace assessments, researchers may be provided a space for testing where there is little

control over the ambient temperature, humidity, and air movement. Hence, it is recommended that measurement conditions be controlled and characterized (reported) as far as reasonably practicable. Measurements during extreme conditions of cold, heat, or RH should be avoided (Du Plessis et al. 2013).

The anatomical position(s) to be measured should be exposed to ambient air for at least 10 min prior to measurement (Berardesca 1997), but ideally for a period corresponding to the acclimation period in the measurement environment.

Application of topical products, washing, occlusion, smoking, and ingestion of caffeinated beverages may influence TEWL and skin hydration values (Du Plessis et al. 2013). Ingestion of caffeinated beverages should be avoided at least 3 h prior to and during the work shift (Crowther et al. 2008). Topical products should not be applied to the intended measuring area and should be avoided for at least 12 h prior to participation/measurement (John 2006; Fluhr and Darlenski 2014). However, in occupational settings such as health care, the food industry, and cosmetology, where frequent (hand) washing or use of topical products and lotions occurs, it is not feasible. The same applies to the use of barrier creams in the workplace. Therefore, the use of any topical product or lotion should be noted according to the type used, frequency of application, and time of last application (Du Plessis et al. 2013). In workplace studies, acute changes in TEWL and skin hydration during or for the duration of a work shift while following normal working procedures are of interest. Because of the acute effects of washing on TEWL and skin hydration (Voegeli 2008), it is recommended that measurements be made before washing or application of topical products and lotions. Wearing of highly occlusive personal protective clothing such as gloves and coverall suits made of various types of textiles and materials is common practice in many work environments. As such, it is important to verify whether the worker (participant) wore protective clothing over an anatomical position and, if so, to record information regarding the type of protective clothing, frequency of use, duration of use, time between last use, and measurement.

No measurement should be made on clinically inflamed or diseased skin or in very close proximity to such a position. If the measurement position is compromised by disease or injury, a nearby position may be used, but should be recorded as such. If a nearby position cannot be identified, the participant should rather be excluded from the study (Du Plessis et al. 2013).

The recommended anatomical position for TEWL and skin hydration measurements in clinical studies is the volar forearm away from the wrist (Berardesca 1997; Rogiers 2001), even though other anatomical positions have also been measured. In the workplace TEWL and skin hydration measurements should be made on anatomical positions relevant to the activities and tasks of workers. Even if another anatomical position is of interest, it is still highly recommended to measure TEWL and skin hydration at the mid-volar forearm as a reference. A complicating factor in all likelihood will be the use of personal protective clothing and respirators, leaving in many instances the volar forearm occluded and only the neck and cheeks not occluded. In these instances, study goals must be considered to determine the most appropriate anatomical positions to be measured, and if measured, factors influencing measurement values should be noted and considered when data is interpreted (Du Plessis et al. 2013). For skin hydration measurements in particular, the presence of body hair may interfere with the sensor-skin contact interface, which may influence measured values (Berardesca 1997). Measurement on extremely hairy positions should be avoided, or, alternatively, hair should be removed, but the skin should be allowed to recover before measurements (Du Plessis et al. 2013).

A horizontal probe angle is of particular importance when using an open-chamber-type TEWL probe as not to disturb natural air convection. External air movements do not interfere with measurements of closed-chamber-type TEWL instruments, but natural convection can also occur inside their measurement chambers. Therefore, angular dependence may also be an issue (Imhof et al. 2014). It is suggested that all TEWL measurements be done on horizontal skin surfaces

irrespective of the type of instrument used (Imhof et al. 2009, 2014). If measuring the cheek or neck, the study participant must lie down, if possible, or adjust his body position to ensure a horizontal measurement area.

Contact pressure between the probe head and skin influences measurements made using open-chamber-type TEWL probes (Gabard and Treffel 2004; Tupker and Pinnagoda 2006) which can be ascribed to probe head design (Imhof et al. 2014). Closed-chamber-type TEWL instruments have minimal sensitivity to contact pressure, but timing of skin contact is of more importance as ambient temperature and RH are measured shortly before skin contact is made. For both types of TEWL instruments, adequate (light) constant pressure should be applied on the probe to ensure leak-free contact between the probe and skin and that the probe does not slide over the skin (Imhof et al. 2009, 2014). Skin hydration probes are equipped with a spring mechanism, which ensures application of adequate contact pressure before a measurement can be made (Barel and Clarys 2006). It should be noted that it is possible to trigger a measurement at lower (incomplete compression of the spring mechanism) and higher pressure, with the latter leading to significantly higher measurement values (Barel and Clarys 2014). The user should develop a technique resulting in repeatable application of constant yet adequate pressure to trigger a measurement.

Measurements should be recorded when a stable signal is achieved. Because of differences in TEWL and skin hydration instruments, a measurement should be considered stable when it meets the criteria as defined by the manufacturer. It is also recommended that all TEWL and skin hydration measurements be made by the same person to reduce variability (Du Plessis et al. 2013). The number of measurements made on each anatomical position is highly variable in published clinical studies. It is recommended that three sequential measurements be made on the same anatomical position and the results averaged. A waiting time of 5 s between sequential skin hydration measurements on the same anatomical position is recommended by one manufacturer (C&K 2004), even though we have found

no statistical significant difference between values of measurements taken at intervals of 1, 5, and 10 s ($p > 0.74$, unpublished data). Furthermore, it is recommended that all measurements be made on a given anatomical position before moving to the next position. Kottner et al. (2014) recommend that if more than one biophysical parameter is measured on the same position, TEWL should be measured first, followed by other parameters. If repeat measurements are made on a specific anatomical position (e.g., before shift and after shift), both sets of measurements must be recorded at the exact same position to reduce errors. The exact same measurement position can be obtained by photographing the measurement position and using the photograph as a reference for future measurements, marking the skin adjacent to the measurement position with a nontoxic ink and/or using a template (Du Plessis et al. 2013).

3.7 Interpretation of Measurement Results

There is a lack of consensus regarding TEWL and skin hydration reference values for normal and/or diseased skin. As an example, there are differences between skin hydration reference values provided by the manufacturer (C&K 2004) and those reported by three independent studies using the same instrument (Barel and Clarys 2006; Heinrich et al. 2003; Packham et al. 2005). As such, it is recommended that results for a given anatomical position be reported and compared as a relative (or percentage) change in TEWL and/or skin hydration values. To illustrate, if the aim of a study is to assess acute changes in TEWL (Δ) caused by exposure to a contaminant, then quantifying the difference in TEWL relative to the before-shift values (baseline, t_0) for a worker or group of workers would be appropriate (Eq. 1):

$$\% \Delta \text{TEWL} = [(\text{TEWL}_{t_1} - \text{TEWL}_{t_0}) / \text{TEWL}_{t_0}] \times 100 \quad (1)$$

where TEWL_{t_0} is TEWL value at baseline or time 0 (e.g., before shift) and TEWL_{t_1} is TEWL value at time interval (e.g., shift interval or end of shift).

If the aim of a study is to assess chronic changes caused by exposure or disease, then expressing the difference in TEWL and/or skin hydration between a worker (or group of workers) and control subject (control group) as a percentage is preferred over absolute values. When using a control group, the subjects in the control group should be matched to workers as reasonably as possible with respect to relevant endogenous, exogenous, and environmental factors, and measurements should be made in a similar environment with the same instruments (Du Plessis et al. 2013).

TEWL and skin hydration results at a given anatomical position should be expressed as the arithmetic mean \pm standard deviation and graphically by bar graphs, but preferably box and whisker plots, displaying the mean, median, minimum, maximum, and percentiles (which may differ between software packages).

4 Data Reporting

To enable meaningful communication of results and possible comparison of results between studies, a basic data set should be collected and reported with study results. Apart from recording and reporting of notable deviations from the guidelines, the following information, as listed by Du Plessis et al. (2013), and amended below, must be reported (a checklist to facilitate collection of pertinent information is also provided in the same publication).

- Endogenous factors
 - (a) The anatomical position(s) and exact measurement site(s) of TEWL and/or skin hydration.
 - (b) Rationale for the choice of anatomical position(s) and site(s).
 - (c) Skin health at time of measurements. For measurements on hands and wrists, health can be documented and assessed using, for example, a validated teledermatology toolkit for standardized hand photographs in nonclinical settings (Steiner et al. 2011).
 - (d) A skin symptoms questionnaire for current symptoms is recommended.

- (e) Date and time of day when measurements were performed. Note that if measurements are made on different days for the same study participant, to the extent feasible, measurements should be made at the same time of day to minimize any possible effects of circadian rhythms.
- Exogenous factors
 - (a) Hygiene (washing) practices prior to measurement, including conformance, or deviations from instructions given to study participants.
 - (b) Use of any topical products, including conformance or deviations from instructions given to study participants. Note also if skin was wiped dry before measurement because of use of topical products.
 - (c) Exposure to chemicals or mechanical damage to the skin as a result of tasks performed.
 - (d) Use of any personal protective clothing or other materials that might have caused occlusion of the skin, including the type of covering, frequency and duration of use, and time since last use.
 - (e) Ingestion of medication, caffeinated beverages, or smoking prior to measurement.
- Environmental factors
 - (a) Calendar date, season, and time of TEWL and skin hydration measurements
 - (b) Average outdoor ambient temperature and RH
 - (c) Ambient workplace temperature and RH
 - (d) Ambient temperature and RH where measurements are made
- Experimental and measurement/instrumentation factors
 - (a) The type of instrument/probe according to model and manufacturer
 - (b) Equilibration time of TEWL instrument and/or hydration instrument in measurement environment
 - (c) Calibration (manufacturer and prior to use, if applicable) of the TEWL instrument and/or skin hydration instrument
 - (d) Frequency with which the calibration was verified during the study
 - (e) Acclimation conditions of study participants prior to measurements, including

duration, ambient temperature, and RH in measurement area

- (f) How the instrument was applied to the skin surface, including handling of the TEWL probe and time to achieve a stable measurement in accordance with the manufacturer instructions
- (g) The number of measurements per anatomical position and lag time between measurements

5 Summary

The skin is frequently and continuously exposed to a variety of physical stressors and chemical contaminants in the work environment with the potential to affect the skin barrier. Therefore, in addition to assessing exposure to a stressor or chemical contaminant, it is also of importance to characterize the condition of the skin, i.e., the barrier function, at the time of exposure. A consensus summary of guidelines and best practices for measurement of TEWL and skin hydration in nonclinical environments, with emphasis on occupational settings as a worst-case scenario, was developed. This chapter presents these guidelines as well as amendments since initial publication thereof. Key points of this guidelines are (i) recognition and minimization, to the extent feasible, of the influences of relevant endogenous-, exogenous-, environmental-, and measurement/instrumentation-related factors; (ii) recommendation of instruments to be used for measurement of in particular TEWL; (iii) recommendation of standardized reporting of measurement results; and (iv) accurate disclosure of notable deviations from the guidelines. The intention of these guidelines is to provide consistency in nonclinical measurement and reporting of TEWL and/or skin hydration results which is essential for comparison of different studies.

The skin has three main mechanical roles: (1) to instantly or permanently match the changes in shape and volume of the under-lying organs and the adipose tissue; (2) to protect them against mechanical external aggressions; and (3) to facilitate the gripping of objects and the ground by palms and soles.

1 A Mechanical View of Skin Anatomy

The skin is a composite material stratified in three layers of different mechanical properties. The superficial layer, the 15- μ m-thick stratum corneum, is very firm but pliable and naturally wrinkled; underneath, the less rigid 50- μ m-thick viable epidermis is also wrinkled; and the under-lying third layer, the 1-mm-thick dermis, is elastic and naturally contracted. These three layers lie on the hypodermis (or subcutis), whose thickness, often filled with adipose tissue, can range from 1 mm to more than 5 cm and behaves like a cushion. Various structures with specific mechanical roles are found in each layer. For example, in its upper half the dermis holds hairs inserted obliquely like posts. This complex structure

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

is, however, compensated by perfect anatomical adjustment and harmony of behaviors (e.g., the creasing of the first two layers corresponds to the contracted state of the dermis), so that in normal *in vivo* conditions each layer behaves mechanically like the whole in spite of very different intrinsic properties. This justifies the investigation of the global mechanical behavior of skin as though it was a homogenous material.

The major mechanical component is the dermis. Like all connective tissues, it is a felting of collagen fibers immersed in a viscous fluid called “ground substance,” rich in glycoproteins. The dermis has two main functions: to maintain the spatial organization of underlying tissues and to resist external mechanical stresses. Anatomically and functionally two parts need to be considered. The thin superficial or subpapillary dermis thickness of 50–200 μm is proportional to the epidermal thickness (Frost and Van Scott 1966). It is made of a loose tissue, rich in glycoproteins, with thin elastic fibers and collagen bundles where the proportion of collagen III is higher than in the deeper reticular dermis (Lapière et al. 1988). It is rich in blood, lymph vessels, and nerves. Its content in water and vascular volume show physiological variations that can alter the mechanical behavior of the skin as a whole. Below this superficial dermis, the remaining dermis, chorion or reticular dermis (about 1 mm thick), is formed by thicker bundles of collagen (2–20 μm) close to one another and connected by large elastic fibers (0.1–0.4 μm). Fewer vessels and nerves are found, but they are bigger. The structure of the dermis under transmission and scanning electron microscopy is described in ► Chap. 41, “Dermis Connective Tissue Histopathology.”

The dermo-epidermal junction is well defined, but both structures are interwoven. Dermal papillae penetrate the epidermis whose lower border shows roughly conical interpapillary rete pegs, thus increasing the interface. In a histological cross-section, the length of the latter can be longer than the straight line by 20 % (Frost and Van Scott 1966). The junctional structure has specific attachment devices whose dimensions and distribution are known (Barton 1988) (see ► Chap. 156, “Main Skin Biological Constants”), and its physical properties have been studied

(Beerens 1977). The contour of the dermo-epidermal junction must not be mistaken for the skin surface relief, which also shapes it, but is more interspaced and has a different pattern.

The viable epidermis (30–80 μm thick) comprises five to ten layers of cells (keratinocytes) with an impressive keratin cytoskeleton (tonofilaments) communicating from one cell to the other by very strong keratin ties (desmosomes) (see ► Chap. 37, “Markers of Epidermal Proliferation and Differentiation”). This configuration makes it more rigid than the other soft tissues. Its mechanical properties are unknown, but when the whole epidermis, including the stratum corneum, is submitted to traction *in vitro* and compared to the stratum corneum alone from the same body site, the following observations are made: increased slopes of the elastic and plastic phases, a higher force, and less strain at rupture and a similar total spent energy (Ferguson J, Agache P, unpublished data). This indicates an increased rigidity due to the sole addition of the viable epidermis. Consequently, the part played by this layer in the skin’s mechanical behavior must not be overlooked.

The limit between the reticular dermis and the hypodermis is irregular and poorly defined. To our knowledge the mechanical properties of the hypodermis, a loose conjunctive tissue often loaded with fat, have not been studied, but levarometry and suction methods would permit an *in vivo*, noninvasive investigation (see ► Chap. 95, “Skin Mechanical Function”). By allowing the skin to move as a whole on the underlying structures, this layer plays a major part in the absorption of external forces having a tangential component. In scars where the hypodermis has disappeared, the skin loses its mobility and sustains considerably higher stretching and friction constraints.

2 Total Skin Mechanical Behavior

When the skin is submitted to a sudden and sustained strain (a creep test), three successive behaviors are found (Fig. 1). Phase I is an immediate extension (U_e) which is considered to be purely elastic because it is too quick for a viscous phenomenon to appear. It is followed by two phases (U_v) in which viscosity plays a part:

Fig. 1 Creep experiment: skin deformation versus time. U_f : deformation at the end of force application. U_e : immediate deformation (elastic). U_{v1} : viscoelastic deformation. U_{v2} : late deformation (entirely viscous). U_a : recovery at

the end of the experiment. R : residual deformation at the end of the experiment. U_r : immediate recovery. U_d : late recovery

Fig. 2 A model of the skin mechanical components involved in a creep experiment (extension phase only)

phase II with variable creep (U_{v1}) and phase III with constant creep (U_{v2}). As the test is carried out *in vivo*, it implies that the strain keeps below 25 % and is reversible. A greater strain, not shown in Fig. 1, would cause irreversible deformation (plastic phase). Such deformations, which are painful, occur only from traumas.

Scientists have proposed an analog model of this behavior (Fig. 2) in which phase I is represented by a spring, phase II by a spring and a dashpot in parallel, and phase III by only a dashpot since it is a linear function of time. The limit between phases I and II is imprecise and depends on the balance between elastic and viscous resistance inside the tissue, which both vary with the body site, age and the individuals. The limit between phases II and III is also imprecise. When the strain suddenly disappears, the skin retracts immediately, but incompletely and goes back through similar phases, with the difference that full recovery requires a long time – from a few minutes to several hours,

depending on the extent of the strain, its duration and the mechanical condition of the skin.

2.1 Elastic Behavior

Whatever the method used (uniaxial extensions (Wijn et al. 1978), torsion (Wijn et al. 1976) suction (Agache et al. 1995), or progressive extension at constant rate (Vasselet and Agache 1987) the skin’s elastic tissue mechanical properties cannot be known from raw data (U_e , U_f , etc.) because the latter depend on both the device and the method. These can only be determined from intrinsic parameters: strain ϵ (relative deformation) and stress σ (force divided by its application area), which are computed from the raw data and the geometry of the deformation (see ▶ Chap. 95, “Skin Mechanical Function”).

The stress/strain curves *in vitro* and *in vivo* are identical and of an exponential type (Fig. 3). The tangents to the curve are the elastic moduli

Fig. 3 Stress–strain curve of the skin (calf) parallel and perpendicular to Langer’s lines (Modified from Wijn et al. (1981))

$E = d\sigma/d\varepsilon$ at different elongations. According to the Fung’s formula (Fung 1972):

$$E = E_0 + k\sigma$$

where E_0 is the modulus for zero stress (Young’s modulus). In some remarkable work conducted by the Nijmegen group in the early 1980s, this linear relation was verified *in vivo* by Wijn et al. (1981) on more than 50 subjects ($r > 0.998$). It implies the following relations:

$$E = E_0 e^{k\varepsilon} \quad \sigma = E_0/k(e^{k\varepsilon} - 1) \quad \text{and} \\ \varepsilon = 1/k \ln(1 + k\sigma/E_0)$$

They show that the elastic moduli during extension are the initial (Young’s) modulus exponentially increased by elongation. The initial modulus E_0 and the multiplying factor k are the two fundamental parameters of the skin’s mechanical behavior under low stress during the supposedly purely elastic phase (phase I of the Kelvin-Voigt analog model, Fig. 2). At the elastic limit, that is for elongation between 20 % and 30 % across and about 10 % along the limb axis, the stress/strain curve bends towards horizontal indicating

plasticity (Manschot and Brakkee 1986). Torsion tests verify the same equations (Wijn et al. 1981), with a shear modulus $G = d\tau/d\gamma$, τ being the shear stress and γ the shear angle (different from the skin twisting angle). The equation $G = G_0 + k\tau$ is also verified. From a biological viewpoint, these equations mean that all the individual spring-like fibers responsible for the stress during this elastic phase have the same force (expressed by the value of k), but that they are exponentially engaged as elongation takes place.

Uniaxial extension elongates only the fibers oriented along the extension axis (Wijn et al. 1976; Piérard and Lapière 1987). At first (E_0), there are few of them, but when the elongation increases, more and more fibers become orientated along this axis and contribute to the resistance. At each value of strain, the elastic modulus E therefore expresses the number of fibers involved and the strength k of each fiber. Manschott and Brakkee (1986), of the Nijmegen group, also used a sinusoidal model of a collagen fiber derived from the anatomy of tendons. In a uniaxial extension experiment in 61 subjects, they were able to calculate the mean fibril diameter, the mean amplitude and slope of the fiber sinusoid, and the number of fibers that lie parallel and perpendicular to Langer’s lines.

Ever since Dupuytren, it has been known that in resting conditions the skin is stretched preferentially in a particular direction, later described by Langer (1978), hence the term Langer’s lines. In their experiments on the human calf, Wijn et al. (1978) observed that the linear relations $E = f(\sigma)$ parallel and perpendicular to the limb axis (at this site it makes a 30° angle with Langer’s lines) were parallel, the only difference being the value of E_0 was higher in the direction of the limb axis (hence closer to Langer’s lines). Accordingly, in resting conditions, there are more fibers orientated in the direction of the Langer’s lines, and the mechanical anisotropy and the increase of the elastic modulus during extension are two independent phenomena. The ratio of the Young’s moduli parallel (//) to and perpendicular (⊥) to the Langer’s lines is the anisotropy parameter of the elastic fibers’ distribution (named A), which is characteristic of each body area.

On the calf in vivo, the value of the Young's modulus (E_0/l) as found by Wijn et al. (1981) from uniaxial extension (Wijn et al. 1981) was 1.714 MPa, with $k = 0.244$ (without units) and $A = 16.0$. The modulus at elastic limit was about 20 MPa along and 4 MPa across the limb axis (Manschot and Brakkee 1986).

On the volar forearm, the value differs depending on the method. From uniaxial extension at 1 % s^{-1} along the limb axis (up to 45° from Langer's lines), Vasselet et al. found $E = 3$ MPa (Vasselet and Agache 1987); Escoffier et al. found $E = 1.12$ MPa (Escoffier et al. 1989) with the torsion method; and using the suction method, the calculated values were lower (e.g., in young adults between 0.13 MPa (Diridollou et al. 2000) and 0.20 MPa (Khatyr F, Varchon D, Agache P, unpublished data), and in those over 50 years around 0.20 MPa (Diridollou et al. 2001)). Obviously, further work comparing the methods at the same place in the same person is needed.

The higher modulus in the calf as compared to the forearm may be related to the need to compensate for the increased hydrostatic pressure. Indeed, using a suction device, the Danish group showed that over the whole body there is a centrifugal decreasing gradient in skin extensibility (U_e parameter). In the evening, it tends to decrease (Gniadecka et al. 1994), suggesting fatigue of the elastic tissue. In the aged, the gradient loosening may be related to the well-known degradation of elastic tissue.

The calf skin's Young's modulus parallel to Langer's lines steadily decreases with age, going from 1 to 4 MPa at 20 years to below 2 MPa at 65 years of age (Wijn et al. 1981). Using a suction device on the volar forearm, Diridollou et al. (2001) found it to be stable until 50 years of age, then rising. The origin of the discrepancy remains obscure. The declined modulus matches the current observation of the lowered skin resiliency with aging.

It is usually thought that the skin's elastic behavior mainly relies upon the elastic fibers of the reticular dermis. However, the Young's modulus of the elastic fibers is close to 0.3 MPa (Burton 1968; Caro et al. 1978). Since elastin

represents less than 4 % of the dry weight of the skin and collagen 80 %, it was speculated (Manschot and Brakkee 1986) that if the elastic fibers alone were responsible for the resistance to extension, the skin elastic modulus would not exceed 0.01 MPa. Consequently, collagen bundles may be deeply involved in the skin's elasticity via their resistance to partial flattening of their twists (Comninou and Yannas 1976). Manschot and Brakkee (1986), through modeling the collagen fibrils, showed that collagen alone could account for the experimental values of the Young's modulus at elastic limit, making the role of elastic fibers "insignificant." This result is not surprising as by this stage the collagen fibers are almost straightened and bear the bulk of the stress. Elastic fibers seem to play a role mostly in low stress. The role of the elastic tissue degradation has been advocated in the aging process and in diseases like *cutis laxa* (Grahame and Holt 1969; Fazio et al. 1989) and *pseudoxanthoma elasticum* (Wijn et al. 1981; Harvey et al. 1975) in which the skin loses its resiliency. In the above studies, the role of the epidermis has been overlooked. This layer follows the creases and plateaus of the skin surface relief. Upon stretching, it is not elongated but partially unfolded (Ferguson and Barbenel 1981). The resistance of the stratum corneum to unfolding in the elastic phase has a modulus (volar forearm, measurement by suction) ten times that of the whole skin on the same area (Panisset et al. 1993). Accordingly, the total skin Young's modulus should be partitioned into a stratum corneum fraction (about 11 %) and a dermis fraction (about 89 %) (Panisset et al. 1993).

2.2 Viscous Phases of Extension (Creep)

In creep tests, the phase II of the skin deformation versus time (U_{v1}) is curvilinear and has been described by a decreasing exponential function according to the equation:

$$U_{v1} = U_{v1\max} \left(1 - e^{-t/r} \right)$$

The phase III (U_{V_2}) is a straight line described as $U_{V_2} = At$ (Vlasblom 1967). Some authors have also suggested $U_{V_2} = At^{1/3}$ (Pichon et al. 1990). These equations are drawn from the analogue model of Fig. 2. The use of this model has been criticized because it is able to fit the experimental curve only if the elastic phase is considered below the elastic limit (Vasselet and Agache 1987), and because it has only two relaxation times (only two dashpots in the model); thus, it assumes that the skin has only two viscosity coefficients, which is evidently an oversimplified although useful approach. According to Vasselet (Vasselet and Agache 1987), the deformation angle θ in torsion tests would be better described in the viscous phase by the logarithmic equation: $\theta = b \cdot \ln(1 + nt)$, where b is the elongation rate and n the elongation before the viscous phase. Unfortunately, these theoretical considerations do not yet have a practical application. In clinical practice, only viscoelastic deformations (U_v , Fig. 1) are usually measured, without any assessment of the intrinsic mechanical parameters (i.e., stress, strain, viscosity coefficients). ► Chapter 96, “Mechanical Behaviour Assessment of the Skin” (Sect. 11.1, “Searching for Intrinsic Mechanical Properties”) shows a simple way to perform the calculation of the intrinsic viscosity parameters 0_1 and 0_2 , with an example.

From a biological point of view, a viscous behavior may originate from both a collagen network deformation and a displacement of the ground substance within the network. The mobility of the latter depends on several factors: network toughness, ground substance viscosity, and perhaps its links to the network through proteoglycans.

The parameter U_v , corrected for skin thickness, remains stable with aging (Escoffier et al. 1989), which is known to be associated with the decrease of proteoglycans in the ground substance, thus lowering its viscosity. The latter assertion is supported by a small but steady decrease of the relaxation time using high torque (Escoffier et al. 1989). As U_v is both viscous and elastic, the lower ground substance viscosity in aged skin might be compensated for by a reduced ability of the collagen network to elongate (increased

rigidity or toughness through molecular cross-linking), but increased strength of the elastic tissue is improbable. The skin extensibility (U_e) decreases only after 75 years (Escoffier et al. 1989).

Using the data analysis method described in ► Sect. 11.1 of the next chapter, the skin viscosity associated with phases II (0_1) and III (0_2) of a creep experiment on volar forearm were found to be around 0.4 MPa and 12 MPa, respectively in young adults (Khatyr F, Varchon D, Agache P, unpublished data). In phase II (viscoelastic), the corresponding elastic modulus was around 0.475 MPa in the same subjects. This shows the steep increase in viscous resistance with small strain increment.

2.3 Recovery Phase

In a creep test, when the stress is suddenly removed, the skin immediately starts to regain its original dimensions (this applies to physiological deformations less than 25 %). As during extension, the recovery goes through an immediate phase (U_r) supposedly only elastic, then a viscoelastic phase (U_d), and finally a long-lasting residual deformation (R) (Fig. 1). In clinical practice, the “skin elasticity” (i.e., its spring-like recoil capacity) is assessed by the ratio between immediate recovery and immediate deformation (U_r/U_e). Both U_e and U_v are always higher than U_r and U_d because to achieve straining the external force must always be higher than the associated internal skin recoiling force and tissue resistance to deformation (i.e., viscosity). During recovery, the viscous resistance is about the same as during extension; whereas, the skin recoiling force is always lower than the applied external force. The skin recoil is rapid in children and takes a long time in the elderly. Consequently, on the volar forearm, the ratio U_r/U_e decreases with aging-regularly from over 0.9 in childhood down to 0.7 after 65 years of age (Escoffier et al. 1989).

In a progressive loading-unloading experiment (see Fig. 47.2), the delayed recovery generates a hysteresis on the force/deformation curve – the

more “elastic” the skin, the smaller the hysteresis loop area. The latter has the dimension of work, as shown by its formula: $3[(\text{loading minus unloading force}) \times \text{deformation}]$. It represents the work of elastic fibers striving against the tissue viscosity. Aging increases viscosity (although that of the ground substance is decreased) as shown by the increased hysteresis area (Diridollou et al. 2001), but it also reduces the number of elastic fibers (the latter mostly in actinic aging), as shown by histological observations. Consequently, both the decreased recoiling force and increased resistance to deformation contribute to the delayed recovery in the elderly.

2.4 Other Characteristics of Mechanical Behavior

- The intracutaneous structures always retain part of the latest deformation they have sustained. This residual deformation is obviously corrected in the course of any subsequent deformation but is not specifically due to it. “Preconditioning” is used to circumvent it.
- If identical elongations are repeated, and the skin has time to recover between each elongation, the constraint increases (Vasselet and Agache 1987). This “hardening” of the skin, similar to that of many other materials (“strain hardening”) is probably a physiological phenomenon, but its biological support remains conjectural-consolidation of the collagen network by new molecular cross-links?
- Like any material, skin shrinks when it is stretched. In mechanics, this phenomenon is described by the Poisson’s ratio (ν) which is the ratio of the relative decreases in transverse dimensions to the relative increase in length. With skin, the Poisson’s ratio probably varies during extension because the ground substance can be attracted into the collagen network at the beginning of the test (hence $\nu < 0.5$) as suggested by ultrasound examination (Diridollou et al. 1998), and then expelled when extension progresses (hence $\nu > 0.5$). As a matter of fact, to achieve tensed suction

blisters, only a 400 mbar suction for 2–3 h is needed; the blister originates from a dermo-epidermal separation into which interstitial liquid flows. For small and short lasting deformations as used in skin tests, the skin does not swell, so the value $\nu = 0.4$ or 0.5 is generally used.

- Attempts to assess the skin’s mechanical impedance have also been made by making its surface vibrate and measuring the parameters at phase II of the analogue model of Fig. 2. The contributing parameters are mainly elastic from 30 to 200 Hz and viscous from 300 to 1000 Hz. Both elasticity and viscosity parameters increase when the skin is compressed (Thompson et al. 1981).
- The skin’s compressibility is a mechanical property of the same or even greater importance than extensibility. Most impacts we sustain are directed perpendicularly to our body’s surface. Furthermore, the skin must bear the weight of the body for long periods of time in sitting or lying positions. Skin resistance to this compression is an essential component of its continuous blood perfusion and constitutes a protecting factor against decubitus ulcers. A 12 KPa pressure on the volar forearm with a 20 mm diameter disk, choosing arbitrarily a Poisson ratio $\nu = 0.3$ and using the formula (Hayes et al. 1972):

$$G = P(1 - \nu)/RKd^4$$

where P is the pressure applied, d the diameter of the disk and K a parameter without dimensions function of t/R , provided a shear modulus G between 1 and 2 kPa (Bader and Bowker 1983).

This modulus decreases in old people (Bader and Bowker 1983). Lanir has also studied the deformations produced by compression and has given their mathematical expression (Lanir 1981). The biological substrate of compressibility mainly consists in the capacity of the dermis ground substance to be ejected laterally, which involves its viscosity, the fiber network tightness and the interstitial pressure. The resistance of the few elastic fibers laid out parallel to the skin surface

and stretched by the compressive shift must also be considered.

2.5 Mechanical Anisotropy

Skin resistance to traction predominates in the Langer's lines direction and varies with body site. These lines have been detected on a corpse from the oval shape of an incision made with a round awl, and they correspond to the main axis of the oval (Fig. 4). Excised skin shrinks more and has minimum extensibility in that direction. It is therefore an anisotropy of the spontaneous skin tension "in resting conditions," which is distinct from the skin tension from positional, muscular or visceral origin. This phenomenon is the source of

Fig. 4 Langer's lines (From the original article, 1861)

the Young's modulus (E_0) anisotropy (Wijn et al. 1981), whose distribution angle shows a maximum in the Langer's lines axis (Manschot et al. 1982) (Fig. 3). These data favor a similar orientation of the elastic fibers involved in the skin tone. Assuming that the fibers are independent, it has been calculated that, on the calf, 76 % were in the direction of the Langer lines and 5.1 % perpendicular (Manschot et al. 1982). Of course, this distribution concerns only the elastic fibers, which are parallel to the skin surface.

Observation of the dermis with scanning electron microscopy confirms this data (Piérard and Lapière 1987). In *retracted* skin the collagen bundles look tortuous, with no special direction, and sinuous elastic fibers are fixed to them in several places, especially in their concave portion. In *nonretracted* skin, the thinnest collagen bundles as well as the elastic fibers are straightened in the direction of the Langer's lines and almost parallel; the thickest bundles remain tortuous and oriented in all directions, but their shape seems to be modified by the traction from the orientated bundles and fibers (Piérard and Lapière 1987). Contrary to common belief in the past, Langer's lines do not reflect an anisotropy of the collagen density but an anisotropy of the reticular dermis collagen bundles' direction and elastic fibers' tension. The latter is quantified *in vivo* by mechanical exploration (Manschot et al. 1982).

The superficial (subpapillary) dermis collagen bundles are not linearly oriented and are not related to the cleavage line orientation (Namikawa et al. 1986). Thus, only the reticular dermis seemingly takes part in the anisotropic skin's mechanical properties.

2.6 In Vitro Mechanical Behavior

The *in vitro* stress-strain curve appears as exponential as *in vivo*. During extension at a constant rate until rupture of a completely relaxed skin sample immersed in an isotonic solution, three phases have been described, with concomitant examination of the tissue under scanning electron microscope (Brown 1973) (Samples were

8 mm wide and taken from the abdomen, where the skin thickness was found to be 1.8 mm by ultrasound (Tan et al. 1982)). The first one, stretching up to about 40 %, corresponded to physiological extensions and *in vivo* studies. It showed low resistance (the less than 10 g, hence $E < 7$ kPa), unfolding of the skin relief and partial alignment of some collagen bundles of the superficial dermis (Brown 1973). In the second phase (stretching from 40 to 70 %), the skin became stiff and the modulus was 510 kPa (assuming that the section remained unchanged), the keratinocytes became elongated, the collagen bundles of the superficial and deep dermis and the elastic fibers lined up in the direction of the traction, but the collagen of the mid-dermis remained sinuous. The next phase was a prerule stage during which the modulus remained constant, and the bundles became compacted and often independent within the network; however, the latter persisted and no free extremities were seen. Rupture occurred at 90 % elongation. This study characterizes the behavior of *immersed* skin, which accounts for the very low modulus and exceptional extensibility in phase I (in *in vitro* extension experiments made in open air the modulus of abdominal skin stretched at $0.7\% \text{ s}^{-1}$ was 7–50 MPa (Kenedi et al. 1965; Daly and Odland 1973)). The author considers that the role of the stratum corneum resistance to the unfolding then extension was negligible; this is probable because of the immersion which might have considerably reduced its unfolding then elongation moduli (Agache et al. 1973; Wildnauer et al. 1971). Since the dermis is a physiologically immersed tissue, the conclusions of these *in vitro* immersion studies are likely to be applicable *in vivo*, but to the dermis only.

For extensions beyond physiological limits, the modulus increases regularly with age, going from 3 MPa in children to 20 MPa after the age of 50 (Rollhauser 1950). At this stage, the skin is barely more extensible than tendon. Plastic and pre-rupture phases may provide data on the structure of collagen, especially chain cross-linking, if the dimension of the fibers can be known through electron microscope examination. These data could be useful for better understanding acquired

or congenital diseases involving the connective tissue. Scar tissue has a higher elastic modulus than the adjacent healthy skin, which implies that the collagen bundles are more tightly compacted and probably more frequently interconnected (Kenedi et al. 1965).

Beyond the phase of physiological extension, the sample is greatly shrunk transversely without becoming thin throughout (Kenedi et al. 1965), and the ratio between narrowing and stretching increases very quickly. This is related to the leak of interstitial fluid during the test, because the Poisson's ratio remains constant afterwards until rupture (i.e., the sample volume does not rise, contrary to nonorganic materials). In adults, its values vary from 0.5 to over 1.3, indicating a diminution of volume at the end of extension. With age, the squeeze of the ground substance occurs for moderate extensions and the loss of volume gets more probable. This corresponds with the decrease of the skin viscosity of the aged skin, and the fact that by this time the dermis holds more free water because of the loss of proteoglycans.

The Rheometer (Dia-Stron Ltd, Andover, Hampshire, UK) is a commercialised device allowing *in vitro* uniaxial extension or compression of skin samples, as well as the study of forced relaxation and shape recovery.

3 Mechanical Behavior of the Stratum Corneum

The stratum corneum (SC) is approximately 15 μm thick except in palms and soles where it reaches 1 mm (► Chap. 23, “Stratum Corneum Histopathology”). It is a dead structure formed by about 19 layers of piled keratinized cells (corneocytes). These are flat (0.3 μm), roughly pentagonal (diameter 30 μm) and separated by 0.07 μm wide intercellular spaces. Each cell has a thick membrane much more resistant than the heart of the cell. The intercellular spaces are filled with stratified lipids and proteinaceous enzymes, and traversed by keratinized cellular binding bridges (corneodesmosomes). The adherence between cells decreases towards the surface, but is always lower than the cell wall

solidity, so that spontaneous desquamation (one cell layer per day) or SC tape stripping only deals with intercellular spaces (details on desquamation are provided in ► [Chap. 25, “Stratum Corneum Desquamation”](#)). The structure and physical properties of the human and animal SC are similar. As a consequence, its mechanical properties have been investigated in pig, rat and humans.

3.1 In Vitro

- In 1956, Peck and Glick (1956), applying a durometer used in the leather industry, noticed that the hardness of dry human SC in vitro is comparable to glass and cannot be softened by mineral oil, lanolin, or glycerin. However, such behavior depends mostly on its hydration. The addition of 10 % of its water is sufficient to make it soft and pliable; the same can be obtained by a 60 % ambient relative humidity (RH) (Blank 1952), but its hardness is still 70 % that of glass, which is noticeable.
- The mechanical behaviour of the SC is also sensitive to temperature, and its rise has the same effect as an RH rise (Wilkes et al. 1973). Between 25 °C and 60 °C, for a 10 % water content, the change in the *force at rupture* and the *extension at rupture* is similar to a change of RH from 26 % to 100 % (Middleton 1969; Spencer 1976). The elastic modulus decreases exponentially, becoming 1000 times lower when the temperature changes from 25 °C to 60 °C. Temperature and water potentiate each other (Spencer 1976; Spencer et al. 1975). Consequently in constant RH conditions, the SC hydration increases by 50 % when the temperature rises from 20 °C to 30 °C, but the

hydration (Fig. 5). A RH shift from 0 % to 100 % is associated with an increase of the *maximum extension* and *rupture work*, and a reduction of the *force at rupture* (Wildnauer et al. 1971; Kligman 1964; Papir et al. 1975). The elastic modulus decreases drastically with a higher RH, and this effect is more marked beyond 60 % (Middleton 1968; Papir et al. 1975; Park and Baddiel 1972). Microruptures of the SC occur in vivo in some conditions (ichthyosis, hyperkeratosis, etc.) or even in healthy skin (subjective feeling of poor skin elasticity on the face, chapping and cracks on the hands of housemaids, cement workers, etc.). This situation is often due to the hardening of the stratum corneum caused by its dryness.

Fig. 5 Stratum corneum mechanical behavior under uniaxial elongation in vitro. Samples taken from the back. Traction at constant rate up to rupture. A RH = 50 %, B RH = 80 %, C RH = 90 % (From (Vasselet 1989), Laboratoire de Biophysique Cutanée, Besançon)

temperature dependence decreases at high RH and abates when RH reaches 90 %.

- The SC force/elongation curve at constant elongation rate shows one, two or three phases depending on the hydration level of the tissue (Fig. 5). The first one, up to a 10 % extension, is considered purely elastic. However, its slope increases if the extension rate rises (Wilkes et al. 1973), thus confirming the viscoelastic nature of the material. Phase II, absent in low RH, is an irreversible elongation with a low slope (so-called plastic phase). Only very hydrated SC shows a third phase, of a rather steep slope, before rupture. Preconditioning does not exist with SC, which is an important difference with the whole skin, indicating the absence of mobile components in the material (Koutroupi and Barbenel 1990). The two main intrinsic parameters of phase I are, therefore, the elastic modulus and the viscosity coefficient. The quasi-static elastic modulus of the back SC (9–10 μm thick (Holbrook and Odland 1974)) is as follows:

E (MPa)	T (°C)	RH (%)	Elongation rate (% s ⁻¹)	Reference
50	22	82	0.42	(Ferguson 1980)
10–200	22	60	0.22	(Vasselet 1989)
210	19	75	0.08	(Koutroupi and Barbenel 1990)

The dynamic modulus was found to be 600 MPa (Takahashi et al. 1981). A thorough investigation of the complex elastic modulus in relation to the stimulation frequency has been carried out (Rasseneur et al. 1982). The other parameters of the force/elongation curve at 25 % min⁻¹ elongation rate in 82 % RH and at 22 °C (Ferguson J, Agache P, unpublished data) are:

Elastic limit	10 % elongation
Elongation at rupture	32–35 %
Force at rupture	15–19 g, hence a strain of 3.7–4.7 MPa

(continued)

Rupture work	7.5–9.0 mJ, which is 1.9–2.3 kJm ⁻² (other authors have found 3.6 kJm ⁻² (Koutroupi and Barbenel 1990))
--------------	---

In an abdominal scar, a considerable increase of the elastic limit (over 4 times the standard deviation) and of the elastic modulus (Ferguson J, Agache P, unpublished data) were observed.

The in vitro behavior of the SC under traction probably reflects the intercellular ties (Frost and Van Scott 1966) because the final rupture is always extracellular, although the corneocytes are very elongated. The most resistant components are the corneodesmosomes which are, therefore, likely to be the structures involved. In the course of elongation, they bear both a direct and a shear force and their numbers fall (Agache et al. 1973). The rupture of a corneodesmosome placed in a drop of water, carried out with a micromanipulator, required a force of 0.19 10⁻³ N (Lévêque et al. 1988). Given that a section of corneodesmosomes is about 7250 nm² (25 nm × 290 nm (Barton 1988)), the stress is 26 GPa. The corneocyte membranes are also very resistant. The same authors observed that the corneocytes placed in a drop of water could be folded easily, but that their maximal extension was 30 % (without breaking) with an elongation modulus of 450 MPa (Lévêque et al. 1988). These figures are about two to eight times higher than those of the SC extended in vitro (see the table above). This suggests that the cumulated section areas of involved desmosomes represent only one eighth to one half of the SC section area. Measurements under electron microscopy could readily confirm this hypothesis.

- The viscous behavior and the constitutive equation of human SC have been studied by traction-relaxation tests and creep tests (Vasselet 1989). The relative relaxation versus Napierian logarithm of time is a straight line, which excludes a single viscosity coefficient. However, the standard viscoelastic model based on the existence of several viscosity coefficients does not permit reconstruction of

the complete traction-relaxation curve. On the other hand, the SC quickly hardens following repeated tractions (strain hardening). The constitutive equation of the elastic and viscoelastic phases of the SC should therefore include one elasticity parameter, two nonlinear viscosity parameters and one strain hardening parameter. Based on torsional creep experiments, Vasselet suggests the following equation which fits the experimental curves:

$$d\epsilon/dt = (dF/dt)/E + Kf^n \epsilon_v^m$$

where the elastic deformation is described by $(dF/dt)/E$ and the viscous deformation by $Kf^n \epsilon_v^m$ (E is the elastic modulus, F the force applied, K and n the intrinsic viscosity parameters, m the strain hardening parameter). The link between these parameters and the anatomical components of the SC are yet to be determined.

- Is the mechanical behavior of the SC directional? In the case of a 5 % extension, there does not appear to be any difference between elongations, either parallel or perpendicular to the skin furrows (Elfbaum and Wolfram 1970). Samples coming from the lower part of the back, where the Langer's lines are horizontal do not show significant differences either (Ferguson J, Agache P, unpublished data). This could be easily explained by the fact that the anisotropic physiological furrows of the SC in vivo are determined by the underlying layers, while the in vitro SC has been separated from them and has become lax in the course of manipulations and exposure to room conditions. As a matter of fact, no furrow was visible on its surface. These results show that the SC does not present any structural anisotropy.
- In vitro, the SC is in environmental conditions which are very different from the physiological situation. In vivo, it is closely associated with the underlying viable layer to which it is strongly attached. To separate them, it is necessary to use proteolytic enzymes, such as trypsin, which destroy the desmosomes of the viable tissue (trypsin above 0.125 % increases the elastic limit and the elasticity modulus in a dose-

dependent way (Ferguson J, Agache P, unpublished data)). Owing to its location, the SC is subjected to humidity and temperature gradients, which decrease from the deepest layers toward the surface. Agache et al. (1973), using human SC sampled on the back (top of a cantharidin blister) with its upper part exposed to the air and its deep side moistened in order to be as close as possible to in vivo conditions, also found a fall in the rupture work when the RH shifted from 40 % to 88 %. However, they observed a decrease of the maximum extension, while the elasticity modulus remained unchanged. These discrepancies with the mechanical behavior under uniform conditions show that the deeper part of the SC has a major influence on its global mechanical behavior. The authors suggest that hyperhydration of the skin surface weakens the SC, thus providing an explanation for the toe web fissuring in "athlete's foot" (Agache et al. 1973).

- The full thickness of the SC matches the creases forming the skin relief. It partly unfolds when the skin is stretched, but does not extend. One can therefore wonder if the intrinsic properties of the SC characterized in vitro are relevant to the mechanical function of the skin in vivo. The answer is positive as far as its hardness and capacity to absorb mechanical shocks are concerned. However, its extensibility is involved only in critical, extra-physiological situations, during high shear strains. The latter can reach 33 % without apparent damage, an extension which would cause the rupture of flat SC (cf. *supra*).

The Rheometer commercialized by Dia-Stron Ltd, (Andover, Hampshire, UK) allows the mechanical study of the SC in vitro by uniaxial extension.

3.2 In Vivo

Hardness. To assess SC hardness in vivo, Peck and Glick (Peck and Glick 1956) measured the penetration depth of needles (0.8 mm, 1.5 mm and

2 mm diameter) according to the force applied (100 g, 200 g, and 400 g). They observed that penetration does not increase after a foot bath, although the SC should have become softer. These results cast some doubt about the soundness of the technique. The question has been resumed by the Cardiff's group (Nicholls et al. 1978; Graves and Edwards 2002), based on the rationale that the stratum corneum should be indented at a velocity greater than $5q10^3 \text{ ms}^{-1}$ and to a depth equivalent to its thickness. A new device, named Microindentometer, was constructed, which permits the skin resistance to indentation to be obtained in a reliable way. However, the authors believe further developments are needed before using it in practice (Graves and Edwards 2002).

Several studies were done using the same type of device to assess diseased skin's hardness in vivo (Falanga and Bucalo 1993; Romanelli and Falanga 1995). These are reviewed in reference (Romanelli and Falanga 2002). In fact, this is the only way to quantitatively rate the severity of the disease instead of a purely clinical rating by pinching or pressing the skin.

Elastic modulus. In vivo, the SC matches the furrows of the skin surface microrelief. The deeper the furrows (Rtm parameter) and the steeper their sides (Δq parameter), the higher their physiological limit of extension, as indicated by the beginning of whitening of the skin (Ferguson and Barbenel 1981). At this limit, the average roughness of the skin surface is reduced by half. The direction of the higher extensibility, examined on the thigh, chest, abdomen, forearm and foot, is perpendicular to the direction of the main furrows (extensibility on the forearm: 10 %//, 27 % \perp). As a consequence, the SC in vivo does not sustain elongation stresses, but only unfolding stresses. However, its resistance to this unfolding is an important feature of the global skin resistance to stretching. The absolute value of its modulus, measured on the volar forearm by a suction method (described in ► Chap. 95, "Skin Mechanical Function"), was 57.8 MPa (Panisset et al. 1993). The extent of this contribution explains why the mechanical behavior of the whole skin can be altered by products that modify the suppleness of the SC, and why it is possible to

assess the variation of the SC mechanical behavior by measuring that of the whole skin.

Resistance to Friction. This is an interesting property of the skin surface when one knows the importance of the friction coefficient in the prehensile function of palms and gripping of objects, as well as the traction of the foot on the ground in walking and running. In 1955, Naylor (Naylor 1955) monitored the friction coefficient (μ) of polyethylene moved at a constant speed and with a pre-determined pressure on the inner part of the tibia's bony area (a zone without fatty tissue) after shaving the hairs. From an initial value of 0.5 μ doubled after degreasing with ether, and peanut oil brought it down to 0.25, thus explaining its alleviation by the lipids of the skin surface. The action of water is more complex: μ is reduced on wet skin (hydrodynamic friction coefficient – water sliding on itself), but increased on moist skin (static friction coefficient). On thoroughly dried skin, the friction coefficient was 0.5 with wool material, and much lower with nylon material (Comaish and Bottoms 1971). The lowest value was found with non woven Teflon ($\mu = 0.2$). Dry talc is an excellent lubricant, but when it is damp its friction coefficient increases considerably.

The kinetics of the static friction coefficient following application of water is worth relating (Highley et al. 1977). As soon as the skin is moistened, a peak appears, in connection with the surface tension of water; it is of short duration because water mixes with the surface hydrophilic lipids which reduce this tension. Then a secondary peak occurs, and although the skin does not look humid any more, it seems to be associated with additional hydration of the skin surface. The formula $f = \mu P^n$, where P is the weight of the applied object and n an empirical number dependent on the tested surface ($n < 1$) (Comaish and Bottoms 1971), allows one to calculate μ from the friction force f. Following the time-course of the static friction coefficient also permits the substantivity of topical preparations to be assessed, especially emulsions.

The question has been revisited recently by Zahouani et al. (2002) who used a steel ball moving over the skin surface, and monitored the vertical load force F_z and the horizontal resisting friction force F_x . When the ball was moved over a distance

Fig. 6 The three phases of the skin friction

Fig. 7 Volar forearm friction force versus vertical load in a 40-year-old-woman

of about 5–15 mm with a velocity in the range of 0.3 to 2 mm/s, registration of the friction force F_x showed three distinct phases (Fig. 6). The first one is a linear increase up to a maximum which defines the static friction coefficient μ_s :

$$\mu_s = \frac{F_{x1,max}}{F_z}$$

The slope of the linear curve corresponds to the horizontal stiffness of the skin, K_x (N/m).

Phase II is a transition regime between the static and dynamic friction. Phase III is the dynamic friction phase, which is generated by the unstable balance between the maximum

friction stress and the creep of the skin relief. It shows an alternate “Stick–slip” motion depending on the local and environmental conditions. The slope of the “Stick” phases provide information about the horizontal stiffness of the skin. In this phase, the dynamic friction coefficient μ_z is defined as the ratio: mean friction force/vertical load.

$$\mu_z = F_{x1,mean}/F_z$$

A test made on a 40-year-old woman (volar forearm) performed under three vertical loads and with a velocity of 600 μms^{-1} showed the dependence of the two skin friction coefficients on the vertical load (Fig. 7), which is in contradiction with Amonton’s Law.

	Normal load F_z	Penetration depth:	Horizontal stiffness: K_x	Static friction coefficient:	Dynamic friction coefficient:
Before hydration	50 mN	1823 μm	51 N/m	1.35	1.12
5 min after hydration	50 mN	1929 μm	41 N/m	2.24	1.55
10 min after hydration	50 mN	1912 μm	51 N/m	0.69	0.65

	Normal load F_z	Penetration depth:	Horizontal stiffness: K_x	Static friction coefficient:	Dynamic friction coefficient:
Before hydration	50 mN	1823 μm	51 N/m	1.35	1.12
5 min after hydration	50 mN	1929 μm	41 N/m	2.24	1.55
10 min after hydration	50 mN	1912 μm	51 N/m	0.69	0.65

Fig. 8 Volar forearm friction force versus skin hydration. *Table:* volar forearm friction parameters after hydration by water

Also of interest is the first increase and then decrease of the static and dynamic parameters after hydration by water (Fig. 8).

Keywords

Ballistometry • Barbenel's method • Borges method • Skin compressibility • Creep • Cutometer • Dermagraph • Dermal torque meter • Dynamic spring rate (DSR) • Extensometer • Gas-bearing electrodynamicometer (GBE) • Indentometry • Kelvin-Voigt model • Levarometry • Linear skin rheometer • Skin mechanical behavior • Skin progressive deformation tests • Skin relaxation tests • Reviscometer • Skin microrelief • Stark's method • Strain in mechanics

Principle Current Uses. Efficacy tests of cosmetics and anti-aging products, measurement of UV impact, follow-up of skin sclerotic diseases (scleroderma, morphea, radiodermatitis, etc.), atrophies (from corticosteroids, in rheumatisms, striae distensae, etc.), diagnosis of connective tissue diseases (Ehlers-Danlos syndromes, elastic pseudoxanthoma, mid-dermis elastolysis, etc.), foresight tests in plastic and cosmetic surgery, characterization of elasticity and viscosity of healthy or pathological skin, and research in skin physiology.

1 Aims

The two main purposes of skin mechanical testing are:

- To follow up and record the mechanical behavior of the skin or one of its components in the course of a disease, a treatment, or following cosmetic application, etc.
- To access the intrinsic mechanical properties and functional condition of the main tissue or structures involved: either elastic components (elastic fibers, connective bundle weaving, stratum corneum pliability), or components with a viscous behavior (interstitial fluid mobility and viscosity, frictions within the tissues)

Since the shape of skin can be changed in different ways (stretching, torsion, compression, etc.) and to different degrees, it is possible to impose a constraint preferentially on a given component and so assess its behavior independently. As a consequence, the assessment of the mechanical behavior opens new fields of anatomical or functional investigation of theoretically all the various components of the skin, because every biological structure has a mechanical behavior and these play a part of the overall skin behavior.

2 Methodology in Biomechanics

The measurement of the skin's mechanical properties is restricted to noninvasive methods designed to be used on the skin *in vivo* and in everyday conditions. The study of its behavior when subjected to excessive, traumatic strains may be interesting in itself but can only be performed *in vitro* (see ► [Sect. 2.6 in Chap. 95, "Skin Mechanical Function"](#) and ► [Sect. 3.1 in Chap. 95, "Skin Mechanical Function"](#)). Several constraints can be used: stretching, torsion, suction, compression, percussion, elevation, etc. For each, the test can be performed in different ways: constant force applied suddenly and deformation measured versus time (creep test, [Fig. 1](#)); increasing force applied at a constant rate and measurement of deformation; increasing strain applied at a constant rate and measurement of the resisting force (traction test, [Fig. 2](#)); permanent deformation applied suddenly and measurement of the resisting force versus time (relaxation test, [Fig. 3](#)); and oscillating stress (dynamic test, for example by propagation of sound).

Although it may be an important step in the clinical evaluation of a skin lesion, the assessment of skin hardness has not yet gained general acceptance. The use of a durometer, an industrial device, needs a firm basis below the skin, which

is not available as some subcutis exists at all body sites. A tentative manual assessment using three standard hardness disks as controls gave satisfactory results with keloids (Flores et al. 1998). After a rapid training on three standard rubber disks of graded hardness, the interobserver variability (13 dermatologists) was 9.25 %. Although this was only a 3-point scale, the method may be useful in clinical practice.

2.1 Descriptive Versus Absolute Mechanical Parameters

Devices in mechanics record deformations or forces. These parameters are called descriptive or phenomenological because they depend on the applied stress (suction, torsion, etc.) and the device used. Such parameters, identifiable on Figs. 1, 2, and 3 (e.g., force F , deformation U_e), describe a behavior under

Fig. 3 Relaxation test. Force (skin resistance) versus time. The extension rate was 1 %/s for 10 s (the Extensometer could not move faster). Consequently, some relaxation took place before the measurement started (Vasselet and Agache 1987)

particular conditions, and comparison with other data is possible only if the latter have been obtained under the same conditions. However, this behavior reflects intrinsic properties of the material, which are of value and worth identifying. Intrinsic properties can be described by parameters of general mechanics, named intrinsic or absolute parameters. These permit comparisons between materials and experimental results whatever the type of test. Conversion of descriptive or phenomenological parameters into absolute parameters is thus highly desirable and scientifically profitable. The observed deformation (length, angle, etc.) should be converted into relative deformation (or strain) ε in %; the force F in newtons is converted into stress σ in pascals; and all of this is given in three dimensions of space. The relative deformation can be computed only if the limits of the area of deformed skin and the geometry of deformation are known with precision. The stress $\sigma = F/a$ is the force applied divided by the area a , in m^2 , of the sample section. The skin thickness at the measurement site must be assessed (usually by ultrasound imaging) to calculate a . The ways to perform conversions will be examined with each method.

2.2 Creep

A creep test curve is depicted in Fig. 1. Deformation types are: immediate deformation Ue (e for

“elastic”), delayed deformation Uv (v for “viscous”) which tends towards an asymptotic limit, the final deformation $Uf = Ue + Uv$ (f for final), immediate recovery Ur (r for recovery), delayed recovery Ud (d for delayed), the total recovery $Ua = Ur + Ud$ (a for added), and the residual deformation R . The limit between Ue and Uv is imprecise. It is usually determined approximately with the naked eye, but there is a simple and accurate solution from the mathematical processing of the Uv curve, which is exponential: $Uv = Uvmax(1 - e^{-t/\tau})$, where $Uvmax = Uf - Ue$. Hence, $\ln(Uvmax - Uv) = Uvmax - t/\tau$ (This equation is valid only if $t \geq 3\tau$ is verified later.). Using this equation, the experimental measurement of some Uv values allows $Uvmax$ to be determined and subsequently Ue . The calculation also gives the time constant τ which is the time it takes Uv to reach 63 % of $Uvmax$. It is a measurement of the viscous displacement rate, and $1/\tau$ is an index of the tissue fluidity.

The same holds true for the limit between Ur and Ud . The time constant of this recovery phase is another measurement of the viscous displacement rate of the same tissue. However, the latter depends on the force generating the movement. As a consequence, the comparison between both fluidity values would more or less be the comparison of the internal recovery force with the externally applied force.

How long does the force have to be applied to let the viscous movement have time to occur and be evaluated accurately? In the past (Sanders 1973; Agachel et al. 1980), a test duration of 2–120 s was used. However, Uv consists of a first short and curvilinear phase (Uv_1), then a second phase, comparable to a straight line (Uv_2), in accordance with the model of Fig. 1 of ► Chap. 95, “Skin Mechanical Function”. The former describes the viscoelastic behavior, while the latter reflects a viscosity which is different (higher) from the first one and has less practical applications. For this reason, most creep tests last only 2–5 s because their main purpose is to assess the elastic resistance, a practical index of the skin tone. To measure the two types of viscosity, it would be necessary to extend the application of force by at least 10 s (see Sect. 11.1).

2.3 Progressive Deformation Tests

Progressive deformation tests provide a graph of force F (newtons) versus deformation U (meters) (Fig. 2). In a cycle comprising an increasing and then decreasing force at a constant pace, the deformation is always more pronounced when the force is decreasing than in the increasing phase at the same force. A hysteresis loop thus appears, whose area is relative to the viscous deformation (Diridollou et al. 2000a). In such tests, the descriptive parameters are the ascending slope (force/elongation), which expresses the skin's increasing stiffness (under these particular experimental conditions), and the hysteresis loop area, $j(F_1 - F_2) \times \text{elongation}$, where F_1 and F_2 are the force during loading and unloading, respectively. In this test, like in the preceding one, the relative deformation must not exceed 15 %. This threshold is often detected by the initiation of pain.

2.4 Relaxation Tests

In relaxation tests, the skin resisting force F is measured continuously versus time (Fig. 3). The sudden stretching induces a resistance force F_0 , whose nature is only elastic (equivalent to U_e in the creep test) because it occurs too fast for viscous movement to appear. The latter starts in the immediate aftermath and is detected by the progressive reduction of the resisting force (relaxation of the elastic structures). Consequently, not only does this test evaluate the immediate deformation U_e , but also the rate and extent of the viscous flow. Although it is a very informative test, none of the commercially available devices can do it and no prototype seems to be in progress. Consequently, it will not be described.

3 Suction

3.1 Implementation

1. To perform a *creep test*, the suction chamber is secured on the skin with double-sided adhesive tape to prevent any skin slippage during

suction. When suction is applied, a roughly hemispherical elevation of the skin appears whose height is measured by the device at short time intervals (less than 1 s). The suction is maintained for a few seconds, then stopped, and then the measurement is continued for the same time length, which is usually not long enough for the skin to regain its initial condition (Fig. 1). The five descriptive parameters to be obtained are: U_e , U_f , U_r , U_a , and R . For a given suction, the elevation will be higher if the skin is more supple. The extent of recovery increases with the skin tone and decreases with its viscosity. Usually U_e decreases over the first four suction cycles and then remains stable. This is a typical preconditioning phenomenon and shows the capacity of the skin to orient its elastic structures in the direction of stretching.

2. For a progressive loading and unloading test, a stepwise increasing suction is applied and the graph of the suction force F versus deformation U_f is recorded (Fig. 2). The tangents to the ascending slope are the successive skin stiffness moduli in the experimental conditions, especially for a given increasing suction rate – as the higher the rate, the steeper the slope. As in creep tests, the first curve is different from the subsequent ones, up to the fourth (preconditioning phenomenon). If a cycle is carried out at the same rate, two other interesting parameters are obtained: the hysteresis loop area and the slope of the descending curve. The ascending slope increases with the skin tone and decreases with its viscosity. The opposite is true for the descending slope. The hysteresis area is related to the skin viscosity.

3.2 Devices

The two devices currently available on the market give the exact limits of the area submitted to suction; therefore, the conversion of the descriptive parameters into absolute parameters is possible. The obtained parameters are the mean of the two directional parameters in the horizontal plane, since the skin is mechanically anisotropic in this plane.

The Dermaflex A² (Gniadecka and Serup 1995) has a 10-mm diameter suction chamber and can achieve suctions up to 0.5 bar for 2–20 s. It is also possible with its software to program 1–30 successive cycles of suction-recovery and to record its graph. Directly available parameters are: (1) distensibility Uf after the first suction (called this as it is a distension), Ue is not provided; (2) the resilient distension $R = Uf - Ua$; (3) the relative elastic retraction (RER) or elasticity index R/Uf (a viscoelasticity index because both elements of the ratio have a viscous component); and finally, (4) the increase of Uf between the first and the last suction, which is a measurement of the preconditioning while the differential area between suction and recovery curves (the hysteresis loop) is an index of skin viscosity. On the adult volar forearm, the approximate values obtained by six cycles of suction at 0.3 bar for 4 s are (Overgaard Olsen and Jemec 1993):

Viscoelastic distensibility	$Uf = 0.65$ mm
Residual distension	$R = 0.60$ mm
Elasticity	$R/Uf = 65$ %
Hysteresis (preconditioning)	$Uf4 - Uf1 = 0.19$ mm

Considering the diameter of the suction chamber (10 mm), the above mentioned parameters are not sensitive to the variations of the stratum corneum's suppleness because this layer is barely involved in the bulging. However, they can be sensitive to the mechanical properties of the hypodermis (resistance of this layer to the upward movement of the skin), even in areas where it looks loose (Panisset 1992; Diridollou et al. 1998).

A simplified device aimed at roughly investigating the skin's softness, which utilizes probes for measuring transepidermal water loss and epidermal hydration in a global apparatus, the Dermalab (Cortex Technology, Hadsund, Denmark), has recently been put on the market (Serup 2002). Within a suction chamber of 10 mm in diameter, a suction is progressively applied until the skin bulging reaches 1.5 mm. A pretension suction and several extension–recovery cycles can be done. The result is expressed as the necessary time and suction, a calculated parameter would be related to the elasticity modulus, and the time and suction necessary

for raising the skin to an intermediary level. This poor scientific device is obviously intended for retail cosmetic traders.

The Cutometer SEM 474 (Courage-Khazaka, Cologne, Germany) has a cylindrical chamber in which a sudden suction of 0.1–0.5 bar (10–50 kPa) can be obtained. Four chambers of different diameters are available: 2, 4, 6 and 8 mm. In the creep mode, suction can be performed for 0.1–60 s. The program can produce successive suction-recovery cycles. The graph of deformation is recorded, and with a cursor system, all the required extension parameters are directly provided (Ue , etc.). The ratios (Uv/Ue , etc.) and preconditioning ought to be calculated. To have accurate values, the suction device has to be applied on the skin with a constant pressure which is ensured by a spring located in the probe (Asserin et al. 1994). On the volar forearm of young adults, the values of Uf for different diameters of chamber and different pressures are displayed in Fig. 4 (Panisset 1992). They indicate that skin resistance with the 8 mm chamber increased, a lower Uf , whereas a reduction was expected. This is the result of a beginning resistance by the hypodermis to the elevation of the skin. The Cutometer can also be used in a *progressive deformation test* mode. In this case, the suction is gradually increased. The device displays the graph of deformation versus the suction force (Fig. 2).

The 2-mm chamber is sensitive to the stratum corneum's mechanical behavior (for example, with a 0.4 bar suction). This is not the case for other diameters. On the volar forearm, using the 2-, 4- and 6-mm chambers even with a 0.5 bar suction does not seem to involve any resistance from the hypodermis, but this is likely with the 8-mm chamber, even for a 0.1-bar suction (Fig. 4) (Panisset 1992). On other sites, where the hypodermis is less loose or scanty, this is much more probable, even with the small chambers. Parameters Ue , Uv , Ur , Uf as well as Uv/Ue and Ur/Uf have been measured by Cua et al. (1990), in 20- to 30-year-old and 70- to 80-year-old subjects and on 11 body sites, using the 2-mm chamber with a 500-mbar pressure for 5 s. The ratios Ur/Ue , Uv/Ue and Ur/Uf in 20- to 30-year-old and 60-

Fig. 4 *U_f* values (Cutometer) on the volar forearm of a 26-year-old subject (Panisset 1992). Five pressures (suction) for each chamber diameter (2, 4, 6, 8 mm). Mean and standard deviation (n = 10 tests per column). The steady *U_f* increase with pressure ceased to be observed with the 8 mm chamber, suggesting a reduced bulging due to hypodermis distension

to 70-year-old subjects, on four body sites, using different chambers and pressure values, and the influence of preconditioning have been investigated by Barel et al. (1998).

The Dermagraph (Rüetschi AG, Yverdon and Murten, Switzerland) uses a vacuum probe of 20 mm in diameter and 442 g in weight. The experiment is a 6-s creep followed by a 4-s recovery. The obtained parameters are the skin’s immediate extensibility *U_e*, the final extensibility *U_f*, the immediate recovery *U_r*, and the ratio *U_f/U_r*. In a study of 22 body areas in 96 healthy volunteers and 10 patients with systemic sclerosis (Häuselmann et al. 2002), it was found that in normal subjects *U_f* and *U_r* were higher in females, higher in torso, and lower in limb extremities. Surprisingly, no change with aging was found. The authors also concluded that “the Dermagraph can be used in longitudinal studies in patients with systemic sclerosis”.

The large suction chamber aperture (20 mm) minimizes the stratum corneum’s influence in the results, but enhances that of the subcutis. Resistance of the latter would decrease the extensibility and consequently skew skin data. Testing subcutis resistance needs comparison of data obtained with several suction forces (see Fig. 4). The assertion of Dermagraph

utility in systemic sclerosis is obviously also valid for the Dermaflex A and the Cutometer SEM 474.

3.3 Conversion of Descriptive Parameters into Absolute Parameters

It is based upon the geometry of the deformation (Panisset 1992; Agache et al. 1992). In a creep experiment, considering that: (1) the skin is a homogeneous and isotropic material (a wrong but useful hypothesis), (2) the skin deformation in the suction chamber is a part of a sphere and its vertical section is the segment of a circle, then the formulas to calculate the strain ϵ and the relative elongation e are as follows:

$$R = (U^2 + r^2)/2U \quad \sin \theta/2 = r/R \quad L = R\theta \text{ (in radians)}$$

$$\sigma = PR/2e \text{ (P expressed in kPa)} \quad \epsilon = (L/2 - r)/r$$

where P is the suction (pascals), U the elevation of the skin in the suction chamber (meters), r the radius of the suction chamber (meters), e the skin thickness (meters), L the length of the arc made by the stretched skin, R the radius of the

circle of this arc, and θ the angle that faces this arc. Depending on whether Ue or Uf is used, the strain, and as a consequence the modulus, will be slightly different. Both choices can be used, but must be indicated.

In a progressive loading-unloading test, using a prototype similar to the Cutometer, but a different model, the formula used to compute the initial stress F_0 , the stress F during loading, and the relative elongation during loading, proved to be more complicated (Diridollou et al. 2000a).

The analysis of the viscous behavior in a creep test (with the calculation of the viscosity coefficient) and in a progressive loading-unloading test (with the calculation of a non-restored energy ratio) are described in Sect. 11.1.

4 Torsion Method

4.1 Equipment

In this method, a ring of skin located between a central disk and a peripheral ring or plaque is submitted to a sudden torsion by application of a constant torque on the central disk (Agache 1995). The resulting rotation angle of the disk is the deformation measured. The Dermal Torque Meter (Dia-Stron Ltd, Andover, Hampshire, UK) is derived from the Twistometer (L'Oréal), which has not been commercialised. The disk and the ring should be glued firmly onto the skin with double-sided adhesive tape. The operator can program 1–20 torsion cycles, selecting their duration (1–99 s), their frequency (intervals from 1 s), the torque intensity ($0\text{--}30 \times 10^{-3}$ Nm with a 0.1×10^{-3} Nm resolution). The torsion angle can be measured from $0^\circ\text{--}40^\circ$ with a 0.02° resolution. The diameter of the central rotating disk is 20 mm, and the peripheral rings can test 1, 3 and 5 mm large skin rings.

In the creep mode, the device records the graph of the angle (in degrees) versus time (seconds) and the standard deformation parameters Ue , etc. A *progressive traction* mode is also available, by measuring the torsion angle at each step of the torque rise. The result is the graph of the torsion

angle versus the applied torque. As in the suction method, the first curve is different from the others, with stability being reached by the fourth one (preconditioning).

A 1-mm skin ring is very sensitive to the stratum corneum's behavior changes (Agache 1995). To assess the whole skin behavior, it is preferable to use the 3-mm ring and a $2\text{--}10 \times 10^{-3}$ Nm torque (de Rigal and Lévêque 1985). On the volar forearm, a 0.028 Nm torque on a 5-mm wide skin ring makes the skin rotate (Ue) of 5.3° in children and 2.6° after the age of 70 (Agache et al. 1980). Greater torques risk involving hypodermis resistance.

When one wants only the relative variation of the elastic modulus, that is $\Delta E/E$, an approximation is given by the following formula: $\Delta E/E = -(\Delta Ue/Ue + \Delta e/e)$, where e and Δe are the skin thickness and its variation (Agache 1995). The measurement of the absolute value of E requires the additional calculations described below.

4.2 Conversion of Descriptive Parameters into Absolute Parameters

As in a suction test, the geometry of the skin deformation is known since the limits of this deformation are well-identified. It is therefore possible to get the absolute parameters of the deformation assuming that the skin is homogeneous and there is no shear gradient within the epidermis (which is wrong but useful). The formula describing the strain σ (N/m^2) and the relative elongation ε (%) on a point located at a distance d from the center of the disk are:

$$\sigma = -C/2 \pi d^2 e \quad \varepsilon = -\sin \alpha / d^2 (1/r^2 - 1/R^2)$$

where C ($\text{N} \cdot \text{m}$) is the applied torque, R (meters) the radius of the plate, r (meters) the radius of the central disk, e (meters) the skin thickness, α (radians) the measured rotation angle (Courtesy of P. Vescovo, Laboratoire de Mécanique Appliquée, Besançon University, France).

Parameters are slightly different if the angle α is taken from U_e or U_f . Both choices are valid but must be indicated for obvious reasons.

The analysis of the viscous behavior and the description of the viscosity coefficient are described in Sect. 11.1.

5 Uniaxial Elongation

To interpret the results, it is necessary to consider the skin mechanical anisotropy and compare the direction of the elongation with Langer's lines. On the other hand, in this kind of test the limits of the stretched area are not known. Consequently, the calculation of the absolute parameters from raw data would be impossible. However, it has been shown that when the ratio width of jaws/sample length is equal or higher than four, the strained skin area is practically limited to the area in between the jaws (Stark 1980). Another way to work this problem out is to apply a finite elements model to the possibly stressed area (i.e., in between and beyond the jaws). This allows the deformation field to be computed over the whole deformed area for a given position and given dimensions of the jaws, whatever the mechanical properties of the tested material, and thus determining its absolute elastic parameters.

5.1 Repeat Creep Experiment

This technique uses the oldest commercialized device aimed at assessing the skin's mechanical behavior – the Gas-Bearing Electrodynamicometer (GBE) (Gas-Bearing Electrodynamicometer, manufactured on request by C.W. Hargens, registered professional engineer, 1006 Preston Road, Erdenheim, Pennsylvania 19038, USA). A small disk is glued to the skin and moved forward and backward with a periodicity of 1 Hz. The stretching of the skin is recorded on the abscissa and the applied force on the ordinate. Each cycle consists of extensions in opposite directions maintained for about 0.5 s each. Although the elongation is mostly elastic, a small viscoelastic deformation is generated

Fig. 5 Gas Bearing Extensometer. Dorsum of hand, RH 20 % ((Cooper et al. 1985), modified). F force (g), ΔL elongation (mm). *A* Before and *B* after water application. The decreasing overall slope together with the ellipse widening (hysteresis) stem from the stratum corneum's increased suppleness and decreased viscosity

during the cycle (hysteresis), and as a consequence the graphs of the cycles are superimposed ellipses (Fig. 5). The steepness of the slope of the ellipse is an indication of the skin stiffness, and the width of the ellipse indicates the capacity of the skin to undergo passive deformation. Both quantities were measured by their projection on the abscissa.

The apparatus (Hargens 1981; Christensen et al. 1977) was made of two electromagnetic devices: one applies an intermittent traction force, and the other measures the movement back and forth. The shaft holding the disk at one extremity and placed on the skin is activated by a magnetic force and moves in a tube filled with air, without contact with its walls to avoid friction, hence the name of the apparatus. The disk is not glued directly on the skin, but is inserted into a small applicator that is attached to the skin by adhesive. It can be removed easily and used elsewhere. The applied forces keep the movement of the applicator to less than 1 mm in each direction. The stretched skin area is unknown. Parameters are therefore only descriptive.

Recently, the original device has been replaced by the newer Linear Skin Rheometer, which is based on the same principle but uses totally different equipment, both more sensitive and precise (Matts and Goodyer 1998; Matts 2002). The probe stuck to the skin transmits an oscillating force parallel to the surface at a frequency of about 0.33 Hz (each cycle lasts 3 s), and both the force and probe displacement (about 1 mm) are measured (3,000 pairs of points over each cycle). A connected computer controls the applied force through a feedback loop aimed at adjusting the force to the skin's response. The following equations are used to model the obtained loop:

$$F = F_{\max} \sin(t) \quad P = P_{\max} \sin(t + T)$$

where F and P are the applied force and probe displacement, respectively, and T is the delayed displacement relative to force. It follows that the hysteresis area is obtained by the formula:

$$F_{\max} \sin(t) P_{\max} \cos(t + T)$$

The axis of the ellipse, indicating skin stiffness, is given by the ratio F_{\max}/P_{\max} and is called the *dynamic spring rate* (DSR) by the author. Conversely, P_{\max}/F_{\max} expresses skin softness.

Applied to ichthyotic skin, the GBE showed an increase of the slope of the ellipse and its narrowing, both phenomena revealing the dehydration of the stratum corneum. Inversely, the application of an emollient was followed by a lasting decrease of the slope and a widening of the ellipse. The same effect was even more marked when the stratum corneum was incised around the applicator, thus confirming the excellent sensitivity of the device to the behavior of this structure. However, different skin sites with identical stratum corneum did not yield the same results, which indicates that other layers of the skin are involved.

5.2 Acoustical Wave Propagation

Assuming that the skin is a thin membrane and the sound propagation is uniaxial, the dynamic

Young's modulus is given by the formula $E = Dc^2$, where D is the density and c the sound propagation velocity.

The Reviscometer RVM 600 (Reviscometer RVM 600, *Courage & Khazaka*, Cologne, Germany) is a new device aimed at evaluating the mechanical behavior of the skin using ultrasound propagation. Two needle probes are placed on the skin 2 mm apart at a low and constant pressure. One emits an acoustic shock wave, the other is a receiver. The emitter-receiver traveling time of the signal is the measured parameter. The wave is acoustic in nature (not to be mistaken for a shear wave!), and is made of a series of unknown frequencies. As the sound propagation velocity remains independent of the frequency, the device should permit the calculation of the stratum corneum's dynamic Young's modulus rather than the overall skin modulus because of the higher velocity in the horny layer.

5.3 Progressive Extension

The Extensometer (The Extensometer, marketed by Cotech and the Stiefel Laboratories, is no longer available) had two pads that were fastened to the skin, one stayed fixed, and the other moved at a constant speed. The resisting force of the skin was measured versus time (Gunner et al. 1979). At first the 10 mm wide pads were 5 mm apart, the speed was 0.35 mm s^{-1} ($3.5 \% \text{ s}^{-1}$), and the maximum elongation was 4 mm. In uniaxial extension, the lateral limits of the stretched area are usually unknown, as seen earlier. However, the stretched skin area might lie exclusively between the pads if the ratio of pad width to sample length was greater than or equal to four (Stark 1980). With the Extensometer, this means that before extension the pads should have been separated by less than 2.5 mm. As that was not the case, it would have been impossible to have access to the elasticity fundamental parameters. Furthermore, since the extension is linear, a correct interpretation also needed to compare the direction of the traction with Langer's lines because the skin is mechanically anisotropic.

The actual deformation could nevertheless be known using the finite elements method. After having chosen a Poisson's ratio, the Young's modulus is calculated by the usual formula $E = F/e l * \epsilon$ where F is the force measured, ϵ the relative elongation measured, e the skin thickness, and $l *$ the *equivalent width* of the sample measured by the finite elements method (Vescovo et al. 2000).

6 Skin Compressibility

6.1 Indentometry

Indentometry is the measurement of the depression caused in the skin by a small disk pushed down vertically. It can be performed only on body sites where the skin covers bones, or it would measure the compressibility of the underlying muscles (Piérard 1984). The graph of the deformation versus time is of creep type. Dikstein's prototype (Manny-Aframian and Dikstein 1995a) used a 10 g/cm^2 load (0.98 kPa) applied on the forehead for 10 s, resulting in a depression of about 0.5 mm. He found that between the ages of 20 and 70 the depression depth decreased but the difference was not significant. The same applied to U_r (80.5 % at the age of 20 compared to 65.5 % at 70). Edema reduced both parameters, while hydration of the stratum corneum had no effect.

Compressibility strongly differs from extensibility because the collagen bundles of the dermis are oriented structurally parallel to the surface and form a protective viscoelastic cushion against direct impacts. Consequently, indentometry mainly evaluates the capacity of the interstitial ground substance to be moved. This depends on its viscosity and the spaces available within the collagen network. To a lesser extent, the vertical stretching of the elastic fibers around the disk (Lanir et al. 1993) and the pressure in the interstitial tissue are also involved.

Lanir tried to define the geometry of the deformation and calculate the resistance resulting from the elastic structures and viscosity as well as the intrinsic parameters of compressibility (Lanir et al. 1990).

Fig. 6 Position of the forearm for a suction test

The technique was recently reexamined by Zahouani et al. (2002) through monitoring the penetration of a spherical indenter in the skin by means of a laser beam deflection measurement and recording the vertical force F_z . The maximum indentation depth during a loading–unloading cycle was $2,000 \text{ }\mu\text{m}$ with a resolution of $0.07 \text{ }\mu\text{m}$, and the load range was 0.1–100 mN. The graph of the loading–unloading cycle at a constant velocity showed a hysteresis loop due to the viscoelastic nature of the skin.

Through the calculation of the radius a of the ball circle of contact with the skin at indentation depth $*$ (Fig. 6), and considering that a is small comparatively to the radius R of the ball (very shallow indentation), the authors were able to compute the pressure on the ball along the radius a ($0 < r < a$) and the absolute mechanical parameters: stress F and strain.

$$\sigma = \frac{3 F_z}{2\pi a^2} \left(1 - \frac{r^2}{a^2} \right) \text{ and } \epsilon = 0,4 \frac{a}{R} (\%)$$

Further treatment of the loading and unloading curves with the calculation of the strain velocity permitted the assessment of mechanical properties of the skin under compression and calculation of the elastic and viscous energy (Fig. 7).

An example of the mechanical response of the skin versus ageing is presented in Fig. 8 and Table 1. The table summarizes the parameters of two females (volar forearm) aged 27 and 51. The total energy dissipated over the cycle (W_T) was divided into its elastic (W_e/W_T) and viscous (W_v/W_T) fractions.

Fig. 7 Analogue models of the skin’s mechanical behavior. A Kelvin-Voigt model of the extension process (situation before extension). Ue phase: R1 spring elongates alone. UV1 phase: R2 spring and V1 dashpot resist together. The V2 dashpot resists over the whole test duration. B Tentative model of the recovery process (situation before recovery). F external stretching force, f skin self-retraction force. During recovery the internal spring and dashpot oppose each other

Additionally, this indentation technique permitted the authors to describe the behavior of the skin surface adhesion force along the whole loading-unloading cycle, and to show the influence of this attractive force on the indentation parameters (Agache et al. 2004). It was also used to study the frictional properties of the skin surface (see ▶ Chap. 95, “Skin Mechanical Function”).

6.2 Ballistometry

This technique (Ballistometer Dia-Stron Ltd, Unit 9, Focus 303, Business Centre, South Way, Andover, UK) records the successive rebounds of a light hammer falling with a given energy onto a surface (Adhoute et al. 1993; Hargens 1995). The kinetic energy can be transformed into rebound, deformation or heat. The more that is transformed into rebound, the more elastic the surface. Because of its kinetic energy, the hammer makes a small depression on the

Fig. 8 Creep experiment data processing. Example of Sect. 11.1: each U has been replaced by its corresponding strain ϵ . A experimental curve, B straight line showing the purely viscous elongation over the whole experiment, C viscoelastic + viscous deformation over time curve: it exactly matches the A curve (except values before 1 s which are not valid: see text). D viscoelastic deformation over time curve, which equals the C curve after subtraction of the B line

Table 1 Influence of aging on indentation parameters (see Fig. 8)

Mechanical parameters	Subject A (27 years)	Subject B (51 Years)
Vertical load: F_z	60 mN	60 mN
Penetration depth: δ	2311 μm	1416 μm
Contact radius: a	3831 μm	2999 μm
Vertical stiffness: K_z	52 N/m	128 N/m
Compression Young's modulus E	7.1 kPa	21 kPa
Elastic fraction: W_e/W_T	90.7 %	81 %
Viscous fraction: W_v/W_T	9.3 %	19 %

skin (compression phase), but since the skin is elastic it sends the energy back to the hammer (restitution phase), hence the rebound. Obviously, the sent back energy is always lower than the initial one, because the deformation is associated with absorption of some energy due to skin viscosity. The height and duration of each rebound is therefore lower than the previous one.

The ballistometry's main parameter is the restitution coefficient $e = (h_2/h_1)^{0.5}$ where h_1 and h_2 are the first and second rebound heights. This ratio stays constant up to the last rebound: $dY/dn = -kY$. Hence, amplitudes of the rebounds are $Y = Y_0 e^{-kn}$, where Y_0 is the height of the falling mass before the test, n the sequential rebound number, and k is the skin absorption coefficient (Adhoute et al. 1993).

The restitution coefficient depends on two factors: it is increased by the skin elasticity and decreased by the skin viscosity. The skin absorption coefficient k is closely related to the restitution coefficient e . Thus, only the first parameter is original, and since it does not depend on experimental conditions, it is more suitable for comparing the results from different laboratories. The hammer impact force on the skin is Moq/L , where Mo is "the hammer momentum", the angular displacement when the hammer reaches the skin surface level, and L is the hammer length. When it is plotted against the penetration depth of the hammer into the skin, a force-deformation curve equivalent to the ascendant part of Fig. 2 of this chapter is obtained (Pugliese and Potts

2002). It should not be mistaken for a stress-strain curve because neither stress (i.e., force divided by skin application area) nor strain (i.e., skin relative deformation) in the three coordinates is known. Consequently, intrinsic skin parameters cannot currently be calculated from ballistometry experiments.

The elastic response depends on the extent of the skin distension (the hammer penetration depth), and the viscous response is all the stronger when this distension is fast (Hargens 1995). From a practical viewpoint, it is advised to use low hammer falling speeds to reduce this viscous component and increase the amplitude of the rebounds, thus providing more accurate measurements. On the other hand, by modifying also the mass of the hammer it might be possible to dissociate and possibly measure the two components of the skin reactivity. Additional theoretical works are necessary to find out if this is possible (Hargens 1995).

In 1976, Tosti et al. (1977) were the first to evaluate the elasticity of the skin surface through its capacity to induce the rebound of a 0.5-g hammer falling from a 2-cm height. For a given body site, the restitution coefficient was found to be constant: 0.5 on the forehead, 0.6 on the dorsum hand, and 0.7 on the thigh. This ratio decreases noticeably with age (Tosti et al. 1977; Pugliese and Potts 2002). The same was observed with the amplitude of the first rebound (Fthenakis et al. 1991; Pugliese and Potts 2002). On the other hand, k ranged between 0.4 and 1.1 and increased with age (Adhoute et al. 1993).

7 Resistance to Skin Lifting

The technique, levarometry, measures the height of a lifted small disk affixed to the skin and pulled vertically. Dikstein's prototype (Manny-Aframian and Dikstein 1995b) measured the elevation of a 2.5-mm diameter disk with tractions between 5–40 g/cm² (0.5–3.9 pKa) for 10 s. The graph of the elevation versus time has a creep type. On the volar forearm, below 2.0 kPa, the elevation was lower in males, and on the forehead, it decreased with ageing regardless of the traction force. The Dikstein apparatus did not use any guard-ring, which allowed the adjacent skin to move up together with the disk.

Levarometry seems to be the simplest method to assess the mechanical behavior of the hypodermis because the skin sustains only a negligible stretch in the course of lifting. The limits of the area subjected to stress are not known; as a consequence, it is not possible to compute the absolute parameters. The device is not commercially available.

8 Identification of Langer's Lines

On all body sites, the skin tension is greater in the direction of Langer's lines (Langer 1978). These are responsible for the anisotropic deformation of incised or excised skin. An incision carried out along Langer's lines widens less and closing it requires less pull. This reflects the intrinsic tension of the skin, which is distinct from the additional tension induced by increases in volume of the underlying tissues, such as muscle contraction, edema, or a particular posture which stretches the skin. The identification of Langer's lines must, therefore, be made on relaxed skin.

8.1 Stark's Method

According to the definition, the direction of the maximum tension can be found by stretching the

skin in several directions with an equal force – the direction of minimum elongation is that of Langer's lines. Stark developed a simple device comparable to a compass: two branches with claws at their extremities part spontaneously by 30 mm under the action of a 14.2 g/mm spring. He could measure the elongation of the skin into eight directions quickly, each measurement requiring only 1.5 s. This device is not commercially available (Stark 1977).

8.2 Borges' Method

This similar method is less accurate, but even quicker, and consists of creasing the skin between the thumb and the index in all directions until the furrows are regular and parallel. They follow Langer's lines. In the other directions, they are impeded by the skin tension that makes them irregular (Borges 1989).

8.3 Barbenel's Method

The measurement of the extensibility of the skin using the suction method is valid only if slippage of the skin into the suction chamber is prevented. If, inversely, this movement is facilitated, the most extensible direction of the skin will appear easily, that is to say perpendicularly to Langer's lines. If the contour of the chamber is drawn in during suction, when the chamber is removed, an oval outline is observed instead of a circle and its main axis corresponds to Langer's lines (Barbenel 1995).

8.4 Skin Microrelief

Apart from the palms and soles, the skin microrelief is made of plateaus separated by valleys. The latter are roughly parallel and orientated in two or three directions, and this layout is characteristic of each body area. The direction of the deepest valleys matches Langer's lines. There may be one or two other preferential

directions, indicating an ordered nonorthogonal mechanical anisotropy. This method has an advantage over the others as it is insensitive to extrinsic skin tensions. Its physiological interpretation is simple. The cutis is normally retracted (skin tension) and extensible, whereas the epidermis has none of these properties. Therefore, the epidermal creasing responsible for the microrelief appears to be a transformation of tension allowing the creases to be flattened by stretching them. The superficial dermis, an intermediary zone between epidermis and cutis, is precisely the place where the skin relief begins. This mechanical transduction is one of its functions (Pierard et al. 2003).

8.5 Acoustical Shockwave Propagation Velocity

As the propagation velocity of a shear stimulus within the skin is direction dependent (Vexler et al. 1999), one may assume that it also holds true for acoustic waves. Consequently, the skin mechanical anisotropy can be assessed using the Reviscometer (see Sect. 5.2), which measures the propagation velocity of an acoustic shockwave along 2 mm in four directions (Nizet et al. 2001).

9 Conditions for a Reliable Measurement

– In suction, torsion, and extension methods, it is necessary to take care that the skin does *not* slip at all into or under the device. Hairs should be shaved, sweating prevented, and any trace of ointment removed. Although the adherence of double-sided adhesive tapes is higher than the low forces exerted on the skin surface, it has to be checked. The use of cyanoacrylate glue ensures that the skin does not move. When publishing, it is recommended to mention with precision the type of adhesive used. Anyway, testing the adhesive device (Tokumura et al. 1999) is mandatory.

- The weight of the measuring apparatus may considerably alter the mechanical behavior of the skin. It should, therefore, be cancelled out, for example by a bracket holding the device so that it only touches the skin. If this is not the case, the pressure on the skin has to be indicated. The Cutometer must always be used exerting the pressure recommended by the manufacturer (Asserin et al. 1994).
- The part of the apparatus which is in contact with the skin must be parallel or perpendicular to the skin, according to the type of method. Any deviation introduces a significant error.
- The subject's posture is a possible factor of exogenous skin tension (adding to its endogenous tension). Unless it is intended to measure this additional tension, the mechanical test should be performed on relaxed skin (Fig. 6). However, the skin must not be crinkled as extension could then be mistaken for flattening out.
- The behavior of the skin is sensitive to the temperature and relative humidity of the test room. These must be indicated. Mechanical tests should be performed after a 20 min wait in the room or in similar conditions, so that the skin and the whole body have time to adapt their behavior to these conditions (for example, vasoconstriction induced by the cold may alter the test results' generalizability). The subject should be in comfortable thermal conditions.
- For repetitive tests at the same site, the tested area should be delineated with precision because the skin behavior may not be identical a few millimeters further away.

10 Conditions for a Correct Interpretation

Most devices measure deformation (U_e , etc.) versus force. Evidently *deformation* and *elongation* are not synonyms. However, deformation is sometimes mistaken for relative elongation, which is also called the strain in mechanics.

Relative elongation ϵ is measured as a percentage of the initial length. Stress σ , which is measured in pascals, is the force divided by the section of skin involved and requires the measurement of the skin thickness. Only these parameters describe the intrinsic mechanical behavior of the skin.

10.1 Definition of the Object of the Research

- If only comparisons are to be made, the measurement of the different deformations and their interrelations is sufficient (e.g., age-related evolution of U_r/U_e (Escoffier et al. 1989) or softening effect of a topical preparation on the stratum corneum (de Rigal and Lévêque 1985)).
- If the study of the change in skin intrinsic behavior (e.g., the elasticity modulus) is also the objective of the study, it is necessary to measure the skin thickness and use the formula: $\Delta E/E = -(\Delta U_e/U_e + \Delta e/e)$, where e and Δe are the skin thickness and variation. An example is the comparison of skin extensibility in Ehlers-Danlos and Marfan syndromes and healthy skin (Bramont et al. 1988).
- Finally, if intrinsic parameters are researched, several tests have to be performed with increasing forces. For each force it is necessary to calculate: the relative elongation, stress, and relaxation time; then, the elasticity modulus E (or shear modulus G); and the viscosity η versus stress. The help of an engineer or physicist may be useful.
- For uniaxial measurements, the skin mechanical anisotropy must be considered, and tests should preferably be performed parallel and perpendicular to Langer's lines. In any case, the direction of the extension in relation to these lines must be known.
- In a mechanical test, the first extension is more important than the following ones for an identical stress. The reason is a small residual deformation is caused by the previous mechanical constraint, even if it is not recent.

Preconditioning the skin consists of repeating the test at least four times in a row so as to eliminate any trace of this unknown previous action and begin the mechanical study in reproducible conditions. Nevertheless, it is possible to study the skin without preconditioning since it is its spontaneous state, even though there is a risk of higher variability. However, mechanical tests should not be conducted in subjects who have exercised intensely in the previous 24 h because their skin may remain abnormally conditioned.

- Knowing the limits of the method is essential for accurate interpretation. For example, the use of an 8 mm diameter suction chamber is more likely to give the measurement of the mechanical resistance of the skin and hypodermis as a whole (Fig. 4) rather than the skin alone.

11 Skin Structure-Rheology Relationships

As mentioned in the introduction, one of the objectives of mechanical function investigations is to obtain data on the mechanical properties of the skin, and further, on the origin of the observed data in terms of intracutaneous structural behavior.

11.1 Searching for Intrinsic Mechanical Properties

11.1.1 Analysis of the Extension Phase

The extension phase is characterized by the opposition between an applied external force and the joint resistance of the elastic and viscous components of the tissue. The Fig. 7a analogue model is used for its analysis. Spring R1 is responsible for the resistance to the immediate deformation U_e (because of the suddenness of the force, no viscous deformation has time to occur); a second spring R2 is responsible, together with the viscosity, for the resistance to deformation in the course of the curvilinear

phase Uv1. Viscosity is represented by dashpots, the first one V1 is extended during Uv1; the second one V2 is deformed during the rectilinear phases Uv2.

Intrinsic Properties of Elastic Structures. The intrinsic properties of elastic structures are computed from the loading phase only. The elasticity modulus E (pascals) in extension experiments and the shear modulus G (pascals) in torsion experiments are the main parameters. In a suction test, E is obtained by the formula (Agache et al. 1992, 1995): $E = (1 - \nu)\sigma/\epsilon$ where σ is the strain, ϵ the relative extension, ν the Poisson's ratio chosen arbitrarily at 0.4 (slight increase in volume) or 0.5 (no change in volume) (see ► Sect. 2.4 in Chap. 95, "Skin Mechanical Function"). The shear modulus G is obtained by the formula: $G = C(1/r^2 - 1/R^2)/4\pi e \sin\alpha$, where $C(N \cdot m)$ is the applied torque, $e(m)$ the skin thickness, r and $R(m)$ the radii of the disk and the guard ring, and α (radians) the rotation angle measured. The formula $E = 2G(1 + \nu)$ permits the shifting from one modulus to the other assuming that the skin is homogeneous and isotropic (an incorrect assumption although acceptable in this particular case).

In a creep experiment using a 0.4 bar suction maintained for 2 s, the average elasticity modulus on the forearm of 20 subjects aged 25.5 ± 2.1 was found to be 814 kPa (Agache et al. 1992). To find out Young's modulus E_0 , which is the intrinsic stiffness of the skin if its natural tension was cancelled (i.e., its elastic structures fully recoiled), it is necessary to perform several creep tests with increasing forces and draw the curve of the elasticity moduli versus the stresses. An ascending straight line is then obtained: its intercept with the ordinate is E_0 ; the negative intercept with the abscissa σ_0 is the natural tension of the skin in resting conditions; and the slope m (without dimensions) measures the intrinsic behavior of the elastic structures of the skin, that is to say their stiffening according to the stress they sustain.

In the course of a progressive traction test using the Kelvin-Voigt model, the deformation would stem almost exclusively from the extension of the spring R1, provided that each step of

the increasing suction was short enough to give the dashpots V1 and V2 no time for stretching; making the final deformation similar to the added U_e of creep tests. Conversely, if the stepwise increasing suction is lengthy, then a viscous deformation has time to take place and the observed deformation would be similar to the added U_f of creep tests. For each stress σ and relative extension ϵ , E is calculated, then the graph of E versus σ is drawn – it is usually an ascending straight line. The extrapolation for $\sigma = 0$ gives the Young's modulus E_0 . In a study on 24 subjects aged between 60 and 70, Barel et al. (1998) found that for a depression between 0.15 and 0.5 bar E stayed apparently constant ($E = E_0$) and was about 146 kPa in the volar forearm, 214 kPa in the forehead, and 272 kPa in the temporal areas. These figures seem rather low. This could be due to a low suction increasing rate which let a viscous deformation take place (through the dashpots) and so diminishes the contribution of the springs. Using another device and another analogue model, Diridollou et al. found $E = 120$ kPa in volar forearm and 230 kPa in forehead (Diridollou et al. 2000b). The forehead values, as found by Barel (Barel et al. 1998) and Diridollou (Diridollou et al. 2000b), although congruent, may be too high because at this location the subcutis is much less developed than in the forearm and might oppose some resistance to the skin bulging. This should be checked before accepting these results.

Intrinsic Properties of the Viscous Flow. The physical parameter is the viscosity coefficient η (in poise = $N \cdot s/m^2 = Pa \cdot s$), which increases with the viscosity of the material.

In the course of a protracted *creep test*, the total viscous deformation is expressed by the equation $U_f - U_e = U_v(1 - e^{-t/\tau}) + At$ (Vlasblom 1967), where $U_v(1 - e^{-t/\tau})$ corresponds to U_{v1} (the curved part of U_v), which represents the joint extensions of the spring R2 and the dashpot V1. While At corresponds to U_{v2} (the straight part of U_v) and the elongation of the dashpot V2 during the entire duration of the application of the force (Fig. 7a). Obviously this model is wrong if

$t = \infty$, but it is valid for mechanical tests of normal duration. There is no globally accepted criterion for defining the limit between U_{V1} and U_{V2} . A priori, it may be assumed that in a creep test lasting at least 10 s, the last 5 s apply to the purely viscous phase and the first five to the viscoelastic phase.

For the calculation of the intrinsic properties, it is first necessary to convert the descriptive parameters (U and F) of each measurement point into absolute parameters (ϵ and σ) using the formulas mentioned in Sect. 3.3. One may assume that the skin does not become thinner significantly and thus that the stress σ remains constant over the whole test. As seen in Fig. 8, the total relative deformation ϵ_t (curve A) is the sum of the deformations ϵ_e (purely elastic, instantaneous), and ϵ_{ve} (viscoelastic, curve C), and ϵ_v (purely viscous, straight line B). Only ϵ_t is known.

First, ϵ_v is calculated (Fig. 8, straight line B). Using the ϵ values at the longest times (for example from 6 to 10 s) the slope of ϵ versus time (parameter A of the global equation), and intercept (ϵ_i) are determined. Dividing the stress σ by the slope gives the viscosity η_2 of the dashpot V2. On the other hand the intercept ϵ_i is the sum: $\epsilon_e + \epsilon_{ve}$. (Fig. 8).

The viscoelastic deformation ϵ_{ve} is then measured at shorter times (for example between 2 and 5 s). It is given by the formula: $\epsilon_i - \epsilon_{ve} = (\epsilon_i - \epsilon_e) \exp - t/\tau$, or: $\ln(\epsilon_i - \epsilon_{ve}) = \ln(\epsilon_i - \epsilon_e) - t/\tau$.

This function is a descending straight line whose slope is $1/\tau$ and intercept $\ln(\epsilon_i - \epsilon_e)$. As a result, ϵ_e is found, and also $E2/\eta1 = t/\tau$. The elasticity moduli of the springs R1 (E_1) and R2 (E_2) are then calculated as follows: $E_1 = (1 - \nu)\sigma/\epsilon_e$, and $E_2 = (1 - \nu)\sigma/\epsilon_{ve}$. Since E_2 is known, $\eta1$ can be obtained.

By using a Cutometer with a 4-mm diameter probe and a 400-mbar suction on the volar forearm, and arbitrarily taking a 1-mm skin thickness and a Poisson's ratio $\nu = 0.4$, the following values are found: $E_1 = 1.09$ MPa, $E_2 = 3.40$ MPa, $\eta1 = 4.5$ MPa · s, and $\eta2 = 110$ MPa · s. With the Cutometer, deformation measurements must not be done before 1 s (suction loading time).

In a torsion creep test or in a progressive traction test, the calculations are much more complex. Using a progressive loading–unloading test, Diridollou et al. (2000b) have computed an “unrestored energy ratio” which reflects the extent of recovery at the end of the test.

11.1.2 Analysis of the Recovery Phase

To our knowledge, analysis of the recovery phase has not yet been done although it is rich in information. To begin with, modeling of the extension phase must be completed by a spring in parallel, which would be the responsible component of even delayed total recovery. The simplest model possible is shown in Fig. 7b. Additional studies seem therefore necessary before this phase can be used to investigate the intrinsic properties of the skin. Similar problems occur for torsional measurements and progressive extension tests.

11.2 Connections between Intrinsic Parameters and Biology

What is the biological counterpart of mechanical parameters? It looks as if skin elastic structural elements (springs) were interwoven with others slowing down their extension and recoil (dashpots).

- The *springs* include, among others:
- The dermal elastic network (number of fibres involved and their stiffness)
- The curvature of collagen bundles (number of curvatures involved and their stiffness)
- The skin relief (especially the folding of the stratum corneum)

These three types of springs are parallel. Current tests measure their behavior as a whole. However, it should soon be possible to measure them separately and to get access to their intrinsic parameters (see (Panisset 1992; Agache et al. 1995; Wijn et al. 1981)). In the example mentioned at the end of the preceding paragraph,

one may imagine that E_1 reflects the behavior (force \times density) of the elastic network, and E_2 the much higher stiffness values of the woven collagen network together with the stratum corneum rigidity.

- The absorbing systems include, especially:
 - The viscosity of the interstitial ground substance (role of the proteoglycans)
 - The difficult flow of the liquids inside the fibre network (because of its tightness, for example)
 - The interstitial pressure (the interstitial liquids expelled in the course of torsion and especially compression must move against it)
 - Friction between proteins and other large molecules

In the example of Sect. 11.1, η_1 likely represents the above mentioned absorbing systems, and η_2 is 24 times more resistant to the gradual dissociation of the dermo-epidermal junction (a suction at this value induces a suction blister in 1 h). The measurement of the absolute parameters of these phenomena is thus of obvious interest.

- Examples of possible weakening of the springs (U_e would increase):
 - Softening effect of emollients on the stratum corneum (de Rigal and Lévêque 1985)
 - Lower quantity and stiffness of collagen (Ehlers Danlos type 2) (Bramont et al. 1988)
- Examples of possible strengthening of the springs (U_e would decrease):
 - Higher quantity and stiffness of collagen (systemic scleroderma) (Agache and Humbert 1993)
 - Elastic fiber regeneration (effect of retinoids on corticosteroid atrophy) (de Lacharriere et al. 1990)
 - More numerous elastic fibers along Langer's lines (Wijn et al. 1981)

- Global thickening of the skin (changes from childhood to adulthood) (Agachel et al. 1980)
- After the age of 65, despite the thinned skin, U_e does not increase, revealing the increase of E (Escoffier et al. 1989)
- Examples of possible increase of viscosity (U_v would decrease):
 - Scleromyxoedema (Pierard 1993)
 - Tightening of the collagen network (change from childhood to adulthood) (Escoffier et al. 1989)
- Examples of possible decrease of viscosity (U_v would increase):
 - Decrease of glycosaminoglycans after the age of 60
 - Decrease of oedema (Piérard-Franchimont et al. 1998)

12 Selecting the Appropriate Method

- Use devices providing recognized variables for the deformations – for creep tests that is: U_e , U_v , U_f , U_r (Sanders 1973), U_a (Barel et al. 1998), U_d (proposed here), and R ; and for ballistometry, the restitution coefficient.
- To guarantee reliance and absence of shift, devices should be checked and calibrated regularly.
- The variations of the mechanical behavior of the stratum corneum are more easily assessed by devices that include a probe attached to the skin because in such cases the force is maximal at the surface. Whatever the apparatus, it is necessary to utilize small probes (chamber of 2-mm diameter for the Cutometer, 1-mm wide skin ring for the Dermal Torque Meter). The smaller the surface involved, the more important the role of the stratum corneum in the deformation because the ratio of stratum corneum thickness to involved surface area increases. Owing to the large diameter of its probe (10 mm) the Dermal A is less sensitive to variations of the stratum corneum

rigidity. Ballistometry is barely capable of detecting them.

- The acquisition of a skin thickness measuring device depends on the objectives. It is needed if absolute parameters and intrinsic properties are wanted, but not for comparative studies in the same individual, when the skin thickness is supposed to stay constant.

13 Progress in Methodology

In conclusion, we mention technological development in skin biomechanics because it is a new and barely mature domain in dermatological science. Achieving a prototype that allows quantitative data to be gathered is a valuable first step, even if the parameters used are purely descriptive and exclusive to this device. It is then possible to carry out tests on products and follow the courses of some diseases. Many prototypes developed in laboratories had and still have this function. A second important stage is to put the device on the market, which is usually a guarantee of soundness and reliability. Compared to prototypes, commercialized equipment have the advantage of being tested and used by everybody, hence they facilitate comparisons between laboratories and the use of the same parameters by all the investigators. Up to now most published papers use purely descriptive (phenomenological) mechanical parameters which depend on the device. However, using skin thickness measurement and simple calculations, absolute and universal mechanical parameters, those of physics, can be obtained, which allows linking the mechanical *behavior* of the skin with its intrinsic *properties*. The latter depend neither on the measurement method, nor on the apparatus. This advance in methodology will contribute to the expansion of the skin mechanical functions assessment and foster its use in clinical medicine in the near future.

1 Introduction

1.1 The Measuring System

The first instrument used to assess skin hardness was a Rex[®] durometer (model 1700, Rex Gauge Company, Inc., Glenview, IL). This instrument is the international standard for measuring the hardness of rubber, plastic, nonmetallic materials, and soft tissue such as skin. The durometer is a portable hand-held device, which is provided with a calibrated gauge that registers linearly the relative degree of hardness on a scale of units divided from 0 to 100 shore units (SU) scale (Fig. 1). This feature is the result of a spring-loaded interior that senses hardness by applying an indentation load on the specimen. The bottom of the durometer has a small, dull indenter which is retractable and is responsible for the measurements registered on the gauge (Fig. 2). The instrument is rested by gravity against the skin and must be held in a vertical position. Initial hardness is defined as that recorded within 1 s of firm contact of the durometer with the skin. For many materials, this initial reading remains unaltered after the first second of measurement (near perfect elasticity). Imperfect elasticity is referred to as plasticity

and is observed when continued contact of the durometer with the surface leads to a higher reading. The degree of this plasticity is referred to as “creep,” and in animal tissue the amount of creep

is minimal. The type of durometer used in dermatology to assess skin hardness is Model 0, which is provided with an 822 g springload. To eliminate operator error, the company has improved the first model with a specified amount of weight (400 g), located on top of the instrument, which is used to depress the indenter without any additional pressure. This constant load principle provides a more consistent reading to the operator every time the gauge is applied to the skin. For measurements on the skin, the durometer is used at 25 °C and four consecutive readings are usually taken at the same site. Between readings, the durometer is reset to 0 and measurements are made with the patient supine, thus avoiding muscle tension or contraction.

1.2 Accuracy and Reproducibility of the Measurements

Durometer readings obtained with four consecutive determinations at the same site in each subject and in different clinical conditions differed constantly by less than 5 % (Falanga and Bucalo 1993; Aghassi et al. 1995). The durometer was tested for interobserver and intraobserver

variability in a study (Seyger et al. 1997) where patients with morphea, a localized form of scleroderma, were investigated for skin induration. The durometer was used in combination with a skin scoring system called MSS (modified skin score) (Zachariae et al. 1994). The interobserver variability in the durometer score was only 0.5 % and was even lower than the interobserver variability of the MSS (0.5 vs. 2.2 %). The intraobserver variability, which is the variation in readings obtained by the same observer, was estimated as 0.5. Insensitive durometer readings were found in different areas of the skin, such as the forehead and dorsal digit, where subcutaneous tissue is less represented. The hypothesis of underlying bone or tendon structure giving higher readings at these sites was raised as a possible explanation for this failure to discriminate between normal and indurated skin (Falanga and Bucalo 1993).

2 Medical Applications

2.1 Scleroderma

Sclerodermatous skin is characterized by induration of the lower dermis and directly underlying tissue, which could be affected diffusely as in systemic sclerosis or in a more localized involvement as in morphea. The degree and extent of skin hardness in scleroderma are used as a prognostic value for the disease and generally assessed subjectively using a clinical skin scoring system. Objective measurements of skin involvement in scleroderma have included the use of ultrasonography, skin elastometers, transcutaneous oxygen tension measurements, and also much more sophisticated techniques such as magnetic resonance imaging. All these methods were able to provide useful information about the extent of skin involvement, but are generally considered not practical for sequential measurements in clinical practice. Falanga and Bucalo (1993) were the first to describe the use of a durometer in combination with systemic sclerosis. They investigated six anatomic sites in 12 patients and in 12 control individuals using the durometer in combination

with skin severity score. A direct relationship between the skin severity score and durometer readings was present for all anatomic sites except the forehead: the higher the skin score, the greater the amount of deflection measured with the durometer ($p = 0.0032$, $p = 0.0002$, and $p = 0.005$ for skin score of 1, 2, and 3, respectively). Moreover, the durometer was able to differentiate between increased levels of skin hardness. In this study, no statistically significant relationships were found among body weight, skin score, diameter of anatomic site measured, and durometer readings. The use of the durometer was not associated with any pain or discomfort. Similar results of increased skin hardness in morphea were obtained by Aghassi et al. (1995) in a study where the durometer was also used in combination with a laser Doppler perfusion imager. In that study the authors found a relationship between age and durometer readings over the ventral aspect of the forearm, in normal controls. Skin hardness rises from birth, reaches a constant level by puberty, and then remains steady until age 65 years, when the skin progressively begins to lose its firm quality. Women had lower durometer readings compared with men, and the instrument was able to define contiguous areas in different degrees of sclerosis in morphea lesions. The efficacy of treatment has been investigated in patients with localized scleroderma by means of durometer readings in two different studies. Moon et al. (2012) investigated 31 patients with systemic sclerosis in order to evaluate the correlation between durometer score and Rodnan skin score (MRSS), scleroderma symptoms, and physical functions. Skin involvement was evaluated with the use of the durometer and MRSS. The other parameters that the authors considered were: health assessment questionnaire (HAQ), disability indices, Keitel function test (KTF) scores, grip strengths, and the scleroderma-visual analog scale (scleroderma-VAS). The total durometer score correlated well with MRSS ($r = 0.537$, $p = 0.002$) and KTF scores ($r = 0.608$, $p < 0.001$), but correlated poorly with HAQ disability indices ($r = 0.202$, $p = 0.276$) and individual scleroderma-VAS scores. Skin hardness measured with the durometer were found to

correlate well with the MRSS scores of fingers, hands, forearms, upper arms, thighs, and feet. This study suggests that these skin sites should be considered when skin hardness is measured with a durometer in patients with systemic sclerosis.

Seyger et al. (1998) evaluated the effect of low-dose methotrexate (15 mg/week) in nine patients with widespread morphea in a 24-week trial using the durometer and other clinical assessments to monitor the therapeutic regimen. A total of seven patients out of nine showed a decrease of durometer readings at the end of the trial, with mean values changing from 101 ± 13.9 before the treatment, to 89.7 ± 10.3 after treatment ($p = 0.07$). The greatest improvement in durometer score among the sites examined was the efficacy in the arm region ($p = 0.03$). In another study, Karrer et al. (2000) evaluated the efficacy of topical photodynamic therapy by means of durometer readings and clinical score in five patients with progressive localized scleroderma who had failed to respond to other therapies. In all patients, the therapy was highly effective as measured by durometer score, which showed a mean reduction of 20 % after a treatment period of 6 months. Kroft et al. (2009) used durometer score and other parameters (surface area measurements, photography, clinical features score) to evaluate the efficacy of treatment for morphea with topical tacrolimus 0.1 %. This study examined 10 patients with active plaque morphea treated with tacrolimus 0.1 % ointment and an emollient (petrolatum) on two selected morphea plaques, applied twice daily for 12 weeks. The results demonstrated an improvement in the scleroderma plaques treated with topical tacrolimus 0.1 %, resulting in a significant reduction in durometer and clinical feature scores.

2.2 Lipodermatosclerosis

Chronic lipodermatosclerosis is characterized by hyperpigmented indurated skin on the medial aspect of the leg and is common in patients with venous insufficiency. The severity of induration of

lipodermatosclerosis has been associated with poor ulcer healing. Nemeth et al. (1989) reported a correlation between the degree of skin induration in lipodermatosclerosis and ulcer healing. They used a clinical score to assess skin induration and found that lipodermatosclerosis was less severe in patients who had ulcers that healed than in two who had ulcers that did not heal. Durometer testing of skin hardness was performed on a group of patients with lipodermatosclerosis with and without venous ulcers (Romanelli and Falanga 1995). A clinical scoring for hardness by a blinded observer was used in combination with durometer measurements at a skin site midway between the upper and lower margin of lipodermatosclerosis. Measurements of transcutaneous oxygen pressure (T_{cp}O₂) at the same site were also performed. Compared with normal skin in control subjects, increased skin severity scores were associated with higher durometer readings ($p < 0.01$). This direct correlation between clinical scores and durometer readings was linear ($r = 0.9621$); the durometer was able to differentiate between increased levels of skin hardness. Thus, a skin severity score of two reflected a higher durometer reading than that of a skin score of 1 ($p = 0.0016$). An inverse and statistically significant relationship ($r = 0.431$; $p = 0.0079$) between T_{cp}O₂ measurements and durometer readings was found in patients and control subjects (Table 1). The correlation between T_{cp}O₂ measurements and durometer readings found in that study confirms the hypothesis of poor oxygen diffusion through dense and thickened skin, as occurs in lipodermatosclerosis. Le Blanc et al. (1997) used a durometer to assess the area of lipodermatosclerosis around venous ulcers and obtain a map of skin induration. Their hypothesis was that maximum skin induration correlated with the presence of ulcers. The authors found that venous ulcers were located in skin that was most affected by lipodermatosclerosis. Durometer measurements showed a progressive and linear decrease from the top of the ulcer edge to the knee ($r = 0.925$). In the same study, the authors tested 14 patients with pitting edema and eight controls without edema. There were no significant

Table 1 Relation between TcPO₂ measurements and durometer readings or clinical severity score (inset)

differences in durometer readings in patients with minimal or more severe edema ($p > 0.05$), regardless of anatomic location.

Choh et al. (2010) used a durometer for the assessment of venous disease. They investigated 107 patients with isolated venous disease and volunteers attending outpatient clinics; for all patients the CEAP classifications were assessed (clinical, aetiological, anatomical, and pathological). The measurement with a durometer was made on the skin 15 cm above the medial malleolus on nonulcerated tissue with patient and limb in recumbency. The authors considered the average of four measurements. The results of this study demonstrated that there is statistically significant evidence that age and CEAP classification correlated with durometry ($p < 0.0001$). Thus, durometry could help in monitoring pre-ulcerative venous disease and in identifying high risk patients.

2.3 Neuropathic Foot

Patients with diabetes with peripheral polyneuropathy are at increased risk of foot ulceration. One of the key events in the pathogenetic

pathway to neuropathic ulceration is hyperkeratosis, which develops in areas of increased pressure. Nonenzymatic glycosylation and autonomic dyshidrosis have been implicated in the pathogenesis of skin hardening. Piaggese et al. (1999) measured skin hardness at three different sites on foot of a selected group of patients with diabetes, avoiding areas with bony prominences. Skin hardness was more pronounced in neuropathic patients than in nonneuropathic patients and controls ($p < 0.01$.) Among neuropathic patients, those with metatarsal hyperkeratosis had significantly higher durometer readings compared with those without hyperkeratosis. Subjects were also evaluated for neuropathy by determining the vibration perception threshold (VPT) with a biothesiometer. This instrument is an electrical device provided with a vibrating probe, which is applied to the test site and to which an increasing vibrating intensity is applied. The lowest of three intensities of vibration defines the VPT. In that study, a significant positive correlation was found between durometer readings and VPT at the malleolus ($r = 0.516$) and the allux ($r = 0.624$) in neuropathic patients (Table 2). Cuaderes et al. (2009) have evaluated skin hardness and pressures of the foot in diabetes patients. Skin hardness was measured with a

Table 2 Correlation between vibration perception threshold at allux (VPT-A) and skin hardness measurements at medial (DMT-M) in neuropathic diabetic patients

durometer applied at 10 sites (plantar side of the allux, third and fifth toes, first, third, and fifth metatarsal heads, medial and lateral midfoot, heel, and the dorsal aspect between the hallux and second toe). The readings of durometer and pressurestat have demonstrated a concordance that was acceptable at the hallux, the third toe, the first, third, and fifth metatarsal heads. Since most diabetic foot ulcers occur in these sites, both durometer and pressurestat may be useful screening tools to determine the degree of risk.

3 Conclusions

Durometry is a technique for measuring skin hardness. The method takes advantage of the ability of the durometer to sense and record hardness on a linear scale, and it is unique in its simplicity and ease of use. Measurements with durometer are highly reproducible in the same subject and in persons with the same degree of skin induration. Data obtained indicate that the durometer may be insensitive when used in areas of skin where the subcutaneous tissue is not well represented. At this stage, the instrument is used as a standard noninvasive tool to measure skin hardness in systemic sclerosis. The authors believe that

durometry could be applied in other dermatological diseases to assess skin involvement and to monitor the efficacy of treatment.

Elasticity • Reviscometer • Aging • Skin moisturization • Skin viscoelasticity • Mechanical properties of the skin

1 Introduction

Reduction of skin elasticity with aging is attributed to skin thinning due to loss of elastin and collagen in the dermal matrix (Jansen and Rottier 1957; Lavker et al. 1987), as well as to loss of subcutaneous tissue mass (fat layers and muscle mass) and stiffening of collagen with increased cross-linking. Age is also expected to affect the directionality of the mechanical properties of the skin. During development, from infancy to adolescence, the skin is expected to respond to tension isotropically to accommodate for growth, while in adulthood this isotropic behavior is expected to regress due to site-specific habituation to tension.

The mechanical strength of the skin is primarily attributed to the dermal matrix, which consists predominantly of collagen and elastin. Collagen molecules form fibrils, fibers, and bundles, which are arranged in a basket-weave pattern. This allows the dermis to deform due to pressure and at the same time to minimize tears. The collagen bundles vary in size as we progress from the upper (papillary) to the deeper

(reticular) layers of the dermis and are normally under tension that ranges from 0 to 20 N/m depending on the body site, direction, and posture (Skin Mechanics 1986; Nizet et al. 2001). Ever since the nineteenth century, surgeons have recognized the fact that this tension load is directional by observing that circular punctures in the skin produce elliptical holes (Nizet et al. 2001). These lines, termed “Langer’s lines” (Langer 1861), represent the directions of skin’s maximum tension and have been identified over the whole body (Cox 1942; Gibson et al. 1969). They are used as the preferred direction in which surgical incisions are made so that the tension across the wound is minimal. Furthermore, it is known that dermal fibroblasts generate tension and change their orientation along the tensile direction (Takakuda and Miyairi 1996). The mechanical properties of the skin are thus expected to follow the anisotropy in tension defined by the Langer’s lines.

A number of techniques have been developed to study the mechanical properties of the skin and their dependence on aging (Elsner 1995; Rodrigues 2001). They are primarily based on the concept that assessing the applied force necessary to pull or push the skin gives an estimate of the elastic and plastic properties of the tissue, and they can be classified in the following categories: (a) instruments that generate a light vacuum on the skin surface and determine the height to which the skin may be pulled under constant suction and then the rate at which the skin returns to its original shape; b) instruments that use two concentric cylinders that are placed in contact with the skin and measure the angular displacement under torque and the rate at which the skin returns to equilibrium once the torque is removed; and (c) instruments that assess the firmness/elasticity of the skin by determining the height recovery of a small mass as it bounces after striking the skin from a predetermined height (Serup and Jemec 2006). All of the above types of instrumentation measure parameters that are affected by the mechanical properties of the skin surface as well as the deeper structures of the dermis and even the subcutaneous tissues. Therefore, the information we can get from them is not always limited to the

skin. These methods do not offer any information on mechanical anisotropy.

Another type of instrument allows for the evaluation of the mechanical properties of a material by measuring of the propagation time of a shear wave between two sensors placed on the material surface. The distance between the sensors and the frequency of the shear wave determine the penetration depth of sampling. The commercial version of this method of accessing viscoelasticity of the skin is the Reviscometer[®] RVM 600. The Reviscometer[®] has been designed to sample up to a few tenths of microns in depth making it suitable for measurements of the mechanical parameters of the epidermis and the papillary layers of the dermis. The applied pulse frequency is in the audible range (4.5 KHz). The velocity of sound in a material depends on the density of the material and tension that is under. Mechanical vibrations propagate faster at the direction of higher tension, and as with a guitar string, the higher the tension, the higher the frequency of oscillation after plucking. As the preferred disposition of the collagen fibers corresponds to the skin’s cleavage lines (Langer’s lines), the speed of propagation of elastic disturbances on the skin will depend strongly on orientation.

Previous investigations have shown a weak dependence of the shear wave propagation time on the skin with aging (Nizet et al. 2001; Dahlgren and Elsnau 1986; Vexler et al. 1999). A common denominator of these studies was that the measurements were performed at a limited number of angular positions of the probe, typically at four positions at increments of 45°. Therefore, directional features with angular width less than 45° were ignored or averaged out. More recent studies have shown a strong correlation between shear wave propagation and age (Ruvolo et al. 2007).

In a previous chapter (Ruvolo Jr et al. 2014), the authors described experiments and studies using the same technique that document changes in density of the tissue and the effects on the speed of sound when active ingredients produced changes in the packing of the viable keratinocytes. In this chapter we demonstrate through a number of studies the sensitivity and utility of the measurement of the viscoelastic properties of the skin

by acoustic shear wave propagation (velocity and angular dispersion). In the studies presented in this chapter, the Reviscometer[®] RVM 600 was used, but other instruments using the same principle of actuation can be used. This technique provides unique information on the directional dependence of elastic parameters of the superficial layers and characterizes the tensile forces acting on the skin surface by measuring the anisotropy of the viscoelastic properties of the skin at different ages, correlating the changes in the anisotropy with structural features of the skin. Thus, we attempt to characterize the tensile forces acting on the skin surface by measuring the anisotropy of the viscoelastic properties of the skin before and after topical application of moisturizers. To this end, we established a new data acquisition methodology for the technique (via Reviscometer[®] RVM 600) with high angular resolution, and we defined a novel mechanical parameter that relates to the anisotropy and coherence of skin viscoelasticity.

2 The Technique-Hardware Description

In 1980 Prof. Hagen Tronnier (1980) developed a method to measure resonance frequencies in the skin. Later, in 1999 Vexler (Vexler et al. 1999) described a viscoelastic skin analyzer that resembles more the commercial instrument (Reviscometer[®] RVM 600, Courage + Khazaka Electronic GmbH, Cologne, Germany).

A noninvasive way to assess the mechanical properties of viscoelastic materials, such as the skin, is by investigating the propagation of a mechanical disturbance along their surface. The speed of propagation of a pulse or of a periodic (wave) mechanical disturbance depends on the tension in the material in the direction of propagation and on the density of the material (Doukas et al. 2001). The amplitude of such a stimulus should be small so that no permanent changes are produced in the material and the coupling between the device producing the perturbation and the medium under study, e.g., the skin, should be robust (Vexler et al. 1999; Potts et al. 1983;

Dorogi et al. 1986; Mridha et al. 1992). The following description is based on the construction and use of the Reviscometer[®] RVM 600.

The probe that comes in contact with the skin includes two piezoelectric transducers spaced by approximately 2 mm and mounted on two independent supports. One transducer generates a small amplitude acoustic pulse, <0.2 mm, in the audible range 4.5 KHz, and the second acts as the receiver. The time it takes for the acoustic pulse to travel from the transmitter to the receiver is defined as the resonance running time (RRT value $\times 10^{-6}$ s). The values of the RRT may be used to calculate the velocity of propagation of the acoustic pulse. If we consider the one-dimensional longitudinal model for the sonic propagation from Dahlgren (Dahlgren and Elsnau 1986), Young's modulus of elasticity (E) of the material is directly related to the square of the sonic transmission velocity, c:

$$E = dc^2 \cdot 10^6 \quad (1)$$

where E is in N/m², d is the density of the skin in g/cm³, and c is in m/s. Therefore, the modulus of elasticity may be determined once the velocity of propagation has been measured.

To ensure good contact (no slipping) between the transducers and the skin, a constant pressure is applied; the pressure that the probe exerts on the skin is regulated by a spring mechanism: a given amount of pressure is necessary for the measurement sequence to start. The probe is held perpendicular to the skin surface by a hollow cylindrical holder that is attached to the surface of the skin with double-sided adhesive tape. The manufacturer made marks on the holder along its periphery at angular intervals of 45°. In all the work presented in this chapter, we used a modified probe-holder assembly by placing a millimeter scale on the probe and another on the holder. We carried out measurements by rotating the probe within the holder so that the lines of the two scales would align with each other. This corresponds to making measurements every 3° for a total interval of 100–180°. Custom acquisition software was developed in LabVIEW 6.0 (National Instruments Corporation, Austin, TX).

Fig. 1 Typical data obtained with a Reviscometer[®] from the upper inner arm of a 47-year-old subject. Data shows same location readings acquired in increments of 3° (black squares) and 45° (red circles)

To demonstrate the need of acquiring data at increased angular resolution, we recorded the Reviscometer readings from the same skin site (upper inner arm) of a volunteer of 47 years at intervals of 45° and of 3° (Fig. 1). It is evident that the features with width less than 45° may be missed. Following the Nyquist sampling criterion, using 3° intervals, we could accurately record features of at least 6° angular dispersion width. Typically for older individuals having narrower maxima, the angular dispersion width can be in the order of 10°. Taking measurements with high angular resolution increases the chances of recording the skin’s radial anisotropy accurately. Increased angular resolution of viscoelasticity readings provides information that would be otherwise missed.

The dependence of the measured RRT values obtained from human skin on the angle of measurement may be described by a Gaussian curve, Fig. 2. Two parameters may be determined from the Gaussian fit function: the full width at half maximum (FWHM) and the amplitude of the curve, which corresponds to the angular anisotropy of the RRT. The anisotropy is defined as the ratio between the maximum and minimum RRT of the measurements on a given skin site:

$$A = \frac{RRT_{max}}{RRT_{min}} \tag{2}$$

The definitions for minimum and maximum RRT values (RRT_{min} and RRT_{max} , correspondingly) as well as the full width at half maximum (FWHM) of the fitted curve are demonstrated in Fig. 2; these correspond to two new mechanical parameters that may be determined in the skin based on measurements with the Reviscometer[®], and they are anisotropy and angular dispersion width (FWHM).

The Reviscometer[®] does not work equally well on all skin sites. Skin sites with high density of vellus hairs present difficulties in the interface between the transducers and the skin. Equally difficult has been to obtain good data from skin sites where the skin is tight such as the calves, the forehead, etc. The instrument gives very reliable and high-quality data from sites where the skin is particularly “soft” to the touch such as the upper inner arm, neck, abdomen, breast, thighs, and in particular the inner aspect and the sides of the torso. It is interesting to note that the sites where good measurements may be made with the Reviscometer[®] are also skin sites where “stretch” marks are likely to appear.

Fig. 2 Illustrates the RRT data obtained from the upper inner arm of the same subject as in Fig. 1. Data was obtained in increments of 3° over a range of 120° . A Gaussian curve was fitted. The relevant parameters obtained from such a fit are shown. These are the minimum RRT (RRT_{min}), maximum RRT (RRT_{max}), and the full width of half maximum ($FWHM$) of the curve

3 Instrument Calibration

Typical RRT reading from anatomical sites like dorsal and ventral forearm ranges from 100 to 450×10^{-6} s. The manufacturer supplies with the instrument an elastomer standard with an $RRT = 230 \pm 30 \times 10^{-6}$ s. The RRT value for the standard is suitable for a great majority of the values obtained in different parts of the body.

When different Reviscometer[®] probes were used to measure skin viscoelasticity of the same skin site, we observed the readings to vary between probes, possibly due to differences in the distance between the transducers and differences in their sensitivities. Therefore, the probes were calibrated against a wider range of viscoelastic standards. To this end, we used the standard thermoplastic elastomers' durometer (Biscoe and Sebastian 1993) test block kits for Shore scale A (Rex Gauge Company Inc., Buffalo Grove, IL) and Shore scale 00 (Corporate Consulting, Service and Instruments, Inc., Akron, Ohio). These materials were chosen because of their wide response range of RRT readings ($200\text{--}1,100 \times 10^{-6}$ s). Measurements were repeated ten times in each sample and the data were averaged. The elastomers were

isotropic in terms of RRT values. All measurements were taken at ambient conditions at a temperature of 18°C and a relative humidity of 40–50 %. Table 1 shows the Shore type, the International Rubber Hardness Degree (IRHD) (ASTM 2003), and the density (g/cm^3) of the standard test blocks used in this study. Shore hardness is a measure of the resistance of material to indentation by a spring-loaded indenter. The hardness testing of plastic material is most commonly measured by the Shore (durometer) hardness test or Rockwell hardness test; the higher the number, the greater is the resistance to indentation. Using Eq. 1 we estimated the speed of sound in each elastomer as illustrated in Table 1. Figure 3a shows the RRT values versus the speed of sound (m/s) on the standards for two different probes, and Fig. 3b. illustrates the same elastomers as a function of Young's modulus (MPa). It can be observed from Fig. 3a, b that the probes have similar responses for elastomers with low RRTs but differ at high RRTs. For the elastomers, we can notice that RRTs presented a higher correlation (Fig. 3a, $R^2 = 0.92$ and $R^2 = 0.94$) with the speed of sound than with Young's modulus (Fig. 3b, $R^2 = 0.81$ and $R^2 = 0.83$). Since Young's modulus is defined as the ratio of the stress over the strain in the range of

stress that Hooke’s law holds during tensile tests making linearizing assumptions, the shear wave propagation (RRTs or the speed of sound) on the elastomers can be a better measurement of the surface elastic properties.

The standard elastomer blocks can be used to correlate the readings from one probe to the other by plotting elastomers measurements as

Table 1 Physical Parameters of the Durometer Test Blocks used for calibration

Hardness Shore Type	IRDH	Young’s Modulus (MPa)	Density (g/cm ³)	Speed of Sound (m/s)
00	31	0.133	0.91	384
00	46.9	0.303	0.92	574
00	54.5	0.412	0.93	669
00	63.1	0.414	0.95	660
00	77.3	0.916	0.98	965
A	29	1.024	1.06	983
A	42.8	1.801	1.22	1215
A	50.2	2.367	1.31	1345

illustrated in Fig. 4. The correlation between the two testing probes can be described by a linear fit ($r^2 = 0.92$). As an example, Fig. 5 illustrates RRT readings, as a function of the angle, taken in the upper inner arm of a 41-year-old subject with two different probes. Taking the readings from the probe with lower sensitivity, Probe 02120709, and applying the linear correction obtained from the readings on the testing blocks ($Y = 220.1 + 1.94 * xScale(X)$), we can observe in Fig. 5 that the readings with the probe with lower sensitivity are much closer to the probe with higher dynamic range.

4 Viscoelastic Properties of the Skin at Different Ages and Different Anatomical Sites

It is well known that the human skin changes with age particularly in becoming more “loose” and less “elastic.” This has been shown on the back of the hand as a “pinch” test where we observe the

Fig. 3 The Reviscometer® data for two different probes as supplied by the manufacturer. (a) Illustrates the viscoelastic properties of the different elastomers as a function of the speed of sound (m/s). (b) The viscoelastic properties of the

different elastomers as a function of Young’s modulus (MPa). Data represents mean value and error bars are the standard deviation of the mean (mean + standard deviation)

Fig. 4 The correlation of RRT probe values for elastomers with different hardness. The figure shows the linear correlation between the two probes. Data represents mean value and *error bars* are the standard deviation of the mean (mean ± standard deviation)

Fig. 5 Illustrates measurement at the upper inner arm performed with two different probes. A linear correction ($y = 220.1 + 1.94 \cdot x$) was applied to the probe 02120709 to obtain the adjusted reading (*red star*)

speed with which the skin returns to its original state after being pinched and in lateral compression between two fingers of the skin – in young skin, the skin surface produces a single “bulge,” whereas old skin produces a multitude of wrinkle patterns. It has been concluded that the elastic properties of the skin must change for such pronounced changes to be observed. However, the

changes documented in measurements using instruments that study the deformation of the surface of the skin when exposed to a negative pressure have been shown to be of the order of 33 % over 50 years age interval (from 10 to 60 years). This number does not provide adequate documentation of the observed changes with age because of the small dynamic range. As the Reviscometer[®]

assesses the superficial layers of the skin, it was felt that monitoring age-related changes in the mechanical properties of the superficial skin would provide a more accurate representation of the observed changes with age.

The study protocols were approved by an independent ethics committee, and subjects were in general good health and gave informed consent. RRT measurements were taken from 239 volunteers with skin types, from very light Caucasian (Types I and II) to African-Americans (Type VI). The volunteers were divided into five age groups: 0–2 years (1.8 ± 1.1 , mean \pm standard deviation), 14–20 years (17 ± 4.2), 24–40 years (32.5 ± 10.6), 55–60 years (57.5 ± 3.5), and 65–75 years (70 ± 7). Measurements with a Reviscometer[®] were taken on the upper inner arm at 15 cm above the elbow from 0° to 100° in 3° increments, where the initial orientation of the probe was chosen as the direction that gave the lowest RRT reading. Reviscometer[®] readings were also taken on the neck and dorsal and ventral forearm of 117 of the volunteers.

The mean value and standard deviation were calculated for each age group and the treated sites. JMP[®] statistical software (SAS Institute Inc., Cary, NC) was used to perform analysis of variance using a standard least squares analysis.

Statistical significance was considered for $P < 0.05$.

In order to ensure the relation between visual appearance and mechanical properties, *in vivo* macroimaging was also performed on the upper inner arm and dorsal forearm of the 239 subjects. A video-microscope image system (HiScope[®], Model KH-2400, Hirox Inc., Tokyo, Japan) was used to acquire close-up images (2.8×2.1 mm image size) of tested area using a $100\times$ magnification lens (Model MX-100Z, Hirox Inc., Tokyo, Japan). This image system allows examination of the skin surface texture or of subsurface features depending on the illumination at a grazing angle. In this study, grazing angle illumination was used to enhance the contrast of skin texture.

Typical RRT profiles recorded from the upper inner arm for three different age groups are shown in Fig. 6. We observed that while the RRT_{\min} values remained fairly constant for the age groups tested, the RRT_{\max} values increased with age. Thus the anisotropy ratio given by Eq. 2 also increased with age (Fig. 7). Furthermore, the width of the RRT profiles becomes narrower, i.e., the angular dispersion width decreases, with age (Fig. 7). These changes are statistically significant ($P < 0.01$) between the age groups. Since RRT anisotropy increases while angular

Fig. 6 Skin viscoelastic properties depend on aging. Representative resonance running time (RRT) profiles recorded from the upper inner arm for three age groups: 0–4 years (green triangles), 24–40 years (red circles), and 65–75 years (blue squares)

Fig. 7 Skin viscoelastic properties show strong age dependence. The anisotropy ratio (*red squares*) increases, while the angular dispersion width (*blue circles*) decreases with age. Measurements were taken on the upper inner arm: * $p < 0.01$, ** $p < 0.001$ when compared with the youngest age group. Data represents mean value and *error bars* are the standard deviation of the mean (mean \pm standard deviation)

Fig. 8 The ratio of anisotropy to angular dispersion width provides a single viscoelasticity parameter that is age dependent that is characterized by a wider dynamic range than each of the two parameters individually: * $p < 0.03$, ** $p < 0.001$ compared with the youngest age group. Data represents mean value and *error bars* are the standard deviation of the mean (mean \pm standard deviation)

dispersion width decreases with age, we can define the ratio of these two as a single viscoelastic parameter that documents the age-dependent changes in the skin and that provides a wider dynamic range than either (Fig. 8). The relationship of this parameter to age is best represented by an exponential equation, and the data may be fitted with the equation:

$$\text{Anisotropy ratio} = \frac{\text{Anisotropy}}{\text{FWHM}} = 0.04 \cdot e^{\frac{\text{age}}{31}} \quad (3)$$

The anisotropy ratio values for each of the older age groups are statistically different compared to those for the youngest group.

The mechanical and physical properties of the skin have been extensively studied (Skin

Mechanics 1986; Rodrigues 2001; Serup and Jemec 2006). These investigations describe the skin as being a viscoelastic medium and interpret the skin with homogeneous density and isotropic elastic moduli. The mechanical properties of the skin stem from contributions of its structural components such as collagen, elastin, keratin, and the purely viscous interstitial fluids (Dahlgren and Elsnau 1986). According to Eq. 1, the speed of shear wave propagation depends on the density of the medium in the direction of the sound propagation. Results presented in this chapter show that the shear wave propagation on the surface of the skin is anisotropic and thus the tissue density and tension that relates to the skin mechanical properties is also anisotropic. These two parameters are independent for non-compressible media, but in the skin or viscoelastic materials, they are probably not independent. We can make an analogy with the strings of a guitar; the sound produced by a string depends on its tension and also the density of the material (type and thickness).

The skin at the upper inner arm sites undergoes considerable changes with age in its structure and therefore its mechanical properties. It is evident in Fig. 6 that the RRT readings of young skin are more isotropic when compared with the other two age groups. For the 24–40 years group, there is a distinct increase in the anisotropy, and for the older group, a very well-defined RRT maximum.

This may also be observed in the skin microrelief imaged by the video-microscope imager. Skin microrelief involves patterns on the ventral forearm that is characteristic for different age groups. The *in vivo* microscopy images of Fig. 9 are representative for the age groups: 0–4 years, 14–24 years, 24–40 years, and 65–75 years. It is evident that the triangular and hexagonal patterns of the younger ages are replaced progressively with linear directional patterns presumably reflecting flattening of dermal papillae and stronger collagen fiber alignment in the papillary dermis. The change of these patterns is accompanied by decrease in viscoelastic anisotropy and increase in angular dispersion width that indicates a strong directional dependence. The anisotropy values for the four subjects imaged

are 2.1 (16 months, Fig. 9a), 2.4 (14 years, Fig. 9b), 4.2 (39 years, Fig. 9c), and 15.6 (70 years, Fig. 9d), and the angular dispersion width values are correspondingly 108°, 84°, 40°, and 35°. The viscoelastic anisotropy relates to cutaneous structural feature changes as a function of age.

We can get a better idea of the co-localization of the directionality of skin microrelief and the angular distribution of the RRT values in Fig. 10. A video-microscope image of the upper inner arm of a 47-year-old subject was imaged using 100× magnification. The transmitter and receiver tips of the Reviscometer transducers are drawn, to scale, and the RRT readings from the same site are over-plotted in polar coordinates. Very importantly, the maximum of the RRT values co-localizes with the skin surface microrelief (Fig. 10). Skin microrelief on the upper inner arm develops with age (Fig. 9) in a fashion that parallels the development of RRT anisotropy. Tensions are progressively developed with age in preferential orientations producing changes in the distribution and shape of the dermatoglyphics. In young skin, the relief lines look more plump and rounded on the top and form star-like patterns. As individuals get older, the glyphic structures become flatter and anisotropic, i.e., not symmetric in all directions but elongated in the direction of permanent tension. The directionality is closely related to the tension. The elongation of the glyphics occurs along the direction of increased tension.

A video-microscope image (Hirox, Japan 100× lens) from the upper inner arm of a 70-year-old subject is illustrated in Fig. 11. This figure shows in scale the relation between the orientation of the probe (transducer tips) and the skin microrelief lines. When the transducer tips are oriented perpendicular to the relief lines as illustrated in Fig. 11a, the RRT value is at minimum, typically around 250×10^{-6} s, corresponding to 1,800 m/s for the speed of the sound (based on the probe calibration). The tension of the skin is at maximum and the shear waves propagate faster along this direction (along the relief lines). Conversely, a maximum of the RRT value is recorded when the transducer tips are placed parallel to the relief lines (Fig. 11b). An

Fig. 9 Illustrates the cutaneous structural feature and viscoelastic changes at different ages. In vivo microscopy images from the upper inner arm representative for the age groups: (a) 0–4 years (Anisotropy = 2.1; FWHM = 108°),

(b) 14–24 years (Anisotropy = 2.4; FWHM = 84°), (c) 24–40 years (Anisotropy = 4.2; FWHM = 40°), and (d) 65–75 years (Anisotropy = 15.6; FWHM = 35°)

RRT value of $1,100 \times 10^{-6}$ s corresponds to a speed of sound of 390 m/s, a value close to that of the speed of sound in the air (340 m/s). This is the direction of lowest skin tension.

Measurements of the anisotropy ratio at different body sites (neck, upper inner arm, ventral forearm, and dorsal forearm) showed that the age dependence is not the same over the whole body (Fig. 12). The rate of change of viscoelastic properties depends on the anatomical site. The anisotropy increases with age and most notably at anatomical sites where the skin is considered to be “tender” or “soft,” such as the upper inner arm and the neck. Interestingly, the most dramatic changes happen on body sites where the skin is considered to be “looser” or “softer” like the neck and the upper inner arm. The viscoelastic

properties of the skin at the ventral and dorsal side of the forearm are not statistically different and do not show any significant change within the age range tested here.

4.1 The Effects of Moisturizers on the Resonance Running Time (RRT): A Better Tool for Assessing What Consumers Relate to as “Soft”

Many different approaches for the management of dry skin have been studied. They can be separated into emollients, humectants, and occlusive agents or a combination of them depending on the treatment approach. There

Fig. 10 The viscoelastic anisotropy of the skin follows the direction of microrelief lines with the line connecting the RRT maxima in a direction perpendicular to the microrelief (Langer's line). As an example, a video-

microscope image (100 \times) of the skin is shown with a plot of the RRT values superimposed plotted as a function of the angle, i.e., in polar coordinates

are many different noninvasive instrumentation and clinical assessment to evaluate improvements and grade xerosis. In this study, we wanted to compare three ingredients commonly used in the cosmetic industry for the treatment of dry skin: glycerin, petrolatum, and dimethicone. Glycerin has been shown to have a wide range of benefits to the skin when topically applied. Glycerin acts as a humectant; one molecule of glycerin binds six molecules of water. Glycerin has also been shown to be a lipid-phase modulator, inhibiting the transition of stratum corneum lipids from liquid to solid crystals. Petrolatum and dimethicone act mostly as occlusive materials by helping reduce the amount of water loss to the environment. Dimethicone is an FDA-monographed ingredient as a skin protectant for concentration ranges from 1 % to 30 %.

This was a blinded clinical study, split lower leg, randomized 3 week study with noninvasive and self-assessment measurements at baseline and week 3 after 1 week washout period with a

mild liquid cleanser. Ninety-eight women (48 Caucasian and 50 African-American) were recruited with self-identified dry skin and use of body moisturizer at least five times per week. $N = 11\text{--}13/\text{treatment cell/ethnic group}$. Tested products were applied twice daily on the lower leg. Tested products were divided in four different groups according to their main treatment approach: Product A (10 % glycerin), Product B (10 % petrolatum), Product C (5 % dimethicone), and Product D (12.5 % glycerin, 4 % petrolatum, and 1.25 % dimethicone). Products A, B, and C were formulated in the same simple emulsion base, and Product D was a more complex emulsion formulation.

The skin hydration properties were assessed by measuring skin conductance (Skicon[®] 200, I.B.S Co., Ltd., Japan), transepidermal water loss (VapoMeter[®], Delfin Technologies, Finland), flaking (D-Squame[®], CuDerm, USA), and 295 nm skin fluorescence (SkinScan[®], Horiba Jobin Yvon Inc., Edison, NJ, USA) and skin viscoelasticity (Reviscometer[®], Courage + Khazaka Electronic GmbH, Cologne, Germany).

Fig. 11 An example of video-microscope image (HiScope, Hirox with $100\times$ lens) of the upper inner arm from a 70-year-old subject. The figure shows in scale the Reviscometer[®] transducer tips in relation to skin dermatoglyphics. **a** The signal propagating in the direction of Langer's lines. Lower values in resonance running time; typical values are between 100×10^{-6} s and 300×10^{-6} s depending on probe response and tested site. **b** The signal propagating perpendicular to the direction of Langer's lines corresponding to high values in RRT. Typical values can reach up to $3,000 \times 10^{-6}$ s depending on probe response and tested site

Glycerin significantly outperformed petrolatum and dimethicone in increasing skin conductance and reducing the desquamation index. Additionally, glycerin also significantly decreased 295 nm skin fluorescence (tryptophan fluorescence) when compared to baseline. Several studies (Kollias et al. 1998; Doukas et al. 2001; Stamatias et al. 2006) suggest that a hyperproliferation state had existed when the skin was dry at baseline and through the use of a humectant, the proliferation rate was returned

to a normal healthy skin level (Russell et al. 2012).

Since there is no statistical difference in terms of ethnicity, we considered all different ethnical groups as one cohort for the viscoelastic assessment. The effects of the treatment over time were evaluated. An example of a viscoelastic measurement as a function of the probe angle for a baseline reading and after 3 weeks treating the lower legs with Product A is illustrated in Fig. 13. We observe a significant decrease in the angular

Fig. 12 The anisotropy ratio increases with age showing greater rate of increase for skin sites that are “softer.” The anisotropy ratio is shown as a function of age for a number of anatomical sites: neck (green diamonds), upper inner arm (black squares), ventral forearm (blue circles), and dorsal forearm (red triangles). Data represents mean value and error bars are the standard deviation of the mean (mean ± standard deviation)

Fig. 13 Resonance running time in 10^{-3} ms as a function of the probe angle (degree) measured on the lower leg before and after 3 weeks of treatment with 10 % glycerin

values of the resonance running time with the treatment indicating significant increase in the local density (lower RRTs), decrease in anisotropy (tension), increase in moisturization, and significant changes in the viscoelasticity of the stratum corneum.

Figure 14 shows the lower leg skin anisotropy measurement before and after 3 weeks of

treatment using 4 different moisturization products (mean values _ standard error). Note that the lower leg does not present a high anisotropy at baseline. Mean anisotropy for the lower leg in this study is around 2.5. For the same age group, the anisotropy of the upper inner arm is about three or four times higher. Product A shows significant decrease in anisotropy ($p < 0.5$)

Fig. 14 Lower leg anisotropy measured with the Reviscometer[®] RVM 600 at baseline and after 3 weeks of treatment. *Error bars* represent the standard deviation (mean for three readings, mean values \pm standard deviation)

when compared with baseline readings, and Product D presents a directional decrease in anisotropy ($p < 0.1$) when compared with baseline readings.

5 Discussion

In this chapter, we investigated the age dependence, site dependence, and the effect of moisturizers on skin viscoelastic properties. To this end, we employed a commercially available instrument (Reviscometer[®] RVM 600, Courage + Khazaka Electronic GmbH, Cologne, Germany), we improved on the acquisition method (measuring at narrow angle intervals), and we defined a parameter that relates the RRT anisotropy and angular dispersion. These parameters provide a wide dynamic range that reflects more accurately the age-dependent changes of skin mechanical properties than the methods proposed so far. Using the modified Reviscometer[®] method, we characterized the directional characteristics of cutaneous viscoelastic properties, and we provided evidence that the directionality relates to the direction of the microrelief lines on the skin surface. These lines develop as the skin ages and correspond to the tension lines described

by the Langer's lines (Langer 1861). This method also can be used in surgeries showing the directions of lower tensions in the skin that can minimize scarring postoperatively.

As shown in Fig. 1, we can see that very important information is lost when we perform the Reviscometer[®] readings at 45° interval recommended by the manufacturer. The proposed 3° interval procedure allows us to resolve skin anisotropy and to define two novel skin mechanical parameters: anisotropy and the angular dispersion width (FWHM).

The mechanical properties of the skin are an important factor in the determination of the "quality" of the skin. They are as important as the visual appearance of the skin. Changes in the visual appearance include pigmented lesions and minor inflammatory lesions that render the skin nonuniform. Changes in the mechanical properties involve large areas of the skin and are believed to be expressions of aging. One of the dominant characteristics of skin aging is loss of elasticity. Although the changes in the mechanical properties of the skin over several decades of life are substantial, objective measurements have failed to capture their magnitude thus far. Moreover, the mechanical properties of the skin are not isotropic (uniform in all directions), and there is a

need to assess this angular anisotropy. During development, from infancy to adolescence, the skin is expected to respond to tension isotropically to accommodate for growth, while in adulthood this isotropic behavior regresses due to site-specific habituation to tension.

The mechanical and physical properties of the skin have been extensively studied (Skin Mechanics 1986; Rodrigues 2001; Serup and Jemec 2006). These investigations describe the skin as being a viscoelastic medium and interpret the skin with homogeneous density and isotropic elastic moduli. The mechanical properties of the skin stem from contributions of its structural components such as collagen, elastin, keratin, and the purely viscous interstitial fluids (Dahlgren and Elsnau 1986). According to Eq. 1, the speed of shear wave propagation depends on the density of the medium in the direction of the sound propagation. Results presented in this paper show that the shear wave propagation on the surface of the skin is anisotropic and thus the tissue density that relates to the skin mechanical properties is also anisotropic.

We report that this anisotropy increases with age and most notably at anatomical sites where the skin is considered to be “tender,” such as the upper inner arm and the neck. Interestingly, the viscoelastic properties of the skin at the ventral and dorsal side of the forearm are not statistically different and do not show any significant change with age.

The skin at the upper inner arm sites changes considerably in structure and mechanical properties with age (Fig. 9). It is evident in Figs. 6 and 7 that the RRT readings of young skin are more isotropic compared with the other two age groups. For the 24–40 year group, there is a distinct increase in the anisotropy, and for the older group, a very well defined RRT maximum.

Very importantly, the maximum of the RRT values co-localizes with the skin surface microrelief (Fig. 10). Skin microrelief on the upper inner arm develops with age (Fig. 9) in a fashion that parallels the development of RRT anisotropy. Tensions are progressively developed with age in preferential orientations

producing changes in the distribution and shape of the dermatoglyphics. In young skin, the relief lines look more plump and rounded on the top. The older we get, the glyphics tend to get flatter and less organized and surface lines are more pronounced.

The orientation of the probe (transducer tips) relative to the skin microrelief lines has a big influence in the measured RRT value. When the transducer tips are oriented perpendicular to the relief lines as illustrated in Fig. 11a, the RRT value is at minimum, typically around 250×10^{-6} s, corresponding to 1,800 m/s for the speed of the sound (based on the probe calibration). The tension of the skin is at maximum and the shear waves propagate faster along this direction (along the relief lines). Conversely, a maximum of the RRT value is recorded when the transducer tips are placed parallel to the relief lines (Fig. 11b). An RRT value of $1,100 \times 10^{-6}$ s corresponds to a speed of sound of 390 m/s, a value close to that of the speed of sound in the air (340 m/s). This is the direction of lowest skin tension. The speed of the sound in the skin depends on both density and direction.

The skin is inhomogeneous and all other mechanical probes produce measures of averages over the area sampled by the probe. Local inhomogeneities which may be thought of as early events in the development of any skin lesion would be missed because their effect would be minimized because of averaging. Although the local inhomogeneity shows uncertainties in the data, we placed the Reviscometer[®] probe on places avoiding vellus hair and erector pillow muscles to minimize the variability.

The 4.5 kHz frequency used in the probe makes the sound waves propagate across the surface of the skin, stratum corneum, epidermis, and the very superficial part of the dermis making it the ideal instrument to assess superficial changes in the tissue. When we apply moisturizers on the skin, we observed a significant reduction of the skin stiffness and tensions induced by dryness (Fig. 13) and arriving at a normal low base level of the natural skin tension.

The use of shear wave propagation may be capable of providing valuable information especially on the mechanical properties of the superficial layers of the skin than the suction probes which provide information that includes the bulk of the structural matrix. This is because it actually provides two measures: one depending on density of the skin and the other depending on the angular anisotropy (tension). In order to be able to capitalize on the use of such instrument, we are forced to work on skin sites that show marked changes in anisotropy with age. Even measuring in areas of the skin with low anisotropy, such as the lower leg, the technique proved to be very useful and sensitive in assessing the changes in mechanical properties of the skin with the use of moisturizers.

In summary, we present here a sensitive method of measuring the mechanical properties of the superficial layers of the skin. We demonstrate that the method can be used to document changes in the mechanical properties of the skin with age and the correlation of the angular anisotropy with these properties to the orientation of dermatoglyphics is also related to the orientation of Langer's lines. In a previous work (Ruvolo Jr et al. 2014), we demonstrated that the use of specific antiaging ingredient (2-(dimethylamino)ethanol) can contract keratinocytes in the viable epidermis, changing the tissue density, and this can be assessed by an increase in the velocity of the sound in the tissue. In this chapter, we demonstrated that the use of moisturizers can reduce skin tensions induced by "dryness" by decreasing skin anisotropy. Finally, the probe produces sound waves that propagate throughout the superficial layers of the skin allowing us to assess density and the tensions of the surface of the tissue.

1 Introduction

In recent decades, various instrumentations were developed for assessing the in vivo skin viscoelasticity (Piérard et al. 2013a; Rodrigues and EEMCO group 2001; Sandford et al. 2013; Shang et al. 2010). The methods relied on various approaches including uniaxial and biaxial stretching, suction, elevation, indentation, torsion, ballistometry, and vibration procedures (Murry and Wickett 1997; Rodrigues and EEMCO group 2001). The devices afford sound although some distinct or even contradictory information. The time-honored suction method aims at measuring the skin deformation caused by any decrease in external pressure exerted over a defined skin area (Cua et al. 1990; Diridollou et al. 2000a; Livarinen et al. 2013; Piérard et al. 1995, 2013a). In such a procedure, skin deformation occurs as a function of the suction force, its time of application, and the area of the stressed skin (Piérard 1999; Piérard et al. 1995; Schlangen et al. 2003). It corresponds to a specific in vivo expression of the overall skin viscoelasticity.

2 Skin Biomechanics

From a physiopathological standpoint, three clinically relevant physical characteristics of skin biomechanics are crucial, namely, (a) the skin stiffness corresponding to the resistance to any shape change, (b) the skin elasticity representing the ability to recover spontaneously the initial shape after deformation, and (c) the skin viscous deformation over time under constant force leading to the creep extension (Piérard et al. 2013a). Over a large part of the body, the overall skin viscoelasticity mainly depends on the extracellular matrix (ECM) of the cutaneous connective tissue forming the dermo-hypodermal layers. Only minimal contribution is expected from the epidermis (Piérard 1999).

The bulk of the regular dermis controlling skin viscoelasticity consists of a complex fibrous network forming the ECM scaffold. The major set of fibrous components corresponds to the collagen fibers determining both the mechanical stability of the tissue and its resistance to deformation. Such a structure fails in severe dermal atrophy or dermatoporosis (Kaya and Saurat 2007). A second set of components is formed by elastic fibers present in smaller amounts. They restore any bent collagen bundle to its relaxed standing position (Langton et al. 2012; Piérard and Lapière 1987). The loosely interconnected complex fiber scaffold is permeated by amorphous hydrated ECM compounds corresponding to proteoglycans, glycoproteins, and glycosaminoglycans. Dermal cells are responsible for maintaining and remodeling the macromolecular matrix. They correspond to several distinct cell types including among others fibroblasts, dermal dendrocytes, mast cells, and myofibroblasts. They potentially exert some contractile activity upon the fibrous networks through the intervention of adhesion molecules (Binaï et al. 2012). Their tensegrity, adhesion properties to ECM fibers, and contractility are therefore important in the force transduction inside the dermis.

As a rule, the *in vivo* ECM viscoelasticity is quite difficult to assess with repeatability and confidence. The global response of skin to any

mechanical stress depends on tensile biomechanical and rheological characteristics expressed by the composite nature of the skin and subcutaneous tissues (Piérard and Lapière 1987). In cutaneous scleroderma, the tissue remodeling affects indiscriminately all levels of the ECM, and the mechanical impact of the coarse collagen networks likely predominates over other structural changes.

In a series of connective tissue disorders including scleroderma, the assessment of the skin viscoelasticity is primordial for evaluating with confidence both the disease severity and any therapeutic response (Piérard et al. 2013b). In general, the overall tensile characteristics of the whole skin are representative of the properties of the dermis and subcutaneous tissues. Obviously, the tensile strength of normal skin contrasts with sclerotic conditions. Healthy skin exhibits both flexibility and relative resistance to deformation, allowing casual body movements and partial temporary reversible compression and distention. Once the forces responsible for skin deformation are released, elasticity allows the skin to return spontaneously and progressively to its initial shape. As such, progressive resistance to deformation, flexibility, and elasticity must be adequately balanced to govern the optimal skin tensile strength. The behavior of the three-dimensional ECM fibrous meshworks combines the response of its components to which the deformation is applied. Such properties represent the functional expression of the structural configuration of the ECM from the molecular level to the macromolecular organization and the microscopic configurations.

In any instances, the viscoelasticity variations of the skin owing to body region, age, and gender outweigh the discrete variations in the intrinsic molecular compositions (Piérard 1999; Piérard et al. 2013a). Due to the composite structure of the dermo-hypodermal tissues, the *in vivo* skin viscoelastic properties are notoriously complex to assess precisely and are difficult to interpret particularly in some pathological conditions (Piérard 1999). The typical mechanical response of each macromolecular component is variable

within the wide range of force intensities encountered in daily life and more exceptional conditions. This fact obviously adds to the difficulties encountered when interpreting experimental and observational data and unraveling the tensile strength complexity of the skin.

3 Connective Tissue Structure

A global interdependence links the structure and mechanical functions of the skin ECM. The basic properties of each fibrous component have been identified *in vitro*. However, the relationships between the structures and functions of skin ECM appear complexified and intricated *in vivo*. The multifaceted way to straight presentations of fibers at rest govern for a large part the ECM viscoelastic properties of the tissue. The variable looseness to compactness configurations of the ECM fibrous networks are determining. The situation is even more complex in presence of physical entanglements between the diverse fibrous structures and networks.

The bulk of the reticular ECM dermis in scleroderma consists of a dense accumulation of collagen fiber. The individual collagen fibrils are packed into fiber units and further in fiber bundles. The way by which fibrils are packed and held together is important with regard to the ECM mechanical properties. Cross-links between collagen molecules are not the primary cause for fibril aggregation in fibers and bundles. Rather, the interfibrillar matrix plays a major role. On a higher hierarchical level, the coarse collagen bundles are interconnected with each other. They are often closely packed and stretched in superimposed planes grossly oriented parallel to the skin surface. Elastic fibers present in smaller amounts normally serve to restore deformed collagen bundles to a relaxed and wavy position. This pattern is hardly possible in skin involved in scleroderma.

Both the thickness and intimate structure of the ECM play prominent and independent mechanical functions. For instance, a major role is occasionally ascribed to the structure, density, and location of the elastic fibers when tensile strength

is involved in discrete skin deformations. In fact, although it is acknowledged that these fibers exhibit typical elastic properties, any change in the overall elastic functional properties of the skin cannot be ascribed solely to them. Many other structures participate in tissue elasticity, and it is practically impossible to disentangle their respective contributions in the tensile response of the skin (Piérard 1999).

The dermis is a heterogeneous structure because it exhibits tremendous differences between its different layers and with the variable extent in solar elastosis. In addition, the volume of the hypodermis and of the eventual sebaceous glands is of equal importance if not greater than the dermal thickness itself in their influence upon the overall tensile functional properties of the skin. In fact, the fat-enriched lobules made of either sebocytes or adipocytes put the dermis under tension, limiting the mobility of skin (Piérard 1999). As a consequence of these uncertainties, the calculation of ratios between *in vivo* tensile stress and tissue strain (Young's modulus, shear modulus, bulk modulus) is only viewed as theoretical concepts with probably little relevance when applied *in vivo* to the complex composite of structures making skin and its subcutaneous tissue.

4 Clinical Assessment of Scleroderma Involvement

Scleroderma represents a heterogeneous group of conditions with distinct clinical manifestations. The main clinical presentations are the localized forms (morphea, monomelic type) and the systemic forms (Walters et al. 2009). The classification of systemic scleroderma distinguishes three grades. Grade I corresponds to acroscleroderma including the Raynaud's syndrome subgroup. Grade II is acroscleroderma with progression of sclerosis from distal to proximal areas of the limbs. Grade III is diffuse scleroderma usually starting on the trunk with rapid progression to acral areas.

Skin involvement in scleroderma is characterized by hardness and hidebound resulting from

massive deposition and straightening of collagen bundles in the dermis and hypodermis. Temporary dermal edema is commonly present. Skin induration and tethering are commonly evaluated according to skin severity scoring extrapolated from clinical palpation (Clements et al. 1990, 1993; Pope et al. 1995). Some overlap exists between different skin scorings including the “skin thickness index” and the “skin tethering/hidebound index.” The skin thickness/hidebinding is scored in a 4-point scale (0, normal; 1, mild; 2, moderate; 3, severe). It is acknowledged that sclerotic skin changes correlate with both the overall disease activity and prognosis of systemic sclerosis. Unfortunately, such assessments remain subjective with low intra- and interobserver reproducibility. In addition, they are not free of bias. According to studies, the modified Rodnan skin score has been calculated from observations gained on 17, 26, or 74 body areas.

5 Instrumental Assessment of the Skin Tensile Strength

Skin involvement in systemic sclerosis most often begins on the acral portion of the limbs, where it usually remains more prominent than on other body sites. It would be conceivable to choose other specific target sites for biomechanical assessments. However, the physical properties of normal skin vary greatly depending on the body site. In addition, computation of many measurements should be performed before recommending a specific body site other than the forearm for comparative assessments of acroscleroderma.

The understanding of skin viscoelasticity is so complex in scleroderma that it is difficult to obtain anything approaching clean results as obtained by scrutinizing the molecular structure of the dermis (Martin et al. 2012). A minimum functional workup is however recommended as early as in Raynaud’s syndrome (Pistorius and Carpentier 2012). However, the correct interpretation of in vivo mechanical measurements requires the basic knowledge of the overall skin microstructure, including the arrangement of collagen and

elastic fibers, and their relation to other ECM components.

In general, the tensile strength, temperature, and thickness of scleroderma skin have been studied noninvasively by a series of distinct methods (Aghassi et al. 1995; Enomoto et al. 1996; Hermanns-Lê et al. 2001; Pauling et al. 2012; Reisfeld 1994; Scheja and Akesson 1997; Seyger et al. 1997; Zhang et al. 2011). It is beyond doubt that the various tissue thicknesses affect the overall tensile strength of the skin in scleroderma. However, it is hazardous and probably misleading to use the dermal thickness measured using ultrasound methods as a major severity criterion for scleroderma. Indeed, although the dermis is often thickened, variations in time are usually large. When the collagen and elastic fibers are stretched at rest during the induration phase, cutaneous edema subsides and skin thickness commonly decreases.

The real value of measuring the skin tensile strength in vivo is occasionally uncertain because confounding factors are not always suspected clinically. These include regional differences in the tensile strength, variability due to body site, posture, and subject age, gender, and cumulative ultraviolet exposures (Diridollou et al. 2000b; Schlangen et al. 2003). Anyway, some measurements are very informative (Fett and Werth 2011; Hermanns-Lê et al. 2013; Piérard et al. 2013b).

Of note, tensile strength of the whole skin is time dependent. Indeed, when skin is stressed by a load, the overall response of the organ alters its shape in a nonlinear way. A rapid extension normally takes place at first to give way to a viscoelastic phase with lower extension. When the force is maintained at a particular level for a period, further extension, known as the creep or viscous extension, gradually takes place (Piérard et al. 2013a). Such phenomenon, resulting from the recent stress history, occurs when a series of stresses are consecutively applied and removed at the same site (Fig. 1). When the deformation (strain) is maintained for a while (days and weeks), tissue remodeling progressively takes place and is responsible for a biological creep corresponding to relaxation distinct from the mechanical creep. Because of the above

Fig. 1 Evaluation of the skin deformation over time during five successive cycles of 2 s suction and relaxation phases. (a) High skin deformation (MD1), biological

elasticity ($MD1-RD1/MD1^{-1}$), and creep extension ($MD5-MD1$). (b) Moderate skin deformability. (c) Low skin deformability

considerations, the time-dependent tensile strength in part depends on the rate of load application, the duration for which it is sustained, the previous stress history, as well as the possible preconditioning of the site. In scleroderma, the biological creep and mechanical creep are reduced, particularly during the sclerotic stage (Fig. 1).

Hidebinding is the most impressive and typical change in scleroderma. This feature is not directly related to the dermal thickening. In fact, it is difficult to pinch sclerotic skin into a fold. Only a few noninvasive bioengineering methods adequately assess the deep fixation and induration of the skin. Among them, the suction method is a close imitation of lifting the skin between the fingers for assessing adequately hidebinding (Piérard et al. 2013b) (Fig. 2). Indeed, an important aspect of the global tensile skin functional

properties is tethering of the ECM skin to the fat layer. In scleroderma it limits the free mobility of the dermis. The quantitative assessment of skin toughness in scleroderma using the suction method is of interest for monitoring both the progression of the disease and the therapeutic efficacy. A limited number of studies on skin viscoelasticity have been carried out until now in patients with scleroderma (Dobrev 1999, 2007; Fett and Werth 2011; Hermanns-Lê et al. 2013; Nikkels-Tassoudji et al. 1996; Piérard-Franchimont et al. 1998). They were performed in experimental designs using distinct devices in absence of any standardized protocol. Hence, results are difficult to compare, even if there is overall agreement concerning the basic and specific changes in the viscoelastic properties of skin.

The size of the test area influences the data (Piérard et al. 1995) which appear conflicting in

Fig. 2 One single cycle of progressive suction and relaxation. (a) High deformability (*MD*) and low residual deformation (*RD*) and hysteresis (*HY*). (b) Low deformability (*MD*), residual deformation (*RD*), and hysteresis (*HY*)

some instances. The superficial dermis of scleroderma can be atrophic, and skin distension measured on a small area (2-mm measuring probe) increases. By contrast, hidebinding the skin to underlying tissues is responsible for low distensibility when measured on a larger surface area. The resistance to vertical stress is essentially due to the dermis rather than the hypodermis, although the relative contribution of each is not easily distinguished. The subcutaneous fat compartment is likely more involved by high suction forces applied to large surface areas than by lower suction to smaller surface areas. The main alterations in scleroderma being localized in the reticular dermis and hypodermis, a large measuring probe and a high suction force might appear to yield more relevant information (Hermanns-Lé et al. 2013). At all stages of scleroderma, the overall skin distensibility decreases. This functional characteristic is linked to the stretching of the collagen fibers and reflects the skin induration and the deep tethering. The viscoelastic ratio is highly variable among patients and even in time in a given patient. This aspect is ascribed in part to fluctuations in dermal edema and ECM load in proteoglycans. The immediate retraction ability following the suction release is often decreased. The biological elasticity is either unmodified or increased, particularly during the terminal sclerotic phase of the disease.

Individual values in scleroderma can be compared to the 10th and 90th percentiles of the normal reference population. According to the evolution in time of the viscoelastic parameters relevant to the clinical presentation, four rheological stages of acroscleroderma were tentatively proposed. They corresponded to the incipient, progressive, overt, and regressive stages, respectively (Piérard et al. 2013b).

6 Assessment of Therapeutic Efficacy

Objective evaluations of skin stiffening have obvious advantages over subjective clinical rating. It is an adjunct to the range of biological and functional evaluations already in use for estimating internal organ involvement by scleroderma. The therapeutic efficacy is commonly different on the different organs affected by scleroderma. For instance, improvement in pulmonary function is not usually correlated with recovery of skin mobility.

Any decrease in skin stiffness in scleroderma does not occur spontaneously or under various ancillary treatments. Only a few clinical studies have reported therapeutic improvements of scleroderma Beyer et al. (2012). They await confirmation using criteria of evidence-based

medicine (Andres et al. 2010; Herrick et al. 1994; Humbert et al. 1990, 1993; Piérard et al. 2013c). Owing to the natural course of acroscleroderma, any therapy resulting in stabilization of the skin involvement should be regarded as beneficial. A drug yielding a prominent regression of cutaneous sclerosis is not yet available.

1 Introduction

The skin is the largest organ in the human body and provides a number of protective, sensory, and regulatory functions (Kanitakis 2002). It is a composite tissue comprised of three main layers (Wilkes et al. 1973): (i) the *epidermis*, a thin layer of cells that undergo continuous renewal and migration toward the external surface; (ii) the *dermis*, comprising of collagen and elastin fibrous networks embedded within a proteoglycan matrix to provide the skin with its mechanical stability; and (iii) the *hypodermis*, the deepest layer composed mainly of adipose tissue, with the role of insulation, energy storage, and shock absorption.

Being a composite tissue, the human skin exhibits a complex, highly nonlinear, anisotropic, viscoelastic, and heterogeneous mechanical response. The overall mechanical behavior of the skin is largely dependent on the tissue composition and the properties of its individual constituents. The major load-bearing tissue component in the skin is collagen, making up 60 % to 80 % of dry tissue weight (Wilkes et al. 1973). In contrast, elastin fibers (1 % to 4 % of dry tissue weight) enable the skin to elastically recoil upon

stretching (Carton et al. 1962) and, together with the proteoglycan ground matrix, determine the overall mechanical response of the skin at low strains (Daly 1969; Harkness and Harkness 1959).

Some of the first measurements of skin properties were made as early as 1880. In his classical study using human cadavers, Langer measured the shape of elliptical wounds created from circular punctures of the skin (Langer 1861; for English translation refer to Langer 1978). The observation of such direction-dependent opening of wounds suggested that *in vivo* skin exists in a state of inherent nonuniform pretension. Histological studies later discovered that the directions of these tension lines are associated with the underlying collagen fiber arrangement (Ridge and Wright 1966; Cox 1941).

The typical stress-strain response of the skin, and how it relates to the geometric arrangement of the collagen network, have been well established in early histological studies (Craik and McNeil 1964; Daly 1966; Finlay 1969). As shown in Fig. 1, the stress-strain response consists of three main phases. In phase I, the majority of the collagen fibers are initially undulated. The gradual increase in stress with strain is thought to correspond to the reorientation of undulated fibers toward the axis of loading before straightening. The gradual stiffening observed in phase II is mainly due to an increasing number of realigned fibers beginning to bear load as they become straightened and stretched. Since there exists a varying degree of fiber undulation, the distinct

nonlinear response of the skin is attributed to this gradual recruitment of fibers resisting tension at different stages of deformation. On the other hand, the anisotropic response is thought to be the result of the nonuniform distribution of fiber orientation. Phase III shows a linear stress response at higher strains. At this stage, the majority of fibers are stretched along the axis of loading; thus, the mechanical response is mostly dependent upon the intrinsic mechanical properties of the fibers.

Being the physical barrier between the body and the external environment, knowledge of the mechanical behavior of skin is relevant across many medical applications. Orientations of Langer's lines have become important considerations when planning surgical incisions to minimize scarring of the skin tissue (Borges and Alexander 1962). Recently, finite element (FE) models of the skin have been used to predict appearance outcome and stress distributions of surgical incisions (Yoshida et al. 2000, 2001; Buganza Tepole et al. 2014a; Flynn 2010; Lott-Crumpler and Chaudhry 2001) and facial surgery (Cavicchi et al. 2009; Koch et al. 1996; Keeve et al. 1998). Similarly, understanding skin friction mechanisms is important for the prevention, and design of treatment, for pressure ulcers (Derler and Gerhardt 2012).

Advances in tissue engineering have led to the development of biomaterials for the treatment of skin injuries such as severe burns and large nevi (Wood 2011). Successful outcomes of using skin

Fig. 1 A typical stress-strain response of human skin. Scanning electron microscope images of parallel sections of the dermis reveal the organization of collagen fibers corresponding to each loading phase (Reproduced from Brown (1973))

replacement rely critically on accurate knowledge of the mechanical properties of natural, healthy skin (MacNeil 2007). Together with mechanical testing of in vitro collagen scaffolds (Blackwood et al. 2008), accurate computational modeling of the skin can shed light on the mechanisms of wound healing, scar formation, and skin graft contraction (Harrison and MacNeil 2008). In addition, there has been growing interest in using skin measurements and modeling to inform the design of consumer products (Hendriks and Franklin 2009) and medical devices (Taberner et al. 2012; Groves et al. 2012) across the pharmaceutical, cosmetics (Paye et al. 2007; Sandford et al. 2013), and animation (Hung et al. 2009; Edward et al. 2012) industries.

Computational modeling is a powerful tool for developing a quantitative understanding of skin mechanics. Furthermore, accurate characterization of skin mechanics is important for modeling the mechanical behavior of other organs and tissues that are tightly tethered to the skin, such as the breast (Lee et al. 2013) and foot (Fontanella et al. 2014). Here, we present a summary of state-of-the-art biomechanical models of the skin, with an emphasis on structurally based constitutive models that can provide useful insights into the tissue structure-function relationship. The success of applying constitutive models often critically relies on accurate and quantitative measurements of skin tissue structural and mechanical properties. We review the current approaches in measuring skin properties and discuss the challenges associated with integrating computational modeling with experimental data measurements.

2 Constitutive Modeling of the Skin

Numerous constitutive models have been developed to describe the mechanical characteristics of the skin. These constitutive models have various functional forms due to specific assumptions related to skin properties (such as nonlinearity, anisotropy, viscoelasticity, and the deformation modes). Skin constitutive models can be divided into two main categories: (i) *phenomenological*

models that use mathematical functions to provide best fits to measured experimental data and (ii) *structural models* that relate constitutive parameters directly to the underlying geometric and mechanical properties of individual tissue components.

2.1 Phenomenological Models

Early phenomenological models were derived from uniaxial tensile tests (Ridge and Wright 1966; Daly 1966; Tong and Fung 1976; Kenedi et al. 1965). Some phenomenological models describe the mechanical response of the skin by its Young's modulus using a linear elastic formulation (Manschot and Brakkee 1986; Agache et al. 1980; Bader and Bowker 1983; Diridollou et al. 2000; Delalleau et al. 2008a). A variety of experimental studies have demonstrated that the mechanical response of the skin is highly nonlinear (Lanir and Fung 1974; Flynn et al. 2011a; Meijer et al. 1999); therefore, the linear elastic approach is an oversimplified representation unless a narrow strain range is specified. More recent strain-invariant-based models have assumed nonlinear, isotropic mechanical properties in the form of Mooney-Rivlin (Hendriks et al. 2003; Shergold et al. 2006) and Ogden models (Shergold et al. 2006; Flynn et al. 2011b, c; Evans and Holt 2009).

The observed nonlinear stiffening with increasing strain in the skin was represented in the 13-parameter model proposed by Tong and Fung (1976), based upon their classical biaxial tensile experiments of rabbit skin. This model has also been used to characterize the mechanical response of in vivo human skin (Flynn et al. 2011b; Kvistedal and Nielsen 2009). Several other nonlinear phenomenological models have been proposed (Veronda and Westmann 1970; Bischoff et al. 2000), and although most are able to provide relatively good fits to the measured experimental skin data, their constitutive parameters generally do not represent any physical attributes of skin tissues. Thus, interpretation of these parameters and models provides limited predictive capability or insight into the relationship

between tissue microstructure and macroscopic mechanical properties of the skin.

2.2 Structural Models

The macroscopic mechanical response of the skin is determined by the organization of its structural constituents, and this has motivated the development of structurally based constitutive models of the skin (Manschot and Brakkee 1986; Decraemer et al. 1980; Diamant et al. 1972; Comninou and Yannas 1976). The pioneering studies of Lanir and colleagues were the first to comprehensively incorporate the geometric and mechanical properties of individual microstructural components into a constitutive model of the skin (Lanir 1979, 1983). Using this approach, the total strain energy of the tissue is assumed to equate to the sum of the strain energies of the collagen and elastin fiber networks embedded within a proteoglycan matrix. Individual fiber components are assumed to be initially undulating, and only begin to resist tension when completely straightened and stretched. Continuous statistical distributions are used to mathematically represent the variations in fiber orientation and undulation. This structural model has been used to characterize the uniaxial response of *in vitro* rat skin (Belkoff and Haut 1991), *in vivo* human skin (Meijer et al. 1999), and multiaxial experiments of *in vitro* pig skin (Jor et al. 2011a). The structural approach has been widely applied in modeling a range of other body organs and tissues, including the myocardium (Horowitz et al. 1988), heart valves (Billiar and Sacks 2000a; Sacks et al. 2006), and pericardium (Sacks 2003).

The use of statistical distributions to represent variations in fiber orientation and undulation is relatively complicated. To address this, invariant-based approaches to structural models have been developed to represent the straightening of collagen fibers using exponential functions instead of statistical distributions (Gasser et al. 2006; Holzapfel and Gasser 2000). The Gasser-Ogden-Holzapfel (GOH) model was initially applied to characterize the mechanics of arterial walls (Holzapfel et al. 2002), myocardium

(Holzapfel and Ogden 2009a), aortic valves (Freed et al. 2005), *in vitro* human skin (Annaidh et al. 2012; Tonge et al. 2013), and skin flaps (Buganza Tepole et al. 2014b). In addition, closed-form analytic expressions have been proposed to describe fibers modeled with a von Mises orientation distribution and an exponential stress-strain function (Raghupathy and Barocas 2009). Such analytic solutions are only attainable for certain statistical distributions and cannot describe variations in fiber undulation (Fan and Sacks 2014). Flynn et al. developed a discrete six-fiber model that can be integrated to provide analytic formulations of the strain energy functions (Flynn et al. 2011d). In this model, six weighted collagen-elastin fiber bundles are oriented such that they pass through opposing vertices of an icosahedron. Collagen fiber undulation is described by a step function, while elastin fibers are modeled using a neo-Hookean constitutive relation. This model provided good fits to biaxial rabbit skin and uniaxial pig skin tensile measurements. However, one limitation of the model is that the weights of the fibers did not provide a pure representation of anisotropy (i.e., isotropy was not achieved when the weights of all fibers were equal). A generalized invariant model (Flynn and Rubin 2012) was later developed to overcome this limitation, although it led to larger errors compared with their earlier model when fitted to the same sets of data.

A transversely isotropic constitutive model (Groves et al. 2013), consisting of three fiber families embedded within an isotropic Veronda-Westmann ground matrix (Veronda and Westmann 1970), was recently used to simulate the uniaxial mechanical response of *in vitro* human and murine skin. The anisotropic nature of the model, initially proposed by Weiss et al. (1996), was described by three fiber families, and the straightening of fibers was represented by an exponential function. Like many other structurally based constitutive models that are able to provide good fits to experimental measurements, this model involves a large number of constitutive parameters (in this case, 14 parameters without considering viscoelasticity), which makes and typically non-unique identification of parameters difficult.

2.3 Time-Dependent Models

The skin is known to exhibit time-dependent mechanical properties, due to effects such as viscoelasticity and preconditioning (Lokshin and Lanir 2009a). Viscoelasticity is thought to be due to the shearing interaction between fibers and the ground matrix, dissipative friction of fibers, and displacement of the interstitial fluid (Wilkes et al. 1973; Oomens et al. 1987; Silver et al. 2001). Preconditioning describes the reduction in maximum stress with load cycling until a repeatable response is observed (Fung 1993). This phenomenon has been observed in both *in vitro* and *in vivo* skin (Lanir and Fung 1974).

Bischoff et al. modeled the force-stretch response of collagen in the skin using an invariant-based eight-chain model (Bischoff et al. 2000), initially proposed by Arruda and Boyce for simulating the response of elastomers (Arruda and Boyce 1993). Although being able to provide relatively good fits to uniaxial *in vitro* human and rat skin (Belkoff and Haut 1991; Gunner et al. 1979; Dunn et al. 1985), this model was not able to simulate the effects of the ground matrix and the anisotropic response caused by the collagen fibers. Instead, anisotropy was modeled by adding an anisotropic prestress state to an isotropic constitutive model. In more recent studies, anisotropic and time-dependent effects were introduced using a three-element rheological formulation (Bischoff et al. 2004) or by assuming quasi-linear viscoelasticity at the fiber level (Bischoff 2006).

Few models of skin mechanics have considered preconditioning effects. Rubin et al. used an empirical approach to model facial skin as a composite of elastic and dissipative components (Rubin and Bodner 2002; Rubin et al. 1998). Lokshin and Lanir proposed a comprehensive structural constitutive formulation that incorporates several characteristics of skin mechanics (including nonlinearity, anisotropy, viscoelasticity, and preconditioning effects) (Lokshin and Lanir 2009a, b). Building upon earlier models (Lanir 1983), this approach assumes quasi-linear viscoelasticity for both the collagen and elastin fiber networks. Preconditioning is accounted for

using two approaches: for collagen fibers, it is assumed that preconditioning results in an increase in the fiber stress-free length while the slope of the stress-strain curve remains unchanged; for elastin fibers, preconditioning is suggested to occur via strain softening of the elastin fibers (i.e., the fiber stress-free length remains unchanged). This model was shown to provide good fits to *in vitro* uniaxial rat and biaxial rabbit skin data. Although the model requires 31 constitutive parameters for the biaxial case, inter-sample variance of the estimated parameters was small compared to other phenomenological models. Parametric analysis demonstrated that most parameters were significant contributors to the model, with the strongest being the fiber orientation and undulation distributions, the fiber stress-strain relationship, and the viscoelasticity and preconditioning effects.

3 Skin Measurements for Mechanics Characterization

Biomechanical modeling of the skin can be a useful technique for predicting the *in vivo* stress state, which is difficult to measure. The development of constitutive models that reflect the intrinsic complex mechanical properties of the skin is not a trivial task. Although state-of-the-art structural models are capable of representing a wide range of skin characteristics, reliable identification of the constitutive parameters remains a major challenge. This is because there are typically a large number of parameters that need to be determined, and these parameters are often correlated for any given set of experimental data. Furthermore, application of computational models is often hindered by the lack of quantitative and *in vivo* experimental data on skin mechanics.

Using numerical-experimental approaches (e.g., inverse FE analysis), identification of constitutive parameters is performed through minimizing the differences between experimental and model-predicted data. Nonunique estimates may arise due to correlation between constitutive parameters, resulting in multiple local minima with similar goodness of fit. In addition,

parameter estimates often exhibit large inter-specimen variation (Tonge et al. 2013), which is in part attributed to the large variability in structural characteristics across individuals or specimens. Since parameters of structural models typically have a physical interpretation (e.g., fiber orientation, undulation, density), measurements of skin microstructure can be directly incorporated into these models to reduce the number of unknown parameters requiring numerical estimation. However, surprisingly few studies have explored the full potential of integrating skin measurements into structural models, mainly due to the challenges associated with quantifying tissue structure in skin.

Accurate characterization of skin mechanics requires a model-based approach for the analyses and interpretation of skin measurements. For such investigations, it is important to consider (1) quantitative measurements of skin tissue structure, ideally performed using noninvasive *in vivo* imaging modalities, and (2) force and deformation measurements from *in vivo* skin subjected to rich sets of three-dimensional (3D) deformations. To obtain such skin measurements, there is a need to develop sophisticated imaging techniques and instrumentation and integrate these into a computational modeling framework.

3.1 Measurements of Skin Structure

3.1.1 Invasive Imaging

From early histological studies, the geometric arrangement of collagen fibers has been shown to play an important role in determining the mechanical response of soft tissues (Craik and McNeil 1964; Finlay 1969; Brown 1973). For this reason, knowledge of collagen orientation in soft tissues has been of great interest over the years.

A number of studies described the degree of collagen fiber anisotropy using a relative index of collagen alignment. Fiber anisotropy was quantified by either (1) fitting ovals to binary, cross-sectional images of the skin using polarized light and taking the major axes of the fitted ovals as the alignment index parameter (Melis et al. 2002), or

(2) performing Fourier analysis and using the width-height ratio of the power spectrum as an estimate of the alignment index (Noorlander et al. 2002; van Zuijlen et al. 2002). An alignment index of zero (or one) represents an isotropic (or aligned) distribution of fibers, respectively. Although being a quantitative measure of fiber anisotropy, these techniques do not characterize the absolute fiber orientations with respect to the body axes, as required for use in structural constitutive modeling based on statistical distributions.

The well-known small angle light-scattering (SALS) imaging technique (Sacks et al. 1997) was developed by Sacks et al. to quantify collagen orientations in samples of soft connective tissues, such as the pericardium and heart valves. This technique uses a laser to illuminate the tissue, and the resulting scattering of light by the fibrous structures is measured. The angular distribution of collagen fibers is directly correlated to the angular distribution of the scattered light. Although the SALS technique can provide experimentally measured angular distributions of collagen fibers for direct incorporation into structural models of various thin soft tissues (Sacks et al. 2006; Sacks 2003; Sacks and Gloeckner 1999; Sacks and Sun 2003), it has been shown that this technique is not suitable for detecting scattered light from considerably thicker tissue such as the skin (Meijer et al. 1999). The SALS technique is also limited to quantification of fiber orientations in the plane of the membrane specimen.

Most conventional high-resolution imaging modalities are limited to relatively small spatial scales (i.e., in the order of hundreds of microns). For imaging tissue structures over larger spatial scales, additional issues associated with image registration and distortion must be addressed. To this end, Jor et al. used extended-volume confocal laser scanning microscopy (CLSM) to image collagen in porcine skin over a field of view of 3 mm by 2 mm (Jor et al. 2011b). Skin sections were stained with picrosirius red, which is a collagen-specific stain. An oblique arrangement of collagen fiber bundles between the epidermis and hypodermis was observed in transverse confocal images (see Fig. 2). To extract quantitative measurements of fiber orientation, a structure-tensor approach

Fig. 2 High-resolution CLSM imaging of transverse sections of *in vitro* porcine skin, showing a distinct lattice organization of collagen fibers in the reticular dermis region (Reprinted with permission from Jor et al. (2011a))

(Jahne 2004) (based on first-order derivatives of the image) was implemented. Orientation data were subsequently fitted to a bimodal, von Mises distribution. Using this approach, fiber orientations could be directly incorporated into a structural constitutive modeling framework using a simple two-parameter mathematical representation. Ni Annaidh et al. performed bright-field microscopy imaging of excised human skin taken parallel to the epidermis, with the collagen fibers rendered visible using a van Gieson stain (Annaidh et al. 2012). Collagen orientation was quantified using automated imaging techniques, and similar to the work of Jor et al., the measured fiber orientations were fitted to von Mises distributions for use in a structurally based constitutive model of skin.

3.1.2 Noninvasive In Vivo Imaging

Conventional microscopy techniques involve excising tissues into thin sections, offering the ability to image tissues with high spatial resolution and to resolve structures deep in the tissues. Routine histology procedures involve tissue sectioning, fixation, and staining, all of which may cause undesirable changes in tissue morphology or its mechanical behavior. In addition, tissue biopsies required for clinical diagnosis are time-consuming and can be painful for the patient. For these reasons, major research efforts have recently been directed toward noninvasive imaging of the skin. Noninvasive imaging may improve

diagnostic capabilities in clinical settings by providing real-time, patient-specific tissue structural information.

The common noninvasive high-resolution imaging modalities for skin tissues include confocal laser scanning microscopy (CLSM), optical coherence tomography (OCT), and two-photon microscopy (TPM). CLSM allows optical sectioning of the tissue by using point illumination and a pinhole to eliminate out-of-focus signal. High resolution in both the planes parallel ($0.5 \mu\text{m}$ to $1.0 \mu\text{m}$) and perpendicular ($3 \mu\text{m}$ to $5 \mu\text{m}$) with respect to the skin surface is usually achieved. However, penetration depth in the skin has been limited to $\sim 350 \mu\text{m}$ (i.e., the superficial papillary dermis region) (Rajadhyaksha et al. 1999). This is mainly due to increased scattering in deeper skin layers, resulting in a reduction of the signal-to-noise ratio with increasing imaging depth (Neerken et al. 2004). *In vivo* CLSM has been used for imaging different structures within both normal (Rajadhyaksha et al. 1995, 1999) and diseased (Scope et al. 2007; González et al. 2006) skin, including epidermal cells, collagen network in the papillary dermis, blood vessels, sebaceous glands, and hair follicles. However, analyses of CLSM images remain qualitative to date. There is no quantitative description of collagen geometric arrangement using *in vivo* CLSM.

OCT is a real-time imaging modality based upon measurements of reflected light as a function of depth (Schmitt 1999; Welzel 2008). Compared

with CLSM, OCT has a greater tissue penetration depth of up to 2 mm (Pierce et al. 2004a), with in-plane resolution in the order of 10 μm . OCT imaging has been extensively used to image tissue structures of in vivo human skin (Welzel 2008; Mogensen et al. 2009). In particular, polarization-sensitive OCT (PS-OCT) takes advantage of the intrinsic birefringent properties of collagen (De Boer et al. 1997, 1999; Pierce et al. 2004b; Saxer et al. 2000). Because collagen has the ability to alter the polarization state of light, PS-OCT can be used to quantify tissue damage by measuring changes in the polarization state of the reflected light. It has been shown that changes in birefringence occur with aging (Sakai et al. 2008), thermal denaturation of collagen fibers associated with burns (Pierce et al. 2004c; Park et al. 2001; Kaiser et al. 2011), and the development of basal skin carcinoma tumors (Strasswimmer et al. 2004). Thus, PS-OCT has the potential to reflect the state of health of the skin by providing additional information on the structural integrity of the collagen network.

On the other hand, TPM uses femtosecond, near-infrared (680 nm to 1,100 nm) lasers to enable high-resolution deep imaging of tissues without the need for staining or external markers (Perry et al. 2012; So et al. 2000; Helmchen and Denk 2005). The laser is focused through the objective lens to ensure that excitation of fluorescence is confined to the objective's focal volume. Penetration depth differs for various types of soft tissues. Imaging depth greater than 1 mm is attainable for highly transparent tissue such as the cornea, whereas penetration depth is limited to 200 μm to 300 μm for highly scattering tissues such as the skin (So et al. 2000). There are two types of TPM nonlinear signals: two-photon excitation fluorescence (TPEF) and second harmonic generation (SHG) (Masters et al. 1998; Baldewecka et al. 2012; Konig and Riemann 2003; Jiang et al. 2011; Raub et al. 2007). Since both techniques involve two photons interacting with the target material, TPEF and SHG signals are typically acquired simultaneously during imaging and later distinguished using spectral emission filters. The intrinsic fluorophores within both the epidermis (e.g., flavins, keratin, and melanin) and the

elastin network contribute to the TPEF signal, while the collagen network is responsible for generating a strong SHG signal due to its non-centrosymmetric triple helix structure. It is thus possible to image both elastin and collagen networks simultaneously, by separating the TPEF and SHG signals, respectively. Upon heating, the structure of the collagen molecule changes to a centrosymmetric random coil, which leads to a reduction in SHG signal intensity. Thus, SHG microscopy has been used to qualitatively observe structural changes in collagen caused by thermal denaturation in various tissues, such as the dermis (Yasui et al. 2010; Lin et al. 2006), cornea (Lin et al. 2005), and tendons (Sun et al. 2006). Recently, in vivo SHG microscopy has been used for assessing burns by analyzing SHG vanishing patterns to quantify the extent of thermal denaturation of dermal collagen (Tanaka et al. 2013).

Since there are clear differences in both the penetration depth and the imaging resolution for CLSM, OCT, and TPM, each imaging modality reveals different information on tissue structure. While OCT imaging provides the greatest penetration depth, it can be difficult to distinguish individual tissue structures due to low in-plane resolution. Instead, OCT provides a measurement of the optical structural heterogeneities within the tissue (Neerken et al. 2004). In addition, CLSM and TPM provide images parallel to the skin surface, whereas OCT imaging typically results in transverse views through the depth of the skin. To provide a comprehensive understanding of skin structure, it is advantageous to develop multimodal imaging techniques to combine complementary measurements from various imaging modalities (Neerken et al. 2004; Masters and So 2001; Yeh et al. 2004).

Current in vivo imaging modalities provide promising means to visualize subsurface skin structures. However, there remains a need to develop techniques to enable imaging depth that spans the complete dermis layer, which is necessary for characterizing the collagen network. Recent developments in photoacoustic microscopy (PAM) have enabled high-resolution imaging deeper than 1 mm below the skin surface (Zhang et al. 2006).

PAM involves the detection of sound waves emitted by the vibration of objects when they reflect light energy. Although *in vivo* PAM has not been shown to reveal collagen structure, it provides additional functional information such as angiogenesis and oxygen saturation (Kaiser et al. 2011). Multimodal imaging that integrates PAM with OCT has been used to investigate the microanatomy and microvasculature in mouse ears (Jiao et al. 2009). In addition, techniques to integrate noninvasive imaging with mechanical testing of tissues have the potential to reveal important information about structural changes in the fibrous network during mechanical loading (Zoumi et al. 2004; Gusachenko et al. 2012). Image analyses techniques require further development in order to better correlate *in vivo* images with conventional histology and to quantify parameters from images for incorporation into structurally based constitutive models of the skin.

3.2 Measurements of Skin Mechanics

Precise mechanical experimentation is essential for the accurate parameterization of constitutive models. Such accuracy relies on tight control of a selected deformation protocol, its associated boundary conditions, and its replication in computational models. Traditional tissue characterization studies were performed *in vitro*. As discussed earlier, excision of tissue for *in vitro* experimentation can alter the structure, loading environment, and mechanical properties of the skin, such as prestress and humidification from underlying tissues. It is currently not possible to completely replicate *in vivo* boundary and environmental conditions; thus, we rely on *in vivo* experimentation for a complete characterization of the skin.

Choosing certain deformation modes can reduce the complexity of boundary conditions that must be recreated in computational models. For *in vivo* studies, relatively straightforward boundary conditions are provided by simple, controlled deformation modes such as extension and/or compression along one axis (Gunner et al. 1979; Coutts et al. 2013; Lim et al. 2008;

Jacquet et al. 2008; Gahagnon et al. 2012) or two axes (Kvistedal and Nielsen 2009; WanAbas 1994), torsion (Escoffier et al. 1989; Leveque et al. 1984; Salter et al. 1993; Finlay 1970; Duggan 1967), suction (Delalleau et al. 2008a, 2009; Hendriks et al. 2003, 2006; Viatour et al. 1995; Krueger et al. 2011; Sutradhar and Miller 2013; Woo et al. 2014), indentation (Groves et al. 2012; Bader and Bowker 1983; Flynn et al. 2011d; Flynn and Rubin 2012; Bischoff et al. 2004; Boyer et al. 2009; Zahouani et al. 2009; Flynn and McCormack 2010; Tran et al. 2005; Moerman et al. 2009; Paillet-Mattei et al. 2008; Delalleau et al. 2006), ballistometry (Woo et al. 2014; Fthenakis et al. 1991), and shear wave propagation (Paye et al. 2007; Zhang and Greenleaf 2007; Zhang et al. 2008; Verhaegen et al. 2010). Each method identifies certain aspects of skin behavior, but development is still required to completely characterize the 3D mechanical properties of the skin. This section describes various deformation modes that have been reported in recent literature and identifies some possible improvements for experimental instrumentation.

Early experimental studies of *in vivo* skin adapted the extensometry tests developed for *in vitro* tissues (Lanir and Fung 1974) and elastomers (Rivlin et al. 1951; Treloar et al. 1976). Extensometry tests stretch the skin within the plane of the surface and can identify the stress-strain anisotropy within the surface plane. *In vivo* extensometry tests typically produce stiffer measures than their *in vitro* counterparts, primarily due to the pretension of the skin. Studies where the extensometer probe tips were shielded from the surrounding tissue have helped to reduce the disparity in such observations (Lim et al. 2008; Jacquet et al. 2008). Biaxial extensometry was thought to provide complete 3D stress-strain characterization, assuming the skin is incompressible. Lanir and Fung (1974) reported that the change in the third dimension of an incompressible material can be fully described by the deformations in the other two dimensions. This interpretation has been widely adopted in the literature (Gunner et al. 1979; Lim et al. 2008; Gahagnon et al. 2012; Delalleau et al. 2008b; Billiar and

Sacks 2000b; Bismuth et al. 2014). However, Holzapfel and Ogden (2009b) demonstrated, with the use of invariants, that biaxial testing alone is not enough to characterize the 3D response of an orthotropic material, regardless of incompressibility. While biaxial extensometry offers useful characterization within the surface plane, further deformation protocols are required for full 3D characterization of skin properties.

Suction devices are perhaps the most widely adopted tools quoted in the literature to date. A negative pressure is imparted on the skin surface and the resulting elevation is measured. These instruments are often used in clinical studies (Jachowicz et al. 2008; Piérard et al. 2013, 2014a, b; Boyer et al. 2012; Luebberding et al. 2014; Ohshima et al. 2013; Osmola-Mañkowska et al. 2013; Bonaparte and Ellis 2014) as they provide readily interpretable measures of the bulk properties of skin with good inter-operator repeatability. Typical clinical measures include viscous and elastic properties of bulk tissue. Although the design of suction devices offers some degree of boundary constraint, studies sometimes include additional guard rings (Piérard et al. 2014a). A useful feature of suction tests has been demonstrated by Hendriks et al. (2006), who showed that different skin layers could be recruited to the overall mechanical response by changing the diameter of the suction device. Ultrasound imaging through the skin layers demonstrated that probes of 2 mm diameter elicited a response only from the most superficial structures, while the dermis was gradually recruited with increasing suction diameter. Devices presented in the literature typically provide single-point measures of surface deflection, rather than making multiple measurements across the skin surface. As such, in the absence of deformation or shape information, suction methods are incapable of resolving anisotropy. Therefore, experimental data from suction devices are typically interpreted using simple models (Delalleau et al. 2008a, 2009; Hendriks et al. 2003, 2006; Viatour et al. 1995; Sutradhar and Miller 2013; Woo et al. 2014). The availability of commercial products such as the Cutometer[®] SEM 575[®] (Courage +Khazaka Electronic GmbH, Koln,

Germany) and Dermaflex[®] (Cortex Technology, Hadsund, Denmark) has ensured that this mode of deformation remains popular in current research.

Indentation devices have also been used to extract material properties of individual layers (Jachowicz et al. 2007). In these experiments, the diameter of an indenter probe tip was varied. Typical indentation experiments are incapable of measuring anisotropy, due to limited deformation measurements and the use of symmetric heads. Anisotropy may be identified if multiple surface or volume measurements are made, or through the use of asymmetric heads. Bischoff et al. proposed the use of an asymmetric head to enable anisotropic characterization, whereby a series of indentations were performed at one site, with the head placed at different orientations (Bischoff et al. 2004). This method has not been demonstrated on the skin but has been successfully applied to anisotropic softgels (Namani et al. 2012). Flynn et al. presented an indentation robot that could perform complex 3D deformation profiles (Flynn et al. 2011a, c, 2013) (see Fig. 3). These tests demonstrated the nonlinear, viscoelastic, and anisotropic properties of the skin on the forearm, upper arm (Flynn et al. 2011a, c), and face (Flynn et al. 2013). Recent studies have focused at the tens of micron scale of epidermal cells (Crichton et al. 2013), which is important for characterization of the topmost cell layers of the skin (Boyer et al. 2009; Boyer and Zahouani 2007; Kendall et al. 2007). Further indentation studies have attempted to characterize the dynamic response of the skin, parameterizing skin into mass, stiffness, and damping terms using sinusoidal deformation perturbations (Boyer et al. 2009) as well as stochastic perturbations (Sandford et al. 2013; Chen and Hunter 2012, 2013). These models treat the skin as a single layer but may prove useful in applications such as microneedle and needle-free transdermal drug delivery (Sandford et al. 2013).

Studies spanning from the 1960s to the 1990s have used torsion tests to characterize the mechanical response of the skin (Escoffier et al. 1989; Salter et al. 1993; Finlay 1970; Duggan 1967). Several studies used the Dermal Torque Meter[™] (Dia-Stron Ltd., Andover, UK), which includes a

Fig. 3 Indentation tests on in vivo human skin using a force-sensitive microrobot, which consists of a probe that can be moved within a volume by actuating three parallel axes (Reprinted with permission from Flynn et al. (2011a))

nonmoving guard ring to separate a region of the skin from the surrounding tissues and a rotational probe to provide measures of elasticity. Torque meters are designed to preferentially assess the mechanical properties of the stratum corneum and remaining epidermal sub-layers by limiting deformations to above the dermis, in the plane parallel to the skin. De Rigal and L ev eque showed that by reducing the size of the torsional probe, the effect of epidermal hydration on the stress-strain response was increased, supporting the hypothesis that these devices preferentially measure the epidermal response (de Rigal and Leveque 1985). Torque meters have been shown to be more sensitive to epidermal hydration than the Cutometer[®] (Murray and Wickett 1997). However, torsion devices seem to have fallen out of favor, possibly due to their inability to measure anisotropy and their relatively isolated response limited to the epidermal layer.

An expanding field of work has started utilizing shear waves or surface acoustic waves for skin measurements. The Reviscometer[®] (Courage+Khazaka Electronic GmbH, Koln, Germany) is a product designed to characterize the anisotropy within the surface plane. This probe includes an emitter needle sensor that induces acoustic shear waves at the surface of the skin, and a receiver needle sensor that measures the time for the wave

to propagate from the emitter to the receiver. This time delay is reported to be inversely proportional to tissue density and stiffness. From such measurements, the degree of fiber alignment, and thus anisotropy, can be interpreted. In vivo studies using this method tend to have been applied to clinical analyses (Paye et al. 2007; Verhaegen et al. 2010; Neto et al. 2014), rather than to constitutive models. However, Zhang et al. (2008) and Zhang and Greenleaf (2007) used their own surface wave tool to generate vibrations between 100 Hz and 400 Hz, and the resulting data were interpreted using a Voigt model, which produced estimates of shear elasticity and shear viscosity of the skin. Li et al. (2012a) presented a method that used a piezoceramic actuator to create impulses that were measured using OCT and interpreted the measurements using a linear constitutive model. Chen et al. (2014) suggested a laser-induced surface acoustic wave device, which was simulated in a FE model of skin containing a melanoma. Similar devices have been developed for other soft materials, such as an air-pulse-derived surface wave system used on corneal tissue-mimicking gel phantoms (Wang et al. 2013), ex vivo myxoma, and adipose tissue (Wang et al. 2012). The utility of these devices is limited in that they do not impose large strains on the tissue. Unless an external device imposes larger deformations, these devices are

restricted to measuring the linear mechanical properties of the skin under small strains.

Complete 3D characterization of *in vivo* skin cannot be achieved by any of the methods outlined above. Each technique lacks the control of boundary and environmental conditions in living subjects, and there is insufficient complexity of deformations to capture all aspects of skin mechanics. A notable confounding factor is the pretension inherent in *in vivo* skin. Although this is well recognized in the literature, authors either tend to ignore it (Lim et al. 2008), account for uniaxial tension (Jacquet et al. 2008), or treat pretension as an unmeasured parameter that must be identified in an optimization process (Flynn et al. 2011c). Measuring pretension *in vivo* would provide significant improvement over current characterization methods. Kvistedal and Nielsen (2009) reported indirect estimates of skin pretension through use of a multi-motor biaxial extensometer. Control of individual motor pairs allowed the assessment and adjustment of biaxial tension in the skin *in vitro*. A similar problem exists with controlling boundary conditions *in vivo*. Techniques described in the literature often tether the skin to a rigid structure using compression and/or adhesives (Flynn et al. 2011a, 2013; Hendriks et al. 2003; Verhaegen et al. 2010; Bischoff et al. 2009). It is typically assumed (without validation) that compression and adhesives applied at the surface of the skin will provide sufficient constraint to the underlying dermis and subcutaneous tissues and that they do not disrupt the mechanical properties of the tissue being measured.

In future studies, skin characterization should aim to create richer data sets by combining multiple deformation and/or imaging modalities to enable more rigorous tests for determining model parameters. By subjecting skin to multiple modes of deformation, the constitutive parameters can be more reliably identified. For example, biaxial stretches coupled with indentation could provide measures in three dimensions while adjusting prestress. For example, Neto et al. suggested that by combining Cutometer[®] with Reviscometer[®] measurements, a more complete characterization of the skin could be

achieved with a reduction in the number of parameters of interest from a single device (Neto et al. 2014). Recent studies have coupled deformation instrumentation with imaging devices. For example, ultrasound has been used to image the dermis under suction to measure and account for changes in dermal thickness.

In vivo CLSM (Rajadhyaksha et al. 1995, 1999) and OCT (Delalleau et al. 2006) are capable of tracking sub-layers within the dermis as it deforms during mechanical characterization studies. The combination of ultrasound (Coutts et al. 2013; Gahagnon et al. 2012; Iagnocco et al. 2010; Mofid et al. 2004; Sandrin et al. 2002) and magnetic resonance imaging (Sinkus et al. 2005) or OCT (Li et al. 2012a, b; Kennedy et al. 2009) with simple mechanical loading has led to a range of elastographic techniques. Elastography provides highly localized, depth-wise estimates of mechanical properties, such as Young's modulus, shear modulus, and shear viscosity. Such methods will inevitably incorporate more sophisticated constitutive models and enhance the cross-sectional characterization of the skin. Of particular significance, elastographic techniques may improve the characterization of the hypodermis (Gennisson and Baldeweck 2004; Van Houten et al. 2003), which has traditionally been neglected due to its inaccessibility.

Digital image correlation methods can be used to track surface deformation of *in vivo* skin (Groves et al. 2012; Evans and Holt 2009; Kvistedal and Nielsen 2009; Staloff and Rafailovitch 2008; Kacenjari et al. 2013) and other tissues (Bischoff et al. 2009; Ji et al. 2011). Malcolm et al. (2002) developed a system that captured heterogeneous two-dimensional strain fields with sub-pixel accuracy, and this technique was applied *in vivo* by Kvistedal and Nielsen (2009). This method has been extended to 3D (Azhar et al. 2011; Parker et al. 2012; HajiRassouliha et al. 2013) and promises to enhance 3D characterization of *in vivo* skin properties. There is no clear frontrunner amongst the various imaging modalities, as the methods have differing degrees of spatial resolution and penetration depth. From the limited overlap in both imaging and mechanical perturbation, it is

apparent that the combination of multiple testing protocols from the same *in vivo* sample provides the best way to comprehensively characterize the structure-function relationships of the skin.

4 Conclusions

Realizing the full potential of using computational modeling to characterize skin mechanics relies critically on the availability of quantitative skin measurements of both tissue structure and mechanical properties. Future scientific advancement should focus upon the development of instrumentation that is capable of measuring the mechanical properties of *in vivo* skin subjected to a comprehensive range of 3D deformations and the tightly integrated modeling techniques used to interpret these data. In order to translate research outcomes into the clinical setting, there is a need to further develop noninvasive, multi-modal imaging capabilities for measuring individual-specific skin properties. The combination of noninvasive imaging with mechanical testing apparatus, and model-based interpretation of the combined datasets will greatly facilitate our understanding of changes in skin microstructure under mechanical loading.

Before entering the atmosphere, the sun’s radiation spectrum ranges from 200 to 2600 nm. At approximately 20–30 km from the earth’s surface, the first alteration occurs, due to the presence of ozone which absorbs ultraviolet C light (100–280 nm). While penetrating deeper into the atmosphere, solar radiation loses energy by molecular diffusion and absorption by water vapor. The types of optical radiation reaching the skin are ultraviolet light (UV), visible light, and infrared (IR). The shortest wavelengths, UVB (290–320 nm) and UVA (320–400 nm), are the most likely to generate biological effects. Some of them are beneficial such as the caloric effect of IR, the anti-rickets action of UVB which transforms 7-dehydrocholesterol into vitamin D, the anti-depressive effect of visible light and IR warmth, and the global anti-inflammatory and anti-allergic effects. Other impacts are harmful or even dangerous such as sunburning (UVB), skin photo-aging (UVA), and photo-cancerogenesis.

To counteract optical radiation, the skin has some adaptable and defensive mechanisms with

individual variation. The main ways of defense are the thickening of the horny layer, the production of melanin, the activation of antioxidant molecules, the DNA repairing systems, and the secretion of cytokines.

1 Stratum Corneum Barrier

1.1 Pilosity

Humans have kept hair only on the scalp, thus indicating their adaptation to the standing position. The scalp is, therefore, well-protected except for young children and people with baldness.

1.2 The Horny Layer

The role of the horny layer as a photoprotector is demonstrated by the impossibility of getting sunburned on the palms and soles where the stratum corneum is thick. Photoprotection is first related to the optical properties of the skin which limit the penetration of radiation (Fig. 1). Less than 8 % of incident light is reflected at the

air–skin interface, whatever the phototype. Over 92 % of the incident light therefore penetrates the skin and undergoes various optical paths through reflection, diffraction, and absorption (Anderson and Parrish 1981). Diffraction is important since the stratum corneum is made up of keratin filaments lined up parallel to the surface, in a pseudocrystalline structure. Absorption of light takes place in melanin, urocanic acid, and keratin, which is rich in polar amino acids. The penetration of optical radiation varies according to the wavelength – only 10 % of radiation under 320 nm (UVB) reaches the dermis (Everett et al. 1966). In contrast, UVA, visible light, and IR traverse the epidermis, the dermis, and partially the subcutis (Fig. 2). Water and liquids with refraction indices higher than water increase UV transmission through the stratum corneum (Solan and Laden 1977; Bruls et al. 1984).

The stratum corneum acts as a photoprotector mostly against UV light. UVB induces hyperkeratosis and stratum corneum thickening, thus reducing UV transmission (Epstein et al. 1970; Sterenborg et al. 1986). There are minor differences in stratum corneum thickening between

Fig. 1 Paths of optical radiation within the skin

Fig. 2 Penetration depth of optical radiation

ances, however photosensitivity varies extensively (Thomson 1955; Weigand et al. 1974). In black subjects, the great photoprotective capacity of the stratum corneum could be due mainly to the diffusion of light by melanin. However, in fair-skinned subjects, the stratum corneum thickness keeps an important role, as it appears that keratin is a better filter than melanin. Vitiligo is an interesting model to study photoprotection induced by epidermal hyperplasia. Skin affected by vitiligo is not pigmented because of the absence of melanin production, and consequently, photoprotection is provided only by the horny layer and the rest of the epidermis. The vitiligo skin compensates for the absence of melanin by epidermal hyperplasia and hyperkeratosis (Gniadecka et al. 1996). Furthermore, photoprotection by UVA alone is lower than by overall sun irradiation because UVA stimulates melanogenesis without causing a significant stratum corneum thickening. However, the relative importance of stratum corneum thickening versus development of pigmentation in photoprotection function is still debated (Westerhof and Uscanga 1998; Bech-Thomsen and Wulf 1995).

1.3 Urocanic Acid

Urocanic acid is produced by histidine deamination through UV activated histidinase (Morrison

1985). Under UVB absorption, it switches from trans- to cis-urocanic acid. This molecule acts as a UVB filter (de Fine Olivarius et al. 1996) and could be the photoreceptor responsible for UV-induced immunosuppression; however, the precise mechanism of this effect is not well understood (Redondo et al. 1996; Lappin et al. 1997).

1.4 Surface Lipids

UV irradiation has beneficial effects on the barrier function of the skin. As a matter of fact, skin irradiated with UVB or UVA appears more resistant to primary irritants, thus indicating the improvement of the barrier function (Lehmann et al. 1991). This improvement is not due to an epidermal hyperplasia which does not appear after UVA irradiation, but coincides with an increase in lipids in the stratum corneum, especially ceramides (Holleran et al. 1997).

2 Melanin Barrier

2.1 Constitutive Pigmentation and Phototype

The color of healthy skin results from the superposition of four colors: yellow from carotenoids in the epidermis, red from oxyhemoglobin in

capillaries, blue from reduced hemoglobin in venules, and yellow-brown from epidermal melanin. The skin color is the result of both a genetically predetermined constitutive pigmentation and an acquired pigmentation in relation to UV irradiation.

Knowing the phototype is a simple way to predict the reactions of the skin facing UV irradiation. The Fitzpatrick's classification (Fitzpatrick 1988) is based on the occurrence of sun-burning and sun-tanning (Table 1). The tanning action spectrum lies mainly in UVB, but at doses next to those triggering sunburn. For subjects with a phototype I or II (light skin), the UVB dose that induces tanning is higher than that causing sunburn; thus, these subjects burn before they tan. It is the opposite for subjects with phototype IV (dark skin) who tan before they burn.

Other classifications (Cesarini 1988) incorporate phenotypic characteristics such as complexion, hair color, and the presence of ephelides (Table 2). There are few papers about dark skin phototypes. At first, all dark skins had been classified in Fitzpatrick's type V (Fitzpatrick 1988). Later, a phototype was found for Asian type dark skin (Kawada 1986). In fact, dark skin is heterogeneous and includes Fitzpatrick's phototypes II, III, IV and V (Youn et al. 1997).

The minimum erythema dose (MED), which corresponds to the smallest quantity of UVB inducing an erythema, is also a simple method to measure photosensitivity. Several papers have shown that a good correlation existed between MED and phototype (Shono et al. 1986; Andreassi et al. 1987). A low MED is observed in subjects with red hair, blue eyes, and freckles. In contrast, other publications have not confirmed the correlation between MED and proneness to sunburn, neither in Caucasians (Westerhof et al. 1990), nor in Asians (Chung et al. 1994). The method involving a chromameter to measure the skin color is more objective than the assessment of the phototype and would provide a more accurate assessment of photosensitivity (Wee et al. 1997).

2.2 Melanin

In human skin, melanin is located in melanosomes, solid spherical particles 20–40 nm in diameter. It is also found as a soluble form in the vesicles of premelanosomes. The melanins are a heterogeneous group of pigments which can be separated into two families according to their chemical structure and color. Pheomelanins, rich

Table 1 Fitzpatrick's classification of phototypes (Fitzpatrick 1988)

Complexion	Phototype	Sunburn	Tan
White	I	Always burn	Do not tan
	II	Burn easily	Tan slightly
	III	Burn moderately	Tan progressively
	IV	Burn a little	Always tan
Dark (Mediterranean, Asian, Arabic)	V	Rarely burn	Tan intensely
Black	VI	Never burn	Tan very intensely

Table 2 Classification of phototypes including phenotypic characteristics

Phototype	Hair	Complexion	Ephelides	Sunburns	Tan
I	Red		+++	Constant ++	0
II	Blond	Fair	++	Constant +	Light tan
III	Blond	Fair	+	Frequent	Clear
	Brown	te	0	Frequent	Medium
IV	Brown	te	0	Rare	Dark
V (Mediterranean)	Brown	Brown	0	Uncommon	Very dark
VI (black)	Black	Black	0	None	Black

Fig. 3 Melanocytes in epidermis basal layer. Caucasian skin. Silver staining (Laboratory of Skin Biophysics, Besançon)

in sulfur, are associated with the yellow or red color predominant in red-haired subjects. Eumelanins, insoluble black or brown pigments, poor in sulfur, are found in brown or black subjects. Both categories are the terminal products of two divergent metabolic pathways after formation of an intermediate compound dopaquinone (Kollias et al. 1991).

The composition of melanin in a given individual depends on genetic and environmental factors. The photoprotection properties are maximal for eumelanins and much lower for pheomelanins. The excellent photoprotection of black skin is due to large amounts of melanin, predominantly eumelanin. The appearance of ephelides, or freckles, in red-haired subjects after exposure could be correlated to the making of eumelanins by melanocytes, which synthesized pheomelanins initially. As a matter of fact, pheomelanins seem to act as actual carcinogens, after phototoxic activation, by generating photoproducts which attack the cells (Menon et al. 1983).

Melanin is synthesized by melanocytes located in the basal layer of the epidermis (Fig. 3), interspersed with keratinocytes close to the basement membrane, where they are easily recognized because they are devoid of keratin tonofilaments (Fig. 4). They produce dendrites, which extend into the epidermal intercellular space of basal and suprabasal layers (Fig. 5). Melanin loaded melanosomes are carried in these dendrites and then eaten by the neighboring keratinocytes where they

take on an umbrella-shaped distribution, which protects the cellular nucleus and DNA (Kaidbey et al. 1979) (Fig. 6). This functional cooperation between keratinocytes and melanocytes led to the concept of *epidermal melanin unit* (Fig. 5), which operates under genetic control and environmental factors.

In healthy skin, the distribution of melanin is different depending on whether a tan is induced by UVB, UVA, or PUVA (Psoralen + UVA). After exposure to UVB, the melanocytes are stimulated, hence both production of melanin and transfer into keratinocytes increase. The latter are also stimulated and proliferate resulting in an increased concentration of melanin in the epidermis. After UVA exposure, a large amount of melanin is found in melanocytes and keratinocytes of the basal layer, although in the rest of the epidermis the melanin concentration remains unchanged. As keratinocytes die to form the horny layer, melanosomes are destroyed and melanin is dispersed in the cytoplasm.

2.3 Photoprotection by Melanin

The photoprotective function of melanin is well established (Morison 1985). Exposed to the sun's rays, the skin darkens and is then less sensitive to ensuing exposures. People with *teskin* are less sensitive to sunlight than fair-skinned individuals. Vilitigo skin MED (no melanin) is lower than that

Fig. 4 Melanocyte in Caucasian skin. *Small arrows* immature melanosome in melanocyte, *arrowheads* mature melanosome in melanocyte, *thick arrows* mature melanosome in neighboring keratinocyte, *D* dermis, *T* keratin tonofilament bundle in neighboring keratinocyte.

of healthy skin. The incidence of skin cancers on uncovered body areas is lower in individuals with pigmented skin compared to individuals with fair skin.

The photoprotection function of melanin is based essentially on UV light absorption capacity (Kollias 1995). It has been studied *in vitro* in cuttlefish (Zeise et al. 1992). *In vivo*, only the comparison of the reflection spectra of pigmented skins with those of nonpigmented skins, such as the skin of subjects suffering from vitiligo (Kollias and Baqer 1985) or albinism, can provide the absorption characteristics of melanin pigmentation. For both cuttlefish and human melanin, maximal absorption would take place at 335 nm. It is implied that melanin protection capacity would be more efficient against UVA than UVB (Kollias and Baqer 1988).

2.4 Photo-induced Pigmentation or Tan

The melanin concentration and distribution in the epidermis can be altered by exposure to radiation. The spectral profile of the pigment obtained varies according to the radiation received. There are two phases in photo-induced pigmentation.

- UVA induces an immediate pigmentation known as Meirowski's phenomenon or Immediate Pigment Darkening (IPD). This occurs within minutes following exposure and disappears in a few hours. However, when the dose received is high enough, the pigmentation is intense and persists several days. It is a grayish pigmentation due to photo oxidation of the existing melanin before melanocytic stimulation (Beitner and Wennersten 1985; Hönigsmann et al. 1986). This immediate pigmentation reflects the individual level of constitutive pigmentation because it is absent or minimal for phototypes I or II (Agin et al. 1985). The immediate pigmentation has no protecting effect against actinic erythema due to UVB. Conversely, in case of a subMED dose, it can facilitate the occurrence of an

erythema by a photoaddition mechanism (Paul and Parrish 1982; Black et al. 1985).

Late UVA pigmentation (by 24–48 h) always precedes the inflammatory reaction, the pigmenting dose being lower than the erythema dose. UVA therefore induces a tan without sunburn. The pigment induced by UVA is characterized by the presence of a component which absorbs in the visible range

- UVB is responsible for late pigmentation or casual tan – the tan starts 2 days after exposure, reaches its maximum approximately on the 20th day and disappears gradually if there is no other exposure. With UVB, an inflammatory reaction or actinic erythema always precedes pigmentation, and there is no detectable pigmentation as long as the erythema is not sufficiently faded. Tanning results from new melanin synthesis as well as morphological and functional alterations of melanocytes and keratinocytes. The number of melanosomes and their transfer to the keratinocytes are strongly augmented. At 9–10 days following UVB exposure, the resulting pigment shows a maximum absorption at 300 nm.
- Visible light induces two types of hyperpigmentation, one is temporary, the other persistent (Kollias and Baqer 1984). The latter appears only after exposure to high radiance ($>720 \text{ J/cm}^2$). Such a huge dose of visible light can be obtained in the same length of time as necessary for UVA persistent pigmentation to appear. With visible light, pigmentation occurs without the inflammatory reaction.
- With PUVA, the pigmentation and inflammatory responses are a sort of combination of those obtained after UVB on one hand and UVA on the other. A maximum absorption at 300 nm is observed for UVB, as well as two absorption bands at 542 and 571 nm due to oxyhemoglobin. This implies that there is a strong vascular component in the pigmentation induced by PUVA. The absorption bands due to oxyhemoglobin persist for several months.

The above discussion shows that the relation between melanocytic stimulation and skin inflammation varies depending on the wavelength. The pigment formed following exposure to UVB, UVA, or PUVA lasts several months, sometimes years, and does not extend beyond the irradiated areas, but remains well delineated. However, UV exposure can induce an increase in the number of melanocytes also in the protected skin, especially in subjects with phototype I or II (Stierner et al. 1989).

The protection provided by late pigmentation varies with the phototype. The darker the phototype, the more easily the subject becomes tanned; and tan is made easier when the subject is already tanned. This gradual natural photoprotection is most efficient against UVB, but paradoxically an effective tan permits longer sun exposures, hence an increase risk of harmful effects in the long term.

3 Anti-Radicals Defense

3.1 Oxygenated Free Radicals

UV induces damage through the endogenous chromophores normally present in the skin. UVB has a direct noxious effect on nucleic acids, urocanic acid, and some proteins. Conversely, UVA initiates photosensitization reactions, which lead to the production of oxygenated free radicals. The latter have a single electron on the outer layer which makes them unstable and very reactive. They will associate their free electron with another electron from an adjacent molecule which will in turn alters its structure. The targets of these oxygenated free radicals are numerous, especially nucleic acids and polyunsaturated fatty acids. Nucleic acids undergo a number of oxidative damages leading to strand breaks, which may disturb the expression of genetic material and cause mutation. The oxidative damages inflicted on the unsaturated fatty acids of the cellular membranes will induce membrane ruptures, inactivation of membrane

receptors, and release cytotoxic substances and mediators of inflammation.

3.2 Antioxidants

To fight off the excessive formation of reactive oxygenated species and the consequences of their formation, the cells have a number of defense systems. The skin has enzymatic systems such as superoxide dismutases, catalases, and peroxidases, and also small antioxidant molecules or free radical scavengers, such as vitamins A, C, and E, β -carotene, glutathione, and trace elements like selenium, zinc, and copper.

Vitamin E, especially α -tocopherol, protects the membranes against oxidation, acts in synergy with other antioxidant systems and can be regenerated by vitamin C (Fryer 1993; Eberlein-König et al. 1998). Vitamin C is a strong antioxidant which could be effective in topical applications (Darr et al. 1992). Carotenoids are yellow, orange, or red pigments, and their role as photoprotectors has been known for a long time. β -carotene, the yellow–orange pigment of carrots, is a precursor of vitamin A. Even absorbed in large quantity, β -carotene does not generate toxicity by hypervitaminosis A. Its antioxidant properties, as well as its provitamin A activity, might be effective against cancer. Lycopene, a carotenoid nonprecursor of vitamin A, seems even more efficient at scavenging oxygen free radicals (Di Mascio et al. 1989). Selenium is a trace element essential for human health and as the active site of glutathione peroxidase, it is directly involved in the extinction of free radical (La Ruche and Césarini 1991). Other antioxidants exist such as zinc, which is one of the active sites of superoxide dismutase. Cysteine derivatives might play a photoprotective role by increasing the intracellular concentrations in glutathione (Steenvoorden and Beijersbergen van Henegouwen 1997).

These antioxidant molecules can prevent some of the damages caused by sun exposure. For example, dyskeratotic cells, or sunburnt cells,

observed in the epidermis 24 h after exposure, are significantly less numerous if superoxide dismutase is injected before or immediately after UV irradiation (Danno et al. 1984). In order to strengthen natural defenses, supplementation in carotenoids, vitamin E, vitamin C, and selenium seem justified, especially as the plasmatic ratio of some of them would decrease after sun exposure (White et al. 1988). The association of several antioxidant molecules would help the skin control the oxidative stress induced by UV light (La Ruche and Césarini 1991).

3.3 Stress Proteins

Any cellular attack results in increased synthesis of stress proteins which temporarily protect the sensitive molecules from a new onslaught (Applegate et al. 1997). Such proteins have been found in the skin following UV or IR exposure.

4 DNA Repair

When anti-free radical defenses are overwhelmed and damages are inflicted on the DNA, there are still some specific enzymatic repair systems. Damages essentially affect thymine, causing the formation of dimers between two adjacent thymines on the same DNA strand.

4.1 Nucleotids Excision–Resynthesis

The repair mechanism by excision-synthesis of nucleotides, which occurs at the start of UV irradiation, is able to discard the bulk of damaged DNA. The mechanism consists in four stages: recognition and incision of the DNA strand carrying the dimer, excision of the damaged DNA, synthesis of a new DNA from the opposite undamaged DNA, and rejoining the two ends of the repaired strand.

The fundamental role of this repair system is demonstrated in xeroderma pigmentosum. In the course of this genetic disease, characterized by a defective repair of UV-induced lesions, early occurrence of skin tumors on exposed skin is observed (Dumaz et al. 1995).

Other repair systems can also be altered, with risks of errors and therefore, of mutagenicity.

4.2 The P53 Gene

Following DNA damage by UV, a P53 gene is activated which increases the synthesis of the P53 protein (Krekels et al. 1997). This natural protein plays a major role in the preservation of the genome integrity – either it facilitates DNA repair by stopping or slowing down the cellular cycle which leaves time for the DNA to be repaired, or it induces cell apoptosis if the DNA lesions are too serious. When a P53 gene mutation occurs, the production of an abnormal P53 protein with altered functions is observed. It is no longer able to induce correct DNA repair, which can lead to the development of tumors.

5 Immune Response

Like numerous cells, keratinocytes secrete cytokines, in small quantities at basal state. Following UV exposure, the secretion increases, especially of IL₁, IL₆, IL₁₀, and TNF- α . Simultaneously, there is an increase of the secretion of prostaglandins, which are important mediators of inflammation (Schwarz and Luger 1989).

UV light is also involved in the skin's immune response by making the Langerhans cells unable to process and present antigens to lymphocytes. This photo-immunosuppression (which may be of interest in developing treatments for some skin allergy diseases) can favor the development of carcinomas (Morison 1989).

In conclusion, two major points should be kept in mind: (1) great individual variation exists in the effectiveness of natural photoprotection, and

(2) in subjects with type I and II phototypes, natural photoprotection is not safe enough, and demands additional artificial photoprotection such as clothing and sunscreens.

Acknowledgments Dr. Rik Roelandts (University of Leuven, Belgium) is warmly acknowledged for reviewing the manuscript.

1 Introduction

The negative effect of solar radiation is usually associated with ultraviolet (UV) radiation (Schade et al. 2005; Norval and Halliday 2011; Matthews et al. 2010a, b; Sklar et al. 2013-; Murphy 2009) due to its ability to generate free radicals in the skin (Zastrow et al. 2004; Darvin et al. 2006a; Halliwell 2007). The action of free radicals can result in oxidative cell damage (Taylor and Sober 1996; Dumay et al. 2001), the development of premature skin aging (Harman 1983; Biesalski and Obermueller-Jevic 2001; Alaluf et al. 2002; Sies and Stahl 2004), and even skin cancer (Krutmann 2001; Moon and Oh 2001). Taking this fact into consideration, different sunscreens are available on the market which provides an efficient defense against both UVB and UVA spectral ranges.

However, human skin is predominantly exposed to near-infrared radiation (NIR: 760–3,000 nm), which comprises approximately 54 % of the total solar radiation that reaches the surface of the earth (Kochevar et al. 1999). Many studies show that NIR could act both

therapeutically and pathologically depending on the applied doses (Bensadoun and Nair 2012; Akhalaya et al. *in press*). Both effects of solar IR on human skin are associated with the generation of ROS, whereby the applied dose plays a crucial role, acting therapeutically (low doses) or pathologically (high doses). This appears to be dependent on the corresponding signaling pathways: NF- κ B for therapeutic effects and AP-1 for pathological effects (Akhalaya et al. *in press*).

The pathological effect of high-dose solar infrared (IR) radiation for human skin is a scientifically accepted phenomenon (Schieke et al. 2002; Schroeder et al. 2008a, b; Cho et al. 2009; Tanaka et al. 2011; Zastrow et al. 2009; Krutmann et al. 2012). Analysis of recent studies shows that IR radiation induces the generation of ROS in the skin (Zastrow et al. 2009; Darvin et al. 2010a, b). The generated free radicals (mostly ROS) underlie all infrared-affected cutaneous effects, such as increased proliferation of cells, gene expression of inflammatory cytokines, and suppression of the synthesis of proinflammatory mediators (Karu 2008; Galluzzi et al. 2012; Schieke et al. 2003; Calles et al. 2010). During NIR exposure, the skin surface temperature increases from 27.6–33.1 °C (Kleesz et al. 2012) to 41–45 °C, which can induce the generation of heat shock radicals (Cho et al. 2009; Shin et al. 2008). The different signaling pathways of NIR-induced ROS and NIR-induced heat shock ROS generation act independently, multiplying the influence on each other by increasing the doses of irradiation and/or increasing the temperature (Akhalaya et al. *in press*).

The defense mechanism of the human body against the action of the excess amount of free radicals is based on the synergistic action of different antioxidants including carotenoids, vitamins, enzymes, and others (Darvin et al. 2006b). In the skin, carotenoids, beta-carotene, and lycopene are known to be powerful antioxidants that act effectively to neutralize ROS, including singlet oxygen (Palozza and Krinsky 1992; Krinsky 2001; Darvin et al. 2011a). The side effect of such interactions with high amounts of radicals can lead to the destruction of the carotenoids and, as a result, depletion of the antioxidant defense

system of the organism (Ribaya-Mercado et al. 1995). The amount of destroyed cutaneous carotenoids can be well correlated with the amount of generated free radicals in the skin, which was confirmed by EPR measurements, showing that carotenoids could serve as marker substances for the entire antioxidant status of the human epidermis (Haag et al. 2011; Lauer et al. 2013). Recently it has become possible to measure the concentration of cutaneous carotenoids noninvasively by resonance Raman spectroscopy (Hata et al. 2000; Darvin et al. 2005a). This method was used in the present study to investigate the influence of IR irradiation on the antioxidant status of human skin.

The present chapter describes the results obtained by noninvasive methods to measure the generation of free radicals in the skin subsequent to NIR and IRA irradiations. In the first step of this study, the stability of the carotenoids in the human skin under exposure with IR irradiation was investigated *in vivo* using resonance Raman spectroscopy. In the second step of this study, EPR spectrometry was used under *in vitro* conditions to analyze whether the obtained changes in the carotenoid concentration during IR irradiation are in fact caused by the generation of free radicals in the skin. In the third step, the concentration of the carotenoids in the skin was varied by topical application of a single antioxidant component formulation containing beta-carotene in order to investigate a potential protective effect on the skin.

2 Materials and Methods

2.1 Resonance Raman Spectroscopy (RRS)

The concentration of carotenoids in human skin was determined quickly and noninvasively with a high sensitivity using resonance Raman spectroscopy. This *in vivo* method was chosen for the measurements because of the advantages in comparison to other methods (Darvin et al. 2013). The main measurement principle is based on the optimal combination of laser excitation wavelengths

and carotenoid absorption as well as the design solution of the setup. The resonance regime of excitation lies in the blue-green range of the spectra, where carotenoids have a maximal absorption, and gives rise to the strong enhancement of the Raman signal of carotenoids, making this method very well suited for measurements in the skin. The argon laser operated at 488 nm and 514.5 nm was used as a source of excitation. The carotenoid concentration was determined by the intensity of the carbon-carbon double bond stretching vibration of the carotenoid molecules line measured at $1,523\text{ cm}^{-1}$. Other Raman lines of carotenoids measured at $1,005\text{ cm}^{-1}$ and $1,156\text{ cm}^{-1}$ were not taken into consideration.

A detailed technical description of resonance Raman spectroscopy of cutaneous carotenoids was previously provided by our group (Darvin et al. 2005a, b).

2.2 Electron Paramagnetic Resonance Spectroscopy (EPR)

The *in vitro* measurement of infrared light-induced free radicals was carried out by EPR spectroscopy using the stable long-lived free radical spin marker 3-carboxy-2,2,5,5-tetramethylpyrrolidine-1-oxyl (PCA) from Sigma (Steinheim, Germany) and a L-band EPR-spectrometer from Magnostech GmbH (Berlin, Germany). The PCA spin marker generates an EPR signal whose intensity corresponds to the PCA concentration.

Due to the interaction between PCA long-lived free radicals and the IR-induced short-lived free radicals, PCA is reduced to its corresponding hydroxylamine, which does not generate any EPR signal. As a result of this recombination, the concentration of PCA marker is decreased, thus providing information about the quantity of generated radicals (Herrling et al. 2003).

PCA was chosen for application on porcine skin samples for scavenging induced free radicals (Herrling et al. 2003) as it is stable in porcine ear skin without irradiation (Haag et al. 2010). A filter paper disc was placed on the punch biopsy and 50 μl PCA (10 mM in water/ethanol 50/50 v/v)

was added. After a 30-min incubation time, the skin samples were washed with water and dried with soft tissue paper, and the initial EPR signals were recorded for each sample. The kinetics of the PCA degradation was measured every 10 min, subsequent to IR irradiation of the samples.

Taking the strong dependence between the intensity of EPR signals and the temperature (Rockenbauer et al. 2006) of the investigative samples into consideration, EPR measurements were performed on the samples after they had cooled down to room temperature (approximately $23\text{ }^{\circ}\text{C}$).

2.3 Sources of Infrared Irradiation

Two infrared sources were used in the study. The first source was a radiator illuminated in the NIR range of the spectra (Philips Infrared RI 1521, Nederland). The second source represented a radiator connected with a water filter in front of the radiation head, which emitted the IRA radiation (Hydrosun Medizintechnik GmbH, Germany).

Both radiators were used for *in vivo* irradiation of human skin at a power density of $170\text{--}190\text{ mW/cm}^2$ for 30 min (doses $306\text{--}342\text{ J/cm}^2$), which is recommended for therapeutic action, and at the power density $105\text{--}115\text{ mW/cm}^2$ for 30 min (doses $189\text{--}207\text{ J/cm}^2$) in case of *in vitro* measurements on porcine ear skin. The reduced power density was performed on the porcine skin samples in order to limit the skin surface temperature to a value of $42\text{ }^{\circ}\text{C}$.

2.4 Determination of the Skin Temperature

The temperature of the skin surface was measured noninvasively subsequent to the infrared irradiation using a noncontact thermometer (Rytek Schlender Messtechnik).

2.5 Experimental Design

The *in vivo* investigations were carried out on the flexor forearms of 12 healthy volunteers (3 males,

9 females) aged between 25 and 35 years. On each flexor forearm, two areas of $4 \times 4 \text{ cm}^2$ were marked with a permanent marker. Before IR irradiation, one area of each arm was pretreated homogeneously with 2 mg/cm^2 of an o/w formulation containing 0.2 % beta-carotene. The other two skin areas remained untreated.

The pretreated and untreated skin areas were irradiated with two different IR radiators operating in NIR and IRA spectral ranges.

The same procedure was performed with the porcine ear skin used for in vitro measurements.

In order to examine the radical formation process in the formulation during IR irradiation, the o/w formulation containing 0.2 % of beta-carotene antioxidant was placed in a cuvette consisting of two glass plates with a 1.0-mm distance holder between them to exclude the insiccation and oxidation. Then IR irradiation emitted by the NIR was performed on 12 samples. The other 12 samples were irradiated with IRA. All measurements were performed at a power density of 170 mW/cm^2 for 30 min. Control measurements without IR irradiation were performed on six samples.

Approval for the in vivo study had been obtained from the Ethics Committee of the Charité – Universitätsmedizin Berlin.

3 Results and Discussion

3.1 Kinetic of Carotenoids Measured with RRS Subsequent to Infrared Irradiation

3.1.1 Beta-Carotene-Containing Formulation

The o/w formulation containing 0.2 % of beta-carotene was measured in vitro before and after IR irradiation with the use of resonance Raman spectroscopy. Control measurements without irradiation were performed at the same time.

The measurements showed no differences in the beta-carotene concentration in the irradiated samples for both NIR and IRA radiators before and after irradiation as well as in control samples.

This indicates that free radicals were not produced in the formulation itself subsequent to the

IRA and NIR irradiations as well as during the IR-induced heating of the sample. Additionally, beta-carotene was not influenced directly by the applied infrared radiations.

3.1.2 Influence of the Infrared Irradiation on the Cutaneous Carotenoid Concentration In Vivo

To increase the level of cutaneous antioxidants artificially, the formulation containing beta-carotene was applied topically. This resulted in an increase of the absolute carotenoid concentration in the skin of volunteers to 1.75 ± 0.29 times on average for all volunteers (Darvin et al. 2011b). The obtained beta-carotene concentration is close to the physiological concentration, thus pro-oxidative effects can most likely be excluded (Darvin et al. 2011a).

The concentration of carotenoids in the skin of all volunteers before and after irradiation with IRA and NIR radiators is shown on Fig. 1a (non-pretreated skin) and 1b (pretreated skin). Obtained degradations were found to be statistically significant ($*p < 0.005$).

As can be seen from the figures, the carotenoid concentration is reduced after IRA and NIR irradiation. On average, the magnitude of the degradation of carotenoids in the skin after IR irradiation was determined at 23 % for IRA and 33 % for the NIR, independently of the pretreatment of the irradiated skin areas. The average destruction of carotenoids obtained after the application of NIR was 10 % higher than after the application of IRA, which was found to be statistically significant. Obtained results are in agreement with previously published results (Darvin et al. 2007, 2009).

The absolute amount of the carotenoids destroyed after IR irradiation on average was higher in the case of the pretreatment with the formulation containing beta-carotene than for the untreated skin (Fig. 1). The antioxidant stability of the formulation containing beta-carotene can be substantially increased if a mixture of different antioxidants at different concentrations is applied. This effect can be investigated using different methods (Darvin et al. 2010c; Meinke et al. 2013).

Fig. 1 Box plot of the carotenoid concentration in the non-pretreated skin area (a) and beta-carotene pretreated skin area (b) of all volunteers before and after irradiation with IRA and NIR radiators measured in different time points. * $p < 0.005$, pairwise comparison with Wilcoxon-signed test

Figure 2 shows the correlation between the individual level of carotenoids in the non-pretreated skin and the magnitude of carotenoids remaining after 30 min of IR irradiation with NIR (a) and IRA (b). As can be seen, correlations with correlation factors $R^2 = 0.60$ and $R^2 = 0.63$ were observed for the NIR and IRA irradiation, respectively. This correlation is not surprising and can be explained by the production of the specific amount of free radicals after IR exposure of the skin. In this case, all volunteers received approximately the same quantity of free radicals, which gave rise to

carotenoid degradation. The volunteers, who had a low initial concentration of carotenoids in their skin, were found to have a higher magnitude of destruction. This means that the volunteers with a high individual level of carotenoid antioxidant substances in the skin had an additional defense potential against the influence of IR irradiation associated with the production of free radicals.

A comparison of the typical degradation dynamics of carotenoids in the untreated and pretreated skin areas in case of both IR radiators showed that a decrease of carotenoids in the skin

Fig. 2 Correlation between the individual level of carotenoids in the skin of 12 volunteers and the magnitude of carotenoids remaining after 30 min of IR irradiation with NIR (a) and IRA (b)

occurs constantly during IR irradiation (data not shown).

3.2 EPR Kinetics Subsequent to Infrared Irradiation In Vitro

Using EPR measurements, the radical formation process was investigated in vitro on porcine ear skin samples, which are considered to be a suitable model for human skin (Haag et al. 2010; Simon and Maibach 2000). Figure 3 shows the average value of the decrease of PCA spin marker in the skin without (“1”), subsequent to IRA (“2”) and NIR (“3”) irradiations. Most of the

measured values were found to be statistically significant.

After the irradiation, the skin surface temperature was measured to be ~ 41.5 °C after the irradiation with NIR and ~ 39 °C with IRA, on average. Further investigations with PCA solutions have shown that PCA is not affected by IR irradiation nor by the resulting increased temperature due to its stability.

Thus, the obtained results showed that IR irradiation produced short-lived free radicals (mostly ROS (Zastrow et al. 2009)) in the skin, which were measured by the degradation of the PCA spin marker. The amount of generated free radicals is approximately 10 % higher for NIR in

Fig. 3 Decay of the PCA in the porcine skin biopsies without (“1”), subsequent to IRA (“2”) and NIR (“3”) irradiation. “*,” significance between “1” and “2”; “**,” significance between “1” and “3”; “***,” significance between “2” and “3” (Wilcoxon test, $p < 0.05$) (Taken from Darwin et al. (2011c))

comparison to the IRA, despite the applied same doses of irradiation.

3.3 Influence of Infrared Radiation-Induced Heat on the Skin

IR irradiation of human skin may increase the skin temperature due to the high absorption by cutaneous water. The pathological changes in human skin can be developed if the skin temperature exceeds 39°C (Akhalaya et al. *in press*; Zastrow et al. 2009; Jung et al. 2010). Under these conditions, the heat shock-induced formation of ROS can be a consequence, which gives rise to the synthesis of MMPs as well as its subsequent pathological action on the skin tissue. However, in the skin, the formation of NIR radiation-induced ROS and heat shock-induced ROS occurs independently on each other by utilizing different pathways (Akhalaya et al. *in press*; Schieke et al. 2002; Lan et al. 2013). They potentiate the influence of each other only when skin temperature exceeds a value of 39°C .

Results obtained *in vivo* show that during IR irradiation, the skin surface temperature increased continuously, reaching maximal values of $39.1 \pm 0.7^{\circ}\text{C}$ subsequent to IRA radiation and

$41.3 \pm 0.6^{\circ}\text{C}$ subsequent to NIR radiation. Thus, it can be supposed that the difference between ROS production for IRA and NIR irradiations in the skin (see Fig. 3) is due to the formation of heat shock-induced ROS in the skin.

4 Conclusion

Free radicals (mostly ROS) are produced in human skin subsequent to IR irradiation, for which mainly the IRA range of the solar IR spectrum is responsible. The ROS generation is dependent of the applied IR doses. The IR radiation-induced heat can act pathologically through the formation of heat shock-induced ROS when the skin temperature exceeds 39°C .

Consequently, during the NIR irradiation of the skin, ROS are produced, and their concentration is increased subsequent to the increase of the IR dose. When the skin temperature exceeds 39°C , the heat shock-induced ROS are additionally produced in the skin, thereby multiplying the action of NIR radiation-induced ROS.

It was shown in the *in vivo* measurements that IR-induced free radicals can be effectively neutralized by cutaneous antioxidants and additionally by the topical application of antioxidant

substances including beta-carotene. The effectiveness of the neutralization of free radicals can be substantially increased if a mixture of different antioxidants at different concentrations is applied. The questions related to the optimization of the mixture of antioxidants used in cosmetic formulations should be investigated in the future, and the utilization of modern noninvasive techniques is expected to be indispensable in this undertaking.

The volunteers with a healthy lifestyle, characterized for instance by the consumption of high amounts of fruit and vegetables, accumulate more antioxidants in their skin and, thus, are better protected against IR-induced damage than other volunteers.

Photosensitization includes the events triggered within the skin by the interaction of a molecule (called photosensitizer or chromophore) and wavelengths usually located in the ultraviolet (UV) light. It may be related either to phototoxicity, an inflammatory reaction depending on UV light dose and chromophore concentration, or to photoallergy, a specific immune reaction requiring a primary sensitization phase.

The *in vivo* testing of a compound's photosensitizing potential is needed in two circumstances:

- To check in a patient a compound suspected to be at the origin of an exogenous photosensitization
- The prospective evaluation of the photosensitizing potential of a drug before its commercialization

Photosensitization tests combine compound introducing into the skin and further skin irradiation using an artificial light source. They are of three types: photopatch tests, photointradermal test, and systemic phototests. In photopatch tests, the compound is applied on the skin which eventually has been previously treated in order to increase penetration (abrasion of the horny layer or scarification). In photointradermal and photopricks test, the compound is intradermally injected in order to bypass the skin barrier. A prior measurement of the minimal erythema dose in UVB and UVA is necessary to help select the appropriate UV light doses. In photodermatoses exploration, one should also try to experimentally reproduce the light-induced eruption.

1 Material

1.1 Light Sources

Different types of sources are available (Anderson 1993; Beani 1987; Hölzle et al. 1987; Leroy et al. 1992).

- The *solar simulator* is the basic equipment. The Xenon arc lamp which emits a continuous spectrum, combined with a water filter to remove infrared ray and a WG305 Schott filter to eliminate shorter UV, is the common way to obtain a spectrum similar to that of solar light. Two devices are widely used in France: one from the CUNOW company, directly derived from equipment used in research and especially the Dermolum 3[®] (Müller, Moosining Germany). Interposition of cut-off filters or of a monochromator enables selecting the appropriate wavelengths.
- *High pressure UVA lamps* (UVA[®]sun 3000, Mutzhas, Munich RFA) are also essential; they emit very high UVA doses with a 330–460 nm spectrum (free from UVB), allowing in less than half an hour 100 J/cm² to be received by the skin placed at 30 cm of the lamp.
- *Fluorescent light tubes* emitting UVB (Philips TL12[®] or Sylvania F75[®]) or UVA (Philips

TL09[®] OR Sylvania F85[®]); these tubes are either of small size for very localized irradiation or easily placed in a phototherapy cabin when bigger.

- *Slides projector with a Schott WG450 filter*: it is used for visible light irradiation, a rarely used test.

1.2 Diaphragms

Exposure time is set and irradiated area outlined through the interposition of a diaphragm between the light source and the skin.

Two types of diaphragm are necessary:

- A pierced plaque (usually 9 holes) 15–20 mm in diameter, covered by a second plaque which is moved manually or motorized. The movement of the front plaque uncovers the holes through which UVA or UVB light penetrates in preset geometrical or arithmetic progression doses. This computer-controlled device called sensitometer is integrated in the Müller solar simulator.
- A plaque with sufficient aperture to irradiate a large skin area, usually 5 × 10 cm².

1.3 Dosimeters

For better soundness, the measuring device should match the source spectrum. Two types of devices are widely used:

- The dosimeters Centra UV-Messgerät[®] (Osram, Munich) and IL9700[®] Research Radiometer (International Light, Newburyport, Massachusetts USA) which have two probes, one to measure UVB, the other UVA.
- Thermopiles (e.g., Kipp Zonen, 93270 Sevrans France) which are connected to a voltmeter are sensitive to the whole spectrum (i.e., UV, visible, and infrared light). If they are calibrated for low energies, they can be connected to a monochromator.

1.4 Subject's Position

The selected skin area, usually the back, must be placed perpendicular to the light source and diaphragms; to facilitate positioning, a laterally and vertically motorized seat is helpful (Leroy and Domp martin 1988).

2 Methodology

2.1 Minimal Erythema Dose (MED)

It is the lowest (A and/or B) UV dose which induces a visible erythema on the whole irradiated area. Its assessment uses a sensitometer. Irradiation by the solar simulator total spectrum results in the polychromatic (UVA and UVB) MED, also called MED_B, because the induced erythema is related almost exclusively to UVB. MED_A is provided either by a solar simulator-induced irradiation filtered by window glass or by a high pressure UVA source.

The tested area is the shoulder or the buttock. Reading is made 24 h after irradiation: MED_B in millijoule/cm² and MED_A in joule/cm². It should be made also immediately and 30 min after irradiation when early abnormal photosensitivity is suspected (e.g., solar urticaria).

The MED quantify the subject's actinic sensitivity which is related to his/her phototype. Accordingly, it is key parameter to select the UV light doses to be used in case of photosensitivity testing.

2.2 Photopatch Test (Syn: Photoepidermotest)

The investigated compound is applied as in any skin patch test, then the tested area is irradiated; the test is declared positive if a reaction appears only after irradiation. Until 1980, photopatch tests were not standardized, thus accounting for their poor reliability by these times (Hölzle et al. 1985). The first standardization attempts were proposed by the photopatch tests Scandinavian group (Thune 1988) followed by the German-Austrian-Swiss group (Hölzle et al. 1991) and the French

group (Beani 1987; Jeanmougin M. et le Groupe de Recherche en Photobiologie Cutanée 1986). A consensus has finally been found although some points are debated.

- The *tested area* is usually the nontanned back skin.
- The *tested compound* (in petrolatum or alcohol) is applied in a Finn Chamber[®], left in place for 24 h before irradiation and 48 h for the nonirradiated control.
- *Irradiation* takes place 24 h after application. However, this length of time may be inadequate, showing the difficulty of a fully standardized procedure because all photoallergens do not react in the same way. As example, for 6-methyl-coumarin the optimal time interval between application and irradiation is shorter, between 30 and 60 min (Jackson et al. 1980).

UVA irradiation is mandatory, as most photosensitizer's absorption spectrum is in UVA. The type of UVA source may affect the results; Przybilla et al. (1991) on a series of 27 compounds in 81 patients found a better efficiency with irradiation by TL09 type UVA fluorescent tubes than by high pressure UVA source. The UVA doses are chosen according to the expected type of reaction. Duguid et al. (1993) have shown, in patients with photoallergic positive patch tests obtained after 5 J/cm² irradiation, that irradiation between 0.7 and 1.9 J/cm² could elicit the same scores. Murphy (Murphy and White 1987), Cronin (1984), and English et al. (1987) have also shown that low doses (1–2 J/cm²) are sufficient to elicit photoallergic reaction. In contrast, elicitation of a dose-dependent phototoxic reaction requires 10 or even 20 J/cm².

However, some molecules have their action spectrum in UVB. Consequently, to prevent any missing in detection, both UVA and UVB irradiation in parallel are now considered mandatory (Beani 1987; Jeanmougin M. et le Groupe de Recherche en Photobiologie Cutanée 1986; Jung 1981; Leroy et al. 1992; Przybilla et al. 1987). The UVB dose to be used is 0.75 MED_B, emitted by a solar simulator.

- Controls comprise skin irradiation without compound and skin irradiation with vehicle alone.
- *Photopatch tests interpretation*: reading is immediate following irradiation, then after 20 min, 24 h, 48 h, and 72 h and if possible later; in accordance with the international regulations regarding patch tests assessment, reactions are quantified:

+: erythema and flat papules or infiltration

++: erythema with papules and vesicles

+++ : erythema with papules and blisters

A reaction limited to the irradiated area is universally considered positive (Gould et al. 1995). However, there is no consensus when both irradiated and nonirradiated areas are positive. The North American Contact Dermatitis group (Menz et al. 1988) and the Scandinavian group (Jansen et al. 1982) diagnose as photo-aggravated contact allergy a stronger reaction in irradiated area. Unless it is obvious, the “aggravation” assessment is subjective, however, and it seems difficult and unrealistic to grade the intensity of an erythema (The reader is advised to see ► Chap. 105, “Skin Barrier Function”. The interpretation of these reactions is, therefore, uncertain.

- *Phototoxic and photoallergic reactions* must be distinguished: the former generates a well-defined erythema of early onset (24th hour) and straight of maximum intensity, sometimes associated with necrosis, whereas the latter evolves gradually and results in an eczema; biopsy may be useful to differentiate the reactions.

Hölzle et al. (1991) and Neuman et al. (1994) have refined the diagnosis through observation of intensity parameters over 4 days: erythema, infiltration, papules, vesicles, and blisters. Responses were classified into four types:

- The first type, called *decrescendo reaction model*, is similar to a contact toxic irritant

reaction: a well-limited erythema, maximum on the first day, fading the following days. The absence of secondary inflammatory reaction suggests either a pharmacological effect of the compound or a phototoxic reaction. Further photo tests are needed before any conclusion is drawn. An example of this type of reaction is obtained with furosemide.

- The second type, named *combined reaction model*, shows an intense erythema on the first day which decreases the following days while on the second day an infiltration appears followed by papules and vesicles on the fourth day. It is interpreted as an initial phototoxic reaction followed by an allergic reaction. Examples of this type of reaction are found with tetrachlorosalicylamide, antiseptics, PABA, “*musk ambrette*,” or fragrance mixtures.
- The third type, the *plateauing reaction model*, shows a persistent erythema from the first up to the fourth day, often associated with an infiltration but rarely with vesicles or blisters. It is found preferentially with chlorpromazine and thioprofenic acid. Its meaning remains unknown.
- The fourth type, called *crescendo reaction model*, mimics an allergic reaction; erythema is not the prevailing sign, but papules and vesicles are present. Examples are given by fentichlor, 4-isopropyl-dibenzoyl-methane, 2-hydroxy-4-methoxy-benzophenone, and p-methoxyisoamylcinnamate.

This time-course based analysis aimed at differentiating pharmacological, phototoxic, and photoallergic reactions on clinical grounds, although potentially very useful, requires additional validation.

2.3 Scarified Photopatch Test

Before applying the tested molecule, control and irradiated areas are scarified diagonally with a small needle exerting a pressure strong enough to cut the epidermis without inducing bleeding (Kaidbey and Kligman 1978b; Kurumaji and Shono 1992). Then the irradiation and

interpretation procedures are not different from standard photopatch tests.

This method is interesting because it facilitates the penetration of compounds that have a low transcutaneous absorption capacity leading to false-negative reactions with standard photopatch tests (Kurumaji and Shono 1992). However, a recent study failed to show a better sensitivity in the diagnosis of drug-induced photosensitization (Conilleau et al. 2000).

2.4 Photointradermal Test

The epidermal barrier is bypassed in this technique. Epstein (1939) was the first to experiment it with sulfanilamide and obtained constant positive results. Schorr and Monash (1963) used it to confirm the phototoxic effect of dimethyl-chlotetracycline and tetracycline. Two key studies stand out in view of the number of tested drugs and the protocol used: the study by Kligman and Breit (1968), later improved by Kaidbey and Kligman (1978a), whose protocol is still the reference. It was recently used in a French study (Peyron and Pedailles 1986). Five intradermal injections, 0.1 ml of the compound diluted solution each, are carried out in the same subject; 15 min later, two sites are irradiated, one with 10 J/cm² UVA, the second one with 0.75 MED_B UVB. There are three controls: nonirradiated compound injected skin, UVA irradiated saline injected skin, and UVB irradiated saline injected skin. Reading takes place immediately, 6 h and 24 h later, as in common photopatch tests.

2.5 Photopricks Test

The prick-test method, widely used in IgE-mediated allergy testing for its low risk of systemic reaction, has recently been adapted to photobiological investigations under the name photopricks test (Bourrain et al. 1997).

The technique consists in three pricks made through a drop of the compound diluted in water covering 1 cm² skin (Stallerpoint[®], Lab. Stallergène, Fresnes, France). The area is

immediately irradiated 5 J/cm² UVA. A nonirradiated prick-test and a prick-test with the irradiated vehicle serve as controls. The same tests can be done in parallel with 0.75 MED_B UVB.

This method has the same purpose as photoscarification, but it is easy to implement and is safe as far as the risk of systemic reaction is concerned.

2.6 Systemic Phototest

It consists in performing photobiological tests after administration of a potential photosensitizer, usually a drug, by its usual oral or injected route (Beani 1987; Diffey and Langtry 1989; Emmett 1986; Ferguson 1995; Ferguson and Johnson 1990, 1993; Guidichi and Maguire 1985; Hölzle et al. 1987; Johnson and Ferguson 1990; Leroy et al. 1992; Ljunggren and Bjellerup 1986; Meola et al. 1993; Schürer et al. 1992). It is imperative that the tested subject do not expose his (her) back to light over the whole test duration.

The two following methods are the most widely used:

- MED_A and MED_B assessment with immediate, early (5, 30, 30 min, and 4 h), and delayed (24, 48, and 72 h) reading: this is mainly used to identify phototoxicity (MEDs are lowered) although a protracted erythema may also (theoretically) indicate photoallergy.
- A phototest: a limited area (5 × 5 cm) on the back is irradiated with either infra-erythema UVB dose (0.5 or 0.75 MED_B) or 10 J/cm² UVA; immediate reading, then 30 min, 1 h, 4 h, 24 h, 48 h, and 72 h, and whenever possible one week after irradiation. Reactions may be phototoxic and/or photoallergic. They are differentiated on clinical grounds (aspect and time course), in some cases with the help of histological examination.
- The drug can be taken in a single dose, 2–3 times the therapeutic dose; because of frequent uncertainty regarding the drug pharmacokinetics, phototests are then repeated at different

times (1/2, 1, 2, 4, 6, and 8 h) after drug intake. Alternatively, the drug can be taken over a period of 5–7 days at usual doses before a single triggering irradiation is carried out when it is assumed that the skin is saturated with the substance.

- A last rarely used *variant* is to study a patient who still takes the drug: gradually increased UVB (5–100 mJ/cm²) and UVA (1–15 J/cm²) doses are given; an erythema arising at a dose lower than expected indicates phototoxicity. The test should be repeated 2 weeks or more after stopping the drug intake and by then the MED must have gone back to normal. The final proof will include a reintroduction test with an additional phototesting. This is often not possible in practice (Gould et al. 1995). In a recent optimization of this technique (Vousden et al. 1999), the MED was calculated before and after 5 days of drug intake, using several wavelengths delivered through a monochromator. A photosensitization index was defined as the ratio of MEDs before and after drug intake. This index would permit to compare the photosensitization potential of various compounds and to define their action spectrum.

3 Selection of the Appropriate Method

3.1 Detection and Quantification of a Compound Phototoxic or Photosensitizing Potential

The purpose of this type of study is to detect a phototoxic or photosensitizing potential of medicines before their commercialization. It is the natural complement of similar studies previously carried out *in vitro* or in animals. The test is performed in healthy phototype II to IV subjects. Exclusion criteria are those commonly used in research in man. In addition, any intake of potentially photosensitizing

drug including oral contraceptive for the 3 months preceding the test must be avoided. The average number of volunteers is usually 30. The standard photobiological tests can only demonstrate a phototoxic potential. They are inappropriate for detecting a photoallergic potential since such reaction requires an earlier sensitization.

3.1.1 Detection of Phototoxic Power

Photopatch tests are the most widely used. Phototoxic reactions are dose dependent, therefore testing use increasing concentrations and progressive UV doses. However, in a prospective study, limitations of the method for compounds systemically taken have been shown (Jeanmougin M. et le Groupe de Recherche en Photobiologie Cutanée 1986). First, the responsible chromophore is often not the native drug but one of its metabolites. Second, the tested drug may not traverse the stratum corneum and thus fail to elicit a response of the viable tissue. Efficiency can be improved through additional procedures which facilitate the cutaneous penetration; however, such protocols are heavier and may raise ethical problems.

Detection is also possible through systemic administration of the drug. A comparison of both MED_A and MED_B before and after 5–7 days drug intake is a method usually preferred over the phototest kinetics observation following a single high dose. Drug administration is randomized between two groups, one taking the verum, the other one the placebo. In some studies additional subgroups are created in order to compare the photosensitizing potential of various drugs within each chemical class; this has been done within the fluoroquinolones (Ferguson and Johnson 1990, 1993) resulting in the following relative risk quantification (Scheife et al. 1993): Fleroxacin ≫ Lomefloxacin, Pefloxacin ≫ Ciprofloxacin > Enoxacin, Norfloxacin, Floxacin.

For detection of phototoxic power, we lack comparative study of efficacy between systemic tests and photopatch tests.

3.1.2 Detection of a Photoallergic Potential: Photo-maximization Test

To detect a photoallergic potential, Kaidbey and Kligman (and 1980) proposed in 1980 a test in man adapted from the maximization test used for detection of potential contact sensitizers. They used a 150 W solar simulator polychromatic light for hypersensitivity induction and UVA light (solar simulator equipped with a WG345 filter) for elicitation.

The induction phase consists in six steps: (1) application of the compound under a 2.5 cm² patch kept for 24 h, (2) irradiation of a 0.8 cm diameter area of the patch with three MED polychromatic light as emitted by the solar simulator, (3) the test area is left uncovered for 48 h, (4) new patch application on the same area for 24 h, (5) the test area is left uncovered for 24 h, and (6) new irradiation as in step 1. This sequence was repeated six times. In fair skin subjects (phototype I and II), the second sensitizing irradiation is usually followed by an intense sometimes blistering inflammatory reaction.

The induced photosensitization is revealed 10–14 days after the last irradiation: a patch test is made on an area different from that used for sensitization and irradiated 4 J/cm² UVA (solar simulator with WG345 filter). Controls include a similar photopatch test with the vehicle only and a nonirradiated patch test. Readings are to be recorded 24 h and 48 h after irradiation. To differentiate phototoxic and photoallergic reactions, the authors recommend to reduce both the concentrations of the tested compound and the irradiation doses.

However interesting this method may be, it raises a major ethical issue, the risk of photosensitizing the volunteers.

3.2 Investigations in Photodermatoses

Obviously, the diagnosis of photodermatosis is established through the patient's interview and clinical examination but if there are no apparent

lesions, the use of photobiological exploration becomes essential (Beani 1987; Emmett 1986; Epstein 1962; Goerz et al. 1995; Hölzle et al. 1987; Leroy et al. 1992; Meola et al. 1993; Selvaag and Thune 1996). Photopatch tests are commonly used but are weighty and time consuming when compared to the experimental reproduction of the lesions, which is the preferred test in the diagnosis. They should be used only if photosensitization is strongly suspected. It is necessary to use them appropriately as one cannot completely avoid the risk of inducing photosensitization by the tests themselves (Meola et al. 1993).

- Here the purpose of a photopatch tests is to look for a photoallergy to the compound, possibly at the origin of the disease, whereas identifying a phototoxic reaction would only suggest the compound is potentially photosensitizing without relation to the disease (the same remark applies to all the above mentioned photobiological tests). Making a difference between the two types of results requires low UV doses and low compound concentrations (British Photodermatology Group Workshop report 1997; Emmett 1986; Goerz et al. 1995; Jeanmougin M. et le Groupe de Recherche en Photobiologie Cutanée 1986; Menz et al. 1988; Schauder 1985) because photoallergic reactions are not dose dependent. Accordingly, the suggested UVA dose is only 5 J/cm²; in case of doubtful reaction, the test should be made again but with still reduced UV doses. The tested compounds are selected according to the patient's history, and tests with standard compounds involving the most usual photosensitizers are also systematically carried out.
- Photopatch test's efficiency in finding the responsible agent is satisfactory in contact photoallergy but poor in systemic drug-induced photoallergy. For example, in the latter case a negative result does not mean nonresponsibility of the suspected drug and a positive result with a drug from the standard battery does not imply its involvement either.

The responsibility of the drug requires that the patient has been in contact with it and that in the patient's history photosensitization bursts match contacts with the drug. Illustration of the poor photopatch test's efficiency and how cautious should be the interpretation in case of suspected photoallergy is given by a recent paper (Conilleau et al. 2000) where among 15 patients suffering from drug photoallergy only three had photopatch tests positive to the suspected compound. This confirms a study from the German-Austrian-Swiss photopatch tests group (870 tested patients): 2,041 photopatch tests were positive but only 108 were considered as evidence of photoallergy with clinical relevance (Hölzle et al. 1991). This low specificity is also shown in a Mayo Clinic's study (Menz et al. 1988), in which only 14 out of 27 positive photopatch tests were confirmed as having clinical relevance.

While it is difficult to explain these false-positive photopatch tests of photoallergic type, possible explanations can be found to the false-negative results: compound low penetration capacity, unsuitable vehicle, inappropriate methodology (UV dose, irradiation time, etc.), and wrong interpretation. In fact, there is a lack of soundness in most investigations related to the diagnosis of drug-induced photoallergy. Especially, facilitated transcutaneous penetration in photopatch tests and the use of systemic tests should increase their reliability. But such tests cannot be used in routine and remain restricted to research laboratories.

Sun protection factor (SPF) • UVA protection factor(UVAPF) • In vivo • In vitro • Critical wavelength • ISO • FDA USA • Waterresistance

There is a well-documented need for effective UVB and UVA photoprotection of the human skin by topically applied sunscreens. To evaluate and standardize the efficacy of the latter, the US FDA published in 1978 (Department of Health, Education, and Welfare and FDA USA 1978) the first method to determine the sun protection factor (SPF). In 1982, the German DIN also published a method (Deutsches Institut für Normung 1984), yet not harmonized with the US one, especially in terms of the amount of applied product (1.5 mg/cm² instead of 2 mg/cm²). The US FDA revised the method in 1988, 1993, and 1999, and the last version was published in 2011 (Department of Health and Human Services and FDA USA 2011).

In 1994, the European Cosmetics Association (COLIPA) published the first European guidelines on the determination of SPF (The European Cosmetic Toiletry and Perfumery Association COLIPA 1994) and, later (2003), a revised version together with the Japanese Cosmetic Industry

Association (JCIA) and the Cosmetic Toiletries and Fragrances Association (CTFA) from South Africa (CTFA SA et al. 2003). This method, called the International SPF test method, was the first step of harmonization. The same method was published again in 2006 (CTFA SA et al. 2006) with the support of the US industry association CTFA (now called PCPC). Australia published an SPF test method in 1993 and revised it in 1998 (Australian/New Zealand Standards 1998). Since the International SPF test method, the US FDA and the Australian methods led to different results; the International Standardization Organization Technical Committee on Cosmetics Products (ISO TC217) decided, in 2006, to elaborate an ISO standard for the *in vivo* determination of the SPF.

In 2006, a request emerged from the European Commission (2006) to obtain standards for assessing both the UVB and the UVA protection afforded by sunscreen products. It was requested to develop *in vitro* methods giving equivalent results to the *in vivo* approach, the latter being the reference. The EU Commission also recommended that the methods used should take into account photo-instability of products to avoid an overestimation of protection factors. *In vivo* SPF and *in vivo* UVAPF (persistent pigment darkening) test methods take photodegradation into account since appropriate UV doses are used to induce erythema on the human skin for SPF determination or pigmentation for UVAPF determination.

When *in vitro* methods are used, they should also take into account this issue to provide relevant evaluation.

1 Determination of the Sun Protection Factor (SPF)

In 2010, the International Standardization Organization (ISO) working group n°7 in charge of the sun protection methods within the technical committee TC 217 on cosmetic products published the first ISO standard on the determination of the SPF

(ISO 24444). This ISO standard (ISO 24444) is based upon the 2006 international test method for SPF determination (CTFA SA et al. 2006). In 2011, the US Food and Drug Agency (FDA) published a final monograph (Department of Health and Human Services and FDA USA 2011) that included an *in vivo* SPF test method also based upon the International SPF test method 2006 and similar to the ISO 24444. However, some differences still exist, as described in Table 1.

This ISO standard has been adopted by the EU and South Africa in 2010, by Australia, Mercosur, Japan, and Mexico in 2012, and Canada in 2013 (Table 2). However, there is no recognition of ISO 24444 by the US FDA. In addition, some countries do not recognize the US FDA method. Practically speaking, this situation implies retesting the same products when marketed in these countries and finally raises ethical and cost issues.

2 Determination of UVA Protection

In 2006, the European Commission recommended to use the persistent pigment darkening (PPD) as endpoint for determining UVA protection through a method similar to the JCIA method (Japan Cosmetic Industry Association (JCIA) 1995) or any *in vitro* method able to provide similar and reliable results. In addition, the critical wavelength, an evaluation of the width of the absorbance of the sunscreen product, should be determined and be at least equal to 370 nm.

2.1 In Vivo UVA Protection

Japan (JCIA) was first to publish (January 1996) an official *in vivo* method to determine the level of UVA protection, adopting the PPD method for assessment of the UVA efficacy of sunscreen products (Japan Cosmetic Industry Association (JCIA) 1995). Korea and China adopted this method in 2001 and 2007, respectively. Finally,

Table 1 Determination of in vivo SPF: main differences between the ISO 24444:2010 and FDA USA 2011 methods

Parameters	ISO 24444 2010	FDA USA 2011
Test subjects	Combination of phototypes I, II, and III and determination of ITA° (skin color) for selection	Phototypes I, II, and III
	(ITA° value >28° very fair, fair skin, and intermediate skin color)	10 subjects maximum, 3 subjects rejected for listed reason
	10–20 subjects according to the statistical criteria for test validation	
	Max 5 subjects rejected for listed reason	
Test conditions	Product application, UV exposure, and MED assessment should be carried out in stable conditions, with a room temperature from 18 to 26 °C	For the evaluation, the subjects should be in the same position as when the site is irradiated
	All steps of the procedure shall be performed in the same position: either an upright, seated, or prone position (excepted powders should be tested in prone position)	
Test sites	Application surface, between 30 and 60 cm ²	Application surface, minimum of 30 cm ²
Product quantity and application	(2.00 +/- 0.05) mg/cm ² ; sensitivity of the balance at least 0.1 mg; method of weighing by loss	2 mg/cm ²
	Droplets on the whole test site, spreading time in the range of 20–50 s, low pressure of application	Spread the product as evenly as possible
	Powders, spatula, finger, applicator puff + water or other suitable solvent	Finger cot without pre-saturation
	Finger cot optional but recommended; when employed the finger cot should not be pre-saturated with the product	Drying time before UV exposure at least 15 min
	Drying time before UV exposure 15–30 min	
UV exposures	Pre-estimation of individual MED _u by experienced technician or by colorimetry (ITA°) or provisional MED _u up to 1 week before the test	Initial MED _u with 1.25 geometric progression
	UV dose progression for the protected and unprotected sites:	UV dose progression for unprotected site, 25 %
	For expected SPF ≤25, 25 % or less	UV dose progression for protected sites:
	For expected SPF >25, 15 % or less	For expected SPF <8, 25 % For expected SPF 8–15, 20 % For expected SPF >15, 15 %
Reference formulations for validation of the test	P2, P3, P7	P2
Statistical validation of the test	95 % confidence interval must be ≤17 % of the mean	No statistical criteria
	Add subjects from 10 to 20 to fulfill the criteria, if not reject the test	

the in vivo UVA method has been standardized by ISO TC217 and published in 2011 under the reference ISO 24442 (ISO 24442), now adopted or accepted in many countries (Table 2).

The PPD skin response has been selected for the development of a standardized protocol because it fulfills the different criteria needed to develop a relevant method to quantify the efficacy

Table 2 Adoption/recognition of ISO standards

	Europe	Australia 2012	South Africa 2013	USA 2011	Canada 2013	Mercosur 2012	Mexico 2012	Japan 2012

			JCIA 1995					
In vitro UVA	ISO 24443	ISO 24443	ISO 24443	FDA 2011	ISO 24443 COLIPA 2011 FDA 2011	COLIPA 2009 or all updates (COLIPA 2011, ISO 24443)	COLIPA 2011, ISO 24443, FDA 2011	No

of sunscreen products against UVAs such as (i) an action spectrum covering the entire UVA range and as flat as possible; (ii) independent of the fluence rate; (iii) a stable endpoint, the PPD reaction appearing stable over 240 min; and (iv) dependent on the UVA doses, classically from 10 to 25 J/cm² for an untreated skin site to allow the minimal pigmentation dose to be determined. Since the PPD response requires doses greater than 10 J.cm⁻² (approximately 40 min of a midday summer sunlight), the photostability of sunscreens is also challenged during PPD test procedure.

The sunscreen-testing protocol developed using this endpoint is similar to the design of the SPF test. The major elements of the protocol include the exposure of skin phototypes II, III, and IV, i.e., subjects prone to elicit an induced pigmentation, a xenon arc solar simulator filtered with a WG335 filter 3 mm in thickness and UG11 filter 1 mm, multiple-incremental doses (25 % progression) of UVA with and without sunscreen protection, and observation of the pigment responses 2–24 h post UVA exposures. The protection index is determined as the ratio of the dose required for a minimally perceptible pigment response in sunscreen treated skin divided by the dose that induces the same response in unprotected skin. It has been demonstrated that using

this protocol, the results are reproducible on a large range of products and various levels of UVA protection.

There are some minor differences between the JCIA protocol and the ISO 24442 standard, among which is the inclusion of a new reference formulation called S2 (mean UVAPF 12.7 with acceptance range [10.7–14.7]) that should be tested together with products of expected UVAPF >12 for validating the test (Moyal et al. 2007).

2.2 In Vitro UVA Protection

In 2007, the European Cosmetics Association (COLIPA, now Cosmetics Europe) published a guideline on the determination of UVA protection factor using an in vitro method (COLIPA 2007). This method has been developed to provide UVA protection factors correlated with in vivo UVA protection factors, i.e., an alternative to the in vivo method. This method was revised in 2011 (COLIPA 2011; Moyal et al. 2013) and published as an ISO standard (ISO 24443) in 2012 (ISO 24443). This method allows both the UVA protection factor and the critical wavelength value to be determined. The procedure comes as follows:

1.3 mg/cm² of sunscreen product is applied to polymethyl methacrylate (PMMA) plate with about 5 μm roughness. The transmission through the sunscreen coated sample is cross-multiplied by the UVA source emission spectrum and the PPD action spectrum. To reduce the operator influence, a calibration step is incorporated into the computations. The spectral absorbance is adjusted by a scalar multiplier so that the predicted SPF matches the clinically measured SPF, yielding an “absolute” absorbance curve from which UVA protection can be predicted using the following equations:

$$SPF_{in\ vitro} = \frac{\int_{\lambda=290nm}^{\lambda=400nm} E(\lambda) * I(\lambda) * d\lambda}{\int_{\lambda=290nm}^{\lambda=400nm} E(\lambda) * I(\lambda) * 10^{-A_0(\lambda)} * d\lambda}$$

SPF_{in vitro, adj} = SPF_{labelled}

$$= \frac{\int_{\lambda=290nm}^{\lambda=400nm} E(\lambda) * I(\lambda) * d\lambda}{\int_{\lambda=290nm}^{\lambda=400nm} E(\lambda) * I(\lambda) * 10^{-A_0(\lambda)*C} * d\lambda}$$

$$UVAPF_0 = \frac{\int_{\lambda=320nm}^{\lambda=400nm} P(\lambda) * I(\lambda) * d\lambda}{\int_{\lambda=320nm}^{\lambda=400nm} P(\lambda) * I(\lambda) * 10^{-A_0(\lambda)*C} * d\lambda}$$

The UVA dose to be delivered for taking into account the product photounstability if any is defined as the initial UVAPF₀ obtained before UV exposure by calculations multiplied by 1.2 J/cm² (e.g., for a UVAPF₀ = 10, the UVA dose will be 10 × 1.2 J/cm² = 12 J/cm²).

$$D = UVAPF_0 \times 1.2 \text{ J/cm}^2$$

Post exposure, the in vitro spectrum is measured again on the same plate and is transformed using the previously determined constant c. The UVAPF is recalculated using this transformed spectrum after the exposure step.

$$UVAPF = \frac{\int_{\lambda=320nm}^{\lambda=400nm} P(\lambda) * I(\lambda) * d\lambda}{\int_{\lambda=320nm}^{\lambda=400nm} P(\lambda) * I(\lambda) * 10^{-A(\lambda)*C} * d\lambda}$$

Results from this in vitro UVA method have been compared to those from the in vivo PPD method for photostable and photounstable sunscreen products. Both a good reproducibility between laboratories and a significant correlation with the in vivo method were found.

2.3 Critical Wavelength

The absorption curve of most sunscreen agents presents a common feature, i.e., its absorption value is high wavelengths around 290 nm and decreases gradually with increasing wavelengths. The width of the curve represents the range of UV wavelengths where the sunscreen agent does absorb, that is to say, whether it has a wide range of absorption. The critical wavelength refers to the wavelength λ_c >290 nm where the area under the absorption curve accounts for 90 % of the total area of the entire absorption spectra (290–400 nm). It can be expressed by the formula

$$\int_{290}^{\lambda_c} A\lambda.d\lambda = 0.9 \int_{290}^{400} A\lambda.d\lambda$$

A (λ), the absorbance of the sunscreen agent at the wavelength of λnm
dλ, the intervals between the wavelengths

Table 3 UVA in vitro: main differences between ISO 24443:2012 and FDA USA 2011

Parameters	ISO 24443:2012	FDA 2011
Substrate/plate	PMMA with 5 μm mean roughness	PMMA with roughness from 2 to 7 μm
	At least 4	At least 3
Application rate	1.3 mg/cm^2 without finger cot	0.75 mg/cm^2 with fingercot
Drying time and temperature	At least 30 min in the dark, temperature 25–35 $^{\circ}\text{C}$	Not defined
UV source irradiance level	40–200 W/m^2	Up to 1500 W/m^2
Irradiation dose	1.2 $\text{J}/\text{cm}^2 \times \text{UVAPF}_0$	4 MEDs (8 J/cm^2)
Temperature during irradiation	25–35 $^{\circ}\text{C}$	Not defined
Correction of the absorbance curve using in vivo SPF value	Yes	No
Reference formulation for test validation	S2 SPF 16 UVAPF acceptance range [10.7–14.7]	No
Statistical validation	95 % confidence interval must be $\leq 17\%$ of the mean UVAPF	No

In 2011, the US FDA published a final rule including a method to determine the critical wavelength (Department of Health and Human Services and FDA USA 2011). This method is however not harmonized with the ISO 24443 standard and can lead to different results. A summary of the main differences between the two methods is provided in Table 3.

2.4 UVA Protection Criteria

Combining both the determination of the level of UVA protection and the critical wavelength method to measure the broadness of UVA absorbance has been first proposed for assessing UVA protection of sunscreen products by the EU Commission (2006) and further adopted by other countries such as Australia, Mercosur, Mexico, and Canada. The value of the UVA protection factor (UVAPF) must be at least one-third that of the SPF.

The critical wavelength value must be ≥ 370 nm to qualify the product as “broad spectrum” in the USA and Canada.

3 Determination of Water Resistance

There are three main protocols for the measurement of water resistance of sunscreen products issued by COLIPA (2005), Australia (2012) (AS/NZS 2604), and the USA (2011) (Department of Health and Human Services and FDA USA 2011). These protocols differ by some technical aspects related to the water immersion procedure (Table 4).

The criteria and the labeling to support the claim water resistant are also different (Table 4).

ISO TC217 WG7 is working on a water resistance standard to harmonize the method.

4 Conclusion

The development of ISO standards and its worldwide adoption is paramount to avoid local retesting especially when only in vivo methods exist. These standards are precious references for both industry and legal authorities. A same method used by all allows better comparability between products and, ultimately, a better information toward consumers.

Table 4 Water resistance: comparison of the main parameters of three methods

	Europe	USA	Australia
Method	COLIPA guidelines for evaluating sun product WR, December 2005	FDA Final Monograph Sunscreen Drug Products for OTC Human Use, 2011	Australian/New Zealand Standard AS/NZS 2604:2012 Sunscreen Products – Evaluation and Classification
Recommended immersion devices	Spa pool, Jacuzzi, or bathtub with water circulation	Indoor fresh water pool, whirlpool or Jacuzzi	Indoor simulated swim test device (SSTD) approximately 1.8 m × 1.8 m
Water temperature	29 ± 2 °C	23–32 °C	33 ± 2 °C
Water agitation	Continuous circulation, no air agitation	Not specified	For each 20 min immersion period: water circulation for 16 min and air agitation for 4 min
Water quality	Drinking water meeting EC council directive 98/83/EC Mg and Ca (combined) content min. 50 mg/ml and max. 500 mg/ml; sanitized with bromide or chlorine or refilling for each volunteer	Drinking water meeting standard 40 CFR part 141	pH between 6.8 and 7.2
Recommended procedure	Measurement of a static SPF and the SPF after water immersion for 20 min, 15 min air-dry, 20 min immersion, air-dry ≥15 min until completely dry	Measurement of the SPF after immersion: 20 min moderate activity in water, 15 min rest, another 20 min moderate activity in water, air-dry period (duration not specified)	Measurement of the SPF after immersion: 20 min immersion in the water, 5 min rest period, another 20 min water immersion For WR claim >40 min the schedule of alternating 20 min immersion and 5 min rest to be continued. After the last immersion period air-dry ≥15 min
Number of subjects	Min. 10 to max. 20 valid values from max. 25 subjects, according to statistical compliance criteria on static SPF	At least 10 valid values from max. 13 subjects	Min. 10 to max. 20 valid values from max. 25 subjects, according to statistical compliance criteria on SPF after immersion
Reference WR product	Yes, P2, to be tested at least every 4 months WR for P2 >50 %	No	No
Calculation of mean WR	For each subject individually: %WR _i = (SPF _w -1)/(SPF _s -1) * 100. The mean %WR is the arithmetic mean of n individual %WR _i values	The WR SPF is the arithmetical mean of all individual SPF _s measured after immersion minus A	The WR SPF is the arithmetical mean of all individual SPF _s measured after immersion

(continued)

Table 4 (continued)

	Europe	USA	Australia
Statistical criteria	A product is water resistant, if the mean %WR – d is $\geq 50\%$ of the static SPF (d is the 90 % unilateral confidence value) and the 95 % bilateral confidence interval of mean static SPF lies within $\pm 17\%$ of the static SPF	The mean WR SPF minus A ($A = t * s / \sqrt{n}$ with t being the Student's t value for 5 % error probability)	The 95 % bilateral confidence interval of mean post immersion SPF lies within $\pm 17\%$ of the static SPF
Labeling	Water resistant (if criteria are fulfilled after 40 min); very water resistant (if criteria are fulfilled after 80 min); SPF before immersion is labeled	Water resistant (40 min), water resistant (80 min) SPF –A determined after immersion is labeled	Water resistant 40 min, 2 h, 4 h SPF after immersion is labeled

Keywords

Stratum corneum barrier function • skin lipids • Water transport in SC- Skin permeability • Transepidermal water loss (TEWL) • Skin hydrolipidic film

Adaptation to terrestrial life necessitates the presence of a highly impermeable epidermal membrane which restrains both insensible water loss from the body, transepidermal water loss (TEWL), and the entrance of exogenous substances into the body. This highly efficient barrier is already present in the newborn in whom the TEWL is close to normal adult values. On the other hand, in premature neonates (<33 weeks effective gestational age), an immature barrier function is manifested by an increased TEWL and percutaneous absorption of xenobiotics, which is well-correlated with the degree of prematurity (Hammarlund and Sedan 1979; Nachman and Esterly 1971; Rutter and Hull 1979). In the severely premature neonate (<28 weeks EGA), this compromised barrier function is an important cause of morbidity resulting from hypothermia, electrolyte imbalance, and cutaneous infections (Belgaumkar and Scott 1975; Lorenz et al. 1982; Maurer et al. 1984). The time required for the development of a fully functional skin barrier in this premature population is reported to be in the order of 2–4 weeks after birth (Evans and Rutter 1986).

The barrier function of the skin resides in the stratum corneum (SC). The permeability of the SC is dependent on the makeup of the intercellular spaces which consist of hydrophobic lipids arranged as lamellar bilayers (Elias and Menon 1991; Elias 1983). These lamellae are predominantly composed of three classes of lipids: ceramides, free fatty acids, and cholesterol (Schürer and Elias 1991). These lipids (or their precursors) are secreted into the intercellular spaces by epidermal lamellar bodies (Odland bodies) at the stratum granulosum–SC interface (Elias and Menon 1991). After secretion, the glucosylceramides and phospholipids are transformed, respectively, by glucosidases and lipases into ceramides and free fatty acids. The cholesterol in

the SC is derived from the hydrolysis of cholesterol sulfate in the intercellular spaces, and by secretion from the lamellar bodies (Williams et al. 1998).

In this chapter, the molecular organization of the intercellular SC lipids is described (nature of lipid constituents, lipid conformation, compositional variation as a function of body site). A study of the skin barrier function correlating macroscopic biophysical measures with the functional status is presented. Finally, a noninvasive method for the determination of SC thickness, *in vivo* and in man, is described.

1 Molecular Organization of the SC

The SC lipids consist of cholesterol esters (15 %), cholesterol (32 %), saturated long-chain fatty acids (16 %), and ceramides (37 %) (Norlen et al. 1998).

The fatty acid composition of abdominal SC is presented in Table 1 (Elias 1990; Lampe et al. 1983). The endogenous free fatty acids are predominantly composed of long-chained

Table 1 Lipid composition of human abdominal SC (Adapted from Elias (1990) and Lampe et al. (1983))

saturated molecules (Norlen et al. 1998). The principal components, characterized by little interindividual variation, are lignoceric (C24:0) and hexacosanoic (C26:0) acids. In addition, traces of longer chain (C32-C36) saturated fatty acids have also been detected in the deeper regions of human forearm SC (Norlen et al. 1998). An analysis of the composition of free fatty acids as a function of SC depth demonstrates a decrease in the levels of C14:0, C16:0, C16:1, C18:0, and C18:1, but an increase in the amount of C24:1 (Bonte et al. 1997). The relative ratios of unsaturated/saturated free fatty acids, fatty acids/cholesterol and fatty acids/ceramides appear to decrease deeper in the SC.

Freeze fracture electron microscopy has shown that corneocytes in the SC are separated by multiple sheets of lipid lamellae (Elias and Friend 1975). These lamellae arise from stacks of lamellar disks that are extruded from the granular cells and then fused edge to edge to form sheets (Lavker 1976). Intercellular lamellae are composed of alternate hydrophobic (electron lucent) and hydrophilic (electron dense) lamellae (Landmann 1988). Each sheet therefore consists of two lipid bilayers, and there are one, two, or more such sheets in each intercellular space (Swartzendruber et al. 1987). A lucent band consisting of a monomolecular layer of N-(ω -hydroxyacyl) sphingosines is chemically bound to the horny cell envelope (Swartzendruber et al. 1987). The interaction between the ceramides and corneocyte protein envelopes probably occur via an ester linkage with glutamine or glutamate residues (Downing 1992). The β -sheet protein conformation of the corneocyte envelope is thought to permit a dense liaison with ceramide molecules thus creating a highly resistant and impermeable envelope (Lazo et al. 1995). As a result, the diffusion of water across the corneocyte is limited by virtue of the hydrophobic coating. Despite the rather low concentration of these covalently bound lipids (1.4 % of the SC mass and 53 % of protein bound lipids), they play a fundamental role in the mechanical and enzymatic resistance of the SC (Wertz and Downing 1987; Wertz et al. 1989). Therefore, Swartzendruber suggested that each corneocyte possesses a lipid envelope that may function both

in corneocyte cohesion and in the barrier properties of the epidermis. A model of the linkage of ω -hydroxyacyl sphingosines to the corneocyte envelope (Swartzendruber et al. 1987) and the arrangement of double bilayers between corneocytes (Swartzendruber et al. 1989) are presented in Figs. 1 and 2.

2 SC Barrier Function and Skin Lipids

2.1 Barrier Function and Skin Lipid Extraction

Previous studies have demonstrated the essential role of the intercellular lipids in percutaneous absorption (Elias and Friend 1975; Nemanic and Elias 1980; Smith et al. 1982) and in the barrier function of the skin (Grubauer et al. 1989; Imokawa et al. 1986; Imokawa and Hattori 1985) showing (a) the importance of lipids in limiting water transport across hairless mouse skin, and (b) that extraction of sphingolipids and neutral lipids using a polar solvent (acetone) resulted in the greatest barrier disruption (Grubauer et al. 1989). The extraction of nonpolar lipids with petroleum ether provoked only a mild perturbation of the barrier (Grubauer et al. 1989). The sphingolipids, and particularly the ceramides, are considered to contribute to this barrier function by stabilizing the intercellular lipid lamellae (Ward and du Reau 1991).

2.2 Recovery of Barrier Function by Skin Lipids

In a similar study, Imokawa et al. (Imokawa et al. 1991) showed that the application of SC lipids to skin previously treated with organic solvents, restored the barrier function and was accompanied by the formation of intercellular lipid lamellae. An equimolar mixture of ceramides, cholesterol, and fatty acids (either essential fatty acids such as linoleic acid, or nonessential fatty acids as palmitic or stearic acids) was shown to accelerate recovery of

Fig. 1 (a) A representative structure of the ω -hydroxyacyl sphingosines liberated from ester linkage with the horny cell envelope. (b) Postulated arrangement

of ω -hydroxyacyl sphingosines esterified with alternating γ -glutamyl groups in a β -pleated polypeptide chain (From Swartzendruber et al. 1987, with permission)

skin barrier function in mice and in humans, in vivo (Mao-Qiang et al. 1996). These lipids are incorporated rapidly (within approximately 2 h) into the cellular layers of the viable epidermis, then into the nascent, budding lamellar bodies, and finally within the intercellular lamellae. The diffusion within the viable epidermis of these endogenous lipids applied to intact human skin is thought to be equally rapid (Mao-Qiang et al. 1995). The application of an equimolar mixture of ceramides, cholesterol, and fatty acids was shown to accelerate barrier function recovery more rapidly than Vaseline (difference observed after 8 h) (Mao-Qiang et al. 1996).

2.3 Effect of Age and Seasonal Variation on SC Lipids

The biosynthesis of the majority of SC lipids, especially that of ceramides, decreases

significantly with age (Rogers et al. 1996). Similarly, SC lipid synthesis decreases during the winter months regardless of the body site. The relative level of ceramide 1 linoleate declines during winter in older subjects, while the relative amount of ceramide 1 oleate increases. The levels of lignoceric and heptadecanoic acids decrease during winter while those of the other fatty acids remain almost constant. The decreased amount of SC lipids in older subjects contributes to their higher susceptibility to altered skin barrier function and skin dryness, particularly in winter.

3 SC Barrier Function and Hydration

The movement of water across the epidermis plays an important role in barrier repair (Grubauer et al. 1989) since the application of an impermeable covering over a damaged barrier

Fig. 2 Diagram of intercellular lipid lamellae based on studies by Swartzendruber et al. (From Swartzendruber et al. 1989, with permission). In gray on the chart (and

black on the electron micrograph) are hydrophilic layers, whereas lipophilic layers are white both on the chart and the electron micrograph image

impedes recovery. Consequently, it is probable that the factors that regulate transcutaneous water transport are able to modulate skin barrier function. The ambient relative humidity also influences the transcutaneous diffusion of water. In a recent study, Denda et al. (1998a) demonstrated that the basal TEWL was reduced by almost 31 % from 19.9 ± 5.0 mg/m²/h to 13.8 ± 2.6 mg/m²/h in animals maintained in a dry (RH < 10 %) versus humid (RH:80 %) environment. Furthermore, the number of

lamellar bodies in the stratum granulosum cells (and their exocytosis) as well as the number of SC layers were elevated in animals maintained in a dry environment (RH < 10 %). Exposure to a low humidity for 48 h results in increased epidermal DNA synthesis (Denda et al. 1998b). The epidermal thickness and dry weight are also increased in a dry environment (Denda et al. 1998b). These changes may correspond to a homeostatic response to counter excessive TEWL in a dry environment (Denda

Table 2 Skin permeability coefficients for water as a function of relative humidity and treatment with hydrophilic/lipophilic agents

Relative humidity (%)	SC thickness (μm)	$10^8 \cdot P$ (cm s^{-1})
46 ^a	11.6	3.9
62 ^a	11.5	5.5
81 ^a	12.4	17.9
93 ^a	15.6	20.0
75 ^b	15.0	11.0

Formulation ^d	Water solubility in formulations	$10^8 \cdot P$ (cm s^{-1})
Diethyleneglycol monoethyl ether (I)	Miscible in all parts	65
Propyleneglycol dipelargonate (II)	<0.001	0.001
Mixture I + II (50/50. v/v)	0.04	0.04

^aThrough human skin (Blank et al. 1984)

^bThrough pig skin (Potts et al. 1991)

^cIn vivo in man (Pirot et al. 1998)

^dThrough hairless mouse skin treated with variable hydrophilic formulations (De Carvalho et al. 1996)

et al. 1998b). Water transport across the skin can be increased in the presence of hydrophilic excipients (e.g., diethyleneglycol monoethyl ether), which favors the partitioning of water towards the external surface in contrast to the presence of lipophilic substances (e.g., propylene glycol dipelargonate) (De Carvalho et al. 1993). Table 2 shows the variation in cutaneous water permeability coefficients as a function of relative humidity and treatment with lipophilic or hydrophilic formulations.

the absence of a convective current, the human body is surrounded by a layer of water vapor. TEWL measurements permit an evaluation of the skin barrier function (Elias and Menon 1991; Grubauer et al. 1989). The insensible water loss from the skin can be calculated from a measurement of the water vapor pressure gradient at the skin surface:

$$\frac{1}{A} \frac{dm}{dt} = -D' \frac{\Delta P}{\Delta x}$$

where $dm/(A dt)$ is the quantity of evaporated water per unit time and surface area ($\text{g m}^{-2}\text{h}^{-1}$), D' is a constant equal to $0.670 \times 10^{-3} \text{ g mhPa}^{-1}$ (at a temperature of 300 K and atmospheric pressure of 101 kPa), $\delta P/\delta x$ is the water vapor pressure gradient (Pa m^{-1}) (Chapman and Cowling 1953; Eckert and Drake 1959). At the skin surface, the water vapor pressure gradient is relatively constant in the absence of external convection currents (Ueda 1956). Consequently, this gradient can be estimated by measuring the difference in water vapor pressure between two discrete points aligned perpendicularly to the skin surface. The vapor pressure is calculated as the product of the relative humidity and the saturated water vapor pressure, which is dependent on temperature. The relative humidity and temperature are measured

4 Characterization of SC Barrier Function

4.1 TEWL Measurement

The diffusion of water from the deeper layers of the epidermis towards the skin surface is an insensible phenomenon (distinct from perspiration), which is limited by the presence of the stratum corneum. Approximately 65 % of insensible water loss (TEWL) is attributed to evaporation from the skin surface. This diffusion depends not only on homeostatic mechanisms, but also on external factors such as humidity, temperature, and atmospheric pressure (Sato et al. 1998). In

using a sensor (rh) and thermistor (th), respectively, which are coupled in a probe (Nilsson 1977). This method does not require regulation of the local water vapor pressure, as with hygrometric measures (which use circulating gas in a ventilated chamber) and gravimetric measures (which use saturated salt solutions in an unventilated chamber).

4.2 Measurement of Water Diffusivity and SC Thickness in Vivo

The diffusion of water in the SC is made complex by the heterogeneous structure of the membrane. El-Shime and Princen (El-Shime and Princen 1978) and Blank et al. (1984) demonstrated that SC water diffusivity increased with increasing membrane water content. The degree of SC hydration modifies its affinity for water (Hansen and Yelin 1972). Despite its heterogeneity, the SC has been regarded as a homogeneous membrane where each cellular layer contributes equally to the TEWL (Kligman 1964). The latter was recently demonstrated by Kalia et al. (1996) and Pirot et al. (1998), who have shown that SC water transport can be simply described in terms of Fick's first law of diffusion:

$$PIE_H = \frac{\gamma \cdot D}{H}$$

where γ is the product of the SC lipid-viable epidermis partition coefficient K of water and ΔC (the water concentration difference across the membrane), and D is the average apparent diffusivity of water across the SC of thickness H . The total SC thickness can be calculated from the x-axis intercept of the function $y = 1/TEWL_{H-x} = f(x)$ (Fig. 3). This methodology was recently used to determine the SC thickness from different body sites (Schwindt et al. 1998) (Fig. 4).

The self-diffusion coefficient of water is approximately $3 \times 10^{-5} \text{ cm}^2/\text{s}$ (Andrussow and Schramm 1969), and is about 100-fold and

Fig. 3 Linear relationship between 1/TEWL and forearm SC thickness for three subjects (From Kalia et al. 1996, with permission)

Fig. 4 Regional variations in SC thickness H for six subjects (From Schwindt et al. 1998, with permission)

10,000-fold smaller in a SC lipid model and SC, respectively (Schwindt et al. 1998).

4.3 TEWL and SC Morphology

Potts and Francoeur (1991) have shown that the intrinsic water diffusivity in the SC is comparable to that obtained in other lipidic membranes. However, the water diffusion pathway across the SC is 50 times greater than the absolute membrane thickness in which the lipids form a continuous, and tortuous, extracellular milieu.

4.4 Electrical Properties: Impedance and Conductance Measurements of the SC

The passage of an electrical current across the SC is dependent on the hydration state of the membrane. Measurements of electrical impedance or resistance have been frequently used to ascertain the SC hydration level. The passage of current across the SC is dependent on (1) the orientation of dipole moments of SC constituents such as keratin, (2) ionic motion within the SC, and (3) water mobility and proton exchange in the SC (Leveque and de Rigal 1983). The SC impedance, measured at high frequency, decreases (1) with increased hydration (Tagami et al. 1980), (2) following the removal of SC layers (i.e., after tape stripping), especially of the outermost layers [34], and (3) after treatment with hydrating agents (Clar et al. 1975). Tagami (Tagami et al. 1994) demonstrated, using measurements of cutaneous conductance at high frequency, that the capacity for water absorption and retention is markedly decreased in psoriatic lesions and in regions treated with Vaseline and a formulation containing urea (10 %). This technique has helped to highlight the correlation between the degree of hydration and the amino acid content in the SC of patients suffering from senile ichthyosis (Horie et al. 1989).

4.5 Infrared Spectroscopy

Water absorbs infrared radiation; this property has been exploited to quantify, noninvasively SC hydration using attenuated total reflectance infrared spectroscopy (ATR-IR). Accordingly, it has been shown that the absorbance at 3400 cm^{-1} ($2.9\text{ }\mu\text{m}$) characteristic of OH stretching vibrations increases in the deeper layers of the SC, suggesting a corresponding increase in water content as a function of SC depth (Baier 1978). Using Fourier transform infrared spectroscopy (FTIR), a water content of $0.12 \pm 0.01\text{ g cm}^{-3}$ (mean \pm SD; $n = 6$) was measured in six human subjects (Potts et al. 1985b). This value increased to $0.22 \pm 0.02\text{ g cm}^{-3}$ after treatment with Vaseline

for 5 h and returned to the initial value 30–45 min after removal of this occlusive layer.

5 Water Transport in the SC

Potts and Francoeur (1990) compared, using FTIR, the variation in SC water permeability and lipid conformation as a function of temperature. Their results demonstrated an important modification in the lipid hydrocarbon chains supporting Träuble's (1971) hypothesis that the diffusion of water occurred through free volume voids created in the lipid infrastructure. In an earlier study, the same group examined skin barrier function in vitro and the SC permeability to water using differential scanning calorimetry and infrared spectroscopy (Golden et al. 1987). At temperatures below $70\text{ }^{\circ}\text{C}$, the movement of water across the SC requires an activation energy of 17 kcal/mol, a value comparable with that obtained for a range of biomembranes. In addition, Golden et al. (1987) have shown that the flux of water is inversely related to the degree of conformational order of SC lipids. In a recent study, Gay et al. (1994) reported that a fraction of the intercellular SC lipids existed in an orthorhombic crystalline arrangement, implicating alkyl chains longer than 22 carbon atoms. Independent x-ray diffraction studies have demonstrated the presence of these structures in the SC of hairless mice (White et al. 1988), premature rats (Wilkes et al. 1973), and humans (Bouwstra et al. 1991; Garson et al. 1991). Such configurations, associated with nonlipid constituents, disappear between $45\text{--}65\text{ }^{\circ}\text{C}$. At physiological temperature, these orthorhombic lipids are thought to play an important role in the SC barrier function. Bouwstra et al. (1992) have shown, using x-ray diffraction, that the SC lipids from human skin are arranged as two types of lamellar structures with repeating distances of 6.4 and 13.4 nm. The introduction of molecules such as cholesterol destroys this configuration (Umemura et al. 1980). According to Gay et al. (1994) these orthorhombic lipids, associated with ceramides, could be located at the level of the corneocyte membranes, which could explain (in part) the poor permeability of these cells. Moreover, Gay et al. (1994) showed a

Fig. 5 Uptake of water in a bilayer: a possible mechanism, a : interfacial area per molecule. d : repeat distance. x : distance between two alkyl chains (From Bouwstra et al. 1991, with permission)

significant change in the infrared CH_2 stretching frequency of the SC lipid alkyl chains at relative humidities above 40 % w/w, suggesting a transition of the orthorhombic lipids and hence a change in barrier function.

Interestingly, no change in the X-ray diffraction pattern of SC lipids is observed as a function of hydration (Bouwstra et al. 1992). According to Bouwstra et al. (1992), water does not induce a swelling of the multilamellar lipid structure. Water can be incorporated into the lipid polar head regions (Fig. 5) and hence increase the interfacial area per lipid molecule without modifying the lamellar repeat distance (Bouwstra et al. 1991). This increase in interfacial area could thus be accompanied by a lateral swelling of alkyl chains and a decreased resistance in the interior of the membrane (Mak et al. 1991).

6 Conclusion

The physiology of the skin barrier function is a complex phenomenon that has only been partially elucidated. The key aspect of this function resides in the SC, at the skin-environment interface. The integrity of the skin barrier function may be evaluated by measurements of TEWL. While the measurement of water transport across the SC is now relatively straight-forward, the intimate understanding of this passive phenomenon is still the object of research and controversy, due in part to the remarkable anisotropic nature of the membrane.

In spite of this heterogeneous character, the diffusion of water across the SC appears to be a homogeneous process. If the thickness of the SC can be determined with some degree of accuracy, the route of water transport and hence, its diffusional pathway are still controversial. The intercellular lipid matrix is the only continuous structure of the SC (from the basal layers to the exterior). A number of different studies have shown that the intercellular lipids contribute to the skin barrier function. Water diffusion across this lipid matrix is considered to occur through the formation of free volume voids, created by thermal fluctuations, in the lipid hydrocarbon chains. Molecules of water can thus be transported across the SC thickness. This phenomenon is dependent on the temperature, the relative humidity, and the hydration state of the membrane. It is probable that an increase in water diffusivity subsequent to an increase in external temperature, relative humidity, and the level of membrane hydration reflects a modification of the orthorhombic configuration of certain intercellular lipids. The elevated SC water content (as a result of increased relative humidity) could subsequently lead to membrane fluidization (Alonso et al. 1996). This effect is probably predominant near the hydrophilic head groups of the fatty acid chains and may contribute to an increased water permeability across the SC. Further studies should help elucidate the level of these orthorhombic lipids and the influence of different treatments on their conformation and the reversibility of their phase

transitions. The study of water transport across the skin is of major interest as it also provides insight into the functional status of the barrier. However, conventional noninvasive methods based on electrical (Clar et al. 1975; Leveque and de Rigal 1983; Tagami et al. 1980), mechanical (de Rigal and L ev eque 1985; Potts et al. 1985a) and spectroscopic (de Rigal et al. 1992; Potts et al. 1985a) properties provide general information regarding bulk water transport across the skin, but do not provide a detailed picture of localized diffusion in the corneocytes and in the intercellular spaces.

1 Definition

Skin absorption occurs from occupational, environmental, consumer skin exposure to chemicals, cosmetics, and pharmaceutical products. Skin absorption is a global term that describes the transport of chemicals from the outer surface of the skin to the systemic circulation (OECD 2004). This is often divided into:

- Penetration, which is the entry of a substance into a particular layer or structure, such as the entrance of a compound into the stratum corneum
- Permeation, which is the penetration through one layer into a second layer that is both functionally and structurally different from the first layer
- Resorption, which is the uptake of a substance into the skin lymph and local vascular system and in most cases will lead to entry into the systemic circulation (systemic absorption)

Skin absorption is a field of interest mainly to pharmacologists and toxicologists. The main purpose is obviously to know the amount of compound (solute) which has penetrated the organism, either its total amount or the amount per skin surface unit.

2 Topical Absorption Process

Skin absorption is related to a flow of matter diffusing through the stratum corneum, the outermost barrier, and subsequent layers. This process is illustrated in Fig. 1 (Lane 2013).

Three principal phases occur during skin absorption:

Phase 1: The solute leaves its vehicle and dissolves in the film coating the skin surface (lipids from the stratum corneum intercellular spaces, sebum, sweat, water, paraffin from the environment, etc.). This change of solvent is directed, and limited, by the solubility ratio, called partition coefficient (K).

Phase 2: The solute enters the stratum corneum intercellular spaces and is distributed according to a linearly decreasing concentration toward the deeper layers; its flow rate is determined by the diffusion coefficient (D). The filling of the stratum corneum is limited by its maximum storage capacity.

Phase 3: The solute penetrates the living tissue. This actual absorption phase begins before the second one has ended. It is controlled, and limited, by the solubility ratio in both tissues (which explains the very low passage of very lipophilic molecules). After a transient phase, this flow reaches a maximum which remains stable as long as the substance is in sufficient quantity on the skin surface. It is the phase of steady-state flux during which the amounts of compound going in and out of the stratum corneum are equal, while the amount stored inside this layer is continuously renewed but keeps identical and maximum. The amount absorbed during this phase is given by the first Fick's law:

$$Q = P A c t \quad (1)$$

This formula expresses the fact that the quantity absorbed Q (g) is proportional to the application area A (cm²), the application time t (hours), the applied concentration C (g/cm³), and a particular factor P (cm h⁻¹) called permeability coefficient. It is important to highlight the fact that the exclusive "motor" of this molecular transfer is the concentration difference (C) on each side of the stratum corneum and that the absorbed quantity (Q) is at any time proportional to this difference. The applied quantity (the "dose") eventually plays a part only through the

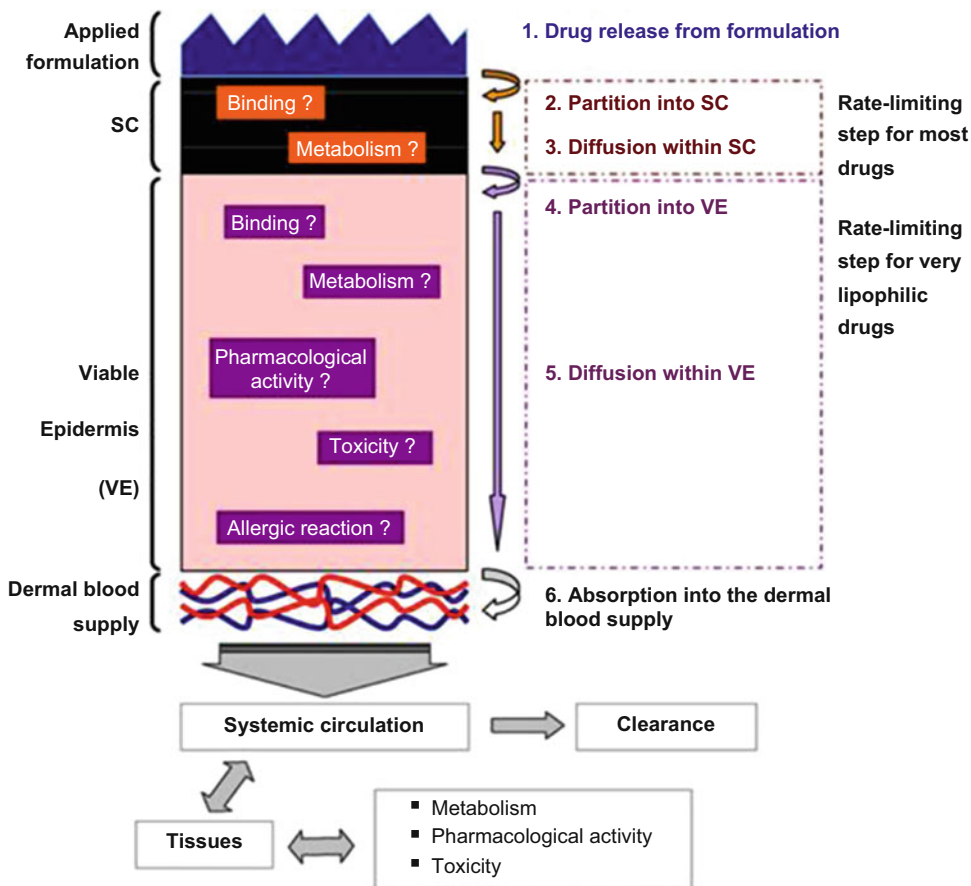

Fig. 1 Schematic representation of the processes involved in drug transport into and across the skin from any topical or transdermal applied formulation (Reported from Lane (2013))

application area or concentration, never through the thickness of the applied coat. This steady-state flux lasts as long as the solute concentration in the applied preparation remains unchanged. Without any new application, it will decrease, inducing the reduction then the end of the absorption.

Mention is made of “infinite dose” when the quantity applied is such that the concentration is not reduced before the steady-state flux has had time to be responsible for the almost entire absorbed quantity. This is usually the case when the quantity of cream applied is over 1 mg/cm², and the application is renewed every hour at least (the absence of visible cream on the skin should be avoided).

The experiment is called “finite dose” type if the amount of compound on the surface is not

sufficient to reach the maximum flux. A typical example is when the molecule has a great affinity for the stratum corneum (it disappears quickly from the formulation and the partition coefficient comes down) or when the applied dose is very small (less than 0.5 mg/cm² cream).

3 Absorption Parameters

The cutaneous or percutaneous absorption is expressed differently depending on whether it refers to the transit through the stratum corneum only or the joint transit through other cutaneous tissues (epidermis, entire skin). The parameters of the flux across the stratum corneum (actual absorption) are those of

Fick's laws. The transepidermal or transcutaneous passage is described by pharmacokinetic parameters requiring compartment models based also on diffusion but not on Fick's laws. Finally, empirical or purely descriptive parameters are used sometimes, in particular when the former cannot be used. The choice of reliable parameters is very important as it guarantees the reliable reading and interpretation of the measures, especially their extrapolation to other situations.

3.1 Parameters Derived from Fick's Laws

J ($\text{g cm}^{-2} \text{h}^{-1}$): steady-state (maximum) absorption flux per unit skin area.

P (cm h^{-1}): permeability coefficient: it characterizes the absorption of a given compound in a given vehicle.

K (no dimensions): solubility of the solute in the stratum corneum divided by its solubility in its vehicle.

D ($\text{cm}^{-2} \text{h}^{-1}$): speed of transfer in the stratum corneum and capacity to penetrate the living tissue.

τ (hours): "lag time."

To use and calculate these parameters, different equations are available (Scheuplein 1978):

Q (g cm^{-2}) indicates a quantity per unit skin area.

C (g cm^{-3}) is the applied concentration.

t (hours) is the application time since the beginning.

e (cm) is the stratum corneum thickness.

Steady-state flux:

$$J = Q/t = PC \quad (2)$$

Permeability coefficient:

$$P = KD/e \text{ hence } J = KDC/e \quad (3)$$

Cumulated amount entered into the stratum corneum (Fig. 1, top curve):

$$Q_{\text{in}} = J(t + 2\tau) \quad (4)$$

Cumulated amount having left the stratum corneum (Fig. 1, bottom curve):

$$Q_{\text{out}} = J(t - \tau) \quad (5)$$

Maximum amount stored in the stratum corneum (Fig. 1, middle curve):

$$Q_{\text{m}} = KCe/2 \quad (6)$$

Lag time:

$$\tau = e^2/6D \quad (7)$$

The actual absorption corresponds to Q_{out} (lower curve). However, during this period of maximum flow, the quantity Q_{m} remains stored in the SC, the leaks toward the living tissue being compensated by an equivalent supply. It may be interesting to know this maximum storage capacity as it constitutes a reservoir (Mitragotri 2003) likely to empty quickly into the living tissue if the diffusion coefficient happens to increase; this occurs in case of hyperhydration of the SC, for example, under occlusion or during a contact allergy patch testing.

At the beginning of the application, before the flow is at its maximum, the second Fick's law is applicable as long as the solute concentration in its vehicle remains unchanged.

3.1.1 Partition Coefficient (K)

It is defined as the ratio "solubility in the stratum corneum/solubility in the applied formulation."

This ratio can be measured in vitro by using powdered stratum corneum from foot callus (Wester and Maibach 1995) or, preferably, stratum corneum from other body sites. The latter is obtained by immersion of an epidermis sample (isolated from dermis using the usual techniques) in 0.01 % trypsin in water (Kligman and Christophers 1964). Five milligrams of stratum corneum is immersed in 100 μl of the tested formulation and left until equilibrium (Scheuplein 1965).

It can be measured in vivo by three procedures. Firstly, by dosing the solute in the stratum

corneum at the stage of constant flow or in its vicinity (therefore after a half hour application at least). Assuming that the SC thickness is made up of 20 layers, and leaving aside the reduction of the weight of the strips with depth, the quantity found in the first 15 strips should represent about three fourths of the total. Knowing this, it is possible to obtain the partition coefficient with the abovementioned Eq. 6. Another method consists in dosing the solute in the first 5 strips, then in the 5 following ones, and so on until 20 strips are completed. The concentration close the surface, obtained through a linear regression, divided by the applied concentration, gives the partition coefficient. The principle of the last method is to measure the constant store during an absorption measurement by the “difference method” (Sect. 4.9) and then apply Eq. 6.

3.1.2 Diffusion Coefficient (D)

It corresponds to the diffusion speed inside the stratum corneum (and also the partition coefficient between living tissue and stratum corneum, although this is not taken into account in the theory). It is theoretically independent from the vehicle (but this is not always confirmed in practice). It can be calculated from J or P only if K is known. Tables of the diffusion coefficient have been drawn up (Table 1): as their use is in $\text{cm}^{-2} \text{h}^{-1}$ (or $\text{cm}^{-2} \text{s}^{-1}$),

concentration must be recorded in g cm^{-3} and skin thickness in cm^2 .

3.1.3 Permeability Coefficient (P)

It characterizes the capacity of a solute to be absorbed from a given vehicle. It can be obtained directly by the “method of differences” (Sect. 4.9), by dividing the steady-state flux by the applied concentration. Other methods which indicate the flux entering not the stratum granulosum but more distal tissue only (dermis, blood, urine) can only give an estimate. The value of P for the same solute but with vehicle B instead of A can be obtained by multiplying P_A by the solubility in A to solubility in B ratio.

The values of P vary widely from one product to another, between 10^{-6} and $5 \cdot 10^{-2} \text{ cm h}^{-1}$ (Mitragotri 2003; Table 2). If *water is the vehicle*,

Table 1 Water diffusion coefficients (D ($\text{cm}^2 \text{h}^{-1} \times 10^6$)) at 30 °C (Scheuplein and Bronaugh 1983)

Body site	e (μm)	D ($\text{cm}^2 \text{h}^{-1} \times 10^6$)
Abdomen	15,0	2,16

Palm	400	29,88
Sole	600	38,16

E (μm): stratum corneum thickness

Table 2 Permeability coefficients (P (cm/h) measured in human skin models (Reported and modified from Mitragotri (2003)

Solute	Molecular weight	Log $K_{o/w}$	Permeability (cm/h)
Skin permeability to hydrophobic solutes ($K_{o/w} > 1$)			
Corticosterone	346	1.94	$1.0 \times 10^{-4} - 5.4 \times 10^{-4}$
Estradiol	272	3.86	$3.0 \times 10^{-3} - 6.1 \times 10^{-3}$
Hydrocortisone	362	1.53	$1.6 \times 10^{-5} - 2.3 \times 10^{-4}$
Progesterone	314	3.77	$1.3 \times 10^{-2} - 3.0 \times 10^{-2}$
Testosterone	288	3.31	$2.2 \times 10^{-3} - 5.3 \times 10^{-3}$
Skin permeability to hydrophilic solutes ($K_{o/w} < 1$)			
Water	18	-1.38	$1.3 \times 10^{-3} - 1.7 \times 10^{-3}$
Ethanol	46	-0.31	8.0×10^{-4}
Urea	60	-2.11	1.5×10^{-4}
Caffeine	194	-0.02	1.0×10^{-4}
Scopolamine	303	-1.58	5.0×10^{-5}
Human serum albumin	65,000	-	1.4×10^{-6}
Dextran	70,000	-	8.0×10^{-6}

it is sometimes not necessary to perform absorption measurements to calculate P , because it can be estimated from the molecular weight (M) and the partition coefficient octanol-water (K_{ow} measurable *in vitro*), according to the following formula:

$$\log P(\text{cm h}^{-1}) = 0.74 \log K_{ow} - 6.0 \cdot 10^{-3}M - 6.36 \quad (8)$$

Knowing P will help predict the steady-state absorption flux, according to Eq. 2, and the quantity that would be absorbed during this time (Eq. 1). To investigate further and be able to draw the curves of Fig. 1, it is necessary to know K or D as well.

3.1.4 Lag Time (τ)

This time, which is the intercept of the steady-state absorption flux straight line with the time axis (Fig. 2), takes place after the absorption has started and reflects the delayed absorption into the viable tissue related to the penetration into the stratum corneum, because the lines of entry into the SC and of entry in the viable tissue are 3τ apart, that is, 0.5 on Fig. 2 normalized absorption curve.

Direct lag time measurement *in vivo* is not possible, but its calculation is easy with Eq. 7. Its variations are in a narrow range. Lag time depends directly on the diffusion coefficient (D) and also shows variations with the vehicle (therefore with coefficient K and the SC store).

3.2 Pharmacokinetic Parameters

After passing through the SC, compounds diffuse through the epidermis and then the dermis and finally enter the blood capillaries. Pharmacologists and toxicologists use compartment models to treat these successive transfers. For example, (Guy et al. 1982) to process the data yielded by the "excreta method" (Sect. 4.1), four successive transfers can be considered: skin surface-SC, SC-living part of the skin, skin-blood, and blood-urine. Knowing the concentrations in the latter compartments, and considering that the transfer flows vary exponentially with time with constant coefficients, all the percutaneous absorption phases can be

processed. Furthermore, the fate of the absorbed amounts in deeper tissue, for example, hypodermis, fat, muscle, or joints, can be predicted (Marty 1976; Schaefer and Redelmeier 1996).

Physiologically based pharmacokinetic modeling (PBPK) takes into account the physiological, metabolic, and chemical-specific parameters to quantitatively simulate the absorption and elimination of a compound and determine the permeability constant (K_p). Although the technique can be elaborated only in animals, due to the necessity of organs sampling, it can be extrapolated to man. The formula to calculate K_p is the following (Thrall et al. 2002):

Fig. 2 Kinetics of skin absorption. The upper curve is the graph of amounts entering the stratum corneum. The lower curve is the graph of amounts entering the viable tissue. The curve in between (difference between the two curve ordinates) depicts the quantity within the stratum corneum. The three curves are normalized; thus, they are valid whatever the applied concentration (C) and the permeability coefficient (KD/e). In abscissa, application time divided by e^2/D (hence with 6τ as the unit time). In ordinate Q/KCe : amounts normalized by the stratum corneum maximum storage capacity. K : partition coefficient; e : stratum corneum thickness; D : diffusion coefficient; F_c : starting of the steady-state flux; τ : lag time. The equations of the three curves are presented in [Appendix 1](#)

$$dQ_{sk}/dt = K_p A_s (C_{liq} - C_{sk}/P_{sk:liq}) + F_{sk} (C_a - C_{sk}/P_{sk:b})$$

where Q_{sk} is the amount of compound in the skin compartment, A_s is the exposed surface area, C_{liq} is the liquid concentration, C_{sk} is the concentration of compound in the skin compartment, $P_{sk:liq}$ is the skin to saline partition coefficient, F_{sk} is the blood flow rate to the skin, C_a is the arterial concentration, and $P_{sk:b}$ is the skin to blood partition coefficient.

The calculation of the transfer coefficients is explained in specialized papers (Wépiepierre 1977). A brief description of their use is given in Sect. 4.2 regarding the “plasma level method.”

3.3 Descriptive Parameters (Not Derived from Fick’s Laws)

If, as the applied amount diminishes, the concentration in the vehicle decreases (“finite dose”), the profile of the absorption flux versus time or of the concentration time course in the target tissue is then an asymmetrical bell-shaped curve ending in asymptote, where three parameters can be found: the maximum flux per cm^2 skin area (J_{max}) and its appearance time (t_{max}) and the area under the curve (AUC) up to t time which indicates the total amount received over the interval t_0 - t . If the flux is recorded until its ending (often several hours or days after exhaustion of the applied amount), the AUC reflects the *total absorbed amount*. The latter can be expressed in % of the applied amount, but this notation is ambiguous and confusing because this percentage would not be valid for another amount. In other words, the total absorbed amount obviously depends on the applied amount but is not proportional to it.

4 Absorption Measurement Methods in Man In Vivo

Several methods to measure cutaneous or percutaneous absorption in man in vivo have been used. An inventory has been made by Schaefer et al. in a book entitled “Skin Permeability” (Schaefer

et al. 1982). These methods mainly concern the absorbed compound in its travel beyond the SC, which could be called the postabsorption. In the following paragraphs, only the leading methods still used today will be mentioned. Because of the small amounts absorbed (the skin is meant to be a barrier: it is only ten times more permeable than Teflon), all the methods require powerful dosage techniques, since the use of radioisotopes is strictly controlled.

4.1 The “Excreta Method”

This was the first method available to measure absorption in man in vivo (Feldmann and Maibach 1965, 1969), in particular for dermocorticosteroids with the use of radiolabeled isotopes. It was successful and is still considered as the reference method. Its principle is to apply on the skin a small quantity of compound in acetone and then collect all the urine over 120 h, thus covering the whole duration of the absorption. The time curve of amounts excreted into urine is drawn (in % of the applied dose). A proportion of the substance may have been captured or metabolized by cutaneous tissues before reaching the plasma; a correction factor is therefore applied. It is estimated by measuring the proportion of the same compound found in the urine during the 120-h period that follows its intravenous injection. The final result is expressed by the ratio *total radioactivity following topical administration/total radioactivity following parenteral administration*, the latter being considered as equivalent to a 100 % absorption. This ratio is named “absolute bioavailability by topical administration” (Maibach and Wester 1989): it varies from 63 % to 75 % for hydrocortisone (Maibach and Wester 1989). These data may be processed by pharmacokinetic modeling (Potts and Guy 1992). Pulmonary elimination can replace urinary elimination for volatile substances (Lauweris et al. 1978; Wester and Maibach 1999).

This method provides two pieces of information: *the percentage of the applied amount eliminated in the urine and the percentage of the applied amount retained and/or metabolized in*

the skin (i.e., not penetrating blood vessels). Both parameters depend on absorption (passage through the SC) but do not measure it. They measure the visceral availability of the absorbed amounts. The method is therefore more pharmacological than toxicological.

The complexity of this experimentation and the fact that the compound has to be intravenously injected are drawbacks which account for its rare use. Nevertheless, it has provided useful comparisons between products administered identically (Wester and Noonan 1978) or between different anatomic sites (Wester and Maibach 1989) or between man and different animal species.

4.2 Breath Analysis

When the tested permeant or its metabolites are excreted at least in part by the lungs, the analysis of exhaled breath can be a way to indirectly assess percutaneous skin absorption. Since the first attempts more than 10 years ago, technical progress has been made to detect and assess in real time minute amounts of volatile compounds, on the order of 1–10 parts-per-billion (10^{-9} concentration) (Thrall et al. 2002). Thus, monitoring percutaneous absorption is made possible (Thrall et al. 2002). Physiologically based pharmacokinetic modeling is usually associated with this technique which is still uncommon due to its complexity.

4.3 Plasma Level Method

The plasma concentration of a compound increases after its absorption by the skin. If the assessment method is very sensitive (e.g., using isotope labeling) or if the absorbed amounts are high, the blood concentration kinetics can be followed. The plasma level results from the difference between what penetrates the blood compartment and what goes out of it to tissues and through elimination especially in the urine. Plasma level versus time shows a bell-shaped asymmetrical curve ending in asymptote. Assuming that compound inflow and outflow are

Fig. 3 Kinetics of plasma concentration following percutaneous absorption. Semi-logarithmic chart. The *straight line* by which angle α is defined is the graph of entries into plasma; it is the difference between the descending line and the experimental curve. $\text{tg}\alpha = k_c$ (observed) et $\text{tg}\beta = k_a$ (calculated)

exponential functions of time, whose rates are characterized by their transfer coefficient k_a and k_c , respectively, both coefficients can be obtained using the logarithm of the concentration versus time curve. This data processing, traditional in pharmacokinetics, uses a simple mathematical formulation (Schaefer et al. 1982; Fig. 3). It is not necessary to wait until the end of the absorption to process the data, but only to have an elimination phase long enough to permit a safe calculation. The parameter k_a describes the concentration raising rate, a consequence of the increased (supposedly exponential) flow of the compound into the plasma. This inflow rate (a quantity of matter per unit time) can be obtained by multiplying the observed concentration by the plasma volume or by using the following formula:

$$\text{Plasma concentration} = \text{inflow}/\text{clearance}.$$

This parameter concerns postabsorption. Assuming that it is proportional to what has penetrated the living epidermis (therefore assuming absence of retention within the skin), it is also, like the absorption rate, proportional to the application area, the applied concentration, the partition coefficient, and the diffusion coefficient of the compound. If these parameters are known for another vehicle or another compound, it is then possible to

anticipate absorption by a simple rule of three. Note that the amount lost either by tissue fixation or metabolism which might occur in the skin can be estimated by difference with the curve of plasma concentration following intravenous injection of the same compound.

In this type of method, only the nontoxic compounds can be studied. Because of the low plasma concentrations always observed (the amount absorbed is diluted in 5 l of blood), this method requires the use of radioactive isotopes or sensitive analytical methods and also a high absorption rate (i.e., on a relatively large skin area and at optimal concentration).

4.4 Absorption Measured by Local Biological Effects

Measurable effects are erythema or skin temperature rise (induced by nicotinic esters), blanching (induced by dermocorticoids), or reduced tactile sensitivity (induced by local anesthetics (Leopold and Maibach 1999)). These are usually studied in "finite dose" situation. The usable parameters are the *appearance time* of the effect, its *maximal intensity* and *the length of time* to reach it, the *duration* of the effect, and the *area under the curve effect time* (Leopold 1999).

Recently the effects have been quantified using standard products, which yield a relative bioavailability, and associated with parameter P of Fick's laws. The concentration time course $C_d = f(t)$ of the compound in its diffusion zone, the dermis, is simulated by a classic open mono-compartment model where inflow depends on P (measured in an infinite dose experiment), the outflow constant k_e and the distribution volume V_d being, respectively, defined at 0.2 h^{-1} and 10 ml. If the efficient minimal concentration is known, traditional equations then provide the theoretical graph of the efficient concentration versus time; as a consequence, the dermal bioavailability is also given, although it is different from the actual absorption since the epidermis has been crossed and may have retained or altered the compound. A linear relationship has been found between P and the inverse of the appearance time of the effect

(Leopold 1998). Knowing P , it is then possible to anticipate this appearance time which is often associated with $C_{d\max}$ and t_{\max} (the latter being the same for the concentration and the efficient concentration).

4.5 Disappearance of a Radioactive Isotope: "Surface Disappearance or Recovery Method"

The progressive reduction of the radiation emitted by a radiolabeled compound applied on the skin has been used to follow up the penetration of the compound and therefore measure its absorption time. The radioactivity versus time is measured using a Geiger-Müller device, placed at a (fixed) small distance from the skin (Wahlberg 1965).

With caffeine, estradiol, and aspirin, all applied in acetone, the radioactivity measured after a 24-h exposure (the skin has been protected to prevent desquamation) was found equal to the sum of the radioactive emissions of the 15–20 "strips" carried out at the same site later (Guy et al. 1987). This shows that the method is likely to measure the amounts stored in the stratum corneum rather than the actual absorption.

4.6 "Suction blister Method"

Since blisters appear at the dermoepidermal junction, this method is the *in vivo* equivalent of the *in vitro* absorption measurement by a static cell; however, it has the advantage of having a physiological collecting phase (Guy et al. 1987; Walker et al. 1993; Averbeck et al. 1989; Treffel et al. 1991a; Huuskonen et al. 1984). The blister forms a compartment distinct from the superficial dermis with which exchanges are somewhat reduced; as a consequence, the blister fluid is less subjected to blood convection than the interstitial fluid, hence the slowing down of the elimination of the absorbed compound and possible slowing down of the absorption.

The compound must be applied when the blister is completely formed to prevent the

intensification of the transfer by an aspiration mechanism (Agren 1990; Humbert et al. 1991). The blister fluid can be sampled only once; absorption can therefore be measured at one time only for each blister; however, it is possible to achieve simultaneously up to 21 blisters on each forearm (Treffel et al. 1991a). The measured result is a concentration in a relatively closed volume that is supposedly hemispherical, hence the possible approximate calculation of the amount which has reached the superficial dermis in a given time. In a study on acitretin absorption (Laugier et al. 1994), the concentrations of acitretin and its metabolites in the blister fluid were obviously lower than in plasma; this could be explained by the capture of the permeated compound by the living epidermis. This method therefore measures the subepidermal bioavailability rather than the actual absorption.

How can we use the parameter obtained, that is to say the *concentration time course in the blister*? Assuming a constant ratio between this concentration and the steady-state absorption flux (which is not always true), one could extrapolate to other situations by a simple rule of three. This would require a measurement in “infinite dose” situation. If it is not the case, the only possible extrapolation of the maximal concentration c_{max} is to another application area.

4.7 Microdialysis

Microdialysis is a continuous sampling technique in which a molecule of interest is collected under the skin. The method involves placing of a fiber (probe) in the dermis. The probe must be inserted under local anesthesia parallel to the skin surface and its insertion depth measured by ultrasound echography at 20 MHz, ensuring that it is not in the hypodermis. The probe is semipermeable and perfused with physiologically relevant media at a slow rate using a microdialysis pump. Compounds can diffuse into or out of the probe depending on the direction of the concentration gradient. Microdialysis gives only a concentration, not a flow, since the distribution volume in the dermis is unknown.

Microdialysis has been successfully used for demonstrating the bioequivalence of topical dosage forms (Narkar 2010a; Stenken et al. 2010) and can be used for monitoring intradermal and subcutaneous tissue drug concentrations after application of transdermal drug formulations (Katikaneni et al. 2011; Paturi et al. 2010; Siddoju et al. 2011).

Holmgaard et al. (2010) have listed 72 publications concerning a number of in vivo microdialysis studies of pharmacokinetics of topically applied drugs, pesticides, and other substances administered as creams, ointments, gels, or in transdermal therapeutic systems (patches). Table 3 reported from Holmgaard et al. (2010) lists the molecule that has been studied in these 72 publications.

4.8 Tape Stripping Method

Tape stripping consists in a sequential application and removal of adhesive tapes onto the skin surface, in order to collect layers of SC (Lademann et al. 2009; Herkenne et al. 2008a; Loffler et al. 2004). It is a minimally invasive method for the removal and sampling of stratum corneum (SC). The removed adhesive films are subsequently analyzed for their drug content and to determine the amount of penetrated and the penetration depth into the skin of topically applied drug. Tape stripping method is also known as the dermatopharmacokinetic (DPK).

To quantify the amount of stratum corneum removed on each tape stripping, different methods can be used:

- Gravimetric: The weight of the SC removed is calculated from the weight difference of the strip of tape prior to application and after removal.
- Spectroscopic: Aggregates of corneocytes reduce transmission of the light resulting in a linear increase of nonspecific absorption in correlation with the number of layers of cells collected SC, called pseudo-absorption (Jacobi et al. 2005; Lademann et al. 2006).

Table 3 Molecules studied by in vivo microdialysis listed studies of topical applications and dermal measurements (in vivo only) from 72 publication reported by Holmgaard et al. (2010)

Substance	MW, g/mol	Log pow	Object
2-Butoxy ethanol	118.18	0.83	Rat, human
2,4-Dichlorophenoxyacetic acid	221.04	2.81	Mouse
5-Fluorouracil	130.08	-0.89	Rat
8-Methoxypsoralen	216.19	2.14	Human
Acetyl salicylate	180.16	1.19	Rat
Acyclovir	225.21	-1.8	Human, rabbit
Ascorbic acid	176.12	-1.88	Human
Aminolevulinic acid	131.13	-4.40	Human

Salicylate esters	250.33	5.97	Human
Salicylic acid	138.13	2.26	Rat, human
Toluene	92.14	2.73	Rat
Tranilast	327.33	3.62	Rat
Valproate	166.20	-0.85	Rat

- Microscopic techniques were used to determine the ratio covering density of the corneocytes adhering to the tape (Lindemann et al. 2003).

In order to remove the SC homogeneously, several parameters should be taken into consideration including application pressure, removal velocity, duration, and anatomical site.

In DPK study for bioequivalence, drug levels should be assessed in at least eight different sites (Fig. 3): at four of the sites, levels are measured during uptake (e.g., 0.25, 0.5, 1, and 3 h post-application), and then, after cleaning the drug from the remaining sites, levels are assessed during clearance (e.g., 4, 6, 8, and 24 h post-application).

4.9 Difference Method

It consists in measuring, at regular intervals, the amount of compound that disappears from the skin surface. The amount which has penetrated the SC, the upper curve of Fig. 2, is measured by deducting it from the amount applied. All the absorption parameters of Fick's laws can then be found.

It is necessary to operate in conditions of infinite dose. If the first samples are taken during the first 2 h, the curve of the total disappeared quantity is biphasic: first a fast penetration rate reflects the filling of the SC, and then a straight line of lower slope indicates the steady-state flux. If the first sampling is carried out after the first hour, it is unlikely that the first slope will be observed, but this is not important. As a matter of fact, the theory shows (Fig. 2) that the intercept of the line with the ordinate (axis of quantities) indicates two thirds of the amount stored in the SC in the steady-state flux phase, hence the possible calculation of this amount. It can then be subtracted from the disappeared quantities, providing the absorbed quantities. Fick's law parameters are obtained by the formulae mentioned in Sect. 3.1. Even the kinetics of the SC filling is accessible. The total absorbed quantities, taking into account the initial period of increasing flux, are given by Eqs. 4 and 5 and the store in the SC by Eq. 6.

Table 4 Absorption of caffeine (Chambin-Remoussenard et al. 1993), an amphiphilic easily absorbed compound

Vehicle	Applied concentration	Measured flux (g cm ⁻² h ⁻¹)	SC store (g cm ⁻²)	P (cm h ⁻¹)	K	D (cm ² h ⁻¹)	τ
Acetone	250 × 10 ⁻⁶	93 × 10 ⁻⁹	645 × 10 ⁻⁹	374 × 10 ⁻⁶	3.43	163 × 10 ⁻⁹	2 h 18
O/W cream	664 × 10 ⁻⁶	87 × 10 ⁻⁹	1400 × 10 ⁻⁹	131 × 10 ⁻⁶	2.81	70 × 10 ⁻⁹	5 h 18

Table 5 Absorption of 5-methoxypsoralen (Treffel et al. 1991b), a very lipophilic poorly absorbed compound

Vehicle	Applied concentration	Measured flux (g cm ⁻² h ⁻¹)	SC store (g cm ⁻²)	P (cm h ⁻¹)	K	D (cm ² h ⁻¹)	τ
O/W cream	29.2 × 10 ⁻⁶	4.5 × 10 ⁻⁹	3.6 × 10 ⁻⁹	154 × 10 ⁻⁶	0.167	1.38 × 10 ⁻⁶	16 min

In the experiment shown in Table 4, computing the regression line of the disappeared amounts versus time gave through its slope the steady-state flux and through its intercept with ordinates two thirds of the store in the SC. This permitted the calculation of the other Fick's law parameters by using Eqs. 2 to 7. It was verified that the *disappeared* quantities (Q_{in}) calculated for 6 h (respectively, 985×10^{-9} g cm⁻² from acetone and 1453×10^{-9} g cm⁻² from the cream) corresponded to the recorded figures (respectively, 995×10^{-9} g cm⁻² and 1443×10^{-9} g cm⁻²). The SC store appeared to equal 7–16 h of steady-state flux from acetone and cream, respectively, and it doubled when the vehicle was an O/W cream rather than acetone, which induced a double lag time τ . On the other hand, D was 2.3 times higher with acetone than with cream, which indicates the (otherwise well-documented) alteration of the cutaneous barrier by the solvent. Over 6 h, the total *absorbed* amounts (Q_{out}) have therefore been 344 ng/cm⁻² from acetone and only 61 ng/cm⁻² from the cream.

In another experiment (Table 5), the total disappeared amount over 6 h was 29.6 ng/cm⁻² (the calculation gave 28.2 ng/cm⁻²) and the absorbed amounts 25.8 ng/cm⁻². The SC store and the partition coefficient were noticeably low, in contrast with the diffusion coefficient 20 times that of caffeine. However, by applying ten times higher concentrations, thereby close to those of caffeine, the absorption flux and the store, although ten times higher, would have remained much lower.

Therefore, the difference method permits measurement (and calculation) of the absorbed and stored amounts. Furthermore, by studying hourly fluxes, it is easy to verify whether the steady-state flux is reached or if the finite dose conditions still apply. The parameters obtained provide a maximum possibility of extrapolation (see Sect. 5). In case of a "finite dose" experiment, it is possible to estimate the time when the applied amount is exhausted and at that moment, to measure the maximal amount stored and absorbed. For products with a limited and known application time (e.g., rinsed products), it is easy to know the maximal stored and absorbed amounts (Fig. 4).

The difference method does not require the use of radioisotope labeling if a sensitive assessment technique is available. The favored analytical methods are high-performance liquid chromatography (Chambin-Remoussenard et al. 1993; Treffel et al. 1991b), spectrophotometry (Treffel et al. 1991b), and gas chromatography. The main difficulty lies in sampling all the substance remaining on the skin surface; if some remains on the skin, the absorbed amount will be overestimated. Inversely, if the collection is aggressive and alters the SC, some of the compound might be removed, inducing an underestimate of the absorbed amount. Finally, as in the previous method, it is essential to ensure that the absorbed compound diffuses freely inside the SC and is neither adsorbed nor chemically linked with an SC constituent: this would increase the store without modifying the absorption flow rate (Mitrageotri 2003).

Fig. 4 Maximum amount that entered in the stratum corneum in case of finite dose. At point F, the applied dose is exhausted. Distance AF: maximum entered the stratum corneum. Distance EF: maximum absorbed. Distance BF: maximum stored. In abscissa, application time divided by e^2/D (hence with 6τ as the unit time). In ordinate Q/KCe : amounts normalized by the stratum corneum maximum storage capacity. K : partition coefficient; e : stratum corneum thickness; D : diffusion coefficient. τ : lag time

If the vehicle is a volatile solvent or a cream, it should be applied in open cells, for example, 2.5-cm-diameter simple rings stuck on the skin (Chambin-Remoussenard et al. 1993; Rougier et al. 1990). The number of cells applied should be equal to the number of samplings (e.g., six cells if the purpose is to follow up the flow for 5 h, because the first sampling is made in part from the initial increasing flux and is used only as a reference for the following period of time). If the vehicle is a liquid or a gas, closed cells are necessary. The Düsseldorf group has developed plastic cells (inner diameter: 4 cm) designed to be applied on the external side of the arm and maintained by a copper ring and Velcro (Leopold and Lippold 1992). At the top is a hole for emptying and filling in without removing the cell. One cell can, therefore, be used to follow the same product for

several hours (it is emptied and filled each hour). Thus, the simultaneous absorption of several products can be studied (Merfort et al. 1994). Thrall et al. used nonoccluded cells covered with “a Muslim patch” containing activated charcoal to trap volatile compounds (Thrall et al. 2002).

4.10 The “Stratum Corneum Gradient Method”

After 15-min application, the skin is washed, 20 subsequent SC strippings are performed, and the compound concentration in each strip is measured (Pirot et al. 1997; Pirot 1996; Higo et al. 1993). The data are then introduced in the equation of the second Fick’s law which describes the concentration gradient versus time, applied concentration and diffusion parameters K and D which can then be obtained, as well as the amount absorbed. If the method is used after the steady-state flux has settled, a rectilinear concentration gradient is found. Therefore, it is sufficient to sample four series of three successive strippings, first to check that the concentration decreases linearly with depth and then to access all Fick’s laws parameters.

In this method, it is necessary to know the depth level and concentration for each strip. The depth level is not the strip number since the stripped amount depends on each subject, body site, and amount of SC already removed. It can be found by dividing the volume removed by the stripped skin surface area. The D-Squame (using a constant pressure maintained 5 s followed by a mild stripping (Dreher et al. 1998)) has the advantage of being easy to use and generates few adhesion changes for a given pressure. The removed volume is obtained by dividing the weight by the density (≈ 1.20). The weight of the SC removed by each strip (100–300 μg) is measured either by weighing the adhesive tape before and after stripping (Pirot et al. 1997) or by protein colorimetric assessment (Dreher et al. 1998). Strips must be immediately stored in a waterproof flask to prevent water loss. The weighing process is long and delicate because of the possible variation in the SC and the disk hydration during the operation.

The protein colorimetric assessment is quicker; it is based on the traditional method of Lowry followed by a spectrophotometric measurement at 750 nm (Dreher et al. 1998). The strips are placed in 1 ml NaOH 1 M and shaken for 2 h. Neutralization is obtained by adding 1 ml HCl 1M for 5–10 s, and then the colorimetric assessment is achieved.

This method also requires the absorbed compound to be assessed in very small SC samples. Photoacoustic spectroscopy, spectrophotometry in UV light, and infrared attenuated total reflectance associated with treatment by Fourier transform (ATR-FTIR) are fast methods. In the latter, with λ between 2250 and 2200 cm^{-1} , that, is 4–5 μm , and for a concentration of 196 nMole in water (saturation), the 4-cyanophenol sampled by stripping was 0.05–1.1 mol and the quantification limit 2.54 nMole/ cm^2 (Pirot et al. 1997; Higo et al. 1993).

4.11 Spectroscopic Methods

A prerequisite for the spectroscopic technique is that the molecule of interest should possess distinct spectral features of sufficient intensity to be able to differentiate from the skin spectrum (Dreher et al. 1998; Kezic 2008). Raman spectroscopy and near-infrared spectroscopy are advanced noninvasive *in vivo* techniques for real-time determination of diffusion of drugs and chemicals into the human skin (Herkenne et al. 2008b; Zhao et al. 2008), Confocal Raman spectroscopy has been used *in vivo* to identify the molecular structure of the skin, level of skin hydration, and effect of moisturizing agents on skin hydration (Caussin et al. 2009; Darlenski et al. 2009) and to study the penetration of certain chemicals like urea and dimethylsulfoxide into the skin (Caspers et al. 2002; Wascotte et al. 2007). It has also been used to show relative effects of different classes of penetration enhancers on topical delivery of retinol (Pudney et al. 2007; Melot et al. 2009). Although its noninvasive nature and possibility of real-time profiling of drugs penetrating into the skin make this technique attractive, a major drawback of Raman spectroscopy is that it

is semiquantitative. It allows relative measurements rather than absolute determination of drug concentration in the skin. Near IR is a noninvasive, quantitative technique which is still in development. Initially, attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR) method was developed by Guy et al. (Stinchcomb et al. 1999; Reddy et al. 2002) to quantify the drug in tape strips in order to avoid drug extraction procedure; however, tape stripping was still required.

4.12 Confocal Laser Scanning Microscopy

Confocal laser scanning microscopy is another tool to quantify dermatopharmacokinetics parameters. The confocal images are possible for fluorescent drugs or probes and do not require to prepare the skin to make optical sections. This tool focuses a beam to a given depth within the tissue and measures the concentration of penetrant or drug molecule at the level of focus. Thus, this tool allows an investigator to generate a concentration profile following topical application of drug product (Mayee and Rawat 2010). The confocal images can be obtained in the plane parallel to sample surface or in the plane perpendicular (Wu et al. 2009). This method has been widely used in assessing drug penetration or distribution in the skin layers following topical application of microparticles, nanoparticles, and vesicular systems such as liposomes, niosomes, etc. (Desai et al. 2013; Khurana et al. 2013; Wang et al. 2013).

5 Prediction of Cutaneous Absorption

The objective of most absorption measurements in toxicology or therapeutics is to be able to predict how much compound will be absorbed in other situations, i.e., be found in the SC, the dermis, and the skin as a whole, or enter the bloodstream and be distributed to internal organs. Other situations means other application area, other body site, diseased skin, different application

times, concentrations, formulations, or other compounds whose parameters P (permeability coefficient), K (partition coefficient), or D (diffusion coefficient) are known. Prediction of absorption in the new situation is made by extrapolation from an experimental situation; it is achieved by simple multiplication by a rule of three of the experimentally found parameter values. For example, given the steady-state flux J of a compound in a previous experiment, what would be the steady-state flux J' of the same compound in another vehicle and in another concentrations, all other things keeping unchanged (same body site, etc.). If the partition coefficients and applied concentrations were known (K and K' and C and C' , respectively), the answer would be $J' = J K' C' / KC$. This important question deserves attention because of the numerous errors found, especially in toxicological practice. What are the conditions for a safe extrapolation? This depends on the parameter(s) used and the means by which the absorption has been expressed.

5.1 Extrapolation to Another Application Area

The *total absorbed quantity* (g) (in a given time in case of an infinite dose and after dose exhaustion in case of finite dose) depends on the application area because the absorption flux is defined per unit area ($\text{g cm}^{-2} \text{h}^{-1}$). Consequently the quantities which penetrate the SC, stay there, or pass through it are directly proportional to the application area. A double area absorbs a double quantity, whatever the experiment is in infinite or finite dose. This is also true for amounts received further down (dermis, plasma); hence, the extrapolation by a rule of three is possible for the plasma inflow rate coefficient (plasma entry fits an exponential function).

It is somehow different for *concentrations* in tissues or blood because they are a quantity per unit of distribution volume. The concentration in the first layers of the living epidermis is obviously independent from the application area. Inside the dermis, the same holds true except at the borders of the area, because of lateral diffusion within the interstitium. Therefore, in general, for a double

application area, the *local* concentration would remain identical. A *local* biological effect, although identical theoretically, might be enhanced through lateral diffusion and reciprocal reinforcement. The *plasma* concentration (g cm^{-3}) is proportional to the ratio inflow/outflow rate coefficients, both rates being exponential. Whereas the inflow rate coefficient is proportional to the application area, the outflow rate coefficient depends on the plasma concentration and so keeps constant. It follows that in case of a doubled application area, the ratio will be double and also the plasma concentration. This is the case whatever the experiment is with infinite or finite dose.

5.2 Extrapolation to Another Application Duration

The cutaneous absorption depends on time and becomes proportional to it as soon as the steady-state flux begins. The rule of three is therefore theoretically possible only for the sampled quantities during this period. However, if it lasts several hours, the absorbed amount before the steady-state flux becomes negligible and one can consider that the steady-state flux has existed since the beginning. Amounts absorbed before the steady-state flux settlement in situation of “infinite dose” cannot be extrapolated by a simple rule of three to a different application duration; it is necessary to have recourse to the graphs of Fig. 2. On the other hand, the descriptive parameters and those of “finite dose” cannot be extrapolated to different times.

5.3 Extrapolation Using Fick's Laws Diffusion Parameters

It is valid only in case of infinite dose:

- From the parameters K (partition coefficient), C (applied concentration), e (SC thickness), or P (permeability coefficient), the extrapolation can be done by simple rule of three, using Eqs. 1 and 3.

- From D or t , it is necessary to use Eqs. 4 or 5 if the phase before the constant flow is to be taken into account. If it is considered negligible (e.g., if the steady-state flux has lasted several hours), D can be used by a simple rule of three; assuming that this steady-state flux has started at time zero, a slight error by excess is then made. To extrapolate to a period anterior to the steady-state flux, it is necessary to use the equations of Appendix 1 or their graphs.
- But D (and therefore P) depends also on the SC barrier condition. This may be known through the transepidermal water loss (TEWL), a parameter easily measured which, for a given atmospheric vapor pressure, reflects the water diffusion coefficient. Now, the diffusion coefficient of all other substances changes usually in parallel. A doubled TEWL would permit anticipating a doubling of any P or D coefficient, therefore of absorbed amount. The measurement of the TEWL is, therefore, worth using systematically for absorption studies in disease (Yosipovitch et al. 1998), in occupational medicine, and in safety testing of topical medicines, cosmetic, and hygiene products, in short, whenever alteration of the barrier function may be suspected (Aalto-Korte and Turpeinen 1996).

5.4 Extrapolation from Parameters

All *Fickian parameters* can serve to extrapolation, provided the experimental as well as the predicted situations are steady-state fluxes. An example is given in Sect. 5, first paragraph.

Pharmacokinetics parameters (i.e., transfer coefficients) deal with post-absorption. Entry coefficients (inflow rates) increase with the cutaneous absorption rate (the steady-state flux), whereas outflow coefficients are generally insensitive because they depend on the concentration within the compartment. Accordingly all events which increase the flux (such as increase of application area, applied concentration, contact duration, permeability or diffusion coefficient, or decreased skin thickness) will also increase proportionally the entry coefficients. However, all the quantity absorbed is not transmitted to the

compartments owing to some retention in the epidermis and/or the dermis, but one may assume that the proportion keeps constant. For example, if the skin absorption flux is thought to have doubled, one can consider that the plasma inflow coefficient will also be doubled, assuming that the retention in the skin will remain a constant fraction of the absorbed amount (which is not always true because of a possible tissue saturation). The same holds true as far as the availability to the dermis is concerned (measured in suction blisters or by hemodialysis) because the compound fixation within the epidermis may not remain a constant fraction of the absorbed quantity. The concentrations in the compartments, especially the blood, are less correlated than the entry coefficients because of the damping effect of the concomitant outflow which depends on the concentration within the compartment only. Thus, if the skin absorption flux is doubled, one cannot consider that the urinary elimination will also be doubled. It should be stressed that only the pharmacokinetics parameters obtained during a steady-state flux can be used for extrapolation.

Descriptive parameters, J_{\max} , t_{\max} , AUC, and % of applied dose, are not liable to any extrapolation. Of course, J_{\max} and AUC increase when the absorption flux increases, but no proportionality factor is then applicable. Unfortunately a number of toxicological data originated from finite dose experiments are wrongly produced in this way. One exception, however the compound and its derivatives *cumulated collection*, can be expected to be proportional to the application area. Finally, as mentioned above, the percentage of the applied dose can never be used to predict the absorbed quantity of another dose, whether the experiment was dose finite or infinite dose type, except though for very small doses.

6 New Devices for Ex Vivo Percutaneous Absorption Measurement

The most common technique for ex vivo measuring of percutaneous absorption is based on the use of excised skin mounted in a diffusion cell system.

The basic design of a diffusion cell consists of an upper donor compartment and a reservoir compartment separated by a skin sample (Organisation for economic cooperation and development test no. 428 2004; Fig. 5).

Usually, ex vivo percutaneous absorption experiments with diffusion cells like “Franz diffusion cell type” are often conducted in open conditions, in which the skin surface is in contact with ambient environment of each laboratory or in occluded condition with skin covering by impermeable membrane. These conditions of use either ambient laboratory or occlusion are peculiar and don’t reflect all real skin exposure conditions.

Actually, the skin surface is subjected to daily gradients in external temperature and humidity which varies almost permanently in both the indoor and outdoor air according to the seasons, geographic regions, and in terms of lifestyle and

daily movements of individuals (Zhang and Yoshino 2013; Rudd and Henderson 2007; Kalamees et al. 2009).

Contact between skin surface and our external environment directly, through clothing or transdermal drug delivery systems, induces a microclimate at the skin surface which arises from heat and material transfer between the skin and the external environment. That microclimate can impact skin properties (Singh and Maibach 2013) and then its interaction with xenobiotics substances that come in contact with the skin (Fritsch et al. 1963; Chang and Riviere 1991, 1993; Meuling et al. 1997). Therefore, variations in environmental parameters must be considered when assessing percutaneous absorption.

To study the influence of external temperature and humidity, a new apparatus has been developed by Lboutounne et al. (2014), (Fig. 6). This

Fig. 5 Franz diffusion cell and its compartments

Fig. 6 Cumulative absorption (ng/cm²) kinetics of caffeine during 24 h of skin exposure, at different environmental conditions. Values are mean ± SEM (n = 5):

(a) 70 %–42 °C and 28 %–42 °C; (b) Open condition and occlusion; (c) 70 %–27 °C and 28 %–27 °C

apparatus was made up of an Inox chamber. The chamber is thermostated by a water bath. Six diffusion cell receiver compartments are fixed to the chamber. Relative humidity and temperature were controlled inside the chamber by a sensor. This sensor is connected to a computer which allowed a monitoring of the two parameters during experiments. Reservoirs are integrated in the chamber and filled with saturated salt solutions to create a precise relative humidity. A given saturated salt solution provides only one relative humidity (RH) at any desired temperature; a different relative humidity must be achieved by selecting another appropriate salt.

This apparatus has been used to study the influence of external temperature and humidity on percutaneous absorption of caffeine. Two different salts were used in this study: sodium chloride (NaCl) that provides 70 % RH and lithium chloride (LiCl) which provides 28 % RH.

The kinetic curve profile of percutaneous absorption of caffeine revealed different shape characteristics depending on environmental exposure conditions (Fig. 7). We observed at 27 °C/28 % RH and in unoccluded condition (27 °C/33 %) a kinetic profile that seems to be “like a finite dose,” whereas at 27 °C/70 % RH or under occlusion, the profile curve went toward an “infinite dose profile.” These kinetic profiles were related to evaporative process of the deposited preparation on skin surface combined with water uptake resulting from water flux through skin. This evaporative process leads to an increase of caffeine concentration in donor compartment, which went toward saturation then beginning of caffeine crystallization until its complete crystallization on the skin surface.

The cumulative amount of caffeine absorbed (ng/cm^2) after 24 h for all environmental conditions and compared with occlusion and open conditions was reported in Fig. 8: in unoccluded conditions and in occlusion, the cumulative amounts of caffeine after 24 h of skin exposure were, respectively, $2.73 \pm 0.61 \mu\text{g}/\text{ml}$ and $9.35 \pm 1.04 \mu\text{g}/\text{ml}$ ($p = 0.018$).

At 27 °C, increased humidity from 28 % RH to 70 % RH leads a significantly increase in percutaneous absorption by a factor 3 after 24 h of exposure with a cumulative amount of $11.87 \pm$

$2.37 \mu\text{g}/\text{ml}$ at 70 % and $3.09 \pm 0.37 \mu\text{g}/\text{ml}$ at 28 % ($p < 0.01$). However, at a temperature of 42 °C, there is less pronounced difference in percutaneous absorption of caffeine between 70 % ($8.12 \pm 2.43 \mu\text{g}/\text{ml}$) and 28 % ($6.5 \pm 1.57 \mu\text{g}/\text{ml}$) ($p > 0.05$).

Results of this study highlight a preponderant role of microclimate above the skin on percutaneous absorption of caffeine.

The device used in this study will be a useful tool to investigate ex vivo, the influence of microclimate above the skin on percutaneous absorption profile. Basing on the described concept, a new diffusion cell for percutaneous absorption studies under controlled environmental conditions was developed (Fig. 9).

7 Concluding Remarks

Below are some strengths and limitations of some major points in skin absorption.

- Before any measurement, one ought to remember that it is first and foremost a passage through the SC, a purely passive diffusion process obeying Fick’s laws. Its kinetics should be remembered with its two phases, transient and steady-state maximum fluxes, and also the events taking place within the SC: entry, storage, going out into the viable epidermis, all depicted by the curves of Fig. 1. One should finally remember the physical variables which control the phenomenon: application area (A), duration of the application (t), partition coefficient (K), applied concentration (C), SC thickness (e), and diffusion coefficient (D).
- When performing a measurement, the “infinite dose” mode is preferable whenever possible because it is more profitable. It provides the maximal possibilities of extrapolation to other situations.
- A measurement of the TEWL before and immediately after a skin absorption measurement is advised, in order to detect a nonspecific modification of the SC barrier in the interval.
- The SC store is a reservoir for further leakage of the compound into the viable tissue. Its

Fig. 7 Cumulative amount (ng/cm²) of caffeine absorbed after 24 h at different environmental conditions. Values are means ± SEM (*n* = 5). † Significantly different compared to occlusion *P* < 0.05, **P* < 0.05, ***P* < 0.01 significantly different compared to open conditions

assessment by SC stripping may be useful in any case, even after short applications, because it may contain large amounts of the compound, and is quickly constituted. After a 30-min application, using the stripping method constitutes a simple and fast way to assess the SC crossing capacity of a compound whatever the formulation.

- Percutaneous absorption (or skin post-absorption) parameters mainly deal with compartments (e.g., dermis or plasma) and concentration data. They can be connected to the

absorption rate through their inflow rate coefficients if they have been measured during a period of constant flow or stable and maximal concentration. Concentrations also depend on outflow rates and thus are less sensitive to the absorption rate. Urine concentrations only depend on blood concentrations.

- The “% of the applied dose” parameter can be used for predicting another dose only if both doses are very small (less than 1 mg formulation per cm²).

Appendix 1: Equations of Curves Graph in Fig. 1

$$y_1 = x + 1/3 - 2/\pi^2 \sum_{n=1}^{\infty} 1/n^2 \exp(-n^2 \pi^2 x) \quad (9)$$

$$y_2 = x - 1/6 - 2/\pi^2 \sum_{n=1}^{\infty} 1/n^2 \exp(-n^2 \pi^2 x) \quad (10)$$

$$y_2 = x - 1/6 - 2/\pi^2 \sum_{n=1}^{\infty} 1/n^2 \exp(-n^2 \pi^2 x) \quad (11)$$

Equation 9: quantity entering the stratum corneum (Fig. 1, upper curve).

Equation 10: quantity entering the viable tissue (Fig. 1, lower curve).

Equation 11: quantity within the stratum corneum (Fig. 1, middle curve).

$x = Dt/e^2$, and $y = Q/KCe$ (i.e., quantity for any partition coefficient K , applied concentration C , and stratum corneum thickness e); KCe is also the maximum possible store within the stratum corneum (the actual store is always half of the maximum, as shown in Fig. 2). Quantities are per unit skin surface area (g/cm^2).

At any time $y_1 = y_2 + y_3$. As soon as the steady-state flux is reached, Eqs. 9, 10, and 11 transform into section “Parameters Derived from Fick’s Laws” (Eqs. 4, 5, and 6, respectively).

skin • cutaneous absorption • skin barrier • nicotinic acid esters • corticosteroids

An investigation of the skin barrier function may be conducted following different approaches in vitro (Franz 1975) or in vivo (Feldmann and Maibach 1965; Rougier et al. 1983) by measuring the amount of a given compound permeating the different skin layers. On the other hand, quantification of a cutaneous (Oestmann et al. 1993) or systemic biological reaction may also be used for studying the skin barrier function. We will only describe cutaneous biological reactions in man after application of pharmacologically active compounds.

1 Skin Barrier Function

1.1 Physiological Basis of Skin Barrier

Although the skin remains a very complex organ, two main layers are characterized from a macroscopic point of view: an external epithelium called epidermis, and a vascularized stroma, the dermis, physiologically supporting the epidermis. The genuine barrier against xenobiotics is located within the epidermis, which itself comprises two main layers, the viable epidermis and the horny layer. The biological reactions that will be

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

measured are mainly vascular responses arising from the dermal microcirculation.

1.2 Pharmacologically Active Molecules

Numerous compounds affect the dermal microcirculation after topical application and influence skin color to be more white or red. For example, nicotinic acid esters are vasodilators inducing a clear erythema. Methyl- (NM, MW = 137.1), ethyl- (NE, MW = 151.2), butyl- (NB, MW = 179.2) and hexyl-nicotinate (NH, MW = 207.3), here quoted by increasing order of lipophilicity, are the most used. Usual concentrations amount to 0.5–10 mM after solubilization in appropriate solvents. These molecules, after crossing the epidermis more or less easily depending on the state of the cutaneous barrier, will dilate the capillary loops in the dermis, then the small arteries of the superficial vascular plexus, and finally the blood vessels of the lower dermal plexus. Thus, the measurement of skin blood flow or of skin color will allow an estimation of the skin barrier function. When considering nicotinic acid esters, the presence or the absence of an erythematous reaction may be an indication of skin barrier function.

Corticosteroids induce a decrease of dermal blood flow (a vasoconstriction). The mechanism (s) of this reaction are poorly understood. The resulting skin whitening, or blanching reaction, may be used for the investigation of skin penetration of the corresponding compounds (Mac Kenzie and Stoughton 1962; Mac Kenzie 1962). However, due to the great differences in pharmacological activity between different corticosteroid molecules (their anti-inflammatory potency is related to their corticosteroid classification), the whitening reaction often does not really reflect percutaneous absorption (also see ► Chap. 133, “Assessment of Erythema and Pallor” Sect. 10). Nevertheless, the measurement of skin color remains of value for cutaneous bioequivalence studies where the same molecule is applied onto the skin in different formulations (Caron et al. 1990; Pershing et al. 1991; Pershing et al. 1992).

2 Skin Color Changes after Nicotinic Acid Ester Application

2.1 Cutaneous Application

Methyl nicotinate is dissolved in water, while the other esters are solubilized using, among others, propylene glycol, isopropanol, or liquid paraffin (Treffel and Gabard 1993; Issachar et al. 1998). Small filter paper discs (diameter <1 cm) are soaked in these different solutions (an aqueous solution of NM 5 mM is often used) and brought into contact with the skin for a short time, usually 15–30 s. The internal (or ventral) side of the forearm is the place of choice for application in humans. Alternatively, the aqueous NM solution may be applied with a micropipette (10–50 µl).

The cutaneous reaction may be followed visually using color charts or precisely and reproducibly measured with a suitable instrument. The measurements are done every 10 min until 40 min, and then at 60 and 90 min. By that time, the vascular reaction generally has vanished and the reddening has disappeared.

2.2 Instruments

Two instruments are commonly used (see ► Chap. 133, “Assessment of Erythema and Pallor”). The Chromameter (Minolta, Japan) allows the precise evaluation of skin color (Wilhem and Maibach 1989) and the laser Doppler velocimeter (Perimed, Sweden and Moor, UK) is used for determination of cutaneous blood flow (Bircher et al. 1994).

2.3 Characteristic Parameters

After cutaneous application of a nicotinic acid ester, several parameters may be evaluated: latency or time lag before appearance of the erythematous reaction, time to peak or maximal value, duration of the erythematous reaction, and area under the erythematous intensity versus time curve. Although both measuring techniques (skin color and skin blood flow) seem

complementary, skin color is more appropriate for the evaluation of nicotinic acid ester penetration. Indeed, the superficial dermal plexus is responsible for the reddening of the skin measured by chromametry. The laser Doppler data also include values from the lower dermal plexus featuring a more important blood flow that may be modified by external factors such as temperature and stress.

2.4 Nicotinic Acid Esters for the Investigation of Skin Barrier Function

The vasodilator properties of NM had already been used by 1962 for the investigation of skin barrier function differences depending on the anatomical site (Cronin and Stoughton 1962). Areas showing a strong or weaker barrier were characterized. These results were later validated using other techniques (Feldmann and Maibach 1967).

Stripping of the horny layer or tearing away the stratum corneum with an adhesive tape diminishes latency and accelerates the appearance of skin reddening (Guessant et al. 1993). Using the same phenomena, racial differences between Caucasian, black and Asian subjects were shown (Guy et al. 1985; Kompaore and Tsuruta 1993). Age may also be a factor influencing the cutaneous response to nicotinic acid ester application (Roskos et al. 1990).

Elsner and Maibach (1991) have shown that the erythematous reaction to NM application was less intense and of shorter duration on vulval skin than on forearm skin. The lower sensitivity of this anatomical region compared to the forearm is one of the factors discussed by the authors to explain this surprising result. Indeed, in this particular case, a skin area with a known reduced barrier function shows a diminished erythematous reaction. The pharmacodynamic aspect of the reaction then becomes important, because percutaneous absorption is not the only factor determining the skin response. Also, circadian rhythms have been shown to influence the cutaneous nicotinic acid ester reaction (Reinberg et al. 1995). These results show that pharmacodynamics must be considered when evaluating skin changes.

3 Skin Color Changes after Corticosteroid Application

3.1 Cutaneous Application

The described method is based on the original work of Mac Kenzie (Mac Kenzie and Stoughton 1962). The different products to be tested (dermatological formulations containing corticosteroids) are applied under occlusion on the inner side of the forearm at the dose of 2–10 mg/cm². The duration of application may vary between 0.25 and 6 h. For each application time, the kinetics of the blanching reaction are followed at 0.25, 0.5, 1, 2, 4, 6, 8, and 24 h on each tested area after cleaning the skin and removing the unpenetrated product.

3.2 Instruments

Although some authors advocate the use of laser Doppler measurements (Anja et al. 1998), visual scoring of skin whitening or measurement of skin color using the Minolta Chromameter seems to be more sensitive and widely used (Mac Kenzie and Stoughton 1962; Mac Kenzie 1962; Caron et al. 1990; Pershing et al. 1991; Pershing et al. 1992; see ► Chap. 133, “Assessment of Erythema and Pallor”).

3.3 Characteristic Parameters

For each application duration, the relevant parameters for quantifying the blanching reaction are: time to maximal value (reaction peak), maximal value, and the area under the time curve. These different parameters may be compared and used for the appreciation of cutaneous bioavailability of different products, but are less suitable for evaluation of percutaneous skin absorption.

4 Conclusion

Skin barrier function may be qualitatively appreciated by the evaluation of biological or pharmacological reactions using nicotinic acid esters or

corticosteroids. However, the skin response represents the sum of complex and intricate phenomena. Indeed, skin barrier state, cutaneous blood vessel sensitivity to the applied compound, corticosteroid potency class, and the level of blood flow in a given skin area, all these factors simultaneously contribute to the measured biological response. Therefore, the quantitative extrapolation of the obtained results as to percutaneous absorption must be done carefully.

Evaporimeter • Fick's law • Open cylinder method • Passive diffusion • Skin barrier function • Skin irritation • Transepidermal water loss (TEWL) • Clinical dermatology • Experimental dermatology • Instruments • Physiological principles • Practical recommendations • Precision • Reproducibility • Sources of error and variation factors • Theoretical principles

The use of noninvasive measurement methods for the examination of different physiological functions of the skin or for the characterization of pharmacological or pathological reactions is recent. Following the development of suitable techniques, instruments are now available for the evaluation of such different cutaneous parameters as color, elasticity, dermal blood flow, hydration of the horny layer, sebum excretion, and, of course, transepidermal water loss (TEWL). This equipment may replace the usual visual evaluation of skin state and are able to catch changes that otherwise would be not detected by the human eye.

Numerous advantages arise from using these techniques: independence toward investigator's subjectivity, numerical results and not ordered nominal data, better standardization of the experiments, better possibilities of interlaboratory comparisons, no requirement of highly specialized personnel, etc. For all these reasons, these new techniques are of growing interest for dermatological laboratories. Moreover, the increasing automation of data acquisition allows for the

simultaneous evaluation of several parameters if necessary.

sake of clarity, only water loss through the horny layer will be considered here.)

1 Transepidermal Water Loss

1.1 Basic Physiological Principles

Water has two possibilities in crossing the skin from the viable tissues toward the outer environment: active transport by sweating and passive diffusion through the horny layer. Sweating (*perspiratio sensibilis*) is one possibility for the body to control its temperature. It may also express psychic stress. Sweating may peak at maximal values of 2–4 l/h. On the contrary, transepidermal water loss (TEWL, *perspiratio insensibilis*) is not visible to the naked eye. Given no air turbulence, the skin is covered by a transition layer where moisture is transferred from the surface of the skin to the surrounding atmosphere, building up a protective sheet toward environment. The quantity of water crossing the stratum corneum on this way is estimated at 300–400 ml per day under normal conditions, that means 1/10th to 1/20th of sweating. Given this difference, it is mandatory to eliminate sweating during TEWL measurements. (Note: Water loss due to expired water vapor is also included in the term *perspiratio insensibilis*. But for the

1.2 Theoretical Principles

The diffusion barrier is situated entirely within the horny layer (Wilson and Maibach 1989; Lévêque 1989). The TEWL is a passive phenomenon due to the water vapor pressure gradient on both sides of the layer. Water concentration in the epidermis, which is well hydrated in contact with the dermis, is estimated to be 48–49 mol. This value is also found at the deeper side of the horny layer. On the other side, water concentration at skin surface, which is in contact with drier surroundings, is lower and was shown to be around 12 mol (ambient conditions: relative humidity 40 %, temperature 31 °C). The pressure gradient thus amounts to 37 mol (Wilson and Maibach 1989). Thus, if the relative humidity of the surrounding air is 100 %, the TEWL will decrease almost to zero, and inversely, if the relative humidity is 0 %, TEWL will be maximal (Fig. 1).

Passive diffusion of water through the horny layer is described by the 1st Fick's law (Schaefer and Redelmeier 1996). At equilibrium, the flux of water (J , mol cm⁻¹ s⁻¹) travelling upon a given distance (δ , cm) is proportional to the concentration gradient (ΔC) and to the diffusion coefficient

Fig. 1 Effect of relative humidity on TEWL: results of three studies

(D, cm²/s). However, the horny layer is not an inert membrane, but shows some affinity to water and Fick's law needs to be modified by the

introduction of a partition coefficient K_m (Wilson and Maibach 1989; Potts and Francoeur 1991):

$$K_m = \frac{\text{(Water concentration in the lower horny layer)}}{\text{(Water concentration in the intercellular space of living epidermis)}}$$

Fick's law thus writes $J = -K_m \times D (\Delta C / \Delta \delta)$

K_m amounts to 0.06 (Potts and Francoeur 1991). The negative symbol “-” shows that the flux is directed toward lower concentrations.

instruments are commercialized using the open cylinder method for measurement, and recent reviews describe this method in detail (Pinnagoda 1994a; Pinnagoda and Tupker 1995).

2 Methods and Measurement Devices

2.1 Introduction

Different measurement methods were described by Wilson and Maibach (1989). Briefly they list:

- Urine osmolarity
- Body weight
- Closed cylinder method: weight of an hygroscopic substance
- Ventilated chamber
- Electrohygrometer
- Thermal conductivity cell
- Dew-point hygrometer
- Electrolytic water vapor analyzer
- Open cylinder

This list is not exhaustive. The results obtained using these different methods are hardly comparable because of the difficulty in measuring TEWL under standardized conditions and the importance of several variation factors (see Sect. 3). A recently published review (Pinnagoda 1994a) shows that the measured values may depend, within certain limits, on the method employed. Wilson and Maibach (1989) described these different techniques with their advantages and drawbacks, but some of these are obsolete and/or not commercially available. For these reasons, only the last one, the most commonly used, will be described. Several

2.2 The Open Cylinder Method

A probe is applied on the skin surface, built as a cylindrical chamber open to the surrounding air. A 0.8–1 cm² skin area (value depends on the instrument) is delimited by the probe and constitutes the bottom of the chamber. Two sensors (semiconductors) measuring relative humidity are situated at two different levels vertically in the chamber. Each is coupled to a thermistor (Fig. 2). The distance from the sensors to the skin surface is calculated for an optimal evaluation of the water vapor pressure gradient arising within the chamber between the skin and the surrounding air.

Water pressure at each level is calculated from the following equation:

$$P = RH \times p_{\text{sat}}$$

p_{sat} is pressure at water saturation. Relative humidity (RH: %) is measured by the semiconductors; p_{sat} is calculated by the instrument, given the air temperature at each sensor level. The vapor pressure difference between the two measurement levels determines the slope of the pressure gradient. The TEWL is directly expressed in $\text{g m}^{-2} \text{h}^{-1}$.

2.3 Instruments

Several instruments using the open cylinder method are available: the Evaporimeter, the

Fig. 2 Schema of the TEWL measuring head

Tewameter, and more recently the DermaLab (for manufacturer's location, see [Evaporimètre®](#); [Tewamètre®](#); [DermaLab®](#)). An evaluation of both the Evaporimeter and the Tewameter and a comparison of the results obtained with these machines were published by Barel and Clarys in 1995 (Barel and Clarys 1995a, b). A similar comparative evaluation of the DermaLab and of the Evaporimeter was recently published by Grove et al. (1999). This last publication also lists previous reports dealing with comparative performance studies of the Evaporimeter. The geometry of the measuring probe and possibly the manufacturer's calibration method vary slightly between the different instruments, as well as the electronic treatment of measured data. Although the values obtained with one instrument are highly correlated to the values obtained with the other, some differences may remain between the values and between their variations after a given challenge (Barel and Clarys 1995b; Grove et al. 1999).

A portable device has recently been put on the market: Model H4300 (Nikkiso YSI Company Ltd, Tokyo, Japan). Its principle is based on the progressive increase in relative humidity inside a closed chamber, due to continuous water evaporation from the skin surface on which the chamber is placed. A linear correlation was found with DermaLab ($R^2 = 0.917$), but the obtained values were much lower (Tagami et al. 2002).

3 Sources of Error, Standardization, and Practical Recommendations

3.1 Introduction

Because of the dependency of the TEWL on the water vapor pressure gradient on the skin surface, every intrinsic or extrinsic factor influencing either the thickness of the transition layer from skin surface to surrounding air or the slope of the gradient within the transition layer will modify the TEWL. Moreover, given the sensitivity of the measuring probes, any change in the environmental microclimate will be detected and will consequently modify the indicated values unless the measuring conditions have been rigorously standardized. Precise recommendations concerning this particular point have been published (Pinnagoda et al. 1990; Rogiers 1995; Pinnagoda 1994b).

3.2 Sources of Error and Variation Factors

Variation factors may be classified as follows:

- Instrumental factors
- Environmental factors
- Individual factors

These factors have already been extensively reviewed (Pinnagoda and Tupker 1995; Barel and Clarys 1995b; Grove et al. 1999; Pinnagoda et al. 1990; Rogiers 1995; Pinnagoda 1994b) and listed (Pinnagoda et al. 1990), and their relative influence has also been evaluated. For these reasons, the interested reader will consult the original publications for more details.

- Instrumental factors
 - Preheating of the instrument: at least 15 min for electronic circuit stabilization. It is not recommended to switch off the instrument between the measurements.
 - Instrument zeroing: After preheating, under measuring conditions (see Sect. 3.4).
 - Measurement technique (see Sect. 3.4 and Pinnagoda et al. (1990); Rogiers (1995)).
 - Variation of zero during the measurements: to be regularly controlled.
 - Humidity and temperature variations in the open chamber: the probe must not be left in place on the skin; avoid contact with sweat.
 - During measurements the probe should remain horizontal.
 - Use of a protecting grid to avoid contact with a test product applied on the skin.
 - Pressure of the probe onto the skin.
 - Regular calibration of the probe following the manufacturer's instructions and as requested by GLPs.

- Inter-instrumental variations (see Grove et al. (1999); Pinnagoda et al. (1990)).
- Precision of the measurements (see Sect. 3.3).

- Environmental factors
 - Air convection and turbulences during the measurements
 - Environmental temperature
 - Environmental humidity
- Individual factors
 - Sweating
 - Skin temperature
 - Anatomical location of the measurement
- Conclusions

The relative importance of these factors is not the same. If a minimal standardization is assured, instrumental factors are less important. The greatest variations are then due to the environmental and individual factors. Figures 3, 4 (Barel and Clarys 1995b), and 5 (Van Kemenade 1998) illustrate, for example, the respective influences of the environmental temperature or relative humidity on measured values. Figure 5, showing recent data, is of particular interest: a sudden variation of the relative humidity from 53 % to 89 % provokes a fall of the TEWL, which thereafter slowly returns but stabilizes at a level lower than starting values. This last phenomenon is due to a change of the hydration of the horny layer, which also depends on the environmental

Fig. 3 Forearm TEWL versus ambient temperature, as measured with Evaporimeter and Tewameter

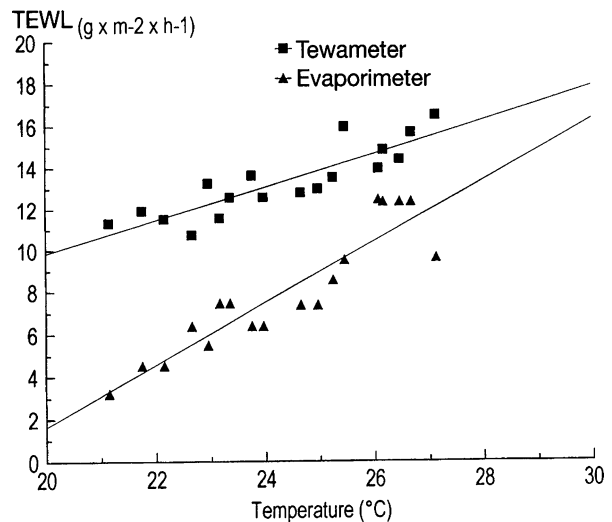

Fig. 4 Forearm TEWL versus ambient relative humidity, as measured with Evaporimeter and Tewameter

Fig. 5 TEWL versus sudden change in ambient relative humidity: within 1 h TEWL raised from 53% to 83%. Line with open squares measured TEWL, black unbroken line modelled TEWL

relative humidity. As to the individual factors, variations between to different anatomical are shown in Table 1 (Clarys et al. 1997).

3.3 Precision and Reproducibility of the Measurements

- Precision
 - The following data are given by the manufacturers:
 - Evaporimeter: Precision $\pm 15\%$ (EP 1), $\pm 5\%$ (EP2)
 - Tewameter: Precision $\pm 15\%$ ($\pm 1.0 \text{ g m}^{-2} \text{ h}^{-1}$ if $\text{RH} < 30\%$), $\pm 10\%$ ($\pm 0.5 \text{ g m}^{-2} \text{ h}^{-1}$ if $\text{RH} > 30\%$)

The precision of the measurements is difficult to check, because the exact value of the TEWL must be measured using a gravimetric method (Wilson and Maibach 1989; Barel and Clarys 1995b). If such measurements are made, it appears that a correction is necessary to obtain absolute values (Petro and Komor 1987), particularly if these values are high and exceed $50 \text{ g m}^{-2} \text{ h}^{-1}$ (Pinnagoda and Tupker 1995; Petro and Komor 1987). This correction is given by the following equation:

$$\text{TEWL}_{\text{corr}} = Bx^k$$

where B is the measured TEWL value ($\text{g m}^{-2} \text{ h}^{-1}$), x a constant ($x = 0.025 \text{ cm}$),

Table 1 Table 1 Mean TEWL for various sites of the body measured with a Tewameter. Mean \pm S.D for 16 volunteers

Body site	TEWL (g/m ² h)
Forehead	20.1 \pm 4.8
Chest	10.7 \pm 1.3
Abdomen	9.9 \pm 1.8
Forearm (inner surface)	10.4 \pm 3.1
Calf	9.6 \pm 1.8

and k the slope of the line: $[\log TEWL = f(\text{distance between the lower sensor and the skin surface})]$. k has been determined for measurements on the volar forearm: $k = -0.049$ (Petro and Komor 1987).

- Reproducibility

The reproducibility of the measurements is good if the measuring conditions have been standardized. Barel and Clarys (1995a, b) found variation coefficients between 3 and 8 %. Pinnagoda et al. published slightly higher values between 8 % and 15 % (Pinnagoda et al. 1989). Grove et al. (1999) published coefficient of variations of 4–47 % depending on the type of equipment used and on the level of the measured values (higher variations encountered if low values are measured).

3.4 Practical Recommendations

The control of environmental factors is only achieved by conducting the measurements in an air-conditioned room, featuring temperature, and relative humidity control. Turbulences and air convection in the near surroundings of the measuring probe are best eliminated by conducting the measurements inside a protecting box, e.g., an incubator with holes for the placement of the forearms (Pinnagoda et al. 1990). An open top should avoid buildup of temperature and water vapor inside the box. The measuring plane should remain horizontal, thus allowing the gradient to be built correctly in the measuring chamber. The pressure of the probe on the skin should remain low.

Control of individual factors is achieved by a strict selection of the study subjects, by allowing enough time for their relaxation before entering the experimental phase of the study ensuring their perfect adaptation to the controlled environmental conditions. For example, it is important to distinguish between atopic and non-atopic subjects, because the TEWL of atopic subjects is elevated in comparison to non-atopic ones, even if the skin of the atopics looks normal. Adaptation to the environmental conditions requires at least 20 min before measurements start. An experimental protocol should be available (Salter 1996), which excludes, for example, subjects having ingested spiced food that may provoke sweating. Stress also may provoke sweating; therefore, individuals should be thoroughly instructed and allowed to relax completely before starting with the study. These conditions ensure better reproducibility and precision of the measurements.

TEWL is tightly correlated to the barrier function of the horny layer. On the other hand, the barrier function also depends on the water content of the horny layer. The relationship between TEWL and the stratum corneum hydration must be considered in particular situations such as in newborn babies or old people or in measurements on a diseased skin (Berardesca and Maibach 1990).

Last but not least, some components of dermatological products may influence the measured values. Morrison (1992) showed that propylene glycol in a formulation could lead to an overestimation of the TEWL due to an interaction of this compound with the measuring probe. Dermatological or cosmetic products contain water that evaporates following application, and this evaporation adds to the underlying TEWL for a certain time. In this case, the measured value is known as skin surface water loss (SSWL). SSWL is also encountered during such particular experiments as the plastic occlusion stress test (POST) featuring a prolonged skin occlusion leading to water accumulation in the horny layer (Berardesca and Maibach 1990; Berardesca and Elsner 1994).

4 Practical Examples

Lastly, some practical examples of the use of TEWL are described in experimental and, more briefly, in clinical dermatology.

4.1 Experimental Dermatology

- Skin barrier function

The results obtained by the group of A. Rougier (1994) or of M. Ponc (Oestmann et al. 1993) show a tight relationship between TEWL and the penetration of some chemicals through the skin, such as benzoic acid, acetylsalicylic acid, caffeine, or hexyl nicotinate. This relationship may still be valid in some pathological situations (Lavrijsen et al. 1993).

- Skin irritation

TEWL is sensitive to skin irritation due to many different substances such as detergents or surfactants (Wilhelm et al. 1989; Effendy and Maibach 1995; Gabard 1991), all-trans retinoic acid (Gabard 1991; Effendy et al. 1996a), alpha-hydroxy acids such as glycolic acid (Effendy et al. 1995), newborn fecal enzymes (Andersen et al. 1994), or vitamin D derivatives (Effendy et al. 1996b; Fullerton and Serup 1997). Sodium lauryl sulfate is probably the most commonly used standard irritant in experimental dermatology. A recent guideline was published by the Standardization Group of the European Society of Contact Dermatitis about the standardization of experiments using this compound (Tupker et al. 1997). Measurement of TEWL may also be beneficial in experiments with animals or for comparison with human skin values (Fullerton and Serup 1997; Gendimenico et al. 1995; Gabard et al. 1995; Von Brenken et al. 1997). Differences may be encountered between various animal species as well as between animals and humans (Effendy et al. 1996b; Fullerton and Serup 1997; Von Brenken et al. 1997).

- Effects of UV irradiation

Differences also are noticed between animals and humans considering the TEWL changes after an UV-B irradiation (Frödin et al. 1988; Haratake et al. 1997).

- Evaluation of topical products

TEWL may be advantageously used for the investigation of some properties of topical products such as moisturizers (skin hydrating creams) after application on the skin. Measurement of the TEWL allows to characterize the changes of the product after application and the effect of different humectants contained in the product and also to precisely evaluate the occlusive properties of the formulation (Gabard 1994; Marti-Mestres et al. 1994).

- Therapeutic effects of topical products

The TEWL also allows the evaluation of the therapeutic effect of topical products applied on diseased skin with a modified barrier function in animals and/or humans (Ghadially et al. 1992; Gabard et al. 1996; Lodén 1996, 1997; Mortz et al. 1997). The composition of the formulations may also be optimized with these experimental models (Zettersten et al. 1997). These experiments show on one side that contradictory results may be obtained if a diseased skin with modified barrier function is treated by a given formulation and on the other side that the obtained results on product efficacy may not be extrapolated in a straightforward manner from animals to humans.

4.2 Clinical Dermatology

Pinnagoda and Tupker (1995) published pertinent examples of improving medical care by the use of TEWL measurements in pathological situations:

- Various types of cutaneous inflammation.
- Follow-up of the course of atopic dermatitis (Aalto-Korte 1995; Seidenari and Giusti 1995): Aalto-Korte (1995) could show that the improvement of skin barrier function as measured by TEWL was accompanied by a decrease of the cutaneous absorption of hydrocortisone used for treatment.

- Psoriasis, different types of ichthyoses.
- Wound healing, regeneration of burned skin.
- Follow-up of newborn babies.
- Possibility of differentiating between an allergic or irritant reaction after patch testing (Giorgini et al. 1996).

This list remains succinct; the interested reader will report with benefit to the publication of Pinnagoda and Tupker (1995) where in-depth information are given about clinical applications of TEWL measurements. Obviously, some complications remain concerning a daily use of this technique in a hospital environment, the most important one being the necessity to conduct the measurements in a controlled and standardized environment.

5 Conclusions

The TEWL mirrors the integrity of the physiological barrier built up by the horny layer. Due to the availability of easy-to-use and precise equipments, the TEWL may now be easily measured. In that way, important information on skin water barrier may be gathered, concerning, for example, the behavior of topical products during development and use, differences between man and animals, etc. This information is pertinent, considering the fact that TEWL remains the most sensitive parameter for the detection of a cutaneous irritation. However, the obtained results are meaningful only if well-standardized measurement conditions are guaranteed. This remains an obstacle to an extended daily use.

Microcollector • Microdialysis • Micropump • No net flux calibration • Relative recovery calibration • Retrodialysis • Suction blisters

The extracellular space represents the junction point of nutriment, mediators, hormones, drugs, and metabolites as well as toxins with cutaneous cell targets. Few techniques nowadays allow the study of these compartments *in vivo* in the dermis. Scientists usually study plasmatic pharmacokinetics to solve the problems with drug dermal kinetics. However, two techniques allow pharmacokinetic or metabolism studies to be performed by studying endogenous or exogenous substance concentrations in extracellular fluids:

1. A relatively old technique, suction blisters (Kiistala 1967)
2. A more recent technique, at least for its cutaneous applications, microdialysis (Anderson et al. 1991)

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

1 Suction Blisters**1.1 History**

The principle of suction blister formation is old, and scientists have continued to improve this technique and develop practical applications. In 1900, Weinfeld reported that subepidermal

blisters could be obtained by using hydrostatical pressure on the epidermal face of human cadaver skin fragments. However, it was Kiistala, in 1967, who really developed the suction blistering technique (Kiistala 1967).

1.2 Principle

A steel cap, perforated by either one or several round holes of definite diameters (4–14 mm), and connected to a tube leading to an electric vacuum pump is applied on the volar forearm. A slight suction pressure (from 200 to 300 mmHg) is applied on the skin. After about 2 h (the length of time varies with each volunteer), the interstitial fluid has accumulated between the dermis and epidermis, which is progressively peeled off. This process involves the formation of a blister, called a suction blister (Fig. 1). The volume of the collected fluid varies from 50 to 150 μL per blister. Five to six chambers may be needed to perform a good pharmacokinetic analysis.

1.3 Applications

This technique permits pharmacokinetic analysis of drugs to be performed by measuring their concentrations in the liquid of the blisters, but also in the roof (composed of living epidermis) and the

floor (composed of living dermis). It allows fundamental pharmacological or/and biochemical studies to be performed.

For example, histamine assays have allowed the characterization of urticarial reactions more accurately (Neittaanmaki et al. 1984) and interleukin assays to characterize some pathologies like psoriasis (Prens et al. 1990), bullous pemphigoid (Schmidt et al. 1996), or mastocytosis (Brockow et al. 2002). Prostaglandin analyses have facilitated the comprehension of their dermal kinetics during sun exposure (Gilchrest et al. 1981). Jensen et al. (1995) have performed suction blisters in six diabetic patients in order to establish a correlation between plas-matic concentrations and extracellular levels of glucose.

The blister fluid is used in pharmacokinetics to assess drugs concentrations, administered topically as well as systemically, and eventually their metabolites (Averbeck et al. 1989). Such kinetics have been obtained with compounds like citroptene or bergaptene topically administered (Treffel et al. 1991), R and S forms of ibuprofen administered orally (Walker et al. 1993), and very lipophilic molecules like acitretin (Surber et al. 1993).

1.4 Limits

- Influence of the peak blistering point: a study performed with rats (Schäfer-Korting

Fig. 1 Suction blisters: apparatus and blisters performed on the volar forearm of a volunteer

et al. 1985) has shown the influence of the peak blistering point on the drug levels as confirmed by other clinical studies with psoralen (Humbert et al. 1991). Drugs administered before the formation of the blister penetrate the skin by diffusion, whereas drugs penetrate the skin by convection if they are administered during the blister formation. This implies a better availability of drugs when they are administered simultaneously to the blister formation. Gupta and Kumar have also reviewed in 2000 the different factors which could influence the suction blister induction time (Gupta and Kumar 2000).

- Influence of age and site on the peak blistering point: Grove et al. showed in 1982 (Grove et al. 1982), with experiments performed after applications of ammonium hydroxide aqueous solution, that the peak blistering point is shorter in older people, whereas the blisters last longer.
- Number of bubbles and wound healing: this technique involves a scar which prevents reuse on the same site for several months. The dimensions of the steel capsule limit the number of points for pharmacokinetics.
- The liquid collected is proteic, which has to be extracted to be analyzed by High Performance Liquid Chromatography, for example.

2 Microdialysis

2.1 History

With microdialysis, it is possible to extract chemical substances contained in extracellular fluids without extracting liquids, and to introduce substances without injecting liquids. One major interest of microdialysis is the possibility to work in sterile conditions, the probe constituting a closed liquid system. This technique has been used for about 25 years in neuropharmacology. Ungerstedt (Ungerstedt and Pycocock 1974) invented microdialysis by introducing a probe in a rat brain for the first time in 1974, and then improved the perfusing method in the 1980s.

For about 10 years, the number of applications and publications in relation to microdialysis has increased continuously. Microdialysis can be used for the study of many tissues such as eyes, muscles, lung, and heart (Elmqvist and Sawchuk 1997). Its application in cutaneous biology is recent (Anderson et al. 1991), but rapidly expanding.

2.2 Principle

The principle is based on the use of probes, equipped at their extremities with semi-permeable membranes. This probe, once inserted into a tissue, can mimic the function of a capillary blood vessel. It is connected at one end to a micropump, which permits perfusing the system at constant flow with a physiological solution (Ringer, phosphate buffer, etc.), and at the other extremity, to a collector which allows collection of dialysates at regular intervals. Microdialysis is, therefore, based on a dynamic diffusion phenomenon. As the liquid reaches the membrane, a concentration gradient is established, and the studied substance goes from the most concentrated medium to the less concentrated one (Fig. 2).

As microdialysis implies a dynamic phenomenon, the concentration of the studied compound in dialysate is only a fraction of its real concentration in the medium where the membrane is located. The Relative Recovery represents the ratio between the concentrations of dialysate and tissue. The results can also be expressed as absolute recovery, which represents the cumulative quantity of recovered substances per time unit.

2.3 Calibration

2.3.1 Relative Recovery

As dialysate represents only a fraction of the quantity actually present in a tissue, it is necessary to estimate this Relative Recovery (R.R.) in vitro in order to use microdialysis in vivo quantitatively. This necessitates several experiments where several parameters will be changed: perfusion rate, nature of the membrane, concentration,

etc. in order to improve the relative recovery and the experimental conditions.

2.3.2 No Net Flux (Le Quellec et al. 1995; Lönnroth et al. 1987)

An in vitro calibration can be a source of mistakes as the diffusion in a tissue is not as

Fig. 2 Schema of a microdialysis probe

simple as in a liquid. Several calibrations in vivo have been suggested, like the No Net Flux. The principle of No Net Flux is based on the fact that the flux direction of a molecule is only directed by the concentration gradient. This means that if the microdialysis probe is perfused with a lower concentration of substances than the dermis concentration, the flux will be from the tissue to the dialysate. If the probe is perfused with greater concentrations than the interstitial fluid, the substances will pass from the probe to the tissue. This technique also consists of perfusing the probe with different concentrations, which have already been chosen in order to be lower and greater than the dermis concentration expected. A line is drawn with the concentration of the perfusate (C_{in}) in abscissa and the difference between perfusate and dialysate in ordinate ($DC = C_{in} - C_{out}$) (Fig. 3). A linear regression allows the assessment of the point of No Net Flux (crossing with the abscissa scale), which represents the concentration of the compound in the tissue, and the slope of the line gives the Absolute Recovery.

2.3.3 Retrodialysis

The concept of retrodialysis is based on the same idea as No Net Flux, only the concentration gradient determines the flux direction through the dialysis membrane. This technique is mainly used for exogenous substances. It assesses the relative decrease of perfused

Fig. 3 Principle of the No Net Flux Method. C_t concentration in the tissue, C_p concentration in the perfusate, C_d concentration in the dialysate

concentration when the probe is placed in a medium where the substance concentration is zero or negligible.

$$R.R. = \Delta c / C_{in}$$

where

- C_{in} = concentration of compound in the perfusate
- C_{out} = concentration of compound in the dialysate
- $D_c = C_{in} - C_{out}$

2.4 Material

2.4.1 Micropump

Several types of pump have been customized, but the principle is always the same: perfusion of a very low volume of liquid at constant flow rate. CMA's pumps (CMA/Microdialysis, Solna, Sweden), allow perfusion at flow rates from 1 nL/min – 1 mL/min, 1–3 syringes simultaneously. The most frequently used perfusion rates vary from 1 to 5 μ L/min. There is also now a portable, battery-operated, micro-processor controlled syringe pump which is very easy to use. The pump is small, with rounded corners and is lightweight. It can be fixed to a belt or carried in an ambulant patient's pocket.

2.4.2 Perfusion Fluid

This liquid has to act like a vehicle for the substances it has to extract. Its composition must be similar to the extracellular fluid composition in order to avoid interaction with biological phenomena which take place around the probe. They are usually perfused with a physiological fluid like Ringer or a phosphate buffer (pH 7.4). Some authors have proposed adding glucose in the dialysis buffer in order to avoid its draining from the extracellular medium and a possible alteration of the cellular metabolism. It can be useful sometimes to add albumin in the dialysate for the study of compounds with a high protein

binding capacity in order to avoid the sticking of these compounds to the membrane and the tubing. The perfusion fluid must not contain any air bubbles or any particles to prevent any alteration of the perfusion speed or reduction of the membrane exchange area.

2.4.3 Probes

Probes can be customized in series or in parallel. The first ones are probes customized from dialysis fibers. The second ones are commercialized by CMA. In these probes, a semi-permeable membrane is glued between the tip of an inner steel cannula and the outer steel shaft. The perfusion fluid enters the membrane space through two holes in the inner cannula and flows into the shaft to the outlet. Different constructions and sizes of microdialysis probes are available for various organs and biological species. The CMA/20 Microdialysis Probe is designed for dialysis experiments in moving soft tissues such as skin and adipose tissue, as well as in blood, vitreous fluid of the eye, etc. As with the other models, the probe is of concentric construction, but is made completely from plastic materials. Due to its flexibility, the probe must be implanted into the tissue with the help of a steel needle and split tubing – the Introducer. The membrane is available in both 20- and 100-kDa cut-off. The CMA 60 Microdialysis Catheter is designed for microdialysis in adipose tissue and resting skeletal muscle. The CMA 60 Microdialysis Catheter has been especially developed to achieve excellent diffusion characteristics. This probe has the EC homologation. The dialyzing polyamide membrane is 30 mm long. Insertion into the tissue is easily achieved with the help of a unique slit cannula introducer that leaves the catheter in place when withdrawn.

2.4.4 Microcollector

An automatic system is used to collect dialysates. The collection can be powered by and controlled through the microinjection pump, which changes vial positions according to the volume preset on the pump. The CMA/140 Microfraction Collector can simultaneously collect fractions from up to

three probes in a range of between 1 to 50 μL with maximal precision. Some systems have a thermo-electric cooling system that cools down to $+4^\circ\text{C}$ when the fractions can be collected in sealed vials. Both are important considerations for the prevention of evaporation and chemical degradation. A needle arm is equipped with a sensor mechanism which makes it possible to collect fractions as small as 1 μL at the bottom of each vial.

2.5 Application in Cutaneous Biology

Microdialysis allows monitoring of the extracellular fluid of a specific tissue continuously (from several hours to several days), as opposed to the suction blisters which allow concentrations to be obtained at specific times only.

2.5.1 Insertion of Probes

The probes are fragile and therefore cannot be inserted without having the recourse of a guide (catheter 20-gauge). The probe can be localized thanks to ultrasonography (Groth 1996; Hegemann et al. 1995) (Fig. 4).

Many studies assess the trauma involved from probe insertion in the skin. Anderson et al. in 1994 (Anderson et al. 1994) and then Groth in 1998 (Groth et al. 1998) have shown the effect of probe insertion, with or without local anesthetics. This

insertion involves the secretion of endogenous substances like histamine. Linden et al. have also shown the interest of studying this reaction, which seems to be predictable of the skin's individual reactivity in general (Linden et al. 2000). The insertion also produces a significant increase of blood flux, as shown by laser Doppler, as well as the appearance of a small erythema (Groth 1998). These reactions tend to decrease and to disappear after 30–120 min. Krogstadt et al. performed a histological study on skin biopsies performed after probe insertion. They have found some slight bleeding but neither edema nor inflammatory reactions after 8–10 h of dialysis (Krogstad et al. 1996). Rapid changes in glucose levels have been detected, showing that the trauma hasn't altered the microdialysis results.

The experiment shows that after a local anesthesia (lidocaine injection or topical EMLA application), insertion is not painful. After 60–90 min, most of the reactions induced by the insertion are over.

The main advantage of microdialysis is that this technique leaves only small scars on the insertion site, and they disappear quickly (Fig. 5).

2.5.2 Monitoring of Endogenous Substances

Another advantage of microdialysis is to allow the continuous monitoring of the endogenous substances' concentration in the dermis compartment, like glucose, lactate, glycerol, and pyruvate. It

Fig. 4 Depth measurement of a microdialysis probe by ultrasound imaging (Dermcup). (a) dermis thickness, (b) probe inner diameter, (c) probe depth

Fig. 5 A microdialysis probe inserted in the volar forearm of a volunteer

allows, for example, glucose and lactate concentrations to be followed in premature babies (De Boer et al. 1994a), lactate concentrations during physical exercises (De Boer et al. 1994b), or glucose concentrations in diabetic patients (Hoss et al. 2001). In 1996, Meyerhoff et al. developed a system combining microdialysis with a detector equipped with an amperometric glucose oxidase electrode (Meyerhoff et al. 1996). A microdialysis probe is inserted into the abdomen of diabetic patients, and their concentration in glucose is monitored by a watch. An alarm starts when concentrations reach critical values.

Microdialysis can be used also as a monitoring technique during a surgical intervention such as transfer flap tissue. It can be a useful tool in predicting flap viability: it has already been shown that the glucose concentration is reduced whereas the lactate and glycerol levels increase during flap ischemia (Röjdmarm et al. 1997).

This technique allows the mechanism of reactions involved in contact dermatitis or different pathologies to be studied, as it has already been done for psoriasis (Krogstad et al. 1997), atopic dermatitis (Rukwied et al. 2000a), mastocytosis (Krogstad and Roupe 2001), with the study of histamine (Anderson et al. 1992; Rukwied et al. 2000b; Horsmanheimo et al. 1996; Petersen et al. 1992, 1997), interleukin concentrations (Anderson et al. 1995), nitric oxide (Katugampola et al. 2000), iron (Leveque et al. 2000), or ascorbic acid (Leveque et al. 2001).

2.5.3 Bioavailability of Exogeneous Substances

The first study on the application of microdialysis in cutaneous biology was published by Anderson in 1991, with a study on the absorption of ethanol (Anderson et al. 1991). Ault et al. have compared the results obtained with microdialysis and Franz Cells, by inserting one microdialysis probe into the receptor chamber of a Franz cell, and another into the dermis of a skin fragment, in order to study the pharmacokinetics of 5-fluorouracil (Ault et al. 1992). The results obtained from both techniques were well correlated.

Other kinds of pharmacokinetics have been performed. This technique is good for screening the bioavailability of different formulations. It has been used, for example, to study the effect of enhancers on the percutaneous absorption of methotrexate and cyclosporine (Matsuyama et al. 1994; Nakashima et al. 1996).

It can also be used to study the pharmacokinetics of transdermal drug delivery systems, as already performed for nicotine (Hegemann et al. 1995b; Müller et al. 1995).

At least one major interest of microdialysis is its use to compare the pharmacokinetics of a drug to its pharmacodynamic characteristics. Several studies have been performed in cancerology (Blöchl-Daum et al. 1996; Joukhadar et al. 2001) or to study the efficacy of antibiotics in bacterial infections (Brunner et al. 2000).

2.6 Limits

2.6.1 Low Volumes

The low perfusion speed used in microdialysis involves the collection of a small volume of fluid (from ca. 10 to 200 μL). It also requires very sensitive analysis techniques like High Performance Liquid Chromatography, Mass Spectrometry or immunology assays (ELISA, etc.). This technique is also interesting because the samples obtained are quite clean; large molecules such as albumin cannot be collected with the classical membranes and the analyses do not require any extraction step.

2.6.2 The Relative Recovery

The recovery depends on several parameters (like perfusion speed, physicochemical properties of the studied compound, etc.). It is therefore necessary to estimate the R.R. for each experiment. This can be possible thanks to some special calibration techniques (cf. Section 2.3, "Instruments" in ► [Chap. 108, "Transepidermal Water Loss"](#)).

2.6.3 Lipophilic Compounds

The poor affinity of lipophilic compounds for the hydrophilic perfusate causes a very poor recovery for this kind of product. A study has been performed on transdermal drug delivery, with good results for nicotine (Hegemann et al. 1995b; Müller et al. 1995), but not for estradiol (Müller et al. 1995). Other studies have also shown this kind of problem with calcipotriol, fusidic acid, and betamethasone valerate, unless they are used at high concentrations or after systemic administration (Groth 1996). The best solution for these products would be to change the dialysate (Kreilgaard et al. 2001).

techniques for in vivo sampling of peripheral compartment pharmacokinetics after systemic administration of acetylsalicylic acid (Benfeldt et al. 1999). Both techniques were in excellent concordance with even closer correlation between maximum concentrations obtained by microdialysis and suction blister fluid sampling.

In spite of these results, the concentrations of theophylline measured with suction blister seemed to be overestimated, whereas those measured in microdialysate were similar to those found in plasma (Muller et al. 1998). Another study has been conducted with the combination of these techniques to clarify the roles of nitric oxide and prostaglandin E2 in the generation of UVB-induced vasodilatation (Rhodes et al. 2001). The results from both techniques provided the involvement of prostaglandin E2 in the production of UV-induced erythema. However, nitric oxide was not detectable in suction blister fluid. This phenomenon could be explained by a protein contamination of the suction blister fluid.

These two techniques are interesting for obtaining pharmacokinetics of drugs or to study the secretion of endogenous substances. However, after comparing the tolerability of the sampling procedure, ease of analysis, and detail in chronology, microdialysis seems superior for sampling in vivo pharmacokinetics in the dermis.

Microdialysis promises to be a main technique in the future. We expect to find the best solution to study lipophilic compounds, in order to improve their recovery and to prevent them from sticking to the membrane and the tubing. This technique is non-invasive, requires only one probe to perform a complete pharmacokinetic analysis without any pain for the volunteer, and can be used ex vivo as well as in vivo, in animals as well as in humans.

3 Conclusion

We have compared two techniques used in cutaneous pharmacological studies: suction blisters and microdialysis. Brunner et al. have found a close correlation between the pharmacokinetic of paracetamol obtained from these techniques and in plasma (Brunner et al. 1998). Benfeldt et al. have also simultaneously investigated these

1 Introduction

Nanoparticles are commonly defined 1–100 nm objects or – at least – one dimension being less than 100 nm. The International Organization for Standardization defines the term “nanomaterial” as “material with any external dimensions in the nanoscale or having internal structure or surface structure in the nanoscale” (EU Commission Recommendation on the definition of nanomaterial 2011). Other definitions have been proposed. A recent proposal is based on surface area rather than size (a nanoparticle should have a specific surface area $>60 \text{ m}^2/\text{cm}^3$), thus reflecting the critical importance of this parameter in governing reactivity and toxicity of nanomaterials (Kreyling et al. 2010). Nanomaterials can be divided into two large groups: ultrafine nanosized particles not intentionally produced and engineered nanoparticles produced in a controlled, engineered way. Engineered nanoparticles, because of their large surface-to-volume ratios, exhibit chemical, physical, and biological properties distinctly different from the same materials in the bulk form, but such properties may lead to adverse effects on human health and environmental systems (Oberdörster et al. 2005).

Nanoparticles, novel carrier systems developed as an alternative to traditional vehicles show important advantages for dermal application of cosmetics and pharmaceuticals.

Nanoparticles are able to increase the penetration of active ingredients into the skin, allowing increased targeting to the epidermis and consequently improve treatment efficiency and reducing the systemic absorption of drugs and cosmetic agents. The biocompatibility of the nanoparticles

and their biodegradation chemical nature has opened new advancements in cosmetic and pharmaceutical industries for effective topical delivery of drugs and active substances. Currently many substances are under investigation for topical drug delivery, however the toxicological investigations are of great importance (Firouz et al. 2016; Nassiri-Kashani et al. 2016; Behtash et al. 2016; Firooz et al. 2015; Nafisi and Maibach 2015; Agudelo et al. 2013a; Agudelo et al. 2013b; Tajmir-Riahi et al. 2014; Nafisi and Maibach 2016; Nafisi et al. 2016).

Nanoparticles can enter the body through inhalation, absorption through the skin or the digestive tract, voluntary injection, or implantation for drug delivery. The skin, the largest organ, is a primary barrier to nanoparticle exposure from naturally occurring and engineered nanomaterials found in the environment and workplace. Thus, the skin may be an unintended route for localized and possibly systemic exposure to nanoparticles released during manufacture, use, and disposal (Proksch et al. 2008; Prow et al. 2011; Labouta and Schneider 2013). Nanoparticles may induce a spectrum of adverse health effects ranging from localized damage (e.g., irritant contact dermatitis) to induction of immune-mediated responses (e.g., allergic contact dermatitis and pulmonary responses) or systemic toxicity (e.g., neurotoxicity and hepatotoxicity) (Poland et al. 2013).

Recently, silica nanoparticles (SNPs) have attracted significant interest because of their unique properties such as hydrophilic surface favoring protracted circulation, following i.v. administration, versatile silane chemistry for surface functionalization, ease of large-scale synthesis, and low cost of NP production (Slowing et al. 2008; Barbe et al. 2004). SNPs are widely applied in chemical industry, agriculture, and cosmetics (Willey 1982). In addition, they are being developed in medical uses including for diagnosis and therapy (Tang and Cheng 2013; Tang et al. 2012), probes for biomarkers for optical imaging (Lee et al. 2009), controlled release drug delivery, as well as gene transfection carriers (Slowing et al. 2008). Such medical approaches

have numerous applications including skin cancer therapy (Scodeller et al. 2013; Benezra et al. 2011; De Louise 2012), transdermal drug delivery (Prausnitz et al. 2012), transcutaneous vaccination, and gene delivery (Bharali et al. 2005). They can act as carrier for drugs with low solubility and might improve drug safety, stability, and performance (De Villiers et al. 2009). With the growing commercialization of silica nanoparticles, human exposure to these materials is increasing, and many aspects related to their toxicity should be studied.

The main goal of this review is to organize the current state of the art relating to skin absorption of silica nanoparticles based on the ten parameters of percutaneous penetration while raising awareness of silica nanomaterials' toxicity among scientists and manufacturers handling them. The importance of such overview stems from percutaneous penetration research tradition dating back to World War II military studies, focused on a one-step penetration model (Tregear 1996). Such work corrected misconceptions (i.e., skin being largely impermeable); subsequent chemical, in vivo and in vitro, experiments document a far more complex penetration model – whose steps may be highly clinically relevant to the nanotoxicity debate.

2 Silica

Silicon dioxide, also known as silica, an oxide of silicon with the chemical formula SiO_2 is the most common element found in nature and is widely distributed in dusts, sands, planetoids, and planets (Georgia State University, Hyperphysics). Silica can be classified into two main classes: crystalline and amorphous. Different forms of silica and their properties are in Table 1.

2.1 Crystalline Silica

Crystalline micron-sized silica is a basic component of soil, sand, granite, and many other minerals (Iier 1979; Unger 1979). Silica exposure is a

serious threat to workers and has been classified as a human lung carcinogen (OSHA 2002).

2.2 Amorphous Silica

Amorphous silica is synthetic silica except biogenic diatomaceous earth, composed of ultimate particles or structural unit less than 1 μm in diameter. Synthetic and natural amorphous silica are important materials for their variety of technological applications due to their physicochemical properties such as surface area, pore properties, bulk density, etc. (Iier 1979; IMA Europe 2014).

2.2.1 Natural Amorphous Silica

Diatoms are microscopic, eukaryotic, unicellular algae ubiquitously present in almost every water habitat on earth. Diatom cell walls are composed of silica (hydrated silicon dioxide) (Iier 1979; IMA Europe 2014).

2.2.2 Synthetic Amorphous Silica (SAS)

Different synthetic amorphous (noncrystalline) silica particles (Table 1) have large specific to geometric surface ratio (Iier 1979). SAS particles are generally regarded to be safe, with no or minimal chronic effects. However, increasing use of various forms of noncrystalline silica particles, and in particular the nanosized, requires more thorough examination of their possible health effects (Choi et al. 2008; Fruijtier-Polloth 2012). They can be categorized as mesoporous and nonporous based on their biomedical applications (Tang and Cheng 2013).

Pyrogenic or Fumed Silica

Pyrogenic or fumed silica, an extremely low bulk density powder with high surface area and synthesized by thermal process, consists of amorphous silica particles fused into branched, chainlike, three-dimensional secondary particles and can agglomerate into tertiary particles (Iier 1979; Willey 1982). Fumed silica is not listed as a carcinogen by OSHA, ECETOC, or NTP (ECETOC 2006). Due to its fineness and thinness, it can easily become airborne, making it an

Table 1 Different forms of silica, including crystalline silica, natural amorphous silica, and synthetic amorphous silica

Silica forms		Synthesis method	Size	Surface area	Applications	Reference
1. Crystalline silica		–	0.5–3 µm	9.4 m ² /g	Manufacture of glass, abrasives, ceramics, enamels, scouring, castings in molds	lier 1979; Unger 1979
2. Amorphous silica	2.1. Natural amorphous	–	0.5–2 µm	High porosity	Filtration agent, abrasive, absorbent, industrial filler	lier 1979; ECETOC 2006; IMA Europe 2014
	2.2. Synthetic amorphous silica (SAS)	Thermal process	5–50 nm	50–600 m ² /g	Counteracts oily or greasy skin feel, raising sun protection, improving storage, stabilize emulsions, temperature, and stability	lier 1979; Willey 1982; ECETOC 2006
				Nonporous Low bulk density		
	2.2.2. Precipitated amorphous silica	Wet process	5–100 nm	30–500 m ² /g Porous	Rubber and plastics, cleaning, thickening, polishing agent in toothpastes, food processing, pharmaceuticals additive as anticaking, absorbent, antiblocking agent in polymer films	lier 1979; ECETOC 2006
	2.2.3. Silica gel	Wet process	30–100 nm	800 m ² /g Porous	Abrasives in carbonless papers, fining agent and catalysis, desiccant, stationary phase in chromatography, anticaking agent, filter aid, emulsifying agent, viscosity control agent, anti-settling agent	lier 1979; ECETOC 2006; IMA Europe 2014
	2.2.4. Nonporous silica nanoparticles	Different synthesis methods	50–2,000 nm	Nonporous and porous Controllable surface properties	Masks in lithography, optical sensor, drug delivery, gene delivery, molecular imaging	Stober and Fink 1968; Xia et al. 2000; Tang and Cheng 2013
2.2.5. Mesoporous silica nanoparticles (MSNs)	Different synthesis methods	2–50 nm	High surface area (>1,000 m ² /g) Porous, high pore volume (0.5–2.5 cm ³ /g) High drug loading capability	Confined-space catalysis; acoustic, thermal, and electrical insulation; enzyme immobilization; drug delivery system; cell marker; gene transfection reagents Imaging modality, bone tissue regeneration	Tang et al. 2012; Slowing et al. 2010; Wan and Zhao 2007; Hoffman et al. 2006; Garcia-Bennett. 2011; Vailet-Regi et al. 2007; Lou et al. 2008; Liu et al. 2011	
2.2.6. Silica host for other NPs	–	–	–	–	Medical imaging, drug delivery	Piao et al. 2008

inhalation risk, capable of causing irritation (Otterstedt and Brandreth 1998).

Precipitated Amorphous Silica

Precipitated amorphous silica, consisting of a three-dimensional network of coagulated primary silica particles and prepared by wet process, is not classified as dangerous regarding physical and chemical hazards (Iier 1979; ECETOC 2006).

Silica Gel

Silica gel also referred to as silica aerogel or hydrated silica is a white, fluffy powder or milky suspension of fine amorphous spherical particles in a liquid phase. It is odorless, tasteless and nontoxic and can be prepared by wet process (Iier 1979; ECETOC 2006; IMA Europe 2014).

Nonporous Silica Nanoparticles

Nonporous silica nanoparticles or monodisperse silica spheres (diameters ranging from 50 to 2 μm) were firstly prepared by Stöber process (Stober and Fink 1968) in which tetraalkoxysilane was added to an excess amount of water containing a low molar-mass alcohol and ammonia. These particles are porous or nonporous. The pores are not some random accidents but an inherent property of them (Van Blaaderm et al. 1992; Xia et al. 2000). Synthesis methods based on the type of silicate ester, alcohol, volume ratios, and reaction condition were developed in order to control the size, shape, and surface properties (Zhang et al. 2003; Xia et al. 2000; Tang and Cheng 2013). Biomedical applications of monodispersed silica spheres for therapy and diagnosis are categorized based on the different active cargoes delivered by silica NPs: drug delivery for small molecule drugs, proteins, or photosensitizers; gene delivery; and molecular imaging by incorporating different contrast agents. Nonporous silica NPs can deliver cargoes through encapsulation or conjugation (Tang and Cheng 2013).

Mesoporous Silica Nanoparticles (MSNs)

Mesoporous silica nanoparticles, characterized by their mesopores (2–50 nm pore size), are widely used for delivery of active payloads based on

physical or chemical adsorption. They have been synthesized as ordered or hollow/rattle-type mesoporous silica structures. Ordered mesoporous silica nanoparticles with uniform pore size and a long-range ordered pore structure were first reported in the early 1990s using surfactants as structure-directing agents (SDAs) (Kresge et al. 1992). Size, morphology, pore size, and structure of MSNs can be rationally designed, and the synthesis process can be freely controlled (Wan and Zhao 2007; Hoffman et al. 2006; Slowing et al. 2010; Garcia-Bennett 2011; Tang et al. 2012). With the abundant availability of various surfactants and a deep understanding of sol–gel chemistry, ordered MSNs with different structures as MCM, SBA, MSU, KIT-1, and FSM have been developed. Until now most research on drug delivery and cancer therapy applications of ordered MSNs are based on MCM-41, MCM-48, and SBA-15 (Tang et al. 2012). Lack of toxicity of various ordered mesoporous silica has been deduced from both in vivo and in vitro studies (Garcia-Bennett 2011; Vallet-Regi et al. 2007; Chen et al. 2013). Hollow/rattle-type mesoporous silica with interstitial hollow space and mesoporous shell has low density and high specific area, which are ideal as new-generation drug delivery systems with extraordinarily high loading capacity. Different synthesis methods (by tuning the composition and concentration of surfactants during synthesis) for preparing hollow and rattle type with various sizes and particle morphology have been reported. Surface chemistry plays a key role in the cellular interactions and toxicity (Tang et al. 2012). They have been actively explored for enzyme immobilization, confined-space catalysis, and acoustic, thermal, and electrical insulation (Lou et al. 2008; Liu et al. 2011).

Silica Host for Other NPs

Silica can be used as a host material for other types of functional NPs (e.g., gold NPs, QDs, and iron oxide NPs) to form hybrid NPs. This important class of silica-based hybrid nanomedicines has been thoroughly reviewed by Piao group (2008). Ultrasmall multimodal silica nanoparticles

(Cornell dots, C dots) have been FDA approved for the first in-human clinical trial for targeted diagnostics of advanced melanoma (Benezra et al. 2011; Friedman 2011).

3 Percutaneous Penetration of Silica Nanoparticles

The skin, a unique barrier composed of several highly organized and heterogeneous layers, also includes a number of appendages such as hair follicles and sweat and sebaceous glands. It is composed of three layers from the outside to inside: epidermis, dermis, and hypodermis. However, from a penetration perspective, epidermis and dermis are the most important. The outermost layer of the epidermis is the *stratum corneum* (SC), to which the main barrier function of the skin is attributed (Bouwstraa et al. 2003; Prausnitz et al. 2012). Four pathways of penetration across the skin have been identified depending on physicochemical properties of the compound: intercellular, transcellular, and two transappendageal – through hair follicles and sweat glands (Scheuplein 1967). Simplified representation of the skin and routes of penetration

are shown in Fig. 1. Percutaneous absorption, a dynamic process, has many components with which a penetrant interacts before possibly gaining systemic access. Accurate assessment of nanoparticle penetration is challenging, with results dependent on ten parameters of percutaneous penetration: (1) physiochemical properties of nanoparticle; (2) vehicle effects; (3) surface area, dose, duration, and frequency of exposure; (4) distribution; (5) sub-anatomical pathways (skin appendages); (6) skin surface conditions; (7) additional factors of skin penetration and permeation; (8) loss from skin surface, exfoliation, and wash effect; (9) elimination and photochemical transformation; and (10) the method of determining absorption and toxicity, which is of high relevance, too. These are issues considered from the perspective of nanoparticles and the potential risks of dermal exposure. Understanding the potential for silica nanoparticle dermal penetration and possible toxicological outcomes is of great importance (Ngo et al. 2012). The following passages overview experiments related to transcutaneously applied silica nanoparticles based on the relevant properties which affect percutaneous penetration. Summary of the literature data is in Table 2.

Fig. 1 Simplified representation of the skin and routes of penetration

Table 2 Summary of literature data on physicochemistry, toxicity, and the percutaneous penetration of silica nanoparticles (SNPs)

	Research question	Study type	Results	Author (year)	
Physicochemical properties of penetrant	SNPs (7, 10–20 nm)	In vitro:	SNPs (7, 10–20 nm) reduced cell viabilities of CHKs in a dose-dependent manner	Park et al. 2010	
	Cytotoxic effect	Human keratinocyte cell line HaCaT	No irritation (SNP; 500 µg/ml)		
	Acute cutaneous toxicity	Human skin equivalent model (HSEM)	No acute cutaneous irritation		
	Skin irritation	In vivo: rabbit; Draize test			
	SNPs (20, 100 nm); negatively charged (NC), weakly negatively charged (WNC)	In vitro:	NC-SNP (20 nm), more toxic than NC-SNP (100 nm)	Park et al. 2013	
	Cytotoxicity	Human keratinocyte cell line HaCaT	NC-SNP (20 nm) more toxic than WNC-SNP (20 nm)		
	ROS generation	Intercellular ROS	No irritation		
	Skin irritation	EpiDerm skin irritation on human skin equivalent model	No phototoxicity		
	Skin phototoxicity	3T3 NRU phototoxicity test in murine 3T3 fibroblast cell	No sensitization		
	Skin sensitization	In vivo: mouse; local lymph node assay (LLNA)			
	SNPs (70, 300, 1,000 nm)	In vitro:			SNPs (70 nm); elevated level of ROS, DNA damage
	Zeta potentials:	LDH release assay	Endocytosis involved in SNP70-mediated cellular effects		Nabeshi et al. 2011a
	SNP-70, -21.6 ± 4.5 mV	Human keratinocyte cell line HaCaT			
SNP-300, -31.3 ± 6.5 mV					
SNP-1,000, -37.7 ± 4.6 mV					
ROS generation; DNA damage					
SNPs (42 ± 3 nm to 291 ± 9); positive and negative surface charges	In vitro: human keratinocyte cell line HaCaT, dendritic cells	Positively charged functionalization of SNP enhanced in vitro cellular uptake	Rancan et al. 2012		
Zeta potentials:	In vivo: cyanoacrylate skin surface stripping (CSSS)	Particles taken up by skin cells in a size-dependent manner			
SNP-42, -22 ± 3 mV		SNP (42 ± 3 nm) found in epidermal and dendritic cells			

(continued)

Table 2 (continued)

	Research question	Study type	Results	Author (year)
	SNP-75, -45 ± 4 mV		SNP (>75 nm) penetration blocked by human skin	
	SNP-200, -56 ± 5 mV			
	SNP-300, -48 ± 2 mV			
	Cellular uptake			
	Skin penetration			
	SNPs (30, 48, 118, 535 nm)	In vitro: mouse keratinocytes HEL-30	All SNP sizes were taken up into the cell, localized into the cytoplasm	Yu et al. 2009
	Cellular uptake, localization	LDH release assay	SNPs 30, 48 nm (100 μ g/mL), more toxic than 118, 535 nm particles	
	ROS formation		ROS formation did not show any significant change between controls and the exposed cells	
	Cytotoxicity		LDH leakage was dose- and size-dependent with exposure to 30, 48 nm SNPs No LDH leakage for either 118 or 535 nm SNPs	
	Fluorescent nonporous SiO ₂ (10–200 nm); different charges	In vitro: normal human dermal fibroblasts	Smallest particles; high, fast cytotoxicity	Quignard et al. 2012
	Zeta potentials:		Genotoxic effects for negatively charged colloids (10 nm)	
	SNP-40, 56 ± 5 mV			
	SNP-200, 50 ± 4 mV			
	SNP- +10, 42 ± 4 mV			
	SNP- -10, -18 ± 4 mV			
	Cytotoxicity			
	Genotoxicity			
	Monodispersed SNPs (80, 500 nm)	In vitro: normal human dermal fibroblasts	SNP (80 nm) more strongly affects cell viability, mitochondrial membrane potential	Zhang et al. 2010
	Zeta potentials:		Both particles internalized into fibroblasts within a short time	
	SNP-80, -5.2 ± 0.2 mV		Cell adhesion, migration affected by uptake of SNPs regardless of size	
	SNP-500, -9.8 ± 1.2 mV			
	In culture medium with 10 % FBS			
	Cytotoxicity, cellular uptake			
	SNPs (30, 70, 100, 300, 1,000 nm)	In vivo: mouse	SNP (different sizes) penetrated skin barrier, induced various immunological effects, allergic diseases; AD	Hirai et al. 2012; Takahashi et al. 2013

(continued)

Table 2 (continued)

	Research question	Study type	Results	Author (year)
	Zeta potentials:	Ear thickness measurements	By decreasing SNP size, IL-18 and TSLP production increased, led to systemic Th2 response, aggravation of AD-like skin lesions as induced by Dp antigen treatment	
	SNP-30, -14.0 ± 0.3 mV	Histopathological analysis		
	SNP-70, -19.5 ± 1.0 mV			
	SNP-100, -24.3 ± 0.5 mV			
	SNP-300, -25.8 ± 0.7 mV			
	SNP-1,000, -33.2 ± 1.4 mV			
	Skin penetration			
	Skin allergic disease			
	SNP coated with bifunctional methoxy-terminated and PEG (7 nm)	In vivo: mouse, M21 melanoma xenograft mouse	Specific tumor targeting	Benezra et al. 2011
	Effect on tumor		High-affinity/avidity binding	
			Favorable tumor-to-blood residence time ratios	
			Enhanced tumor-selective	
			Longer-term pharmacokinetic clearance	
	Functionalized mesoporous silica (FMS; 30 nm) bound to monoclonal antibody (mAb) to CTLA4	In vivo: mouse established melanomas derived from SC injection of cells from the SW1 clone	More antitumor activity of FMS-anti-CTLA4 than that of anti-CTLA4 alone	Lei et al. 2010
	Antitumor activity		No toxicity	
	Release kinetics			
Vehicle effect	Dermal delivery of silica microparticles (3 μ m) in water and in 65 % ethanolic <i>Spilanthes</i> extract	Ex vivo: percutaneous absorption human skin	SNP (3 μ m) penetrated living epidermis	Boonen et al. 2011
	Skin penetration		By formulating in 65 % ethanolic medium, reached dermis	
	Dermal delivery of lipophilic fluorescent probe: all- <i>trans</i> -retinol-acridine orange 10-nonyl bromide (AONB) using SNP coating of negatively charged lecithin and positively charged oleylamine	Ex vivo: percutaneous absorption porcine skin	Increased skin retention and depth of penetration to upper dermis for all- <i>trans</i> -retinol-AONB	Ghouchi-Eskandar et al. 2009a
	Dermal delivery of all- <i>trans</i> -retinol by SNP-coated submicron oil-in-water emulsions	Ex vivo: percutaneous absorption porcine skin	Sustained release, targeted dermal delivery of all- <i>trans</i> -retinol from oil-in-water emulsions	Ghouchi-Eskandar et al. 2009b

Table 2 (continued)

	Research question	Study type	Results	Author (year)
	Dermal delivery of quercetin using lipid nanoparticles and colloidal silica	In vivo: percutaneous absorption human skin; tape stripping	Increased diffusion down to <i>stratum corneum</i>	Scalia et al. 2013
	Dermal delivery of quercetin using MCM-41 (plain or octyl-functionalized)	In vitro: DPPH assay	Increased efficiency of quercetin encapsulated by MCM-41	Berlier et al. 2013a
	Dermal delivery of rutin using NH ₂ -MCM-41	In vitro:	Greater accumulation in porcine skin	Berlier et al. 2013b
	Diffusion	DPPH assay	Maintained antioxidant properties	
	Antiradical activity	Ex vivo: percutaneous absorption porcine skin	Better activity and photostability	
	UV irradiation			
	Skin permeation			
	Dermal delivery of Trolox using MCM-41	In vitro:	Slower release of Trolox by inclusion in MCM-41	Gastaldi et al. 2012
	Photodegradation	Release	Increased photostability for complex particularly in O/W emulsion	
	Antiradical activity	DPPH assay	Maintained radical scavenging activity of Trolox	
	Dermal delivery of octyl methoxycinnamate (OMC) using MCM-41 formulated in Emulgel	In vitro: release	Increased release rate in Emulgel	Ambrogi et al. 2013
	Release		Broader photoprotection range, improvement of sunscreen photostability	
	Photostability			
	Hyaluronidase (Hyal) immobilized on SNP as adjuvants of carboplatin (CP)	In vivo: mouse bearing A375 human melanoma	Enhanced tumor volume reduction with SNP-Hyal compared to non-immobilized Hyal	Scodeller et al. 2013
	Antitumor			
	Dermal delivery of caffeine using silica nanocomposites	Ex vivo: percutaneous absorption of pig skin	Reduced, delayed permeation	Pilloni et al. 2013
	Skin permeation studies			
Surface area, dose, duration, and frequency of exposure	Skin penetration of consumers exposed to spray atmosphere of SAS nanoparticles	Modeling of consumer exposure	Skin penetration was unlikely	Michel et al. 2013
		Modeling of environmental exposure	Low toxicity	
			No systemic exposure	
Distribution	SNPs (70, 300, 1,000 nm)	In vitro:	Mutagenic activity in vitro	Nabeshi et al. 2011b
	Zeta potentials:	Human keratinocyte cell line HaCaT		
	SNP-70, -21.6 ± 4.5 mV	DNA damage (Comet assay)		
	SNP-300, -31.3 ± 6.5 mV	Mutagenicity assay (Ames test)

	SNP-1,000, -37.7 ± 4.6 mV	In vivo: mice BALB/c		
	Cellular localization			
	Cytotoxicity			
	Skin penetration			
	Systemic effects			
	SNP (70 nm)	In vivo: mouse	SNPs (70 nm) observed in keratinocyte layer, Langerhans cells, and dermis of mouse	Tsunoda et al. 2011
	(No information for Zeta potential or charge)		After 3 days, SNP detected in cervical lymph node cells	
	Skin penetration			
	Systemic effect			
Sub-anatomical pathways (skin appendages)	Silica oxide (300–1,000 nm)	In vitro: human terminal and vellus hairs from Caucasian males, porcine hair follicle	Best follicle penetration of SNP 646 nm in size	Lademann et al. 2009
	(No information for Zeta potential or charge)		Optimal particle size corresponded to structure of hair and follicles	
	Influence of hair cuticula thickness on penetration into hair follicles			
Skin surface conditions	AHAPS-SiO ₂ (55 ± 6 nm)	In vivo: SKH1 mouse	Penetration of AHAPS-SiO ₂ through skin was not observed	Ostrowski et al. 2014
	(No information for Zeta potential or charge)		After subcutaneous injection, AHAPS-SiO ₂ were incorporated by macrophages, transported to regional lymph node	
	Skin penetration on intact skin, tape-stripped, inflamed skin		No adverse effects on cells, tissues	
	Subcutaneous injection			
Additional factors of skin penetration and permeation	No research			
Loss from skin surface, exfoliation, and wash effect	No research			
Elimination and photochemical transformation	No research			
Method of determining absorption and toxicity	No research			

3.1 Physiochemical Properties of Silica Nanoparticles

Physiochemical properties of the penetrant may be the most pervasive factor influencing penetration since they influence interactions with the skin components (cell layers, cell membranes, lipids) and the extent to which nanoparticles penetrate or release associated ingredients into the skin. Physiochemical properties influencing nanoparticle penetration resemble the major factors influencing the penetration of chemicals across the skin. It is generally viewed that nanoparticle size, agglomeration/aggregation state, shape, crystal structure, chemical composition, surface chemistry, surface charge, porosity, dose, exposure time, and applied formulation are major factors which influence nanoparticle dermal penetration and toxicity (Poland et al. 2013; Thurn et al. 2007; Ngo et al. 2012).

There exist experiments which relate the physicochemical properties of silica nanoparticles to their percutaneous penetration (Table 2).

The relationship between different sizes of SNP ranging from 291 ± 9 to 42 ± 3 nm (single-unit size) with positive and negative surface charges and skin penetration has recently been examined.

Despite partial silica particle aggregation occurring after transfer in physiological media, particles were taken up by skin cells in a size-dependent manner, and SNPs above 75 nm in size did not penetrate human skin. Functionalization of the particle surface with positively charged groups enhanced *in vitro* cellular uptake, despite the fact that a large fraction of the positively charged particles were aggregated leading to lower internalization ratios especially by primary skin cells (Rancan et al. 2012).

Hair follicles represent important shunt routes into the skin for drugs and chemicals (Oberg et al. 2008). *In vitro* studies of nanoparticles sized from 122 to 1,000 nm suggested that particles in the size range of 400–700 nm had optimal penetration depth in porcine hair follicles compared to those smaller or larger. Depending on nanoparticle size, different depths and thereby

different target structures within the hair follicle can be reached (Patzelt et al. 2011). For single silica oxide particles ranging in size from 300 to 1,000 nm, follicle penetration depth increased between 300 and 646 nm-sized particles and then decreased for particles larger than 646 nm (Lademann et al. 2009). It can be concluded that the optimal particle size for the deepest penetration corresponds approximately to the rough surface structure of the hair.

Having overcome the skin barrier, amorphous silica nanoparticles (SNPs) can induce various immunological effects and allergic diseases such as AD as intradermal injection of mite antigen (Dp) plus silica particles (diameter of single-unit size: 30–1,000 nm) into the ear of NC/Nga mice resulted in AD-like skin lesions. DP-induced sensitization and signs of AD were aggravated by SNP in a size-dependent manner compared to that of Dp alone. Clinical signs were correlated with excessive induction of total IgE and Dp-specific IgE and were associated with induction of IL-18 and thymic stromal lymphopoietin (TSLP) which led to systemic Th2 response in the skin lesions (Hirai et al. 2012; Takahashi et al. 2013; Table 2).

Park et al. (2013) studied cytotoxicity on keratinocytes and ROS generation by negatively charged NC and weakly negatively charged WNC-SNPs (20 and 100 nm in size). Smaller-sized NC-SNPs appeared more toxic than the larger sized (100 nm), and NC-SNPs (20 nm) showed more toxicity than the respective WNC-SNPs (20 nm). Skin irritation and contact sensitization were not detected (Park et al. 2013). Compared to larger SNPs (single unit 300, 1,000 nm), the SNPs of 70 nm diameter induced an elevated level of reactive oxygen species (ROS), leading to DNA damage of HaCaT cells, a spontaneously transformed human keratinocyte cell line (Nabeshi et al. 2011a). Proliferation of HaCaT cells was inhibited in a dose- and size-dependent manner (Nabeshi et al. 2011b). Viability and mitochondrial membrane potential of human dermal fibroblasts were more strongly affected by SNPs 80 nm in size, but adhesion and migration ability of the fibroblasts were impaired by SNPs, single units being 80 and

500 nm in diameter (Zhang et al. 2010). Moreover, cellular uptake and localization of amorphous SNPs (30, 48, 118, and 535 nm) in mouse keratinocytes (HEL-30) appeared to be independent of particle size. Dose-dependent LDH leakage and significant cytotoxicity at high concentrations (100 $\mu\text{g}/\text{mL}$), however, were seen with exposure to 30 and 48 nm nanoparticles. No LDH leakage was observed for the larger nanoparticles. Redox potential of cells (GSH level) was reduced significantly only with SNP 30 nm in size at concentrations of 50 $\mu\text{g}/\text{mL}$ and higher (Yu et al. 2009). Fate of fluorescent nonporous SiO_2 nanoparticles (single-unit diameter: 10–200 nm) varying in charge (negative and positive) was studied in normal human dermal fibroblasts. Uptake of silica nanoparticles was determined by fluorescence spectroscopy and TEM. Largest particles did not impact on cellular function. Outside and inside the fibroblasts, extensive aggregation was seen with smaller SNPs, either negatively or positively charged. Small SNPs of either charge induced major detrimental effects on fibroblast viability, and exposure to negatively charged particles 10 nm in diameter resulted in genotoxic effects. Fluorescence reading revealed that positively charged silica nanoparticles (>40 nm) were taken as aggregates followed by a significant decrease in the size of the SNPs located in endocytic vesicles, and both colloidal and soluble species were released without impact on cellular function (Quignard et al. 2012). In summary, size and charge of amorphous silica nanoparticles are critical for biological effects, and particles below 100 nm in size are more toxic (Table 2).

In addition, particle surface area may play a crucial role in the toxicity of SNPs which can be related to their surface interfacing with the biological milieu (Elias et al. 2000; Waters et al. 2009; Napierska et al. 2010) and forming a protein corona. Even a minor surface modification can change biological effect, and surface functionalization, such as for binding of specific ligands, allow nanoparticle targeting of specific cell populations and subcellular components. Moreover, adsorbed proteins forming the corona can change the extent and depth of penetration as well

as cytotoxicity (Oberdörster et al. 2005). In order to target M21 melanomas in a xenograft mouse model, multimodal silica nanoparticles were coated with bifunctional methoxy-terminated polyethylene glycol (PEG) chains (~ 0.5 kDa; 7 nm). Neutral-charged PEG-functionalized SNPs were poorly uptaken by noncancer cells, and the bifunctional group enabled attachment of the integrin targeting RGDY peptide labeled with ^{124}I (Benezra et al. 2011). In another study, functionalized mesoporous silica (FMS) with a rigid, uniform, open nanopore geometry of tens of nanometers was used for loading of a monoclonal antibody (mAb) binding to CTLA4 – an immunoregulatory molecule overexpressed in melanoma (Leach et al. 1996). Protein spontaneously entrapped in FMS and release of the entrapped proteins from FMS were controlled based on the functional groups and pore sizes. This strategy enhanced inhibition of tumor growth compared to the free antibody given systemically (Lei et al. 2010; Table 2). Further study is needed to assess the effect of surface modification of nanoparticles on mAb penetration and toxicity following topical use as peptides which are rapidly degraded in human skin by proteinases (Do et al. 2014).

3.2 Vehicle Effects

One general approach to overcoming the barrier properties of the skin is to use penetration enhancers or nanoparticles that help promote drug diffusion through the *stratum corneum* to viable epidermis and dermis. Dermal absorption of a compound will be influenced by vehicle solubility and partitioning of the compound between vehicle and skin. Agents that are more soluble in an aqueous vehicle may tend towards limited absorption into the lipid-rich SC. Vehicle pH may influence the ionization state of the compound and the rate of partitioning into *stratum corneum* (Ngo et al. 2012). It also affects colloidal stability and agglomeration status which may alter penetration dynamics. Vehicle-dependent effects on penetration behavior of drugs following topical application have been widely

examined (Smith and Maibach 2006). There is also an increasing understanding of the effects of nanoparticles on penetration enhancement in general (Korting and Schäfer-Korting 2010; Alnasif et al. 2014).

Oil-based microemulsions, solvents or surfactants, referred to as penetration enhancers, accelerants, adjuvants, or absorption promoters, act by reducing drug binding and interactions with skin components (Ngo et al. 2012). For silica particles, skin penetration studies showed that silica microparticles (3 μm) could penetrate living epidermis and, when formulated in the 65 % ethanolic medium, even reach the dermis. This demonstrated the relevance of the vehicle in which silica microparticles were presented (Boonen et al. 2011).

Nanoemulsions are oil dispersed in water and have been used for penetration enhancement of hydrophilic and lipophilic substances. Nanoemulsions are transparent, and their small size and hydrophilic exterior may facilitate transport of active ingredients across the *stratum corneum* of the epidermis (Nohynek et al. 2007). Eskandar and coworkers investigated SNP-coated submicron oil-in-water emulsions for stabilization and skin penetration of lipophilic agents, retinol and a fluorescent dye, namely, acridine orange 10-nonyl bromide. Lecithin and oleylamine addition, respectively, were used for the induction of negative and positive charge to the emulsion. Both formulations improved retinol resistance towards UV-induced degradation, controlled release, and significantly enhanced the penetration of both agents into excised porcine skin compared to free agent used for control. With the positively charged formulation, penetration was even seen in the upper dermis without major penetration of the agents (Ghouchi-Eskandar et al. 2009a, b). Moreover, solid-state nanoparticle-coated emulsion prepared by freeze-drying significantly enhanced retinol stability (Ghouchi-Eskandar et al. 2012; Table 2).

Flavonoids such as quercetin and rutin are used in topical cosmetic and pharmaceutical products because of their antioxidant and radical scavenging properties, but their application is limited by their poor physicochemical stability. In human

volunteers, addition of colloidal silica (average particle diameter: 486 nm) to an emulsion significantly increased the quercetin penetration into *stratum corneum* to 26.7 ± 4.1 % of the applied dose, the enhancement being more marked in the deep *stratum corneum* sampled by tape stripping. Silica particles were detectable in the intermediate region of human *stratum corneum* and hence could act as a carrier for quercetin (Scalia et al. 2013). Mesoporous silica (MCM-41) has widely been proposed as a vehicle able to improve the penetration and performance of drugs. Complexes of quercetin with plain or octyl-functionalized MCM-41 were formed based on host/guest interaction due to the formation of Si-OH/quercetin hydrogen-bonded adducts and strengthened by octyl functionalization. Immobilization of quercetin particularly on octyl-functionalized silica increased stability without undermining the antioxidant efficacy of quercetin opening the way for an innovative employment of mesoporous composite materials in the skin care field and topical products (Berlier et al. 2013a). Moreover, immobilization of rutin in the pores of in aminopropyl silica (NH₂-MCM-41) stabilized the agent against UV degradation and enhanced the accumulation in porcine skin *ex vivo* while maintaining rutin's antioxidant properties (Berlier et al. 2013b). Octyl methoxycinnamate is an efficient and widely used UV filter yet shows light susceptibility (photoinstability) and potential skin permeation which is not wanted with sunscreen products. For improvement of photostability and safety, octyl methoxycinnamate was entrapped in the pores of the mesoporous silicate MCM-41, pore openings were plugged, and the loaded nanoparticles incorporated into a lipid-based cosmetic formulation allowed a broader photoprotection range and remarkable improvement of sunscreen photostability (Ambrogi et al. 2013). In addition, inclusion of Trolox (a water-soluble analog of vitamin E) in the MCM-41 matrix retarded *in vitro* release and increased photostability for complexed agent particularly in O/W emulsion. Importantly, the radical scavenging activity of Trolox was maintained after immobilization (Gastaldi et al. 2012; Table 2).

Recently, hyaluronidase (degrading enzyme of hyaluronic acid) was immobilized on 250 nm SNPs as adjuvants of carboplatin (CP) and peritumorally injected in A375 human melanoma-bearing mice. Enzyme activity was maintained, SNP-immobilized hyaluronidase cleaved hyaluronic acid overexpressed by the tumor cells, and tumor volume was significantly more declined compared to non-immobilized Hyal used for comparison (Scodeller et al. 2013; Table 2).

In cases where skin penetration is not desired, penetration reducers can inhibit the compound from entering the systemic circulation (Trommer and Neubert 2006). Barrier-enhancing emulsions have reduced the penetration of exogenous proteins into the hair follicles to varying degrees (Meinke et al. 2011). Caffeine loading to a silica nanocomposite resulting in the formulation of both core shell and multilayered caffeine-silica structures reduced and delayed caffeine permeation of pig skin in comparison with the reference gel, independently from the amount of the tested formulation (Pilloni et al. 2013; Table 2).

3.3 Surface Area, Dose, Duration, and Frequency of Exposure

Following skin contact, amount of chemical absorbed, which is often expressed as dose per area (cm^2), depends greatly on several conditions of exposure (Ngo et al. 2012). Increasing surface area over which a chemical is in contact will increase absorption. Percent absorption also depends upon the concentration and dose applied per unit area. For many compounds, percent absorption at relatively high concentrations is inversely related to applied dose (Wester et al. 1980). In other words, percent absorbed increases as skin loading decreases, and the function is nonlinear. This is attributed to saturation of the absorptive skin capacity. Despite a decrease in efficiency of absorption, in terms of percent absorption, a continued increase in total penetration, in mass, can be observed with increased dose. Similarly, with multiple applications and frequency of exposures, the skin may become

saturated and resist penetration from subsequent doses (Wester et al. 1977; Wester et al. 1980). Moreover, dermal penetration tends to increase with duration of contact or exposure, and compounds retained in the skin layers may become released available after the contact material had been removed from the skin surface. Experimental protocols often set periods of exposure and sample collection that may not be relevant. It is often necessary to extrapolate long-term exposure from short-term data. In general, total absorption of a compound appears to be linearly correlated with the amount of penetration into the *stratum corneum* observed shortly after application (Rougier et al. 1987). While many studies investigate dermal absorption of a compound following a single dose, multiple or repeated exposures are more clinically relevant to real life (Ngo et al. 2012). Synthetic amorphous silicon dioxide (SiO_2) nanoparticles have been widely used in a glass cleaner formulation (spray application). Workers and consumers are frequently exposed to it during production and used as spray application. Percutaneous penetration of SiO_2 is unlikely as the hydrophilic character of uncoated SiO_2 does not favor skin penetration (Michel et al. 2013; Table 2). Engineered nanomaterials are incorporated into textile products; nanotextiles include nanosilica, nanolayered silica, nano-silver, nano- TiO_2 , nano- ZnO , nano-alumina (Al_2O_3), carbon black, and carbon nanotubes (Som et al. 2011). These nanomaterials are used to improve textile properties such as wrinkle resistance, water repellency, antimicrobial and antistatic properties, and UV and flammability resistance. Since there is continuous and intimate contact between clothing and skin, transfer and absorption of nanomaterials under these conditions should be considered (Ngo et al. 2012).

3.4 Distribution

Once the *stratum corneum* has been breached, interactions with the deeper components of the permeability barrier and finally access to the vascular system and thus systemic availability will

again depend on the physicochemical properties of the penetrant in question (Menczel and Maibach 1970). Perfusion of the dermis promotes absorption and creates a sink for chemicals that have traversed the epidermis. Subsequent distribution of a chemical to target sites or organs within the body will also depend on blood flow. By reducing local blood flow, such as with the use of a vasoconstrictor, systemic absorption can be inhibited. At the same time, drug penetration into deeper tissue layers adjacent to the application site may be enhanced by reduced blood flow (Higaki et al. 2005). Local and systemic toxicity following dermal absorption of drugs or chemicals across the skin has been widely evaluated (Alikhan and Maibach 2011). Proposed toxic effects of nanoparticles entering the systemic circulation include perturbation of the immune system, as well as other organ systems.

Once more, size and surface physicochemical properties of silica nanoparticles contribute decisively to their biological effects. Following 3 days of topical application to mouse, SNPs (70 nm in size) were observed in keratinocyte layer including the Langerhans cells, dermis, and lymph node (Tsunoda 2011). Application of SNP (single-unit size) to the ears of mice (250 µg/ear/day) for 28 days resulted in particles being detected in the skin, regional lymph nodes, and parenchymal hepatocytes present in the liver, cerebral cortex, and hippocampus (Nabeshi et al. 2011b; Table 2).

Yet analysis was based upon murine skin and TEM analysis with no confirmation that the electron-dense regions were, in fact, particles of interest. More experimental data – including those generated in human skin – is needed to confirm the results.

3.5 Sub-anatomical Pathways (Skin Appendages)

Although the *stratum corneum* plays a critical role in the function of permeability barrier, there are many components with which a penetrant interacts before entering the body. In recent years, it

has been suggested that skin appendages represent important shunt routes into skin for drugs and chemicals. Skin appendages include hair follicles, sebaceous glands, and sweat glands, which originate in the dermis (Ngo et al. 2012; Poland et al. 2013). Particle size influences the penetration depth, with different follicle structures interacting with particles of particular size (Patzelt et al. 2011; Toll et al. 2004; Vogt et al. 2006). For silica oxide particles ranging in size from 300 to 1,000 nm, follicle penetration depth increased up to about 650 nm-sized particles and then decreased for larger particles. It can be suggested that the optimal particle size for the deepest penetration corresponded approximately to the structure of hair and follicles (Lademann et al. 2009; Table 2).

3.6 Skin Surface Condition

Surface conditions including hydration, occlusion, pH, and temperature are the factors which affect skin absorption (Ngo et al. 2010). The degree of interactions with the different skin components determines the time and the chemical residues that persist or accumulate in the skin as well as the time required to traverse the different layers and enter the systemic circulation (Jacobi et al. 2007; Lademann et al. 2006).

Importantly, structure and integrity of skin will be compromised by damage or disease. Chemical or physical skin insults may cause change in the skin's barrier function, resulting in the increased permeability of numerous compounds (Ngo et al. 2010). However, a recent study on the penetration of *N*-(6-aminohexyl)-aminopropyltrimethoxysilane nanoparticles (55 ± 6 nm diameter) on intact, tape-stripped, or on inflamed skin of SKH1 mice with induced allergic contact dermatitis showed no penetration of the rigid particles through the skin regardless of the kind of barrier disruption. After subcutaneous injection, however, the nanoparticles were incorporated by macrophages and transported to the regional lymph node; adverse effects were not detected (Ostrowski et al. 2014).

3.7 Additional Factors of Skin Penetration and Permeation

The extent of dermal absorption varies from one body region to another and partially attributed to skin thickness and the number of cell layers in the SC (Ngo et al. 2010). Besides regional variation, population variability may be of relevance. Variability in skin properties reported for different groups in human population provides a potential basis for differences in the rate and extent of drug absorption between the various skin types (Mangelsdorf et al. 2006).

3.8 Loss from Skin Surface, Exfoliation, and Wash Effect

Persistence of a chemical on the skin will depend on its resistance to removal or inactivation which depends on the mechanisms of removal of nanoparticles from the skin surface including volatilization, sweating, washing, friction with or transfer to other surfaces, and exfoliation (Ngo et al. 2010). Washing influences the absorption of nanoparticles into the skin. Washing and rubbing an area of substance-treated skin can remove part of the dose. Washing the application site between doses, a common step in experimental protocols of dermal absorption studies, may enhance percutaneous absorption (Ngo et al. 2010).

3.9 Elimination and Photochemical Transformation

The skin is capable of a wide range of metabolic functions and is recognized as a significant site of biotransformation and photochemical transformation. Cutaneous metabolism and photochemical transformation play essential role in absorption of compounds by transforming them into metabolites (Götz et al. 2012; Jäckh et al. 2011; Bätz et al. 2013; Ngo et al. 2010). Depending on the compound, elimination may or may not be in proportion to the dose absorbed (Marzulli and Maibach 1975; Nigg and Stamper 1989).

3.10 Method of Determining Absorption and Toxicity

When evaluating dermal data, differences in experimental parameters such as animal species, anatomical site, skin sample preparation, skin disease presence, role of penetration enhancers, and exposure conditions affect the interpretation and comparisons between studies. It is important to control experimental condition in a systematic way (Ngo et al. 2012).

Only recently, a predictive mathematical approach has been described which allows to take formulation effects into consideration, too (Guth et al. 2014). Yet applicability for nanoparticle-based formulations requires evaluation.

For silica nanoparticles, present experimental data focus on physicochemical properties; vehicle effects; surface area, dose, duration, and frequency of exposure; distribution; and sub-anatomical pathways. Information regarding physicochemical properties of SNPs is not sufficient to draw a robust conclusion for their skin penetration; vehicle effects need more study; the experiments on dose relationships, exposure duration, surface area, frequency, and sub-anatomical pathways are minimal; and no information exists on the other parameters. More experimental data are needed to understand factors which affect the percutaneous penetration of silica nanoparticles. Research gaps in percutaneous penetration of silica nanoparticles (SNPs) are in Tables 2 and 3.

4 Skin Absorption and Toxicity of Silica Nanoparticles

Penetration of a material through the skin barrier can trigger numerous toxic effects, both local and systemic. Compounds that reach the *stratum granulosum*, for example, can interact with the viable keratinocytes and trigger an inflammatory reaction. Compounds that reach the *stratum spinosum* can interact with Langerhans cells (from the immune system) and initiate an allergic reaction responsible for phenomenon such as contact dermatitis. Skin cancer may also be induced

Table 3 Research gaps in percutaneous penetration of silica nanoparticles (SNPs)

10 Factors affecting percutaneous penetration of nanoparticles (Ngo et al. 2012)		Researches on silica nanoparticles (SNPs)
1	Physiochemical properties of the nanoparticle	+
2	Vehicle effects	+
3	Surface area, dose, duration, and frequency of exposure	Minimal research
4	Distribution	Minimal research
5	Sub-anatomical pathways (skin appendages)	Minimal research
6	Skin surface conditions	Minimal research
7	Additional factors of skin penetration and permeation	No research
8	Loss from skin surface, exfoliation, and wash effect	No research
9	Elimination and photochemical transformation	No research
10	Method of determining absorption and toxicity	No research

following dermal exposure depending on the chemical and its ability to penetrate skin and reach the viable layers, where it can potentially transform normal cells or enhance proliferation of transformed cells. All of these effects can be grouped as dermal toxicity. However, when a compound manages to cross the epidermis, it becomes accessible to dermis and potentially accessible to the systemic circulatory and lymphatic systems. As a result such compounds can cause damage in distal organs, by translocation through the circulatory system or by triggering systemic reactions. These can lead to a wide range of toxic effects and disease such as systemic inflammation, organ toxicity, and cancer (Poland et al. 2013; Raju and Rom 1998; Napierska et al. 2010; Crosera et al. 2009). Toxicity of NPs can depend on not only the material itself but also the administration route to the living body. In particular, intraperitoneal and intravenous injection may lead to fatal outcomes (Hudson et al. 2008). I

It is important to evaluate safety of nanoparticles using specific toxicological studies prior to a wider implementation. General toxicological principles of compounds are discussed by Hayes (Hayes and Kruger 2014). Regulatory aspects of exposure to toxic substances are specified by Wilhelm (Wilhelm et al. 2012). There remains the need to increase the predictability of current nanoparticle toxicity testing by transitioning from qualitative, descriptive animal testing to quantitative, mechanistic, and pathway-based toxicity testing in human cells or cell lines using high-throughput approaches. Standard methods and platform should be used to investigate

the numerous biophysicochemical interactions at the nano-/bio-interface (Nel et al. 2013). Classical investigation protocols must be adapted and re-standardized to the new nanosized compounds. Cell cultures (Bernstein and Vaughan 1999), Franz diffusion cells (Franz 1975), tape stripping (Escobar-Chávez et al. 2008), and human skin implantations on animals are powerful tools to study particle interaction with human dermal tissue. However, new methods and new technique applications have to be developed (Monteiro-Riviere and Inman 2006; SCCP 2007). In particular microscopy techniques like coherent anti-Stokes Raman scattering (CARS), transmission electron microscopy (TEM), confocal laser scanning microscope (CLSM), fluorescence-lifetime imaging microscopy (FLIM), near-infrared II fluorescence, and other ion beam techniques are necessary to visualize nanoparticles into biological structures (Alnasif et al. 2014; Moger et al. 2008; Welsher et al. 2011).

Because silica nanoparticles are widely used nanomaterials, chances of being exposed to SNPs in daily life are high. There are major concerns about the biocompatibility, toxicity, in vivo biodistribution, and efficacy of SNPs of various particle sizes. While some data reports that silica particles are biocompatible, nontoxic, and stable (ECETOC 2006; OECD 2004; Butz 2009; Gamer et al. 2006; Mavon et al. 2007; Pfluecker et al. 2001; Fruijtier-Polloth et al. 2012; Low et al. 2009; Rosenholm et al. 2011; Michel et al. 2013), others show that the uptake of nanoparticles by cells may eventually lead to perturbation of cellular pathways and induce toxicity (Hirai et al. 2012;

Park et al. 2010, 2013; Quignard et al. 2012; Nabeshi et al. 2011a, b; Takahashi et al. 2013; Yu et al. 2009). Toxicity of silica NPs depends strongly on their physicochemical properties such as particle size, shape, porosity, chemical purity, and solubility (Yu et al. 2011, 2012; Waters et al. 2009). Particle surface area play a crucial role in the toxicity of silica (Elias et al. 2000; Zhang et al. 2010) which can be related to their surface interfacing with the biological milieu rather than to particle size or shape (Fenoglio et al. 2000). In vivo toxicology data associated with the nanoparticles has led to persistent and valid safety concerns prompting particle-design modifications including size, composition, and surface chemistry (Schipper et al. 2009) and need for rapid clearance from the body within a reasonable timescale (Choi et al. 2010).

5 Conclusions

Loading to SNPs can improve physicochemical stability of labile drugs and to adjust the release profile and skin penetration. Yet, the results of this literature survey show that the data related to toxicity of SNPs are few and are insufficient to clearly identify and characterize the health hazards SNPs may pose, and defining the appropriate conditions for safe use of these materials is currently not possible.

Accurate assessment of nanoparticle penetration depends on ten parameters of percutaneous penetration. For silica nanoparticles, experimental data are focused on six parameters, and there is no data on the other parameters (Tables 2 and 3). Moreover, only results from short-term in vivo studies of silica nanoparticles are available while data following chronic dermal effects are still to be awaited. In addition, relationships among SNPs, physicochemical properties, absorbency, localization, and biological responses are not well understood. Besides relative lack of information on the safety or hazards of SNPs, often conflicting evidence is emerging in the literature as a result of a general lack of standard procedures, as well as insufficient characterization of silica nanomaterials in biological systems.

Information is insufficient to clearly identify and characterize the health hazards SNPs may pose, and defining the appropriate conditions for safe use of these materials is currently not possible.

There are gaps in understanding human and environmental risk that manufactured silica nanoparticles may pose for those occupationally exposed and for consumers. There is need for assessing the health and environmental impacts, the nanoparticle life cycle, the human exposure routes, the behavior of nanoparticles in the body, and the risk for workers. In particular, dermal absorption and skin penetration of nanoparticles need an evaluation by the most advanced analytical techniques. Understanding the behavior of NPs when they contact the skin surface and their interaction with the different skin layers would ultimately lead to the design of the “ideal” carrier or diagnostic agent in terms of the physicochemical parameters of the NPs, in addition to other factors (e.g., formulation and environmental factors) influencing skin penetration of NPs.

1 Introduction

Hydration of the skin is often achieved through occlusion. Occlusion refers to the impervious-to-water covering of the skin directly or indirectly by various means, including tape, gloves, impermeable dressings, and even transdermal devices (Kligman 1996). Certain topical vehicles, e.g., petrolatum and paraffin, contain fats and/or polymer oils that may generate occlusive effects by reducing water loss (Berardesca and Maibach 1988). The epidermis of healthy skin provides an efficient barrier against the infiltration of exogenous and potentially harmful substances, and the stratum corneum typically has a water content of 10–20 % by weight. Skin occlusion increases the water content of the stratum corneum up to 50 %, and even a short time occlusion (30 min) results in significantly increased hydration (Bucks et al. 1991; Bucks and Maibach 1999a; Ryatt et al. 1986). By increasing stratum corneum hydration, occlusion influences percutaneous absorption by altering the partitioning between the chemical penetrant and the skin and swelling corneocytes and possibly altering the intercellular lipid phase organization, increasing skin surface

temperature, and increasing blood flow (Bucks and Maibach 1999a; Ryatt et al. 1986; Haftek et al. 1998).

In general, occlusion is widely utilized to enhance the penetration of applied drugs in clinical practice; however, occlusion does not increase the percutaneous absorption of all chemicals (Bucks et al. 1991; Bucks and Maibach 1999a). In fact, evidence suggests skin occlusion is more complex than previously thought as it can induce changes in epidermal lipid content, DNA synthesis, epidermal turnover, skin pH, epidermal morphology, sweat glands, and Langerhans cell stresses (Aly et al. 1978; Rajka et al. 1981; Faergemann et al. 1983; Alvarez et al. 1983; Eaglstein 1984; Mertz and Eaglstein 1984; Silverman et al. 1989; Agner and Serup 1993; Matsumura et al. 1995; Berardesca and Maibach 1996; Leow and Maibach 1997; Denda et al. 1998; Kömüves et al. 1999; Fluhr et al. 1999; Warner et al. 1999). This overview focuses on what effect occlusion has on the in vitro and in vivo percutaneous absorption of compounds of varying lipophilicities/hydrophilicities. As few cosmetic ingredients have been studied, other chemical classes noted here may provide guidance for the formulator.

2 Results of In Vitro Experiments

After examining the research articles generated by the search results, five original research articles were obtained that used in vitro occlusion models

and provided insight regarding the role of partition coefficients in predicting occlusion's effects on percutaneous penetration; articles that dealt with occlusion and percutaneous penetration but did not shed light on how the lipophilicity/hydrophilicity of a compound could affect occlusion efficacy were excluded. The log of the octanol-water partition coefficients (log Kow) reported here was taken from the publications cited, or they were taken from values obtained from The PubChem Project (<http://pubchem.ncbi.nlm.nih.gov/>) and LogKow, a databank of evaluated octanol-water partition coefficients (<http://logkow.cisti.nrc.ca/logkow/>).

Gummer investigated the in vitro percutaneous penetration of methanol and ethanol through full-thickness, excised guinea pig skin at varying volumes and under various occlusive conditions (Gummer and Maibach 1986). Though neither compound demonstrated an increase in penetration with increasing dose volume, they determined that occlusion significantly enhanced penetration ($p < 0.01$) when compared to nonocclusion (see Table 1). Also, the nature of the occlusive material greatly affected both the penetrated amounts of the compounds and the profiles of the amount penetrating per hour. Methanol showed both a greater penetration rate and a greater total penetration than ethanol even though both alcohols have similar octanol-water coefficients. The larger molecular size of ethanol may explain why it penetrated excised guinea pig skin more slowly.

Table 1 In vitro penetration of 14C-labeled methanol and ethanol through guinea pig skin. Occlusion-enhanced penetration of both chemicals compared to nonocclusion. *SD* standard deviation, *ER* enhancement ratio (penetration of occluded chemical divided by penetration of nonoccluded chemical under otherwise identical conditions including dosing) (Modified from Gummer and Maibach 1986)

Volume of alcohol (μL)	Occlusive device	Penetration: % of applied dose \pm SD	
		Methanol	Ethanol
50	None	0.48 \pm 0.09	0.94 \pm 0.14
100	None	1.33 \pm 0.30	0.38 \pm 0.04
200	None	1.40 \pm 0.07	0.29 \pm 0.01
100	Parafilm	13.2 \pm 2.7 (ER = 9.9 \pm 3.0)	8.10 \pm 0.43 (ER = 21 \pm 2.5)
100	Gel bond	34.8 \pm 1.8 (ER = 26 \pm 6.1)	23.5 \pm 1.6 (ER = 62 \pm 7.8)
100	Hill Top chamber	44.2 \pm 3.0 (ER = 33 \pm 7.8)	27.10 \pm 2.54 (ER = 71 \pm 10)

Treffel et al. compared the in vitro permeation profiles of two compounds with different physiochemical properties, citropten (lipophilic) and caffeine (amphiphilic), under occluded versus nonoccluded conditions over a 24-hour period using an in vitro model involving human abdominal skin (Treffel et al. 1992). The data demonstrated that occlusion increased the permeation of citropten (partition coefficient = 2.17) 1.6 times over nonoccluded conditions ($p < 0.05$), but occlusion did not enhance the permeation of caffeine (partition coefficient = 0.02). Their results bolster the idea that occlusion does not enhance the percutaneous penetration of all compounds, especially hydrophilic compounds (Bucks et al. 1991).

Roper et al. determined the percutaneous absorption of 2-phenoxyethanol (lipophilic compound; $\log Kow = 1.16$) applied in methanol through nonoccluded rat and human skin in vitro in two diffusion cell systems over 24 h (Roper et al. 1997; Pomona College Medicinal Chemistry Project et al. 1987). Under nonoccluded conditions, 2-phenoxyethanol was greatly lost by evaporation, but once occlusion was applied, evaporation was decreased and total absorption increased.

Taylor et al. studied the effect occlusion exerts upon the in vitro percutaneous penetration of the model penetrant linoleic acid ($\log Kow = 7.05$) dissolved in solvents of two different volatilities, ethanol and cyclomethicone (Taylor et al. 2002; D'Amboise and Hanai 1982). Using porcine skin, nonocclusion resulted in a greater skin concentration of linoleic acid dissolved in an ethanolic vehicle when compared to occlusion ($p < 0.05$); similar statistically significant trends were observed when linoleic acid was dissolved in the less volatile organic solvent cyclomethicone, i.e., nonocclusion resulted in greater percutaneous absorption of linoleic acid in cyclomethicone than occlusion. Then, the authors compared these studies with the percutaneous penetration of glycerol, a hydrophilic molecule, dissolved in an aqueous solution. They did not find statistically significant differences in the concentrations of glycerol in the skin and the receptor cell when comparing the occluded and nonoccluded

conditions. The authors attributed their results, which revealed that occlusion did not enhance the percutaneous penetration of the lipophilic compound linoleic acid, to the increase in the concentration gradient of linoleic acid enabled by nonocclusion due to the unimpeded evaporation of the volatile solvents, which provided a greater driving force for percutaneous absorption than occlusion, which prevented evaporation. They found these findings consistent with experiments conducted by Stinchomb et al. which revealed that by increasing the volatility of solvents, one can increase the concentration of the penetrant in the donor phase and enhance the deposition and delivery of the penetrant into the skin (Stinchomb et al. 1999).

Brooks and Riviere used isolated perfused porcine skin flap (IPPSF) topical experiments to study the percutaneous absorption of ^{14}C -labeled phenol ($\log Kow = 1.50$) versus para-nitrophenol (PNP) ($\log Kow = 1.91$) at two concentrations (4 versus 40 $\mu\text{g}/\text{cm}^2$) in two vehicles (acetone versus ethanol) under occluded versus nonoccluded conditions for 8 h in order to determine if dose, vehicle, or occlusion had significant effects on percutaneous penetration (see Tables 2 and 3) (Brooks and Riviere 1996; Korenman and Gorokhov 1973; Brecken-Folse et al. 1994). For phenol, occlusion enhanced the absorption, penetration into tissues, and total recoveries when compared to nonoccluded conditions. Phenol's absorption and penetration into tissues was greater when dissolved in an ethanol vehicle compared to the acetone vehicle under nonocclusive conditions, but phenol's absorption and penetration under occlusive conditions was greater with acetone than with ethanol. Phenol in acetone had a greater percentage of applied dose penetration into tissues at a low dose rather than a high dose, which could suggest a fixed absorption rate for the penetrant (this was also seen for PNP, but only under occlusion). With regard to PNP, neither its dose, vehicle, nor occlusion had a significant effect on total recovery of labeled PNP. These findings led the authors to conclude that absorption of phenol and PNP are dependent upon the vehicle, occlusion, and penetrant.

Table 2 Effects of dose, vehicle, and occlusion on percutaneous penetration of phenol. *SD* standard deviation, *ER* enhancement ratio (penetration of occluded chemical divided by penetration of nonoccluded chemical under otherwise identical conditions including dosing) (Modified from Brooks and Riviere 1996)

	Dose ($\mu\text{g}/\text{cm}^2$)	Penetration (% dose)
Nonoccluded phenol in acetone, 40 $\mu\text{g}/\text{cm}^2$		
Mean \pm SD	40.0 \pm 0.00	2.60 \pm 0.03
Nonoccluded phenol in EtOH, 40 $\mu\text{g}/\text{cm}^2$		
Mean \pm SD	40.0 \pm 0.00	8.49 \pm 3.80
Occluded phenol in acetone, 40 $\mu\text{g}/\text{cm}^2$

3 Results of In Vivo Experiments

Feldmann was the first to correlate the increased pharmacologic effect of hydrocortisone under occlusive conditions with the pharmacokinetics of the penetration of ^{14}C hydrocortisone through

normal skin (Feldmann and Maibach 1965). Following the topical application of ^{14}C hydrocortisone to the ventral forearm of human volunteers, the rate and extent of ^{14}C -labeled excretion was measured. The application site was either nonoccluded or occluded with plastic wrap. For the nonoccluded condition, the application site

Table 4 Total excretion data summary for topical application of ^{14}C hydrocortisone to the ventral forearm of human volunteers. The total excretion is the total amount of ^{14}C hydrocortisone excreted in urine after 10 days reported as the percentage of the dose applied (Modified from Feldmann and Maibach 1965)

Method of topical administration	Total excretion (% of dose)	Ratio to unmodified skin
Unmodified	0.46 %	1×
Occluded	4.48	10×
Stripped	0.91	2×
Stripped and occluded	14.91	32×

was washed 24 h post application, while for the occluded skin condition, the plastic wrap was left in place for 96 h post application before the site was washed. The urine for both conditions was collected for 10 days. The percent of the applied dose excreted into the urine after 10 days was 0.46 ± 0.2 (mean \pm SD) for the nonoccluded condition and 4.48 ± 2.7 for the occluded condition (Table 4). The occlusive condition significantly increased (tenfold) the cumulative absorption of hydrocortisone compared to the nonoccluded condition ($p = 0.01$). The authors noted that the difference of application duration (24 h exposure for the nonoccluded site versus 96 h exposure for the occluded site) could affect absorption as measured by the cumulative amount of drug excreted into urine, but the significant difference observed in percent dose absorbed at 12 and 24 h between occluded and nonoccluded conditions could not be explained by differences in application duration.

Feldmann then later studied the effect of occlusion on the percutaneous penetration of pesticides (Maibach et al. 1974). They applied ^{14}C -radiolabeled pesticides to the forearm of volunteers, and the rate and extent of ^{14}C -labeled urinary excretion was determined using sensitive methods that allowed the doses to be in micrograms, far below the toxic range of any pesticide. From their experiments, it is evident occlusion has a variable effect on penetration; at a minimum, occlusion increased the penetration of azodrin approximately threefold while at the other extreme, it increased the penetration of malathion almost tenfold (Table 5 and Fig. 1). In general, as the octanol-water partition coefficients increased, occlusion had a greater effect on enhancing penetration, though enhancement by occlusion peaked for malathion

and then decreased as the octanol-water partition coefficients further increased. In order to understand how occlusion duration affects penetration, the authors of the study then documented the effects of occluding malathion under variable amounts of time (Table 6). As the occlusion duration increased, the penetration of malathion increased as well, and that by 2 h of occlusion, the penetration had almost doubled, and that by 8 h, penetration almost increased by fourfold. There have been few, if any experiments, besides this one that have documented the effect of occlusion duration on percutaneous penetration.

Guy et al. studied how occlusion impacts the percutaneous absorption of a variety of steroids (progesterone, testosterone, estradiol, and hydrocortisone) in vivo (Guy et al. 1987). In the control studies, they applied the ^{14}C -radiolabeled steroids dissolved in acetone to the ventral forearm of volunteers and then tracked the elimination of the compounds into urine. In the occlusive studies, after evaporation of the acetone vehicle, the site of application was covered with a plastic (Hill Top) chamber. In all cases, the application sites were washed after 24 h using a standardized procedure (Bucks et al. 1985). In the occlusive studies, the authors covered the administration site again with a new chamber after the washing. These studies reveal that occlusion significantly increased the percutaneous absorption of estradiol, testosterone, and progesterone but not that of hydrocortisone, which had the lowest octanol-water partition coefficient among the steroids used (Table 7 and Fig. 2). Moreover, under both occlusion and nonocclusion, percutaneous absorption increased with increasing octanol-water partition coefficient up to testosterone but declined for progesterone.

Table 5 Effect of occlusion on the penetration of pesticides. K_{ow} = octanol-water partition coefficients. *ER* enhancement ratio (penetration of occluded chemical divided by penetration of nonoccluded chemical under otherwise identical conditions including dosing) (Modified from Maibach et al. 1974)

24	62.8

Bucks et al. measured the percutaneous absorption of these same four steroids (hydrocortisone, estradiol, testosterone, and progesterone) in vivo in man under occluded and “protected” (i.e., covered but nonocclusive) conditions (Bucks et al. 1988). Using the same methodology as Guy et al., the ^{14}C -labeled chemicals were applied in acetone to the ventral forearm of volunteers. After vehicle evaporation, the application

sites were covered with a semirigid polypropylene chamber for 24 h; intact chambers were used as the occlusive condition, while the “protected” condition was created by boring several small holes through the chamber. Urine was then collected for 7 days post application. In excellent agreement with the previous study by Guy et al., steroid absorption increased with increasing lipophilicity up to a point, but the penetration of progesterone (the most hydrophobic of the steroids) did not continue the trend. With the exception of hydrocortisone, 24 h occlusion significantly increased ($p < 0.01$) percutaneous absorption of the steroids. From these studies, it seemed occlusion enhanced the percutaneous absorption of the more lipophilic steroids but not that of hydrocortisone, the most water-soluble steroid.

Bucks then investigated the effect of occlusion on the in vivo percutaneous absorption of phenols (Bucks et al. 1987, 1988). Nine ^{14}C -ring-labeled

Table 7 Occlusion's effects on percutaneous absorption of steroids in man as a function of penetrant octanol-water partition coefficient. The exposure period was 24 h at 4 $\mu\text{g}/\text{cm}^2$ prior to washing with soap and water. K_{ow} = octanol-water partition coefficient. *SD* standard deviation, *ER* enhancement ratio (penetration of occluded chemical divided by penetration of nonoccluded chemical under otherwise identical conditions including dosing) (Modified from Guy et al. 1987; Bucks and Maibach 1999b)

Compound	log K_{ow}	% applied dose absorbed (mean \pm SD)		ER
		Nonoccluded	Occluded

Fig. 2 Log K_{ow} of enhancement ratio (ER) of steroids. This figure plots the ER of the various steroids as a function of their log K_{ow} s. K_{ow} = octanol-water partition coefficient (Modified from Guy et al. 1987; Bucks and Maibach 1999b)

para-substituted phenols (4-aminophenol, 4-acetamidophenol, 4-propionylamidophenol, phenol, 4-cyanophenol, 4-nitrophenol, 4-iodophenol, 4-heptyloxyphenol, and 4-pentyloxyphenol) were applied in ethanol to the ventral forearm of male volunteers. After vehicle evaporation, the application site was covered with either an occlusive or protective chamber. After 24 h, the chamber was removed, and the site washed. The application site was then recovered with a new chamber of the same type. Urine was collected for 7 days. On the seventh day, the second chamber was removed, the application site washed, and the upper layers of stratum corneum removed from the application site by tape stripping. These studies indicate that occlusion significantly increased ($p < 0.05$) the absorption of phenol, heptyloxyphenol, and pentyloxyphenol, but occlusion did not significantly increase the absorption of aminophenol, acetaminophen, propionylamidophenol, cyanophenol, nitrophenol, and iodophenol (Table 8 and

Fig. 3). The two compounds with the lowest octanol-water partition coefficient demonstrated the least enhancement in absorption under occlusion.

Afterwards Bronaugh et al. investigated the effect of occlusion on the percutaneous absorption of six additional volatile compounds (benzyl acetate, benzamide, benzoic acid, benzophenone, benzyl benzoate, and benzyl alcohol) in vivo in rhesus monkeys and humans for 24 h employing two occlusion methods, plastic wrap and glass chamber (Bronaugh et al. 1990). In general, occlusion enhanced the absorption of these compounds (Table 9). However, differences in absorption were observed between the plastic wrap and glass chamber occlusive conditions. Benzoic acid and benzyl acetate absorption were lower under the plastic wrap condition compared to the nonocclusive conditions; the authors conjectured that this discrepancy may be due to compound sequestration by the plastic. Glass chamber occlusion resulted in greater absorption than the

Table 8 Percutaneous absorption of phenols in humans under occluded and protected conditions. Compounds were applied topically in a single dose ($2\text{--}4\ \mu\text{g}/\text{cm}^2$) from 95 % ethanol to the ventral forearm for 24 h. After 24 h, site was washed with soap and water

Compound	log Kow	% Dose absorbed (mean \pm SD)		ER

nonoccluded and plastic wrap occlusion conditions for all the compounds except benzyl benzoate and benzophenone (benzyl benzoate had greater absorption under plastic wrap occlusion than glass chamber occlusion while benzophenone had the same magnitude increase in percent dose absorbed for both occlusive conditions). The authors attempted to correlate the compounds' octanol-water partition coefficients with their occlusion-enhanced skin permeation, but surprisingly, no apparent trends were found. One explanation for this lack of correlation could be that the volatile chemicals evaporated prior to application of the occluding device, which can impact subsequent measures of penetration (Gilpin et al. 2009).

Pellanda et al. investigated the effect of pre- and post-occlusion on the permeation of triamcinolone acetonide ($\log Kow = 2.53$) into the stratum corneum (Pellanda et al. 2007). Their two experiments involved the forearms of ten healthy volunteers. In experiment 1, they applied triamcinolone acetonide (TACA) in acetone to three sites per arm with one arm being pre-occluded for 16 h. In experiment 2, the same dose of TACA in acetone was applied on two sites per arm with one arm being occluded after application till skin sampling. Then, stratum corneum samples were removed by tape stripping at 0.5, 4, and 24 h for experiment 1 and at 4 and 24 h for experiment 2. The amount of corneocytes adhering to the tape strips were quantified directly using a spectrophotometer, and the amount of TACA adhering to each tape was quantified using high-performance liquid chromatography (HPLC). They found that pre-occlusion produced no significant effect on TACA penetration into the stratum corneum, while occlusion after application enhanced TACA penetration significantly by a factor of 2.

4 Discussion

In the nineteenth century, petrolatum was widely used, especially in extemporaneous pharmacist-produced prescriptions, and it remains in use in

numerous cosmetic formulations, especially moisturizers, in the twenty-first century. In addition, cosmetic formulations often use oils, especially mineral oil, for their occlusive effects. The general availability of robust evaporimeters has allowed laboratories to readily quantify the degree of occlusion, i.e., inhibition of transepidermal water loss, produced by an ingredient being considered for final formulation.

The data presented here represents a first step in relating the effect of this occlusion on penetration. Note, however, that these studies summarized were performed with total occlusion; much work remains to be done in generating penetration data with the usually less occlusive cosmetic ingredients. Further, we have little data on the effect of occlusive ingredients on those anatomic sites that are partially occluded, such as the axilla, groin, inframammary folds, and toe webs. At least one of these sites – the axilla – demonstrates increased flux compared to the forearm (Feldmann and Maibach 1967).

Skin occlusion can increase the hydration of the stratum corneum up to 50 %, which can have substantial effects on the percutaneous absorption of penetrants by altering the partitioning between the chemical penetrant and the skin, swelling corneocytes, and promoting the uptake of water into the intercellular lipid domains (Bucks et al. 1991; Bucks and Maibach 1999a; Ryatt et al. 1986; Haftek et al. 1998). Though occlusion is widely utilized to enhance the penetration of applied drugs in clinical practice, occlusion does not increase the percutaneous absorption of all chemicals; it is not well understood which chemicals occlusion enhances the penetration through skin (Bucks et al. 1991; Bucks and Maibach 1999a). Here we focus on what effect occlusion has on the percutaneous absorption of compounds of varying lipophilicities/hydrophilicities.

First, occlusion enhances the percutaneous absorption of many but not all compounds. For example, Guy et al. and Bucks et al. found that when measuring occlusion's effects on the

penetration of steroids, the most hydrophilic steroid of the ones being tested, hydrocortisone, did not demonstrate statistically significant enhanced penetration under occlusion (Guy et al. 1987; Bucks et al. 1988). Moreover, Bucks et al. also demonstrated that occlusion did not significantly enhance the penetration of many phenols being tested (Bucks et al. 1987).

Second, occlusion seems to enhance the penetration of very lipophilic compounds more so than very hydrophilic compounds. Bucks et al. and Guy et al. showed that occlusion enhanced the penetration of the most lipophilic steroids (as measured by octanol-water partition coefficient) more so than the least lipophilic ones (Guy et al. 1987; Bucks and Maibach 1999b; Bucks et al. 1988). In addition, Bucks et al. demonstrated that the phenols with the lowest octanol-water partition coefficients had the least enhancement in penetration under occlusion (Bucks and Maibach 1999b; Bucks et al. 1987, 1988).

Thirdly, though occlusion enhances the penetration of the most lipophilic compounds and often fails to enhance the penetration of the least lipophilic steroids, a relationship between a compound's octanol-water partition coefficient and its occlusion-induced enhancement cannot be delineated. With regard to steroid penetration through skin, these studies showed that while a positive relationship exists between a penetrant's octanol-water partition coefficient and its occlusion-enhanced penetration, this relationship is not a linear one (Guy et al. 1987; Bucks et al. 1988). However, with regard to occlusion's effects on the penetration of phenols, no relationship was found between the octanol-water partition coefficient of the penetrant and the extent of its penetration under occlusion (Bucks and Maibach 1999b; Bucks et al. 1987). After investigating the effect of occlusion on the penetration of volatile compounds in vivo in rhesus monkeys, Bronaugh et al. failed to correlate the penetrant's octanol-water partition coefficients with occlusion-enhanced skin permeation (Bronaugh et al. 1990).

Finally, the general shape of the figures plotting the enhancement ratios (the ratio of occlusion-enhanced penetration over

nonoccluded penetration) as a function of the logarithms of octanol-water partition coefficients suggests that the enhancement in penetration afforded by occlusion increases up to a point as the partition coefficients increase, but then this enhancement declines as the partition coefficients further rise (see Figs. 1, 2, and 3). Occlusion may enhance the penetration of lipophilic compounds more so than hydrophilic ones due to the rich lipid composition of the stratum corneum, but as the partition coefficients further increase, permeation may be hindered for these very lipophilic compounds as the water content present in the epidermis, which occlusion only increases, assumes a larger role in limiting the permeation of lipophilic compounds.

Moreover, though the data regarding the effect of time on occlusion's effect on penetration is limited, it seems penetration increases with increasing duration of occlusion. However, the study that was presented only documented the effect of occlusion duration for one chemical, the lipophilic compound malathion. More experiments investigating the effect of occlusion duration on a range of chemicals, both lipophilic and hydrophilic, are needed.

In conclusion, occlusion does not universally enhance percutaneous penetration. Occlusion may enhance the penetration of the most lipophilic compounds but often fails to increase the penetration of compounds that are relatively hydrophilic. The in vivo studies reinforce the conclusions drawn from in vitro studies that partition coefficients cannot reliably predict the effect of occlusion on percutaneous penetration. It seems the degree of penetration enhancement provided by occlusion is compound-specific and may be influenced by vehicle selection, temperature, humidity, and method of occlusion. As in many areas of skin biology, what seems to be a simple issue may, in fact, be complex – which seems to be the case for the effect of partition coefficient and occlusion on penetration. Taken together, this data provides some insights to aid the formulator especially interested in occlusive vehicles and should lead to experiments that will provide data on ingredients such as petrolatum, oils, etc., which are presumably not fully occlusive.

1 Introduction

In the past decade, multiphoton tomography (MPT) has emerged as a powerful noninvasive label-free 3D-imaging technique for in vivo human skin characterization (König and Riemann 2003; König et al. 2007; König 2008, 2012). MPT has superior submicron spatial resolution, single-photon sensitivity, and functional imaging capability compared to other 3D tissue imaging techniques such as 20–100 MHz ultrasound (Korting et al. 1999, 2010a), optical coherence tomography (OCT) (Drexler and Fujimoto 2008; König et al. 2009; Anness et al. 2011), and confocal reflectance microscopy (Rajadhyaksha 1999; Koehler et al. 2011, Table 1).

Furthermore, two-photon excited fluorescence elastin can be easily co-registered with collagen where the signal is based on second-harmonic generation (SHG) (König and Riemann 2003; Campagnola et al. 2001). This allows to

US ultrasound, OCT optical coherence tomography, CRM confocal reflectance microscopy (confocal laser scanning microscopy), MPT multiphoton tomography

characterize the dermal fiber networks and to determine the skin age by the parameter *skin aging index SAAID* (Lin et al. 2005; Koehler et al. 2006). The physical taken tissue sample, the slicing, the staining, and the microscopic visualization are not required.

MPT opens the way to provide label-free optical biopsies with the best spatial resolution of all clinical tissue imaging methods. The biopsies can be obtained within seconds by femtosecond laser beam scanning in different skin depths (optical sectioning) with a typical section thickness of 2 μm . The lateral resolution is about 300–400 nm. This allows even the imaging of intratissue organelles, nuclei, and single dermal fibers.

2 Principle of Multiphoton Tomography

The tomographs are based on near-infrared (NIR) laser radiation in the spectral range of 700–1,000 nm which corresponds to the *optical window of cells and tissues*. This provides a high light penetration depth. However, laser class 1M clinical multiphoton tomographs have a signal depth limitation of 200–320 μm due to the working distance of the high-numerical-aperture focusing optics.

The MPT signals of the human skin are mainly based on two-photon autofluorescence (AF) and SHG. These signals provide sufficient information to image the morphological features of cells and the extracellular matrix (ECM) such as the cell nucleus, single mitochondria, dendrites, dermal papillae (DP), hair shafts, microvessels, elastin fibers, and collagen structures. The dermal-

epidermal junction (DEJ) can be easily visualized in 3D.

Endogenous fluorophores include keratin, NAD(P)H, flavins, melanin, and a variety of porphyrins (König and Schneckenburger 1994; Breunig et al. 2010). SHG-active components include fibrillar collagens, muscle components (myosin rod domains), and nerves.

MPT provides not only morphological features. It can be used for functional imaging due to the detection of the biosensors NAD(P)H and flavins. Both types of coenzymes are involved in the respiratory chain activity and therefore in the cell's metabolism. The oxidized coenzyme NAD(P) does not fluoresce. Therefore, any oxidation by reactive oxygen species (ROS) results in a decrease of autofluorescence. The action of ROS scavengers results in an AF increase. The ratios of (i) NAD(P)H/flavins and (ii) free NAD(P)H/bound NAD(P)H are further parameters of cellular metabolism (Chance 1962; Schneckenburger and König 1992).

MPT provides information of the ratio of NAD(P)H-protein complexes (bound NAD(P)H) and free NAD(P)H (non-bound) by the method of fluorescence lifetime imaging (FLIM) (Bugiel et al. 1989; König and Wabnitz 1990; Becker 2005; König et al. 2010b). The fluorescence lifetime τ is a characteristic parameter of the fluorophore and its microenvironment and nearly independent on concentration. Free and bound NAD(P)H have typical fluorescence lifetimes of 0.3 ns and 2.2 ns, respectively. The porphyrin *protoporphyrin IX* that is produced by the skin bacterium *Propionibacterium acnes* has a typical τ value of 11 ns, whereas the flavin *flavomononucleotide* (FMN) has a lifetime of 5.3 ns (König and

Fig. 1 Scheme of signal generation. Two-photon processes result in fluorescence and second-harmonic generation. Three-photon processes result in third-harmonic generation. CARS requires two laser beams

Schneckenburger 1994; König et al. 2010b). Therefore, FLIM provides a further contrast mechanism to image different types of fluorophores and their binding behavior.

Very recent MPT developments include also chemical fingerprint information based on an additional coherent anti-Stokes Raman scattering (CARS) module (König et al. 2011a; Breunig et al. 2012, 2013; Weinigel 2014). CARS provides similar information as Raman spectroscopy and depicts molecule vibration signals. However, CARS imaging has the advantage of being several orders faster than Raman imaging. MPT-CARS tomography provides an optical CARS section within 1 s without any averaging. In contrast to the one-beam multiphoton tomographs for AF, FLIM, and SHG, the add-on CARS module requires a second laser beam that has to overlap in time and space with the first beam within the target.

The certified multiphoton CARS tomograph MPTflex-CARS provides information on lipids

based on the CH stretch vibration and on water. More chemical information can be obtained by tuning the laser wavelengths of the two-beam module to a specific spectral region of interest.

Figure 1 describes schematically the various nonlinear processes in multiphoton tomography and lists the sources of signals (AF, SHG, THG, CARS) generated in the non-labeled human skin. All processes require high transient light intensities that are provided by tight focusing of the femtosecond laser beams. Eighty million laser pulses per second at very low picjoule pulse energy and a mean power of 2–20 mW are applied. One optical section of $0.3 \times 0.3 \text{ mm}^2$ that consists of 512×512 pixels can be acquired within 1 s.

Figure 2 shows the two types of certified flexible multiphoton tomographs. The tomograph MPTflex is for fluorescence and SHG imaging. The larger system MPTflex-CARS has an additional wavelength extension unit based on a

Fig. 2 The multiphoton tomographs MPTflex and MPTflex-CARS

photonic-crystal fiber (CARS module) to generate a second laser beam at the spectral range of 900–1,200 nm. This additional laser beam can be also used to realize third-harmonic generation (THG) (Débarre et al. 2006) in order to visualize membranes such as from erythrocytes. Both systems possess a flexible mechanical/optical arm with a patented 360° scan head as demonstrated in Fig. 3.

The older certified multiphoton tomographs of the first generation called *DermalInspect* (JenLab GmbH, Jena, Germany) are not flexible and require a vibration-controlled optical table.

Figure 4 shows a typical stack of horizontal multiphoton sections of the normal forearm skin. The major signal from the outermost layer *stratum corneum* originates from keratin-containing corneocytes. Going deeper into the living epidermis, the images are dominated by NAD (P)H-containing keratinocytes. Upon reaching the

Fig. 3 The flexible scan head provides easy access to various skin regions

Fig. 4 Multiphoton tomographs provide stacks of optical sections within seconds

Fig. 5 Multiphoton tomography provides the best resolution of all tissue imaging techniques ($0.3 \mu\text{m}$ lateral resolution). Even deep-tissue single-mitochondria and single-elastin fibers can be imaged noninvasively and label-free

stratum basale, the fluorophore melanin provides the highest fluorescence quantum yield. Therefore, keratinocytes with melanin tend to provide stronger signals than keratinocytes without melanin. At the DEJ, first SHG signals occur from the top of the dermal papillae.

Using the zoom function, the tomographs allow a very close look into single living cells deep into the epidermis. As depicted in Fig. 5, the extremely

high submicron spatial resolution allows even the visualization of a single intracellular intratissue mitochondrion. The images in Fig. 6 demonstrate the corresponding FLIM image where the pseudo-color depicts the fluorescence lifetime.

Wide-field high-resolution images up to $3 \times 3 \text{ mm}^2$ can be generated mosaic-like by the motorized scan head. Also vertical sections (x, z -scans) can also obtained (Fig. 7).

Fig. 6 The pseudocolor-coded FLIM image depicts the mean fluorescence lifetime per pixel as fourth dimension. The image shows the distribution of intradermal fluorescent tattoo nanoparticles and a typical fluorescence decay curve of a single particle

Fig. 7 Vertical section (x,z-scans) can also be generated with the multiphoton tomograph

3 Applications

Major applications of multiphoton tomography are the evaluation of human pathological skin as well as the in situ intradermal detection of pharmaceuticals and cosmetics.

Medical investigations include:

- i. The early diagnosis of *malignant melanoma* and other skin cancers (Dimitrow et al. 2009; Seidenari et al. 2012a; Patalay et al. 2012)
- ii. Early diagnosis of *dermatitis* and monitoring of treatment effects (Huck et al. 2016)
- iii. The optimization of chronic wound management and photodynamic therapy of *actinic keratosis*
- iv. Intradermal lipid distribution of patients with *psoriasis* and skin cancer (Breunig et al. 2012, 2013; Weinigel) as well as
- v. The evaluation of skin aging induced by UV exposure and smoking (Koehler et al. 2008, 2009)

Also the in situ distribution and characterization of tattoo nanoparticles in the skin has been studied (König).

Furthermore, multiphoton tomographs are involved in the astronaut's health program of the European Space Agency (ESA) to test preflight and post-flight skin conditions of the astronauts and to evaluate the effects of long-term (6 months) extraterrestrial work at the international space lab ISS.

The major cosmetic and pharmaceutical companies employ multiphoton tomographs to evaluate and study:

- i. The biosafety of sunscreen nanoparticles (Zvyagin et al. 2008; Sanchez et al. 2010; Darvin et al. 2012)
- ii. The skin age and the efficacy of antiaging products (Bazin et al. 2010; Decenciere et al. 2013; Puschmann et al. 2012; Miyamaoto and Kudoh 2013)
- iii. Melanin types and dyes in hairs (Ehlers et al. 2007)
- iv. The skin barrier function (Richter et al. 2004)
- v. The effects of cosmetics on cellular metabolism
- vi. Drug delivery (König et al. 2006, 2011b; Roberts et al. 2008; Prowv et al. 2011)
- vii. The use of multiphoton tomography in tissue engineering (Roberts et al. 2011)

4 Skin Aging Index SAAID

Multiphoton tomography allows the accurate determination of the skin age by measuring age-associated alterations in the extracellular matrix, in particular the fiber network. The quantitative parameter SAAID characterizes the collagen-elastin ratio of the dermis. It is defined as

$$\text{SAAID} = (\text{SHG} - \text{AF}) / (\text{SHG} + \text{AF})$$

with values between -1 and 1 . Negative values mean that the elastin autofluorescence is stronger than the SHG signal from collagen. A value of 0 means that both signals are similar. The parameter depends on the relative tissue position and requires statistical analysis. The SAAID correlates with the biological age of healthy

volunteers as shown by in vivo multiphoton tomography on healthy subjects. Smoking and tanning influence the SAAID values and show skin ages older than biological ages.

The multiphoton tomographs employ two or more photodetectors (photomultipliers). This allows the simultaneous imaging of the elastin fiber network by AF and the collagen network by SHG within one scan. The detectors can operate in the analogue mode (signal intensities) and in the single-photon counting (SPC) mode.

For quantitative imaging, two approaches are currently undertaken. The first one is based on the computation of the mean intensities or counts of AF and SHG signals. The second one is based on pixel densities.

The company L'Oreal developed an automatic 3D segmentation software to analyze the dermal-epidermal junction (DEJ), the skin surface, and the elastin-collagen networks (Decenciere et al. 2013). In particular, they calculated a 3D SAAID index where a huge number of voxels from the upper dermis was considered. A mean epidermal thickness of young vs. old European skin of 66 μm versus 59 μm was determined. The density of elastic fibers was found to be increased with age, whereas the density of collagen did not differ between young and old skin. The SAAID decreased with age.

The company Beiersdorf named the elastin-to-collagen ratio as the ELCOR parameter. ELCOR is indirectly proportional to the SAAID index. As expected, an increase of the ELCOR values with age was measured when studying the volar forearm skin of chronically sun-exposed with sun-protected skin (Puschmann et al. 2012).

The company Procter & Gamble studied cellular metabolism in dependence on age by measuring the NAD(P)H values in the *stratum granulosum* of 59 Japanese female indoor workers (Miyamaoto and Kudoh 2013). Interestingly, they found statistically different NAD(P)H levels of 38.8 vs. 32.7 in the young group (20s) compared with elderly women (60s), respectively. New cosmetic care products for aging skin focus.

5 FLIM Tomography to Study Dermatitis

In addition to the three spatial dimensions, a fourth dimension can be added based on fluorescence lifetime imaging (FLIM). In principle, the arrival times of the emitted photons with regard to the femtosecond excitation pulses are measured using time-correlated single-photon counting (TCSPC). The typical temporal resolution is 270 ps. The fourth dimension *fluorescence lifetime* can be depicted as color-coded signal per pixel where the color reflects, e.g., a mean fluorescence lifetime per pixel based on a bi-exponential deconvolution. SHG can be detected as component with a lifetime “zero.”

The hospital at the University of Muenster, Germany, is using the FLIM module to measure the skin inflammation and to study the effects of cortisone treatment to patients suffering from severe dermatitis (Huck et al. 2016). The clinicians found a strong correlation between the strength of disease and the mean autofluorescence lifetime of the epidermis and observed a lifetime change as a result of treatment effects (Fig. 7).

Other groups work on multiphoton FLIM tomography to evaluate the clinical potential for early tumor diagnostics (Arginelli et al. 2013; Manfredini et al. 2013; Seidenari et al. 2012b, c; Koehler et al. 2012; Benati et al. 2011; Patalay et al. 2011).

The FLIM modality in the multiphoton tomographs is based on SPC. Typically, 100 photons are counted within 1 pixel for 12 μs beam dwell times. SPC provides therefore real photon numbers from region of interests that can be used for quantitative imaging and the generation of intratissue concentration maps.

6 CARS of Psoriasis

The multiphoton tomograph MPTflex-CARS is employed in clinical studies on the Charite, Berlin, on patients suffering from skin cancer, the head and feet syndrome, and psoriasis (König et al. 2011a, Breunig et al. 2012, 2013). The tomograph was employed to visualize the C=H

Fig. 8 Multiphoton CARS tomography. (a) Optical AF section showing NAD(P)H distribution. (b) Optical CARS section showing lipid distribution. (c) Overlay (König 2011a)

stretch vibration which mainly indicates lipids. Figure 8 demonstrates one section out of an optical biopsy that contained information on AF, and CARS. The autofluorescence image depicts mainly the distribution of the reduced coenzyme NAD(P)H, whereas the CARS image shows the lipid distribution of the exact same intratissue section. As seen, the CARS image provides additional information. In the study on patients suffering from psoriasis, significant modifications of the lipid distribution were found compared to healthy skin areas. Multiple clinical studies are currently going on trace chemotherapeutics in the sweat pores and their

microenvironment of cancer patients as well as to study drug delivery.

7 Conclusion

Multiphoton tomography (MPT) is a novel, high-resolution, and safe (Fischer et al. 2008) high-tech skin imaging modality based on near-infrared femtosecond laser technology. MPT provides morphological and functional optical biopsies (e.g., Balu et al. 2013) within seconds and with submicron resolution without any labeling.

Fig. 9 Multiphoton tomography can be used in early detection of malignant melanoma. Melanocytes can be easily imaged as well as cell-cell distances, irregular morphology, and pleophorism

It has the potential to reduce significantly the number of physically taken skin biopsies, to support personalized medicine by evaluating therapeutic strategies and providing rapid diagnostic images, as well as to measure drug delivery. One major application is the early diagnosis of pigmented lesions. Fig. 9 shows typical optical

sections of a patient suffering from malignant melanoma.

Multiphoton tomography is also employed in research and test centers of major cosmetic companies to prove the biosafety of sunscreen and make-up nanoparticles and the efficacy of antiaging products.

Storage Conditions of the Skin Affect Tissue Structure and In Vitro Percutaneous Penetration

Human skin • In vitro • Storage conditions • Skin structure • Percutaneous penetration • Two-photon excitation fluorescence microscopy

Humans are exposed dermally due to unintentional occupational skin exposure as well as following intentional use of cosmetics and topically applied pharmaceutical drugs. In all cases valid information on the potential for percutaneous penetration and temporary deposition of the relevant chemical or drug within the skin is needed to perform an initial and credible hazard assessment.

In vivo studies are often seen as the gold standard for this kind of assessments. However, for ethical, logistic, and cost-related reasons, we need alternative methods that can replace in vivo studies in humans as well as experimental animals. The implementation of more recent legislation in Europe banning the use of experimental animals in relation to testing of cosmetic products has

further pushed forward the replacement of in vivo methods and refinement of experimental in vitro models to study skin penetration.

Different organizations have issued recommendations and guidelines for the study of in vitro percutaneous penetration. One of the most cited of these guidelines is the OECD guideline 428 (OECD 428 2004). As a guideline it does not describe a single ideal in vitro method, but rather outlines different options and choices to be made when doing this kind of experiments. The different decisions to be taken relate to using static or flow-through systems, using full-thickness skin or dermatomed skin, using animal or human skin, using one or the other donor and receptor fluids, and using fresh or frozen skin. Thus, several in vitro methodological procedures are acceptable as long as they are based on valid arguments – valid in the sense that the experimental model reflects the problem to be addressed and will allow a trustworthy answer to the research question.

As stratum corneum is seen as the main barrier for percutaneous penetration, especially for the vast majority of compounds dependent on passive diffusion, the status of the epidermal barrier is

significant. Being composed of a stacked layer of dead cells, the storage by freezing of the skin for later *in vitro* experiments has long been accepted instead of using fresh skin, though it has more recently been questioned.

The problem is relevant, as it for logistic and other practical reasons is difficult to perform *in vitro* studies on percutaneous penetration on fresh human skin obtained directly from surgery. Skin samples are therefore stored until experimental procedures can be initiated. Skin samples may be kept viable at 4 °C for 2–4 weeks (DeBono et al. 1998), though gradually losing its metabolic capacity within days (Fahmy et al. 1993). The physical characteristics responsible for barrier properties and integrity in relation to passive diffusion across the skin are maintained for longer (Bronaugh et al. 1986). Storage at low temperatures may generate small ice crystals, which may potentially impair the structure and thereby the integrity of the skin depending on degree and length of freezing conditions. As a consequence, most guidelines for experimental studies on percutaneous penetration address this issue.

However, requirements stated in different guidelines are not all that specific as to storage conditions. Some recommend storage at –20 °C, whereas others also accept storage at lower temperatures. Recommendations from the European Centre for the Validation of Alternative Methods (ECVAM) and the International Programme on Chemical Safety (IPCS) state that storage of the skin at –20 °C for up to a year is acceptable (Howes et al. 1996; IPCS: Dermal absorption 2006), whereas the EU Scientific Committee on Consumer Products (SCCP) states that the skin can be stored at –20 °C or lower (SCCP/0970/06 2006). All recommendations appear to rely on a single paper published in 1986 stating that human skin can usually be stored at –20 °C for up to a year with no changes in water permeability, but in some cases with apparent deterioration of the barrier (Bronaugh et al. 1986). Moreover, this study from 1986 did not actually judge the influence of storage at –20 °C on a comparison with fresh skin, but based the evaluation on cadaver skin. Given that cadaver skin has most often been sampled following unknown conditions for an

unspecified time period, this might not be the optimal skin source as a basis for all existing guidelines on storage of the skin before experimental studies. The present OECD guideline 428 for the testing of chemicals avoids this dilemma by not describing specific requirements concerning storage conditions, but instead requires that evidence should be presented that the barrier function of the skin is maintained (OECD 428 2004).

Recently, imaging techniques based on nonlinear optics have been developed to an extent that allows pictorial description of skin structures including visualization of the different skin strata and associated dynamical information (Masters and So 2001; Brewer et al. 2013; Bloksgaard et al. 2013). For example, the two-photon excitation fluorescence microscopy (TPEFM) technique is noninvasive and based on a nonlinear process in which a fluorophore absorbs two photons simultaneously. This mode of excitation offers advantages compared to traditional laser scanning confocal fluorescence microscopy (LSCM). As infrared light is utilized as excitation source, the penetration depth can be up to 900 µm, almost fivefold higher than regular confocal fluorescence microscopy, allowing in-depth, three-dimensional examination of relatively thick biological specimens (Bloksgaard et al. 2013).

Based on this technique, a recent image analysis of the skin stored at –20 °C and –80 °C (Nielsen et al. 2011) revealed clear discrepancies from the normal distribution of keratinocytes in fresh skin as well as extensive cell desquamation in stratum corneum and apparent swelling of cells causing a larger average cell size in the deeper layers of the skin and an induction of broader canyons between polygonal clusters of the epidermis (Fig. 1). The structural changes in upper as well as deeper regions of epidermis observed via imaging techniques demonstrate that storage of human skin at –80 °C induces significant structural changes in the skin that will potentially affect percutaneous penetration of chemicals (Nielsen et al. 2011). The structural effects on the skin stored at –20 °C were less prominent and appeared limited to the upper strata of stratum corneum (Nielsen et al. 2011).

^aStatistically increased compared to penetration rate through fresh skin

The limited more recently published data in the open literature on the influence of storage of the skin at -20°C on the percutaneous penetration of topically applied chemicals is presented in Table 1. From each of the available studies, the ratio between the comparable groups with fresh skin and skin frozen at -20°C is calculated. It should be noted that all numbers on flux come with significant standard deviations and together with an often limited group size, this causes the differences compared to fresh skin experiments to remain statistically insignificant for most cases including all cases with human skin. However, in those cases with statistical differences, the flux is always increased following freezing indicating a varying degree of damage to the skin

barrier. It is perhaps also noteworthy that the one case deviating significantly from the other cases was performed on the skin from the ear (Sintov and Botner 2006), whereas the rest of the experiments were performed on abdominal skin (Sintov and Botner 2006; Payne et al. 2013; Nielsen et al. 2011; Dennerlein et al. 2013).

Only but a few studies have tested the influence of storage temperatures lower than -20°C on the percutaneous penetration of different penetrants. These studies include testing the penetration of caffeine through human skin after storage at -80°C , measuring penetration of the T-2 toxin (a mycotoxin) through human and monkey skin after storage at -60°C , and evaluating the penetration of N,N-diethyl-*m*-toluamide through pig

skin stored at $-80\text{ }^{\circ}\text{C}$ (Nielsen et al. 2011; Kemppainen et al. 1986; Hawkins and Reifenrath 1984). These three studies all demonstrate significantly increased penetration rate through the skin stored at these low temperatures.

The image analysis demonstrates that storage of human skin at $-20\text{ }^{\circ}\text{C}$ causes visible structural changes in only but the upper epidermal strata of the skin. The upper strata will be expected to act as a stronger barrier to hydrophilic compounds as to lipophilic compounds due to its more lipophilic character. A structural damage to the upper layers could therefore be expected to have a more pronounced effect on the penetration of hydrophilic compounds as compared to lipophilic compounds. This suggestion fits well with observations demonstrating that applying hydrophilic compounds in a lipophilic microemulsion eliminates the influence of freezing on the percutaneous penetration (Sintov and Botner 2006). The suggestion that a specific stratum of the epidermal membrane acts as a stronger barrier toward hydrophilic compounds and another stratum for more lipophilic compounds requires, however, more supporting evidence from experimental studies.

The observed effect of storage at $-20\text{ }^{\circ}\text{C}$ on the percutaneous penetration through human skin is less than 50 % (Nielsen et al. 2011; Dennerlein et al. 2013). Considering the inherent variability in these studies related to interindividual variability between skin donors (50–60 %) and interlaboratory variability (up to ten times), the observed effects of skin storage at $-20\text{ }^{\circ}\text{C}$ are relatively limited. Instead of prescribing specific storage conditions, the more pragmatic and functional approach, until more documentation is available, is therefore to follow the recommendations given in the OECD guidelines that skin specimens used for in vitro studies on percutaneous penetration should have intact barrier integrity, which can be tested and reported based on different well-described methods.

Based on presently available data, it can be concluded:

1. Storage of human skin at $-80\text{ }^{\circ}\text{C}$ causes significant structural changes in upper as well as

more deeper parts of stratum corneum. These more severe changes correspond to significantly increased percutaneous penetration of chemicals applied to skin specimens stored at very low temperatures. Storage of human skin for later use in in vitro studies on percutaneous penetration is therefore not recommended at these low temperatures.

2. Storage of human skin at $-20\text{ }^{\circ}\text{C}$ causes structural changes in the upper stratum corneum observable with image techniques such as TPEFM. The presently available literature does, however, not support that the observed structural damage to the integrity is sufficient to cause a general and significantly increased in vitro percutaneous penetration across human skin stored at $-20\text{ }^{\circ}\text{C}$. The use of the skin stored at $-20\text{ }^{\circ}\text{C}$ for in vitro studies on percutaneous penetration therefore seems acceptable as long as the barrier integrity is documented.

1 Introduction

Healthy full-term newborn skin is well developed and functional at birth, despite being exposed to water and amniotic fluid for 9 months. The epidermis is thick and the stratum corneum (SC) layers are well formed. Transepidermal water loss (TEWL) is very low at birth for full-term infants and equal to or lower than adults, indicating a highly effective skin barrier (Cunico et al. 1977; Yosipovitch et al. 2000). However, the question is, how does the full-term infant develop an excellent barrier while in water? Usually, continuous exposure to water causes significant skin damage, including maceration of the SC and disruption of its well-organized structure and injury to the epidermis. Typically, skin cultures have to be exposed to dry conditions for cornification to occur. If the epidermis is covered with water, the SC does not form (Supp et al. 1999). Yet, in utero, the SC forms to cover the epidermis in the high water environment.

Vernix caseosa is the mixture of sebaceous gland secretions, lanugo, and desquamated epithelial cells that covers the skin of the fetus during the last trimester of gestation and appears in varying amounts on newborn infants. Vernix from full-

term infants is a remarkably consistent mixture of 80 % water, 10 % protein, and 10 % lipid fractions, consisting primarily of cornified cells embedded in an amorphous lipid matrix (Hoeger et al. 2002; Pickens et al. 2000; Rissmann et al. 2006). There are flat, differentiated corneocytes with cell envelopes are 1–2 μm thick. The cells lack distinct nuclei, corneodesmosomes, and organization. They have lower keratin levels than mature stratum corneum cells, varying in stage of keratinization (Pickens et al. 2000; Agorastos et al. 1988). Most of the water is localized to the intracorneocyte region, but small, round structures have been observed in the nonlamellar lipid matrix (Pickens et al. 2000; Rissmann et al. 2006). They are believed to be hydrated domains and pools of rapidly releasable extracorneocyte water (Tansirikongkol et al. 2008).

This chapter will address this question: based on the structure and composition, what could vernix do for the epidermal barrier?

2 Vernix Composition and Structure

2.1 Formation

Vernix begins to coat the fetal skin surface from head to toe and back to front during the last trimester, presumably under hormonal control (Hoath et al. 2006). Vernix includes lipids of the types made by sebaceous gland (Rissmann et al. 2006; Nicolaidis et al. 1972), and the cornified cells may originate from hair follicles, analogous to the production of terminally differentiated infundibular keratinocytes in acne (Kurokawa et al. 2009). Vernix extrudes onto the interfollicular epidermis through the hair shaft, spreads over the surface throughout gestation (Hardman et al. 1998) and, presumably, protects the epidermis from exposure to amniotic fluid (Fig. 1; Youssef et al. 2001). It is likely that fetal epidermis has a high water flux potential driven by osmotic gradients since cornification is incomplete. Isolated vernix corneocytes

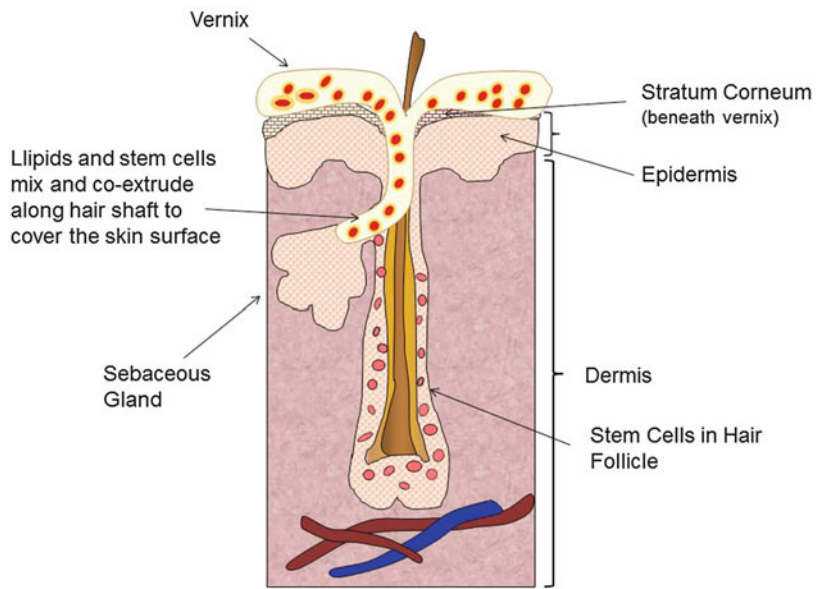

can swell and contract as a function of a hypoosmotic or hyperosmotic environment (Hoath et al. 2006) supporting a potential role for vernix in osmoregulation intra-amniotically. Vernix may impose a semi-regulated barrier and/or physiological gradient for transepidermal water and nutrients in utero, facilitating cornification via increased DNA and lipid synthesis. The asymmetric submerged culture model is consistent with this hypothesis (Thakoersing et al. 2010).

2.2 Lipids

Vernix contains free lipids including sterol esters, wax esters, dihydroxy wax esters, squalene, triglycerides, diacylglycerol, monoacylglycerol, phospholipids, cholesterol, fatty acids, and ceramides (Rissmann et al. 2006; Tollin et al. 2005). The vernix lipids bound to the corneocytes include ω -hydroxy acids (bound to corneocyte envelope), fatty acids, ω -hydroxyceramides CerA (sphingosine), and CerB (6-hydroxysphingosine) (Rissmann et al. 2006). Unlike native SC where cholesterol, free fatty acids, and ceramides constitute 80 % of total lipids, these classes represent 10 % of vernix lipids, and nonpolar species are the major components. The free fatty acids are dominated by saturated chain lengths C16:0 (14 %) and C24:0 (24.5 %). C18:lin-9 (6.4 %) is the most abundant monounsaturated fatty acid, and C18:2n-6 (9.6 %) is the highest polyunsaturated fatty acid (Tollin et al. 2005). Branched chains are 29 % of the fatty acids and include 30 different chain lengths, from 11 to 26 carbons (Ran-Ressler et al. 2008). In contrast, SC fatty acids are straight chained and generally 22 or 24 carbons (Wertz 2006). The lower levels of long chain ceramides and high fraction of unsaturated or branched chains may lead to the more fluid, nonlamellar organization seen in vernix (Rissmann et al. 2006). Covalently bound lipids comprise about 1 % of vernix (Rissmann et al. 2006), generally the same as in SC, although vernix has higher levels of ω -hydroxeicosanoic acid and nearly absent levels of ω -hydroxyacid with 30 C-atoms (Rissmann et al. 2006).

Fig. 1 Vernix formation.

Vernix extrudes onto the interfollicular epidermis through the hair shaft and spreads over the surface throughout gestation and, presumably, protects the epidermis from exposure to amniotic fluid

Vernix from female and male newborns differed significantly in wax esters and triglycerides; two classes are believed to originate from the sebaceous glands. For both, the relative amounts of longer-chain-length lipids were greater in females versus males (Mikova et al. 2014). The shorter carbon chain species were higher in males versus females. Given that the composition of epidermal lipids changes during gestation, it is possible that the vernix composition changes throughout the last trimester. In infants of 31–40 weeks gestation, the cholesterol/squalene ratio decreased around 36 weeks, reflecting increased squalene and suggesting a surge in sebaceous gland function near birth (Wysocki et al. 1981). The variation as a function of gestational age and the implications for SC development is largely unexplored.

2.3 Proteins

An analysis of vernix ($n = 34$ infants) using liquid chromatography and tandem mass spectrometry identified 203 proteins and grouped them via protein analysis software (Holm et al. 2014). The major classes were hydrolases (14.4 %), proteases (10.8 %), enzyme modulators (10.8 %), cytoskeletal proteins (9.8), structural proteins (6.9 %),

transfer/carrier proteins (5.6 %), calcium-binding proteins (5.6 %), immunity proteins (5.6 %), and signaling molecules (4.9 %) (Table 1). Polyubiquitin-C regulates innate and adaptive immunity and calmodulin-like protein 5 is associated with late keratinocyte differentiation and SC formation. Both were negatively associated with the development of atopic dermatitis by 24 months compared to infants without disease (Holm et al. 2014). The SC proteins keratins 1, 10, and 11, involucrin, and filaggrin are present in vernix (Narendran et al. 2010; Visscher et al. 2011a). Analysis of the free amino acid (FAA) component of natural moisturizing factor (NMF) revealed higher levels of glutamic acid and histidine and lower levels of glycine and serine compared to the amino acid profile of filaggrin (McKinley-Grant et al. 1989) ($p < 0.05$, Table 2).

2.4 Antimicrobial Activity

Vernix contains antimicrobial agents, including proteins and lipids, and exhibits a range of bioactivity against common fungal and bacterial pathogens (Tollin et al. 2005; Akinbi et al. 2004; Marchini et al. 2002; Yoshio et al. 2003). The innate immune proteins,

calgranulin A, B, and C, cystatin A, and UGRP-1 have been identified (Tollin et al. 2005). Lactoferrin, lysozyme, secretory leukocyte protease inhibitor, and human neutrophil peptides 1–3 were found in vernix from healthy full-term births (Akinbi et al. 2004). These antimicrobial peptides appear as hydrated inclusion bodies that may result from process-induced coalescence (Fig. 2). The presence of a quick release pool of soluble antimicrobials would be a major benefit

Table 1 Classes of proteins identified in vernix caseosa (Holm et al. 2014)

for the fetus faced with chorioamnionitis or other intrauterine infection, although this hypothesis has not yet been tested. Vernix samples had muramidase activity and were active against the growth of group B *Streptococcus*, *L. monocytogenes*, and *K. pneumoniae*. The cathelicidin LL-37, known to protect keratinocytes from apoptosis (Bouzari et al. 2009), was found and demonstrated antimicrobial activity against *B. megaterium* Bm11 (gram positive) (Marchini et al. 2002). Combinations of vernix lipids and LL-37 in ratios of 3:1 and 7:1 displayed greater antimicrobial inhibition than LL-37 alone, indicating synergetic innate immunity. Vernix and amniotic fluid from healthy infants showed activity to Bm11 and *C. albicans* (Yoshio et al. 2003).

3 Treatments

Epidermal barrier treatments based on vernix derive from the chemical composition, the physical structure, and the resulting properties that they confer (impart). The properties of vernix suggest several uses for treating the epidermal barrier for common skin maladies.

3.1 Hydration/Moisturization

Vernix has a higher than typical water content compared to conventional ointments. It loses

Table 2 Amino acid composition of vernix relative to fully hydrolyzed filaggrin (McKinley-Grant et al. 1989)

	Vernix (pmoles/ μ g soluble protein)	Indexed to glycine	Filaggrin (pmoles/ μ g filaggrin)	Indexed to glycine
Glycine	78.5 \pm 19	1.0	2981	1.0
Serine	114.6 \pm 13	1.4	2640	0.9
Glutamic acid	284.6 \pm 27	3.6	1100	0.4
Histidine	459.4 \pm 92	5.8	900	0.3
Arginine	151.4 \pm 12	1.9	500	0.2
Citrulline	134.6 \pm 13	1.7	70	0.02

The values are from the HPLC analysis as pmoles amino acid per μ g soluble protein (extracted from tapes) for native vernix and adult skin. For comparison, the relative amino acids in filaggrin are given as pmoles per μ g of protein based on the composition from full acid hydrolysis (McKinley-Grant et al. 1989). The FAAs for vernix, adult skin, and filaggrin are also shown as indices, i.e., normalized to glycine

Fig. 2 Electron micrographs of vernix showing antimicrobial peptides. Lactoferrin, lysozyme, secretory leukocyte protease inhibitor, and human neutrophil peptides 1–3 were found in vernix from healthy full-term births. These antimicrobial peptides appear as hydrated inclusion bodies that may result from process-induced coalescence as shown in electron micrographs of vernix stained for lactoferrin and lysozyme

and resorbs water, indicating a use for SC hydration (Tansirikongkol et al. 2008). The free amino acid levels in vernix are about 0.3 $\mu\text{mol per cm}^2$ which may account in part for the slow water release and water resorption. The water holding capacity for vernix-treated adult volar forearm skin was higher than an untreated control ($p < 0.05$) (Bautista et al. 2000). The water holding capacity for skin treated with a water-in-oil cream (Eucerin[®]), an anhydrous barrier (petrolatum), and a low-water cream (Aquaphor[®]) did not differ from untreated skin (Fig. 3). The water-binding capacity (peak sorption following application of exogenous water) of vernix-treated skin was higher than the untreated control, while values for Eucerin, petrolatum, and Aquaphor were lower ($p < 0.05$).

Infant skin hydration decreases over the first day and then increases during the first 2 weeks, in contrast to mother's skin where hydration is relatively constant, suggesting adaptive changes to the postnatal environment (Visscher et al. 2000). Vernix was left on the skin in one group of newborns and wiped off for another group. Vernix-treated skin was significantly more hydrated and less erythematous at birth and 24 h later versus skin where vernix was removed ($p < 0.05$) (Visscher et al. 2005). Vernix-retained skin had higher levels of FAA 24 h after birth ($p < 0.05$), paralleling the higher hydration.

3.2 Skin Surface Acidity

An acidic skin surface is necessary for the effective functioning of enzymes in stratum corneum formation and integrity, i.e., lipid metabolism, bilayer structure, ceramide synthesis, processing of GlcCer precursors to form ceramide for SC lipids, and desquamation (Schmid-Wendtner and Korting 2006; Rippke et al. 2002; Holleran et al. 2006), for bacterial homeostasis, skin colonization, and inhibition of pathogenic bacteria (Aly et al. 1978; Puhvel et al. 1975; Fluhr et al. 2001). Acidification enhances SC integrity and cohesion in neonatal and aged skin (Hachem et al. 2010; Hatano et al. 2009). The apparent skin pH was lower for infants with vernix retained after birth and 24 h than when vernix was removed ($p < 0.05$) (Visscher et al. 2005). Vernix may facilitate colonization with commensal organisms.

3.3 Stratum Corneum Barrier Repair

Alteration of the skin environment after SC damage has profound effects on the rate and effectiveness of barrier repair. Damaged SC treated with semipermeable films recovers more quickly than under complete occlusion or no occlusion, as reported after tape stripping and in premature

Fig. 3 Water holding capacity for vernix, PBC, and a water-in-oil cream.

The water holding capacity for vernix-treated adult volar forearm skin was higher than an untreated control ($p < 0.05$). The water holding capacity for skin treated with a water-in-oil cream (Eucerin[®]), an anhydrous barrier (PBC), and a low-water cream (Aquaphor[®]) did not differ from untreated skin.

*Indicates significantly different from all other treatments ($p < 0.05$) (Adapted from Bautista et al. 2000)

infants (Schunck et al. 2005; Visscher et al. 2001; Bhandari et al. 2005; Mancini et al. 1994). This artificial barrier can be provided by creams, ointments, films, or dressings. Vernix films are semipermeable, with water vapor transmission rates of 19–70 g/m²/h, depending upon thickness, while petrolatum-based films are in the occlusive range (Gunt 2002; Tansirikongkol et al. 2007a; Visscher et al. 2002).

The effects of twice-daily application of vernix and a petrolatum-based cream (PBC) (both 2.5 mg/cm²) on early-stage SC repair were compared versus a fully occlusive film and untreated skin (tape stripped, no occlusion) in adult forearm skin tape stripped to achieve TEWL of 29–50 g/m²/h, comparable to values for infants < 30 weeks gestation (Visscher et al. 2011a; Sedin et al. 1983). Vernix and PBC facilitated barrier repair with higher rates of recovery than full occlusion ($p < 0.05$) (Fig. 4a). Both were comparable to the recovery for untreated (stripped) skin. Skin hydration (immediate reading) was higher for PBC than vernix and untreated. Vernix-treated skin tended to be more hydrated than untreated ($p = 0.06$). Taken together, the data suggest that vernix treatment results in a more hydrated SC than without treatment (no occlusion). Visual erythema was higher for full occlusion than untreated (stripped, no occlusion) vernix and PBC ($p < 0.05$). Visual dryness

was greater for full occlusion versus no occlusion and vernix ($p < 0.05$). PBC was drier than no occlusion ($p < 0.05$) and directionally drier than vernix ($p = 0.09$) (Fig. 5). Following complete SC removal via tape stripping in hairless mice, TEWL was 79 g/m²/h. One application of vernix and PBC (both at 5 mg/cm²) enhanced SC barrier repair versus no treatment, but recovery was more rapid with vernix than PBC (Fig. 4b). Skin treated with PBC was more erythematous than with vernix or untreated (Oudshoorn et al. 2009a).

3.4 Wound Healing

Wounds at the epidermal and superficial dermal level were created on a minipig with an erbium: YAG laser at ablation depths of 20 or 25 μm and treated twice daily with vernix, a PBC (both at 2.5 mg/cm²), or left untreated (wounded, no occlusion) for 7 days (Visscher et al. 2011b). Wounds from 20 μm ablation recovered more quickly with vernix or PBC versus no treatment, and the recovery was greater on day 2 for PBC versus vernix. Repair rates were similar for all sites on day 7, although recovery was not complete, i.e., 76–88 % (Fig. 4c). Both vernix and PBC produced similar recovery for 25 μm ablation. Wound-healing effects of vernix on lower extremity ulcers have been reported (Zhukov et al. 1992).

Fig. 4 (a, b, c) Effect of vernix on barrier recovery. The effect of vernix treatment on epidermal damage in three investigations is shown in **a**, **b**, and **c**. **(a)** The effects of twice-daily application of vernix and a petrolatum-based cream (*PBC*) (both 2.5 mg/cm^2) on early-stage SC repair were compared versus a fully occlusive film and untreated skin (tape stripped, no occlusion) in adult forearm tape-stripped skin. Vernix and PBC facilitated barrier repair with higher rates of recovery than full occlusion ($p < 0.05$). Both were comparable to the recovery for untreated (stripped) skin. *Indicates significant difference versus untreated, tape-stripped skin. **(b)** One application of vernix and PBC (both at 5 mg/cm^2) enhanced SC barrier repair in hairless mice versus no treatment, but recovery was more

rapid with vernix than PBC. Skin treated with PBC was more erythematous than with vernix or untreated. **(c)** Wounds from $20 \mu\text{m}$ laser ablation in the minipig recovered more quickly with vernix or PBC versus no treatment, and the recovery was greater on day 2 for PBC versus vernix. Repair rates were similar for all sites on day 7, although recovery was not complete, i.e., 76–88%. Both vernix and PBC produced similar recovery for $25 \mu\text{m}$ ablation. *Indicates significant difference from untreated (damaged) and vernix ($p < 0.05$) (a adapted from Visscher et al. 2011b; b adapted from Oudshoorn et al. 2009a; c used with permission from Visscher et al. 2011b)

The free amino acids in vernix may have a role in wound healing. Repair rates were increased, and infection was controlled for wounds, including burns and diabetic ulcers, when nutrients (amino acids, salts, ascorbic acid, D-glucose polysaccharide) were applied after daily debridement (Silvetti 1981). Sericin, a mixture of silk proteins, peptides, and amino acids, healed wounds more quickly than the PBC control in rats (Aramwit and Sangcakul 2007). Treatment with four amino acids (glycine, L-lysine, L-proline, L-leucine) and

hyaluronic acid increased wound healing (Corsetti et al. 2009).

3.5 Synthetic Vernix

Topical creams based on native vernix caseosa as a prototype have been reported. Formulas with high water content and vernix-like lipids have water release profiles similar to native vernix and water vapor transport rates in the

Fig. 5 Effect of vernix on skin dryness. The effects of twice-daily application of vernix and a petrolatum-based cream (PBC) (both 2.5 mg/cm^2) on early-stage SC repair were compared versus a fully occlusive film and untreated skin (tape stripped, no occlusion) in adult forearm tape-stripped skin. Visual dryness was greater for full occlusion

versus no occlusion and vernix ($p < 0.05$). PBC was drier than no occlusion ($p < 0.05$) and directionally drier than vernix ($p = 0.09$). *Indicates significantly different from no occlusion and vernix. #Indicates directional difference versus vernix and a significant difference from no occlusion (Adapted from Visscher et al. 2011b)

“semipermeable” range (Tansirikongkol et al. 2007a). Synthetic lipid mixtures, based on the vernix lipid composition and formulated to match the thermal and structural properties, were comparable to native vernix and provided increased barrier repair versus a PBC in the hairless mouse (Rissmann et al. 2008). Formulas with lipid-coated microgel particles in a ratio of 2:1 particles/lipid most closely resembled the water release profile of native vernix (Rissmann et al. 2009). Synthetic formulations with hydrated moieties, a version with the physiological lipid mixture, and native vernix were more effective than PBC for SC barrier repair (Oudshoorn et al. 2009b).

4 Summary

Vernix has multiple physical and biological functions that are provided simultaneously, e.g., wound healing with antimicrobial activity, during gestation and immediately after birth. They are multifunctional compared to conventional creams. Vernix functions as a skin cleanser (Moraille et al. 2005). In vitro, it has a low surface energy, suggesting that it creates a protective

hydrophobic layer around the fetus (Youssef et al. 2001). Vernix contains multiple cytokines, including $\text{IL1}\alpha$, $\text{IL1}\beta$, $\text{TNF}\alpha$, IL-6, IL-8, and MCP, although the role is the subject of future investigations (Narendran et al. 2010). Vernix contains the SC lipids, cholesterol, ceramides, and fatty acids (e.g., oleic, linoleic, and long chain species) and non-SC lipids, e.g., sterol esters, triglycerides, and squalene (Rissmann et al. 2006; Tollin et al. 2005). The ceramide component, e.g., type and ratio to other lipid classes, influences the barrier properties in SC model systems (Kessner et al. 2008). Vernix films impede penetration of the exogenous enzyme chymotrypsin (found in meconium) in vitro (Tansirikongkol et al. 2007b) and, hypothetically establish epidermal-amniotic fluid gradients of water, nutrients, and electrolytes necessary for normal architecture and barrier formation (Thakoersing et al. 2010). Vernix films are semipermeable, unlike those of petrolatum-based creams. Premature infants of 26.2 weeks GA (mean) were treated with PBC twice daily and compared to a cohort without daily application (PBC applied only to local dryness or compromise) (Edwards et al. 2004). Nosocomial infection rates were higher for the PBC infants of

501–750 g. Since PBC at levels $> 1 \text{ g/cm}^2$ are occlusive to water vapor transport (Gunt 2002; Joseph 2002), the applied amount may be sufficiently occlusive to delay SC barrier development and/or to permit growth of coagulase-negative *Staphylococcus* (Visscher 2003).

Overall, vernix facilitates development of the stratum corneum protective barrier in the normal, full-term infant through a variety of protective and adaptive mechanisms. Very premature infants are born before vernix is fully distributed on the skin in utero and, consequently, may be deprived of the benefits. Epidermal barrier treatments based on vernix may protect them from vulnerabilities including delayed barrier maturation, delayed acid mantle formation, infection, and water loss.

Near the end of the 1980s, the first research results concerning skin property changes resulting from covering the skin with diapers and garment fabrics (fiber-based materials) appeared in the literature (Zimmerer et al. 1986; Hatch et al. 1987; Wester et al. 1985). The bioengineering instruments used were a focused microwave probe to determine the water content of the SC, an evaporimeter to assess the rate of evaporation of transepidermal water from the skin surface, and a laser Doppler velocimeter instrument to measure capillary blood. Low interest in using bioengineering instruments to study the effect of diapers (Campbell et al. 1987; Davis et al. 1989; Wilson and Dallas 1990; Berg et al. 1994; Akin et al. 1997; Grove et al. 1998, 2002; Odio et al. 2000a, b; Partsch et al. 2000; Zhai et al. 2002; Visscher et al. 2000) and garment fabrics (Hatch et al. 1990a, b, 1992a, 1997; Barker et al. 1990; Markee et al. 1990, 1991; Cameron et al. 1997) has continued. Research results about the effects of washing the skin with cloth towels (textile products) and baby wipes (paper products) using bioengineering instruments have become available (Priestley et al. 1996; Farage 2000; Odio and Friedlander; Odio et al. 2001).

This chapter reviews studies whose results have advanced our knowledge about the effects of fiber-based materials on the human skin with the use of bioengineering instrumentation. The emphasis is on how fiber-based materials change properties of the skin they cover and/or contact. Readers are referred to sources of information about the bioengineering instrumentation used (Berardesca et al. 1995; Elsner et al. 2002; Hatch et al. 1992b). Our purpose is to encourage further work in this area.

1 Diapers/Incontinence Products

1.1 Specifications and Aims

Cloth diapers and incontinence products may be a large rectangle piece of fabric which has to be folded by the caregiver, a large rectangle of cloth

prefolded and sewn to create a multiple-layered product, or a form-fitted multilayer textile product. Cloth diapers are intended to be laundered after each use and reused. The fiber content of the fabric comprising cloth diaper is usually cotton because this fiber is absorbent, soft, and resistant enough to acids, alkalis, and abrasive action to make a satisfactory diaper. Some cloth diapers are made with a polypropylene section, a section that contacts the wearer's skin. Waterproof pants are usually put on over the cloth diaper to reduce contamination of the environment as the diaper becomes soiled. In contrast, disposable diapers and disposable incontinent products are one-time use products made entirely or partially of paper products. Minimally, they have a top (liner) sheet that contacts the skin when the diaper is worn, an absorbent core layer, and a bottom sheet (back or outer) that serves the same function as the waterproof pants in the cloth diaper ensemble. Disposable products may have six layers: top sheet, intake layer, secondary layer, absorbent core, tissue layer, and bottom sheet (Grove et al. 1998).

The engineering of a diaper/incontinence product system is based on keeping the diapered area of the skin as close to the hydration level as it would be if un-diapered. Keeping the diapered area as close to normal hydration as possible is of considerable interest because it has been shown that skin permeability, CO₂ emission, frictional trauma, and growth of pathogenic microorganisms are increased as skin hydration increases, and the skin's barrier properties are also compromised (Aly et al. 1978; Zhai and Maibach 2001a, b, 2002). The clinical consequence of such an environment under diapers is erythema, mild rash, and outright diaper dermatitis, conditions unpleasant to the wearer and care provider.

Wearing of cloth or disposable diapers by infants or the wearing of cloth or disposable incontinence products by incontinent individuals creates a fairly closed environment; how closed it is depends on the fit of the product, the specific materials used, and the specific layering system. Fit influences (1) the amount of air passing between the product and the skin surface and, therefore, the amount of water carried out of the system as vaporous water and (2) how close

moisture (urine) is to the skin surface when the diaper becomes wet. The type of materials influences moisture properties, softness, and the coefficient of friction. Which properties are needed depends on the location of the material in the assemblage (system). Desirable features of top sheet materials are low absorbency and high wickability, plus a low coefficient of friction because it is in direct contact with the skin. Properties for the absorbent layer's material are high absorbency and high water retention. Properties for the bottom sheet are high water vapor permeability (breathability) and high waterproofness (high resistance to the passage of liquid water).

This section reviews those studies in which bioengineering instrumentation was used to compare marketplace products, to develop improved diapering systems, and to enhance experimental produces for studying the effects of diapers/incontinence product on the skin. They are presented in chronological order that best reveals the advancement in diapers/incontinence product design and adjustment of methodologies to detect differences due to product design.

1.2 Evaluating Conventional Disposables and Cloth Diapers

Zimmerer et al. (1986), the first team to publish study results, were interested in the alteration in skin wetness due to covering the skin with wet and dry conventional disposable and cloth diapers. In addition to assessing skin wetness, they assessed changes in skin friction, the skin's susceptibility to abrasion damage, its permeability, and its support of microbial growth. Adults wore prepared diaper patches on their arms which had been preloaded with synthetic urine, a procedural method that the research team had established was as valid as placing the materials on infants in the diapered area. An evaporimeter was used to measure the rate of evaporative water loss off the skin surface following removal of the diaper materials from the subject's forearms. Evaporative water loss (EWL) rates were proportional to diaper wetness. The wetter the diaper patches, the greater the EWL rate. At equivalent water loadings, cloth diaper

material produced greater EWL rates than the disposable diaper. Increased EWL rates were accompanied by undesirable increases in the coefficient of friction, abrasion damage, skin permeability, and microbial growth. An increase in the coefficient of friction results in the skin more easily damaged by abrasion and that exhibits a reduced barrier capacity.

1.3 Evaluating Absorbent Core Materials

Absorbent gel disposable diapers were compared to reusable cloth and conventional disposable diapers in a study by Campbell et al. (1987). Differences in skin health were expected because adding the gel material to the absorbent middle layer of the diaper would increase absorbent capacity and moisture holding/binding capability relative to the other two diaper designs. In this investigation, 1,614 infants were assigned to wear the three different diapers. Like Zimmerer et al. (1986), the main focus was studying the hydration state of the skirt. An evaporimeter was used to collect EWL rate data. The measurement sites were located in the suprapubic and buttock areas and assessment was done before and immediately after the diaper was removed. The skin under the absorbent gel disposable diapers was significantly less wet, closer to normal skin pH, and had a lower degree of diaper dermatitis than the skin under the conventional disposable or reusable cloth diapers. The results were consistent with the researchers' hypothesis that better control in the diaper area of skin wetness, skin pH, and prevention of the mixing of urine and feces produce a better diaper environment.

Fluff absorbent and fluff plus absorbent polymer diapers were used in a study by Davis et al. (1989). Differences were expected because the addition of absorbent polymers to the absorbent inner layer of the diaper should improve fluid binding and help control the pH in the diaper environment. Skin effects were assessed for the change in skin hydration, alteration of skin pH, and occurrence and severity of diaper dermatitis. The clinical study involved approximately

150 infants over 15 weeks, with each infant wearing fluff diapers and absorbent polymer diapers. Again, an evaporimeter was used as well as an electrical conductance instrument to assess water content. Urine loads in the diapers were determined gravimetrically. Expert graders also evaluated infants' diapered skin. Results showed that diapers with absorbent polymer provided a better skin environment than those with fluff because skin wetness was lower and pH control better compared to the fluff absorbent only diaper. In addition, the clinicians' grades indicated a directional reduction in diaper rash severity under the diaper with the absorbent polymer.

Five brands of superabsorbent (SA) diapers were compared to five brands of reusable cloth diapers and four brands of conventional disposables by Wilson and Dallas (1990). Using the Zimmerer et al. model, they asked 80 healthy volunteers to wear a 2 in. wet diaper patch on their volar forearms for 2 h. This team was interested in the relationship between diaper wetness (the amount of synthetic urine remaining in the patch at the end of 2 h of skirt contact) and skin wetness at that same time. The same amount of synthetic urine was placed in each patch (preloaded); the amount represented a moderate amount based on the previous work of Zimmerer et al. (1986). An evaporimeter was used to measure excess skin wetness attributed to the patches. The amount of moisture retained in the patches was determined at the time of removal. The SA disposable diapers kept the skin drier and retained more synthetic urine than cloth reusable and conventional disposable diapers. The SA brands evaluated did an equally adequate job in keeping the skin dry and in retaining moisture. Conventional disposable diapers were less able to keep the skin dry than SA diapers and were not superior to cloth products in most instances. Cloth diapers' ability to lower skin wetness depended on their construction: those with several layers of the same fabric were less successful in keeping the skin dry than ones that contained middle layers of unwoven components. Among these results, the most interesting one is that the diapers that retained the most preloaded moisture during the 2 h wearing period, the SA type, were also those where the skin was

the least hydrated. So the amount of moisture in these diapers was not related to increased skin hydration. This result makes sense when one realizes that the underlying idea for the SA diaper design is to move moisture away from the skin and retain it at a distance from the skin surface so it is not available to hydrate the skin. Odio and Friedlander (Odio and Friedlander) suggested that the reason significant differences were not found among the SA brands was that the methodology was not designed to detect these differences.

Akin et al. (1997) worked to design a methodology to more reliably and realistically assess the effectiveness of absorbent articles in mitigating skin hydration. Changes made were to (1) cover a greater amount of skin surface, (2) measure the amount of water retained in the core (absorbent layer) and in the top sheet rather than total water retained, and (3) load the diaper with urine after its placement on the skin rather than preloading it.

They wrapped disposable diapers with different absorbent structures around the forearms of adult volunteers, then loaded the diaper with urine substitute, and held the wet diaper in place for 1 h. Then they measured the hydration of the volar region by evaporimeter and compared that data to data obtained by measuring skin hydration in the diaper region of children who had worn control-loaded diapers in the usual way. The amounts of fluid retained in various portions of the diaper were measured. One result was that evaporative water loss measurements on adult forearms were a reliable test for comparing the effectiveness of absorbent articles in preventing skin hydration provided that (1) the complete garment was used and (2) fluid was loaded into the garment in a manner that simulated normal urination. Other results were that (1) the skin on adult forearms and skin in the diaper region of children were concordant in their response to wet diapers, and (2) skin wetness was directly related to the amount of liquid retained in layers close to the skin. This methodology was used by subsequent researchers.

Also, highly important to note here is a study by Berg et al. (1994) which was conducted to evaluate the strength of the association of diaper dermatitis with skin wetness and pH. Data was

collected in four diaper clinical trials involving 1,601 infants and over 15,000 individual measurements of skin wetness, skin pH, and observations of diaper rash severity. The data was statistically analyzed. Subjects wore their own diaper product for 4 weeks to establish baseline data, then wore a test diaper product for 8 weeks, and then their own diaper again for 4 weeks. Berg et al. (1994) provide no description of the test diaper but it is likely it is a superabsorbent disposable given the year in which the study was conducted and the company that employed the authors. The skin of the diapered area was visually evaluated for evidence of diaper dermatitis by trained graders every 2 weeks of the 16-week trial. Skin wetness and skin pH measurements were taken at each grading session. Mean EWL values for each infant were calculated as the mean of front and back readings at all-time points, minus a control value obtained on undiapered skin of the thigh. Areas of dermatitis were avoided.

Diapered skin wetness was significantly elevated compared with that of adjacent undiapered skin. Therefore, both pH and skin wetness have an impact on diaper dermatitis. At each grading period, elevated physical measurements were associated with elevated diaper dermatitis grades. Skin wetness was more strongly associated with diaper dermatitis than pH at each grading period.

A retrospective evaluation of 12 clinical studies conducted before and after the introduction of absorbent gelling materials by Odio et al. (Odio and Friedlander) was undertaken to determine whether utilization of these absorbent materials was associated with a marked reduction in the severity of diaper dermatitis. Six of the clinical trials were conducted before the introduction of the new diapers and six following involving 4,000 children. The severity of diaper dermatitis was less after the new core material introduction.

1.4 Evaluating Bottom Sheet Materials

Superabsorbent diapers that differed in type of bottom (back) sheet material were studied by Grove

et al. (1998). One diaper (E) had a waterproof breathable bottom sheet and two others (A and B) had a conventional waterproof bottom sheet. Except for the bottom sheet, diaper E was identical to B. In waterproof breathable bottom sheet diapers, the microporous membrane used for the back sheet is permeable to air and water vapor (is breathable) but impervious to liquid (waterproof). In the study, an intact diaper was attached to the adult forearm or a child wore the diaper. The diapers were loaded with liquid, simulating urination during actual use. After a 1 h exposure period, the hydration state of the underlying skin was evaluated using computerized evaporimetry as well as by using electrical conductance. Comparative studies were also run in the diaper region of children who wore both types of SA diapers. Test diapers were dissected and fluid distribution within various layers was measured gravimetrically.

Both the adult and child model methods gave identical evaporimeter readings of skin hydration for the three test diapers. In each case the diapers were shown to be significantly different from each other with $p < 0.001$. Commercial diaper A left the skin wetter while the experimental breathable diaper E kept the skin significantly dryer. The correlation coefficient of adult and child tests was 0.895. The adult EWL measurements were higher than children's due to differences in probe placement.

Conductance (skin hydration) data also showed the same differences as evaporimetry but there was more variability in the data. Although diapers A and B contained superabsorbent polymer (SAP) at about the same levels, diaper A caused significantly more skin hydration in all tests with all procedures. The apparent cause of this difference was thought to be due to differences in the liquid distribution in the diapers – in diaper A almost 12 % of the total fluid volume remained in the skin-accessible layers and was able to contact the epidermis. In diaper B, virtually all of the fluid was locked into the absorbent core and away from the skin surface. This difference in liquid distribution is consistent with the skin dryness performance of the two products. Diaper E caused the least amount of skin hydration. It had a breathable bottom sheet (outer layer).

Lane et al. (1990) confirmed that disposable diapers containing absorbent gelling material resulted in fewer occurrences and less severe diaper dermatitis after testing 140 infants diapered in either conventional cellulose core disposable diapers and diapers containing the cellulose core plus the gel material. Akin et al. (2001) later determined that children who wore gel diapers with a breathable outer layer had fewer occurrences of *Candida* and common diaper dermatitis than when wearing gel diaper without the breathable outer layer. They also provide a water vapor transmission rate for the breathable film as $>3,000 \text{ g/m}^2/\text{day}$ and for an occlusive bottom sheet film as zero.

1.5 Evaluating Top Layer Materials

A disposable diaper designed with a top (inner) layer supposedly capable of delivering to the skin a formulation intended to protect that skin from over-hydration, and irritation was studied by Odio et al. (2000a, b). The objectives of the first phase were to (1) determine the extent of the delivery of the formulation from the top sheet during normal use of the diaper and (2) whether the amount transferred was sufficient to have an impact on the skin surface microtopography. The objective of the second phase was to assess skin condition. The formulation incorporated into the top layer of the experimental diaper was petrolatum because this formulation has a history of promoting healthier skin in diapered areas by enhancing SC's barrier function and rendering it more resilient to hydrating, irritant, and mechanical insults.

To study the delivery of the petrolatum, 60 children, 16–24 months of age, were assigned randomly to one of two groups. Group one children had two tapes attached to their buttocks. After wearing the experimental diaper for 3 h, one tape was removed, and after a second experimental diaper was worn for 3 h, the other type was removed. Group 2 children also had two tapes affixed to their buttocks. These children wore experimental diapers for a 24 h period, times for

diaper changes being done according to the parent's normal routine.

Parents were not to wipe the tapes. One tape was removed at 18 h. When these children returned to the laboratory at 24 h, the second tape was removed. Subsequently, the tapes were extracted and the amount of petrolatum transferred was calculated. Results were that during normal diaper use, formulation transfer from the diaper to the skin occurred in a cumulative, time-dependent manner.

To study the effect of the delivered petrolatum on skin microtopography, two independent, blinded, and randomized clinical trials were conducted on 110 children. In time period 1 at the first visit, a skin surface replica was taken on each buttock of each child in an area free of evidence of skin damage. Children were then assigned to a group in which they would only wear the control diaper for 9 days or to a group in which they would wear only the experimental diaper for 9 days. The control diaper was identical to the experimental diaper except for the absence of the petrolatum formulation. The control diaper was the superabsorbent type (the core being AGM/cellulose). Parents were given instructions about bathing and diapering the child. On day 10, a second skin replica was made. Children who wore the experimental diaper were dismissed from the study. Those who had worn the control diaper were then assigned randomly to a group to remain on the control diaper or to use the experimental diaper for 1 week. All children returned to the lab on day 18 and another skin replica was taken the same as for visits 1 and 2. The day 10 roughness measurement served as the baseline against which the day 18 roughness measurements could be compared. Importantly, one set of this comparison data (day 10–18) is for children who had worn a high-quality control diaper for an extended period of time before wearing the experimental diaper. Results were that the use of the formulation-treated diaper was associated with significant reduction in skin surface roughness compared to the control diaper.

In phase two, two studies were conducted. The first was designed to determine whether repeated use of the formulation-treated diaper would improve the erythema profile of diapered skin relative to that of infants wearing the control diaper. The second study determined the effect of the test diaper on the diaper rash profile of children during a 4-week period of use of the control and test products. A noticeable reduction in the severity of erythema occurred among the infants who used the test diaper compared to those who wore the control product. There was also a noticeable reduction in the severity of erythema for the infants wearing the control diaper, establishing that wearing a high-quality formulation-free diaper assists with diapered area skin health. Even though the rash scores varied markedly over time for both groups, results were that there was a consistent reduction in diaper dermatitis among children using the test product compared to the control product.

1.6 Other Investigations

Partsch et al. (2000) and Grove et al. (2002) evaluated change in the scrotal, skin, and/or core temperatures under the diapered area of young boys. The procedure used by Partsch et al. was to record scrotal temperatures over a 24 h period in the child's home using a Thermoport device which was designed for long-term monitoring in adult males. One series of temperatures was taken while the child wore a disposable diaper (German Pampers Premium, Proctor and Gamble) and while wearing a reusable diaper (whether a protective cover was worn or not is not known). They found that mean scrotal temperatures under the disposable diapers were significantly higher than under the reusable diapers. The procedure used by Grove et al. (2002) was to continuously monitor scrotal and skin surface temperatures under controlled laboratory conditions using temperature probes designed for pediatric studies. Temperature of the tympanic membrane was measured using an infrared thermometer as an estimate of

core temperature for each individual at various times during the 2 h session. The subjects were 70 normal healthy boys, 3–25 months old. The diapering situations included reusable cloth diapers used with and without a protective cover and various disposable diapers. The findings were that scrotal temperatures were the same during the wearing of disposable diapers and reusable cloth diapers with protective cover. Scrotal temperature was lower when the reusable diaper was worn without the cover. On average scrotal temperature was significantly lower than core temperature. Skin surface temperatures increased when covered by a diaper.

Zhai et al. (2002) investigated the relationship of stratum corneum hydration and skin permeability as a result of covering adult skin with wet occlusive patches and wet diapers for 10 min, 30 min, and 3 h. Nine women wore the patches on their forearms after baseline values for water evaporation rate (WER), skin blood flow volume (BFV), capacitance (Cap), and redness (a^*) were determined. Immediately after removal of the patches, either 20 μ L of methyl or hexyl nicotinate was applied to various sites. WER and Cap readings were recorded at designated sites 0, 5, 10, 15, and 20 min after nicotinate application. The a^* and BFV measurements were made on each nicotinate-challenged site 5, 10, 15, 20, 30, 40, and 60 min after the nicotinate application. Findings were that wet patches and diapers increased skin hyperhydration proportional to exposure time. Permeation of nicotinate increased for hydrated skin versus control, as soon as 10 min of patch exposure. There was no evidence of increased permeation rates with increased hyperhydration once a relatively low threshold of hyperhydration was achieved. The researchers concluded that there were no meaningful differences in permeation following either diapering simulation and suggested that the “WER-Area Under the Curve Method was superior to capacitance for measuring the absolute extent of hyperhydration.”

Visscher et al. (2000) investigated (1) the normative features of newborn SC hydration and

barrier properties during the first month of life, (2) identified differences in skin hydration and barrier properties of diapered skin versus undiapered control sites, and (3) compared the barrier properties and hydration of infant skin with those of adult skin under similar environmental conditions. One purpose of the study was to determine whether newborn children's mothers' volar forearms might be used to learn about the hydration effects of diapering newborns. Thirty-one term infants were evaluated in the hospital on postnatal day 1 and at home on days 4, 7, 14, 21, and 28 for a total of six visits. Measurements included baseline skin hydration, continuous capacitive reactance, and environmental conditions. The skin sites were below the waistband of the diaper above the symphysis pubis and above the waistband. Measurements were taken 25 min after diaper removal to allow evaporation of surface moisture. Changes in epidermal barrier properties over the first 4 weeks of life included an increase in surface hydration, a decrease in transepidermal water movement under occlusion, a decrease in surface water desorption rate, and an increase in surface pH. Diapered and undiapered regions were indistinguishable at birth but exhibited differential behavior over the first 14 days, with the diapered region showing a higher pH and increased hydration. Maternal measurements remained constant throughout the period. They concluded that healthy newborn skin undergoes progressive changes in epidermal barrier properties over the first 28 days. Adult skin testing does not replicate newborn skin during the first month of life.

2 Garment Fabrics

2.1 Specifications

Fabric is a thin, planar material whose smallest material unit is a textile fiber, a unit of matter that is characterized by having a length at least 100 times its diameter or width and which can be spun into yarn or made into fabric. The diameter of textile fibers is small – generally, 0.0004–0.002 in. (10–50 μm). Their length varies from $\sim 7/8$ in.

(~ 1.8 cm) to many miles. The other material component of fabrics is yarn, long thin structures composed of fibers. In addition to fiber content, a fabric may also have a colorant content (dyes and pigments) and a chemical finish content. Fabric is the most suitable material for covering the human body because it usually allows insensible perspiration (TEW) to pass through it and it moves as the body moves (bends, stretches, etc.).

Placing garment fabric over the skin does not usually create nearly the occlusive environment that results from the wearing of diapers/incontinence products. However, placing any garment fabric on the skin has the potential to change skin properties. Fabrics differ from each other in water vapor permeability (a property commonly called breathability), in absorbance of water vapor, in capability to absorb, adsorb, and imbibe liquid water, in wicking ability (the ability to move water from one surface to the other by capillarity), in softness (ease of bending), and in surface characteristics. Like diapers, garment fabrics may become saturated with water, the water in this case being most often perspiration or rainwater. Continuing to wear wet fabrics after swimming, snorkeling, and other water activities keeps a water supply near the skin surface. Wetted fabric may be a source of water to increase SC hydration. Wetted fabric may lie closer to the skin surface than dry fabric and may alter the degree of friction of the fabric on the skin.

The motivation for studying the effect of fabric on skin properties does not lie in the need to reduce a singular major skin health such as underlies the study of the effect of diapers on the skin they cover. Rather, the motivations have been to learn (1) under what wearing conditions can changes be detected and (2) what properties of the fabric may account for the differences in the magnitude of change. The long-term motivation is that test procedures might be developed that would aid in evaluating high-performance sports apparel and occupational protective garment systems (systems in which the outer layer of the system provides a barrier to wearer generated moisture dissipation).

In this section, we review a series of studies in which the effect of garment fabric on the skin was

studied. These studies are grouped by the type of fabric used in the experiment.

2.2 Triacetate and Polyester Fabrics Experiment

In the earliest study (Hatch et al. 1987), our objective was to (1) determine whether a change in SC hydration could be detected after being covered by a fabric swatch using available bioengineering instrumentation and (2) whether the fiber composition of the fabric made a difference in the hydration state of the skin lying under it. Two woven dress weight fabrics that were alike except in fiber composition were selected. The fiber composition of one was polyester (a manufactured synthetic fiber with poor moisture absorption) and the other triacetate (a manufactured cellulosic fiber with moisture absorption capacity about five times greater than polyester). Swatches of each of these fabrics were placed on a sedentary subject's forearms with and without a covering of occlusive plastic film. A focused microwave probe was used to assess SC water content and an evaporimeter measured rate of transepidermal water loss (TEWL) before and after removal of the fabric swatches.

Placement of either triacetate or polyester on the forearm without a covering of film did not cause detectable changes in water content or evaporation measured immediately after fabric removal even when the fabric had been in contact with the skin for 90 min. SC water content and evaporation increased as the fabric film remained on the forearm longer. SC water content was generally greater at polyester/film-covered forearm sites than at triacetate/film-covered sites, but there was not a significant statistical difference due to fabric type (fiber composition). Forearm water evaporation after fabric swatch removal was also greater for polyester/film sites than for triacetate/film sites; this difference was statistically significant. Occluded fabric placed on the skin, therefore, influenced SC water content and water evaporation rate. The data suggest that fiber absorption differences influenced the hydration of the covered skin. The triacetate fabric was

absorbing more of the transepidermal water than the polyester fabric.

Encouraged by these results, our team decided to undertake a study in which we would investigate changes in skin hydration due to (1) activity level of subject (sedentary, vigorously active, and resting after activity), (2) the exercise environment (hot-humid and hot-dry), and (3) the moisture holding capacity of the fabric of the exercise garments. Another objective was to assess comfort sensations (wet sensation and skin contact comfort) of the fabric to confirm differences in the bioengineering instrumentation results. We also were interested in whether the stiffness of fibers might alter capillary blood flow and designed this experiment to include this objective.

2.3 Jersey Knit Garments Experiment

Three jersey knit fabrics were made. The fabric construction, jersey knit, is that one usually used for the manufacture of T-shirts. One fabric was made entirely from cotton fibers, one from 1.5 denier polyester, and one from 3.5 denier polyester. Cotton fiber, known to be highly absorbent, and polyester fiber, known to absorb little or no moisture, were of interest because of the large difference in absorbent capacity. Two deniers (weight per unit length) of polyester fiber were used so that the stiffness of the fibers were different. A 3.5 denier polyester is the maximum size polyester fiber used for garment fabrics. The fabric made from it was noticeable rougher than the fabric made from the 1.5 denier fiber. Each fabric was characterized instrumentally for its comfort properties (absorption, heat conductivity, etc.) (Hatch et al. 1990a) and its mechanical and surface properties related to wearing comfort (Barker et al. 1990).

The three jersey knit fabrics (100 % cotton, 100 % 1.5 denier polyester, 100 % 3.5 denier polyester) were made into long sleeve T-shirts and pants of various sizes. The upper back section was designed with a zippered section so that instrumental measurements could be taken on the upper back. Ten female subjects were enrolled

into the study after it was ascertained that they were capable of doing the exercise routine in the experimental environments. For each session, they first acclimated in the exercise chamber, and baseline measurements were taken including rate of evaporative water loss using an evaporimeter, water content of the SC using a focused microwave probe, and capillary blood flow using laser Doppler velocimetry. In six sessions, each subject exercised and rested in a hot, humid environment wearing each of the three garments and then in a hot, dry environment wearing each of the three garments. Garments were laundered between sessions. Cutaneous assessments (rate of evaporative water loss, water content of the SC, and capillary blood flow) were made under the fabric 20 min following placement of the fabric on the skin, after 40 min of vigorous exercise, and 20 min after exercise ceased. Subjects were asked for their perceptions of contact comfort using a standard contact comfort scale.

2.3.1 Skin Hydration Results

Rate of skin evaporative water loss from the skin surface was lower in the higher humidity environment at all TEWL measurement times (Hatch et al. 1990b). More water accumulated in the subjects' SC when they exercised in the humid environment. Capillary blood flow was not significantly influenced by environment. Skin temperature statistically differed in the two environments, but differences were negligible. Statistically significant differences in the physiological measurements did exist as a result of fabric type. The researchers speculated that the results might have been different with snugger garments.

There were no significant differences in water evaporation or SC water content due to the type of fabric (Markee et al. 1991). Calculation of thermophysiological comfort limits (Hatch et al. 1990a) for each of the fabrics based on heat and moisture measurements supported the nonsignificant results. The large differences in water absorption capability of the fabrics did not influence skin hydration state. This result probably reflects the fact that the fabrics did not lie on the skin surface. All three fabrics increased the

level of SC water content and water evaporation due to placement on the skin surface. Exercise level (sedentary, vigorous, resting) significantly influenced skin wetness state. Further, subjects did not indicate differences between the fabrics for wetness or thermal sensations, a result explainable in terms of the extremely small differences in water and heat transport fabric data and the statistically insignificant differences in SC hydration and evaporative water loss from the skin surface (Hatch et al. 1990a). The regression model for wetness sensation showed that SC water content and evaporative water loss were statistically significant determinants.

2.3.2 Effect on Blood Flow

No statistically significant differences in capillary blood flow were detected at upper back measurement sites when ten female subjects exercised in garments made from the jersey knit fabrics of differing fiber contents (Markee et al. 1991). This occurred even though the characterization testing showed that the fabrics differed in fiber and fabric stiffness as well as in other low-stress mechanical properties (Barker et al. 1990). Unfortunately, we probably took the laser Doppler measurements on the wrong skin site. We had noted redness at the tops of the shoulders of the subjects with the fairest skin following 40 min of exercise when the 3.5 denier polyester garment was worn. However, no laser Doppler measurements were taken at these sites during the exercise protocol. We speculated that the stiffness of the polyester fiber was causing the redness, and the skin/fabric contact at the tops of the shoulders was greater enough in this region for the redness to develop.

The link between blood flow and perceived sensations was addressed by regression analysis (Markee et al. 1990). Skin temperature was a significant determinant of perceived thermal comfort in the regression model, but capillary blood flow was not. Capillary blood flow was the only physiological factor with a statistically significant effect on overall comfort. The researchers suspected a link between the mechanical and surface features of the fabric and capillary blood flow.

2.4 Jersey Knit Fabric Swatch Experiments

Further work was undertaken with the jersey knit fabrics because we were surprised to observe that our female subjects' upper back SC were as hydrated under their cotton exercise garments as under their polyester exercise garments (Hatch et al. 1992a). This was particularly noteworthy because the cotton T-shirts were wetted more with sweat over the measurement sites than the polyester T-shirts. We expected to find a significant difference in SC hydration, not only under the cotton and polyester garments but also under the two polyester fabrics that contained different denier fibers. The purpose of this study was to determine the effect of fiber type and fabric moisture content on SC hydration. The six combinations of treatments were cotton at regain, 38.6 %, and 75 % moisture content; 3.5 % polyester at regain and at saturation (38.6 %), and 1.5 denier polyester at saturation (38.6 %). Using an occluded plastic dome, fabric swatches were placed on both normal and hydrated volar forearm skin of subjects for a specified time period and then removed. Two minutes after removal, evaporative water loss and skin temperatures were measured. The design of the study was a randomized complete block with all possible treatment combinations applied to each subject. Data were analyzed using analyses of variance on the linear and quadratic coefficients of best fit lines and Bonferroni t-tests.

For normal skin, SC hydration generally increased as fabric moisture content increased. The SC was significantly drier after being in contact with cotton fabric at regain than at the two moisture content levels above regain and also under polyester fabric. For hydrated skin, the hydration state was significantly lower under the cotton fabric at regain than at 38.6 % moisture content and at saturation, but was not significantly different under the polyester fabric at regain and at saturation.

Some of these results were not as expected and needed yet further examination. We wondered whether the observed decrease in evaporative water loss from time 30 to time 60 was statistically

significant for the cotton/44 % and polyester/35 % treatments, and also if the observed increase in evaporative water loss from time 30 to time 60 was statistically significant, for the cotton/75 % treatment. Further, we wondered whether the explanation we offered in that paper about these results was correct. This was our first experiment in which the fabrics were wet prior to placement. We designed an experiment to monitor the amount of moisture in the fabric as well as the alteration in evaporative water loss from the SC. In the last of this sequence of studies (Hatch et al. 1997), the objective was to examine the relationship between fabric moisture content at the time of fabric removal and level of SC hydration so that the role of fabric moisture might be better understood.

Three fabric/moisture treatments were placed on the SC – 3.5 denier polyester fabric with an initial moisture content of 35 % and cotton fabrics with either 44 % or 75 % initial moisture content – then covered with an occlusive dome. SC evaporative water loss (EWL) is measured before treatment placement and after 30 and 60 min of contact. The amount of moisture in the fabric at time of removal was calculated in two different ways; the three analyses of variance were done using the evaporative water loss and the two fabric final moisture content data sets. The rate of TEWL is significantly higher after 30 min of treatment contact with SC than after 60 min of contact. The amount of moisture in the fabrics is significantly less at time 60 than at time 30, implying that the SC is more hydrated at 30 min than at 60 min. However, the fabrics contain less moisture when removed at 60 min than at 30 min. As fabric moisture content decreases, SC hydration decreases. The question we are not able to answer is “Where does the moisture go that is initially in the fabric?”

2.5 Wool Fabric

Wester et al. (1985) were interested in whether the insulating nature of certain fabrics altered human capillary blood flow. Capillary blood flow was measured using laser Doppler velocimetry, a

noninvasive low-power laser light optical technique. Two fabrics that differed significantly in thermal conductivity, a fourfold difference as determined by the guarded hot plate method, were placed on the upper arm often on female volunteers. Blood flow was significantly higher under the fabric with the lower thermal conductivity.

Wester et al. (1985) also investigated whether the abrasive nature and/or prickly nature of certain fabrics might alter capillary blood flow. Two wool fabrics were selected that differed substantially in contact sensation – one was soft, the other coarse. The thermal effect was controlled by layering the fabrics before they were worn under a tricot top on the upper back. On one side of the upper back, the coarse fabric contacted the skin, and on the other side, the soft fabric contacted the skin. Skin blood flow increased from 0 to 3 h, but there was no statistically significant difference between the fabrics. Six of the nine volunteers, however, showed higher blood flow when the coarse fabric was next to the skin than when the softer fabric was next to the skin. The researchers concluded that fabric influences skin blood flow but that it is not known whether the prickling or abrasive action of the fabric's fibers on the skin altered blood flow or whether any flow alteration was undetectable due to instrumentation and methodological limitations.

2.6 Multiple Fabric Skin Hydration Experiment

Cameron et al. (1997) investigated the effects of fabric made from natural and synthetic fibers and film on transepidermal water loss from the SC using an occluded system. Sixteen fabrics differing in fiber type and construction were placed on the volar forearm of 35 female subjects in a dry state (standard moisture regain) and a wetted state. Each fabric was in place for 40 min before TEWL was measured. There was no statistically significant difference in TEWL measurements on a control skin site from the beginning to the end of the

75-min test session in a controlled, conditioned environment. Placement of dry fabrics on the skin did not significantly affect the hydration level of the SC, though all dry fabrics did increase the hydration level slightly. Wetted wool and cotton fabrics significantly hydrated the SC when levels were compared to either normal skin or skin covered by dry fabrics. Of the seven synthetic fiber fabrics tested in the wetted state, three acrylic, PTFE, and spun nylon significantly increased the SC hydration level. These three fabrics and the natural fiber fabrics had comparable wetted moisture content.

In summary, much remains to be accomplished in studying the effect of garment fabrics on the skin. Using bioengineering instrumentation remains a viable avenue for the development of high-performance fabrics in which moisture management is a key issue.

3 Cleansing Cloths for Infants

Cleansing cloths to clean the diapered area of infants are of two major types: cotton wash cloths which are textile products and disposable wipes which are usually considered paper products. Disposable baby wipes have been used in North America for over 30 years and cotton wash cloths for even longer. Which of the two types of products and which type of disposable wipe is the safest to use have been recently investigated using bioengineering instrumentation.

3.1 Effect on Skin pH

Priestley et al. (1996) investigated changes in skin pH after the use of disposable baby wipes. They enrolled 317 babies with non-diseased skin ages 4–12 months of both genders into the study. They set up a double-blind safety in use comparison of four different brands of baby wipes over a 10-week period. For the first 2 weeks, the babies' skins were cleaned with only soap and water after each diaper change. Then, in the next 8-week

period, each baby was allocated one or other of the products for normal home use. The wipes differed in cleansing lotion formulation (emollients, preservative, pH) and fibrous composition.

Results were that there were no clinically detectable differences (erythema, frequency of rashes, edema, and desquamation) among the wipes. There were significant changes in the pH of pubic and buttock skin inside the diaper area. In particular, the brand of wipes with the lower pH (2.8) in the lotion reduced the mean skin pH from 5.6 to 5.0 ($p < 0.01$), and those with a pH of 5.5 had no significant effect. Wipes of pH 3.7 gave a final skin pH of 5.4, but the downward trend was not statistically significant. The authors note that skin pH was depressed by topical application of lotion in the wipes during the experimental period which was only a fraction of the total time wipes might be used on each infant. A longer time frame should be used to know the long-term effect.

3.2 Forearm Test Method Development

Farage (2000) developed a modified forearm-controlled application test method for evaluating the mildness of disposable wipe products on the skin. The procedure developed includes a semi-occlusive patch system, a system intended to mimic the hydrated conditions common to the skin in the diaper area, and repeated washing cycles. Visual scoring is done for erythema and dryness and instrumental scoring for redness (chromometer) and transepidermal water loss (evaporimeter). The procedure includes details for obtaining the hydration level recommended, applying the test products, and test duration to achieve significant endpoints for all product assessments.

Four baby wipe disposable products were selected once the protocol was established. Differences were found among the products on all assessments. The products were not described. What characteristics of the products accounted for the differences in skin state is therefore not available.

3.3 Suitability of Wipe Use on Dermatitis Skin

Odio et al. (Odio and Friedlander) investigated the suitability of using infant wipes on children with dermatitis skin. They looked for possible differences in rates of skin repair at a tape-stripped skin site that was not wiped and at a tape-stripped site that was wiped with a high-quality baby wipe. The tape stripping was done on the volar forearm of adults until a stable rate in transepidermal water loss was achieved at approximately $30 \text{ g/m}^2/\text{h}$ above base rate (a condition thought to correspond with that observed on the skin of children who are experiencing a moderate to severe diaper dermatitis reaction). One tape-stripped site served as a control, and the other was rubbed with the wipe in a manner simulating the amount of wiping a child's skin might experience in a normal day. A single grader, who did not know which treatment was applied to each site, scored the sites for degree of erythema. Results were that erythema scores declined at a relatively uniform rate during the course of the 4 days of the study at both control and wipe-treated sites; importantly, scores remained comparable between sites through the entire study, and by day 4, erythema was almost completely gone at the control and test site. It was concluded that the use of a high-quality infant wipe does not interfere with the normal process of skin repair.

3.4 Cotton Washcloth and Water Versus Disposable Baby Wipes

Odio et al. (2001) designed four experiments to study the effects on skin cleansed with water and a high-quality cotton washcloth intended for hygiene care of children and with two different brands of high-quality disposable baby wipes.

Study 1 was an 8-day in-use skin mildness comparison of the products on 82 children. All children were in good health at the enrollment visit, weighing 16–28 lbs, were disposable diaper wearers, and had Fitzpatrick skin types I–III.

None had known contact allergies, presented with moderate or greater erythema or rash in the diaper area, or took medication that might influence skin condition or might increase stool frequency. They all wore the same disposable diaper immediately following enrollment in the study. Usual cleansing practices at diaper changes were done during the first week but no lotions, creams, or powders were used after cleansing. Half of the infant then cleansed with one of the wipe products for 8 days and the other half with the cotton washcloths and water. Again, no lotions, creams, or powders were used. No instructions were provided for cleansing. Assessments were visual skin erythema by an experienced grader, skin barrier status by evaporimetry, and skin surface microtopography.

Skin redness observed in the genital region of infants who were cleansed with the cloth and water was not different than that of infants who were cleansed with the disposable wipe. However, in the perianal area, where cleansing tends to be more vigorously done for hygiene reasons, skin redness scores were statistically higher for the children cleansed with cloth and water than for those cleansed with the disposable wipe. No significant changes occurred in TEWL as a result of cleaning with both products. Surface roughness of skin increased for infants cleansed with cloth plus water, but not for those cleansed with the disposable baby wipe, but the difference was not statistically significant.

Study 2 was a 2-week study to evaluate change in baseline transepidermal water loss due to controlled cleansing using (1) a washcloth with water, (2) a washcloth with soap and water, and (3) a baby wipe on degradation of skin barrier integrity using the Farage test procedure (Farage 2000) on 24 females 18–45 years old. They were in good health, had skin types I–III, and agreed to adhere to specific skin-cleansing routines and not use skin care products that might interfere with the study. They were not taking medication that would affect skin condition, nor were they pregnant or lactating.

Subjects suspended the use of all skin care products on forearms 1 week before the first clinic visit, a visit during which volar arm skin sites

were demarcated and assigned a treatment. Cleansing was done at the clinic on days 1 through 5, spaced at 90 min intervals. There were three cleansing sessions of 30 s duration and one of 60 s duration. TEWL loss was assessed on day 1 prior to initial cleaning and on day 5, 90 min after the last cleansing.

Repeated, daily cleansing using disposable wipes yielded no detectable change in skin barrier integrity (elevated TEWL). However, cleansing with the washcloth (both with water and with water and soap) resulted in a statistically significant increase from the baseline indicating detectable degradation of the epidermis. The degradation was greater when soap was used.

Study 3 was a 5-day study to evaluate the rate of skin repair following controlled cleansing with two brands of disposable wipes and with the cloth plus water. On day 1, erythema scores and baseline TEWL measurements were taken at a control and two treatment volar forearm sites of 24 female subjects. Subjects met the same criteria for inclusion as in study 1. Sites were tape stripped until the rate was about 50 g/m²/h. Cleansing of the treatment sites was done in the clinic on four consecutive days. Erythema scores and TEWL measurements were taken each day.

Skin repair, as evidenced by a return of TEWL measurements to the baseline measurement, and reduction of skin redness scores proceeded at comparable rates at sites cleansed with disposable wipes and the control site. In contrast, the sites cleansed with the washcloth and water showed a pronounced delay in the rate of barrier recovery.

Study 4 was designed to determine stinging sensation of wipe lotions on compromised skin, especially nasolabial folds. One side was exposed to wipe lotion and the other to water (negative control). Neurosensory response was scored from 0 (no sensation) to 5.0 (extreme stinging). Females eligible for this study had to have no evidence of epidermal damage in the study area and had a sting response to 10 % lactic acid. Facial skin care products were not used for 1 week except the use of soap for cleaning. TEWL measurements were taken on day 1 and 2, the days the subjects became familiar with the sting test. On day 3, TEWL is taken and then the skin tape

stripped. This was repeated on the afternoon of day 3, the morning and afternoon of day 4, and the morning of day 5. On the afternoon of day 5, a final TEWL measurement was taken at each nasolabial fold. Water was applied to one fold and lotion to the other. Two minutes later each subject graded the sensation. Fifteen minutes later, lactic acid was applied to both folds and the subjects rated the sensation to verify the sting sensitivity of the subjects.

Sting responses were not statistically different for water application and wipe lotion application to the compromised skin of the female subjects. The sensations evoked by both treatments were below the sting range of the scoring scale.

Overall, the results of the four studies showed that cleansing with high-quality baby wipes leads to less compromised skin. The results of this study should not be generalized to all wipe products as there are many brands available in the marketplace.

4 Disperse Dye Effects on the Skin

4.1 Evaluating Commercial and Pure Textile Dyes

Malinauskine (Malinauskiene et al. 2011) explored disperse dyes, D Orange 1 and D Yellow 3, and its sensitizers present in the commercial dye. Two disperse dye azo-dyes (D Orange 1 and D Yellow 3) were tested because they were found to most frequently result in a positive testing in their dermatitis department. The tests were carried out on ten patients who previously tested positive for reactions with D Orange 1 and D Yellow 3. The test was carried out using commercial dye and purified dye. Diluted purified dye, water-soluble residues of D Orange 1 and D Yellow 3 diluted to a concentration of 1.0 % w/v in distilled water, and naphthalene sulfonate 1.0 % aq w/v were used for the patch testing. The commercial dye was separated into its water-soluble and fat-soluble fractions where the samples were then diluted to a concentration of 1.0 % w/v using distilled water. The patch testing for the commercial dyes was done using thin-layer

chromatography to separate the dye from any impurities. The separated spots are then cut from the TLC and placed on the back of the patients for 48 h using Scanpor tape. The pure dyes did not require any separation using TLC for patch testing. The test showed that there was some reactivity on different spots of the TLC which indicates that there are sensitizers present in commercial dyes DO1 and DY3 that are not present in purified DO1 and DY3.

4.2 Interaction Between Skin Bacteria and Textile Dyes

Malinauskine et al. (2012) further investigated the effects of human skin bacteria breaking down textile dyes into corresponding aromatic amines. Studies have also show that a cross-reactivity between disperse dyes and para-amino compounds could result in positive reactions or cross-sensitization. This test was carried out on ten patients who have previously tested positive for reactions with D Orange 1 and D Yellow 3. Possible azo degradation pathways for both D Orange 1 and D Yellow 3 were found to be p-aminodiphenylamine, 4-Nitroaniline, 4-Aminoacetanilide, and 2-Amino-p-cresol. Furthermore, the para-amino compounds, black rubber mix, and p-phenylenediamine (PPD) were also patch tested. Black rubber mix contains a mixture of *N*-cyclohexyl-*N'*-phenyl-4-phenylenediamine (CPPD), *N,N'*-Diphenyl-4-phenylenediamine (DPPD), and *N*-Isopropyl-*N'*-phenyl-4-phenylenediamine (IPPD). Pure samples of each of these chemicals were obtained for the test. High-performance liquid chromatography was done on the pure samples D Orange 1 and D Yellow 3 to confirm that none of the azo-degraded chemicals were present. The patch tested was done using purified DO1 and DY3, PPD, CPPD, DPPD, and IPPD all dissolved in acetone and prepared as 1.0 % wt/vol. The patients were also tested with different concentrations of the purified dyes; previous patients who reacted +++ to 1.0 % concentrations were tested with 0.01 %, while people who previously did not react to the dyes were tested with the highest concentration, 1.0 %. The patients were also tested with possible azo-dye

degradations, p-Aminodiphenylamine, 4-nitroaniline, 4-aminoacetanilide, and 2-amino-p-cresol, at concentrations equimolar to the dilution series of DO1 and DY3 starting at 1.0 % wt/vol. Patch testing were done using Finn chambers on Scanpor tape using 15 μ L and left on the back for 48 h. Results showed that all patients who react positive to DO1 also react positive to p-aminodiphenylamine, a possible metabolite of the former. Also, patients who reacted positively to DY3 also reacted positive to 2-Amino-p-cresol, which is a precursor to DY3. The results of the test show that it is possible that major sensitizers in ACD from DO1 and DY3 can be due to their metabolites, p-aminodiphenylamine, and 2-Amino-p-cresol, respectively, which might be formed through the azoreductase pathway of skin bacteria.

5 Footwear Dermatitis

Svecova (Švecová et al. 2013) investigated contact dermatitis due to the mold inhibitor, dimethyl fumarate (DMF), found in footwear. DMF has been shown to be a potent sensitizer in very low concentrations and may acute dermatitis. Tests were carried out on nine female patients who were admitted to the University Hospital Department of Dermatology in Bratislava, Slovakia for footwear acute contact dermatitis associated with DMF. Patch testing was done using textile lining from the patients' boots that caused their contact dermatitis and 0.1 % of commercially prepared DMF. The patch testing was carried out on the patients using Curates patch test chambers which were left on for 2 days. Furthermore, chemical analysis was used on the footwear that caused the patients' skin reactions. The shoes were extracted for samples then tested using gas chromatography/mass spectrometry (GC/MS), atomic absorption spectroscopy (AAS), and UV-Vis. The results of the patch testing confirmed that the patients' ACD was caused by their footwear. Additionally, seven of the nine patients tested positive to the 0.1 % DMF patch test. Chemical analyses of the sample material from the patients' shoes detected DMF at concentrations of 25–80 mg/kg, much higher than the allowed

concentration of 0.1 mg/kg in EU. The analysis of the textile lining confirmed that DMF is the only chemical that could cause ACD. The lining of the material could have also contributed to the development of ACD due to its insulating and chemical properties which results in warmth, humidity, and occlusive environment, conditions that would contribute to the leaching of any allergens. Skin penetration can also be enhanced by sweating which can result in an increased penetration of the allergen. The results of the tests confirm the presence of DMF and its contribution of causing ACD in the patients.

6 Conclusion

The use of bioengineering instruments has allowed the study of the effects of fiber-based materials on the skin they cover and/or contact. The development of diapers and incontinence products has been enhanced because the effects of changing components of the system on the skin environment can be assessed instrumentally as well as by trained clinicians. Additionally, the safety of using baby wipe products has been advanced because skin effects can be assessed instrumentally using adult subjects. Effects of garment fabrics on human skin are not as well studied, but promising outcomes can be achieved by the use of these instruments.

7 Interpretation: Skin Tolerance

As noted here, we have some information on how skin tolerates (or does not) fabric. Even though considerable progress has been made, the experimental data remains sparse – and would benefit from further in-depth data such as effects of ethnicity, age, gender, regional anatomic variation, and climate.

As to safety (dermatotoxicology and percutaneous absorption) of chemical transfer from fabric to skin, much remains to be done. At present, the safety of nano-silver is being investigated, yet this represents but one chemical class. Ngo details the 15 principles of percutaneous penetration

including transfer (from fabric) and a critique of knowledge of percutaneous penetration of nanos such as silver-treated fabric (Mai et al. 2012, 2013).

1 Modeling TEWL-Desorption Curves

1.1 Introduction

The accurate assessment of skin barrier function represents a challenge, one that has been undertaken by multiple approaches. TEWL is traditionally recognized to be indicative of this skin property (Lotte et al. 1987; Pinnagoda and Tupker 1995); however, several works have reported a poor correlation between damage inflicted to the skin and changes in TEWL values (Chilcott et al. 2002; Bashir et al. 2001). Additionally, the methodology is limited by providing only instantaneous data susceptible to great variability (anatomical, climatic, circadian, sweat gland activity).

Dynamic strategies have been developed to overcome the pitfalls of this variability. The skin response to determined stimuli can be evaluated, enabling a more thorough investigation of the factors that influence the skin water dynamics in the superficial and in the deeper layers. The plastic occlusion stress test (POST) is an example of this approach, based on a prolonged skin occlusion (usually 24 h). It aims to noninvasively quantify

functional parameters of the stratum corneum in order to better assess barrier function (Turek et al. 1982; Werner et al. 1982; Berardesca et al. 1990, 1993; Berardesca and Maibach 1990; Piérard-Franchimont et al. 1995). Initial protocols fitted the skin surface water loss (SSWL) curves obtained when occlusion was terminated, either using bi-exponential regression analysis or by transforming the data in log and then using simple regression analysis (Berardesca and Maibach 1990; Fluhr et al. 1999). It can be argued that these models are too simplistic to describe the complex water balance between the different layers of the skin.

Further developments on the mathematical modeling of the TEWL curves that result from a POST (Rodrigues et al. 1999; Rosado et al. 2005) have enabled a more detailed quantitative characterization of the dynamic water balance established between the deep and the superficial skin structures (Pinto et al. 2002). In this section, the discriminative capacity of the model to two different types of variation in the cutaneous barrier is presented – insults inflicted to the skin (tape stripping, skin surface biopsy, and lipid extraction with ether:acetone) or differences in two distinct anatomical regions.

1.2 Methods

Fourteen volunteers (mean age 27.2 ± 9.8) participated in this study after informed consent. A total of nine volunteers were tested in each type of study conducted: effect of tape stripping, effect of lipid extraction, effect of skin surface biopsy, and difference between wrist and mid volar forearm (Rosado et al. 2005). The procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation and with the Helsinki Declaration.

One site was marked in each volar forearm of the volunteer. One arm was assigned as the untreated control, and on the other arm (treated site) one of three different insults to the skin barrier was performed: 20 tape strips, lipid extraction with a 1:1 mixture of ether:acetone, or four skinsurface biopsies (SSB) with cyanoacrylate (Marks and

Dawber 1971). Both sites (control and treated) were then covered with an occlusive patch for 24 h, after which the desorption curves were recorded. The same procedure was applied to the study of anatomical differences. The occlusion and measurements were conducted in the same arm, on one site in the mid volar forearm and another in the wrist. After patch removal, TEWL measurements were continuously registered for 30 min. The mathematical model was adjusted to the data points using a specially modified simplex routine and the software ADAPT written in Fortran. Calculated parameters considered relevant to the study were $t_{1/2\text{evap}}$ (evaporation half-life) and DWM (dynamic water mass) (Rodrigues et al. 1999). Nonparametric comparative analysis (Wilcoxon sign-rank test) was used in this study. A 0.05 significance level was adopted.

1.3 Mathematical Model

A bi-compartmental model was employed to describe the in vivo mechanisms of water distribution (Rodrigues et al. 1999). There is no direct correspondence with the histological organization of the human skin: compartment 1 represents the skin barrier with poor water content and compartment 2 represents the fully hydrated deeper layers of the skin.

Occluding the skin with a patch dramatically changes the water balance between these two compartments. From the water flux established according to Fick's first law of diffusion and the compartmental model defined, the variable TEWL can be modulated by a set of two linear first order differential equations (Rodrigues et al. 1999). After solving, in order to compartment 1, the solution is in the form of an algebraic sum of two exponential terms (Eq. 1).

$$\text{TEWL} = B + I(e^{-K_{\text{evap}} \times t} - e^{-K_{\text{hydr}} \times t}) \quad (1)$$

where:

B – baseline effect

I – multiplicative parameter common to both exponentials

K_{evap} – evaporation rate constant (used to evaluate the barrier function)

K_{hydr} – hydration rate constant related to the distribution of the water through both compartments

The two exponentials are affected by the macroconstants K_{evap} and K_{hydr} . The latter represents the water initially eliminated and is related to the occlusion period and to the water retention capacity of the stratum corneum. K_{evap} describes the evaporation process to the exterior and is affected by changes to the barrier function. These are the most important parameters provided by the model. The baseline effect is also relevant and represents the basal finite amount of water continuously lost through the skin. The model describes this physiological process using the variable B , which at $t = 0$ is equal to TEWL.

A transformation of K_{evap} is suggested, to simplify data interpretation (Eq. 2)

$$t_{1/2\text{evap}} = \frac{Ln(2)}{K_{\text{evap}}} \quad (2)$$

where $t_{1/2\text{evap}}$ represents the evaporation half-life period – the time the system takes to reduce its water loss to half.

Dynamic water mass (DWM) represents the relevant water mass involved in the desorption process. The area under the curve from t_{max} obtains this parameter until the end of the process.

The final analysis of this work was performed adjusting the experimental data to the model to obtain the most important and relevant parameters, namely K_{evap} , $t_{1/2\text{evap}}$, t_{max} , and DWM.

1.4 Results

The different desorption curves obtained after a 24 h occlusion are represented in Fig. 1. It can be seen that in the site where four-skin surface biopsies (SSB) were performed (Fig. 1a), the decay in the curves is faster than that obtained in the untreated control site. This fact is reflected in $t_{1/2\text{evap}}$ (Table 1), which was lower in the SSB site

($p = 0.008$); however, DWM was not significantly different from the controls ($p = 0.735$). The difference between the parameters obtained in the tape stripped and lipid extraction sites and the controls is less marked and never reaches a statistical level of significance (Table 1).

The results reflecting anatomical differences are quite distinct. When a 24 h occlusion is performed in the wrist, the decay in the curves is slower than that occurring in the mid volar forearm (Fig. 1b). These results are expressed by an approximately twofold increase in the $t_{1/2\text{evap}}$ and in the DWM (Table 2). There are statistically significant differences between the parameters obtained in the two anatomical sites ($p = 0.018$ for $t_{1/2\text{evap}}$ and $p = 0.028$ for DWM).

1.5 Discussion

Dramatic differences in the hydric dynamics of the skin submitted to SSB, the most aggressive insult applied, are clearly revealed by the data obtained by this work. Additionally, well-defined anatomical differences were found between the skin of the wrist and the mid volar forearm.

The lower $t_{1/2\text{evap}}$ obtained in the site where SSB was performed can be attributed to reduced water accumulation in the stratum corneum, since this layer has been “thinned” by the procedure. Superficial water accumulates during the occlusion period, but because it is not bound, it is released immediately as soon as occlusion ceases. This is supported by the fact that DWM is not different to that of the control, since the faster decay rate observed in the SSB sites is then compensated by a faster decay to basal values. Interestingly, these results also indicate that even though many layers of corneocytes have been removed, no significant damage to skin barrier function is observed.

The results obtained in the wrist have a different interpretation. The corneocytes in this anatomical region have a smaller diameter than in the volar forearm (Rouquier 1994), large blood vessels are closer to the surface, and basal TEWL is significantly higher (Rodrigues and Pereira 1998). These differences contribute to the higher

Fig. 1 POST desorption curves obtained after 24 h occlusion: **(a)** insults to the barrier – SSB (mean values, $n = 9$), **(b)** anatomical differences – mid volar forearm and wrist (mean values, $n = 9$)

Table 1 Parameters obtained in the study of the impact of different insults to the skin barrier (mean \pm SD, $n = 9$)

Insult performed	$t_{1/2\text{evap}}$ (min)		DWM (g/m^2)	
Lipid extraction	3.03 ± 1.19	$p > 0.05$	833.9 ± 138.8	$p > 0.05$
Control	3.64 ± 0.52		722.4 ± 61.6	
Tape stripping	3.33 ± 2.04	$p > 0.05$	727.4 ± 235.0	$p > 0.05$
Control	3.60 ± 1.26		793.9 ± 153.0	
Skin surface biopsy	1.94 ± 0.85	$p = 0.008$	833.2 ± 144.2	$p > 0.05$
Control	4.30 ± 1.36		836.3 ± 226.0	

Table 2 Parameters obtained in the study of anatomical differences (mean \pm SD, $n = 9$)

Anatomical site	$t_{1/2\text{evap}}$ (min)		DWM (g/m^2)	
Wrist	13.73 ± 5.49	$p = 0.018$	1513.7 ± 421.0	$p = 0.028$
Mid volar forearm	3.67 ± 1.13		875.3 ± 120.3	

values of $t_{1/2\text{evap}}$ and DWM. More water accumulates during the occlusion, and the different functionality of the barrier at this site slows down its release and allows more water to be lost.

The other perturbations of the skin barrier caused more subtle changes in the water dynamics which could not be so clearly assessed by this methodology, and the results likely reflect the “milder” impact of these procedures. Solvent mixtures are reported to extract primarily the superficial lipids, including sebaceous gland lipids, cholesterol, and free fatty acids. Work conducted by Jokura et al. (1995) showed that lipid extraction of intact stratum corneum with ether:acetone (1:1) did not induce any significant change in the nuclear magnetic resonance spectrum and did not significantly affect stratum corneum elasticity. Visscher et al. performed a similar study where the impact of ether:acetone in TEWL and Moisture Accumulation Test (MAT) was assessed (Visscher et al. 2003). This group observed significant increases in TEWL but no effects in MAT.

In contrast, there are conflicting reports in the literature regarding the extent of damage inflicted by tape stripping (Cernasov and Macchio 1997; Ohman and Vahlquist 1994; Rosado and Rodrigues 2003), and it is widely accepted that depending on the adhesive and pressure applied, differing amounts of cells are removed in each tape strip (Bashir et al. 2001).

In conclusion, the work shows that compartmental modeling of the TEWL desorption curves provides detailed information on the water retention capacity of the skin and on cutaneous water dynamics.

2 Applications of the Methodology

2.1 Assessment of Dry Skin

2.1.1 Introduction

One of the most widely occurring skin disorders is dry skin, or xerosis. It is the result of a range of environmental and pathological factors that affect epidermal proliferation and differentiation (Engelke et al. 1997). The stratum corneum lipid

bilayers and the epidermal components are altered, which results in a decrease in the water content and reduced barrier function (Rogers et al. 1996).

In the clinical practice, xerosis is commonly evaluated by subjective visual scoring systems (Kligman 1987; Serup 1995). The most commonly employed strategies to quantitatively assess xerosis have been measurements of skin capacitance and/or transepidermal water loss (TEWL), both with limitations that have been previously discussed.

In this section, the methodology of mathematical modeling of POST TEWL curves is applied to the quantitative assessment of differences between normal and dry skin.

2.1.2 Material and Methods

Twenty healthy female volunteers, aged between 20 and 55 (mean 30.4 ± 13.4 years old), participated in this study. Ten volunteers were classified with normal skin and ten with dry skin. The work was developed in accordance with the ethics requirements and following the relevant experimental guidelines. The skin type was evaluated by self-assessment and clinical scoring systems (Kligman 1987). Since xerosis is generally more severe in the frontal aspect of the leg, the entire study was conducted on this anatomical site. There was a 1 week pretrial period, during which volunteers were requested to refrain from applying any product containing moisturizing ingredients to the test sites, and bathing habits were standardized.

All volunteers were submitted to the POST methodology previously described (Rosado and Rodrigues 2006). The mathematical model was adjusted to the data points and relevant parameters were calculated.

Nonparametric comparative analysis (Wilcoxon sign-rank test) was used in this study. A 0.05 significance level was adopted.

2.1.3 Results

The desorption curves obtained after removal of the occlusive patch, applied for 24 h, are represented in Fig. 2. It can be readily appreciated that dry and normal skin present different profiles.

Fig. 2 Desorption profiles obtained after removal of the occlusive patch (mean, $n = 10$)

Table 3 Parameters obtained in the study (mean \pm SD, $n = 10$)

	$t_{1/2\text{evap}}$ (min)		DWM (g/m^2)	
Normal skin	2.03 ± 0.91	$p = 0.018$	497.46 ± 80.87	$p = 0.059$
Dry skin	3.95 ± 1.90		613.58 ± 130.99	

In normal skin, the decrease in TEWL after occlusion is rapid and pronounced. Conversely, when dry skin is occluded, TEWL decreases at a slower pace. These results are translated in a higher $t_{1/2\text{evap}}$ for dry skin, almost double of that obtained in normal skin, and in a more elevated DWM (Table 3). There is a marked statistical difference between the $t_{1/2\text{evap}}$ results ($p = 0.018$) and a less pronounced difference for DWM ($p = 0.059$).

2.1.4 Discussion

The first attempts to quantify skin dryness were essentially based in the visual observation and grading of parameters such as flake size, roughness, and color (Kligman 1987; Serup 1995). This approach is subjective, but nevertheless, in the clinical perception of dry skin there is an evident need for the integration of different parameters which can only be perceived through the human intervention (Grove et al. 2002). Many noninvasive bioengineering devices using electrical properties or photothermal or acoustic techniques have been developed over the last three decades with applications in this area (Imhof et al. 1990; Pines and Cunningham 1981). These devices are very useful to study stratum corneum function and

competence in moisture content and retention. However, dynamic tests are in general more informative, principally because they are not reliant on single measurements.

The marked differences observed in the results of this study confirm the applicability of the methodology. Subjects with dry skin presented a greater water accumulation capacity and different water dynamics. The higher DWM can be explained by two factors. First, the weakened barrier function causes a higher loss of water through the skin. Additionally, dry skin has an increased rate of proliferation of epidermal cells, but the desquamation of corneocytes is impaired, which contributes to epidermal thickening. This leads to a greater capacity to accumulate water and, therefore, to the higher amount of water released after occlusion. The $t_{1/2\text{evap}}$ is extended because the mass of water being released is greater.

These findings confirm that the modeling of the TEWL curves resulting from a POST is a sensitive methodology, able to detect differences in the water dynamics and barrier function of normal and dry skin. This advocates its potential application to efficacy testing of products that are used to reestablish skin hydration.

2.2 Assessment of Moisturizers and Barrier Function Restoration

2.2.1 Introduction

Moisturizers are among the most universally employed personal care products. Many formulations aim not only to increase skin hydration but also to treat the underlying causes of dryness and restore barrier function and have even been classified by some authors as “therapeutic moisturizers” (Kligman 1987).

One of the most consensually accepted approaches to the study of the efficacy of moisturizers is the regression method developed by Kligman (1987), where after application of the product for 2 weeks, the rate of regression to the original state is measured, usually using a visual scoring system. One of the main drawbacks of this methodology is the fact that it must be conducted for a period of a minimum of 5 weeks. Other strategies based in the measurement of skin capacitance or TEWL provide insufficient information.

In this section, the discriminative capacity of the mathematical modeling of POST TEWL curves is applied to the efficacy testing of moisturizing products.

2.2.2 Methods

Fifteen female volunteers with severe dry skin participated in this study, after informed consent

(mean age 43.9 ± 11.6 years) (Rosado et al. 2009). The entire study was conducted on the lower leg. All volunteers exhibited marked xerosis, as well as uniform dryness across contralateral sites. The work was developed in accordance with the ethical requirements and following the relevant experimental guidelines.

There was a 1 week pretrial period, during which volunteers were requested to refrain from applying any product containing moisturizing ingredients to the test sites. Bathing habits were also standardized.

A moisturizing cream containing 15 % urea (Kératosane[®] 15, Uriage, France) was applied to the test areas twice daily by all volunteers for 2 weeks. At the end of the 2 week application period, all volunteers were submitted to the POST methodology previously described (Rogiers 2001; Pinnagoda et al. 1990). The mathematical model was adjusted to the data points and relevant parameters were calculated.

2.2.3 Results

The TEWL desorption curves obtained in the control and treated sites after removal of the occlusive patch are represented in Fig. 3. It can be seen that in the site that was treated for 2 weeks with cream, the decay in the curves is slower than that obtained in the untreated control site. Additionally, the area under the curve is lower in the control (untreated)

Fig. 3 TEWL decay profiles obtained in the study (mean \pm SD, $n = 12$)

Table 4 Parameters obtained in the study of the efficacy of moisturizers (mean \pm SD, $n = 12$)

	k_{evap}		$t_{1/2\text{evap}}$ (min)		DWM (g/m^2)	
Treated site	0.102 ± 0.083	$p = 0.002$	11.43 ± 8.42	$p = 0.005$	955.7 ± 266.6	$p = 0.010$
Control site	0.334 ± 0.170		2.54 ± 1.39		650.3 ± 104.8	

dry skin. The previously mentioned features have been transformed in quantitative parameters by the mathematical model adjusted to the TEWL data points (Table 4). The obtained parameters show statistically significant differences between the different kinetic parameters obtained in the control and treated sites (nonparametric Wilcoxon rank-sign test): a slower K_{evap} in the treated site, as well as a higher $t_{1/2\text{evap}}$ and DWM.

2.2.4 Discussion

Moisturizers are widely used, and almost every type of cosmetic incorporates moisturizing ingredients. Even though dry skin is far from being a life-threatening condition, the symptoms of severe xerosis are unpleasant, and for these patients the use of moisturizers is important to maintaining quality of life. Some formulations claim not only to improve barrier function but also to create an environment optimal to healing and prevention of recurrent damage (Yokota and Maibach 2006).

The regression method developed by Kligman (1987) measures the rate of regression to the original state using a visual scoring system after application of the product for 2 weeks. One significant drawback of this methodology is the fact that it must be conducted for a period of a minimum of 5 weeks.

The use of noninvasive bioengineering equipment has led to other strategies, such as measurements of electrical capacitance. Other methods use a model that examines regeneration of skin barrier function after aggression (usually with aqueous solutions of sodium lauryl sulfate), when compared to irritated untreated skin (Held et al. 2001). Another approach investigates the efficacy, the tolerance, and the effects of moisturizers on quality of life (Giordano-Labadie et al. 2006).

One of the earlier attempts to use TEWL measurements and occlusion (that is, inhibition of

water evaporation from the skin surface) to assess moisturizers was performed by Rietschel (1978). The moisturizers were applied to a plastic film and the skin, and an objective rank ordering of moisturizers was achieved by monitoring moisture enhancement of applied substances.

Further developments on the mathematical modeling of the TEWL curves that result from a POST have contributed to a more accurate quantitative description of the cutaneous water mass balance over time (Rodrigues et al. 1999), and it is reasonable to assume that the method could be used in the study of moisturizing products.

The results obtained in this investigation established significant differences between the different kinetic parameters obtained in the control and treated sites. The data obtained in the site treated with cream exhibit a slower decay in the TEWL values and a higher water mass released after removal of the occlusion. This can be attributed to the presence of hygroscopic excipients (urea, glycerine, lactic acid, and pyrrolidone carboxylic acid sodium). The increase in the DWM and $t_{1/2\text{evap}}$ can be explained by two factors: the previously explained higher accumulation of water in the stratum corneum and the keratolytic action of urea that leads to a thinning of the stratum corneum, which in turn leads to a higher TEWL than that occurring through the thicker dry skin. Urea has been associated to improved epidermal lipid biosynthesis and improved barrier performance (Loden 2000). The alterations observed in the water dynamics indicate the previously mentioned effect and confirm the efficacy of the cosmetic formulation.

The efficacy testing approach developed in this study is compatible with home application of the product, which is an important factor to ensure compliance by the volunteers. When the methodology is compared to the regression test, its main benefit is that it can be completed in 3 weeks and, if the volunteers are experienced, it is possible to

reduce the number of visits to the research center to two.

2.3 Assessment of Barrier Impairment in Sensitive Skin

2.3.1 Introduction

Sensitive skin is a subjective and vague affliction that almost half of the world's population declares to suffer from, and the skincare market offers numerous products that claim to be particularly suitable for this type of consumer (Kligman et al. 2006; Willis et al. 2001). The characterization of sensitive skin is difficult, due to the wide variety of causes and symptoms that it may include (Pons-Guiraud 2004), ranging from obvious cutaneous alterations such as redness or dryness to complaints that are subjective and sensory, with signs such as stinging, burning, or itching (Frosch and Kligman 1982).

Skin sensitivity seems to be associated to an impaired skin barrier function (Kligman et al. 2006), enabling the penetration of substances that stimulate the keratinocytes and Langerhans cells to produce mediators that are involved in its characteristic inflammatory response (Willis et al. 2001; Frosch and Kligman 1982; Farage et al. 2006). Another factor that may equally contribute to a higher cutaneous susceptibility is a neurosensory hyperreactivity, causing the self-perceived sensations of discomfort when sensitive skin is exposed (Willis et al. 2001).

The lack of visible clinical signs and the high subjectivity associated to sensitive skin have hampered the development of a simple method to diagnose and quantitatively analyze this condition. The more common approaches are scoring of signs of irritation, assessment of the subjective (neurosensory) responses, and skin function tests (Primavera and Berardesca 2005; Issachar et al. 1997; Yosipovitch and Maibach 1998; Lee and Maibach 1995; Marriott et al. 2005; Gean et al. 1989; Seidenari et al. 1998; Bornkessel et al. 2005).

In this section, the mathematical modeling of POST TEWL curves is applied to the quantitative analysis of sensitive skin.

2.3.2 Methods

A total of 33 healthy female volunteers participated in the study (Pinto et al. 2011). Fifteen volunteers constituted the group of subjects with self-perceived sensitive skin (age range 23–64, mean age 54 ± 10 years). The remaining 18 volunteers formed the control group, with self-perceived normal skin (age range 20–58, mean age 34 ± 10 years). The work was developed in accordance with the ethical requirements and following the relevant experimental guidelines.

A site was selected in the back of the hand of each volunteer, between the thumb and the index finger, and the baseline TEWL values were registered with a Tewameter TM 300[®] (CK Electronics, GmbH, Germany), following published guidelines (Rogiers 2001). All subjects were then submitted to the POST methodology previously described (Rogiers 2001; Pinnagoda et al. 1990). The mathematical model was adjusted to the data points and relevant parameters were calculated.

Nonparametric comparative analysis (Wilcoxon sign-rank test) was used in this study. A 0.05 significance level was adopted.

2.3.3 Results

The mean basal TEWL values exhibited by the volunteers of the two groups (normal and sensitive skin) were compared, and no statistically significant differences were found ($p = 0.059$).

The desorption curves obtained after a 24 h occlusion, as well as the model fitting to the experimental data are represented in Fig. 4. It can be seen that the decay in the curves obtained in volunteers with normal skin is faster than that obtained in the sensitive skin subjects. Additionally, the area under the curve is smaller in the normal skin group.

Relevant quantitative parameters were determined by the mathematical model adjusted to the TEWL data points (Table 5). These results epitomize statistically significant differences between the different kinetic parameters obtained in the two groups, translated in higher $t_{1/2\text{evap}}$ and DWM in the sensitive skin volunteers.

The continuous lines observed in Fig. 4 represent the calculated data obtained by application of

Fig. 4 POST desorption curves obtained after 24 h occlusion (mean ± SD); the continuous lines represent the calculated data obtained by application of the model to the median individual parameters

Table 5 Parameters obtained in the study (mean ± SD)

Group	$t_{1/2\text{evap}}$ (min)		DWM (g/m^2)	
Sensitive skin	33.81 ± 39.72	$p = 0.005$	1216.45 ± 299.83	$p = 0.0001$
Normal skin	10.15 ± 5.34		787.51 ± 196.98	

the model to the median individual parameters. These data points are within the range of standard deviation of the mean experimental results, indicating that a good fit was achieved between the data generated by the model and the experimental data.

2.3.4 Discussion

Multiple attempts have been made to find the ideal method to test sensitive skin. Irritant reactivity tests measure objective signs of irritation after long-term application of model substances under occlusion; however, this does not reflect the real-life situation. Sensory reactivity tests are based on the sensory information that is reported by the individuals, normally expressed in a subjective magnitude scale. Dermal function tests relying on bioengineering methodologies have had a limited application, since negligible differences were found in the baseline biophysical parameters of individuals with sensitive skin.

Sensitive skin is a multifactorial skin condition, attributed to neurosensory hyperreactivity, a lower discomfort threshold, and an incompetent cutaneous barrier. It is irrefutable that TEWL measurements constitute an essential tool to ascertain barrier function; however, its limitations have been described earlier and may explain the difficulties experienced by researchers attempting to detect differences in subjects with sensitive skin (Seidenari et al. 1998; Distante et al. 2002), as well as the results from this study that were described previously in the text.

This study aimed to identify unequivocal substantiation of barrier impairment via the modeling of the TEWL curves resulting from a POST. This methodology would then be used as the basis of a reproducible, noninvasive, and cost-effective test to assess sensitive skin.

The results obtained in the present work confirm the previous assumptions. Statistically significant differences were established between the

different kinetic parameters obtained in the normal and sensitive skin groups. The scrutiny of the kinetic data and desorption profiles obtained in the subjects with sensitive skin points to a slower decay in the TEWL values and a higher water mass released after removal of occlusion, which translate into higher values of $t_{1/2\text{evap}}$ and DWM. An increase in both parameters can be explained by an impaired barrier function. The impaired barrier causes more water accumulation during the occlusion. Thus, a higher mass of water is lost with a higher half-life time once the patch is removed.

In conclusion, this investigation successfully correlates the elusive sensory complaints with impairment in the cutaneous barrier. A new clinical relevance to this quantitative strategy has emerged, one that can be applied both in the early diagnosis and characterization of the skin sensitivity syndrome and in the efficacy assessment of topical products designed for individuals with this skin condition.

3 Conclusions

TEWL is one of the most popular noninvasive variables from skin bioengineering and has become the main indicator of in vivo epidermal barrier function. Differing measurement guidelines have been known for quite some time and have been progressively adopted, but only a few papers have focused on the need to assess such variables from a dynamic point of view. In 1982, Hachiro Tagami and coworkers (1982) did set a basis for the measurement of epidermal hygroscopicity, motivating the development of stress tests such as the POST (Berardesca et al. 1990; Berardesca and Maibach 1990; Jokura et al. 1995) to quantify skin water modifications following occlusion. Gioia and Celleno (2002) proposed an original physical model to simulate the dynamics of epidermal (free) water evaporation and TEWL in hydrated skin. The model was developed to study the behavior of hydrated skin when occluded by permeable/impermeable materials and was applied to the effect of diapers on normal and nonnormal skin. TEWL modeling was also

applied to analyze the barrier and the driving force components of TEWL in irritancy testing (Endo et al. 2007).

To our knowledge, none of these approaches have been able to equate to other practical applications involving the quantification of the in vivo skin barrier. In contrast, our model was applied to different testing conditions and its discriminative capacity clearly proven. In fact, our model is inspired by the particular histological-functional organization of the human skin, justifying the compartmental analysis approach. This means a close relationship between the model and the in vivo physiology from the conceptual point of view, strengthening the value of the kinetic assumptions behind the simulation of the mechanisms of water distribution in vivo following occlusion (POST).

Thus, the compartmental modeling of the TEWL desorption curves clearly describes the cutaneous water dynamics in different conditions, providing a unique way to rigorously quantify this central characteristic of human in vivo skin. Furthermore, its conceptual frame and construction allows an easy access to common users, motivating the development of current easy-to-wear programs that will help to improve TEWL data quality and expand the utility of this variable.

Keywords

Burning test • Corneosurfametry • Dansyl chloride test • Histamine itching test • Irritants • Irritating effect • Kligman and Wooding test • Oclusive tests • Skin hypersensitivity reactions • Skin irritability testing • Skin irritation • Skin irritation proneness • Soap chamber test • Sting test

1 Applications

Cosmetology (tests of tolerance, selection of subjects for tolerance tests), Regulation acts fulfilment (identification of primary irritants), Occupational medicine (detection of subjects at risk and health-hazard products, measurement of skin alterations of occupational origin), Allergology (identification of irritants and orthoergic reactions).

2 Definition

The terms reactivity and irritation proneness, although close, are not synonyms. Reactivity implies the capacity to develop certain symptoms following an external stimulus, whatever the type of symptom induced (erythema, papule, pustule, visible desquamation, pigmentation. . .). Irritability on the other hand applies only to the capacity to produce an erythema or an unpleasant subjective feeling (tension, burning sensation, itch).

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

However all these cutaneous signs are “intolerance reactions” of a so-called “orthoergic” mechanism, therefore implying no immunological factor; allergic reactivity is described in the following ► [Chap. 118, “Cutaneous Testing: Detection and Assessment of Allergy.”](#)

Usually an acute (primary) “irritant” is a product which produces an intolerance reaction in more than 90 % (in fact, more than 50 %) of healthy subjects when it is applied on the skin in usual conditions (concentration, vehicle, mode of application) (Wahlberg and Maibach 1980). Such compounds are called “primary irritants” and a list of them has been established by the European Union (Annexe à la Directive 92/69 CEE du 31 juillet 1992). The interest of this list is twofold: (1) to entice manufacturers to find a substitute, (2) if this is not possible, to inform about possible health hazards and specific precautions to be taken. The legal obligation to evaluate the potential irritating effect of all the products that may be in contact with the human skin has led to perform a series of tests in healthy subjects.

This first selection is of little interest in cosmetology where the purpose is to detect in much less aggressive compounds, those who are susceptible to induce very moderately noxious or unpleasant side-effects in a minority of people. It is therefore necessary to seek subjects who may be intolerant to these products, subjects with “sensitive” skin, who make only a small portion of healthy population. It is difficult to identify them because of the variability of reactions and the dependence on both ambient conditions (temperature, wind, humidity, sun exposure) and physiological conditions (menstrual, circadian and annual cycle, etc. . .). In this case, the measurement deals with the subject irritability rather than the product aggressivity.

3 Detection of Acute (Primary) Irritants

Screening tests are used to determine if a product should be classified among primary irritants. This may be associated with the study the reactivity of subjects who professionally may come in contact with such products. This practice is considered

non ethical in some countries, because it would lead to selection of workers on a basis of the possible occurrence of orthoergic dermatitis, which often is not severe enough to justify a ban. However it may be useful before job for people prone to contact allergy because the latter (which would justify a ban) is considerably activated by orthoergic dermatitis.

3.1 Lists of Primary Irritants

They indicate the concentration limit above which the product is considered irritant for healthy people. The lists below are not comprehensive.

European Union list (Annexe à la Directive 92/69 CEE du 31 juillet 1992)

Based on the Draize test in rabbits, it remains valid until it can be replaced by tests in humans.

Willis et al. list (Willis et al. 1988)

After a 48-h application in a small Finn chamber, the products listed below have been registered as irritants because about 75 % of the subjects studied have developed a 2 + erythema:

Benzalkonium chloride	0.5 % in water
Sodium lauryl sulfate	5 % in water
Croton oil	0.8 % yellow petrolatum
Dithranol	0.02 % yellow petrolatum
Nonanoic acid	80 % propane-1-ol
Propylene glycol	100 % in water
NaOH	2 % in water

Frosch and Kligman list (Frosch and Kligman 1976)

Ninety products are assessed by the chamber-scarification test.

York et al. list (York et al. 1996)

The irritant effect is evaluated compared to 20 % sodium lauryl sulphate (SLS), graded as “irritant” by the EU. SLS 20 % caused irritation in 45–50 % of the subjects after a 15-min to 4-h exposure in York et al.’s experiment. For example this test classifies NaOH 0.5 % as an “irritant” (60 % of the subjects were “irritated”

at 1 h, compared to 12 % by SLS 20 %). The list includes 27 products already registered by the EU and shows 8 points of discrepancy with the EU classification.

3.2 Assessment of the Irritating Effect

Not all products are irritating to the same extent and in the same way. In other words, the plot *irritation = f(concentration)* and *irritation = f(exposure duration)* are not identical, which complicates the implementation and interpretation of the tests. Furthermore, the type of irritation depends on the biological effect, which leads to the use of *specific tests* for tensioactives, organic solvents, acids, alkalis, pro-inflammatory substances, mechanical irritants, etc... To compensate for the use of the product over a long time by the future consumer, *maximisation* is often necessary (e.g., by using concentrations beyond real life situations, or through preliminary skin damage). It is also possible to perform tests with *repeated exposure*. The possible part played by the vehicle must not be overlooked because it may have its own irritability and/or enhance the penetration of the active product. Irritation can be delayed; hence the necessity to read the test not only at the end of exposure but also up to 72 h later. Table 1 shows the most common problems and their answers.

It is essential to use an internationally admitted positive standard which plays two parts: validation of the test and classification in relation to other studies. It must have an accurate chemical

definition, an average pH and should have been designed in order to meet three specific conditions regarding its innocuousness: absence of general toxicity, carcinogenicity, sensitiveness potential. As a *general standard* as well as a *detergents standard*, sodium lauryl sulfate (= sodium dodecylsulfate) (SLS) is widely accepted. Its properties and mode of use have been the subject of extensive general review (Tupker et al. 1997). Taking the European Union list as a reference, a 20 % concentration has been proposed (Basketter et al. 1994). This high concentration is valid only for the determination of primary irritants.

The selection of a *standard solvent* is more delicate because the irritation potency varies considerably from one solvent to another and raises steeply with concentration (Frosch and Kurte 1994). The mixture chloroform-methanol has been suggested (see Sect. 4.2, third item).

Various *standard vehicles* have been used: water, ethanol, petrolatum gelly, talc powder, vanishing cream USP, according to the vehicle chosen for the test, depending on anticipated contact conditions.

3.2.1 Open Tests

- Alkali resistance test (Burckhardt 1964; Locher 1962) (► Chap. 12, “Measurement of Skin Surface Acidity”)
- Test of resistance to organic solvents (Leder 1943) and chloroform-methanol (Klaschka et al. 1972). The latter has been modified by Frosch and Kurte (1994) (cf Sect. 4.2 Burning test).
- Test with ammoniac, benzalkonium chloride, croton oil, kerosene, DMSO

Table 1 Ten main difficulties to overcome during primary irritants detection tests

Problem	Possible solution
1. Current use over a long time period	Maximisation
2. Repeated use	Repetitive tests (Cumulative Irritation Assay)
3. Variation in the time for reaction	Immediate reading by at 72 h
4. Various types of reaction	Use the reactivity limit or perform a specific test
5. Interindividual variability	Panel of very sensitive subjects
6. Need to avoid strong reactions	Stop application early enough
7. Intraindividual variability	Use positive (standard irritant) and negative control
8. Influence of the vehicle	Specific test with standard vehicle
9. Different investigators	Instrumental measurements
10. Quantification is of little use	Observe the irritation threshold only

These tests mainly apply to corrosive or very irritating substances, thus justifying very short exposure times (seconds or minutes). Their aggressiveness pose ethical problems. For this reason, most of them are abandoned, especially as alternative methods *in vitro* are available for most of them (Rougier et al. 1994; Whittle 1993).

3.2.2 Kligman and Wooding Test (Kligman and Wooding 1967)

The object of this test is to take into account the effect of repeated applications (from 10 to 20 days). It is based on the measurement in each subject of the onset time of the reaction, which is more easily detected than intensity. This eliminates almost completely the risk of over-reaction which is often unpredictable because of the very large variability of individual sensitivity. The objective was also to determine the irritation threshold according to the rules of toxicology and to have a unique test for all types of reaction.

The authors noticed that, for a given concentration, the % of irritated patients versus duration of application fits a sigmoid curve. Hence their idea to measure, for each concentration, the duration of application which induces a reaction in 50 % of studied subjects (Irritative Time IT50), and for a 24 h application, the minimal

concentration inducing reaction in 50 % of subjects (Irritative Dose ID50). The first index is used for mild irritants, the second one for stronger irritants. A standard substance, used as a base to classify products, is introduced into the test. The test is performed on the back of the subject using occlusive patch-tests, (its sensitivity was found similar to that of the face). The authors indicate that the variability from one observer to the other is lower when assessing whether irritation does exist or not than the degree of irritation, because it is easier for the naked eye to detect the smallest erythema than to evaluate its intensity.

Bahmer and Feldmann (1995) updated this clever method by replacing patch-tests by applications in large Finn Chamber (diameter 12 mm, surface 113 mm²); the studied areas (volar forearm) are examined every 24 h including a new application of the product exactly in the same place, the maximal application duration being 12 days. The proportion $p(t)$ of patients showing irritation onset at time t is obtained by the formula $p(t) = 1/[1 + (\tau/t)^\lambda]$ where τ is IT50 and λ is the slope of the sigmoid curve at time τ , which indicates the rate of irritation increase when application is protracted (Fig. 1). This method becomes also applicable to moderately irritant products. The following table is an example (Bahmer and Feldmann 1995):

Fig. 1 Kligman and Wooding test as modified by Bahmer and Feldmann. Percent of irritated subjects versus 0.05 % SLS application time. The curve was drawn from experimental points and § 2.2.2 formula. Intersection with the horizontal dotted line corresponds to irritation occurring in 50 % of tested subjects (IT 50 % = 6,8 days)

SLS concentration	τ (days)	λ (% irritated subjects per application supplementary day)
0.05 %	6.8	12.5
0.10 %	5.2	22.7
0.25 %	3.6	29.4

3.2.3 Other Global Occlusive Tests (Non Comprehensive List)

- The classic occlusive patch test read at 24, 48 and 96 h should be abandoned because of the risk of false negatives (Frosch and Pilz 1995).
- The *Chamber Scarification Test* (Frosch and Kligman 1976) consists in making eight crossed scarifications (using a 30 gauge needle) on the tested area in order to increase the skin irritability. The product is then applied in a Dühring chamber (diameter 12 mm, 113 mm²) once a day for 3 days. Reading takes place 30 min after the last application, grading intensity from 0 to 5. The “scarification index” (irritation threshold on healthy skin/threshold on irritated skin) expresses the capacity of the tested product to irritate the skin in these conditions. In this way the irritant potency of 70 substances has been classified in four categories: low 0–0.4; mild 0.5–1.4; moderate 1.5–2.4; strong 2.2–4.0.

On the other hand, the authors propose constituting very sensitive panels of “hyperirritable” subjects selected because they have shown a bright erythema with oedema and small vesicles following application of SLS at 5 % in water for 24 h on volar forearm. Because of its irritative potency 2–50 times higher than an ordinary patch, this test is rarely performed today.

- The *Basketter test* (Basketter et al. 1994) purpose is to classify primary irritants without causing severe lesions in volunteers. The irritant standard is 20 % SLS. To lessen variability between investigators, only the irritation threshold is considered. To obviate intense reaction, the successive exposure times are progressive: 1/4, 1/2, 1, 2, 3, 4 h (maximum) with interruption of the process as soon as intolerance appears (1/4 h and 1/2 are optional

for a priori poorly irritant substances). A Plain Hill Top Chamber (diameter 25 mm, surface 490 mm²) has been selected in order to increase the irritative effect. Out of 30 subjects, the number of subjects who have developed intolerance is counted for each concentration. The tested concentration is graded “irritant” if this number is not significantly lower than the number obtained with 20 % SLS.

4 Detection and Assessment of Hypersensitivity Reactions

These measurements have two objectives: to detect hypersensitive subjects and to assess tolerance of products which are not primary irritants. They involve mostly cosmetologists, but also allergologists who are interested in non allergic irritation.

4.1 Irritation Patterns

Intolerance to SLS, a standard compound of irritants and detergents, is manifested by erythema and desquamation which evolve in skin surface fissuring (Tupker et al. 1997). Irritation may also be only subjective: stinging, burning sensation, feeling skin tensed, itch. All these signs are never found in the same subject altogether and are not connected. Accordingly specific tests and selective subjects panels are needed to let them appear.

The most sensitive subjects are those in the course of an eczema or who in the past experienced eczema or orthoergic dermatitis. Otherwise they are women, children, subjects with very clear skin and I and II phototypes. The least sensitive subjects are men and subjects over 50.

Skin irritability increases in winter and when the absolute atmospheric humidity is low (Uter et al. 1998; Basketter et al. 1996). It increases also in the pre-menstrual phase (Agner et al. 1990), and if the skin is warm (Clarys et al. 1997). It intensifies with any other simultaneous aggression (sun, wind, mechanical factor...) (Frosch 1992).

Irritability depends on the *body site*: in decreasing order (Frosch 1992): face, back, elbow crease, forearm, leg, wrist. It increases in parallel to the *application area*. Prior application of W/O emulsion or urea cream decreases it (Loden and Andersson 1996).

It is essential to consider all these factors when implementing the test and reading the results. It is therefore mandatory to use a positive control (in addition to the negative control) so as not to be influenced by the possible variation of the overall panel sensitivity with time.

4.2 Irritability Testing

4.2.1 General Tests

For clinical assessment it is recommended to determine the *irritation threshold*, for which the eye or touch have a high discriminating power. Tests will assess either the irritant minimal concentration for a constant application time, or the minimal application time for a constant concentration. The Kligman & Wooding test modified by Bahmer and Feldmann (1995) may be used, as well as the Basketter's test (Basketter et al. 1994), but as a positive control, with substitution of 20 % SLS by a lower concentration for example 0.05 %, 0.10 % or 0.25 %.

4.2.2 Sting Test (Sensory Irritation) (Frosch and Kligman 1977)

Some people complain of a stinging sensation following application of certain creams. Typically the stinging feeling starts one or two minutes after application of the cosmetic, intensifies during the following 5–10 min when it becomes intense, then subsides and disappears in 15–20 min; it is rarely associated with an erythema. It must be differentiated from a burning sensation or itch, the latter being typically associated with the desire to scratch the skin.

The purpose of the Sting Test is to select a panel of subjects able to detect substances that could cause this type of reaction. Because of the rarity of the phenomenon, it has to be performed

on women (size of the panel: 5–10) who have already developed similar episodes or believe they have a "sensitive skin" (Grove et al. 1984).

The typical protocol consists firstly in inducing a profuse (thermal) sweating of the face. A cotton bud impregnated with a water solution of lactic acid at 5 % is rubbed on the area between nose and cheek, with the symmetrical side as a control. The feeling is assessed as soon as the product is applied (immediate scoring), then at 2.5 min, 5 min and 8 min (retarded score = mean of the last 3 scores) by a scale from 0 to 3+. The "stinging potential" of a subject is evaluated as follows: light for a score between 0.4 and 1, moderate between 1 and 2, and important between 2 and 3. The test can be performed at ambient temperature and without sweating using 10 % lactic acid (Grove et al. 1984).

Only the face is responsive to this phenomenon, with the following decreasing sensitivity: paranasal creases > cheeks > chin > lower eyelid > retroauricular area.

Stinging is enhanced by actinic erythema, skin irritation, stripping of the stratum corneum.

The origin of the stinging phenomenon may be an abnormal sensitivity of the skin to acids or a particular reactivity of the acidic coat of the skin surface. The skin pH, which decreases immediately after application of lactic acid, is restored faster in "stingers" in the 15–30 min following application (Issachar et al. 1997).

4.2.3 Burning Test (Grove et al. 1984)

The object of this test is to identify (and possibly select for a specific panel) the subjects who have a propensity to burning sensation (often associated with propensity to stinging) following the application of some cosmetics.

A depression is produced in the skin using the greased extremity of a cylindrical metal bar (diameter 8 mm). Then 10 µl of a chloroform-methanol mixture (20:80) is poured into this hollow which is immediately sealed with a plastic film. The appearance time of an intense burning sensation is measured with a chronometer and the product immediately removed. On the face, where this test is usually performed, it varies from 3 to

30 s. The paranasal creases are the most sensitive site.

4.2.4 Histamine Itching Test (Grove et al. 1984)

This test has been developed to identify the (rare) people who often feel itchy after applying cosmetics. 10 µl of 4 % histamine are placed in a depression in the skin produced using the same procedure as in the burning test. The subject indicates the intensity of the pruritus on a scale from 0 to 3+, after 2.5 min, 5 min and 10 min. At the end of this process, the histamine papule which always appears even in the absence of pruritus (about 50 % of cases) is measured. Contrarily to the stinging and burning sensations which are easily identified, feeling itchy is more difficult to recognise and requires the training of the volunteers.

4.2.5 Soap Chamber Test

The objective is to assess the irritancy potential of soaps and detergents specifically. The typical test (Frosch and Kligman 1979) consists in applying 100 µl of a 8 % watery solution of the soap, heated at 40 °C, on the forearm, in a Dühring chamber. The application lasts 24 h the first day (on a Monday) and 6 h the 4 following days. Reading is done 3 days later (the next Monday), looking for erythema (4 grades), desquamation (3 grades) and fissuring (3 grades). The delay between the end of the test and the reading permits specific effects to appear. The final score is the sum of the means of the three parameters.

For the assessment of mild soaps which alter the stratum corneum barrier prior to induce an erythema, Simion et al. (1991) proposed the following modifications: first reading 3 h after the first application of 24 h (in order to stop the experiment for the 3+ reactive subjects); then renewed application for 21 h and final reading 3 h later. They also suggest to use water as a positive control. In order to increase the test efficacy, they recommend using a panel of volunteers selected from their being intolerant to detergents, and to reject subjects with $TEWL > 8 \text{ gm}^{-2}\text{h}^{-1}$. At each reading, the clinical score is completed by an instrumental erythema and TEWL measurement.

4.3 Clinical Assessment of Irritation

The eye is a remarkable detector of the erythema threshold. But it is less effective in evaluating intensity. The same applies to desquamation. Conversely the touch and eye are not reliable to evaluate the small alterations of the skin relief. Non instrumental erythema measurements are discussed in this book, ► Chap. 105, “Skin Barrier Function.” As for the other signs, a few examples of structured scales which have already been used are listed below:

Clinical scoring of skin dryness (Paye et al. 1994)

0	No squames or dandruff: smooth relief
1	A few squames, or slightly irregular relief
2	Mild dandruff, squames, small wrinkles
3	Noticeable desquamation, evident wrinkles
4	Severe desquamation, very visible wrinkles

Clinical scoring of superficial fissuring (Frosch and Kligman 1979)

0	No change
1	Thin cracks
2	1 or several fissures
3	Large fissures with exsudation or haemorrhage

Clinical scoring of desquamation (sight and touch) (Frosch and Kligman 1979)

0	No visible desquamation
1	Mild
2	Moderate
3	Severe with large squames.

Purely subjective symptoms (dryness feeling, tense skin sensation, pruritus, stinging and/or burning) are better appreciated by their threshold (the symptom exists or not) than by their intensity. However it is sometimes useful to record intensity, even in a very approximate way (Finkey 1987), or to use a device designed for autoevaluation as in the measurement of pruritus (this book, ► Chap. 131, “Itch Metrology”).

4.4 Sensitive Skin

Sensitive or reactive skin is a fairly common condition. Being still poorly defined and almost purely subjective, its definition, actual prevalence, recognition, testing and treatment make a challenge for both dermatologists and cosmetologists. A valuable attempt to answer most of these questions was made in a recent thesis from which were drawn the following data (De Lacharrière 2002).

The condition has been termed “status cosmeticus” in 1990 (Fisher 1990), but was first recognized as an entity in 1986 by Thiers who wrote (Thiers 1986) “Usually one deals with a woman aged about 30 years, often with a clear complexion. . . . From a short time, she complains that her face, seldom her hands too, badly react to every applied product, whether sophisticated or not. In a couple of seconds the patient feels a warm and burning sensation rather than itch. The treated skin at once strongly reddens, but without immediate weal neither late vesicle formation. Within a few hours, sometimes only the day after, all symptoms subside. When redness has faded out, one or two days later, a fine and transient desquamation appears. One is impressed by the intensity of the erythema, and of the burning sensation, the scanty desquamation, the absence of any sign of allergy such as urticaria, or eczema. Once the reaction has settled, any new attempt induces a relapse.”

In a survey conducted in a randomly selected British population (2058 women and 260 men) (Willis et al. 2001), the incidence of the self-reported condition was 51.4 % for women and 38.2 % for men, and 10.0 % and 5.8 % respectively for a “very sensitive” skin. In another population in the USA (800 women) comprising Afro-Americans, Asians, Euro-Americans, and Hispanics, the prevalence was similar (52 %) (Jourdain 2002). Among 2000 Chinese women (Yang et al. 2002) the mean incidence was 36.1 % and showed a regular decreases with aging (e.g., 49.1 % and 20.1 % in the 18–20 y and 51–55 y groups, respectively).

The conditions (as found in 887 English women with sensitive skin (De Lacharrière 2002)) involves sensorial signs: itching, stinging, burning, and skin tightness sensation occurring on

the face (nose paranasal, forehead, perioral area, cheekbone, chin). Erythema was absent or faint. “Dry skin” was often associated, but was not so dry as to induce increased roughness and desquamation (both assessed (De Lacharrière 2002)). In another survey (1037 randomly selected English women (De Lacharrière 2002)) the condition was found not associated with present or past allergy (atopic dermatitis, contact eczema). This was confirmed later (De Lacharrière et al. 2001). In Caucasians the symptoms are mostly triggered either by contact with hard water, soap, make-up removers, or by environmental factors (wind, cold or warm weather, fast temperature change), or by both. Spicy food may also generate skin reaction especially in the Asians (Jourdain 2002; Yang et al. 2002). In England proneness to blushing and seborrhea are also predisposing factors. The stinging test (10 % lactic acid cotton tip gently rubbed 10 times) showed positive in 48 out of 88 English subjects, that is only in “moderately” and “very” (not in “slightly”) reactive skins (De Lacharrière 2002).

Neither an increased TEWL (De Lacharrière 2002) nor an increased sensitivity to SLS (0.5–3 %) (Reiche et al. 1998) implying an impaired skin barrier, were found associated with sensitive skin. The skin hydration (capacitance) was normal (De Lacharrière 2002). But the sebum excretion rate (as found with Sebutape) was significantly increased (De Lacharrière 2002).

All these data led the author to presumably rely the condition to an increased superficial skin vessels and/or sensorial nerves reactivity. Accordingly testing with capsaicin was undertaken: 0.05 ml of 0.075 % capsaicin in a cream (Zostrix[®]) over 4 cm² on the jaw angle, with scoring at 3, 5, 10, 20, and 30 min for stinging (0–3), burning (0–3), itching (0–3) (De Lacharrière et al. 1997). Both stinging and itching scores were significantly higher in sensitive skin, increasing in parallel with the severity of the condition. In contrast, no difference was observed in patients with and without contact allergy (De Lacharrière et al. 1997). Brain activated areas during a lactic acid stinging test were examined in nine women with sensitive skin as compared with nine control women, using

functional magnetic resonance imaging (Querleux et al. 2002). Whereas in controls only the opposite side Sylvian nose paranasal area was activated, in sensitive persons activation was bilateral and associated with that of the prefrontal (as in pain sensation) and cingular areas. This experiment suggests that sensitive skin may be a functional neurosensory condition close to hypersensitivity to pain (Querleux et al. 2002).

The conclusion of this set of experiments is that sensitive skin can be detected using an appropriate questionnaire and confirmed by testing with lactic acid and capsaicin. Owing to the lack of difference between the author's grade 1 (slight) sensitive skin and controls, "true" sensitive skin should perhaps be restricted to grade 2 (moderate) and 3 (very) sensitive skin, that is people experiencing.

4.5 Instrumental Assessment of Irritation

4.5.1 Invisible Erythema and Vasodilatation

Some devices are more sensitive than the eye and capable to detect "infra-clinical erythemas." Contrary to allergic or actinic reaction, these mild or minimal irritations are characterised by vasodilatation limited to the sub-epidermal vascular plexus, the deep blood flow keeping barely elevated or normal. They are therefore better assessed by the techniques specific to superficial skin blood flow (reflectometry or spectroreflectometry (Nangia et al. 1996), green laser-doppler, capillaroscopy) (see ► Chap. 133, "Assessment of Erythema and Pallor"). Laser-doppler may be useful to detect stingers, independently of an erythema (Lammintausta et al. 1992).

4.5.2 TEWL

In mild erythemas induced by irritation TEWL is increased in proportion to the severity of the irritation. Because this water flux reflects the permeability of the stratum corneum its intensification is observed following a barrier damage due to detergents and other substances aggressive to the horny layer. It is sensitive to SLS and reacts

in a dose-dependent and linear way, which is not the case of the clinical response (Tupker et al. 1997). Following an occlusive test, TEWL must always be measured at least 1 h after the end of application, the skin being left uncovered (Tupker et al. 1997). Furthermore, a high basal TEWL has a prospective value (Murahata et al. 1986), indicating a more permeable stratum corneum and a resulting increased tendency to irritation.

4.5.3 Impedance

The measurement of conductance has given inconstant results. The quotient of the absolute impedance at 20 kHz by the impedance at 1 MHz (irritation index) decreases when the irritation increases (Ollmar and Emtestam 1992). This would be an indirect measurement of the intercellular oedema of the viable epidermis.

Whilst TEWL and stratum corneum capacitance remain unchanged, the sorption-desorption test and moisture-accumulation test detected a barrier alteration one hour after a 15-min application of 0.1 % SLS, through significant reductions of hygroscopicity (water sorption), water holding capacity and moisture accumulation (Treffel and Gabard 1996).

4.5.4 Skin Relief (Using Silicon Polymer Replicas)

On the volar forearm, hyperhydration is associated with the narrowing of the furrows and the dilatation of the plateaus, the surface of which can become wrinkled. After application of an irritant for 24 h, the normal triangular pattern recedes, desquamation occurs, the crests crossing the plateaux become larger, and in particular the furrows become deeper. These alterations seem reproducible and related to the intensity of the irritation (Kawai et al. 1992; Sato et al. 1996). They are similar to what is observed when the stratum corneum is dehydrated.

4.5.5 Desquamation (Agache 2004)

A static quantification (D-Squames, turbine method) and a dynamic measurement (reduced stratum corneum renewal time) have been used to detect and assess some damage of the horny

layer and alteration of the viable epidermis behaviour, respectively.

4.5.6 Dansyl Chloride Test (Fluorescence Under Wood Light)

This test measures how the storage of dansyl chloride (DC) by the stratum corneum is reduced under the effect of the application of the tested product; it seems to be associated with its irritating effect (Paye et al. 1994). It is not known whether the DC is extracted by the detergent or whether its absorption by the living tissue is facilitated. The sensitivity of the test may be similar to that of TEWL.

On two areas on the volar forearm DC 5 % in petrolatum gelly (vaseline) is applied under semi-occlusive patch for 18 h later. After patch removal the skin is thoroughly rinsed with tap water and the homogeneity of the fluorescence under Wood light is checked. During the following 7 days, no soap or detergent is applied, therefore the test begins 8 days after DC application. In the morning, on one of the areas (the other serving as control) 0.15 ml of the tested preparation heated at 40 °C is applied in a Hill Top Chamber for 30 min and the skin is thoroughly rinsed. The same procedure (30 min application, ablation, rinsing) is renewed twice in the same day, with a minimum interval of 1 h 30. After the last operation, a visual measurement of the reduction of fluorescence compared to the control site is achieved, using a scale from 0 to 4. The authors found it to be correlated with the irritation grade (even in absence of erythema) (Paye et al. 1994).

4.5.7 Corneosurfametry (Stratum Corneum Alteration Test) (Piérard et al. 1994, 1995; Goffin et al. 1995)

As the stratum corneum acts as a barrier against penetration of foreign substances into the living tissue, its integrity is essential in the protection against irritation. Piérard et al. noticed that the first sign of alteration of the stratum corneum by detergents was an increase of its colorability by Polychrome Multiple Stain (a mixture of fuchsine and toluidine blue). Corneosurfametry consists in measuring this effect on the most superficial

layers obtained by stripping with cyanoacrylate glue. It is, therefore, an *in vitro* test carried out on material that has been sampled *in vivo*.

Each sampling is put in contact with the tested product for 2 h at 20 °C. It is then rinsed with tap water and stained for 3 min. Its color is then measured with a Chromameter CR200 according to the system $L^*a^*b^*$. It is also possible to observe the type of stratum corneum alteration using a microscope. The authors use 3 parameters: (i) the ratio luminance/chroma, named CIM (Colorimetric Index of Mildness), (ii) the global difference in colour with the effect of water application called CSMI (CorneoSurfaMetry Index), (iii) the added differences of both previous indices with water indices, called ODC (Overall Difference in Corneosurfametry)¹.

The CSMI after application of detergents differs significantly from the CSMI after application of water. This permits to classify the products in relation to water and a standard detergent, for example 1 % SLS. Furthermore the effect of water alone is a way to detect and assess the stratum corneum fragility and makes it possible to compare or rely this factor with the skin irritability. In this way the authors have found different proneness to irritation in six body sites, as well as a different stratum corneum stainability in subjects with dermatitis of the hands and forearms (Henry et al. 1997).

4.5.8 Mediators of Inflammation Assessment in Stratum Corneum (Perkins et al. 1999, 2001)

This method uses the ability of stratum corneum to store peptides up to its uppermost layers originating in the viable tissue. Consequently, inflammatory mediators such as Interleukin-1'' (IL-1'') can be collected at the skin surface to detect a

¹ $CIM = L^* \cdot (a^{*2} + b^{*2})^{0.5}$; $CSMI = [\Delta L^{*2} + \Delta(a^{*2} + b^{*2})]^{0.5}$; $ODC = [(\Delta CIM)^2 + (\Delta CSMI)^2]^{0.5}$. However, CIM is redundant because L^* and $(a^{*2} + b^{*2})^{0.5}$ are inversely correlated; furthermore it evolves parallel to CSMI. The ODC index is also redundant because it adds up the same variation expressed differently. Only the CSMI index has a clear significance: the colour difference in colour between treatment with water and with the tested product.

cutaneous inflammation even in the absence of clinical signs. The authors used Sebutape, applied for only 1 min, to collect a thin layer of stratum corneum in which human IL-1 α , its receptor antagonist IL-1RA, and IL-8 could be assessed using specific ELISA kits (R&D Systems, Minneapolis, MN, USA.). Total protein in the sample was also assessed, using the Pierce enhanced microtiter assay (Pierce, Rockford, IL, USA) with bovine serum albumin used as the standard, in order to calculate the ratio cytokine/protein which is independent of the amount of stratum corneum collected. IL-1 α was recovered from all normal subjects, at a level depending on the body site, whereas IL-8 was absent. No age related differences were found. The ratio IL-1 α /IL-1RA was higher in sun exposed areas (face, lower leg in females) as compared to covered sites (upper back, upper arm, under arm, upper leg), most probably signaling subliminal inflammation. Upon skin irritation (heat rash, erythema, diaper rash in infants) IL-1 α levels were significantly elevated. In babies suffering of diaper dermatitis, a correlation was found between the rash grade and IL-1 α level. In these infants, IL-8 was also found in the Sebutape samplings at measurable level. Skin application of 20 % SLS for 1 h was followed 24 h later by a strong increase of both IL-1 α and IL-8, while water application only induced a smaller but clear cut augmentation. Consequently, the method seems promising for detection and monitoring sub-clinical skin irritation.

Patients often turn to dermatologists because of problems of skin allergy, either of an external origin (contact allergy) or associated with allergenic compounds intake (endogenous allergic reaction). Skin tests are also frequently used to confirm the allergic mechanism of noncutaneous diseases (asthma, conjunctivitis). Investigations apply mainly to either immediate IgE-mediated Gell and Coombs' type I allergy or delayed, cell-mediated type IV allergy. The reading is also immediate or delayed, depending on the mechanism involved.

1 Immediate Hypersensitivity (or Allergy) Testing

The principle of these tests is to reproduce the Lewis triad within 20 min by applying the allergen on or into the skin. (Hypersensitivity refers to a general mechanism, whereas allergy refers to its clinical manifestations.) Common uses of immediate hypersensitivity tests in dermatology are atopy, investigation about possible allergy to molds or foods, contact urticaria, reaction to

Table 1 Causes of false negative prick tests

Skin hyporeactivity (positive controls are negative): deficient mastocytes and/or neuromediators
Current 15 min is not the proper reading time: incorrect allergen formulation, very low allergen penetration
Medicine weakening effect: it can be detected through the controls
H1 antihistamines, imipramine, phenothiazine, and dopamine induce constantly false negatives
Hypnotics, theophylline, beta-mimetics, nonsteroidal anti-inflammatory drugs, and paracetamol may induce false negatives
Long-term corticosteroid systemic or topical therapy can render prick tests difficult to interpret

medicine, oral syndrome, anaphylactic shock, and some visceral diseases (Castelain and Castelain 1992; Lachapelle and Maibach 2012). One should always keep in mind that hypersensitivity refers to a general mechanism, whereas allergy refers to its clinical manifestations.

In order to interpret the test, patients must meet some requirements. The skin must be able to develop a type I reaction; this response may be disturbed by drug intake (Table 1) or by aging (it decreases with age). The response may also be different with the tested body site.

1.1 Immediate Hypersensitivity

1.1.1 Intradermal Skin Tests

It was the first allergy test to be described (Mantoux 1908; Lachapelle and Maibach 2012; Bernstein and Storms 1995a, b). A solution with the allergen is injected into the superficial dermis. Usually, 0.02–0.03 ml produces a 3–5 mm diameter papule. Reading is done by comparison with a negative control (the vehicle alone) (Fig. 1). The advantages of this method are good reproducibility, sensitivity, and the possibility to use a dilution series (the only method that can assess the threshold and intensity of the allergic reaction). Its drawbacks are the pain it may induce, the necessary use of injectable substances only (e.g., medicine, venom, airborne allergens prepared for such test), and mainly the risk to generate a systemic anaphylactic reaction. Some believe that the sensitivity of this test is too high and poses a risk of false positivity; the use of control “healthy subjects” may overcome this risk, but raises ethical questions. The risk of inducing a sensitization is also discussed.

1.1.2 Prick Test

Method

Described as early as 1924 by Lewis and Grant, this test became widely used only after its modification by Pepys in 1972 (Pepys 1975). A drop of the allergenic mixture is put on the skin, and then a puncture is made of the skin through the drop, avoiding bleeding; reading takes place after 15–20 min. For a well-trained operator, the puncture is practically standardized. The usually tested sites are the volar forearm and the back. A minimum distance of 4 cm between tests is essential to avoid reading problems in case of strong positivity. Disposable pins are mandatory. Common material is in plastic (Stallerpoint, Allerbiopoint). The prick through the allergen-containing drop should be done on the skin tensed between thumb and forefinger, without twisting the pin (Fig. 2). For the purpose of standardization, the Coated Phazest[®] which contains the allergen was tried.

The prick test differs from

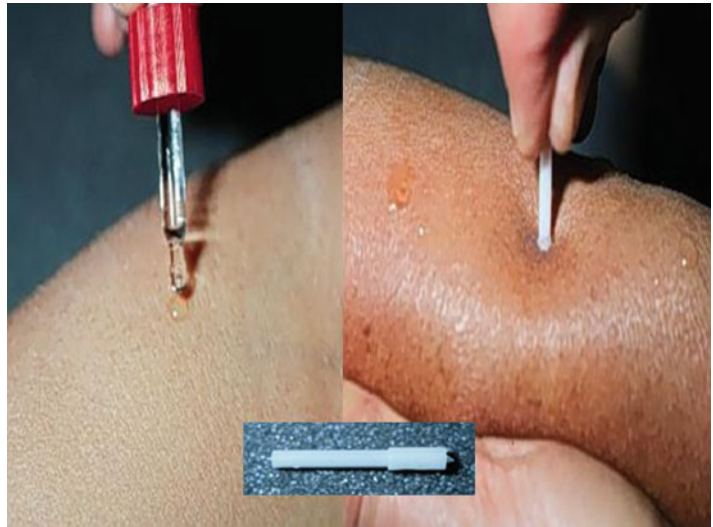

- The open test: the product such as a cosmetic product is placed on the skin without epidermal wounding.
- The open patch test, such as SAFT (Skin Application Food Test), where the allergen is placed on the skin, and sometimes occluded for 15 min, but without epidermal wounding.
- The linear nonstandardized non-bloody epidermal scarification, on which the allergen is placed afterwards.
- The intradermal test.

These tests are read after 15–20 min, sometimes more.

Fig. 1 IDR, positive reaction at 20 min

Fig. 2 Prick testing; a drop of allergen is put on the skin and then pricked through the stretched skin

Allergens

There is no “standard kit” of allergens. Samples are on the market, most of them in a phenyl-glycerol-saline solution. Some allergens (e.g., dermatophagoides, cat hairs) are standardized, and their dilution is expressed in reactivity index (IR) defined by the reaction of the prick carried out in specific conditions compared to the codeine control, but most of them are not, and variations are possible between kits. They must be refrigerated and shaken before use. Regarding food samples, the allergens on the market can be used, but in most cases crude or frozen pieces of food or more reactive freshly made mixtures are tested. Medicines are used at their usual concentration or with dilution depending

on clinical history. The skin reactivity is tested by positive control (histamine 10 mg/ml) and a negative control (the allergen vehicle). The drop is wiped off at the time of the reading.

Reading

After 15/20 min, the whole tested area is patted dry with absorbing paper. When tests are patted dry one after the other, care should be taken not to carry the allergen from one prick to another. The Lewis triad pattern varies with age: vivid erythema in newborn babies and papule only in old subjects.

Negative criteria: A test is negative if comparable to the negative control, while the positive controls are clearly positive. A papular negative

control indicates dermographism; in that case a similar reaction with tested compounds should be considered as negative.

Positive criteria: The reading of the prick tests is not standardized. Pruritus, pseudopodia, and the comparison of the papule and erythema (flare) diameters with those of the positive controls attest a positive test. Reading is not quantitative; no dilution series is used. Pseudopods are interesting to be noted; they are seen mainly if the reaction is allergic (Fig. 3).

Dubious tests: The test cannot be interpreted if positive controls are negative or if the negative control produces a reaction (Fig. 4).

Late reaction: Some allergens induce a flare and papule reaction which appears within 12 h and may last up to 48 h (e.g., cockroach test). There is no explanation to these types of reaction which cannot be used in diagnosis, except in adverse drug reactions where they point to a possible delayed hypersensitivity.

Modulating Factors of Prick Tests

The skin reactivity is altered by strong pressure, thinness of the skin, mastocyte density, and substance P concentration. Treatment by beta blockers or IMAO does not seem to interfere with reactivity of prick tests; however the efficacy of adrenaline in case of anaphylactic reaction may be hindered. The prick tests' reproducibility is

good only if the possible enhancing or attenuating factors have been eliminated at the time of the test.

Enhancing Factors and False Positive Tests

Tests performed while clinical signs of allergy are present (e.g., a seasonal rhinitis) will be more strongly positive. Some allergens (e.g., hymenoptera venom, Gruyère cheese) contain vasoactive substances and can produce positive tests by direct histamine release. A test may be considered as indicating a type I hypersensitivity only if at least ten healthy controls (a debated figure) tested

Fig. 3 Prick test: Lewis triad and pseudopods

Fig. 4 Prick testing, positive reaction at day 2 with drugs

in the same conditions remain negative or if IgE specific of the allergen are found in the patient's blood.

Attenuating Factors and False Negative Tests

Tests performed too near a severe allergic bout with total mastocytes degranulation can be false negative. Some medicines (e.g., corticosteroids, antihistamines) make the tests attenuated or negative. Desensitization weakens positive tests to the allergen. Some peripheral neuropathies might render prick tests negative, but children suffering from spinal dysraphism can be tested in the anesthetic zone without any problem.

Adverse Effects

Since 1987 no death has been attributed to prick tests, but nonstandardized allergens may generate anaphylactic reactions or delayed and persisting inflammatory reactions (e.g., plant sap). Focal reactions are possible; it is necessary to have at one's disposal corticosteroids, epinephrine/adrenalin, and injectable antihistamines as well as respiratory ventilation material.

Diagnostic Value of Prick Tests

The prick test is an easy to use method whatever the subject's age; several allergens can be tested in one consultation; the specificity of the method is good; however its sensitivity is poor (250 times less sensitive than the intradermal test) (Menardo et al. 1982). Faced with a suggestive clinical case and a negative prick, it is possible to repeat the test and maybe to complete it with an intradermal test. A prick test positive alone does not mean that the patient is allergic. Interpretation must always be connected to the clinical history, and if any doubt arises the prick test can be followed by provocation tests, but it raises ethical questions. The assumed mechanism of a positive reaction to an allergen may be confirmed by the specific IgE assessment; if its blood level is abnormally high, then the patient obviously presents a type I sensitization, but allergy is based on clinical signs only. The results of the prick test are not quantitative and cannot be used to quantify this allergy nor type I sensitization.

1.1.3 Other Tests

Other tests are used, but in a more unusual way: open test, scratch test, and prick test followed by occlusion. The principle is always the same: to reproduce the Lewis triad.

The most interesting test is the *open test*. The allergen is placed onto the skin, in conditions similar to when it induced reaction. The test is positive if the Lewis triad appears within 20 min or more. The test is indicated in case of anaphylactic reaction to an allergen for which there is no standardized extract (drugs, cosmetics); if it is negative, then a prick test can be carried out.

The *labial provocation test* can be used, with caution, especially for food (Menardo et al. 1982). The piece of food is held for 2 min by the hand inserted in a vinyl glove on the vermilion border of the lower lip. The test is positive if redness and pruritus appear within 20 min. As penetration through mucus membranes is fast and high, there may be in case of high hypersensitivity a risk of excessive lacrimation, nasal discharge, bronchial spasm, and shock.

Oral provocation tests are always thought over for awhile before implemented. Their main use is the detection of food allergy in atopic children (Rancé and Dutau 1997) when the labial provocation test is negative. For drugs, provocation tests are questionable.

Usage tests are contraindicated in case of contact urticaria as they bear a nonnegligible risk of anaphylactic shock.

Reintroduction tests are only aimed at confirming the innocuousness of a drug that was suspected in the first place then cleared, especially to make the patient feel secure. These tests must be carried out in a hospital ward because there is a nonnegligible vital risk (Bock 1991).

2 Delayed Hypersensitivity

The principle of these tests is to reproduce the lesion of delayed hypersensitivity (eczema in type) by the "mini-reintroduction" of the allergen into the target organ, namely, the skin. Indications are contact dermatitis, atopic dermatitis (Lachapelle et al. 1992; Giordano-Labadie

et al. 1999; Isolauri and Turjanmaa 1996), adverse drug reactions (Barbaud et al. 2001; Lachapelle and Tennstedt 1998), and atypical contact dermatitis.

The test can be interpreted correctly (Pons-Guiraud 1995) only if the patient is compliant and well informed.

He must have normal cellular immunity, and one should remember that the latter is reduced during pregnancy and is strongly weakened by cyclosporin, azathioprin, corticosteroid therapy, and ACTH and when CD4 lymphocytes are lower than 500/cm³. Topical ultraviolet ray or immunodepressive drug on the tested zone in the preceding month should be banned.

2.1 Main Tests of Delayed Hypersensitivity

2.1.1 Epicutaneous Patch Testing

Material and Method

The main clinical sign of contact allergy is an eczema localized primarily at the site of contact with allergen (Lachapelle and Maibach 2012; Lachapelle et al. 1992). The patch test aims at reproducing the disease on a small area. It is usually achieved on the back by applying the allergen under occlusion, formerly under a gauze pad, today in a metal or plastic chamber (Finn Chamber, square chambers of Van der Bend, etc.) (Lachapelle 2010). Following removal of the chamber protecting lid, a minimal amount (from 15 µl in Finn Chambers to 20 µl in Van der Bend of liquid or 20 mg allergen in petrolatum jelly deposited with a syringe (Bruze et al. 2007; Fig. 5)) is placed at its center. If necessary the surplus is wiped off, and then the preparation is attached to the patient's skin. The place and content of each chamber are carefully recorded in the patient's file, usually using a sketch. The material is maintained in place with Mefix[®]. The chamber is removed after 48 h, and their positions are marked on the patient's back with a fluorescent-yellow pen (which will necessitate a wood lamp for detection 72 or 96 h later) or with a dermatographic pen (marketed by companies

selling equipment for patch testing). When positive, the test shows the typical eczematous lesions, namely, erythema, edema, and vesicles. A first reading is made immediately after the chamber is removed; the patient has to return 1 or 2 days later for a second reading. The patients should be informed before the tests so that they can make necessary arrangements.

The manual positioning of allergens in the chambers is a worrying source of variation. The TRUE Test[®] is a standardized patch test method where the chamber contains the allergen in an inert gel; it is found on the market at a free price (more than € 15 or US \$ 12 for a standard ICDRG series which contains allergens that are not updated).

Allergens

Those on the market have a definite concentration and a vehicle adapted to skin penetration (Lachapelle 1995; Fischer 1995). There is standard series (or baseline series) that contains allergens whose overall positivity rate is 1 % at least, when used systematically in people suffering from contact allergy. Its contents are updated at regular intervals. It palliates some failings in the patient history evaluation, and it can be complemented by an additional series also "routinely" used and set up from the physician's experience (Raison 2012). Baseline series vary according to geographical areas; the International Standard Series recommended by the ICDRG (International Contact Dermatitis Research Group) contains 21 allergens, and the European baseline series contains 28 allergens. Depending on the information provided by the patient, additional series can also be used (hairdressers, textiles, cosmetics, eyelids, feet, etc.), as well as the patient's own products (nonfoaming cosmetics and medical topics are tested under occlusion). For the emergent allergens, concentration is empirical or based on multicentric studies and subject to frequent revision (de Groot 2008).

Patch Test Reading

Reading takes place after 48 h, 72 h, or 96 h. *It should conform to a fixed standard.* The ICDRG

Fig. 5 20 mg of each allergen in petrolatum should be in the Finn Chambers

international score is used, based on the presence or absence of eczema basic lesions (Lachapelle and Maibach 2012; Vigan 1995).

A positive test of irritant type has no value as far as allergy is concerned. Such effects are the so-called soap effect, shampoo effect, follicular vesicles, croton effect, blistering effect, and necrosis.

If the positive test is of allergic type, it is then scored in cross (Table 2). The reading of epicutaneous patch tests is mainly clinical; the contribution of histology is limited because in case of doubt, it is also uncertain. TEWL measurement, colorimetry, and laser Doppler have been used, but the results were not convincing enough to be used in current practice.

The ICDRG grading records semiquantitatively the intensity of the allergic reaction. The appearance time (often the quicker is the appearance time, and the more sensitized is the patient) is also a way to assess this intensity. Pruritus is not considered in the score, whereas it is a typical symptom of eczema because it is too subjective. Calibration of this patch test reading is necessary (Svedman et al. 2012).

Unwanted Effects

They are rare (Castelain 1995; Inerot and Möller 2000; Kamphof et al. 2003; Vigan 1996) and take the following forms:

Table 2 Reading score of epicutaneous patch tests

Europe	USA	
NT	NT	Not tested
-	0	Negative reaction (but false negative are possible)
+?	1	Doubtful reaction = erythema only
+	2	Weak reaction = erythema and slight infiltration, possible small papule (no vesicle)
++	3	Strong reaction = erythema, infiltration, and vesicles
+++	4	Extreme reaction = erythema, infiltration, coalescent vesicles, and blister
IR	IR	Irritant reaction (false positive)

- False positive reactions: impurities contaminating the allergen, allergy to the support or the vehicle, angry back syndrome, irritation from too long application time, or too high concentration.
- Negative false reaction: too early reading, inappropriate testing, antigenic extinction phenomenon, too low concentration, too short occlusion, and photo allergy.
- Irritant reaction and atopic dermatitis outbreak on the tested area.
- Persistent depigmentation and complication special to some allergens (vegetables, *p*-amino compounds, acrylates, etc.).
- Keloid scars or persistent pigmentation, usually due to a technical error (Fig. 6).

Fig. 6 Patch testing, keloid scars due to a technical error

- Immediate-type reaction with a risk of anaphylaxis; this reaction is often revealed at first by the patient who complains about a pruritus during the test and confirmed when a urticarial papule is seen when the chamber is lifted. The allergen must then be removed immediately and the patient kept under observation and treated if necessary.
- Distant eczema outbreak or flare up: the area affected by eczema is reactivated although it has healed.
- Active sensitization: they should be considered when the test becomes positive beyond 1 week (Van Ketel 1973) and when the allergen is tested again, the new test reacts in usual reading. Active sensitization has to be differentiated from booster effect (Vigan et al. 1997).

Interpretation of Positive Tests

A positive test is valid only when its relevance is established, that is: (i) when the allergen is found in products in contact with the patient, (ii) when the topography of the skin lesions is compatible

with this contact, and (iii) when eviction induces recovery (Dooms-Goossens 1996). Contact may be direct, or by proxy, or airborne, or transmitted by the hands. Systemic contact ought to be considered sometimes. Relevance may be actual or past. Some tests are relevant only through crossed reactivity. The test is all the more relevant if its score is ++ or +++, but this varies according to the allergens.

A positive test is of diagnostic value for type IV allergy (late or delayed hypersensitivity) in the following conditions: (1) if the allergen is known and standardized or (2) if the allergen is unknown and the patient reacts to increasing dilutions, whereas control subjects remain negative.

2.1.2 Open Test

It is used to test foaming products or manufactured products of uncertain composition and pH $3 \ll 9$ (Dooms-Goossens 1990). A drop of the product investigated is placed on the skin of the patient's back. When dried, if there is no reaction, it is covered by a microporous adhesive. Reading takes place as for patch tests. If the application area becomes red or whitish before being covered, the product is immediately rinsed by an adapted solvent (petrolatum for a lipophilic product, water for a hydrophilic substance).

2.1.3 ROAT (Repeated Open Application Test)

It is used whenever the patch test is not possible, (in case of allergic reaction to some cosmetic allergens, the patient may try a ROAT for any new cosmetic; this obviates the absence of labeling) or if it is negative, while the clinical significance is obvious, or if a manufactured product has a weak (+?, +) positive reaction (Dooms-Goossens 1995). The patient applies the tested substance on the elbow crease, or the outer side of the arm, every morning and evening (Fig. 7). No reaction within 15 days implies that the test is negative.

2.1.4 Usage Test

If all the tests are negative in spite of their obvious pertinence, the product may be used

Fig. 7 ROAT, positive reaction to a cream at day 4

again in normal conditions, as a test for confirmation or denial of allergy. This test is rarely used. In case of positivity, it is often difficult to confirm the type IV hypersensitivity mechanism.

2.1.5 Intradermal Test

Its main use is to detect hypersensitivity to tuberculin, a particular type of cellular (= late = delayed) hypersensitivity. Reading takes place after 48 h and semiquantification indicates the degree of hypersensitivity. It is today largely replaced by multipuncture kits. Tests to microbial and fungal antigens have been gradually abandoned because of the difficulty in determining relevance. Tests to drugs may give delayed reactions even in the absence of immediate reactions; they are then often associated with positive patch tests to the drug (Fig. 8). These delayed reactions can evolve during weeks and result in residual atrophy. To avoid such a complication, it is preferable to start testing medicines with open tests or prick tests with immediate reading, to continue with epicutaneous tests with monitoring during 30 min to detect an immediate reaction under occlusion, and then perform the reading after 48/72 h; finally in the absence of delayed reaction terminate by an intradermal test. This attitude is not valid for all medicines and all type of reaction (e.g., curares, because curare allergy is always type 1).

3 Hypersensitivity to Cosmetics

3.1 Allergy to Cosmetics, Testing, and Risk Assessment

Immediate hypersensitivity reactions can be diagnosed by open immediate reading tests and if they are negative, immediate reading pricks tests; sometimes the test can turn positive in 1 h, so patients have to be surveyed longer than for other prick tests (Lauriere et al. 2006; Chinuki et al. 2011). These tests must be carried out in a hospital ward because there is a nonnegligible vital risk. Delayed hypersensitivity reactions can be diagnosed by adapted tests, with delayed reading. In the case of cosmetics, it is necessary to be aware of false positive tests, due to the presence of lauryl sulfate, for example, and false negative tests due to the low concentration of allergen in the finished product. To test some components of a finished product which has induced a positive reaction, it is essential to know their INCI name, concentration, vehicle, and pH. A too acidic or too alkaline pH precludes tests with the nonmodified compound.

3.2 Assessment of the Allergic Potential

It is not possible to assess the type I allergic potential of a new component of cosmetics in humans using a predictive test because of possible systemic unwanted effects (anaphylaxis); however, the allergic potential can be evaluated retrospectively through cosmetovigilance (Chinuki et al. 2011).

The various predictive methods of the type IV allergic potential are confronted with the fact that conditions in which the assessment takes place are different from the actual conditions of use (Kligman and Basketter 1995) and to the ban prohibiting the sale of cosmetic products tested on animals.

Epicutaneous patch testing achieved before marketing in (well informed) volunteers suffering of contact allergy to other products and thus more susceptible to develop allergy may be useful and,

Fig. 8 IDR, positive reaction at D4, in the same time patch test are positive

in case of positivity, prevent the marketing, but the negativity of these tests does not provide any conclusion, and it raises ethical questions. Usage tests on control subjects and ROAT can have the same usefulness, but they raise epidemiological questions. So this kind of methods to predict the allergic potential tend to be given up and to be replaced by alternative method and Quantitative Structure Relationship method (Grace et al. 2004).

Active “cosmetosurveillance” (Vigan et al. 1996) implies the epicutaneous patch testing of all newly introduced products. This may be done in well-informed patients in addition to their being tested with the standard series. In this way an allergenic potential can be early detected. When negative, the test read at 48 and 72 or 96 h as usual, must be reevaluated after 15 days to detect a possible active sensitization. Some ethical questions have to be solved.

Cosmetovigilance can detect emergent allergen (Salverda et al. 2013).

4 Conclusion

Methods which assess allergy by skin tests require soundness and rigor to avert risks for the patient. Some of them are vital (anaphylaxis); others are irreversible (scars, depigmentation). The physician who performs these investigations is liable

for them and must be in a position to foresee the risk in order to assume responsibility. Skin tests in humans are the only method to detect allergic reactions; they are more reliable than *in vitro* tests.

Skin tests are the only possible methods to detect allergens and set up actions for individual and collective prevention. However it is essential that test reading is done in sound conditions (good lighting, proper time) and by an experienced physician; a positive test may affect the patient’s life (Frimat 1995).

Intensity of type I sensitization can be assessed only by intradermal tests, whereas epicutaneous testing is the best method to evidence type IV reactions. Patch testing implementation is optimized by standardization which permits semiquantification. For a well-known and standardized allergen, the ICDRG grading and the positivity appearance time are the two parameters of the intensity of the reaction. For an unknown allergen, an idea of this intensity will be given by the reactions with different dilutions. Finally, cutaneous tests cannot always be used to predict the allergic potential of a substance, but through active cosmetosurveillance and cosmetovigilance they can help to detect and assess it as soon as it appears.

Skin thermal exchange • Heat transfer • Heat balance equation • Cold environment • Hot environment

Man regulates his internal body temperature within a normal range, with limits around 37 °C. This endothermia relates only to the internal part of the body (core), as the peripheral part, represented by the skin, can vary greatly (from a few degrees up to 44 °C).

Regulation of the body temperature at a constant level is under the control of the thermoregulatory system located within the hypothalamus. The hypothalamic centers, which are also sensitive to the circulating blood temperature, are constantly informed of the thermal state of the various parts of the body. For that purpose there are peripheral (cutaneous) thermoreceptors, which respond specifically to warm or cold stimulation. Some of these sensors operate in static mode (temperature level), while others operate in dynamic mode (rate of temperature change) or both. The various thermal information is integrated inside the thermoregulatory center, which is, according to the thermostat principle (with a set point at 37 °C), sensitive to any perceived deviation compared to the set point (error signal) and triggers the thermoregulatory reactions involved in the adaptation to increased cold or heat.

The thermoregulatory adjustments required for the maintenance of endothermia aim toward

equilibrating the heat gains and heat losses of the human body, and obtaining a heat balance of zero (thermal equilibrium). This balance (B) corresponds to the sum of the internal heat production (M, metabolic) and various heat fluxes (occurring at the skin surface at a pulmonary level): convective (C), conductive (K), radiative (R), and evaporative (E)

$$B = M \pm R \pm C \pm K - E$$

The metabolic heat production (M) associated with cellular activity in a resting condition is minimal ($50 \text{ W}\cdot\text{m}^{-2}$), but can be greatly increased ($500 \text{ W}\cdot\text{m}^{-2}$) during intense physical exercise. Heat, which is almost exclusively produced at the core level, is then carried away towards the skin, the site of thermal exchanges with the environment. This transportation is carried out by either tissue conduction or blood convection:

- *Tissue conduction* ($H_{k,t}$), is the transfer of heat by contact between different tissues, but this is of little importance as this process accounts for only 10–15 % and is reliant upon the formula:

$$H_{k,t} = h_{k,t} (T_{co} - \bar{T}_{sk}) \cdot A_k \text{ in W}$$

where $H_{k,t}$ represents the coefficient of the tissue conductance, T_{co} the core temperature, \bar{T}_{sk} the mean skin temperature, and A_k the tissue area where heat exchange occurs by conduction.

- *Blood convection* represents the most important means of the core–skin heat transfer, and is reliant upon the following equation:

$$H_c = F_{sk} \cdot c_b \cdot \rho \cdot (T_{ar} - T_v) \text{ in W}$$

where F_{sk} represents the global skin blood flow, c_b the specific heat of the blood, ρ the blood density, and $(T_{ar} - T_v)$ the temperature difference between arterial blood and venous blood. Therefore the arterial-venous network is a true heat

conducting system, removing heat from the muscles and active organs toward the other parts of the body, although it is mainly at the skin level that heat can be lost.

1 Heat Transfer between the Skin and the Environment

Heat transfer between the skin and the environment occurs by conduction (K), convection (C), radiation (R), and evaporation (E).

- *Heat exchanges by conduction* (K) occur by direct contact between the skin and the environment and are reliant upon the formula:

$$K = h_k (T_s - T_{sk}) \cdot A_k \text{ in W}$$

where h_k represents the thermal conductivity of body parts in contact with each other, T_s the temperature of those parts, T_{sk} the skin temperature in contact, and A_k the contact area.

- *Heat exchanges by convection* (C), used for instance when warming the air of a room (by an electric resistance heater), are reliant upon the formula:

$$C = h_c (T_{db} - \bar{T}_{sk}) \cdot A_c \text{ in W}$$

where h_c represents the heat exchange coefficient by convection, T_{db} the dry bulb (air) temperature, \bar{T}_{sk} the mean skin temperature, and A_c the area where the exchange takes place. The air velocity increases these convective heat exchanges significantly by modifying h_c according to the formula:

$$h_c = K_c \cdot V_a^{0,6}$$

where K_c depends upon the shape of the body and V_a is the air velocity. In the absence of wind, convection is said to be natural convection; in the presence of wind it is said to be forced convection. Note that the reading of the dry bulb

thermometer gives us the exact value of the air temperature.

- *Heat exchanges by radiation (R)* are a little more complex to understand. Any body, living or inert, emits a radiation called radiance (R), which relies upon the formula: $R_t = \epsilon \sigma T^4$, where R_t is the body emissivity, ϵ is the Stefan-Boltzmann constant ($5.67 \times 10^{-8} \text{ W.m}^{-2} \cdot \text{K}^4$), and T the absolute body temperature in Kelvin (K).

Any body surface which faces any other surface exchanges heat by radiation. Knowing that for infrared heat exchange the skin has an emissivity of almost 1 (0.97), the intensity of the heat exchange between the skin and the environment can be rewritten as follows:

$$R = h_r (\bar{T}_r - \bar{T}_{sk}) \cdot A_r \text{ in W}$$

where h_r is the linearized heat exchange by radiation, \bar{T}_r the mean radiant temperature of the environment, \bar{T}_{sk} the mean skin temperature, and A_r the exchange surface.

As we generally do not know the value of A_r exactly, we express it as:

$$A_r = \frac{A_f}{A_d} \cdot A_d$$

where A_d is the DuBois area (total skin surface area) given by the formula:

$$A_d = 0,2025 \text{ M}^{0,425} \cdot T^{0,725}$$

where $M(\text{kg}) = \text{body mass} = \text{weight}/9.81 \text{ m.s}^{-2}$, and $T(\text{m}) = \text{height}$; $\frac{A_f}{A_d}$ corresponds to the percentage of the skin area which exchanges heat with the environment, generally 70 % (the remaining 30 % corresponds to the human body parts which exchange between themselves: the inside of the legs, the inside of the arms, between the chin and torso, etc.).

- *Heat exchanges by evaporation (E)* occur when sweat evaporates from the skin surface:

for every gram of sweat that evaporates 2.42 kJ are eliminated. This is reliant upon:

$$E = h_c (P_a - P_{sk}) A_e \text{ in W}$$

where h_c is the heat exchange coefficient by convective evaporation, which is linearly linked to the heat transfer coefficient, A_e is the evaporating surface, and $(P_a - P_{sk})$ is the difference between the ambient water vapor pressure and the saturated water vapor pressure at skin temperature. P_a generally being unknown, one can write

$$A_c = A_d \cdot \frac{A_e}{A_d}$$

where A_d is the DuBois area (total skin surface area; see above for calculation) and $\frac{A_e}{A_d}$ is the skin wettedness expressed as a percentage. The concept of skin wettedness is interesting because it describes fairly well the severity of the heat strain. A 30 % skin wettedness is associated with discomfort; at 50 % skin wettedness sweat starts to drip from the body; at levels higher than 85 % skin wettedness corresponds to very severe exposure. For any given situation (h_c , A_e fixed), the heat exchange by evaporation will be proportional to the water vapor pressure difference ($P_a - P_{sk}$). As a consequence, the closer P_a is to P_{sk} (5.8–6.6 kPa), the less evaporation takes place and the more sweat drips from the body without any efficient thermolytic effect.

In summary, the heat exchanges by K, C, and R are called dry heat exchanges, because they are essentially proportional to the difference between the skin temperature and that of the environment (T_{sk} , T_{db} , and T_r). Heat exchange by evaporation, also called latent heat exchange, is essentially proportional to the water vapor pressure difference between air and skin. These exchanges are linked to the skin temperature and therefore under the control of the thermoregulatory system. They can be assessed for the overall body (because thermal equilibrium is required for maintenance of endothermia) but they can also be assessed

locally (because they are at the origin of the thermal sensation and this may cause discomfort).

1.1 Additional Heat Exchanges Originating at the Level of the Respiratory System

Inspired air enters the respiratory tract at the dry bulb temperature, but leaves at approximately 35 °C, thus some heat exchange occurs by respiratory convection (C_{resp}). In the same way, inspired air enters the lungs at a humidity corresponding to the humidity level of ambient air. It leaves completely saturated at 35 °C; thus, some heat exchange also occurs by respiratory evaporation (E_{resp}). These heat exchanges ($C_{\text{resp}} + E_{\text{resp}}$) are not regulated because they are not under thermoregulatory control. Their intensity depends totally upon the ambient conditions and the respiratory ventilation rate. They are often negligible, except during intense physical exercise in dry environments.

2 Heat Balance Equation

The heat balance equation $B = M + K + C + R + E$ is defined as the sum of different components, which, by definition, will be allocated a positive (+) value if they correspond to a heat gain, and a negative (−) value in the case of heat loss. Given this, the equation is written:

$$B = M \pm K \pm C \pm R - E \quad \text{in } \text{W}\cdot\text{m}^{-2}$$

So:

- M is always positive, as it is an internal heat production
- E is always negative, as it always heat loss (except in special cases where condensation could occur on the skin)
- K, R, and C can either be positive or negative depending upon the temperature difference between the skin and the environment.

Therefore, B can either be zero (thermoequilibrium), positive or negative.

In summary, when the heat balance equation is zero ($B = 0$), heat gains and heat losses are balanced and endothermia is maintained.

When heat gains and losses are unbalanced ($B \neq 0$), heat storage (S) can occur: this frequently happens during heat exposure and/or during physical exercise. On the other hand, heat debt (D) will take place especially during exposure to cold. In these two cases endothermia is at risk from the dangers of hyperthermia (heat) or hypothermia (cold).

2.1 Heat Balance in Cold Environments

The zero thermal balance in a cold environment dictates that $M = -R - C - K - E$, which means that the metabolic heat production M must offset all the heat losses (R, C, K, and E) to maintain endothermia. Therefore, two thermoregulatory reactions can be triggered against the cold:

- A reduction of heat losses by increasing the cutaneous insulation: peripheral vasoconstriction (diverting blood from the skin) leads to a decrease in the mean skin temperature, therefore reducing the temperature difference.
- An increase in internal heat production by either shivering, which corresponds specifically to muscular activity in the fight against the cold, and can reach between 200 and 250 $\text{W}\cdot\text{m}^{-2}$, or by voluntary physical activity (up to 500 $\text{W}\cdot\text{m}^{-2}$). Nevertheless, neither shivering nor physical activity can be maintained for long periods of time, rendering man particularly susceptible to the cold.
- Other heat sources may exist, notably the specific dynamic action of food intake, which has negligible importance. Regarding the non-shivering thermogenesis, well known in rodents, it is unlikely to occur and if so only in the case of developing adaptive mechanisms.

In summary, without the help of clothes or heated areas, in humans the cold climate often results in an unbalanced heat equation leading to a heat debt (hypothermia), the importance of which depends upon the intensity of the cold stress, its duration, and the type of environment the body is exposed to (water > air). The skin, thanks to the thermal insulation induced by peripheral vasoconstriction, plays a major role in the reduction of heat loss. It is the excessive physiological insulation that plays a part in the appearance of frostbite. Some adaptive mechanisms appear to reduce the intensity of the skin heat losses; for example, increased subcutaneous fat thickness which reduces peripheral thermal conductivity.

2.2 Heat Balance in Hot Environments

The balanced thermal equation in the heat is written $E = M \pm R \pm C \pm K$, which means that evaporation of sweat is the only means of heat loss compensating for the internal (M) and external ($R \pm C \pm K$) heat gains. Thus endothermia is maintained if $E = M \pm R \pm C \pm K$, and E represents the required evaporation (E_{req}) necessary to achieve zero thermal balance. The ambient evaporative capacity restricts the evaporation of sweat to an E_{max} value, which mainly depends upon the temperature and the humidity of the ambient air. Thus, when $E_{max} > E_{req}$ endothermia can be guaranteed, but when $E_{max} < E_{req}$, heat storage (S) will occur, leading to hyperthermia, the importance of which depends upon the severity of the climatic conditions, the activity level of the person, and the duration of heat exposure.

Hyperthermia in the form of heat stroke is a serious condition which often results in death. A limitation of the thermolytic capacity depends upon the maximum sweating capacity of the subject. This can reach between 2 to 3 litres of sweat per hour, but this sweating rate can only be maintained for short periods of time. On the other hand, sweat losses, if not correctly counterbalanced by fluid intake, can lead to dehydration associated with hypothermia, tachycardia, and osmotic imbalance.

3 Conclusion

The skin is the site of heat exchanges between man and his environment. Its capacity to modify the intensity of these exchanges via vasomotor control means that it plays an essential role in the fight against environmental thermal stress. The development of millions of sweat glands allowing secretion and excretion of sweat makes it a unique location for heat loss in warm conditions.

Digestive tract temperature • Esophageal temperature • Hyperthermia • Mean skin temperature • Rectal temperature • Skin blood flow • Sublingual temperature • Sweat rate measurement • Thermal shivering • Tympanic temperature • Vaginal temperature

It is worth noting that an international standard (ISO 9886) provides guidelines for measurement and interpretation.

1 Thermal Shivering

1.1 Qualitative Aspect

Shivering corresponds to the isometric contraction of certain muscles, all the energy of which is converted into heat. It can easily be detected from the electromyographic activity of the muscles that are commonly involved. The detecting electrodes are generally located above the masseter muscles or on the scapular area. Shivering is at first localized and then tends to spread to meet the required heat. Electromyography permits accurate detection of the onset of shivering: this is interesting, for instance, when studying the cold adaptation process, although it does not allow quantitative analysis.

1.2 Quantitative Aspect

As muscular activity requires energy (see ► [Chap. 121, “Functional Assessment of Thermoregulation in man”](#)), shivering results in an increase in oxygen consumption. In normal conditions, when the respiratory quotient is normal ($=0.8$) (from combined oxidation of fats, carbohydrates, and proteins), each liter of oxygen consumed per hour in addition to the resting metabolism generates 5.6 W. Shivering assessment under hypothermic conditions is therefore carried out by measurement of the oxygen uptake and carbon dioxide elimination (knowledge of the respiratory quotient MCO_2/MO_2 gives a better estimation of the O_2 energy equivalent). For

instance, a mild hypothermia which would require a heat production of 100 W corresponds to an additional oxygen consumption of 300 ml/min, which imposes an approximately twofold increase in the oxygen consumption observed at rest to maintain a stable core temperature.

2 Rectal Temperature

The thermosensor (with a disposable probe, or a probe which can be sterilized and used again with the same subject) is introduced into the rectum approximately 10–12 cm beyond the anal sphincter. Although inert, it is influenced by its location inside the rectum, i.e., whether it is in direct contact with the rectal wall, by the temperature of the venous blood returning from the inferior limbs. To avoid a possible injury it is essential to ensure that there are no hemorrhoids.

3 Esophageal Temperature

The thermosensor is introduced via the nose into the esophagus, aided by swallowing at the opportune moment small amounts of water stored in the mouth. Generally, a distance of about 40 cm between the probe and the nasal passage is necessary to give an accurate measurement. When located in the esophagus the sensor gives an accurate reading of the arterial blood temperature (due to the proximity of the heart and the aorta (Bregelmann et al. 1979)). This measure can be affected by a high respiratory rate (during effort) and is of course directly influenced by the temperature of ingested fluids and the resulting local evaporation.

4 Tympanic Temperature

In the case of a contact measurement (Brinnet and Cabanac 1989), the probe is usually at the tip of a very soft spring. Nevertheless the contact of the probe with the membrane is painful and is associated with the perception of a loud noise. The ear canal must be very clean (no wax) and well protected against external influences (e.g., ear

plugs and monaural headphones filled with isolating material) to avoid mistakes linked with the environmental temperature. Indirect measurement using an infrared thermometer seems easier because it is less invasive. However, it implies a rectilinear auditory canal, no obstruction, and expertise of the operator. Often an incorrect measure of the tympanic temperature is in fact a correct measure of the auditory canal temperature.

5 Sublingual Temperature

Sensors (with a disposable probe) are introduced underneath the tongue as deeply as possible. The subject must be asked to breathe only through the nose to ensure a correct measure (Mairiaux et al. 1983). Any breathing through the mouth will lead to an underestimation of the temperature due to saliva evaporation. Measuring the oral temperature under physical activity is difficult; consequently it can be done during a short resting period between two phases of activity.

6 Digestive Tract Temperature

The sensor (consisting of a radiobattery) is ingested by the subject and moves along the digestive tract, allowing a radiologic tracing to be made. The sensor transmits variations in core temperature and is subject to fluctuations related to its location (contact/no contact with the feces or the intestinal walls).

7 Vaginal Temperature

This non-invasive measurement gives a correct value of the core temperature.

8 Mean Skin Temperature (Agache 2004)

Measurement of the local skin temperatures can be extrapolated to the total skin area, which is termed mean skin temperature. Local

measurements are carried out by either contact or infrared thermometry. If the measurement is made by contact, the point of contact should not be under any pressure nor covered with anything that would insulate the sensor or restrict any evaporation that may occur locally. Calculation of the mean skin temperature is then carried out by averaging the local measures, each of them proportionally weighted to the percentage of the body surface it represents. Increase in the local skin temperature is usually lower than its decrease under cold stress. It does not depend upon internal heat production except in the case of intense physical exercise (see ► [Chap. 121, "Functional Assessment of Thermoregulation in man"](#)). Nevertheless, it is not totally independent of the adjustment of the hypothalamic thermostat, as demonstrated by the cutaneous hypothermia under fever conditions.

9 Heart Rate Measurement

Counting the QRS complexes on the electrocardiogram gives a measurement of the heart rate. This has become easy since personal, portable cardiofrequency meters (e.g., the Sport-tester model) became available. Ignoring the extra-cardiac activity associated with emotional influences, one can state that the heart rate is the sum of three components, each of which is subject dependent:

- A basal component, which can be assessed at rest under thermal neutrality
- An activity component linearly related to the intensity of the physical effort involved in carrying out a standard task
- A thermal component directly proportional to the heat storage, which originates from both environmental conditions and metabolic heat production

Indirect assessment of the thermal strain through heart rate measurement therefore requires previous knowledge of the subject's physical and thermal reactivity (Vogt et al. 1973).

10 Sweat Rate Measurement (Agache and Candas 2004a, b)

Assessments of the total sweat lost over a time interval can be achieved either by weighing the subject before and after, and eventually adding the quantity of sweat lost in the clothing, or by monitoring the subject's weight. The body mass variation is a reflection of the water losses due to sweating, after taking into account the body mass losses due to respiratory gas exchange and respiratory evaporation. Sweating can sometimes be divided into two parts; first the evaporative rate and second the dripping rate (the latter without cooling efficiency). To do this it is necessary to use two scales, one to measure the total body mass over time, the other to weight the dripped sweat (usually using an oil-containing tub located underneath the subject (Candas et al. 1980)). The evaporation rate is obtained by subtracting the dripping rate from the total sweat rate.

The measurement can be made at one body site only, either by collecting the sweat dripped from a determined surface area in a plastic pouch container (Risson et al. 1991), or by assessing the change in water content of a gas before and after it passes over the skin in a chamber (Graichen et al. 1982). However, extrapolating the results of such methods to the whole body area will usually give an overestimated figure. In the first method monitoring of the sweat rate is not possible, and the method is mostly used to estimate the electrolyte content of the collected sweat (detection of cystic fibrosis) (Boisvert et al. 1997). Furthermore, the obtained data are overestimated because the absence of evaporation increases the local skin temperature, which in turn stimulates the secretory process. But they could also be underestimated, because local excessive skin moisture can trigger a negative feedback of the sudomotor capacity (this phenomena is described as hidromeiosis) (Candas et al. 1979). In the second method the difference in water content of the gas entering and leaving the chamber is determined by a hygrometric technique. The method enables monitoring of the sweat rate. Such a technique is difficult to set up as it is not mobile and requires expensive devices (measurement of ventilation rate, of air

temperature, and of its humidity content). However, the obtained results certainly represent the most accurate sweating intensity figure.

-
- 11 Skin Blood Flow (see ► Chaps. 48, "Skin Blood Flow: Histophysiology," ► 53, "Skin Capillaroscopy," ► 56, "Epicutaneous 133-Xenon Clearance," ► 58, "Transcutaneous Oxygen Pressure," ► 50, "Skin Microcirculation: Choosing the Appropriate Method," ► 49, "Photoplethysmography in the Evaluation of Skin Conditions," ► 52, "Assessment of Cutaneous Microvascular Function Using Laser Doppler Flowmetry and Acetylcholine Iontophoresis," Agache 2004a, b)**

The individual capacity to withstand the heat is reliant upon vasomotor reactions. Indeed, exposure to heat, physical activity or both implies vasodilation in order to remove the internal heat towards the periphery, where it will be lost. Cutaneous blood flow (or more accurately, its variation) can be assessed either by plethysmography on a limb (for example a strain gauge placed around the arm) or on small skin areas by thermal clearance, or through the Doppler effect (laser-Doppler), which monitors local skin blood flow changes in arbitrary units.

12 Selecting a Method for Assessing Resistance to Hyperthermia

Selection of the appropriate thermal stimulus and physical parameters depends on what you are looking for and on financial constraints. To achieve hyperthermia in the absence of a climatic chamber, a heated room or a sauna can be used. It is simpler and more controllable to put the subject into

a hot bath. Ergometric bicycles, rowing machines, and treadmills are also able to induce thermoregulatory responses. The wearing of clothes, especially those that are impermeable, accelerates the process, leading to heat storage. Nevertheless, it is worth knowing that regardless of the mode of stimulation, at least 40 min are necessary in order to establish steady body temperature and associated thermophysical reactions. Finally, local sweat collection will take an additional 15–20 min for correct measurement of the sweat flow.

Therefore, the functional investigation of the thermoregulatory system requires a one-hour test for its complete implementation, except if the constraint is such that the heat storage is intense and continuous, in which case accidents may occur rapidly. During this time, all of the above-mentioned variables can be recorded. Whichever method is used, the internal temperature must not exceed 39 °C (102.2 °F) and the heart rate must permanently stay under the figure (190 minus age) for safety reasons. In such a case after 1 h, the total body water loss should not exceed 700–800 g. The local flow from the stimulated area is equal to or slightly lower than 1 mg.min⁻¹.cm⁻² at rest, and can reach 2–3 mg.min⁻¹.cm⁻² during intense exercise.

1 Resistance to Heat

With the exception of local sweating stimulation to determine the sweating capacity or the electrolyte content of the sweat, there is no simple test allowing assessment of the individual capacity to face thermal stress. All techniques require either the use of a climatic chamber or physical exercise of a certain duration so as to provoke an increase in core temperature, which elicits thermoregulatory processes.

It is obvious that it is the combination of both work and heat that triggers the most important responses. The exposure will be yet more severe if the ambient humidity level is higher, as the possible evaporation will be reduced.

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title *Measuring the Skin*. The content has not been changed.

1.1 Parameters Involved in Assessing Heat Tolerance

Although the most interesting variable for the physician or the physiologist is the core temperature (because it is a regulated quantity and a survival factor), the skin temperature is also a major one. In fact, for a man at rest who has an internal metabolic production of around 100 W, internal heat transfer towards the periphery is possible only because there is a difference of a few degrees (3 or 4) between the core and skin temperatures. Any exposure to heat reduces the difference between the temperature of the core and that of the skin. This thermal difference is an index of heat tolerance (Pandolf and Goldman 1978). If the skin temperature became equal to or higher than the core temperature, the body would become unable to eliminate its own internal heat. Nevertheless, the thermal difference between the core and the skin can be as low as some tenths of a degree (2 or 3 tenths). In the more tolerant subjects, a more rapid sweating onset, a higher sweating rate, and a better vasomotor response allow this difference to remain around 1 °C. Passing from a non-adapted state (e.g., 0.2 °C difference between core and skin) to a more tolerant one (e.g., 0.6 °C) would reduce the cardiovascular cost by 300 %. The total metabolic heat must be transported by the blood from the active cells towards the periphery. The additional cardiac cost is a function of the core-skin thermal gradient amplitude because the heart rate has to compensate for the reduction in internal heat transfer due to a reduced thermal gradient. Therefore the heat rate is a good index for thermal stress assessment (Vogt et al. 1973) as far as the metabolic strain can be disregarded. Recently, Israeli colleagues have proposed an assessment of heat tolerance called cumulative heat stress index (CHSI), which integrates the heart rate variations and those of the core temperature (Frank et al. 1996).

The sweating rate is, of course, a good reflection of the thermoregulatory capacities. The higher the sweating rate, the greater is the evaporative capacity, capable of preventing excessive heat accumulation. An adequate distribution of sweat production is more beneficial than local

oversweating because it is only the evaporated sweat that cools the body down. The evaporation is more effective if it takes place all over the body. It is because the sweat evaporation is faster and greater that the skin temperature increases less in a tolerant subject. And it is because the subject becomes more tolerant that the skin temperature increases less, therefore reducing the core temperature increase. All these thermophysiological parameters are interdependent, and this is the reason why one cannot favor the measurement of one or another.

The simplest parameter to measure is the heart rate. In a tolerant subject it increases on average by 30–35 beats per minute for each degree increase of the core temperature. In less-tolerant individuals, the increase in heart rate can be much higher. Next is the core temperature (rectal, esophageal, tympanic, vaginal, sublingual, auditory canal): it reflects the internal heat storage. Then comes the assessment of the sweating rate, which can easily be done by weighing the subject before and after heat exposure. Precise measurement of local sweating requires special laboratory equipment (Agache and Candas 2004a). Determination of the mean skin temperature is somewhat complex because it requires the use of several sensors (a minimum of four, an optimum of ten) to take into account the non-uniformity of the cutaneous thermal state. However, the core-skin temperature gradient may not be not a good predictor of the risk of hyperthermia in cool or cold conditions. While the core temperature may increase drastically due to high internal heat production, the skin temperature, which mainly depends on the thermal environment, may not change in such cases, and the core-skin thermal gradient can be high without avoiding the risk of hyperthermia. It is worth noting that certain hormones, notably those which regulate the body water content (ADH, renin-angiotensin, natriuretic factor), are also secreted in cases of severe heat exposure. Cortisol has been shown to be a good index of thermal stress in man exposed to heat (Follenius et al. 1982) but hormonal assessments are invasive and do not allow rapid diagnosis.

Finally, heat exposure often involves a large vasodilation; the non-resistant subject rapidly

reddens facially, does not exhibit complete wettedness (only some sweat droplets are visible instead of generalized sweating), and checking the pulse indicates an obvious tachycardia. Such simple observations make it possible to conclude that the subject exhibits poor heat tolerance. Conversely, the quantitative determination of heat tolerance requires more sophisticated methods.

1.2 Inducing Hyperthermia

Three types of thermal stress can be used and combined to induce heat storage:

- External strain: heat exposure
- Internal strain: performing physical exercise (both of these have a direct effect since they trigger an accumulation of heat either received or produced)
- Indirect external strain, which by reducing the likely evaporation will reduce the capacity to remove heat either received or produced.

1.2.1 Use of a Climatic Chamber (Exogenous Thermal Strain)

It is obvious that to increase the core temperature, exposure to heat is required. Climatic chambers are specially designed for this. If the experimenter (or the practitioner) wishes to control the hyperthermia, he or she must first control the experimental equipment. Existing climatic chambers are regulated by a collection of sensors that make the provided environment stable.

Air temperature is the most important factor to control. As for a heat source, any heat generator may be used. But to maintain a constant air temperature, air renewal is required. This can be achieved by injecting new air, at a rate that depends on air velocity (and vice versa). Determination of the air velocity is therefore important to ensure the correct renewal rate, but also because the air velocity modifies the convective and evaporative heat exchanges (see ► [Chap. 119, “Thermal Exchanges in Man”](#)).

As explained in Agache (2004) heat exchange between man and his environment is also dependent upon the temperature of the surrounding

surfaces. It is difficult to effectively control all of the wall surfaces of the climatic chamber. The simplest way is to use as a chamber a small enclosure such as a box or a tunnel constructed of two walls, between which water can be circulated. Control of the water temperature is easy provided the enclosure has suitable external thermal insulation. In the case of a larger room (similar to a normal-sized living room), an easy and cheap way of rapidly obtaining controlled wall temperatures is to force them to have the same temperature as the air. To do this, the walls are doubled inside the room by a polyurethane film which is stretched tight against all surfaces (except for the floor), the internal side of this film (the one facing the wall) being aluminized, thus reflecting the radiant heat, and then to actively circulate the room ambient air between this film and the walls.

The most difficult parameter to control is the air humidity level, corresponding to the ambient water vapor partial pressure. This parameter is very important for the evaporative rate (Agache and Candas 2004b). To humidify the air, it is necessary to vaporize water or to inject the vapor: this can be done by pouring water onto hot solids (as in a sauna), or by blowing overheated and water-saturated air onto temperature controlled surfaces (like the air escaping out of a pressure cooker valve). Nevertheless, maintenance of a constant level in the water vapor partial pressure is difficult and its regulation requires measuring tools, humidifiers and/or absorbers, which are expensive. Only specialized laboratories have them.

1.2.2 Thermal Strain Due to Effort (Endogenous Thermal Strain)

In the case of muscular exercise, heat is produced directly within the muscle and distributed inside the body. To be strictly endogenous, the strain should be imposed on a naked individual exposed to a thermal environment of 33 °C. In fact, in such a case the dry heat exchanges (convective and radioactive) are equal to zero. Since the difference between ambient and skin temperatures is zero, all the heat produced is of metabolic origin and must be eliminated by evaporation of sweat.

To carry out this physical and thermal strain, the tools generally used are:

- The ergometric bicycle
- The treadmill
- The rowing machine
- A staircase or a “step test”

The very low mechanical output of the human body at work (from a few to 22 %) implies that the majority of the effort results in heat production. The main physiological difference between the external heat load and the strictly internal heat load lies in the recruitment of the cardiovascular system. For the same resulting sweating intensity due to either of these two methods, the heart rate always increases more under effort because the redistribution needs of the blood supply are obviously more important when exercising.

1.2.3 Combined Heat Strain

The possibilities of combined heat stresses are numerous and result from the addition of heat exposure and effort. In everyday life conditions, the heat exposure is more radiative (the most frequent example in our climates is the presence of intense solar radiation), or sometimes more convective (in cases of warm air), but it is always combined.

1.2.4 Indirect Thermal Strain

The human body fights against hyperthermia by producing sweat and then evaporating it at the surface of the skin. Any increase in the ambient humidity level, or any hindrance of the evaporative capacity (for instance, by insulating some or all of the skin with non-permeable garments) will result in a more or less important reduction in the possible evaporation and therefore in some heat accumulation. The same is true in the case of exposure in warm water since no evaporation can occur in water.

1.3 Modifying Factors to Heat Tolerance

The acclimatization or acclimation (Acclimatization is increased tolerance to heat induced by a

prolonged stay in hot climates. Acclimation is the same phenomenon artificially produced, for example by repeated exposures in a heat-controlled room) phenomenon (that is: heat adaptation) increases the capacity to fight against the thermal environment, as a result of:

- The time reduction of sweat onset (the subject sweats sooner)
- The increase in the sweating sensitivity (central and local effects allow the subject to sweat more)

The increased thermolytic capacity notably increases the difference in temperature between the core and the periphery, therefore reducing the cardiac cost linked to the internal heat transfer.

The electrolyte concentration of the excreted sweat decreases with heat acclimation but the total electrolyte losses are nevertheless increased due to a larger sweat loss. This higher water loss increases the risk of dehydration and is associated with detrimental consequences (tachycardia, hypovolemia, osmoconcentration, hyperthermia, and heat stroke).

2 Resistance to Cold

Man is relatively well equipped to fight against the heat, but his resistance to cold is weaker. In fact, without any technological help (houses, shelter, clothing) he would never be able to leave tropical or subtropical areas. Human resistance to cold (Bittel and Savourey 1995) is assessed using two criteria: pain and heat debt (hypothermia).

2.1 Cold Resistance and Pain

This resistance, or more precisely cold tolerance, is directly dependent upon the mean skin temperature level (T_{sk}). In fact, if T_{sk} is around 33 °C (i.e., within the thermal comfort range), any cold exposure induces a drop in the mean skin temperature by the direct cold effect and by peripheral vasoconstriction associated with cold exposure.

The intensity of this drop is a function of both the cold stress intensity and its duration. Thus a T_{sk} of 31 °C is felt as a cold sensation, a T_{sk} of 30 °C as an uncomfortable cold stress associated with shivering, and a T_{sk} of 28 °C as extremely cold. A T_{sk} of 25 °C represents a threshold limit of tolerance with intolerable pain and numbness.

Fortunately, some skin areas (notably those at the extremities; hands and feet) exhibit much lower thresholds. For instance, at the hand level, a 20 °C T_{sk} is felt as uncomfortably cold, 15 °C as extremely cold and 5 °C represents the threshold tolerance with an unsupportable pain. This 5 °C threshold is commonly used to determine the cold sensitivity of the extremities and to quantify the beneficial effect of the cold adaptation.

The skin temperature of the extremities may also reach negative values, leading to frostbite characterized by frozen tissues. This frostbite is enhanced by increased peripheral vasoconstriction limiting the heat losses.

2.2 Cold Tolerance and Heat Debt: Hypothermia

Hypothermia is an undesired decrease in the core temperature, below 35 °C and is generally measured in the rectum (T_{re}). It is a consequence of the heat imbalance, the heat production being lower than the heat losses (see ► Chap. 119, “Thermal Exchanges in Man”) Again, the intensity of the hypothermia is a function of both the intensity of the cold stress and its duration. The cold tolerance, and as a consequence the survival prediction, is dependent upon the depth of the hypothermia. Hypothermia is said to be ‘light’ for a core temperature between 34 °C and 35 °C: the subject is conscious and shivering, the skin is pale and cold with gooseflesh, and the survival forecast is good. Hypothermia is ‘moderate’ for a T_{re} ranging between 32 °C and 34 °C and ‘severe’ or ‘deep’ for a T_{re} between 25 °C and 32 °C. Of course, the number of observed symptoms and their seriousness increase with the intensity of the hypothermia. Nevertheless, in each case the skin is cold and dry, sometimes thick with a waxy appearance, and the extremities are cyanotic.

Some obvious signs allow assessment of the intensity of hypothermia: shivering disappears below 32 °C and is replaced by muscular rigidity. At 30 °C the subject is unconscious and the stretch reflexes have disappeared. Between 28 °C and 30 °C ventricular fibrillation generally appears, which signals the beginning of death. Below 25 °C, the muscular rigidity disappears and the subject becomes limp. The assessment of the degree of hypothermia defined by the rectal temperature remains a subject of debate, as this temperature is only one of the local core temperatures. In fact, the temperatures of the vital organs (e.g., heart, brain) may not always be at this same level. Nevertheless, the rectal temperature remains the classic criterion to determine the degree of hypothermia.

2.3 Factors Affecting Cold Tolerance

Physical exercise, through metabolic heat production, is a beneficial factor favoring cold resistance (Bittel et al. 1988). In the same way, the calorie intake should be increased in relation to the intensity of the cold stress. On the other hand, contrary to popular belief and habits, alcohol intake under cold stress is contraindicated for preventative or therapeutic reasons. In fact, alcohol has an anesthetic effect on the thermoregulatory centers and is detrimental to the thermal balance. In addition, pain, which is an important alarm signal, is reduced or may even vanish under alcohol intoxication.

Finally, clothing insulation remains the main way for the human body to resist the cold. The insulation must be adapted to the intensity of the cold and to the physical activity of the subject. Some other physiological factors may favor resistance to cold: subcutaneous fat thickness (fat is three times more insulating than the skin) provides a real ‘physiological garment’, and the level of maximum oxygen uptake capacity (VO_2 max) corresponds to a heat quantity capacity related to the level of fitness.

2.4 General Cold Resistance Tests

The overall cold tolerance is measured during a whole-body cold exposure, which triggers the thermoregulatory responses. The peripheral vasoconstriction is sudden, thereby decreasing the skin temperatures and thus reducing the heat losses. Several minutes later, metabolic heat production is increased as a result of shivering (the time to onset of shivering = d). This time, and the intensity of shivering are both related to the intensity of cold stress and its duration. Nevertheless, the shivering heat production cannot exceed a maximum value corresponding to approximately five times the resting heat production, which means $5 \times 50 = 250 \text{ W}\cdot\text{m}^{-2}$. When the cold stress is relatively important the heat debt appears, revealing hypothermia. Cold tolerance tests can be carried out either in air or in water.

2.4.1 Cold Tests in Air

Cold tests in air are usually performed in laboratories capable of calculating the heat balance equation. A climatic chamber is used in which the ambient parameters are controlled and reproducible. There is no real standard cold test that has been widely adopted; however, the most widely used in France is that of the Centre de Recherches du Service de Santé des Armées (Army Health Research Center) thermophysiology department. It consists of exposing a naked subject, at rest in a supine position, for 2 h to a 1 °C ambient temperature, 30 % relative humidity and 0.8 m.s⁻¹ air velocity, an environment leading to maximum shivering intensity.

During this overall exposure to cold, all the ambient parameters are measured (air temperature, air humidity, wall temperatures, air velocity) as well as the physiological variables required to calculate the heat balance (the methods for these assessments have been described in ► [Chap. 120, "Thermophysiological Parameters in Man"](#)).

The core temperature usually considered is either the rectal or the esophageal temperature. It must be noted that the tympanic temperature and, even worse, the oral temperature are not reliable in the case of cold exposure. The local skin temperatures are measured at ten sites so as to calculate a

mean skin temperature. Assessment of the muscular activity (shivering) against the cold is obtained by three cutaneous electrodes placed on the anterior aspect of the thigh (quadriceps) and at the thoracic level (pectoral muscles). Metabolic heat production produced by shivering is measured by respiratory techniques: ventilation rate measurement (Fleisch flow meter or ultrasound) and the CO₂ and O₂ concentration in expired air. It is then possible to calculate the oxygen uptake and the metabolic heat production once the oxygen energy equivalent is known from the respiratory quotient (CO₂/O₂). Finally, the electrocardiogram is continuously recorded to ensure the safety of the investigation. The cold test performed in air, in a thoroughly controlled environment, makes it possible to calculate an accurate heat balance equation and to precisely determine the heat debt (in kJ). The latter can be expressed in terms of a core temperature decrease on the following basis: 3.48 kJ.kg⁻¹ correspond to a 1 °C drop in mean body temperature (i.e., a 244 kJ heat debt for a 70 kg man). On the other hand, this test never leads to a core temperature decrease below 35.5 °C, except in exceptional cases.

2.4.2 Cold Tests in Water

The resting naked subject is completely (except for the head) immersed in water, the temperature of which varies between 15 °C and 18 °C. This corresponds to a severe cold stress because water has a heat conductance 25 times that of the air. In these conditions, the heat debt occurs rapidly, and the threshold of 35.5 °C core temperature, signaling the suspension of immersion, is reached within a relatively brief time (between 15 and 45 min depending upon the subject's cold tolerance). The cold tolerance is then expressed as a duration corresponding to the time necessary to reach the 35.5 °C level. Repeated cold immersions are used to develop the overall cold adaptation phenomenon.

2.5 Local Tests for Cold Exposure

These tests are used to quantify the local tolerance of the extremities (mainly the hands). The most common one consists of hand exposure in stirred

water at 5 °C (Savoirey et al. 1992). In this situation, taking certain technical precautions, it is possible to measure the local skin temperature (sites in hands and fingers) and also the local cutaneous and subcutaneous skin blood flow (laser Doppler technique).

As soon as the hand is immersed, its temperature drops rapidly, to stabilize within a few minutes around the level of the water temperature (5 °C). At this level, for subjects who are not locally adapted the pain is intense and becomes unsupported after 5 min of immersion.

If immersion is sustained, paradoxical vasodilation, called cold-induced vasodilation (CIVD), occurs at the level of the immersed extremities (Lewis phenomenon, "hunting reaction"). This CIVD provokes an increase in the local skin temperature by a few degrees, leading to reduced pain intensity. CIVD lasts for a few minutes and is repeated at regular intervals more or less frequently depending upon the level of cold adaptation. Repeated immersions (once or twice a day) over a period of several weeks (1 month) leads to an efficient local adaptation and therefore a marked increase in cold tolerance. In this case, CIVD occurs sooner and is reproduced more frequently and more intensively. Therefore, local cold tolerance of the extremities can be characterized by a tolerance time (onset of unsupported pain), and adaptation will be characterized by a longer time (1 h or more) associated with an increased local skin temperature (Savoirey et al. 1996).

Thus, where the whole-body or local cold tolerance is concerned, skin behavior plays a major role in its level, not only through its insulation associated with vasoconstriction, but also through the pain generated under periods of intense cold.

1 Introduction

As an interface between the environment and the body core, the skin plays a vital role in protecting the body and maintaining a thermal equilibrium around 37 °C. Autonomic responses serve to maintain thermal balance by initiating several physiological responses. However behavioral thermoregulation reduces the need for autonomic thermoregulation as humans make a conscious decision to protect their thermal status. This is often based on emotional feelings associated

with their thermal state and comfort/discomfort (Li 2001). It usually involves taking off or putting on clothing, moving into shaded areas, or adjusting indoor temperatures. This suggests that our sensation of temperature change is directly linked to our primary behavioral response.

The mechanisms associated with behavioral thermoregulation involve the thermoreceptors, which upon stimulation relay information to the brain about the surrounding environment. They are distributed around the periphery (skin) and central locations, including major organs and along the spinal cord (Bullock et al. 2001). The location, density, and distribution of thermoreceptors in the skin play an important role in our perception of temperature. These receptors transiently increase or decrease their firing rates depending upon the direction and magnitude of the change in skin temperature, and this ultimately influences the thermal sensation experienced (Bullock et al. 2001). Differences in perceptions of heat and cold are related to several factors including the reported larger numbers of cold-activated sensors than warm-activated sensors and a faster firing rate of the receptors upon cold stimulation compared to warm stimulation (Hensel 1981). The variation of thermoreceptors distribution across the body surface and the unequal number of warm and cold receptors helps explain why regional differences in thermal sensation exist.

2 Methodological Considerations

Different methodologies have been employed to investigate regional thermal sensitivity, and this can produce confounding results if the techniques used are not fully understood. The two main methods to assess thermal sensitivity are measurements of (1) thermal thresholds, which are the upper and lower limits for detection of cold or warm thermal sensations, and (2) thermal intensity rating (magnitude estimation) which is the estimation of the level of cold or warmth in response to a given stimulus. These methods produce different findings as one location may be sensitive enough to detect small temperature

changes, but the degree of sensation it experiences for a given stimulus temperature may be lower than other locations. Both techniques can determine the sensitivity across regions, but the type of sensitivity is different and it is therefore important for researchers to define and differentiate between the methods used.

2.1 Thermal Thresholds

Three different types of thermal thresholds exist, namely, the absolute threshold, difference threshold, and terminal threshold.

Measuring the absolute threshold, also referred to as threshold detection, involves applying a stimulus, and participants respond to the stimulus once they sense a temperature change. It is the highest stimulus temperature capable of producing a cool sensation (cool threshold) or the lowest stimulus temperature capable of producing a warm sensation (warm threshold). Absolute thermal thresholds are measured with the method of limits, which consists of exposing a participant to a stimulus of changing intensity, starting from a neutral temperature. It is crucial that the stimulus temperature changes with a *low* and *constant* rate of change, as the measurement would be otherwise inaccurate due to the important influence of rate of change in temperature on thermoreceptors' activity. The participant is asked to indicate the first onset of a cool or warm sensation.

Difference threshold is the extent of change in a stimulus necessary to produce a noticeable difference. It is measured in the same way as the absolute threshold described above, but is presented as a change in temperature from neutrality needed to provoke a cool or warm thermal sensation (Lee et al. 2010).

Terminal threshold is the magnitude of a stimulus above which there is no further increase in the perceived intensity of the appropriate nature of that stimulus. For example, if thermal sensation values increase with an increasing stimulator temperature up to 40 °C, but do not increase any further with a further rise in temperature, then the terminal threshold is 40 °C. Above the terminal thermal threshold level, pain usually occurs.

In all thresholds discussed above, skin thermal sensitivity is related to a specific temperature; the lower the temperature for warmth and the higher the temperature threshold for cold, the more sensitive the area is. The values reported can be compared between body sites to a given temperature or one specific body site compared to a variety of different temperatures. One limitation of the method of limits is that a reaction time artifact exists, which can increase the value of the absolute threshold considerably (Yarnitsky and Ochoa 1990). The reaction time artifact is larger for warming than cooling, since the primary afferents are slower conducting, and is most extreme for more distal body sites. It can however be diminished by using a slow rate of temperature change (Yarnitsky and Ochoa 1990). Furthermore, another disadvantage of this method is that the subject may become accustomed to reporting that they perceive a stimulus and may continue reporting the same way even beyond the threshold (error of habituation). Conversely, the subject may also anticipate that the stimulus is about to become detectable or undetectable and may make a premature judgment (error of expectation) (Meilgaard et al. 2007). Hence the order of presenting stimuli should avoid any anticipatory knowledge.

2.2 Intensity Rating

The degree of the sensation experienced in response to a fixed stimulus is known as magnitude estimation or intensity rating. An area of the skin is stimulated with a thermal stimulus at a fixed temperature, and participants rate the degree of sensation experienced on a predetermined perceptual scale (see below for more information). The intensity rating is driven by the difference between skin temperature and stimulus temperature. As the skin temperature will change upon contact with the stimulator, the temperature difference between skin and stimulus will reduce over time. Apart from a strong response at the start of any stimulus (Hensel 1981), this initially stronger stimulus leads to a stronger “transient response” at the start and then a more stable

“steady-state” response (typically after 10–20 s; Ouzzahra et al. 2012).

Transient responses must take into account initial skin temperature and the initial sensations reported expressed relative to that value. As skin temperature naturally varies across the body, one option to accommodate for this is to adjust the stimulus in order to create the same stimulus magnitude relative to the local skin temperature before the stimulus. This is done by measuring the local skin temperature before application of the stimulus and then setting the stimulus to a fixed temperature change in relation to the actual local skin temperature. Alternatively, a transient response (TS) could be divided by the difference between pre-stimulus skin temperature (T_{sk}) and stimulus temperature, often expressed as $TS/\Delta T_{sk}$. Both approaches will allow for comparison across multiple sites where T_{sk} is known to vary across the body in a variety of conditions (Choi et al. 1997; Fournet et al. 2013). When the stimulus is held for long enough to cause skin temperature to approach or reach stimulus temperature, this is referred to as a steady-state response (Ouzzahra et al. 2012). As a result this removes the effect of the initial T_{sk} and absolute values in thermal sensation should be reported and compared across regions. The choice for any of these approaches should be guided by the application of the research. This may be related to a fixed stimulus value (e.g., effects of a *constant* room or water temperature) or relative (e.g., effects of a *changing* room or water temperature). Finally, T_{sk} in some locations may not reach the stimulus temperature, depending on the interplay of insulative fat layers and local blood flow. For example, Nakamura et al. (2008) found that applying the same cold stimulus at different areas of the skin resulted in different levels of ΔT_{sk} and suggested that these regional differences in heat loss are likely caused by differences in skin blood flow due to vasomotor status and tissue vascularity. In that case, if one wants to calculate sensitivity in terms of $TS/\Delta T_{sk}$, one needs to track T_{sk} during the stimulus. This can be done using a very thin thermocouple which will determine “contact temperature” (Jay and Havenith 2003, 2004, 2006) or by measuring local T_{sk} immediately before and

after application of the stimulus (e.g., by an infrared thermometer; Ouzzahra et al. 2012; Gerrett et al. 2014).

In both cases, on a scale ranging from 0 to 10 or neutral to extremely hot/cold, a more intense absolute or relative local thermal sensation represents a more sensitive body site, and values can be compared between sites for intensity scores or individual sites compared to a variety of different temperature.

2.3 Perceptual Scales

The scales used in the literature vary but most often are unipolar or bipolar Likert scales ranging from 0 or “neutral” to extreme cases such as “extremely hot” or “extremely cold.” The most frequently reported are modified versions of the ASHRAE thermal sensation scale (ASHRAE 1997). The original scale ranged from 1 (cold) to 7 (hot) with 4 designated as “comfortable.” It has been modified by numerous researchers and typically ranges from -10 (extremely cold) to $+10$ (extremely hot) with a “neutral” zero (Gerrett 2012). The purpose of this was to allow assessment in extreme environments, and it can also be argued that this prevents a “ceiling effect” when rating thermal sensations. Scales have also been altered slightly and numbers have been inserted between each category vote to increase the sensitivity of the scale. More recently, visual analogue scales (VAS) are being used which involves presenting the participant a straight line (no numbers) with labels at either end. Participants are asked to rate a construct (sensation, comfort, regional sensations, etc.) by marking a point along the line which reflects their current status (Leon et al. 2008). They are reported to have a greater accuracy for detecting humans’ perceptions as the participant is not forced to make ratings according to numbers or restricted to verbal categories which may not reflect their true current status (Leon et al. 2008). Davey et al. (2007) compared VAS with ASHRAE Likert scale in stable and dynamic thermal environments, and their evidence supports the notion

that VAS has greater reproducibility and reflects body temperature more so than Likert scales. Research has also combined elements of a Likert scale with a VAS (see Fig. 2) to assess thermal sensations in response to a thermal stimulus (Ouzzahra et al. 2012; Gerrett et al. 2014).

2.4 Stimulation

Specific details about the stimulus used are extremely important and can influence reported thermal sensitivity. Of primary importance is the temperature of the stimulus as both direction and magnitude will influence thermal sensitivity when using intensity rating/magnitude estimation. A greater gap between the stimulus temperature and that of the stimulated skin will result in more intense thermal sensations. When deciding upon the stimulus temperature, consideration needs to be given to the range of temperatures stimulated by different thermoreceptors. Recent knowledge suggests that the principal temperature sensors in the nerve endings belong to the transient receptor potential (TRP) family which are activated by distinct temperatures (Schepers and Ringkamp 2008; Ständer and Luger 2009). Table 1 highlights the TRP family, the temperature range of stimulation, and the sensation they evoke once stimulated.

When using threshold detection techniques, the rate of change in stimulus temperature will have a strong influence upon thermal sensitivity. A fast temperature change causes the firing rate of the receptors to overshoot, sending strong signals to the brain. This has been shown to cause strong thermal sensations in comparison to slow continual changes in temperature (Hensel 1981). In addition, when the skin is exposed to changing temperatures, the thermal threshold is influenced by the initial temperature and the rate of change of temperature (Hensel 1950). The surface area exposed to the thermal stimulus will also impact thermal sensitivity. For example, when submerging a whole hand into a flask of warm water and a fingertip in another (of the same temperature), the water would feel warmer when it surrounds the

Table 1 Description of the transient receptor potential (TRP) family, the temperature range of stimulation, and the sensation they evoke once stimulated (Ständer and Luger 2009)^a indicates myelinated fiber

Receptor	Stimulated by . . .	Sensation evoked
TRPV1	Noxious heat (>42 °C), protons, capsaicin, anandamide,	Cold, heat, burning pain
TRPV2	Noxious heat (>52 °C)	Pain induced by heat
TRPV3	Warmth (>33 °C)	Warmth
TRPV4	Warmth (~25 °C)	Warmth
TRMP8 (on Aδ fiber) ^a ;	Cold (8–28 °C and menthol)	Cold
TRPA1	Noxious cold (<17 °C), wasabi, horseradish	Pain induced by cold burning

whole hand in comparison to the fingertip (Ross and Murray 1996). Stevens et al. (1974) found the larger the area for a given stimulation, the greater the magnitude estimation. This condition refers to the spatial summation, in that the sensation is relative to the surface area stimulated and therefore to the number of thermoreceptors activated.

In the literature the thermal stimulus has been applied using contact or non-contact methods, such as thermal radiant lamps (Nadel et al. 1973), water-perfused suits (Cotter and Taylor 2005), thermal probes (Gerrett et al. 2014; Ouzzahra et al. 2012), or specialized clothing garments where the microclimate temperature is changed (Zhang et al. 2004). Non-contact methods are more difficult to implement, especially in regional sensitivity studies due to the difficulty in isolating specific areas on the body. However, they do ensure that only the thermoreceptors are stimulated. Contact methods such as thermal probe application or water-perfused suits are more common and easily implemented. However, the possibility of a “dual” neural stimulus between mechanoreceptors and thermoreceptors of any region cannot be excluded, particularly in areas sensitive to touch.

2.5 An Example Method

Regional differences in thermal sensitivity should provide specific instructions about assessing the exact locations for both dependent and independent samples. Recent research by Gerrett et al. (2014) measured 31 locations across the body and Fig. 1 provides an overview of potential measurement areas. Washable pen markings may

be used on the body to indicate each measurement site for the application of the thermal probe. The testing sequence of the segments should be randomized or in small groups balanced using a Latin square type approach, to prevent any order effects.

Participants should be allowed to rest in the testing area to allow skin temperature and physiological responses to stabilize. During the rest period, participants should be familiarized with the sensation scales and allowed to practice rating their sensations to a range of stimuli strengths across different regions on the body to reduce response variability. After the rest period, the thermal sensitivity of each area to the desired stimulus should be determined. Each test area should be subjected to the following: the measurement of T_{sk} using an infrared thermometers or skin thermistors followed by probe application for the desired duration. The probe should be applied to the skin by the same investigator to ensure consistent pressure applied to each location and individual. Alternatively, a pressure gauge may be applied to the probe to ensure equal pressure during testing (see Filingeri et al. 2014). Participants should rate their thermal sensation on a predetermined perception scale (see Fig. 2 as an example) at designated times.

A thermal stimulator typically consists of a temperature controller and temperature stimulator. Some researchers have used patches of water-perfused tubes as stimulus (Nakamura et al. 2008) or water-perfused suits with local control (Ouzzahra 2012). Most recent studies have used an electrical stimulator (Fig. 2) (Fowler et al. 1987; Gerrett et al. 2014; Ouzzahra et al. 2012). The stimulator has a Peltier element which cools down or warms up the stimulator,

Fig. 1 Distribution of sample locations across the body in Gerrett et al. (2014) and Ouzzahra (2012)

depending on the direction of the current. The stimulator shown in Fig. 3, also referred to as thermal probe, is a metal block that comes in various sizes which can be set at temperatures ranging from 5 to 50 °C. Its cooling or warming depends upon the applied current direction, which can be changed by the controls situated on the temperature controller. The probe also encloses a temperature sensor for close control of the stimulus temperature, which is directly connected to the digital readout of the temperature controller.

To avoid an effect of surprise on transient responses, a verbal warning of the location of each out-of-sight body area prior to stimulation (e.g., “lateral lower back”) should be given. Distractions should be minimized throughout any thermal sensitivity test. Any sweat produced during testing should be wiped away before the probe application to avoid the skin surface conductivity being affected.

3 Results: Body Mapping

Regional sensitivity data has been reported in tables or graphs (Cotter 1997; Nakamura et al. 2008), but this can be quite cumbersome to interpret, especially with a large number of regional comparisons. Gerrett et al. (2014) and Ouzzahra et al. (2012) generated body maps (similar to the body mapping of sweating by Smith & Havenith 2012) to display regional differences in thermal sensitivity to warmth (40 °C) and cold (20 °C). In order to generate the body maps, Ouzzahra et al. (2012) and Gerrett et al. (2014) used similar procedures detailed below.

After measuring skin temperature using infrared thermometer, a fixed temperature probe (Fig. 3) was placed directly onto the skin and participants were instructed to rate thermal sensation immediately after contact (*transient thermal sensation*), and/or 10 s after contact (*steady-state*

thermal sensation). The thermal sensation scale for innocuous cold or warmth stimuli shown in Fig. 2 was used. This procedure was repeated for numerous locations across the body at rest and during an exercise bout consisting of cycling at

30 % $\dot{V}\text{-O}_2\text{ max}$. Results are presented as body maps assuming symmetry (e.g., Claus et al. 1987; Meh and Denišlić 1994) and are presented utilizing color codes to highlight the differences in thermal sensitivity (see Figs. 4, 5, 6, 7, and 8). A greater number has a darker color and represents a skin region which is more sensitive to warmth in terms of response magnitude.

3.1 Gender

Gender differences in thermal sensitivity to cold (20 °C) and warmth (40 °C) exist, not only in terms of the overall sensitivity but also in terms of its regional distribution. Females had significantly stronger thermal sensations (i.e., more sensitive) than males to both a warm (40 °C) and cold stimulus (20 °C) at all locations. This finding adds to the current body of literature surrounding the general concept of perception to a variety of stimuli between genders. Previous research has found females to be significantly more sensitive than males to cold and warmth using the method of limits (Golja et al. 2003; Lautenbacher and Strian

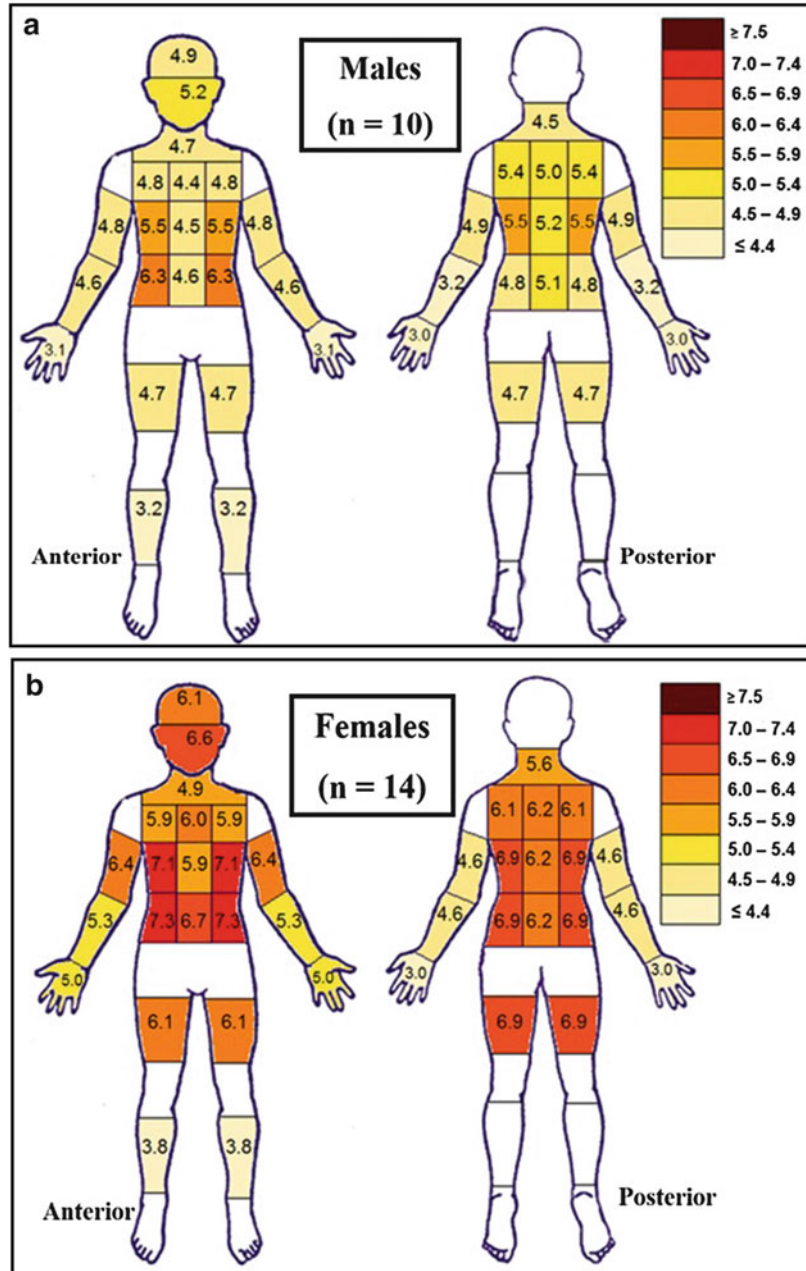

Fig. 3 Thermal sensitivity tester (left) and its application onto the skin (right)

Fig. 4 Regional steady-state thermal sensations in response to a cold stimulus (20 °C) in males (a) and females (b) at rest (Ouzzahra et al. 2012)

1991; Kenshalo 1986), and this study confirms such gender differences using an intensity rating method. The greater thermal sensitivity to cold and warmth found in females may be attributed to several physiological and morphological differences between genders. Differences in the density of thermoreceptors are likely to play a major role in thermal sensitivity differences between

genders. Using 3 mm punch biopsies, Gøransson et al. (2004) found that the density of epidermal nerve fibers at the leg is significantly greater in women compared with men. It is widely accepted that thermoreceptors distribution varies across the body (e.g., Strughold and Porz 1931), and it is possible that this regional distribution varies between genders, although no study has

Fig. 5 Male regional steady-state thermal response to a warm stimulus (40 °C) during rest and exercise. All areas were significantly lower than females ($p < 0.05$). Areas shaded in black were not investigated

systematically investigated thermoreceptors distribution across the body in males and females.

Morphological factors such as hair density may also explain some of the differences found. Ouzzahra et al. (2012) showed some of the largest differences at the abdomen, posterior lower arm, and anterior thigh between males and females to a cold stimulus. Although females were not analyzed for hair density, these sites coincide with body areas which are naturally more hairy in men than women. Men’s hair may have therefore acted as an insulator for the skin, introducing thermal resistance between the stimulus (thermal probe)

and the skin. This would not be the case in the female participants who do not tend to have abdominal hair and usually shave their legs. Hair distribution and shaving have been previously mentioned as potential factors playing a role in the gender differences in thermal and pain sensitivity (Caissie et al. 2007). Moreover, skin thickness may also be a factor involved in the greater sensitivity in the female group (Golja et al. 2003). Indeed, it has been shown that females’ skin is thinner than that of males (Sandby-Moller et al. 2003), and it is therefore possible that males’ thicker skin act as a barrier between the

Fig. 6 Female regional steady-state thermal response to a warm stimulus (40 °C) during rest and exercise. All areas were significantly higher than males ($p < 0.05$). Areas shaded in black were not investigated

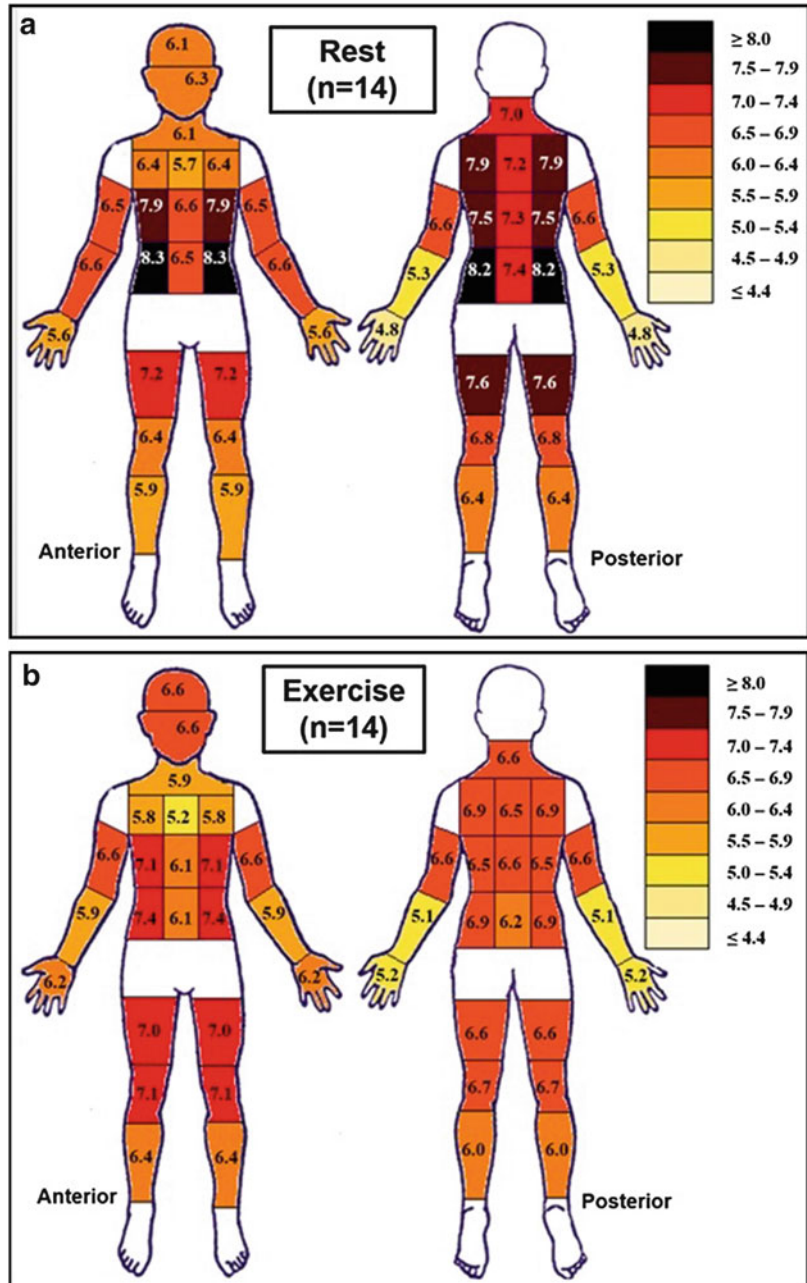

thermal stimulus and the thermoreceptors, thereby reducing the intensity with which these are effectively stimulated. Finally, the differences in thermal sensitivity to cold and warmth between males and females could perhaps be explained on the basis of previous observations in another cutaneous sensory system such as pain. In addition it has been suggested that the menstrual phase may have unique interacting effects on pain thresholds (Giamberardino et al. 1997). All things

considered, it is likely that the complex interaction of these factors resulted in the differences between males and female across the body found in the present and previous studies.

3.2 Regional Distribution

The results from both Ouzzahra et al. (2012) and Gerrett et al. (2014) showed that regional

Fig. 7 Regional steady-state thermal sensations in response to a cold stimulus (15 °C) during rest (a) and exercise (b) in male participants (Ouzzahra et al. 2011)

variations in thermal sensation exist for both genders, but are more prominent for females. In agreement with the literature, the pattern over the body indicated a higher sensitivity at the head and the torso and the lowest at the extremities. This regional variation in thermal sensation may be due to several physiological

variables. The two most commonly reported parameters are the uneven distribution of cutaneous thermoreceptors and the existence of a weighing of thermoafferent information by the integration center in the central nervous system (Burke and Mekjavić 1991). The rate of change in skin temperature (ΔT_{sk} rate) may also explain

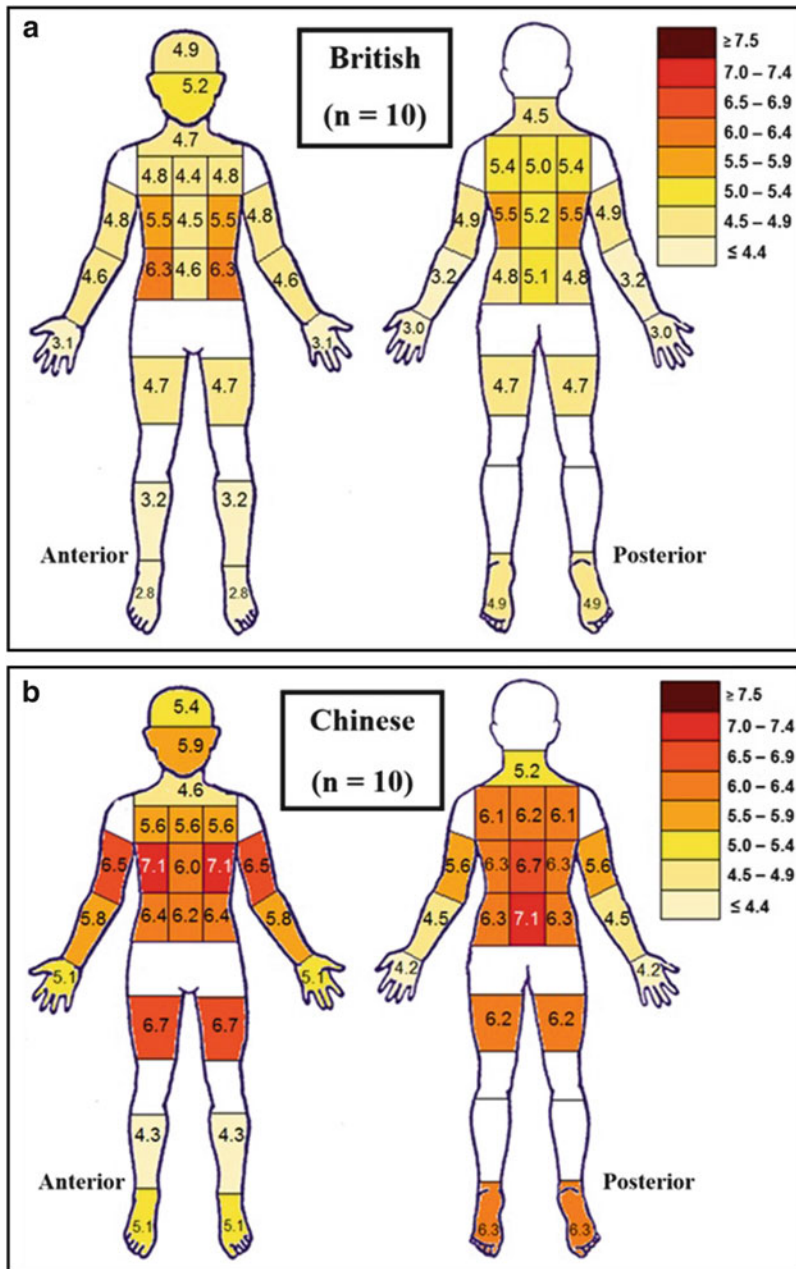

Fig. 8 (continued)

the differences in thermal sensitivity between body sites. Indeed, it is well established that different areas of the body lose their heat content more readily than others due to regional differences in skin blood flow (Nakamura et al. 2008).

Another similarity in these studies was that the lateral areas of the torso were more sensitive than the medial areas. As stated earlier, the thermal probe makes contact with the skin, and in doing so, it stimulates both thermoreceptors and mechanoceptors simultaneously. The possibility of a

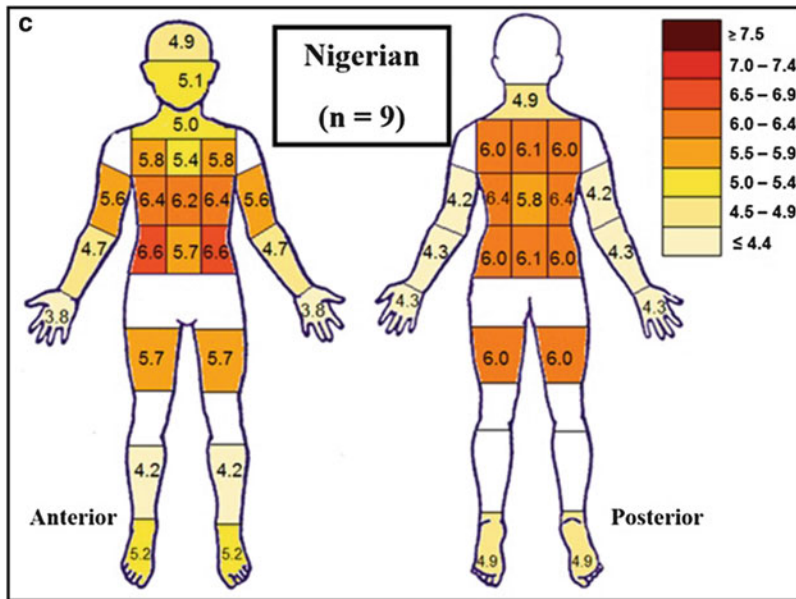

Fig. 8 Regional steady-state thermal sensations in response to a cold stimulus (20 °C) in males from three different ethnic groups: (a) British, (b) Chinese, (c) Nigerian (Ouzzahra et al. 2012)

“dual” neural stimulus between mechanoreceptors and thermoreceptors of any region cannot be excluded, particularly in areas such as the lateral torso which may be more sensitive to touch.

3.3 Rest and Exercise

In another study, Ouzzahra et al. (2011) investigated the effects of exercise on thermal sensitivity to cold (15 °C) on 28 sites across the upper and lower body (see Fig. 7). Participants were more sensitive to cold stimuli at rest than during exercise, and this was significant in 11 of the skin sites tested. One logical explanation for this is the increase in T_{sk} with exercise, resulting in thermoreceptors being stimulated with a greater ΔT_{sk} , which will increase the impulse frequency and in turn influence thermal sensation. The present data confirmed that T_{sk} may in part explain the decrease in sensitivity to cold, as suggested by a significant increase in mean T_{sk} . Similarly, Gerrett et al. (2014) found that exercise caused a reduction in thermal warmth sensation to a hot thermal stimulus in males but only at select locations for females (Figs. 5 and 6). Interestingly, the

distribution of sensitivity to cold was more homogenous during exercise, but this was not observed in response to a warm stimulus.

Exercise itself has been reported to cause a reduction in perception to a variety of stimuli, particularly tactile and pain sensitivity due to exercise-induced analgesia (EIAs) (Guieu et al. 1992; Kempainen et al. 1985, 1986; Pertovaara et al. 1984; Paalasmaa et al. 1991). EIA is thought to be due to a reduction in the transmission of sensory information to the thalamus and somatosensory cortex associated with one of the following: movement, increased activity in proprioceptive and muscles afferents, increase in arousal, and reduction in attention (Koltyn 2000). As the thermal state of the body did not change from rest to exercise in the presented study of Gerrett et al. (2014), changes in thermal sensitivity may be a result of EIA.

3.4 Ethnicity

Lastly, Ouzzahra (2012) also investigated differences in thermal sensitivity to cold between groups of individuals from different ethnic

backgrounds. A total of 29 participants all living in the UK were recruited: 10 Caucasians from Great Britain, 10 Asians from China, and 9 Africans from Nigeria. Thermal sensitivity to cold was tested at 27 body sites with a 20 °C thermal probe, and participants reported their local transient and steady-state cold sensations. Photos of the participants' front torso, arms, back, and legs were then taken, and local hairiness density was rated at nine sites using a five-point scale (Garn 1951). Body maps of cold sensations were created and are presented in Fig. 8 (steady state).

Results revealed that areas of high thermal sensitivity to cold included the lateral abdomen in all groups, the medial lower back in the Chinese group, and the medial upper abdomen in the Nigerian group. A total of 13 significant differences and trends ($0.05 \leq p \leq 0.1$) were found between ethnicities before Bonferroni corrections for the steady-state thermal sensations (see Ouzzahra (2012) for specific details). Most of these were between the British and the Chinese groups, with a greater (colder) thermal sensation found in the Chinese group. The Nigerian group was also more sensitive to cold than the British group at the central upper abdomen ($p = 0.052$) and the dorsal foot ($p = 0.017$).

The idea that thermal sensitivity may vary between humans of different geographical origins has been suggested before. For example, the extinct Fuegian tribes of South America were known to tolerate freezing conditions with minimal thermal protection. It is widely believed that selective forces within these populations favored extraordinary cold tolerance (Hernandez et al. 1997). Another example is the prehistoric Polynesians who, similarly to the Fuegians, lived in a cool and wet marine environment. Visser and Dias (1999) examined skulls of two prehistoric Polynesian groups from New Zealand, the Moriori and Maori, and of one contemporary Indian group. They analyzed the sensory nerve dimensions, based on the area of cranial nerve foramina. These features are of interest, because the cross-sectional area of a nerve is directly proportional to the number of axons and hence the number sensory receptors represented. Comparisons showed significantly

lower cranial cutaneous sensory nerve foramina size in the prehistoric Polynesian groups, compared with the contemporary Indian group. This was interpreted as a lower facial cutaneous sensory nerve supply in the Polynesians. The authors proposed that reduced skin sensory nerve supply may have been selected as an adaptation to a cool and wet environment.

Besides these potential neurological differences, research has also explored several physiological characteristics which differ between ethnic groups and may result from environmental factors. These include adaptations in body mass, body shape and surface area, cranial morphology, skin color, body composition, metabolic rate, and peripheral vasoconstriction (see Lambert et al. 2008 for a complete review). One factor which may explain the thermal sensation differences found between ethnicities in the present study is the density of body hair. Despite the small sample used, the present results confirm the widespread notion that European individuals have a greater body hair density than their Asian and African counterparts. More importantly, the significantly higher body hair density found in the British group corresponds well with their lower thermal sensitivity, compared to the Chinese group. In humans, hair mainly has an insulation role and therefore serves to protect from the cold (Johnson et al. 1993). It seems reasonable to suggest that, in the present experiment, hair may have acted as an insulator for the skin, introducing thermal resistance between the stimulus (thermal probe) and the skin. This was in agreement with the significant correlation found in the cold sensation versus body hair density analysis, indicating that body regions with lower levels of local hairiness were associated with greater (colder) local thermal sensations. According to Hooton (1946), the loss of body hair in man must have taken place in a tropical climate, since such an adaptation is unlikely to take place in a cold environment. Other theories suggest that the loss of hairy covering in man is associated with an increase in subcutaneous fat layers. According to Keith (1912), humanization, which resulted in a richer variety and a more ample command of food all year round,

may be one of the reasons for the loss in human body hair. Indeed, such an improvement in pre- and postnatal nutrition may have brought about the increase in fat deposition, which in turn may have rendered body hair less needed, since a subcutaneous fat layer similarly preserves the warmth of the body (Hooton 1946). Prior to modernization, individuals indigenous to cold climates were typically relatively muscular, and the regional distribution of muscle and fat characteristics of these people is thought to maximize insulation (Beall and Steegmann 2000). As pointed out by Hooton (1946), it is also perfectly possible that some human groups may have retained, or even redeveloped, body hair at a late period of human evolution.

4 Conclusion

In order to test regional thermal sensitivity, the first step is to define sensitivity and determine whether a magnitude estimation or thermal threshold approach is most appropriate, and in the first case, whether to work with a fixed stimulus temperature or with a stimulus temperature relative to local skin temperature. Following this the desired temperature to stimulate designated TRP receptors must be determined. The duration of stimulation and the surface area will influence thermal sensitivity, but these should be standardized across regions. Transient responses can be expressed relative to the change in skin temperature. Steady-state responses should not be taken before skin temperature stabilizes and/or the response is stable. The correct timing for this should be determined during pilot studies. Strict care should be taken over assessing regional differences and ensuring precision over testing the same location within and between individuals. When presenting the data from multiple locations, body maps prove to portray this information most clearly.

Skin temperature • Thermal imaging • Raynaud's phenomenon • Fever detection

1 Principle

The human body is endothermic. Human skin functions as an interface between the body core stable temperature (around 37 °C) and the variable environment temperature. Except in extreme cases such as strong sun-heat exposure, the skin surface is cooler than the blood. Therefore it should be possible to measure the variation of the skin blood perfusion by those of the skin surface temperature.

In normal conditions the latter depends on the outside temperature, the heat coming from the blood (variable with its location in the skin and transfer ability), and the heat generated by the skin (mostly the epidermis and appendages) metabolic activity. When inflammation or a high metabolic rate tumor develops within the skin or close deeper tissue, a heat conductive transfer is added. Practically the production of metabolic heat by healthy skin ($0.16 \text{ cal min}^{-1} \text{ cm}^{-2}$) (Houdas and Ring 1982) or even psoriatic skin ($0.27 \text{ cal min}^{-1} \text{ cm}^{-2}$) is too low to interfere.

1.1 Contact Measurements: Thermometry

When a thermometer is applied on the skin, its temperature and the skin temperature are both modified at the point of contact (Stüttgen et al. 1989; Ring 1995). For the temperature at equilibrium to be very near the initial skin temperature, it is essential to comply with the following items: small contact area, low thermal sensor inertia, and moderate initial difference between temperatures. Furthermore, the skin heat being in continuous production induces its accumulation as soon as there is an occlusion of the skin surface. Contact skin temperature measurements must therefore be brief as possible.

1.2 Point Measurement

Thermometers use a variety of physical principles: thermocouples, electric resistance, thermistors, and semiconductors.

Thermocouples are an application of the thermal-electric effect. In a circuit made of two different metals (e.g., copper-constantan), a voltage is produced if the junctions are at different temperatures. This type of thermometer consists in a small applicator located at one of the junctions, the other being maintained at a stable temperature (reference temperature). A galvanometer records the generated voltage. The result is immediately displayed.

Metal resistance thermometers have an electric circuit consisting of a generator and a resistance (in nickel or platinum) which varies with temperature. The resistance is in the applicator which consequently has a large application area. However it is possible to find Pt sensors with a small contact area (less than 1 mm²). The results are also displayed instantaneously.

Thermistors are also resistance thermometers, but provided with complex linearization electronics. Unfortunately they do not age well and it is necessary to recalibrate them regularly. Disposable probes are now available thus eliminating the need of cleansing and disinfection.

Semiconductors are based on a similar principle: the resistivity of the sensor varies with temperature. They are more durable and stable than thermistors and do not require frequent recalibration.

During application of contact thermometers, pressure must be avoided: this alters the blood flow, and the recorded temperature can be more like the interior of the skin, while the purpose of the measurement is to record the skin surface temperature.

For a point measurement, application should be made for 1 or 2 s only to prevent a disturbance of the temperature from occlusion or pressure. Metallic resistance and thermistor thermometers can have a preheated sensor, which may slightly modify the skin temperature. As a consequence they are preferably used for temperature monitoring over time, such as in intensive care.

The skin temperature in resting and neutral thermal conditions (i.e., the subject is naked, in resting position; in a room where the air and the walls are at the same temperature, close to 30 °C, the relative humidity is below 50 %, and the movement of the air is low (0.1 m to 0.2 m/s)) varies with body sites (Table 1), because each of them has its own vasculature pattern due to its anatomy and reactivity and has a specific thermal environment. Such diversity explains why the assessment of mean or average skin temperature requires measurements in numerous places. Modern infrared cameras can now image a whole body anterior and posterior from which total body mean temperatures can be readily calculated. Table 1 shows firstly the forehead as a relatively stable temperature and the large variability of the temperature in the extremities and then the homogenization of the temperatures in hot conditions and, in the opposite situation, great topographical diversity in cold conditions.

Skin temperature has a considerable inertia when compared to the variations in the arterial supply it depends on. For example, for a blood flow increase over 4 min followed by a plateau, the skin temperature rise may be seen only 6 min later and may plateau in 7 min.

Table 1 Current temperature on various body sites in an adult subject naked and lying supine in various environmental temperatures (Houdas and Ring 1982)

Body site	Cool (20 °C)	Thermal neutrality	Warm (40 °C)
Forehead	32.0	34.8	36.1
Palm	24.0	32.9	36.6
Volar forearm	27.7	33.6	36.7
Arm, anterior aspect	28.0	33.4	37.3
Chest, anterior	31.9	34.5	36.8
Close to umbilicus	31.3	34.4	36.2
Iliac fossa	30.7	34.7	36.1
Thigh anterior aspect	27.9	33.4	36.3
Leg, anterior aspect	25.8	32.7	36.4
Dorsum foot	20.0	31.1	37.0

1.3 Bidimensional Measurements (Mapping)

1.3.1 Noncontact Measurement: Thermography

Any warm surface emits an electromagnetic radiation whose energy is a function of the fourth power of its absolute temperature, according to the equation $E = \sigma \epsilon T^4$ where σ is the Stefan-Boltzmann radiation constant and ϵ the surface emissivity. Between 32 °C and 36 °C (305–309 K), the skin surface emission is mainly at 10.5 μm , in the infrared (IR). It is therefore possible to measure, at a distance, the skin surface temperature by its IR radiation. Since water absorbs IR, the detected radiation is emitted by the stratum corneum, not by the underlying living tissues which are in a water environment. Like contact thermometry, thermography measures the skin superficial temperature. It provides the absolute temperature, but is mainly used to reveal topographical differences and follow variations on a quantitative image. Mapping of temperature distribution, absence of contact, and possibility of sustained observation provide many advantages over the contact methods. In recent years there has been a dramatic rise in the use of tympanic membrane radiometry, which has in many hospitals and clinics become more commonly used than contact thermometers for routine temperature assessment.

1.3.2 Thermal Imaging Cameras

IR cameras are of different types, depending on the IR detector, the image capture mode, and its processing (Ring et al. 2009). Cameras with cooled indium antimonide (AGA system) mainly detect 2–5.5 μm IR, which are wavelengths outside the absorbing zones of water. Mercury cadmium telluride IR cameras mainly detect 7–12.5 μm IR.

There are now a number of infrared cameras that use a focal plane array detector that can operate over a broader spectral band. Most of these do not need the cooling required for earlier detectors. There are continuous improvements and increasing numbers of detector elements. As a result modern systems are much easier to use in medicine. Excellent images can be obtained from 640×480 focal plane arrays. Compared to the earlier single-element scanners, they provide high resolution at high speed (real time). These improvements, together with a range of IR-transmitting lenses, also result in smaller compact cameras. In most cases now, a digital output signal can be directly fed to a small computer (earlier systems required the signal to pass through an analogue to digital converter, which increased the risk of calibration drift). With decreasing costs and improved reliability, thermal imaging is more available to clinicians who wish to use the technique. It is still recommended that the user purchases a blackbody temperature

reference source, which is needed to make regular checks on calibration of temperature, especially with the uncooled cameras. The thermographic signal is normally examined by computer image analysis.

1.3.3 Thermographic Image

The ranges of grays or colors indicate the difference of temperature (maximal thermal resolution 0.2 °C) in relation to a reference temperature selected by the operator. The larger the thermal resolution, the smaller the displayed temperature range. To obtain a good topographic discrimination, it is therefore necessary to choose the appropriate range, based on a reference temperature close to the average temperature of the zone investigated.

Finding both the temperature difference among body sites and especially hot or cold areas is easier in cool environmental conditions (Table 1), hence the choice of 22–23 °C as a usual examination room temperature.

For a selected ambient temperature, the skin temperature distribution is remarkably constant in the same individual. The fingertips are normally colder than the dorsal hands except in reactive hyperemia (Fig. 1a), but if the difference is over 2 °C, it indicates a vascular disease of the extremities (Fig. 1b). The warmest area is the head and the coldest the toes, and the difference is 4 °C in neutral thermal conditions, exceeding 10 °C in cold environmental conditions.

Reactive hyperemia, systemic or local cold test, heat test, and various pharmacological tests can be followed by thermography in real time with image registration at regular intervals or at some important times. For example, to measure the degree of a Raynaud syndrome and follow up the treatment, the generally used procedure is (Ring 1995):

- The patient remains seated in the examination room for 15 min, in neutral thermal conditions (in a room where the air and the walls are at the same temperature, close to 30 °C, the relative humidity is below 50 %, and the movement of the air is low (0.1 m to 0.2 m/s); in practice, the subject is neither cold nor too hot and does not feel any hot or cold air flow) with his forearms undressed.
- Thermogram of the dorsal side of both hands.
- The hands, in thin and transparent plastic gloves, are immersed up to the wrists in a 20 °C water bath for 1 min.
- Thermogram 10 min after removing the hands from the bath.

1.3.4 Interpretation

The thermograph image indicates an excessive or deficient heat supply to the skin surface. It may be due to a variation (increase or decrease) of the skin perfusion by the warm blood coming from the deeper parts or of a thermal transmission from underlying tissues.

Fig. 1 (a) Reactive hyperemia in normal hands post-cooling by 1 min 20 °C water (hand protected by thin plastic gloves). (b) Thermogram of hands of a Raynaud's phenomenon patient after same water immersion as above

The first case applies to active (i.e., arteriolar) vasodilatation: opening of the “skin radiator” valve. A passive vasodilatation, for example, by increase of the venous pressure only (standing up from lying), remains invisible. The “skin radiator” is the subepidermal vascular plexus; therefore, any active erythema has a thermographic version. But the skin can be normally perfused and warm without erythema, and thermography can then show the topography of this invisible active vasodilatation. In inflammation, thermography is a means of assessing the extent of the process and its intensity (by the degree of thermal increase).

In the second case, a deeper source of heat, without involvement of the subepidermal plexus, is shown by thermography. The skin is warmer along the subcutaneous normal veins and varicose veins. The warm thermographic image of actively growing tumors depends on their intense angiogenesis, which usually connected with their proliferating activity.

Thermography detects the transmission to the skin surface of heat produced in deeper tissues. Any disruption in this transfer, such as edema or thickened tissues, impairs the image. A typical example is the papular urticaria. Accordingly a hyperthermia in an edematous zone would be most likely related to active vasodilatation of the subepidermal plexus.

These principles have resulted in some of the most interesting uses of thermography:

- Detection and delineation of invisible cutaneous, subcutaneous, or deeper tissue inflammation, since without erythema: for example, the persistent peri-lesion vasodilatation after healing in psoriasis, the lymph or blood drainage path of a tumor, and the degree of inflammation of a joint.
- Invisible vasoconstriction detection (Stüttgen and Flesch 1985) (e.g., in healed psoriasis lesions) or analysis (the blanched area induced by topical corticosteroids spreads beyond the area of hypothermia, which would indicate a preferential effect of the drug on capillaries rather than arterioles).
- Investigation of angiodysplasias in order to discern hyperperfused (warm), stagnant (cold), and normally perfused zones and to follow them up during treatment.
- Assessment of malignant tumor growth (generally associated with hyperthermia).
- The dermatological use of thermography is well developed and illustrated in the work of Stüttgen and Flesch (1985).

2 Good Practice

2.1 Examination Room

- An air lock is an ideal way to reduce temperature changes and drafts occurring on entrance or exit. This air lock may also be used as a cubicle for the patient to undress (Ammer and Ring 2013).
- The volume of the room must include air conditioning. Surface: 8–12 m². Maximal height 2.5 m in order to reduce temperature differences between the floor and the ceiling, which are reproduced between the patient’s feet and head in standing position.
- Thermal insulation of the walls of the room can improve thermal stability.
- Air conditioning is essential, preferably set at 22–23 °C, so that the skin temperature differences are clearly revealed but allowing the undressed patient to feel comfortable. It is most efficient if left to operate day and night continuously. The relative humidity must not exceed 50 % since the stratum corneum hydration alters its emissivity.
- To reduce thermal currents to the minimum, it is recommended to block up the windows because they let the cold and the sun in.
- Avoid reflecting materials (aluminum, steel) or paint any reflecting surfaces. Walls should also be covered in nonreflecting paint.
- Room lighting should be operated by cold light or fluorescent tubes providing indirect lighting.

The central heating radiators should be placed as far as possible from the examination table, in any case not less than 2 m.

2.2 Method

- The subject should stay at least 15 min at room temperature before the examination takes place.
- Clothes strongly modify the thermal environment of the skin. The subject must therefore be undressed 15 min before the test.
- Alcohol or spicy food must be avoided 2 h prior to the examination to avoid the risk of facial, thorax, or extremity flush, in spite of the absence of erythema.
- The skin must be dry as humidity absorbs IR. Wet skin looks cold. A wound can appear to be 2 °C below its actual temperature.
- The subject must be placed at least 15 cm from the nearest wall, to avoid heat reflection, and 2 m from any source of heat.
- There should be no entrance or exit from the room during the examination.

2.3 Commercial Equipment

Most modern infrared cameras today are better equipped with faster detectors than the earlier systems of more than 30 years ago. Focal plane arrays are fast and efficient, providing images at real-time video speeds. There is now a wider range of cameras that operate successfully for medical applications without the need for detector cooling (Ring et al. 2009). However, it is always recommended that such systems should be used with an external blackbody reference temperature source. Time to reach stability can vary, and it is necessary to take a series of images for measurement from a known stable temperature reference source to verify when an individual camera is ready for image capture and temperature measurement. Modern systems also generate a digital thermal image, so that connection to a computer can be by fire wire or by wireless transmission. In many cases, a storage provision within the camera itself can be used, allowing the operator to download to the computer at a later time for detailed image analysis. In recent years the image and temperature resolution has increased. Currently many systems provide thermal images at

320 × 240 pixels, with 640 × 480 and upward becoming readily available at higher cost. Manufacturers and agencies exist now in many countries around the world. A large company that has integrated several well-known manufacturers is based in Sweden and the USA with a wide range of systems for many different applications in medicine science and industry. Whatever the choice of camera system selected for medical studies, it is important that regular maintenance by the company be undertaken. A thermal camera may perform to the manufacturer's specification for a period of time from leaving the factory, but is subject to offset drift, and multielement detectors can be affected by individual pixel and detector loss, which the manufacturer needs to deal with on a regular basis.

Reproducible results with thermal imaging depend on rigorous technique by the operator. Standardized procedures are now commonly adopted and can be found in the literature.

3 Clinical Applications

A number of modern reviews indicate that some applications have become more widely accepted in clinical medicine than others (Ring and Ammer 2012; Lahiri et al. 2012). Inflammatory lesions such as those found in the arthritides, rheumatoid arthritis, osteoarthritis, gout, psoriatic arthropathies, scleroderma, etc. can be effectively monitored by thermal imaging. The effect of anti-inflammatory treatments can be objectively monitored and has been documented in controlled clinical trials. Topical agents applied to the skin may be observed as a dynamic process (Fig. 2). In peripheral vascular diseases, skin temperature monitored by thermal imaging can be efficiently studied, particularly where a thermal or pharmacological challenge has been applied. Raynaud's phenomenon and vibration injury (hand-arm vibration syndrome) and complex regional pain syndrome are examples.

Due to the international concerns of pandemic influenza and the massive increase in air travel, attention has been focused on the use of thermal imaging in fever screening. The International

Fig. 2 Response to nicotinic acid spray to the calf

Fig. 3 (a) Thermogram of the face of a young male without fever. The cheeks and nose are the coolest areas. (b) Thermogram of the face of a young male with fever.

The forehead, cheeks, and nose are cooler due to sweating. There is increased heat at the inner canthi of the eyes.

Standards Organization has published two documents that specify the minimum technical requirements for this and also the required procedure to capture meaningful information from a close-up thermal image of the face. It is now shown that from such a close-up image, the temperature measured at the inner canthus of the eye can provide discriminatory evidence of systemic fever in children and adults compared to nonfebrile subjects (Fig. 3a, b) (Ring et al. 2013).

4 Conclusion

The technical performance of thermal imaging cameras, together with the power of computing and image processing, has transformed this technique in recent years. As a result the physiological knowledge of skin temperature in health and disease has also improved. From noninvasive monitoring of treatments to studies

in high-performance sport science, infrared thermal imaging has matured and when correctly performed can be a valuable and reliable objective imaging procedure in certain aspects of clinical medicine. The very high costs of the past have fallen, and performance has risen, making this technique more accessible than in the former years of its development.

Reliability • Reproducibility • Validity • Skin temperature • Infrared thermography • Humans • Healthy • Overweight • Patients • Software

By measuring the skin temperature (Tsk), there are a lot of factors, which could influence the results (Fernández-Cuevas et al. 2015). Among them, validity and reliability are two of the most important ones to take into account in order to obtain the more accurate and consistent results. Those adjectives – accurate and consistent – seem to be similar but they are not. On the one hand, accuracy is directly related to validity, and **validity** refers to whether a measurement is well founded and corresponds accurately to the real world. On the other hand, **reliability** is related to consistency because it refers to the degree to which the measurement gives the same result in repeated measurements.

Infrared thermography (IRT) is a rapid and non-invasive technology widely used to assess Tsk. In this case, the validity refers to how well IRT measures Tsk and, consequently, permits appropriate interpretation of Tsk scores. However, the reliability of IRT shows if this technology gives the same results in different situations (with different observers or software). Besides, Tsk reproducibility is related to the concept of reliability, and it is used here to describe the consistency of the temperature of the skin itself along the time.

In this chapter, a review of results about validity and reliability of IRT and reproducibility of Tsk will be shown, as well as a discussion about

the convenience of using manual methods or software to analyze IRT images.

1 Infrared Thermography

Infrared thermography (IRT) is a safe, noninvasive, and low-cost technique that allows the rapid and noncontact recording of the irradiated energy released from the body (Akimov and Son'kin 2011; Merla et al. 2005; Ng 2009; Costello et al. 2012; Hildebrandt et al. 2012). IRT measures skin temperature (T_{sk}), and since it started to be used with human beings (the early 1960s), the development of this technique focused on discovering the validity of IRT to diagnose pathologies (Liu and Xu 2000). Due to conflicting results and a lack of methodological standards and quality assurance (Head and Elliott 2002), the IRT was replaced by emerging and more accurate technologies such as X-rays, ultrasound devices, or magnetic resonance: from initial enthusiastic interest to almost complete obscurity.

However, the technological improvements of IRT in the last years have made possible a resurgence of this technique (Jiang et al. 2005; Vainer 2005; Cheng et al. 2009; Spalding et al. 2008; Skala et al. 2011), paving the way to new applications of IRT for humans not only focused on the diagnosis (Marins et al. 2015). Even if IRT has been widely used in pathological conditions, there are much less data available from healthy subjects (Zaproudina et al. 2008). Moreover, the increase of interest on the application of IRT, not only in the medical sector but also in other fields as the physical activity with healthy subjects, makes it more necessary to increase the knowledge concerning the factors affecting the application of IRT on humans (Costello et al. 2012; Zaproudina et al. 2008; Ring and Ammer 2012), as well as the reproducibility of IRT measurements in different potential groups of application as children, elderly, overweight, disabled, or physically active subjects.

Ring recently defended and described the new features of IRT technology and the improvement on standardization protocols (Ring and Ammer 2012). Nevertheless, most research groups keep on analyzing IRT images using the software

packages provided by the camera manufacturers, which are mainly created for industrial or architectural purposes, rarely adapted to human analysis (Murawski et al. 2003). Specific IRT software for humans is rare, but its reliability results are excellent by comparing with manual techniques. Therefore, there is a remarkable necessity of a larger supply on software to analyze IRT images of human beings.

2 Validity

As it was mentioned, validity refers to whether a measurement is well founded and corresponds accurately to the real world. In the case of IRT, validity would be the ability to estimate temperatures of an object's surface from its infrared radiation as recorded using a thermal camera. Burnham et al. (2006) demonstrated a good validity of a skin infrared thermometer ($r = 0.92$), but only Sherman et al. (1996) published a study of the validation of "video thermography."

Among the several technical improvements that have been made in IRT in the previous decades, certain aspects, such as the number of frames per seconds, the resolution, and the weight of the equipment, have notably improved.

Accuracy is directly related to the validity of IRT given that it refers to how close the thermal readings of an IRT camera are to the true temperature. Even if the accuracy has improved, IRT-based measurements are more than 1 °C (or 1 %) different from the actual temperature (in the best cameras). This is not a large error in the evaluation of a building or in an industrial setting. However, considering how important precision is in measuring human temperatures (more than 0.25 °C of side-to-side asymmetry is considered to be abnormal), poor accuracy could represent one of the weakest points of IRT. Nevertheless, since we work by comparing T_{sk} from bilateral ROIs on the same image, the potential error will be the same, and therefore it will not affect the final results in terms of asymmetry.

The validity of IRT as a diagnostic tool has been conclusively demonstrated in the context of several pathologies and injuries, including reflex

sympathetic dystrophy (Bruehl et al. 1996), stress fractures (Goodman et al. 1985), pneumothorax (Rich et al. 2004), dermatological pathologies (George et al. 2008), and diabetes (Sivanandam et al. 2012). However, studies of its validity have been performed only for specific applications (Owens et al. 2004; Roy et al. 2006).

Burnham et al. (2006) demonstrated a good validity of a skin infrared thermometer (ICC =

0.92) (see Table 1), but only Sherman et al. (1996) published a study of the validation of “video thermography,” that is to say IRT.

To avoid the potential errors in IRT camera measurement accuracy ($\pm 2\%$ or $\pm 1\%$ in the best cases), certain authors place a constant and known temperature source into the thermogram to calibrate the measurement of the thermal imager. Ring and Ammer (2000) assert that, despite the

Table 1 Reliability results (ICC) of several published articles about IRT validity

Year	Author	N	Sample	Pathology	Technique	ROI	ICC

internal reference temperature of many current thermal systems, using a reference source for calibration is highly recommended to improve the IRT results (Simpson et al. 2008). We therefore suggest the use of a calibration source for using IRT on humans until camera providers improve the imager's accuracy within the 20–50 °C range.

3 Reliability

Reliability refers to the degree to which the measurement gives the same result in repeated measurements. Likewise, repeatability and reproducibility are sub-terms of reliability, all of them related to consistency. In quantitative research, reliability studies aim to prove the consistency of analysis methods or instruments, as for example, if a manual analysis methodology gives the same results independently of the observer who takes the IRT image. Reproducibility is more related to the consistency of results along the time, which means, to investigate if Tsk is consistent now, in 5 s, 24 h, or 2 months (see Fig. 1). Repeatability is related to the consistency of findings obtained after the same procedure was repeated (Bartlett and Frost 2008).

However, both concepts are often mixed in the literature, and reliability is with no doubt the most used to describe the consistency of Tsk. According to statistics, there are different ways to investigate the reliability and reproducibility.

Intra-class correlation coefficient (ICC) is the most common coefficient to describe the consistency (intra- and inter-examiner). In addition to this two-way mixed model, coefficient of variation (CV) represents another useful coefficient to show the dispersion of data, but less current in the literature. Lastly, Bland-Altman plots are an illustrative way to visualize the dispersion of data with agreement limits (see Fig. 2).

Although Tsk should be constant over time (Frim et al. 1990) and symmetric on both sides of the body (Uematsu et al. 1988; Niu et al. 2001), the list of the factors that affect the skin temperature is tremendously large (Ring and Ammer 2000) that the infeasibility of controlling for all of these factors could be considered one of the weakest points of IRT.

Therefore, to improve the applicability of IRT, better cameras with more advanced features should be developed, and the behavior of skin temperature due to the influence of different extrinsic and intrinsic factors should be studied.

3.1 IRT Software Reliability

Traditionally, human IRT images have been processed manually using IRT applications that were designed for other purposes or sectors (i.e., industry, construction, etc.). In this sense, certain authors reported inter-examiner variations (Plaughter et al. 1991; Zaproudina et al. 2008;

Fig. 1 Representation of the difference between reliability and reproducibility study design

Fig. 2 Example of Bland-Altman plots for intra-examiner agreement between the same observer in two thermograms (separated by 5 s) showing dispersion of data (Fernández-Cuevas 2012)

Costa et al. 2013) due to the difficulty of manually selecting the region of interest (ROI) from the human IRT images (Ammer 2003).

Therefore, in addition to the efforts that have been made to create standardized protocols and guidelines (Ring and Ammer 2000; Schwartz 2006; Ammer 2008), there is a remarkable necessity of specific software program to make this difficult task more simple, efficient, and reliable. Nowadays, the supply of specific software is poor. On the one hand, there are some laborious solutions created by some research groups to analyze IRT images automatically (Murawski et al. 2003; Vardasca 2008; Fournet et al. 2013). On the other hand, a few specific software to investigate and analyze IRT images of humans are developed and sold by private companies, as TotalVision™ (infrared screening), Meditherm IRIS™ (breast cancer company), and Termotracker® and its new version ThermoHuman® (ThermoHuman, from sports sector).

From all of them, Termotracker® is the only one to have published reliable results (Fernández-Cuevas et al. 2012). This software uses a computer vision algorithm, which automatically identifies the body shape and ROIs from the IRT images, generating a database with the primary data of the considered ROI. The reliability results of Termotracker® are almost perfect (Fernández-

Cuevas et al. 2012), and the new version ThermoHuman® will improve those results. By comparing the results with those that were obtained by manual methods (Zaproudina et al. 2008), the higher reliability, even with respect to the ICCs for the intra-examiner data, may be due to the automatic ROI identification process, a task that was performed by an observer in similar studies (Selfe et al. 2006; Hildebrandt et al. 2009b; Denoble et al. 2010).

In general terms, some studies that have examined inter- and intra-examiner reliability of IRT cameras reported good results (Selfe et al. 2006; Littlejohn 2008; Spalding et al. 2008; Zaproudina et al. 2008; Hildebrandt et al. 2009b; Denoble et al. 2010; Pauling et al. 2011), but none achieved such excellent ICCs as the results that are reported in Fernández-Cuevas (2012), and the reason lies surely in the fact of applying a computer vision. The automation on the process of determining the ROIs improves the IRT reliability and allows for a more rapid and more efficient IRT analysis of the thermograms from humans. Although the results reached by Termotracker® are not perfect (ICC = 0.999), there is no doubt that software solutions are faster and more accurate to analyze IRT images than manual methods, and therefore, there is a clear necessity of further investigation and supply of new specific software.

3.2 Reproducibility of IRT Values

IRT reliability has been examined in several works, both with patients (Selfe et al. 2006; Spalding et al. 2008; Hildebrandt et al. 2009b; Denoble et al. 2010; Costa et al. 2013; Choi et al. 2013) and healthy subjects (Zaproudina et al. 2008; Littlejohn 2008; Pauling et al. 2011). The majority of these studies achieved ICCs that ranged between 0.4 and 0.9 (see Table 1). However, certain of these studies reported the influence of factors, such as technical errors, the physiological variability from 1 day to another (Zaproudina et al. 2008), or the existence of previous injuries (Hildebrandt et al. 2009b). Recently, a study was performed (Fernández-Cuevas 2012) with only one examiner, following an adaptation of the guidelines from the European Association of Thermology (EAT) (Ammer 2008). Three consecutive thermograms from healthy subjects were taken, separating the first two thermograms by only 5 s and waiting 24 h to record the third thermogram under similar conditions as the two first assessments. With this study design, the aim was to identify the influence of time on Tsk variability and to avoid the potential influence of the factors that are mentioned in previous research.

According to the Littlejohn (2008) classification of ICC values (poor: 0–0.39, Fair: 0.40–0.59, Good: 0.60–0.79 and Excellent: 0.80–1.0), the results of this study (Fernández-Cuevas 2012) revealed excellent ICC values between the two first thermograms (5 s between readings), both in terms of the Tsk values (mean ICC = 0.991) and the side-to-side differences (ΔT) (mean ICC = 0.953); these results are nearly perfect. They suggest that the slight variation between the first two readings may be due not to the variability of Tsk but to small variations in the infrared camera; therefore, a calibration system with a black body was used (Plassmann et al. 2006). Moreover, when comparing the results of Tsk from thermograms 1 and 3 (separated by 24 h), which were conducted in similar conditions as other authors have used (Zaproudina et al. 2008; Hildebrandt et al. 2009b), the ICC outcomes differed depending on the ROI. With respect to Tsk values, the better ICCs were those from the muscle and central ROIs (i.e., abdominal, back, thigh, lumbar,

dorsal), and the worst ICCs were for the joint ROIs (i.e., knee, ankle, elbow). These results are similar with those of Zaproudina et al. (2008), who demonstrated lower ICC values for the distal and joint ROI, such as the knee.

Moreover, there is a growing use of thermal asymmetries in the application of IRT on humans (Feldman and Nickoloff 1984; Uematsu et al. 1988; Niu et al. 2001; Vardasca 2008) to calculate the side-to-side differences (ΔT) in selected bilateral ROIs. A recent study (Fernández-Cuevas 2012) indicated that, when tracking a single ROI over time (e.g., monitoring an injury), muscular and central ROIs measurements are more reproducible. However, when examining asymmetries or bilateral values (ΔT), which are actually very useful tools with which to detect pathologies (Niu et al. 2001) or injury risks (Gómez Carmona 2012), the most reliable ΔT values are for the joints and the central ROI (i.e., the pectoral and shoulder ROIs).

4 Conclusions

The validity of IRT to assess Tsk has been proven, but it could improve if infrared cameras would be conceived to human applications. Although there are differences in the methodology among studies, most of them show good reproducibility results. However, it has been also demonstrated that the reproducibility of the Tsk measurements slightly decreased with some factors as the regions of interest (ROI) analyzed and the time between measurements. Regarding reliability results, specific software solutions seem to be the best option to analyze IRT images, but the supply of them is still poor.

1 Introduction

The skin is the largest organ of our body covering approximately 6 m² and providing us with a waterproof protective barrier between our body structures and the environment. However, as a thermal interface, the skin is remarkably adept at managing heat transfers between the metabolic core and the environmental conditions. In cold environments, vasoconstriction of the blood flow within the skin layers functions as an outer body insulator, protecting the core organs from hypothermia. In hot environments, blood flow can be dramatically increased to the skin to transform the tissue into a surface radiator that encourages heat transfers into the environment. The ratio of radiant heat emitted is 0.98 as compared to a black body perfect emitter of 1.0 (Flesch 1985), with no wavelength differences observed between skin colors as detected by infrared imaging (Jones and Plassmann 2008). Thus, the skin can be

USA
e-mail: Pascodd@auburn.edu

thought of as a thermal chameleon, which alters its function in response to the core-environment heat transfers to provide precise core temperature regulation maintained within a small critical survival zone.

2 Neural Control of the Skin Surface

Neural vasomotor control of the vascular topography within the cutaneous skin layers regulates the appropriate core to skin to environment heat transfers for thermoregulation. The reflex neural regulation modulates the blood flow by way of sympathetic vasoconstriction or vasodilation of the arterial branches that feed the transverse (perforator) vessels which culminate in numerous cutaneous circulatory plexus. Further blood flow regulation occurs in the acral tissue regions (finger/toe digits, ears, nose, cheeks, lips, palmer surfaces of the hand and feet) that are structurally supplied with arteriovenous anastomoses (AVAs). The AVAs are thick-walled, low-resistance vessels that have a direct vascular pathway between the arterioles and venules that regulates plexus blood flow by sympathetic adrenergic vasoconstrictor activity. In the nonacral tissue regions (legs, arms, and chest), blood flow is under the dual control of adrenergic (vasoconstriction) and noradrenergic (vasodilation). For a more in-depth review of the regional sympathetic reflex regulation and skin blood flow, the reader is directed to Johnson and Proppe (1996), Charkoudian (2003), and Pascoe et al. (2006). It is important to recognize these differences in regional blood flow regulation when investigating, measuring, or interpreting the skin temperature surfaces across the various regions of the body.

3 Mean Skin Temperature Calculations

An understanding of the dynamic responses of the skin to internal and external thermal environments and measurements of a mean skin temperature has been a challenge due to the skin's contoured surface area and the constraints of the equipment used to measure the skin surface. The earliest published skin temperature measures were made by Davy in 1814 by holding a thermometer against the skin surface (Burton 1934). The advent of the skin thermocouple at the turn of the century provided greater measurement accuracy, improved testing procedures, and has been the dominant measurement device over the past century.

A "precise" mean skin temperature would require an accurate measurement device and would be derived from an infinite number of body temperature points. All mean skin temperature formulas rely on the assumption that a finite number of skin temperature measures can provide a correct and reliable estimate of mean skin temperature (Teichner 1958). Thermistor measures also assume that areas within the body regions are homogeneous in temperature and representative of the mean skin temperature for that surface area. Intuitively, the more sites a researcher measures, the more representative and reliable the measure of mean skin temperature will be for either regional or whole-body measures. To address this issue, Winslow et al. (1936) produced pivotal research that examined the convective and radiant exchanges of humans under varying environmental conditions. From this research, it has been advocated that 15 recommended sites could provide a "reasonable" maximum for conducting investigations related to the thermal exchanges from the skin surface area. The 15 recommended sites are located in seven regional areas defined as (Fig. 1):

$$\begin{aligned} \text{Mean } T_s = & T_s \text{ Head}(A + B + L)/3 \\ & + T_s \text{ Arms}(D + F)/2 + T_s \text{ Hands}(G) \\ & + T_s \text{ Trunk } (C + E + M + N)/4 \\ & + T_s \text{ Thighs } (H + P0)/2 + T_s \text{ Legs}(J + Q)/2 + T_s \text{ Feet } (K) \end{aligned}$$

Fig. 1 Site locations, percent of relative area, and approximate integral proportions. Illustration of the 15 “optimal” measurement sites (Image drawn by Jason Adams, Auburn University)

This has been identified as the “optimal method” to determine whole-body mean skin temperature and the standard method used to compare the “accuracy” of other proposed formulas. The “accuracy” of the estimated mean skin temperature formula is determined by the agreement frequency percentage, which calculates the number of values that are within $\pm 0.2\text{ }^{\circ}\text{C}$ when compared to standard measure, where the $0.2\text{ }^{\circ}\text{C}$ allows for

the error of the thermocouple device measurement. Using the same 15 sites, Winslow et al. (1936) proposed that the seven DuBois regions could be reduced to four by combining the arms and hands into the upper extremity and combining the thighs, legs, and feet into the lower extremity.

The research literature has focused on four basic formula approaches: (1) unweighted

average of the sites recorded; (2) weighted formulas based on regional surface averages as defined within population norms; (3) variable weighting based on individually determined surface areas, often determined by the DuBois linear formula; and (4) weighted formulas that incorporate factors that describe both the surface area and the thermoregulatory response to thermal stimuli (Nadel et al. 1973; Crawshaw et al. 1975). This fourth approach recognized that while the surface areas of the various regions help to explain the exposed surface available for heat exchange (conduction, convection, and radiation), differences in regional blood flow, temperature, and sweat gland distribution that contribute to measurable differences in the regional area's ability to dissipate heat through evaporation may not be adequately expressed. Comparative evaluations for various formulas used for mean skin temperature calculations can be found in the following research articles: Mitchell and Wyndham (1969), Lund and Gisolfi (1974), Olsen (1984), and Choi et al. (1997).

Due to the complexity of using 15 site measures, researchers have investigated the validity of monitoring fewer sites from which numerous mean skin temperature formulas have emerged. Mean skin temperature formulas have been devised using 3–15 measurement sites. Under resting conditions, the core environment is often considered homeothermic where the regional peripheral blood flow and temperatures are variable (poikilothermic) and more dependent upon environmental conditions. In colder external environmental conditions, regional skin temperatures are more heterogeneous, and variances across the region can be substantial. In warmer conditions, the skin temperature is more homogeneous and fairly consistent across the surface area. According to prevailing environmental conditions, some researchers have altered the number of measurement sites for the sake of convenience and reduced data handling to avoid measurement situations that would interfere with the research variables. Olsen (1984) used stepwise regression analysis of more than 800 tests from which he concluded that in warm environments 2–4 sites may be adequate, neutral conditions would

require 4–8 sites, and cold environments would require between 8 and 12 sites to demonstrate a high degree of accuracy. Other researchers (Teichner et al. 1958; Veghte 1965; Jirak et al. 1975; Olsen 1984) have analyzed multiple data sources and have stated that at least six to seven sites need to be measured to assure accuracy of the estimated mean skin temperature. Some of the increased variance in regional skin temperatures in the cold can be attributed to the distribution of subcutaneous fat often associated with lower temperatures in areas of greater fat disposition (Livingston et al. 1987). Furthermore, the external environment, exercise metabolism, and clothing create an insulation effect (clo) that strongly influences thermal comfort and creates a microenvironment and thermal barrier that can alter or inhibit the skin surface thermoregulatory responses (Mairiaux et al. 1987; Mehnert et al. 2000). It is also important to recognize that these factors strongly influence the “accuracy” of mean skin temperature measures as determined by the agreement frequency percentage calculation such that a formula could be expected to perform differently under varying conditions, especially environmental temperature.

Potential errors in probe measurement can be attributed to poorly defined probe locations, regional point-to-point variations in temperature, different assigned numerical factoring values that try to account for regional contributions to the thermal status of the individual, and discrepancies created when comparing weighted calculations to the proportional unweighted measures of mean skin temperature. The regional point-to-point variation will be greatly influenced by the environment, where the magnitude of temperature variations has been reported from 7.2 °C to 3.6 °C (Jirak et al. 1975; Firm et al. 1990; Hunold et al. 1992) and deviations of microcirculation in the skin of 300 % within a few centimeters (Hunold et al. 1992). The accuracy of the probe, probe shape, mounting pressure, and adjoining wiring and the microenvironment created by skin surface attachment have provided methodological challenges. However, the thermocouple probe is still the favorite device for skin temperature measures under clothing.

4 Thermographic Measurements of the Skin Surface

In the 1960s, the development of infrared thermographic devices provided researchers with a method of obtaining a noncontact “thermal map” or thermal pictures of the skin surface area. In principle, this device detects the heat that is emitted (reminder: skin emissivity is 0.98) from the skin surface which greatly increases the number of measurement sites from a few probes to more than 10,000 digital pixel temperature-imaging points. The noncontact image removes researchers’ concern over the influence of probe attachment to skin temperature measures while providing a very sensitive increment of measure (0.05 °C). From these images, thermography imaging programs can quickly provide the mean, high, low, and standard deviation of the selected skin surface region. While this imaging may appear to provide all thermal points of interest, there may be a 10 % loss of image accuracy around the border of the body image (projection angle more than 45°) and another 10 % that may be influenced by a thick hair cover (Choi et al. 1977). Additionally, the detection of heat emitted from the skin using infrared thermography is altered by clothing, more specifically the ability of heat transfers to pass through the clothing fabric.

The measured skin surface temperature is a combination of radiant heat from the core and environment and the influence of convective air movements, evaporative cooling during sweating, and conductive heat transfers when the skin is in contact with other surfaces. The radiant source of heat coming from the core is delivered to the skin via peripheral blood flow into the skin vascular plexus. Infrared imaging does not measure blood flow, but the skin temperature measures are strongly correlated to the anatomical distribution and blood flow to the surface area (Fig. 2).

These thermatomes, skin surface temperature patterns, allow the researchers to identify and understand the temperature distribution across the skin surface area, which negates the problem of probe placement. Within regional skin surface areas, the thermal image will have distinct areas

with the same temperature (isotherms). These isotherms represent the blood flow distribution to the skin vascular plexus and the conduction of heat to the adjacent skin tissue layers. Within thermocouple research literature, researchers have observed regional skin surface areas that have a homogeneous temperature distribution that may practically be used to estimate the mean skin temperature of a region. This depends upon the proportional size of the isotherm in the region and the potentially sizeable variances in tissue temperatures across the skin surface that may shift the mean away from the isotherm mean temperature. These isotherms can change in accordance to exposures to varying environmental temperatures (see Fig. 3; Livingstone et al. 1988; Hunold et al. 1992), with greater heterogeneity in the surface temperatures observed when the skin is exposed to colder environments. As such, a same site probe location can provide discrepant measures due to the varying distribution of skin temperatures and fluctuating isothermal patterns.

Thermography is more adept than thermocouples when observing and measuring differences in local skin temperature as a result of radiant heat transfers due to posture and adjoining body parts (arms and torso) and the impact of convective air flow created by movement (mostly arms and legs). Additionally, the importance of the acral regions in heat transfers that modulate thermoregulation cannot be overlooked. As an example, if you feel hot while in bed at night, the simple act of sticking a foot outside of the bed covers changes your thermal status. A single thermal probe is unlikely to adequately describe the thermal response of acral regions (e.g., hands, feet), whereas thermography views the entire skin surface thermal response.

To understand the variances in skin temperature, Pascoe et al. (2012) investigated the mean skin temperatures within body regions in men and women while exposed to three environmental conditions (20, 30, 40 °C; all trials at 40 % relative humidity). Participants equilibrated on separate days within an environmental chamber for 20 min prior to thermographic measurements. The regional skin temperatures were determined from the mean temperature calculated (thermal image program)

Fig. 2 Vascular image and thermal image. Images depicting the close correlation between the skin vascularity and skin temperature (Image provided by Dr. Robert Ensley)

from the combined pixels within each regional surface area. No significant differences were found between men and women, so their data were combined. The regional skin temperatures in Figs. 4 and 5 demonstrate several key points:

1. The distribution and differences in regional thermal skin temperatures are linked to the environmental conditions.
2. The torso regional temperatures show a more homogeneous distribution when compared to

Fig. 4 Mean skin temperatures of torso across environmental conditions. Mean skin temperature of torso regions at 20, 30, and 40 °C as determined from thermographic images. *RS* right scapula, *LUC* left upper chest, *RA* right arm, *LLB* left lower back

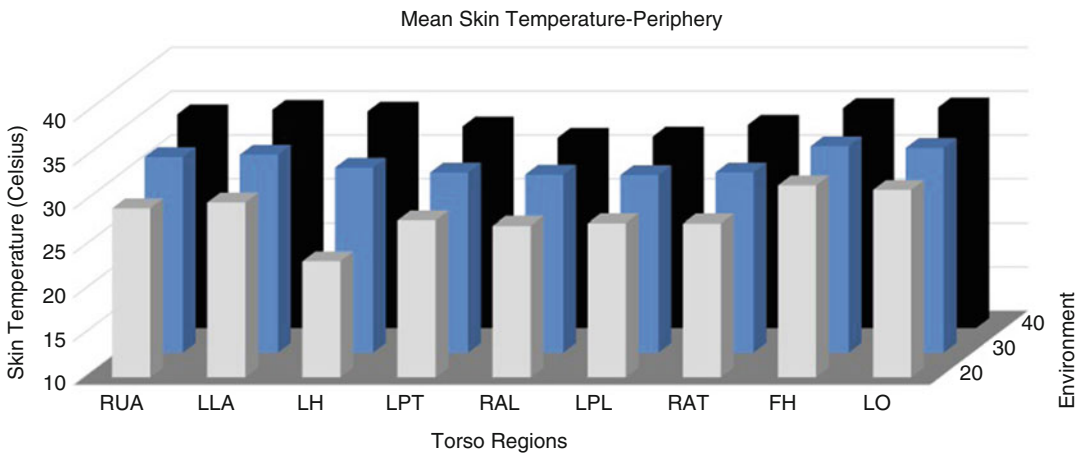

Fig. 5 Mean skin temperature of periphery across environmental conditions. Mean skin temperature of periphery regions at 20, 30, and 40 °C as determined from thermographic images. *RUA* right upper arm, *LLA* left lower arm,

LH left hand (posterior view), *LPT* left posterior thigh, *RAL* right anterior leg, *LPL* left posterior leg, *RAT* right anterior thigh, *FH* forehead, *LO* lower occipital

heterogeneous thermal responses of the peripheral regions.

3. The greater variance of temperatures within the extremities can be attributed to the heat transfer properties of the acral regions (mostly hands and feet), which explains why the skin in the proximal portions of the limbs responds differently to the same environmental stressor (Clark). This observation illustrates the importance of the arteriovenous anastomoses within the acral regions for heat exchange and thermoregulation.
4. The variance in the temperature measures within and between regions suggests the

potential for research error that can be observed when using formulas that vary in measurement site location, exposures to different environmental conditions, and the number of sites.

This potential error may be compounded by adding a “weighting” factor whose estimate of the mean skin temperature accuracy, as determined by the agreement frequency, varies according to environmental conditions and whether the individual is nude or clothed (Teichner 1958; Choi et al. 1977; Livingstone 1987).

Fig. 6 Range of regional temperatures across environmental conditions. Variance of skin temperatures for optimal regions at 20, 30, and 40 °C as determined from thermographic images. *RUA* right upper arm, *LLA* left lower arm, *LH* left hand (posterior view), *LPT* left posterior

thigh, *RAL* right anterior leg, *LPL* left posterior leg, *RAT* right anterior thigh, *FH* forehead, *LO* lower occipital, *RS* right scapula, *LUC* left upper chest, *RA* right arm, *LLB* left lower back

In Fig. 6, the range of temperatures within a region (high minus low measurement) demonstrates the variance in temperatures within and between regional skin temperatures surfaces. The figure clearly depicts the greater variance in regional areas during the colder exposure. This is consistent with the research literature and supports the need for using more thermistor probes when investigating mean skin temperature in colder environments (Olsen 1984). Unlike thermistors where a site may or may not represent the regional mean, thermographic skin temperature measures are able to capture all pixel sites from which a mean temperature is determined.

It is important to remember that the skin serves as an interface between the core thermal environment and the external environmental conditions. A majority of the research studies investigating mean skin temperature have been performed in the nude during resting conditions. Clothing can interfere with the normal regulatory processes, often creating a microenvironment that increases both temperature and humidity. The increased humidity reduces the skin to air vapor pressure which interferes with evaporative cooling. The wearing of loose clothing may reduce some of the thermal stress through clothing movement (pumping action) that increases the convective air movements. The insulation effect of clothing,

clothing layers, and location of clothing all affect the distribution of skin temperatures (Nielsen and Nielsen 1984). In the clothed individual, the ability to access the skin surface area for infrared imaging may dictate whether the researcher uses thermistors or thermography. During work/exercise, the increase in the metabolic heat production must be regulated by skin heat transfers. Using thermography, Clark et al. (1977) observed an initial drop in skin temperatures with the initiation of exercise with a subsequent increase in skin temperatures over active muscle areas. They concluded the change in distribution patterns from the resting state were due to the direct heat transfer from the muscle tissue to the skin surface. While sweating would be expected to provide evaporative cooling, the wiping of sweat from the skin did change the thermal pattern. This demonstrated that the wetness of the skin does not significantly influence the skin surface emissivity.

5 Summary

When reviewing and interpreting the literature on mean skin temperature, the reader must be cognizant of the experimental influence of the following factors:

1. Measuring device and measuring accuracy: thermistor probes, attachment, infrared thermography-defined surface area, and sensitivity;
2. Environmental conditions: temperature, humidity, wind, and direct/indirect radiant heat sources [sunlight, incandescent lights, and heaters];
3. Activity level of the participants: passive or exercising [intensity, duration, mode of exercise, exercise or body movements that increase the convective air flow across the skin surface];
4. Layers of clothing, clothing fit, and heat transfer and moisture transport properties of fabric; and
5. Choice of mean skin temperature formulas: number of sites being evaluated, weight or unweighted.

All of these conditional factors explain the differences observed in the measures of mean skin temperature and research citations, but these factors also complicate our understanding of the thermoregulatory responses observed through the modulation of perfusion to our interactive skin tissue.

Autonomic nervous system fibers • Cell innervation • Cutaneous innervation • Merkel cells • Neurotransmitters • Sensitive axons • Sensory epidermal formations

Sensory epidermal formations are mainly nerve fibers and Merkel cells. Skin innervation is highly dense, but with density and morphology variable with body site. Merkel cells (less than 1 % of epidermal cells) are neuroendocrine cells. Their distribution is also variable.

1 Cutaneous Innervation (Reznik 1996; Misery 2000; Saxod 1996)

In the skin, only axons are found, and especially nerve endings, whereas nerve cells which contain nuclei are localized in spinal nerve ganglions. These nerve fibers are immunoreactive for PGP9.5, neurofilaments, and some neurotransmitters. They are associated to Schwann cells, which express S100 protein and produce myelin. Skin nerve supply is double: from the sensitive or somatic nervous system and from the autonomic or vegetative nervous system.

1.1 Autonomic Nervous System Fibers

Autonomic nervous system fibers usually come from the sympathetic chains and are not myelinated.

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

They innervate vascular network, hair muscles, and sweat glands. They express tyrosine hydroxylase and contain many neurotransmitters (catecholamines, neuropeptides). Acetylcholine is only expressed by parasympathetic fibers and sympathetic fibers of sweat glands (the only case in the sympathetic system). The nervous network is superimposed on the vascular network. Sweat glands are surrounded by numerous nerve fibers, mainly around secretory coils but also along excretory ducts. Sebaceous glands are not innervated, and they are not neuropeptide- but hormone-dependent (Lever and Schaumburg-Lever 1983).

1.2 Sensitive Axons

Sensitive axons come from sensitive ganglions and define skin territories, which are named dermatomes (Figs. 1 and 2). They are myelinated in the dermis and not in the epidermis. From a plexus in the deep dermis, nerve fibers ascend toward the

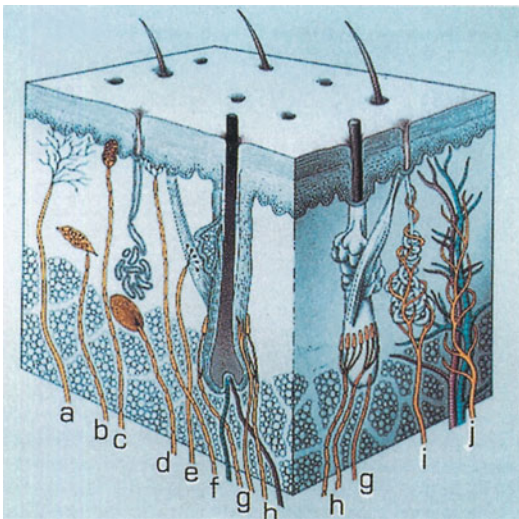

Fig. 1 Schematic view of the sensory corpuscles location within the skin. *a* Free nerve endings; *b* Ruffini corpuscle; *c* Meissner corpuscle; *d* Pacini corpuscle (above which a sweat gland is shown); *e* nerve of the piloarrector muscle; *f* nerve of a Merkel complex; *g* free nerve endings around a hair follicle; *h* perifollicular lanceolated corpuscle (above which piloarrector muscle and sebaceous gland are shown); *i* nerves to sweat glands; *j* perivascular sympathetic plexus (Courtesy of Professor Michel Reznik, University of Liège, Belgium)

surface and form a second plexus at the junction between reticular and superficial dermis (Fig. 2a). Nerve endings can be free, dilated or corpuscular.

In both dermis and epidermis, free nerve endings are very numerous (Figs. 1 and 2a, d, e). Their diameters vary from 1–2 μm (C fibers) to 2–5 μm (A δ fibers). They express neuropeptides, such as substance P or calcitonin gene-related peptide (CGRP). Hairs are surrounded with a dense network of nerve fibers, which is modulated by hair cycle (Fig. 2c). Free nerve endings are found at the opening of sebaceous glands.

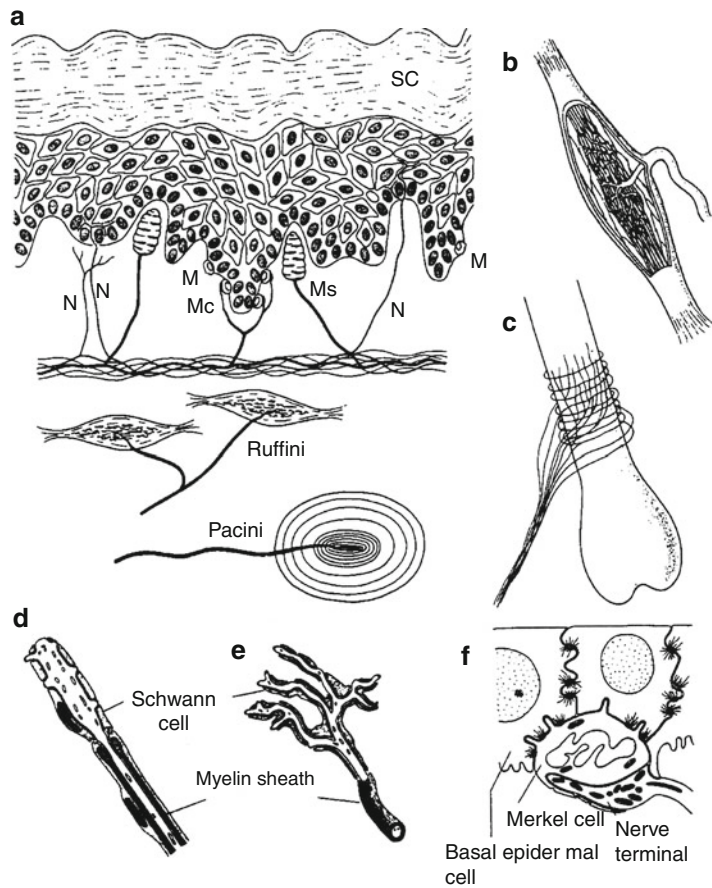

Dilated endings are lanceolated endings and Merkel-Ranvier disks. Lanceolated endings have a lance-shaped ending and are localized around the hair close to the outer root sheath. Merkel-Ranvier disks are in contact with Merkel cells but are localized at the dermal side of the dermo-epidermal junction (Fig. 2a, f).

Corpuscular endings are not numerous. They are mainly localized on the face, hands, feet, and genitalia. Several types are described. Ruffini endings are ovoid and 0.2–1 mm in length (Fig. 2a, b); they predominate around hair follicles and blood vessels. Wegner-Meissner corpuscles are bulboid endings (30 \times 150 μm) in the dermal papillae (Fig. 2a). Vater-Pacini corpuscles are onion-like and reach 1–2 mm in length (see ► Chap. 118, “Cutaneous Testing: Detection and Assessment of Allergy”). They are located between the deep dermis and the hypodermis. Muco-cutaneous corpuscles, 50 μm in diameter, do not possess a well-defined capsule. They are found on the lips, anus, and genitalia. Golgi-Mazzoni corpuscles are bulboid; they are more frequent in the mucosae than in the skin.

2 Merkel Cells (Saxod 1996; Gaudillère and Misery 1994; Tachibana 1995) (Fig. 3)

Merkel cells are hybrid cells. They are neuroendocrine cells because they produce neurotransmitters and hormones, secreted in neurosecretory granules then excreted. They express neuroendocrine markers, such as neuronal specific enolase

Fig. 2 (a–f) Cutaneous nerve endings: *A* in hairless skin. *M* Merkel cell, *Mc* Merkel corpuscle, *Ms* Meissner corpuscle, *P* upper dermis neural plexus, *SC* stratum corneum. (NSE), S100 protein, PGP9.5, chromogranin A or synaptophysin. But they are also epithelial cells because they express cytokeratins 8, 18, 19, and 20 or epithelial membrane antigen (EMA). They probably originate from the same stem cells as do keratinocytes.

They are found in larger number on lips, palms, and finger extremities. Localized in the basal layer of the epidermis (Fig. 2a, f) and the epidermal appendages, they possess dendrites and neurosecretory granules (Fig. 3). They are usually single but can be arranged into Merkel corpuscles or complexes (Fig. 3a). During embryonic life, nerve fibers develop towards these cells to constitute Merkel-Ranvier disks (Fig. 2f). Merkel cells are usually associated with a nerve terminal (Fig. 3). The function of the association between the Merkel cell and the nerve ending remains unclear but seems to be sensory.

Fig. 3 Merkel cells (green) associated with nerve endings (red)

3 Cell Innervation (Chédotal and Hamel 1993; Misery 1997)

Nerve fibers are known to be in contact with cutaneous cells. These data are commonly accepted for skin vascular cells, sweat gland cells, and hair follicle cells. These contacts do not appear to be synapses. Neurotransmitter secretion is paracrine. True synapses are only observed with hair arrector muscles.

Synapse-like connections between an axon and a cutaneous or an immune cell have been described recently. Hence, close contacts between the membranes of nerve endings and non-neural cells are probably the sites where exchanges take place. Such connections have been observed with cells of the skin immune system: mast cells, dermal dendrocytes, and Langerhans cells. In the epidermis, most Langerhans cells, many melanocytes, and some keratinocytes have synapse-like connections with nerve terminals.

Skin is the organ of the fifth sense, rich in neurosensory formations. Hence, it is an

important source of information for the nervous system. But the reverse also holds true.

Autonomic nervous system • Cold/heat sensitivity • Dynamic sensitivity • Fast adapting fibers • Low threshold mechanoreceptors • Mechanonociceptors • Nociceptors • Polymodal nociceptors • Slow adapting fibers • Static sensitivity • Thermoreceptors

The functional characteristics of the various types of skin receptors are better known thanks to electrophysiological studies in animals and microneurographic studies in humans which allow to record the unitary fibers response to an electrical or sensitive stimulation.

Three types of receptors are distinguished: the low threshold mechanoreceptors, the thermoreceptors and the nociceptors. The functional characteristics of the skin autonomic nervous system will be briefly treated at the end of this chapter.

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

1 Low Threshold Mechanoreceptors

They are now well individualised (Iggo and Andres 1982) and their structural characteristics are described in ► Chap. 128, “Sensory Function of the Skin.” Their distribution varies according to the type of skin, either hairless or hairy, and this is associated with their function. Microneurographic recordings and the study of the receptive fields have allowed to distinguish four types of primary

afferent fibers (PAF) distributed in two units (Johansson and Vallbo 1983).

1.1 Type I Units

Type I units have small and distinct receptive fields. They have several high sensitivity zones because each PAF is connected to several mechanoreceptors in different places. Type I units comprise:

1. Fast adapting fibers I (FA I): the discharge occurs only during stimulus initialization or interruption. Their response is therefore phasic and they code for low frequency sinusoidal stimuli perceived as a localized shiver. They are connected to the Meissner corpuscles
2. Slow adapting fibers (SA I) which are active over the whole duration of the stimulus (tonic activity). They also respond on a phasic mode, with a lower and more constant threshold than the FA I. They are connected to the Merkel complexes.

1.2 Type II Units

On the opposite, type II units have wide receptive fields with imprecise limits and overlapping areas. The following fibers types are found:

- Fast adapting fibers (FA II) which are activated by high frequency sinusoidal stimuli (100 Hz) and perceived as vibrations of the sub-cutaneous tissues. They are connected to the Pacini corpuscles;
- Slow adapting fibers (SA II) which respond to sustained or phasic depressions of the skin surface. They are connected to the Ruffini corpuscles.

1.3 Distribution and Function

These physiological data must be correlated to the distribution of the different under-types of mechanoreceptors in order to understand their specific functions.

Type I units are more numerous on the palm with maximum density on the fingertips (FA I, 140/cm²; SA I, 70/cm²). On the opposite the type II units distribution is more uniform with a lower density (Knibestöl and Vallbo 1980).

FA I and SA I mechanoreceptors are particularly involved in tactile discrimination. In 1835, Weber showed that humans could perceive two distinct stimuli at a distance of 1–2 mm on the fingertips. Since then different experimental paradigms have shown that this distance could be reduced to 0.84 mm, even 0.17 mm (Johnson and Pkillips 1981; Loomis 1979). SA I are also plainly involved in the perception of shapes, roughness and surface sampling (Johnson and Hsiao 1992). Inversely, even when the FA I are activated by a moving stimulus, the perception of movement on the skin surface requires a sub-cortical and cortical somesthetic coding.

Finally types SA I and SA II units have a dynamic sensitivity (phasic activity proportional to the movement rapidity) and a static sensitivity (tonic activity which in case of a sustained joint position, for example, is proportional to the flexion angle) which can be compared to that of the neuromuscular units. They may therefore be able to inform the nervous system about the joints position and movement.

2 Thermoreceptors

The morphological aspect of the thermoreceptors does not allow to differentiate them from other neuron free endings. They can only be differentiated by their functional characteristics (Spray 1986). They have a low basal tonic activity associated with the skin temperature. However they do not respond to mechanical stimuli. Their response mode is of a phasic type with a low activation threshold, contrary to the nociceptors.

2.1 Sensitivity to Heat

The neuron free endings involved in heat sensitivity are mainly of type C. They are less numerous than those which code for cold. Their

receptive fields diameter is 1 mm. They are activated for temperature variations between 30 °C and 45 °C with a maximal sensitivity between 41 °C and 45 °C. Above 45 °C the thermal nociceptors are also activated while the thermoreceptors discharge frequency decreases.

2.2 Sensitivity to Cold

It corresponds to thermoreceptors activation (fibers A δ and C). Their receptive fields are small, with a diameter of about 100 μ m. They code for thermal variations within the range of 0.5–20 °C from the basal skin temperature. In this range they are activated by a sharp drop in temperature and inhibited when the temperature variation returns to basal state. There is therefore an overlapping zone between both types of thermal sensitivity (30–40 °C). In this range corresponding to the skin physiological temperature, both fibers types are active.

In some particular conditions receptors to cold can be activated by a warm stimulus. When a temperature of 45 °C is applied on a small area of the skin, the receptors to cold are activated with a perception of “paradoxical cold” (Vallbo et al. 1979).

3 Nociceptors

They are mainly constituted by slightly or not myelinated free ends. Contrary to mechanoreceptors, their activation threshold is high and their response increases parallel to the stimulus intensity. Two types of nociceptors are distinguished and their function is now better known (Chaouch and Besson 1986).

3.1 Mechanonociceptors

They are traditionally associated with the slightly myelinated A δ fibers. Their receptive fields are large (1–2 cm) and separated by zones where stimulation is inefficient. They give a quick and well located stinging, pinching or cutting sensation. Their response is proportional to the stimulus intensity but reduced by its repetition (inactivation phenomenon).

3.2 Polymodal Nociceptors

Their primary afferent fibers are mainly of type C and not myelinated, but a smaller number of A δ fibers has been described in monkeys and humans (Adriaensen et al. 1983, 1984; Torebjörk and Hallin 1974). Their receptive fields area varies from 1 mm² to 1 cm² and has either a homogenous sensitivity zone or maximal sensitivity zones. They respond to sharp and strong mechanical stimulations with functional characteristics identical to those of the mechanonociceptors. Then can also code temperature rises above 43 °C as painful. In this case the subject may feel a sharp sudden heat followed by a longer delayed heat sensation. This type of perception corresponds to the initial activation of fast conduction A δ fibers (5–52 m/s) then slower C fibers (0.5–1.4 m/s). Finally they respond to chemical stimuli, especially to pain-generating substances which are found in inflammation (bradykinine, histamine) and to irritants.

As in the case of A δ fibers, a repeated stimulus can cause an inactivation phenomenon, and especially sensitization. In this situation for a stimulus of a given intensity the response threshold decreases and the polymodal nociceptors discharge frequency increases.

Furthermore recent works have shown the presence of C fibers, called silent, in the skin, viscera and joints which are inactive in physiological conditions (Michaelis et al. 1996). Their activation may be induced by the inflammation neuromediators. Could they be a “new” type of nociceptors with a very high activation threshold? Or are they part of a peripheral physiological stage in the sensitization process of the central nervous system responsible for secondary hyperalgesia? Both hypotheses are still debated.

4 Role of the Autonomic Nervous System

As mentioned in ► [Chap. 128, “Sensory Function of the Skin,”](#) the skin autonomic innervation belongs to the sympathetic nervous system (Reznik 1996; Vallbo et al. 1979). It regulates sweating, skin and muscular blood flow as well

as piloerection during sudden changes in our outer or inner environment (“fight and flight”). Finally, there is probably a physiological connection between the polymodal nociceptors and the autonomic nervous system, especially in the phenomenon of neurogenic inflammation.

Sensory function (touch) is one of the most important functions of the skin-nervous system but is not the only one (Misery 1997). Autonomic nervous system controls vasodilatation (and thus thermoregulation), pilo-arrection, sebaceous excretion, and sweat secretion and excretion. Sensory nerve fibers are also able to strongly modulate skin immunity, skin trophicity, hair growth, cutaneous effects of ultraviolet light (photo-protection and immunosuppression), keratinocyte differentiation or proliferation, and all other functions of the skin, thanks to an antidromic secretion of neuropeptides and neural growth factors. Hence, they also modulate wound healing and inflammation and exert effects on the time course of skin diseases.

1 The Cutaneous Sensitivity

Following an external stimulus, the signal generated in the skin is conveyed by activated C and A δ fibers of the neurosensory system to the neuron cell (Reznik 1996; Boulais and Misery 2007). At this level the information is received through a

L. Misery (✉)
 Department of Dermatology, University Hospital of Brest,
 Brest, France
 e-mail: laurent.misery@chu-brest.fr

receptor, and then the electric potential of the cell membrane is altered and neurotransmitters are produced. The nervous impulse is conveyed to sensitive ganglions then to the spinal cord. A second neuron, via the spinothalamic funiculus, transmits the information to the thalamus, at the brain basis. A third neuron conducts the impulse to the temporal cortex. At all levels, the “gate control,” exerted by intermediary neurons, regulates the system.

In the epidermis, Merkel cells (Boulais and Misery 2007) have a specific sensory function, especially in mechanoreception, in a close interaction with A β fibers. Other epidermal cells (mainly keratinocytes) could also have sensory functions because they express sensor proteins (Boulais and Misery 2008), and the epidermis can be considered as the forefront of the sensory system (Denda et al. 2007).

Anatomical and functional classifications of cutaneous neuroreceptors are not superimposable. Indeed, a same anatomical type of nerve endings is able to receive and transmit different types of information. Four functional types of receptors are defined: mechanoreceptors, thermoreceptors, nociceptors, and pruriceptors (Table 1).

1.1 Mechanoreceptors

There could have a slow accommodation (response over the whole duration of stimulus) or a rapid accommodation (response at the beginning and the end of the stimulus).

In non-hairy skin, type I receptors (Merkel cells and Meissner corpuscles) have small and well-limited receptive fields and the conduction velocity

is 55–60 m/s. Type II receptors (Ruffini and Pacini corpuscles) have broader and less limited receptive fields and the conduction velocity is 45–50 m/s. In hairy skin, mechanoreceptors are perifollicular free nerve endings, Merkel complexes, lanceolated endings, and Ruffini corpuscles.

1.2 Thermoreceptors

They are mainly C fibers and have a very slow conduction velocity (0.5 m/s). The impulse frequency is proportional to the stimulus intensity and frequency. Two different receptors have been isolated: cold receptors (<30 °C) and heat receptors (32–48 °C). There is an overlap area around 30–40 °C, where variations of temperature are more important than temperature for activation of these receptors, which explains the possibility of paradoxical cold. Temperatures lower than 20 °C or higher than 45 °C are discerned as painful.

1.3 Nociceptors

They are unmyelinated free nerve endings (Cesaro 1994). Three types are described:

- A δ fibers, sensitive to strong mechanical stimulations (bite, pinching, cut)
- Common C fibers, sensitive to mechanical, thermal, and chemical stimuli and to numerous mediators (neurotransmitters, cytokines, eicosanoids, etc.)
- “Silent” C fibers, activated only after a chemical or biochemical sensitization, especially by mediators of inflammation

Table 1 Sensory receptors in the skin

Type	Subtype	Stimuli	Type of nerve ending
Mechanoreceptor	Type I	Quivering, touch	Meissner, A β , C
	Type II	Vibration, pressure	Pacini, Ruffini, A β
Thermoreceptor	Cold	<30 °C	C, A δ
	Heat	32–48 °C	C
Nociceptor	Mechano-	Excessive mechanostimulation	A β , A δ
	Polymodal	Inflammatory mediators	C
Pruriceptor	See Table 2		

1.4 Pruriceptors

These receptors have been recently isolated (Schmelz et al. 1997) and are specific of pruritus or rather selective for pruritus. Itch is specific of the skin and some close mucosa and seems to originate in epidermal and maybe subepidermal nerve fibers, A δ fibers, and mainly C fibers.

It has been initially shown that there were mechano-insensitive and heat-insensitive C fibers that discharged upon histamine iontophoresis and whose firing frequency paralleled the itch magnitude rating on a visual analog scale (Schmelz et al. 1997). Then histamine-sensitive mechano-insensitive spinal neurons with very low conduction velocity and conveying impulses to a distinct part of the hypothalamus were discovered in the cat (Andrew and Craig 2001). These data point to “a specific population of chemo-nociceptors responsible for itch forming a labeled line for itch processing” (Schmelz 2002).

Since these discoveries, many others have been performed and the following classification of pruriceptors can be proposed, dividing them in two types (Misery and Ständer 2010) (Table 2):

- Histamine-dependent pruriceptors
- Histamine independent that are mainly activated by cysteine or serine proteases like mucunain or tryptase, through PAR-2 receptors.

2 Pain

The international definition of pain is “a sensory and emotional experience, which is disagreeable and linked to a potential or existing tissular lesion, or described as such a lesion” (Cesaro 1994). It corresponds to an excess of nociception, and accordingly, pain appears beyond a threshold. Cutaneous pain is mainly acute, and generated by physical, chemical, or thermal traumas, but can be chronic. Pain is not so frequent in the course of skin diseases (mainly in leg ulcers or in de-epidermization processes like in Lyell’s syndrome) but it can be present in the course of

Table 2 Pruriceptors

Fibers C	Histamine (H1R)	Cowhage (PAR-2)
Mécano-insensibles (TRPV1–)	+	–
Mécano-sensibles (TRPV1+)	+	+

neurological or neuro-dermatological diseases. The central integration of pain plays an important part, through its psychological repercussions.

From nociceptive receptors, painful information is conveyed by the usual ways (see above). Intimate mechanisms of pain remain far from elucidated. External painful stimuli as well as numerous chemical substances, such as bradykinin, histamine, serotonin, prostaglandins, interleukin-1, etc., are able to modify or induce nociceptor activation. Substance P is the most well known and the most important mediator of pain, but others have been more recently described (CGRP, somatostatin, glutamate, etc.).

At all levels (the skin, spinal cord, brain), a “gate control” is permanently in operation. Serotonin and norepinephrine but particularly endorphins and enkephalins have endogenous analgesic effects. Pain is usually due to an excessive stimulus but can be also related to a lack of normal sensation gate control.

3 Itch

Pruritus or itch is an unpleasant sensation that causes a need to scratch (Misery and Ständer 2010; Bernhard 1994). Pruritus does not appear as a minimal pain, as it is often thought, because they are two different sensations. It occurs on the skin and external mucous membranes (genitalia, lips) rather than internal ones; it induces scratching, is exacerbated by heat or morphine-related drugs and soothed by cold, and can be triggered by very low stimuli. Pain is not specifically cutaneous, induces withdrawal, is exacerbated by cold and soothed by heat and morphine-related drugs, and is experienced beyond a relatively high threshold.

Pruritus can be acute or chronic. It occurs in a variety of circumstances: inflammatory skin

diseases, accumulation of toxins (related to liver or kidney diseases), and systemic diseases (mainly blood and endocrine diseases). Exogenous agents (chemical products, drugs) can induce itch. But it can be only neurogenic or psychogenic.

Central integration of pruritus is very important, but there is no one itch center because itch is related to interactions between sensory, motor, and affective areas in the brain. Gate control probably exists at different levels. Senile pruritus and maybe diabetic pruritus or certain neurological pruritus seem to be due to desafferentation.

Histamine is the most well-known mediator of itch, but it plays no role in most cases. That explains why antihistamines are usually ineffective. Substance P, serotonin, and prostaglandins are probably more important factors. Endogenous or exogenous morphine-related compounds can also induce pruritus, as well as cytokines such as interleukin-2 or interferon- α , some proteases (trypsin, papain), or kinins (kallikrein, bradykinin), and can be soothed by substances such as ciclosporin.

Boundaries method • Forced selection method • Laser stimulators • Levels method • Peltier's effect • Stairs method • Tactile sense • Thermal sensory analyser (TSA) • Threshold value

The clinical investigation of the skin sensory function is well codified. For long, a cotton pad, a needle, a diapason (100 or 128 Hz), hot or cold water have been the main tools used by clinicians. Pieces of different fabrics or other various objects in metal, wood, or plastic which can be calibrated can also be used. It is then possible to investigate the perception of shapes, weights and textures. However these tools are not standardised and their main drawback is their selection by the investigator. Quantitative exploration, more adapted to clinical research and psychophysiology, requires several standardised and reproducible techniques which necessitate a more costly and complicated equipment.

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

1 Tactile Sense

Blix and Von Frey were the first to develop a standardised method. They used human or horses hairs which are better because of their stiffness and changeable diameter and length. The pressure exerted by a hair on the skin, measured in g/m^2 , allowed to test the skin low threshold receptors. Von-Frey (1897) developed a standardised system

involving one hair placed in a graduated beaker. The pressure could be adjusted by the investigator. Depending on its intensity, a touch sensation, then a pressure sensation could be induced. Beyond a certain threshold and(or) according to the tested site (mucous membrane, cornea), it was possible to obtain a painful sensation. The interest of this method was to provide reliable and reproducible results. This technique is still valid, although its implementation is often time-consuming.

Since then, laboratories have developed more sophisticated stimulators using computer technology and robotics (Dotson 1997). These systems have been set up to meet the specific requirements of some groups working on peripheral neuropathies (reviewed in Dick et al. (1993)). The patient is placed in comfortable conditions in a quiet room and the stimulator is placed on different sites selected by the investigator (hand, foot, face, etc.). In these conditions :

1. The stimulus is measured by the device. Its physical characteristics are therefore constant from one experiment to the other;
2. The device proposes varied and reproducible experimental paradigms. They permit obtaining normative values established in each laboratory on healthy subjects. They are used as references to assess the sensitive thresholds in patients. These paradigms, independent from the stimuli physical characteristics, are described in the following chapter;
3. It is possible to select the type of stimulus (pressure, vibration, differentiation, shifting. . .) and its intensity, and therefore to study with accuracy the different types of receptors or fibers affected by a disease.

Sensitivity to skin mechanical distension has been measured using a suction device (Cutometer SEM 474, C + K Elektronik, Köln, Germany) (Martalo et al. 2001). Two parameters were selected : the pull sensation threshold during a progressing suction force (25 mbar/s), and the pull sensation threshold following sudden suction at increasing force. The latter was found significantly lower. The authors speculate that a

progressive suction might stimulate slow adaptating nerve endings whereas sudden suction would involve fast adaptating nerve endings. Accordingly the method could permit measuring separately these two types of mechanoreceptors.

2 Temperature Perception and Pain

The most accessible method is the one using a Peltier's effect based thermode. Many authors use the Thermal Sensory Analyzer (TSA-2001[®]) developed by the MEDOC company. This stimulator, attached to the skin, consists of a contact plaque (30 × 30 mm), three thermistances and a water circuit. In the Peltier's effect, an electric current runs through a semiconductor and produces a temperature gradient in the contact plaque. The gradient direction depends on the current direction. The water circuit permits to cool down or heat up the surface opposite the contact plaque. The stimulator mechanism allows temperature changing rates of 0.3 °C/s up to a maximum of 2–4 °C depending on the type of stimulation, cold or heat respectively. The thermistances allow to continuously monitor the contact plaque and the hydraulic circuit temperatures, the latter acting as a safety device. The patient has at his disposal a response box with two buttons: one is for affirmative answers, the other for negative answers. The whole TSA-2001 system is connected to a computer which selects and rules the different stimulation methods

2.1 The Boundaries Method

The temperature applied on the skin rises gradually at a constant rate starting from a neutral temperature (no thermal sensation). When the patient feels the selected sensation (heat, cold, pain) he presses the YES key, thus establishing a threshold value. This test is repeated and the final threshold value is defined as the mean of all test. The thresholds obtained with this method are often over-evaluated.

2.2 The Levels Method

In this technique, prior to the test, the investigator chooses the temperature step which will be added to the adaptation temperature during the first stimulation. This step must be sufficiently high. If the subject answers YES, this step is divided by two and again added to the adaptation temperature. If the answer is NO, the temperature is increased by the full step. This operation is repeated in order to refine the threshold value which is defined as the mean of the last positive value and the last negative value.

The stairs method is a variant in which the investigator chooses three stimulation steps (large, intermediate and fine) to refine the threshold search.

2.3 Forced Selection Method

Its principle is to propose two stimulations to the subject, at random (one is significant, the other neutral) to which he must answer by yes or no. The efficient stimulation is generally selected among three pre-defined steps. The threshold admittedly corresponds to the intensity which generates 50 % of positive responses. This method takes longer than the previous ones, but is the most rigorous (Arendt-Nielsen 1990) because it reduces the bias obviously associated with both the subject and investigator.

The TSA 2001 device is therefore perfectly adapted to the study of threshold to heat and cold (whether painful or not). The radiant stimulator (Socrel Model DS 20[®] Ugo Basile, Varese, Italy) is used in some studies, however less frequently since it provides one type of stimulus only (heat).

Since its development by Mor et al. (1975), the laser (type CO₂ or Argon) has been of increasing interest in the investigation of nociception. Investigators have at their disposal a stimulation unit which controls the laser CO₂ activation intensity and frequency. However the constraints of this technique must be considered :

1. Stimulation of various sites is possible only if the device is equipped with an articulated arm comprising sophisticated mirror sets. This accessory is mandatory in skin exploration;
2. High intensity or high frequency stimulations generate an erythema, and sometimes a blister. The damage will appear even more easily if the stimulation is delivered to aged or fair skinned subjects.
3. Both the investigator and the control subject or the patient must wear protecting glasses. They prevent cornea lesions caused by the CO₂ laser if the beam accidentally veers off course. This type of laser cannot be responsible for retinal lesions because it is absorbed in the cornea.
4. Only the investigator and the patient should be allowed in the room.

The laser CO₂ generates a very steep rise in temperature (600 °C/s) in the most superficial layers of the epidermis thus activating in a synchronous manner the polymodal receptors to heat, either A δ or C fibers. The skin basal temperature is reached again in 200 ms. The sensation perceived by the patient is either heat attributed to C fibers, or a more or less burning sting attributed to A δ fibers. Above a certain intensity which varies according to individuals, the patient perceives two sensations, first a burning sting (A δ fibers) followed by delayed heat involving the concomitant activation of the slow C fibers. A work by Bromm and Treede (1984) using microneurography showed that the A α and A β fibers do not respond to this type of stimulus. Taking into account the distribution of the polymodal receptors, it is therefore possible to stimulate preferentially A δ or C receptors according to the stimulus diameter (Bragard et al. 1996). The latter can be adjusted through lenses integrated in the stimulator.

Laser stimulators, still at a development stage, are mainly used to study the cortical projections of the spinothalamic paths in humans (Bromm et al. 1991; Valeriani et al. 1996). It is then possible: (1) to record evoked responses on the scalp using surface electrodes; (2) to observe metabolism modifications in functional imaging; (3) to test the efficiency of analgesics or topical preparations such as

EMLA ointment or capsaicin (Beydoun et al. 1996).

It is also possible to activate the mechanonociceptors with a stimulator which delivers a force expressed in g onto the skin surface (Basile algometer[®]; Ugo Basile, Varese, Italy).

3 Sympathetic Nerve Functioning

A direct correlation was found between firing rate and amplitude of the sympathetic nerves and the sweat response on palms and soles (Macefield and Wallin 1996), measured in terms of the number and amplitude of spontaneous skin conductance waves. This was used to investigate the development of the sympathetic nervous system associated with arousal in the first year of life. The mean skin conductance level at 88 Hz, the number of waves per second, and the amplitude of the waves were measured during spontaneous skin conductance changes, and after auditory stimulation (Hernes et al. 2002).

4 Conclusion

The various techniques to study the skin neurosensorial functions are more adapted to clinical research than current practice. Their implementation is heavy and requires important and costly logistics (computer scientists, technicians, engineers. . .). It often implies work in collaboration with people in the industry. Their interest is growing however, especially as they open the way to more accurate studies on the skin neurosensorial functions.

Quantitative thermal testing • Thermal sensory analyzer • Warm sensation • Cold sensation • Cold pain • Warm pain • Itch magnitude • Itch duration • Thermoreceptors • Nociceptors • Mechanoreceptors • Polymodal nociceptors • Diabetic neuropathy

1 The TSA-ii Model, and How It Works?

TSA-ii unit is connected to a laptop or computer for user interface and control of functions of the unit through the unit's software that can be loaded onto the CPU. A thermode that delivers temperature/pain sensations to the subject is also attached to the TSA-ii unit and is controlled by the software on a computer. Also attached to the TSA unit is a handheld control that can terminate the temperature signal coming in from the unit through the thermode if the subject feels pain in pain threshold testing as well as communicate sensation perception (hot/cold) to the machine once a sensation is appreciated, simply by pressing a button on the handheld control. The software records this threshold and also automatically compares the subject's threshold perception of sensation to his/her age-specific normal values.

The machine uses a Peltier's effect-based thermode and is, in effect, a thermal stimulator. This thermode is attached to the skin and has a contact plaque (or contact surface) of 30 × 30 mm, three thermistors (that measure the local skin surface temperature), and a water circuit. An electric current runs through a semiconductor and produces a temperature change in the contact surface of the thermode. The water circuit allows for cooling and heating of a surface opposite to the contact surface. Temperature can be changed at a rate of 0.3 °C, up to a maximum of 2–4 °C. The thermistors continuously check the temperatures of the contact surface and the hydraulic circuit temperatures (which act as a safety device). As described above, the patient has a control box with

two buttons: one for affirmative responses and the other for negative responses. Finally, the whole TSA is also connected to a computer, which provides the interface to select and control different stimulation methods.

2 Receptors Involved in Thermal Sensation Induced by TSA Machine

Thermoreceptors: Contrary to nociceptors, thermoreceptors have a low activation threshold. The neuron-free endings that are sensitive to heat are comprised of type C fibers and are less numerous than those sensing for cold. Their diameters are 1 mm and activated for temperature variations between 30 °C and 45 °C with max sensitivity between 41 °C and 45 °C. Above 45 °C, nociceptor nerve endings are activated and the thermoreceptor decreases its firing.

Cold sensitivity is conveyed through the thermoreceptor nerve ending activation carried by fibers A-Delta and C. The receptive field is small as the free nerve ending has a diameter of 100 μm. They fire sensory signals when the temperature range is 0.5–20 °C; in this range they are activated especially if there is a sharp drop in temperature. They stop firing once the temperature range is back to the body's basal level. In the temperature range of 30–40 °C, both cold and warm fiber types can be active.

Nociceptor: These receptors are innervated by slightly or nonmyelinated nerve endings. These fiber types have a **high** threshold of activation, and their response increases in parallel to the intensity of the stimulus. Two types of nociceptors exist: mechanonociceptors and polymodal nociceptors.

Mechanonociceptors: These are slightly myelinated A-Delta fibers. Receptive fields are large (1–2 cm) and these are involved in quick and well-located stinging, pinching, and cutting sensations. Response is proportional to intensity but decreases on repetitive stimuli (inactivation phenomenon).

Polymodal Nociceptors: Primary afferent fibers are Type C and not myelinated; there are a

smaller number of A-Delta fibers as well. Receptive field is 1 mm² to 1 cm². These receptors respond to sharp and strong mechanical stimulations; they also code for temperature rising above 43 °C as painful. In this case, the subject feels a sharp, sudden heat followed by a longer delayed heat sensation. This is an example of initial fast conducting A-Delta activation and then activation of slower C fibers. C fibers respond to chemical stimuli such as bradykinin, histamine, and other irritants as well (Fig. 1 and 2).

3 Clinical Applications

Different medical conditions that utilize the TSA's abilities and testing are fibromyalgia, painful neuropathies, lumbar radiculopathies, small fiber allodynia in Complex Regional Pain Syndrome (CRPS), underlying central nervous system impairment in difficult-to-diagnose patients, **early detection of diabetic neuropathy of small caliber fibers**, entrapment and toxic neuropathies, testing to detect malingerers, and nerve root compression/inflammation.

4 Clinical Experiments Utilizing the TSA

4.1 Antipruritic and Thermal Sensation Effects of Hydrocortisone Creams in Human Skin

This experiment measured the effects of topical corticosteroids on thermal sensation and itch induced by histamine injections that were intradermal (Zhai et al.).

Itch was measured via (i) itch magnitude and (ii) duration; and thermal sensation was measured using the TSA unit, with categories of warm sensation (WS), cold sensation (CS), cold pain (CP), and warm pain (WP). Itch magnitude was measured each minute for 10 min using a Visual Analogue Scale (VSA).

Histamine was injected in four separate areas spanning both forearms, and these four areas were each applied with (i) hydrocortisone 1 %, hydrocortisone 2.5 %, placebo, and histamine ONLY, which may have served as control. This was a double-blind, random, comparative, controlled, single-dose, and single-center study involving 18 subjects; 2.5 % hydrocortisone considerably reduced **itch duration** from 12.6 + or - 11.0 min (mean + or - SD) to 8.6 + or - 8.2 min (reducing rate being 32 %) as well as **itch magnitude** at minutes 3, 6, 7, and overall ($p = 0.03$). Placebo, 1 % and 2.5 % hydrocortisone significantly altered **cold sensation threshold** ($p < 0.05$).

The data suggest that topical application of 2.5 % hydrocortisone may be significantly beneficial for histamine-induced itch.

4.2 Quantitative Sensory Testing: Effect of Site and Skin Temperature on Thermal Thresholds

Objective was to determine the effect of different sites and local skin temperature on thermal thresholds. Cool and warm detection (coolDT, warmDT) and cold and heat pain thresholds (coldPT and heatPT) were compared in 46 normal volunteers at the (i) thenar eminence (TE), (ii) dorsum of hand (DH), (iii) volar surface of the wrist (VW), and (iv) dorsum of foot (DF) (Hagander et al.).

The hand was more sensitive to warm and cool sensation than the foot. In regards to the upper limb, TE was more sensitive for warm than DH and VW, although this difference is clinically negligible. DH and VW were equally sensitive to warm, and TE, DH, and VW are equally sensitive to cool sensation. Interindividual variance is least at TE. Warm and cool thresholds are independent of local skin temperature (range 27–37 °C). TE is less sensitive for cold *pain*, but otherwise the hand and foot are equally sensitive to thermal pain.

Fig. 1 TSA-iiNeuroSensory Analyzer System, with a laptop showing the loaded software interface (From: <http://www.medoc-web.com/products/tsa-ii>)

Fig. 2 (a) 30 × 30 mm thermode. (b) 16 × 16 mm thermode. (c) 5 × 5mm thermode (From: <http://www.medoc-web.com/products/tsa-ii/tsa-ii-accessories>)

TE is preferred for thermal sensation thresholds as it has least interindividual variability. TE is also preferred in evaluating hyperalgesia to cold due to the higher threshold to cold pain.

By determining the effect of different anatomical locations, as well as local skin temperature, on thermal thresholds, the goal is therefore to essentially compare and contrast the thermal thresholds at different sites of the human body: hand, wrist, and foot areas in general; and if there are any differences of thermal threshold sensation/pain at these sites, a preferred site of testing for a particular sensory threshold can be identified. Thus, four thermal modalities as mentioned above were tested (coolDT, warm DT, coldPT, and heatPT), and the effect of local skin temperature

on cool and warm thresholds at the hand and the need to warm or cool the skin prior to testing was also tested.

4.3 Effect of Venlafaxine on Ongoing and Experimentally Induced Pain in Neuropathic Pain Patients: A Double-Blind, Placebo-Controlled Study

A randomized double-blind placebo controlled study investigated the effectiveness and safety of Venlafaxine XR (SNRI reuptake inhibitor) 75 and 150 mg, on ongoing pain and quantitative sensory testing in 60 patients with neuropathic pain for 8 weeks (Yucel et al. 2005).

Allodynia and pin-prick pain showed a significant decrease in venlafaxine groups compared to placebo. Pain threshold and summation threshold for electrical stimuli, as well as summation threshold for heat stimuli, showed that these thresholds increased significantly following treatment with venlafaxine, that is, more stimulus is required to produce the sensation.

Moreover, the degree of summation of electrical and heat stimuli decreased in the venlafaxine groups compared to placebo.

Therefore, Venlafaxine has significant effect on pain as well as electrical and thermal temporal summations.

4.4 Concentration-Effect Relationships for Intravenous Alfentanil and Ketamine Infusions in Human Volunteers: Effects on Acute Thresholds and Capsaicin-Evoked Hyperpathia

Ketamine and Alfentanil both decreased capsaicin-induced pain and increased the threshold of von Frey hair induced pain. Alfentanil also increased the thresholds for cool and warm sensation detection (Wallace et al. 2002).

Furthermore, the authors state that these studies provide a usefulness in human pain models for phase 1 clinical trials, as these experiments can help define efficacy of analgesics.

4.5 Oral Opioid Administration and Hyperalgesia in Patients with Cancer or Chronic Nonmalignant Pain

This study challenged the finding of previous research that after parenteral administration of opioids, animals had an increased latency for paw withdrawal to heat and mechanical stimuli, that is, after the opioid, they would more quickly withdraw their paws on painful stimulation and that, likewise, there is an increased pain sensitivity

in humans after postoperative infusions of short-acting opioids, or in drug addicts (Reznikov et al. 2005).

This study explored any possibility of difference between opioid and nonopioid analgesic treatment in cancer-related or chronic nonmalignant pain subjects.

The results showed no differences were found for gender, age, duration of pain, or duration of treatment. No differences were found in punctuate, pressure, and heat pain thresholds or suprathreshold heat pain intensity.

Therefore, like nonopioid analgesics, common doses of opioid analgesics do not result in abnormal sensitivity to pain as purposed by previous research.

4.6 fMRI Measurement of CNS Responses to Naloxone Infusion and Subsequent Mild Noxious Thermal Stimuli in Healthy Volunteers

Using the fMRI machine (functional magnetic resonance imaging) and thermal stimuli via TSA, a study was done to understand the effects of naloxone on opioid systems and the drug's effect on the CNS response to mild noxious heat. Out of the two groups, normal saline and naloxone, naloxone group shows more cortical and subcortical activation. With a 46 °C stimulus, there was activation in insula, orbitofrontal cortex, thalamus, and hippocampus, in contrast to the normal saline group.

These results show that naloxone has effects in brain regions (cortical & subcortical) when given alone, that is, without psychophysical (heat) stimulation, and with heat stimulation has effects in different regions of the brain producing activation in regions with high levels of mu-opioid receptors that maybe involved in endogenous analgesia. Furthermore, the authors add that this study shows that fMRI can detect subtle changes in brain activation due to pharmacological agents without cognitive effects.

4.7 Dexmedetomidine Pharmacodynamics: Part II: Crossover Comparison of the Analgesic Effect of Dexmedetomidine and Remifentanil in Healthy Volunteers

Sigmoid curves shift to the right for both remifentanil and dexmedetomidine; however, the curve is less steep for dexmedetomidine (Cortinez et al. 2004).

In conclusion, dexmedetomidine is not as effective an analgesic as remifentanil, and the difference may be attributed to different mechanisms of actions of each drug. Dexmedetomidine does have a sedative effect, although authors conclude remifentanil is superior as an analgesic.

4.8 Effect of Remifentanil on the Heat Pain Threshold in Volunteers

This study investigated analgesic properties of remifentanil using heat pain threshold delivered via TSA, and it showed that there were dose-dependent increases in heat pain threshold with the drug. Analgesic effect was opioid mediated, and $0.05 \mu\text{g Kg}^{-1} \text{min}^{-1}$ was found to be an effective and safe increment in healthy volunteers. Remifentanil led to an increase in heat pain threshold differing significantly from placebo (Gustorff et al. 2001).

4.9 Placebo-Controlled Comparison of a Morphine/Dextromethorphan Combination with Morphine on Experimental Pain and Hyperalgesia in Healthy Volunteers

Both morphine alone and in combination with dextromethorphan decreased painful or noxious thermal stimuli delivered via TSA and had somewhat of an effect on secondary hyperalgesia

delivered by brush and von Frey hair stimulation when compared with placebo. However, in clinical trials with humans, morphine/dextromethorphan combo did not provide superior analgesic effect, although this finding is opposite to the preclinical animal trials with the same drugs where there was a potentiation of analgesic effect with the combo.

Thus, adding 1:1 dextromethorphan and morphine combo does not improve analgesia over morphine alone in regards to noxious thermal stimuli and cutaneous sensitization.

This study allows for a possibility of determining optimal dosing or dose ratios in opioid analgesic combination studies.

4.10 Age Differences in Orofacial Sensory Thresholds

This study divides its subjects into two bimodal groups those <45 years of age and those >65 years of age and undertakes testing that aims to determine threshold differences between the two groups, involving thermal (executed by TSA) as well as pain and others. Therefore, thresholds for warm, cool, pain, touch, two-point discrimination, and taste were done (Heft and Robinson 2010).

All thresholds were elevated in the older individuals, and males were less sensitive to females to cool at the chin, touch, and sour taste. The study concludes that there are elevations in sense thresholds for multimodal somatosensory and gustatory senses.

4.11 Disturbances of C-Fiber-Mediated Sensibility in Lumbosacral Disk Disease

This study takes nine patients with lumbosacral disease and compares them with nineteen healthy individuals. Comparison is made between the sensory function of dermatomes in the feet ipsilateral to and contralateral to the leg with lumbosacral disk disease. These results were compared with 19 healthy individuals (Lautenbacher 1994).

Warmth threshold was increased ipsilateral to the lesion, but heat pain threshold is decreased contralateral to the lesion while normal ipsilateral to the lesion. Warmth threshold is normal in the contralateral dermatome. Hence, there is speculation that lumbosacral disk disease may increase sensitivity to pain due to nerve root compression.

4.12 Comparative Study of the Cutaneous Sensation of Leprosy-Suspected Lesions Using Semmes-Weinstein Monofilaments and Quantitative Thermal Testing

This study compared warm perception thresholds (WPT), cold perception thresholds (CPT), and warm and cold perception intervals (WCPI) with touch-pressure thresholds measured via Semmes-Weinstein monofilament (SWM), and hence, these thresholds are described using SWM. These tests were done on leprosy-suspected skin lesions (patch); 108 were total participants, 82 of which were diagnosed with leprosy. Further, the touch-pressure thresholds were measured at via SWN at 0.05 g, 0.2 g, 2 g, 4 g, 10 g, and 300 g (Villarroel et al. 2007).

The results showed a sensitivity of 81.7 % and specificity of 96.1 %, while warm perception threshold (WPT) was 90.2 % and cold perception 92.2 %, with combined 100 % specificity. In those diagnosed with leprosy, lesions that had SWN 0.05 g showed significantly different WPT, CPT, and WCPI values when compared to skin lesions of different etiologies.

In leprosy subjects, as the touch-pressure thresholds (SWN) rise, so do the WPT, CPT, and WCPI. Some exceptions with SWN of 0.05 and 0.2 g did not have increased WPT or CPT. However, all patients with SWN 2.0 g or above did have altered WPT and CPT. In regards to the WCPI, subjects with 0.05 g pressure thresholds had altered WCPI in the skin lesions.

In conclusion, although thermal testing is more sensitive, pressure thresholds also act as valid screening methods to detect cutaneous forms of

leprosy, and these results can help extrapolate the thermal thresholds based on the results above.

4.13 A Comparison of Quantitative Sensory Testing with Skin Biopsy in Small Fiber Neuropathy

This study correlated QST testing and skin biopsies in small nerve fiber neuropathy. It determined that assuming skin biopsies are the gold standard for detecting small fiber neuropathy, the sensitivity of QST for detecting similar neuropathies is high provided that both warm and cold sense thresholds are tested, but the specificity is low at 46 % (Scott et al. 2003).

4.14 Clinical Applications of Quantitative Sensory Testing (QST)

4.14.1 Diabetes Mellitus

QST was used for evaluating and staging diabetic polyneuropathy (PNP). It was set of criteria for assessing severity of diabetic neuropathy based on warm and cold threshold abnormality that was suggested. A significant correlation was found between thermal abnormalities and clinical examination of small fiber function and suggested that these criteria can be used for long-term management of patients (Zaslansky and Yarnitsky).

Combining thermal and vibratory tests gave a joint sensitivity of 92–95 %, with specificity of 77–86 %.

A “warmth sensitivity index,” the range between warmth sensory threshold and heat pain threshold, was suggested as a sensitive tool for detection of neuropathy in diabetics with no clinical evidence of neuropathy.

Natural history of diabetic neuropathy by QST parameters: 201 **well-established** NIDDM patients were followed for 2 years. The increase for vibratory and thermal thresholds during this period was significant between baseline and first year, and between first and second years; for example, warm sensory thresholds increased from 2.6 °C (median value) at baseline to 3 °C

after 1 year, and 3.4 °C after 2 years. Similarly, cold thresholds were 1.9 °C, 2.3 °C, and 2.7 °C, respectively, for baseline, first year, and second year. In contrast, 71 newly diagnosed NIDDM patients had only slight deterioration in VT at the feet over 5 years.

Polyneuropathy was assessed by a pain score, sensory clinical exam, NCS, autonomic function, and *thermal* and vibratory thresholds of the foot. The only parameters to change were a significant reduction in thermal scores that paralleled a decrease in pain scores, which confirms the importance of thermal sensation quantification in patients with diabetic neuropathy.

4.14.2 Alcoholic Polyneuropathy (PNP)

Fifty chronic alcoholics were examined for PNP. All had history of alcohol abuse for more than 7 years, daily alcohol consumption more than 100 g and a positive Munich Alcoholism Test. Six thermal sensation parameters were tested behind the internal malleolus, using the method of limits (Zaslansky and Yarnitsky).

Thresholds for cold sensation were raised in 62 % of patients, warmth sensation in 24 %, and heat pain in 22 %.

4.14.3 Vincristine and Cisplatin Neurotoxicity

Vincristine was seen to have vibratory and thermal sensation alterations, while cisplatin only had vibratory changes (Zaslansky and Yarnitsky).

4.14.4 Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barre Syndrome (GBS))

Twenty-two patients with GBS were tested with the TSA; average was 49 (range 17–49), being tested at outset of disease, at peak disease, and at resolution. At initial sensory testing, 68 % patients had at least one thermal threshold abnormality; at peak of disease, cold sensation at ankle and wrist was abnormal in 73 %, and heat thresholds at ankle and wrist were abnormal in 55 % and 50 % of patients (Zaslansky and Yarnitsky).

4.14.5 Myotonic Dystrophy

Myotonic dystrophy is a pure motor/muscular disorder without any sensory components, but thermal testing revealed otherwise. Twenty-four patients with 0.2–22 years duration of clinical symptoms were tested, and thermal thresholds

Fig. 3 This graph measures the effect on histamine-induced itch magnitude after application of placebo, 1 % hydrocortisone, and 2.5 % hydrocortisone. VAS measures itch magnitude (Modified from Zhai et al.)

were abnormal in 83 %, more at ankle (79 %) than wrist (50 %). Heat sensation was more frequently abnormal than cold sensation. Vibratory sensation at the foot was also deranged in 21 % of patients. Therefore, researchers conclude that Myotonic dystrophy is not a pure motor disease.

The TSA machine is of great use in understanding the thermal thresholds of subjects and more importantly these thresholds in patients with peripheral nerve disease. Not only thermal thresholds can be assessed, but nociceptive nerve function as well, by inducing heat and cold pain through the TSA machine: nerve

endings can code for pain stimuli if the temperature rises above a certain threshold as described above through the different experiments.

This allows researchers and clinicians to assess a person's sensory function by comparing the person's threshold results to normative data, which is available in the software of the TSA machine. As a result, diabetic patients, others with peripheral neuropathies, and their physicians can have a better understanding of how a particular disease process is affecting the patient by picking up any deviations from normative thermal thresholds delineated by the TSA machine. This

Fig. 4 Cool and warm detection thresholds for different anatomic sites. Rectangles measuring the median, 75th, 25th percentiles. Bars measuring 95th and 5th percentiles (Modified from Hagander et al.)

Fig. 5 Error bars measure 95th and 5th percentiles; rectangle measures 75th and 25th (Modified from Hagander et al.)

can be valuable for doctors and patients in diagnosing, managing, as well as prognosing the disease involving the peripheral sensory nerves. Hence, the TSA is an indispensable machine in medicine, and there is no doubt about its precision and accuracy as it inputs data based on the direct responses of the subject, by clicking of the controller, and therefore, the TSA provides an intimate measurement of thermal perception (Figs. 3, 4, and 5).

Itch or pruritus is defined as “disagreeable cutaneous sensation inducing the need to scratch.” These two words are nowadays used as synonyms, “pruritus” being more a medical word than “itch” (Bernhard 1994; Misery and Ständer 2010).

Pathophysiology remains partially unknown but huge breakthroughs have been recently performed (see chapter . . .). Therapeutic possibilities are relatively limited, except etiological treatments. Itch metrology is difficult. However, it is indispensable to evaluate itch in clinical and therapeutic studies. Itch is usually evaluated through human or animal in vivo models. The main instruments of measure are itch experience and scratching.

1 Experimental Induction of Pruritus

Itch can be induced by intradermal injection of histamine, serotonin, substance P, 48/80 compound, codeine, kallikrein, bradykinin, papain, or trypsin or by intravenous injection of morphinics or interleukin-2 (Wallengren 1993; Theunis et al. 2008). In practice, experimental induction of pruritus is usually obtained by intradermal or subcutaneous injection of 48/80 compound (3–100 µg), substance P (10–300 µg), or histamine (3–300 µg) or codeine (Theunis et al. 2008). There is a dose effect but too high doses lead to pain rather than pruritus. The induction of pruritus by cowhage (*Mucuna pruriens*) (Papoiu et al. 2011), which activates PAR-2+ pruriceptors, is a new used technique but a limitation is that the release of proteases is not controlled.

Pruritus can also be provoked by low electric currents. This technique is still discussed because electric currents should induce paresthesia (or pain) rather than itch. They are also able to inhibit itch by stimulation of afferent nerve fibers (Ekbohm 1995). However, electrical stimulation with stimulus durations $>$ or $=$ 2 ms and frequencies $>$ or $=$ 50 Hz seems to evoke a pure itch (Ikoma et al. 2005).

The mechanical induction of itch by esthesiometer (WEST-itch™, Connecticut Bioinstruments Inc.) has been proposed. This device is formed by nylon fibers with different diameters (Weinstein et al. 1995). Five bundles of nylon fibers allow different levels of stimulation. This equipment is simple but somewhat expensive.

2 Qualitative Aspects of Pruritus

The evaluation of qualitative aspects of pruritus is based on clinical examination and anamnesis (Misery and Ständer 2010; Misery 2012). Clinical examination is focused on scratching lesions (quantity, deepness, localization, disposition), prurigo lesions, dermatographism, and lichenification.

Cutaneous or systemic symptoms can be associated and they can orientate etiological diagnosis. A glazed aspect of nails is in favor of intense and old itch. History specifies itch features:

- Date and mode of beginning (sudden or progressive)
- Course (acute, paroxysmic, or chronic)
- Chronology (moment of the day, period of the year)
- Intensity (discomfort in working, everyday life, affective life, or sleep)
- Topography
- Aggravating factors (sweating, sport, bath, shower, meal) or soothing factors (cold, relaxation)
- Associated context (diseases, drugs, chemical products)
- Collective pruritus or not
- Effects of treatments

It is necessary to discriminate what is really pruritus and what is paresthesia, dysesthesia, or pain (that could be associated with itch, especially in neuropathic pruritus). It may be difficult in certain languages, especially in Africa or in Middle East, because there is no traditional word to differentiate these sensations.

There is no universally accepted questionnaire on pruritus (Weisshaar et al. 2012), whereas there is some on pain. In order to study qualitative aspects of itch, the Eppendorf itch questionnaire (Darsow et al. 1997) or the Brest questionnaire (Brenaut et al. 2013) could be used.

3 Intensity Measurement of Pruritus

The intensity of pruritus can be correctly evaluated only by the transcription of its experience by a human being. The appreciation by an observer is a bad method. Measurement of scratching intensity is possible with animals or humans but is only an indirect reflection of pruritus (see below). The measurement of itch intensity is difficult because it is subjective and dependent of experimental

conditions (e.g., deepness of injection of an itch inducer). Nonetheless, several methods have been proposed for the evaluation of itch intensity. They are inspired by pain evaluation scales.

Measurement scales are available. Some types are possible: nominal, ordinal, interval, or ratio scales. Nominal scales are the most simple (e.g., pruritus or not). Ordinal scales are semiquantitative (no pruritus, weak pruritus, moderate pruritus, severe pruritus). Interval scales are more accurate (from 1 to 8, from 1 to 10, from 0 to 11 for the Esthesiometer[®]). Ratio scale is more efficient because a true zero is defined and 2 means the double of 1. In therapeutic scales, the three first scales are the most often used. Statistical analysis of these scales is parametric (interval, ratio) or not (ordinal, nominal).

Ratio estimation scales allow comparisons of intensity of pruritus between themselves. The subject estimates intensities of itching induced by electric current of different intensities, saying, for example, “30 % more” or “30 % less.” This method is criticized and is not used on itching induced by diseases.

With magnitude estimation scales, the subjects can choose a number without any limitation. This type of scale is relatively reliable and has been used in the measurement of various human sensations.

Graphic rating scales are simple, convenient, well validated, and the most commonly used. We personally prefer them. The subject indicates by a mark on a vertical or horizontal line the intensity of pruritus. Each extreme of the line represents “no itch” or “maximal itch.” Most often a 10-cm scale is used, with or without cutoff points. The investigator converts the marking to a score by measuring the distance between the zero end (no itch) and the perpendicular mark on the line with a grid. The advantages of such scales are simplicity, sensitivity, and reproducibility. Nonetheless, some subjects may cluster their rating marks at the midpoint and the extremes of the scale. Others may have a decreased ability to think abstractly. Results are comparable in a same subject but not between several subjects.

Numerical rating scales are sometimes used for therapeutic studies. There is a need to propose a limited but discriminating quantity of numbers, as 3, 5, or 10 numbers. The validity of these scales has been shown for ratings of pain, but it is not yet the case for itch because numerical rating scales have been rarely evaluated for itch research.

Itch can be recorded by some proceedings. Itching is induced and then the subject indicates what he experiences with a pen or a plotter related to a potentiometer (Ekblom et al. 1984). The time interval between itch provocation and start/stop of itch is recorded as well as the perceived itch intensity. This allows the calculation of several itch variables: latency before itch, duration of itch, peak value of itch, and a total itch index (= area under the curve). This index reflects both the intensity of itch and its duration. A computerized system (PainTrack[™] or SymTrack[™], Styrex AB, Uppsala, Sweden) allows the continuous recording of itch sensation, as for arterial pressure. This proceeding could be the best to evaluate itching and to estimate efficacy of a treatment but it is little used.

The International Forum for the Study of Itch gives some recommendations (Ständer et al. 2013) to clarify the measurement of the intensity of itch:

- Visual analogue scale (VAS) is not an optimal instrument, but currently it cannot be dispensed with.
- Alternatively, numerical rating scale (NRS) can be used.
- VAS or NRS should be used in combination with verbal rating scale.
- Explanation and test run are recommended.

4 Measurement of Scratching Intensity

The appreciation of pruritus through scratching in humans or in animals is often used but its interest is limited. A weak pruritus does not induce scratching. Paresthesia, dysesthesia, or pain can induce scratching. The presence of probes on the

skin surface can induce pruritus or be embarrassment for movements. Nonetheless, some techniques are available to measure scratching (Savin 1995).

The intensity of scratching can be estimated by quantity and size of excoriations, prurigo lesions, or dermographism lesions. A video record can be useful to observe scratching.

The recording of scratching is not easy because scratching is not a regular activity. Duration, frequency, intensity, direction, amplitude, and localization of scratching actions are highly variable. It is difficult to separate one movement of scratching from the next. Several methods have been invented in order to measure one or several parameters of scratching.

The amplitude of movements can be registered, thanks to special wristwatches measuring the duration of scratching through movements in space by detectors of electromagnetic movements (Summerfield and Welch 1980). This method is particularly interesting for studying pruritus during sleeping time.

Beds with detectors of vibrations can be used to detect movements of scratching. These movements are different from other movements by their irregular and repetitive characteristics (Felix and Shuste 1975).

Electrodes posed on forearms can measure muscular movements (Savin et al. 1973). This technique is convenient and reproducible. Beginning and end of the movements as their amplitude and their number can be assessed. This exam can be associated with registration of sleep to detect variations according to different phases of sleep.

Electroencephalogram can be coupled with measurements of pressure induced by scratching, thanks to probes on hands or nails (Brown and Kalucy 1975). More accurate measures are allowed by a proceeding inspired by this one and associating a computer and vibration transducers (using piezoelectric current) (Bergasa and Jones 1991).

Another proceeding has been recently proposed (Endo et al. 1997). Scratch-Monitor[®] is a little box with button which detects variations of pressure and a recording module attached to one

hand. Number of movements is counted. Sensitivity is moderate.

5 Conclusions and Perspectives

Quantitative measurement of pruritus is difficult. Clinical examination and anamnesis allow an individual but inaccurate evaluation. For scientific working, especially therapeutic assays, there is a need to use simple techniques of measurement of pruritus or scratching. Scales of pruritus will probably remain the main methods to assess itch.

In our opinion, the methods revolutionizing studies on pruritus in the future could be:

- In vitro studies, on a reconstructed skin associated with nerve fibers or on cocultures of nerve fibers and epidermal cells (Pereira et al. 2010)
- Studies on the cerebral integration of itch, by using positron emission tomography (PET) or functional resonance magnetic imagery (fMRI) (Bergeret et al. 2011)

Acetate sheets • Morphometry • Lesion surface
• Point counting • Videocapillaroscopy

Morphometry embraces a number of methods aimed at measuring images or objects of irregular contour or shape as well as image density within a frame, using simple means associated with counting. As skin diseases mostly develop in the plane of the body surface, two-dimensional morphometry can be a valuable tool for the dermatologist who requires rapid and inexpensive measurement. However, the method is poorly known in dermatology because it was principally developed for research in tissue microscopy and ultrastructure.

Novices are advised to read Bahmer and Smolle (1992) and Loud and Anversa (1984) first.

1 Lesion Area

Point counting is the accurate method (Bahmer 1997). The rationale is that in a large area divided into equal squares, the center of each square can represent its area. Thus, when a squared grid with lines d cm apart is superimposed on a skin lesion, counting how many squares lie inside the lesion can be replaced by counting how many centers lie inside the lesion. As the square centers themselves can be replaced by the grid crossing points, the

Fig. 1 Fictitious contour of a leg ulcer as seen through a 0.5-cm-spaced grid. As 31 crossing points lie inside the ulcer and 3 lie exactly on the border ($n = 34$), the ulcer area is $34 \times 0.5^2 = 8.5 \text{ cm}^2$. As the grid crosses the outline 24 times vertically and 25 times horizontally, $n = 49$ and $P = 0.5 \times 49\pi/4 = 19.2 \text{ cm}$. $\text{RF} = 64 \times 34/\pi 49^2 = 0.29 \text{ cm}^{-1}$

lesion area (A) is the count of crossing points (n) multiplied by the unit square area (d^2). The formula is straightforward:

$$A = n d^2$$

(points falling just on the outline should be taken).

Example To find the area of a leg ulcer, a transparent sheet on which a grid with lines 1 cm apart has been printed is applied on the lesion. If 26 crossing points have been counted inside the lesion or on its border, the ulcer area is 26 cm^2 . See also Fig. 1.

Caution To avoid uncertainties with thick lines, a crossing point is defined as the precise outline of the upper right angle of the cross, and not its center, as shown below:

Accuracy The method is valid only if either the lesion has a random outline or the grid has been randomly superimposed on the lesion. The method is only an estimate, but surprisingly adequate. For a given object, the smaller the grid interval, and the higher the number of counted points, the more accurate the assessment is. Using a grid with lines 0.5 cm apart: for a circle 1.6 cm in diameter: $\pi^2 = 2.01 \text{ cm}^2$, $A = 0.25 \times 9 = 2.25 \text{ cm}^2$ (+12 %); for a circle 2.6 cm in diameter: $\pi^2 = 5.31 \text{ cm}^2$, $A = 0.25 \times 21 = 5.25 \text{ cm}^2$ (-0.9 %). In the same way, using grids with small intervals favors more reliable measurement. The most appropriate grid spacing can be deduced from Weibel's nomogram (Weibel 1979). The theoretical efficiency of point counting has been studied by Gundersen (Gundersen et al. 1981; Gundersen and Jensen 1987).

2 Lesion (Line) Contour (Length)

A squared grid (interval width = d) is randomly applied on the lesion or the linear feature to be measured (Bahmer and Smolle 1992). Counting the number (N) of intersections of the grid's both horizontal and vertical lines with outline gives the perimeter (P) or the feature length, using the formula:

$$P = N\pi d/4$$

Examples Examples include measuring the perimeter of a leg ulcer (Fig. 1) or the length of telangiectasias (Fig. 2).

Accuracy Using a 0.5-cm interval grid, accuracy is as follows:

- For a circle 1.6 cm in diameter: $2\pi r = 5 \text{ cm}$, $P = 0.5 \times 12\pi/4 = 4.7 \text{ cm}$ (-6 %)
- For a circle 2.6 cm in diameter: $2\pi r = 8.2 \text{ cm}$, $P = 0.5 \times 20\pi/4 = 7.9 \text{ cm}$ (-3.7 %)

Fig. 2 Tracing of several telangiectasias in the medial aspect of the thigh as seen through a 0.5-cm-spaced grid. The lengths are: 1 4.3 cm, 2 5.5 cm, 3 6.3 cm, 4 (ramified) 10.2 cm, 5 4.7 cm, 6 4.3 cm

3 Shape Regularity

A shape regularity factor RF (Bahmer and Smolle 1992) can be computed using the above-mentioned n and N parameters of the lesion irrespective of the grid interval, with the formula:

$$RF = 64n/\pi N^2$$

The RF lies between 0 (extremely irregular) and 1 (circle).

Example See Fig. 1.

Accuracy Using a 0.5-cm interval grid: for a circle 1.6 cm in diameter: $RF = 64 \times 9/12^2\pi = 1.27$; for a circle 2.6 cm in diameter: $RF = 64 \times 21/20\pi = 1.06$.

4 Area Fraction and Distribution

In disseminated lesions, counting their number and mean area is a way to assess the extent of the disease. A reference area, within which lesions will be counted, is determined on the grid. It may be the area of the printed sheet (e.g., 210×297 mm or a 7.25×10.5 " sheet) or any other whose number of crossing points is known or easy to compute. To prevent errors it has been stated that the boundaries of the reference area must be divided into two parts: upper and left sides (marked by thin lines in Fig. 3), and lower and right sides (marked by thick lines in Fig. 3). The latter should be extended beyond the boundaries in order to solve the problem of corner points (Weibel 1979; Bahmer and Smolle 1992).

The grid is put on the skin and all lesions located within the reference area, or crossing or touching its boundaries, except those touching the thick line (also called the forbidden lines (Gundersen et al. 1981)) even beyond the reference area, are counted. The ratio of this number to the number of crossing points in the reference area gives the lesion average area as a fraction of the reference area. As the latter is known, the lesion's absolute average area is obtained. If needed, the distribution of lesions according to area can be found by counting separately the lesions including one point (area = d^2), two points (area = $2 d^2$), etc.

An imperative rule for counting is that only the lesions or features that do not touch or are not crossed by the limits of the reference area can be counted: accordingly, the latter should be clearly delineated on the grid.

Taking into account the biological variation and the frequent fuzziness of boundaries, counting approximately 100 points provides a satisfactory precision (Gundersen et al. 1981). The most appropriate grid spacing can be deducted from Weibel's nomogram (Weibel 1979). The theoretical efficiency of point counting has been studied by Gundersen (Gundersen et al. 1981; Gundersen and Jensen 1987).

Fig. 3 Fictitious skin lesions. Assessment of area fraction and distribution. This figure is aimed at showing (1) the layout of the so-called forbidden lines (*thick lines*) and (2) the objects (lesions) that should be taken for counting crossing points, and those which should not be taken (*in gray*) because they touch the forbidden lines. The grid is omitted purposely to simplify the image

5 Field of Application

Disposable plastic or acetate sheets can easily be printed with a grid with adequate spacing using current squared paper (usually 5 mm spacing) or home-drawn (e.g., 2 mm spacing for small lesions, 10 mm and 20 mm spacing for larger ones).

Leg ulcer shape assessment takes only a few minutes, the main difficulty being determining the outline of the lesion. Such rapidity makes it possible to follow the progress of lesions over time in current practice as well as in drug trials. Changes in nail fungus involvement area with time is another possible application.

In psoriasis, showing a small number of lesions, following up plaque areas over time is easy and fast. The method has also been proposed to improve PASI rating (Bahmer 1989).

Atopic dermatitis extent can be assessed the same way, although lesion delineation is more difficult. Obviating the problem and in addition rating disease severity has been proposed by

Bahmer et al. (1991) (see ► Chap. 136, “Clinical Scoring of Atopic Dermatitis”).

Area is a parameter of positive prick or patch tests. Its quantification is quickly done using a 2-mm interval grid. The latter may easily be made on paper by the clinician and then photographed at the desired reduction on a transparent sheet.

Superimposing a grid on the computer screen displaying a videocapillaroscopy image can calculate the vessel diameters and lengths and the fraction of dermis occupied by blood vasculature.

Morphometry can also be performed on photographs, preferentially enlarged so that more points can be counted, or on slides projected on a grid printed screen. This is an easy task for clinicians. For example, following the number and size distribution of pigmented nevi during adolescence, quantifying the size and distribution of skin lesions in leprosy, following the number and size distribution of bullae in bullous diseases during treatment, quantifying vitiligo, etc., make this technique very useful in current dermatological practice.

In assessment of sweat or sebum excretion by mapping the gland output, the global area, average area, and size distribution of spots can be easily obtained using the area fraction and distribution method on an enlarged photograph or image. In the same way, microscopic dimensions, such as cell sizes, the size and shape of nuclei in malignant/benign tumors, etc. can be assessed rapidly. Indeed for decades, biological research was the only field of application for morphometry.

6 Other Morphometry Parameters

Point counting is especially useful for assessing morphological parameters of two-dimensional shapes or features, as is the case of most skin lesions. Morphometry can also be used to assess the three-dimensional morphology of microscopic objects; when focusing at various depths, each

plane can be considered as a slice and assessed separately. It is a fast and easy task (Loud and Anversa 1984).

Videocapillaroscopy images obtained at different depths in the skin can be processed in this way using point counting in a 3D setting; as the vessel diameters and lengths are known, the overall volume and size of the skin vasculature can be obtained. The same holds true for cutaneous innervation in health and sensory neuropathies. For histological preparations, special tools (dissector, fractionator, nucleator) have been designed (Gundersen et al. 1988a, b; Elias and Hyde 1983; Aherne and Dunhill 1982; Russ 1986).

Colorimetry • Erythema • Gray levels color chart • Hyperemia test • Minimal erythema dose (MED) • Pallor • Red color chart • Vasoconstriction

Healthy skin has a red component which comes from the subepidermal vascular plexus visible through the stratum corneum. The deeper vessels are invisible or look bluish if they are voluminous. The purpura is visible only if it is located in the superficial dermis. It is brighter in color because the red blood cells are extravascular. The red component of the skin depends on the subepidermal plexus volume, the vasodilatation level, and the overlying epidermal thickness and translucency. A thin epidermis above a rich plexus gives the skin color a homogeneous pink component, as in the case of newborn babies.

Erythema is defined by the accentuation of the skin's red component. Whether macular like in morbilliform or roseoliform rashes, or diffuse like in erythematous patches or scarlatiniform erythemas, the excessive coloring is induced by the vasodilatation of the subepidermal plexus, with or without deeper vasodilatation. As far as measurement is concerned, two main types of erythemas are distinguishable: those generated by the isolated vasodilatation of the subepidermal and perifollicular plexuses, and those which concern all of the skin's vascular networks, including the subcutaneous plexus.

- In the first category, only the skin color measurements are helpful, the assessment of the absorption wavelengths of hemoglobin, and capillaroscopy.
- In the second category (assessment of superficial and deep vasodilatation), it is possible to use photoplethysmography, laser Doppler, thermal clearance, epicutaneous xenon clearance, and skin thermometry (see the dedicated chapters).

Only valid methods for measuring isolated superficial vasodilatation are described below.

Consequently, these are only the ones that can measure the erythematous component of global vasodilatation. Quantitative capillaroscopy, a most promising one, is detailed in ► [Chap. 60, "Evaluation of Port-Wine Stains and Its Treatment."](#)

1 Psychosensorial Techniques

It is common to assess erythema on a five point scale: 0, (+), +, ++, +++. Only four of them quantify the erythema, and the zero value describes the adjacent healthy skin. Some authors use a seven point scale (Westerhof et al. 1986) or a ten point scale (Kollias et al. 1997). The aim of the assessment is to work out two parameters: whether an erythema exists, and its intensity.

- To determine the *erythema threshold*, it is important, especially in photobiology, to find the minimal erythema dose (MED). In an investigation in 21 subjects and 42 photo tests, Lock-Andersen and Wulf (1996) studied the variability of two groups of four observers, well-trained people in one group and less trained people in the second one, working double blind with a five point scale. To detect the onset of a poorly delineated erythema, the variation coefficient was 4.6 % for the untrained group and 7.3 % for the other one, with 11.9 % and 23.2 % detected respectively for the MED (threshold dose for a well-defined erythema, as used in photobiology). These data tend to show that the poorly delineated erythema threshold is better detected with the naked eye than a well-defined erythema threshold and that training has no influence at this level. The intraindividual agreement in two double blind measurements of the same erythema threshold was 90.5 % in the untrained group and 92.9 % in the other.
- The measurement of the *erythema intensity*, following stepwise actinic exposures increasing by 25 % each time, was studied in the course of the same experiment. The agreement between observers decreased with the erythema intensity, reaching 54.8 % only in

the untrained group and 52.0 % in the other one, for class 5 (+++) erythemas; the agreement between two measurements by the same observer was 64.3 % and 71.4 %, respectively. These figures show the large variability of visual measurements, even done by specialists.

Erythema is the more difficult to detect and assess when the skin is pigmented. It is, therefore, essential to be aware of seasonal variations of pigmentation, even moderate, when comparisons are to be made. In black people, the measurement is only slightly reliable, especially since the basic color is often variable and nonhomogeneous.

In every psychosensorial assessment, the lower and upper limits of the measurement scale should be specified. For the measurement of the red component in healthy skin, zero is bloodless skin (pressure with a glass plate, proximal occlusion). To measure a localized redness (erythema), zero is the adjacent healthy skin. At the other end, what is a *very severe* erythema? It may be useful to set up reproducible conditions, but which ones?

The human eye is therefore not able to assess an erythema properly, but only to estimate its intensity. However, it is very sensitive in the detection of redness, but as visual memory is short and unreliable, to detect and grade small differences the areas need to be studied simultaneously and side by side.

2 Visual Assessment Using a Color Chart

2.1 Red Color Chart

A range (ten grades, increasing in 10 % increments) of saturated red Kodak gelatin films (CCR series) placed between two Plexiglas sheets was used as an erythema assessment scale in pig and mouse (Argenbright and Forbes 1982). The films were placed one after the other on the skin, beginning by the lowest grade (lightest color), and the first grade making the erythema limits invisible was considered the appropriate measure. The

advantages and drawbacks of these color charts are described in ► [Chap. 6, “The Measurement of Skin Color.”](#)

2.2 Gray Levels Color Chart

If the skin is examined through green glasses (which convert red into black) the erythema looks gray. When observed simultaneously, it can then be compared to the gray levels of a chart whose luminance (% of clearness) is known. Erythema is then quantified by its degree of luminance. The adaptation of a green filter on a pair of glasses does not present technical difficulty. The gray levels can be easily computer generated and calibrated with a colorimeter.

The advantages of this technique are the absence of contact with the skin, the possibility of eliminating the specular reflection by selecting the angle of vision, and the reference to international physical units which permits comparisons. However, the sensitivity of this method is poor because luminance is weakly influenced by erythema.

3 Photography

Color photography does not provide a reliable quantification of erythema (see ► [Chap. 6, “The Measurement of Skin Color.”](#)). Monochromatic photography uses the same principle as the color chart with gray levels. The skin is photographed (annular flash) with white light through a green filter (540 nm) in the center of a circular chart of 21 levels of gray each varying by 2 % luminance (Breit et al. 1982). The filter and the color chart are attached to the camera so that the incidence angle of the light remains constant. The measurement consists of finding the level of gray matching the erythematous area on the photograph. The device can be achieved with any good camera. The chart has to be made and then calibrated by the user, as explained in the previous chapter. Unfortunately, this simple and cheap method does not measure the chromatic component of the erythema (red), which is its main element, but only the decrease in lightness of this chromatic component.

4 Colorimetry

The red component of healthy skin is measured by colorimeters from the reflectance of three wavelengths, located in the red, green, and blue, and then expressed by parameters L^* and a^* of the Commission Internationale de l'Eclairage (see ► Chap. 6, "The Measurement of Skin Color"). This absolute classification system determines the position in a 3D virtual space for any color. The vertical dimension L^* defines its lightness (or value, or luminance) from zero (black) to 100 (maximal lightness). In each horizontal plane its hue (or chromaticity, or chroma) is defined along two perpendicular axes, one in abscissa (from $-a^*$ = green to $+a^*$ = red), and the other in ordinate (from $-b^*$ = blue to $+b^*$ = yellow). In the final plane, the distance to the origin characterizes its purity, or saturation, or brightness. An erythema increases the parameters a^* which is a measure of the intensity of red, and reduces the parameter L^* which expresses the skin lightness. However, L^* is less correlated than a^* to erythema. Measuring the parameter a^* is equivalent to measuring the quantity of hemoglobin (HbO_2) in the superficial dermis. The erythematous component of 23 body areas studied in winter on ten subjects with the Minolta CR200 chromameter, using the parameters a^* and L^* , were measured by Serup's group (Takiwaki et al. 1994).

It is possible to study the red component of the skin by considering L^* and a^* simultaneously in a vertical plane formed by axes L^* and a^* . In this plane, all the red components of the normal skin of the back in Caucasians (established with the Minolta CR200 chromameter) were found located within a curvilinear area centered on $a^* = 12$; its extreme coordinates were 53 and 75 % for L^* and +2 to +17 for a^* (Fig. 1) (Lock-Andersen et al. 1998). The more a subject's skin was pigmented, the darker the red component, and therefore located in the lower part of the area. Mediterranean type and black subjects show L^* values less than 50 %. As each skin color is defined by its coordinates L^* , a^* , and b^* , erythema and healthy skin can be distinguished by

Fig. 1 Envelope in the L^*a^* plane of the skin's red component in Caucasians (dorsum foot). ◇ very light, ○ light, Δ intermediary, ▽ pigmented. Arrow pointing downward indicates the skin color shift when skin pigmentation increases (From Chardon et al. (1991), with permission)

their coordinate differences (ΔL^* , Δa^* and Δb^*). The difference in hue is $(\Delta a^{*2} + \Delta b^{*2})^{0.5}$ and the difference in lightness and redness is $(\Delta L^{*2} + \Delta a^{*2})^{0.5}$, formulas which are deduced easily from the orthogonal tridimensional structure of the colors' virtual space.

5 Reflectometry (Takiwaki and Serup 1995)

Erythema is related to the dilatation of the subepidermal vessels, therefore to the increased amount of hemoglobin (HbO_2 and/or Hb) in the superficial dermis. As the pigment concentration varies like the inverse of the reflectance (IR), reflectometry is a way to assess this quantity. The technique uses the logarithm of IR (LIR). However, these

Fig. 2 Hemoglobins, bilirubin, and melanin absorption spectrums (Modified after Rox Anderson and Parrish (1981))

wavelengths are also absorbed by melanin. The amount of the latter is determined at wavelengths not absorbed by HbO₂, then subtracted from the LIR.

Reflectometers use green light (from 546 to 568 nm, depending on device), to measure LIR at 543 and 576 nm (HbO₂ absorption peaks), 554 nm (Hb absorption peak), and above 620 nm (red, melanin absorption) where absorption by HbO₂ is negligible but that of Hb, although low, is not (Fig. 2). These devices are small and portable and provide HbO₂ and melanin indices immediately. The Erythema Meter (Dia-Stron, Andover, UK) uses a white light (accordingly it is barely influenced by the ambient light) and measures the reflectance at 546 nm (green) and 672 nm (red). The Derma-Spectrometer (Cortex Technology ApS, Hadsund, Denmark) uses electroluminescent diodes emitting at 568 nm (green) and 655 nm (red). It adjusts the possible contamination by ambient light and allows the measurement at different temperatures. The Mexameter Mx 16 (Courage + Khazaka Electronic, Cologne, Germany) uses electroluminescent diodes emitting

at 568 nm (green), 660 and 880 nm (red and infra-red). The constant application pressure is ensured by a spring. A beep warns of any excessive penetration of exterior light into the probe. UV-Optimise (PBI Medical, Denmark) uses 555 and 660 nm wavelengths; it does not provide indices, but quantifies the pigmentation and the red component of the skin independently, each on a scale between 0 % and 100 %, with the zero corresponding to bloodless skin and 100 % a very dark facial nevus flammeus (purple).

The distribution of the erythema index on 23 body sites in ten subjects showed a remarkable correlation with the value of the parameter a^* in the same location (Takiwaki et al. 1994; Takiwaki and Serup 1995).

6 Spectrophotometers and Spectrocolorimeters

These devices are based on the same principle as the reflectometers, but are more accurate and effective because they can use all the spectrum

wavelengths. According to Clarke et al. (1981), to assess the skin's red component ($\text{HbO}_2 + \text{Hb}$), the interval 415–425 nm (Soret's band) is the most reliable. They have thus evaluated the differences in complexion of 34 pairs of twins.

Andersen and Bjerring (1990) calculated the melanin index by using the interval 360–390 nm (near UVA). To distinguish HbO_2 from Hb he analyzed the reflectance at 543 and 576 nm (HbO_2 absorption peaks) and at 554 nm (Hb absorption peak) taking into account the melanin index. The skin received the polychromatic light of a xenon arc (Osram XBO 150), carried by an optic fiber (Hirschmann, Germany). The retrodiffused light was collected by an integration sphere and conducted by optic fiber to a monochromator (Jobin and Yvon H 20, France) which takes a measurement at every 5 nm between 355 and 700 nm. Each reflectance is detected by a photomultiplier (Hamamatsu, Japan), digitalized, then computer analyzed.

Kollias calculated the melanin index from the 620 and 720 nm wavelengths (both in red) (Kollias and Baqer 1986), and the blood pigments apparent concentrations were measured at 560, 577 and 630 nm after correction for melanin. The light source of a spectrophotometer (HP 8452A DAS) was replaced by a tungsten halogen lamp, and the light conducted to the skin by optical fiber. The retrodiffused light collection was also carried out by a beam of quartz optical fibers. The device scanned the spectrum every 2 nm between 400 and 820 nm.

7 Green Light Laser Doppler

This device (Periflux 4001 Master; Perimed, Stockholm, Sweden) lights the skin with a 543 nm (green) monochromatic light and measures the wavelength shifted retrodiffused light due to contact with moving red blood cells (Doppler effect). The absorption of green by hemoglobin considerably reduces the signal and limits the investigation to the subepidermal plexus. An index of the subepidermal blood flow is provided through multiplication of the retrodiffused light

amount (the moving blood cells' concentration) by the average wavelength shift (the cells average speed). This is the main interesting feature of this device, as no other equivalent equipment is available.

8 Conditions for a Reliable Measurement

- These devices are designed to be used on flat surfaces, which is not the case for skin. Relief may let ambient light penetrate the retrodiffused light collecting chamber. It is necessary to shave the hairy areas and place the subject in a position which reduces any risk of deep creases of the surface.
- For the same reason, measurement in excessive light (direct sunlight, etc.) should be avoided.
- Wet skin or skin with ointment may facilitate specular reflection and artificially alter the data provided by colorimeters and reflectometers. Between 5 % and 7 % of the incident light is diffused by the skin microrelief. The application of a topical that fills the furrows increases light penetration.
- Hydration increases the stratum corneum translucency and can increase the erythema index as well as the parameters $L^*a^*b^*$. This is more obvious for substances with a refraction index close to that of the stratum corneum (stratum corneum 1.54; air 1.00). As glycerol and acetic acid refraction indices are close to 1.54, these compounds are still more efficient than water (Solan and Laden 1977).
- The device needs to be recalibrated prior to each use with the standards provided:
 - It should be held perpendicular to the skin
 - Excessive pressure which could alter the erythema should be avoided
 - A control measurement on the adjacent nonerythematous skin is mandatory
 - As the skin color is often nonhomogeneous (lentigo, achromias, etc.), only average indices from three iterative measurements should be used

Fig. 3 Skin reflectance spectrum of black (A), Asian (B) and Caucasian (C) subjects (Koran et al. 1991), modified). Ordinate: % retro-diffused light. Abscissa: wavelength

- Erythema assessment using a reflectometer is valid only on barely pigmented skin, because the subtracted melanin index, which is measured in red light, is supposed to be identical in green light. However, this is not true, particularly with darker pigmentation, because the melanin spectrum linearly decreases from green to red, with a slope all the steeper because pigmentation is intense (Fig. 3). Consequently, it is not possible to compare the erythema indices of body sites with different melanin indices.
- As pigmentation reduces light retrodiffusion considerably, erythema measurements on dark skin are unsound.
- When interpreting the results, it is essential to consider the relative proportion of HbO₂ and Hb, their color being that of arterial and venous blood, respectively. In the absence of venous backflow or hindrance to normal venous flow, the skin blood is of arterial type. This is also the case in erythemas of active vasodilatation such as in inflammation or from a reactive hyperemia. The measurement of $(\Delta L^*2 + \Delta a^*2)^{0.5}$ or HbO₂ is then appropriate. Inversely, in case of blood stasis or venous backflow, the vasodilatation is passive and the reduced Hb fraction may be important, and induce some change of the color of erythema. Such is the

case in dependent limbs or when the skin has been compressed over a long period of time by the body weight. The measurement of HbO₂ may then be insufficient. It is also important to remember that reduced Hb may augment the melanin index, while skin pigmentation stays unchanged (Agner 1992; Takiwaki and Serup 1994). Consequently, to detect the shift in skin hue due to higher Hb levels colorimetric measurement of $(\Delta a^*2 + \Delta b^*2)^{0.5}$ must supplement that of $(\Delta L^*2 + \Delta a^*2)^{0.5}$.

9 Choosing the Appropriate Method

The suitable method to assess a red component or an erythema will depend on its origin and the physical characteristics of the method.

9.1 Selection According to the Characteristics of the Device

- Colorimeters reconstitute the color of the erythema from reflectance and provide its L*a*b* components. Their capacity to characterize any color, thus erythemas of various hues, is their

main advantage. However, these parameters are indirectly associated with the chromophore skin content (Kollias et al. 1995) and are obtained from three wavelengths only.

- Inversely, the erythema indices given by reflectometers are directly associated with the amount of chromophore, both HbO₂ and Hb since their absorption peaks are very close. They should therefore theoretically be more specific. Comparative studies have shown their results strongly correlated with parameter a* (Takiwaki et al. 1994; Barel et al. 1998), but with a variation coefficient lower than that of a*.
- Spectrophotometers provide more accurate measurements than the above mentioned devices because many more wavelengths are used. They allow the measurement of Hb and HbO₂ separately.
- The green laser Doppler signal is associated with the amount of chromophores and the speed of the blood cells in the subepidermal vascular plexus (Ubbink et al. 1996a; Jünger et al. 1996).
- Instrumental techniques which measure the global skin blood flow rely more heavily on deep circulation whose volume and flow rate are much more important. Therefore, their results sometimes seem in conflict with those of reflectance based methods. The difference is obvious with the measurement of the skin temperature which is very sensitive to global active (arteriolar) vasodilatation, but seems to ignore the superficial blood flow when it is increased separately (Lock-Andersen et al. 1998).
- Since the laser Doppler only deals with circulating red blood cells, it may indicate an increased flow during skin blanching by vasoconstriction, a surprising result probably due to blood flow acceleration. When a limb is lifted higher than heart level its signal increases while the erythema index decreases, and inversely when the limb is lowered (Chardon et al. 1991). Laser Doppler is, therefore, not sensitive to blood stasis, even in deeper dermis or subcutis.
- Clearance methods (thermal clearance, epicutaneous xenon clearance) also based on

the skin blood flow rate, ignore erythemas by passive vasodilatation.

- Conversely, photoplethysmography is an excellent method to measure global variations of the blood volume, associated with active or passive vasodilatation. However, this technique, which uses red or near infrared light, ignores superficial circulation.

9.2 Selection According to the Erythema

- All important active erythemas have a deep component, and therefore are measurable by all the skin blood flow measurement techniques. The relationship between the stimulus intensity and the ensuing signal is linear until clinical assessment grade (++). Beyond this, the signal is saturated, probably because vasodilatation is near its maximum.
- Actinic erythema implies superficial and deep vasodilatation, seemingly from the beginning. It can therefore be measured by all techniques. However, slight erythemas (below MED) seem more reliably measured by reflectance than by imaging laser Doppler (Lock-Andersen et al. 1998).
- Allergic erythemas also seem global and likely to be measured by all techniques. For example, thermography shows that skin temperature rises over allergic patch tests, but not always over irritation patch tests (Baillie et al. 1990).
- Irritative erythemas over a small area seem to mainly involve superficial microvasculature. In such cases, colorimetry (Gawkrodger et al. 1991), reflectometry, and spectrorimetry are preferable. For example, irritation induced by 1 % sodium lauryl sulfate under occlusion for 2 days increased the erythema index much more than the LDF signal, and the erythema index at D2 and D4 was more important than in allergic erythema (Gawkrodger et al. 1991). Moderate and intense irritations are associated with both superficial and deep vasodilatation. The green laser Doppler seems a promising

tool, but has not been used yet for this indication.

- To ascertain if an erythema has a deep component, thermography is a more appropriate technique because it seems insensitive to vasodilatation limited to the superficial dermis, and in particular to the red component changes (Lock-Andersen et al. 1998).
- To detect an infraclinical erythema, that is a vasodilatation of the subepidermal vessels without visible erythema, colorimetry, reflectometry, spectrophotometry and green laser Doppler are the favored methods. During irritation induced by 1 % sodium lauryl sulfate under occlusion for 2 days, the erythema index increased before the appearance of the clinical erythema [19]. The same was obtained after application of anti-pyrine 5 % in water under occlusion for 24 h (Nangia et al. 1996). However, remember that the increased signal may be also related to the sole increased permeability of the stratum corneum to light (especially when it is hydrated, as after occlusion), or to the sole reduction of regular reflectance from an attenuated skin microrelief, and/or from the furrows being filled with a substance whose refraction index is close to that of the stratum corneum (e.g., glycerol (Solan and Laden 1977)).
- Quantitative capillaroscopy (now useable on any body site, see ► Chap. 118, “Cutaneous Testing: Detection and Assessment of Allergy”) together with green laser Doppler may become the reference method to assess superficial vasodilatation, especially at the preclinical stage. Capillaroscopy is sensitive to both active and passive vasodilatations (venular backflow) whereas green laser Doppler is sensitive only to active ones (Ubbink et al. 1996b). To our knowledge the use of these techniques to assess erythemas has not yet been published.
- Laser Doppler might be able to detect deep vasodilatations, such as in actinic or allergic erythema (Wahlberg 1989) and in some irritative erythemas, during their infraclinical stage (Wahlberg and Wahlberg 1984, 1985).
- Irritative erythemas (sodium lauryl sulfate (Kollias et al. 1995), retinoic acid (Kollias

et al. 1997), trauma (e.g., after a slap) (Feather et al. 1988) are associated with the isolated increase of HbO₂. The actinic erythema is associated with the joint increase of HbO₂ and Hb (Andersen and Bjerring 1990). Stasis erythema, especially by increase of the hydrostatic pressure, is associated with the isolated increase of Hb (Kollias and Baqer 1986; Feather et al. 1988).

10 Pallor

Vasoconstriction is an important physiological phenomenon which is worth measuring in some diseases, such as excessive sensitivity to cold or arterial hypertension. It has also been used to assess the activity of topical corticosteroids or their cutaneous absorption in relation to the formulation (Poelman et al. 1984). All the methods used to measure vasodilatation are not valid to assess vasoconstriction. Laser Doppler particularly, which is only sensitive to moving blood cells, may not give out any signal although the clinical blanching is obvious (Noon et al. 1996). Furthermore, a pseudo skin blood flow increase has been shown by imaging laser Doppler (red light) during blanching induced by topical corticosteroids (Sommer et al. 1998), probably caused by blood cells acceleration under vascular narrowing.

10.1 Direct Measurement of Vasoconstriction

Assessment of blanching is reliable using reflectometry by the simple difference of the erythema indices (Noon et al. 1996; Feather et al. 1982; Lévêque et al. 1985). However, because of the time required before the appearance of vasoconstriction (several hours), time during which the blood flow may be altered, replacing the erythema index of the treated zone by the difference between this index and that of an adjacent untreated zone is recommended (Sommer et al. 1998).

Using a spectrophotometric (therefore more accurate) measurement of reflectance, Andersen et al. (Andersen et al. 1993) have shown that the blanching induced by corticosteroids of small and moderate strength came from a decrease of reduced Hb (venuloconstriction) and that the HbO₂ content (arteriolar constriction) was reduced only by the most powerful corticosteroids. The measurement must also consider the kinetics of the phenomenon, which is biphasic, following the application of betamethazone valerate. Venos constriction begins about 3 h after cream removal, and peaks at about the 12th hour. By the 24th hour, the condition has gone back to normal. However, by the 32nd hour, a vasodilatation appears although the corticosteroids blood concentration is at its highest level, and peaks by the 72nd hour while the corticosteroids plasmatic concentration is still elevated (Andersen 1997; Andersen and Maibach 1995).

Colorimetry also detects blanching and provides a classification of corticosteroids similar to visual classification, but it seems less accurate (Queille-Roussel et al. 1991; Broby-Johansen et al. 1990).

Green laser Doppler seems a promising technique to measure blanching, but it has been used until now only to show superficial vasoconstriction to cold (Czastrau et al. 1996; Jepsen et al. 1996).

10.2 Reactive Hyperemia Test with Vasoconstrictor

Reactive hyperemia is easily measured by laser Doppler. Its reduction following topical corticosteroids can be measured by the same method (Bisgaard et al. 1986). Techniques based on reflectance measurement can also be used. However, the latter method is indirect, which introduces an additional risk of variability.

In conclusion, the whitening induced by topical corticosteroids is a venular vasoconstriction of the subepidermal plexus easily detectable with the naked eye and possibly accompanied by the acceleration of the skin blood flow. Reflectometry and spectrophotometry presently appear to constitute the most reliable measurement methods. Methods

present too many hazards and should therefore be replaced, whenever possible, by instrumental techniques. To assess blanching in relation to deep vasoconstriction, such as the one induced by cold, all methods of skin blood flow measurement are usable because the phenomenon is global and concerns all types of vessels.

Cosmetic skin type • Sebum • Acne vulgaris • Bioengineering devices

Cosmetic facial skin type or cosmetic skin type is not a term that has been defined either scientifically or medically (Youn et al. 2002). Nevertheless, most people commonly use this term to explain their usual sebum-associated facial skin condition and to efficiently select facial cosmetics so as to prevent problems caused by skincare products that are not appropriate for their facial skin condition (Choi et al. 2013; Youn et al. 2013). This terminology was in the territory of myth, consisting of subjective feelings about the skin expressed by people with problematic skin and even by people with normal skin. Thus, the subjectivity inherent in the concept of cosmetic skin type always represented a hurdle for dermatologists. With recent improvements in bioengineering techniques for the skin, cosmetic skin type is now objectively measurable and classifiable (Youn et al. 2002; Youn 2010).

1 Definition of Cosmetic Facial Skin Type

In general, cosmetic facial skin is classified into three major types: oily, normal, and dry (Youn et al. 2005a). The oily and dry types are at the extremes of a subjective feeling of oiliness or dryness. The normal type is intermediate between the

oily and dry types. Cosmetic skin type is a term that was spontaneously developed by laypersons, as mentioned earlier. Consequently, clear-cut criteria for classification that exclusively fit each skin type did not exist. In the past, questionnaires describing skin type-related symptoms (STRS) (Choi et al. 2013) were used to differentiate cosmetic facial skin types (Table 1). Classification by these STRS questionnaires inevitably results in an overlap of skin types. The combination type is the fourth cosmetic skin type and is the most frequently encountered type (Youn et al. 2005a). Combination skin type indicates regional differences in sebum-associated skin type on an individual's face.

Following the development of sebum measuring devices, there have been some efforts to incorporate the concept of cosmetic skin type into the scientific field (Youn et al. 2002, 2005a; Choi et al. 2013; Youn 2010). The Sebumeter[®] is the

most commonly used bioengineering device for sebum measurement. The SM 815 is the most recent model and can measure surface sebum secretion amounts in the range 0–350 $\mu\text{g}/\text{cm}^2$. To define a cosmetic skin type with the Sebumeter[®] or another sebum measuring device, one should keep in mind that regional sebum secretion amounts vary from one facial site to another. Thus, sebum measurement should be controlled and remeasured from time to time. Youn et al. suggested that sebum should be measured at five sites on the face, and the forehead (mid-glabella), nose (tip of the nose), both cheeks (the most protruding areas of the zygoma), and chin (mental prominence) are the controlled measurement points (Youn et al. 2002). Among these five sites, the forehead, nose, and chin constitute the high sebum-secreting zone (the so-called T zone), while the cheeks constitute the low sebum-secreting zone (the so-called U zone). By integrating these five points into a whole, we can simply calculate the sebum amounts at these five sites. This calculation is termed the mean facial sebum excretion (MFSE) (Youn et al. 2002). It can be easily memorized and calculated, but this arithmetic mean cannot reflect the exact areas of high sebum secretion or low sebum secretion contributing to whole face sebum secretion. Area weighting is needed to correct this inequality in sebum secretion. The new area-weighted formula for the evaluation of facial sebum secretion is as follows (Youn et al. 2013):

AW whole face sebum excretion

$$= \frac{6 \times \text{forehead sebum} + 1 \times \text{nose sebum} + 2 \times \text{chin sebum} + 5 \times \text{right cheek sebum} + 5 \times \text{left chin sebum}}{19}$$

This equation was previously suggested for the calculation of mean facial pH (Youn et al. 2013) and was derived from the rule of fours (Yoon et al. 2008) for the estimation of regional facial areas. The rule of fours calculation introduced the area-weighted concept by considering the proportional area of the facial region and could also be applied to the mean of the facial sebum. However, the arithmetic mean has been used in most research dealing with sebum secretion.

In fact, when attempting to classify cosmetic facial skin types, the mean sebum secretion of the

whole face is not meaningful. It is necessary to divide the face into a high sebum-secreting T zone and a low sebum-secreting U zone and calculate the mean of each zone (Youn et al. 2005a). The T zone and U zone have fundamentally different basal sebum secretion amounts, and the same standard values cannot be applied to each area. Choi et al. suggested a 95 % confidence interval of the casual sebum secretion amount in each area for the four cosmetic facial skin types (Table 2) (Choi et al. 2013). The definition of the combination

Table 2 The casual sebum level of four cosmetic skin types according to the facial zone (Adapted from the study by Choi et al.)

	Dry	Normal	Combination	Oily
T zone	120.8–174.9	139.8–206.7	190.4–223.6	204.6–235.4
U zone	55.4–113.6	78.8–150.8	109.8–145.5	120.6–153.7
Whole face	97.3–147.6	118.7–180.9	159.8–190.6	172.5–201.1

The unit of sebum amount is $\mu\text{g}/\text{cm}^2$ as measured by the Sebumeter[®]

type is different from those of the other three types (Youn et al. 2005a). The combination type should show a mismatch of sebum secretion amounts between the T zone and the U zone. Examples of combination skin types are an oily T zone with a normal U zone, a normal T zone with a dry U zone, and an oily T zone with a dry U zone. In general, the MFSE of combination skin types is in-between those of the oily skin type and the normal skin type (Youn et al. 2005a).

2 Factors Affecting Cosmetic Skin Type

Cosmetic skin type is always affected by the amount and change of facial sebum secretion and partly by the facial hydration status. In fact, the degree of hydration changes according to the environmental humidity and can also be changed by the application of moisturizers. Thus, facial sebum secretion, which can be affected by external factors to a relatively lesser degree than hydration status, is the main determining factor of cosmetic skin type.

Cosmetic facial skin type is not fixed throughout a person's lifetime because the sebum secretion amount is not steady. This variation in the sebum secretion amount is affected by either internal or external factors. The sebum secretion amount shows diurnal variations, and therefore set measurement conditions are needed to achieve precise sebum measurements in standard conditions for the purpose of comparing intra- or inter-personal changes. The major external factor that substantially impacts sebum secretion is seasonal change. Sebum secretion is highest in the summer, and summer sebum secretion values are statistically different from those of the other three

seasons. This means that there is a certain possibility for facial skin type change, especially for a change into a more oily skin type in the summer season (Youn et al. 2005a; Sakuma and Maibach 2012). Interestingly, cosmetic skin type as measured by sebum amount does not show any change toward a more dry skin type in the winter season (Youn et al. 2005a).

Aging is a major internal factor that affects sebum secretion amount. Sebum secretion amounts in males remain stable with increasing age, whereas sebum secretion amounts in females progressively decrease (Luebberding et al. 2013; Choi et al. 2011). This means that aging women could show a change of cosmetic skin type from an oilier type to a drier type over their lifetimes.

3 Measurement by Bioengineering Devices

As mentioned earlier, the Sebumeter[®] is the most commonly used scientific device for measuring sebum amounts. The main strength of the Sebumeter[®] for cosmetic skin type classification is that it is a simple, fast, and easily quantifiable device. Other sebum measuring devices or tools like the Sebufix[®] (Dobrev 2007) or Sebutape[®] (Clarys and Barel 1995) cannot measure sebum numerically in a convenient way. The Sebumeter[®] is also valuable for cosmetic skin type determination because many reports exist on its use in the assessment of sebum-related normal skin physiology. Practically, this is a relatively expensive device for the routine assessment of cosmetic facial skin type. Cheaper informal devices are used in cosmetics shops for cosmetic facial skin type determination.

There are some imaging devices with CCD cameras and UV illumination that could be used to

determine cosmetic facial skin type (Kim et al. 2013) by analyzing sebum amounts from UV photographs using computer software. Most of these types of devices are not fully validated by clinical studies with large numbers of normal subjects.

4 Association with Acne Vulgaris

Two main interests triggered by the concept of cosmetic facial skin type are the selection of skin type appropriate cosmetics and the association of skin type with the development of facial skin lesions such as acne vulgaris (Youn 2010; Youn et al. 2005b; Kim et al. 2006).

Increased sebum secretion is one of the main pathogenetic mechanisms of acne, and it is usually observed that acne patients subjectively regard their facial skin type as oily without any objective evidences. In a study (Choi et al. 2013) of 709 acne patients, subjectively determined skin type results as assessed by STRS indicated 302 oily type patients, 303 combination type patients, 40 normal type patients, and 64 dry type patients. Most acne patients feel that they have oily or combination skin types. The study also objectively reevaluated the acne patients' cosmetic skin types with Sebumeter[®] measurements. This revealed a skin type distribution of 126 oily type patients, 379 combination type patients, 143 normal type patients, and 61 dry type patients. Interestingly, the number of objectively determined oily skin type patients was lower than the number of subjectively determined oily type patients. Combination type is the most common skin type in acne patients. This finding may be attributed to ordinary people's prejudice that acne patients have oilier skin compared with people with normal skin. Most combination types show an oily type T zone and a normal type U zone. This suggests that the increased sebum secretion caused by androgen activity is mainly located in the T zone area. Alternately, we can postulate that the sebaceous glands located in the T zone start functioning earlier than the sebaceous glands in the U zone. Regarding this assumption,

it is worth noting that early-onset, adolescent type acne is mainly distributed in the T zone (Choi et al. 2011). By contrast, late-onset, postadolescent acne generally presents with more acne lesions in the U zone as compared with adolescent acne.

Additional very useful information provided by the former study (Choi et al. 2013) is that subjective skin type as determined by the subjective assumptions of general people is relatively well correlated with objective determinations made by bioengineering measurements. Therefore, even when expensive measuring devices are not available, we can simply determine subjects' cosmetic skin types by using reliable STRS questionnaires. To increase the validity of the questionnaire, clearer differentiation between the oily type and combination type is needed. Many people with combination type skin mischaracterize their skin as the oily type because they focus on the oilier T zone when evaluating their cosmetic skin type (Youn 2010).

5 New Cosmetic Skin Area: O Zone

When we attempt to measure facial sebum secretion in all regions of the face, it is obvious that there are regional differences in the amounts of sebum secretion. The concept of a high sebum-secreting T zone and a low sebum-secreting U zone existed even before facial sebum could be measured quantitatively. Differences in sebum secretion between these two zones are so obvious that laypersons may discriminate between them without measurement. However, in the current bioengineering era, we were able to identify a third, different zone that shows distinctive characteristics as compared with the other areas. The perioral area, which was formerly a part of the T zone, has intermediate sebum-secreting characteristics that fall between those of the T zone and the U zone. A study that described the perioral area as a new cosmetic zone named it the "O" zone (Youn et al. 2014). The mean sebum secretion amount of the T zone excluding the perioral area was

$218.04 \pm 126.28 \mu\text{g}/\text{cm}^2$ and the U zone sebum secretion amount was $122.63 \pm 110.99 \mu\text{g}/\text{cm}^2$. The mean sebum secretion amount was $193.26 \pm 125.84 \mu\text{g}/\text{cm}^2$ for the O zone, and while this value was closer to the sebum secretion amount of the T zone than the U zone, it showed a statistical difference from the T zone amount. Therefore, the O zone is a moderate to high sebum-secreting zone that differs from the other areas, especially from the former T zone.

The difference of sebum secretion capability in the O zone would be somewhat affected by the age-related lesion distribution pattern in acne patients. Additionally, perioral dermatitis also implies that the O zone area possesses certain physiological and pathological differences. This regional difference of the O zone area should be elucidated in more detailed topographic studies.

6 Future of Cosmetic Skin Type Determination

Converting the general public's common sense beliefs into those based on academic science is always difficult. While cosmetic skin type is a measurable element that has been studied by many researchers, it remains in the layperson's domain. This is because subjective skin type assessment is very cheap and more easily accessible than objective assessment and because most people do not require further scientific evaluation for the selection of facial cosmetics. Thus, researchers who try to develop an easy way of measuring skin type should incorporate objectivity into subjective skin type determinations. Another important aspect of cosmetic skin type determination is simultaneous wide multifocal measurement. Current sebum measurements have been limited to the anatomical focus of the small application area of the Sebumeter[®] cassette. Direct contact quantitative measurement of all areas of interest is ideal for approaching the real sebum secretion amount. Innovative technological improvements will ultimately achieve this goal.

1 Introduction and Definition

Cellulite is a very common clinical condition in which there is modification of skin topography evident by skin dimpling and nodularity, giving an orange peel, cottage cheese, or mattress aspect to the skin (Segers et al. 1984; Scherwitz and Braun-Falco 1978; Hexsel et al. 2009a; Khan et al. 2010), more commonly presenting on the buttocks, lower limbs, and abdomen. It is a localized metabolic and a complex architectural multifactorial disorder of the subcutaneous tissue (Hexsel et al. 2009a; Khan et al. 2010). This condition can be found in different age groups and in both sexes, but the prevalence is higher in females after puberty and in obese patients, being reported as a normal manifestation of obesity (Hexsel and Mazzuco 2000). On the other hand, cellulite is also present in nonobese individuals (Hexsel et al. 2009a; Khan et al. 2010).

The pathophysiology of cellulite is complex, and there are many theories to elucidate it. The majority of the theories involve alterations to the adipose tissue and microcirculation causing fibrosclerosis of the connective tissue. It is considered a noninflammatory, degenerative

Fig. 1 Sequence of magnetic resonance imaging of a patient in an area with a cellulite depression. The first slice (a) shows a skin marker identifying the cellulite

depression. The second slice (b) shows typical, thicker, ramified, and perpendicular fibrous septum

condition, producing alterations to the hypodermis producing irregular undulations on the skin overlying the affected areas (Hexsel et al. 2010).

Differences in subcutaneous tissue architecture between men and women may explain the female sex predominance of this condition (Nürmberger and Müller 1978). In women, bands of connective tissue are oriented radially or perpendicular to the skin surface (Nürmberger and Müller 1978; De la Casa et al. 2012). As the fat layer expands, herniation of subcutaneous fat within fibrous connective tissue occurs, leading to a puckered appearance of the skin (Querleux et al. 2002; Piérard et al. 2000). In men, these septa adopt an oblique zigzag pattern, which holds the fat layer and prevents the projection of the adipose tissue on the skin surface (De la Casa et al. 2012; Querleux et al. 2002; Piérard et al. 2000) (Fig. 1).

The skin surface alterations are comprised of depressed and raised areas, compared to normal adjacent skin. Depressed lesions occur due to the presence of fibrous septa that pull the skin surface down, and raised areas are the projection of underlying fat to the skin surface (Hexsel et al. 2009a). Recent studies have shown the anatomic structures involved in cellulite. One of those studies utilizing MRI analysis concludes that cellulite

depressions on the buttocks are associated with the presence of underlying fibrous septa, (Hexsel et al. 2009b) which pulls the skin surface down, projecting the underlying fat to the skin surface and resulting in the raised areas (Hexsel 2001). It was found that all fibrous septa in the examined areas were perpendicular to the skin surface and most of them were ramified (Hexsel et al. 2009a).

Despite the morphological basis which explains the clinical presentation of cellulite, the pathophysiology of cellulite is still not fully elucidated. It seems to be a physiological phenomenon or at least that it has a physiological origin (De la Casa et al. 2012). It is a multi-causal disorder, with the coexistence of a number of factors that trigger, perpetuate, or exacerbate it (De la Casa et al. 2012). Flaccidity, laxity, or sagging of the skin further aggravates morphological alterations in the majority of patients (Hexsel et al. 2009a). Minor factors, such as weight gain or loss, localized tissue vascularity and postinflammatory changes, hormonal and genetic influences, and lifestyle, may also have an important role in cellulite's pathogenesis (Khan et al. 2010).

With the purpose of measuring cellulite severity and the effects of treatment modalities, a

comprehensive objective method of measuring cellulite was developed and is presented in this chapter, the new *Cellulite Severity Scale* (CSS) (Hexsel et al. 2009a). It considers important clinical and morphological aspects involved in the cellulite for its classification.

2 Classification and Scoring

Cellulite classification and scoring is of great relevance to accurately follow up treatment outcomes. This is also important to determine the more appropriate treatment for each patient. The evaluation of a patient with cellulite is mostly performed with clinical examination, and two classifications have already been developed aiming to determine different degrees of this condition. Cellulite must be evaluated with patients in standing position with relaxed muscles, so as to correctly identify the depressed and raised lesions of cellulite that are clearly apparent, regardless of pinch test or muscular contraction (Hexsel and Mazzuco 2000).

Nümberger and Müller (1978) have described the most widely used classification until the last few years. They classified cellulite in degrees 0 to III, which varied from the complete absence of cellulite to its occurrence in a more severe degree (Table 1). A pinch test can be done to make the lesions more evident or to differentiate grades 0 from I.

Although largely used and practical, the abovementioned classification does not comprise all important additional morphologic aspects of cellulite and, thus, is not comprehensive enough to identify individual needs for treatment and to evaluate different treatment responses. Aiming to fulfill

this gap, Hexsel, Dal’Forno, and Hexsel published the *Cellulite Severity Scale* (Hexsel et al. 2009a) (Table 2), which is based on five important clinical and morphological aspects of cellulite providing a more detailed classification for cellulite: (A) number of evident depressed lesions, (B) depth of depressions, (C) morphologic appearance of skin surface alterations, (D) grade of flaccidity or sagging skin, and (E) grade of cellulite. Each of these items is graded from zero to three. The total sum of the scores of each item indicates the cellulite grading as mild, moderate, or severe, as shown in Table 3.

The *Cellulite Severity Scale* (Hexsel et al. 2009a) is an alpha-phonumeric scale. Its main advantage is that it can indicate which morphological aspect is the most significant component of cellulite for each patient, allowing the physician to determine the most suitable treatment for the patient. For example, a patient with important laxity (e.g., grade 3 of letter D) and mild depressed lesions (e.g., grade 1 of letter B) should be treated for laxity to have an important improvement in cellulite grading rather than undergoing a Subcision[®], which aims the treatment of depressed lesions.

De La Casa Almeida and cols (2013) assessed the intra- and interobserver reliability of the application of the CSS to a Spanish female population. They observed excellent reliability and internal consistency when used to evaluate cellulite on the buttocks and back of the thighs considered together. However, they considered that the dimension grade of laxity, flaccidity, or sagging skin does not contribute positively to the final consistency of the scale and suggested further analysis in greater depth in future studies.

The CSS has been used in some studies for the assessment of cellulite improvement after

Table 1 Classification of cellulite based on clinical criteria (Piérard et al. 2000)

Grade or stage	Clinical characteristics
0 (zero)	Skin surface is smooth
I	The skin surface is smooth while the subject is standing or lying, but the alterations to the skin surface can be seen by pinching the skin or with muscle contraction
II	The orange skin or mattress appearance is evident when standing, without the use of any manipulation (skin pinching or muscle contraction)
III	The alterations described in grade or stage II are present together with raised areas and nodules

Table 2 Hexsel, Dal’Forno, and Hexsel e Cellulite Severity Scale (CSS) (Hexsel et al. 2010)

(A) Number of evident depressions	
This item refers to the total number of evident depressions by visual inspection in the area to be examined. The scores are expressed as follows:	
ZERO = None/no depressions	
1. A small amount: 1–4 depressions are visible	
2. A moderate amount: 5–9 depressions are visible	
3. A large amount: 10 or more depressions are visible	
(B) Depth of depressions	
This item evaluates the depth of depressions by visual inspection of the affected areas; comparison to the pictures of CSS is recommended	
ZERO = No depressions	
1. Superficial depressions	
2. Medium depth depressions	
3. Deep depressions	
(C) Morphological appearance of skin surface alterations	
Item C assesses the different morphological patterns of skin surface alterations; comparison with the pictures of CSS is recommended	
ZERO = No raised areas	
1. “Orange peel” appearance	
2. “Cottage cheese” appearance	
3. “Mattress” appearance	
(D) Grade of laxity, flaccidity, or sagging skin	
Laxity, flaccidity, or sagging skin confers the affected skin a draped appearance. This effect aggravates the appearance of cellulite. Item D assesses the grade of flaccidity, and comparison to the pictures of CSS is recommended	
ZERO = Absence of laxity, flaccidity, or sagging skin	
1. Slight draped appearance	
2. Moderate draped appearance	
3. Severe draped appearance	
(E) Classification scale by Nürnberger and Müller	
This item is based on the current classification of cellulite shown in Table 1. Patients should be evaluated in the standing position with relaxed gluteus muscles. However, if the patient has no evident depressions, they should be asked to contract their gluteus muscles or the <i>pinch test</i> should be applied (by pinching the skin between the thumb and index finger) in order to differentiate between scores 0 and 1 (see Fig. 1, item E – contracted)	
ZERO = Zero grade	
1. First grade	
2. Second grade	
3. Third grade	

Table 3 New classification of cellulite based on the results of scores of Cellulite Severity Scale

Points	New classification of cellulite
1–5	Mild
6–10	Moderate
11–15	Severe

different treatments, being an objective and reliable tool to evaluate clinical trial outcomes (Hexsel et al. 2011, 2013; Knobloch et al. 2010).

Alexiades-Armenakas (Alexiades-Armenakas et al. 2008) and cols used a quantitative four-

point grading scale to assess cellulite in a clinical trial that studied the use of unipolar radio-frequency treatment to improve the appearance of cellulite. However, there is no reference of validation of this scale (Table 4).

Table 4 Comprehensive cellulite grading scale

Grade	Contour	Dimple density	Dimple distribution	Dimple depth	Diameter % change
0	Smooth	0	0	0	$100 \times \{[\text{pre-post}]/\text{pre}\}$
1	1 indentation	1–2/site	1 site	Shallow (1–2 mm)	
2	2 indentations	3–5/site	2 sites	Moderate (3–4 mm)	
3	3 indentations	6–8/site	3 sites	Advanced (5–6 mm)	
4	>3 indentations	>9/site	$4 \geq$ sites	Deep (>7 mm)	

Sites (graded individually): buttock, anterior thigh upper, anterior thigh lower, posterior thigh upper, posterior thigh lower; upper refers to upper one-half and lower to lower one-half of thigh length

Diameter: mean difference in diameter (mm) on photographic superimposition

Atopic dermatitis • Eczema outcome • Eczema area and severity index • Severity scoring of atopic dermatitis

1 Introduction

Atopic dermatitis (AD) is a common inflammatory skin disease, affecting approximately 10–30 % of children and 2–3 % of adults (Bieber and Bussmann 2012; Eichenfield et al. 2014; Williams et al. 1999). Atopic dermatitis is characterized by eczematous skin eruptions, often accompanied by other atopic disorders such as asthma and allergic rhinoconjunctivitis. Pathogenesis of AD involves genetic, immunologic, and environmental factors causing skin barrier dysfunction as well as immune dysregulation leading to the constellation of clinical findings. Pruritus, dry skin, erythema, edema, erosions and excoriations, oozing and crusting, and lichenification are key clinical manifestations of AD. AD, also known as atopic eczema, is a chronically relapsing course. Providing better care for affected individuals highlights the need for comprehensive evaluation of disease activity and measurements of disease severity. This chapter reviews validated scoring methods

developed for comprehensive evaluation of disease severity in atopic dermatitis.

2 Diagnosis

AD is diagnosed clinically based on history, morphology, distribution, and other clinical signs. Hanifin and Rajka developed the first formal diagnostic criteria in 1980 (Hanifin and Rajka 1980). Several groups have proposed other diagnostic criteria, but the most widely accepted set of criteria is developed by the United Kingdom (UK) Working Party (Williams et al. 1994, 1999; Haileamlak et al. 2005; Gu et al. 2001). Both the Hanifin and Rajka and UK Working Party diagnostic principles have been validated and tested in different populations and are presented in Table 1 (De et al. 2006; Mevorah et al. 1988; Loden et al. 1998; Samochocki et al. 2000).

3 Clinical Scoring

Measurement of disease activity is key in clinical management and monitoring of individual patients. Standardization of measurement tools and harmonizing outcome measures is critical, in evidence-based practice. Considering high disease burden of AD, multiple scoring methods have been developed over the past decades (Table 2), but a few are considered reliable and validated.

Disease severity in atopic dermatitis can be measured based on subjective assessment of symptoms, objective measurements of clinical features, and tools to assess quality of life. Additional data may be obtained from epigenetic testing, bioengineering methods, and some inflammatory markers; however, these methods are not validated for measurements of disease activity (Gutgesell et al. 2002; Rodriguez et al. 2014).

The need for standard, reliable, and clinically meaningful outcome measures prompted foundation of the Harmonising Outcome Measures for Eczema (HOME) initiative in 2008, with the goal

to facilitate evidence-based multidisciplinary consensus on core outcome sets (COS). Two levels of COS include outcome domains and outcome measures (The HOME (Harmonising Outcome Measures for Eczema) 2014). In general, outcome domains relate to the concept that needs to be measured (e.g., clinical signs of atopic eczema), and outcome measures relate to the methods that are used to measure them (e.g., the Eczema Area and Severity Index (EASI) to measure signs) (Fig. 1; The HOME (Harmonising Outcome Measures for Eczema) 2014; Schmitt et al. 2007, 2013, 2014; Sidbury et al. 2014).

In a recent systematic review on properties of outcome measures for clinical signs of AD, two scoring methods, namely, Eczema Area and Severity Index (EASI) (Tofte et al. 1998) and Severity Scoring of Atopic Dermatitis (SCORAD) index (*Severity scoring of atopic dermatitis: The SCORAD index. consensus report of the european task force on atopic dermatitis 1993*), were found to have the best measurement properties. The Six Area, Six Sign Atopic Dermatitis (SASSAD) (Berth-Jones 1996) severity score and Three-Item Severity (TIS) (Wolkerstorfer et al. 1999) score fulfill some quality criteria, but unclear about all required measures. Patient-Oriented Eczema Measure (POEM) (Charman et al. 2004) was found reliable and responsive but had inadequate content validity for assessing clinical signs of AD. This chapter focuses on these scoring methods.

4 Severity Scoring of Atopic Dermatitis (SCORAD) Index

Severity Scoring of Atopic Dermatitis is a composite scoring index based on objective data (extent and intensity of involvement) and subjective symptoms (itching and sleep loss) (Severity Scoring of Atopic Dermatitis 1993). SCORAD was developed in the early 1990s by the European Task Force on Atopic Dermatitis and remains a major scoring method. The score is calculated based on the following measures (Fig. 2):

Table 1 Diagnostic features of atopic dermatitis (Hanifin and Rajka 1980; Williams et al. 1994; Williams 2005)

Hanifin and Rajka criteria	UK Working Party's diagnostic criteria for AD ^a
Major features (3 out of 4 present)	Must have
Pruritus	An itchy skin condition (or parental report of scratching or rubbing in a child)
Typical morphology and distribution of skin lesions	
Chronic or chronically relapsing dermatitis	
Personal or family history of atopy	
Minor features (3 out of 23 present)	Three or more of the following
Xerosis	History of involvement of the skin creases such as folds of elbows, behind the knees, fronts of ankles, the neck, and around the eyes ^b
Ichthyosis/palmar hyperlinearity/keratosis pilaris	A personal history of asthma or hay fever (or history of atopic disease in a first-degree relative in children under 4 years of age)
Immediate (type I) skin test reactivity	A history of generally dry skin in the last year
Elevated serum IgE	Visible flexural eczema (or eczema involving the cheeks/forehead and extensor limbs in children under 4 years of age)
Early age of onset	Onset under 2 years of age (not used if child is under 4 years of age)
Tendency toward cutaneous infections/ impaired cell-mediated immunity	
Tendency toward nonspecific hand or foot dermatitis	
Nipple eczema	
Cheilitis	
Recurrent conjunctivitis	
Dennie–Morgan infraorbital fold	
Keratoconus	
Anterior subcapsular cataract	
Orbital darkening	
Facial pallor/erythema	
Pityriasis alba	
Anterior neck folds	
Pruritus when sweating	
Intolerance to wool and lipid solvents	
Perifollicular accentuation	
Food intolerance	
Course influenced by environmental/ emotional factors	
White dermographism/delayed blanch	

^aModified in 2005^bOriginal 1994 guidelines also included the cheeks in young children

- (A) Extent of involvement; rule of 9 is applied in adults and modified in children (see Fig. 2). Score for each area is added up, and the total area is referred to as “A” (maximum score is 100 referring to 100 % body surface area).
- (B) Intensity of the signs in the representative area of eczema is scored as none (0), mild

(1), moderate (2), or severe (3). The assessed signs are:

- Erythema
- Edema/papulation
- Oozing/crusting
- Excoriations
- Lichenification

Table 2 Named eczema outcome measures

ADAM (Charman et al. 1999b)	Atopic Dermatitis Assessment Measure
ADASI (Bahmer et al. 1991; Bahmer 1992)	Atopic Dermatitis Area and Severity Index
ADAS (Baek et al. 2015)	Atopic Dermatitis Antecubital Severity
ADSI (Van Leent et al. 1998)	Atopic Dermatitis Severity Index
BCSS (Verwimp et al. 1995)	Basic Clinical Scoring System
EASI (Tofte et al. 1998)	Eczema Area and Severity Index
FSSS (Mastrandrea et al. 2005)	Four-Step Severity Score
IGADA (Schachner et al. 2005)	Investigator's Global Atopic Dermatitis Assessment
Leicester (Berth-Jones and Graham-Brown 1993)	Leicester Index
NESS (Emerson et al. 2000)	Nottingham Eczema Severity Score
OSAAD (Sugarman et al. 2003)	Objective Severity Assessment of Atopic Dermatitis
POEM (Charman et al. 2004)	Patient-Oriented Eczema Measure
PO-SCORAD (Stalder et al. 2011)	Patient-Oriented Scoring of Atopic Dermatitis
RL Score (Rajka and Langeland 1989)	Rajka and Langeland Score
SA-EASI (Housman et al. 2002)	Self-Administered Eczema Area and Severity Index
SASSAD (Berth-Jones 1996)	Six Area, Six Sign Atopic Dermatitis severity score
SCORAD (<i>Severity scoring of atopic dermatitis: The SCORAD index. consensus report of the european task force on atopic dermatitis 1993</i>)	Severity Scoring of Atopic Dermatitis index
SIS (Kagi et al. 1992)	Skin Intensity Score
SSS (Costa et al. 1989)	Simple Scoring System
TBSA (vanJoost et al. 1994)	Six-Area Total Body Severity Assessment
TISS (Wolkerstorfer et al. 1999)	Three-Item Severity Score
WAZ-S (Silny et al. 2005)	(Polish acronym for atopic dermatitis severity score)

- Dryness (this is assessed in an area where there is no inflammation)

The intensity scores are added together to make "B" (maximum score is 18).

(C) Subjective symptoms for the last 3 days or nights include:

- Pruritus (visual analog scale 0–10)
- Sleep loss (visual analog scale 0–10)

These scores are added to give "C" (maximum score 20).

The SCORAD for each individual is calculated based on this formula $A/5 + 7B/2 + C$.

5 Eczema Area and Severity Index (EASI)

EASI is an objective scoring method that measures both extent and severity of involvement in four anatomical areas (Tofte et al. 1998). The intensity of clinical signs of inflammation including erythema, induration/papulation, excoriation, and lichenification is assessed as defined below. Symptoms like pruritus, as well as secondary signs like xerosis, and scaling are excluded from assessments. Anatomic regions include the head and neck, upper extremities, trunk, and lower

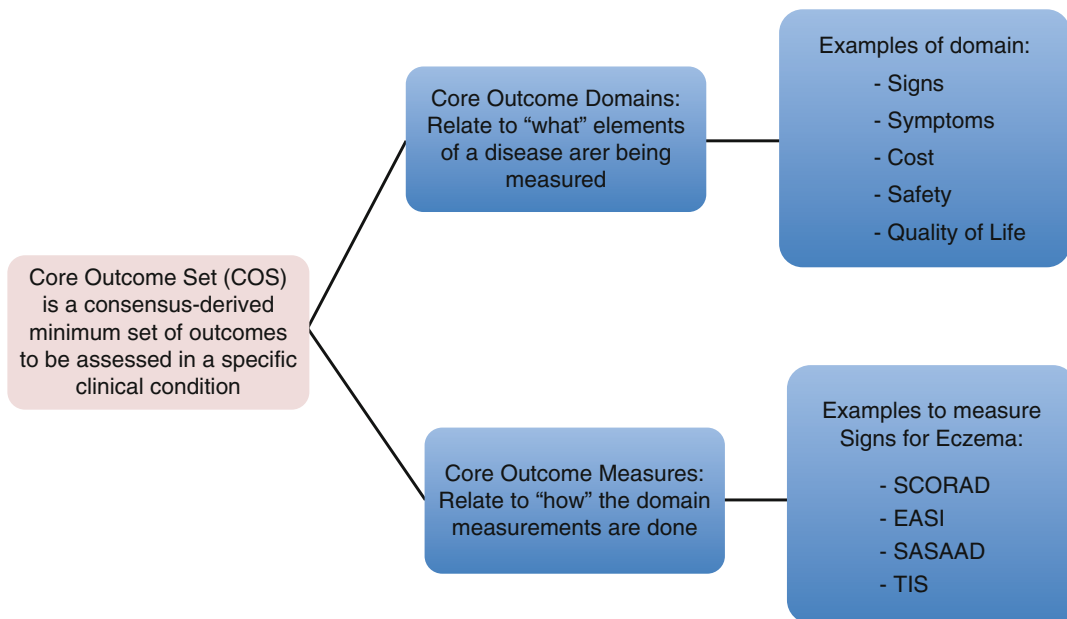

Fig. 1 Core outcome domains and core outcome measures (The HOME (Harmonising Outcome Measures for Eczema) 2014; Schmitt et al. 2015)

extremities. The percentage of areas involved in each of the four body regions is assigned a proportional score from 0 to 6 during the analysis: none (0), 1–9 % (1), 10–29 % (2), 30–49 % (3), 50–69 % (4), 70–89 % (5), and 90–100 % (6). The intensity of erythema, induration/papulation/edema, excoriation, and lichenification of the eczema is assessed as none (0), mild (1), moderate (2), and severe (3).

Calculation methods are summarized in Fig. 3, and case scenario is presented to better clarify these calculations:

A 6 year old girl presents with a flare of atopic eczema. She has involvement of neck with mild erythema and scant excoriations (about 20 % of head and neck involved), bilateral antecubitals and forearms are involved with moderate erythema, several excoriations and moderate lichenification (about 15 % of upper limbs involved), on flexor knees she has deep dark erythematous plaques with moderate edema, several excoriations and moderate lichenification (9 % of lower limbs are involved). On trunk she has mild xerosis otherwise clear. The four intensity scores are added up for each body regions as follows:

- Head and neck (mild erythema and scant excoriations) \times (area of involvement 20% of head

and neck) \times (0.2 for age < 7) = $(1 + 0 + 1 + 0) \times 2 \times 0.2 = 1.2$

- Upper Limbs (moderate erythema, several excoriations and moderate lichenification) \times (15 % of upper limbs) \times 0.2 = $(2 + 0 + 2 + 2) \times 2 \times 0.2 = 2.4$
- Trunk (xerosis) = 0
- Lower limbs with deep dark erythema, moderate edema, several excoriations and moderate lichenification) \times (9% of lower limbs) \times 0.3 = $(3 + 2 + 2 + 2) \times 1 \times 0.3 = 2.7$

$$\text{EASI} = 1.2 + 2.4 + 2.7 = 6.3$$

The EASI is a valid and internally consistent scoring method with adequate intraobserver reliability, intermediate interobserver reliability, and adequate responsiveness (Schmitt et al. 2013). The use of (at least) EASI in future atopic eczema trials is recommended for improved evidence-based communications (Schmitt et al. 2015).

5.1 Three-Item Severity (TIS) Score

Three-Item Severity (TIS) score is a simple objective scoring method based on only three intensity

Severity Scoring of Atopic Dermatitis index (SCORAD)

A: Extent (percentage of area involved)

Figures within parenthesis are used
For children under 2 years

B: Intensity

Criteria	Intensity	Means of Calculation
Erythema		Intensity items [average representative area 0=Absence 1=mild 2=moderate 3=sever
Edema/papulation		
Oozing/Crusting		
Excoriations		
Lichenification		*Dryness is evaluated on uninvolved skin
Dryness*		

C: Subjective Symptoms (Pruritus and Sleep loss)

Visual analog scale (average for the last 3 Days or nights)	Pruritus (0-10) <input type="text"/>	<input type="text"/>
	Sleep Loss (0-10) <input type="text"/>	<input type="text"/>

SCORAD : $A/5 + 7B/2 + C$

Fig. 2 Severity Scoring of Atopic Dermatitis (SCORAD) index (*Severity scoring of atopic dermatitis: the SCORAD index. consensus report of the european task force on atopic dermatitis 1993*)

items (erythema, edema/papulation, and excoriations) (Wolkerstorfer et al. 1999). Similar to SCORAD, each item is scored based on the most representative lesion, meaning that different items may be scored on different sites. Intensity of the signs in the representative area of eczema is scored as none (0), mild (1), moderate (2), or severe (3). The assessed signs are:

- Erythema
- Edema/papulation
- Excoriations

The range of TIS score lies between 0 and 9. TIS score is a reliable and simple scoring system with good content validity. It is applicable in routine clinical practice and for screening purposes in clinical trials (Wolkerstorfer et al. 1999).

6 Six Area, Six Sign Atopic Dermatitis (SASSAD) Severity Score

In this method, disease activity is assessed by grading six signs (erythema, exudation, excoriation, dryness, cracking, and lichenification), each on a scale of 0 (absent), 1 (mild), 2 (moderate), or 3 (severe), at each of six sites: arms, hands, legs, feet, head and neck, and trunk (Berth-Jones 1996). The maximum score is 108. This method eliminates risk of unreliable body surface area measurements by inexperienced observer (Berth-Jones 1996; Charman et al. 1999a). As an outcome measure, SASSAD meets some quality items and has the potential to be recommended in clinical trials, depending on further validation studies.

Eczema Area and Severity Index (EASI)

• **Body regions**

- Head/neck
- Upper limbs
- Trunk
- Lower limbs

• **Scoring of areas of Involvement in each anatomical region (Area)**

0	1	2	3	4	5	6
No eruption	<10%	10%-29%	30-49%	50-69%	70-89%	90-100%

• **Calculation of Intensity**

Criteria	0	1	2	3
Erythema (E)	None	Faintly detectable erythema, very light pink	Dull red, clearly distinguishable	Deep, dark red
Infiltration/Papulation (I)	None	Barely perceptible elevation	Clearly perceptible elevation	Extensive elevation
Excoriation (Ex)	None	Scant evidence of excoriation No erosion or crust	Several linear mark, some erosion or crust	Many erosive and/or crusty lesions
Lichenification (L)	None	Light thickening of skin discernable only by touch	Definite thickening of skin with exaggerated markings and markings and visible criss-cross pattern	Thickened Indurated skin and visible exaggerated criss-cross pattern

• **Calculations**

Head/Neck	$(E+ I + Ex + L) \times Area \times 0.1$ (In children 0-7 years $(E+ I + Ex + L) \times Area \times 0.2$)	
Upper limbs	$(E+ I + Ex + L) \times Area \times 0.2$	
Trunk	$(E+ I + Ex + L) \times Area \times 0.3$	
Lower limbs	$(E+ I + Ex + L) \times Area \times 0.4$ (In children 0-7 years $(E+ I + Ex + L) \times Area \times 0.3$)	
EASI	Sum of the above four body areas	Total score =

Fig. 3 Eczema Area and Severity Index (EASI) (Tofte et al. 1998)

7 Patient-Oriented Eczema Measure (POEM)

This is a subjective scoring system based on a questionnaire focusing on seven symptoms, using a simple 5-point scale of frequency of occurrence during the previous week (Charman et al. 2004). The maximum total score is 28. Patients are asked to circle one response for each question. Questions are as follows:

1. Over the last week, on how many days has your/your child's skin been **itchy** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

2. Over the last week, on how many nights has your/your child's **sleep been disturbed** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

(continued)

3. Over the last week, on how many days has your/your child's skin been **bleeding** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

4. Over the last week, on how many days has your/your child's skin been **weeping or oozing clear fluid** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

5. Over the last week, on how many days has your/your child's skin been **cracked** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

6. Over the last week, on how many days has your/your child's skin been **flaking off** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

7. Over the last week, on how many days has your/your child's skin been **felt dry or rough** because of the eczema?

No days	1-2 days	3-4 days	5-6 days	Every day
---------	----------	----------	----------	-----------

POEM is a useful tool in clinical monitoring of patients with atopic eczema, but it is not recommended as a sole outcome measure in clinical trials.

8 Conclusion

The need to establish core outcome sets for atopic dermatitis is a priority for advancing evidence-based treatments. Harmonising Outcome Measures for Eczema (HOME) initiative has defined clinical signs, symptoms, quality of life, and long-term control of atopic dermatitis flares as core outcome domains for atopic dermatitis trials (Schmitt et al. 2015). In systematic review of measurement instruments for assessment of clinical signs of atopic dermatitis, EASI and SCORAD have been identified as extensively validated (Schmitt et al. 2015). However, the objective of SCORAD, despite providing adequate validity, responsiveness, and interobserver reliability, lacks clear intraobserver reliability. In a recent international consensus study, EASI was identified as the preferred measurement instrument to be used in future atopic eczema trial (Schmitt et al. 2015). Additional information and recourses are available and highly recommended through <http://homeforeczema.org>.

Body surface area (BSA) • Dermatology Index of Disease Severity (DIDS) • Evaluation for Prognosis with Average PASI (E-PAP) • Lattice System Global Psoriasis Score (LS-GPS) • Psoriasis area and severity index (PASI) • Salford Psoriasis Index (SPI) • Self-administered psoriasis area and severity index (SAPASI)

1 The Body Surface Area

The main methods for assessing the severity of psoriasis incorporate an estimation of involved surface area (Ashcroft et al. 1999). One side of a flat closed hand is thought to represent an area of 1 % of the total body surface area. Nevertheless, planimetric investigations give another estimation of the hand surface, which in fact represents 0.70–0.76 % of the body surface area (BSA) (Long et al. 1992).

The rule of nines method assumes that the total BSA comprises the head (9 %), anterior trunk (upper, 9 %; lower, 9 %), posterior trunk (upper, 9 %; lower, 9 %), each leg (anterior, 9 %; posterior 9 %), each arm (9 %), and genitalia (1 %).

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

2 The Psoriasis Area and Severity Index

Four main body areas are assessed by the Psoriasis Area and Severity Index (PASI) (Fredriksson and Pettersson 1978): head (h), trunk (t), upper extremities (u), and lower extremities (l), assumed to weigh 10 %, 20 %, 30 %, and 40 % of the total body area, respectively.

The extent of psoriatic involvement of these four main areas (A_h , A_t , A_u , and A_l) is given a numerical value: 0 = no involvement; 1 = <10 %; 2 = >10 %, but <30 %; 3 = >30 %, but <50 %; 4 = >50 %, but <70 %; 5 = >70 %, but <90 %, and 6 = 90–100 %.

In order to evaluate three clinical signs, erythema (E), infiltration (I), and desquamation (D) are assessed using a 0–4 scale, where 0 = no; 1 = slight; 2 = moderate; 3 = severe; 4 = very severe.

The PASI is the sum of each area score. The formula is as follows:

$$\begin{aligned} \text{PASI} &= 0,1A_h (E_h + I_h + D_h) \\ &+ 0,3 A_t(E_t + I_t + D_t) \\ &+ 0,2 A_u(E_u + I_u + D_u) \\ &+ 0,4 A_l(E_l + I_l + D_l) \text{Maximum} \\ &= (0,1 \times 6 \times 12) + (0,3 \times 6 \times 12) \\ &+ (0,2 \times 6 \times 12) + (0,4 \times 6 \times 12) \\ &= 72 \end{aligned}$$

Example:

1. Involvement \times weight of area

Head	5 (75 % involved) \times 0.1 = 0.5
Upper limbs	3 (1/3 area involved) \times 0.3 = 0.9
Trunk	1 (less 10 % involved) \times 0.2 = 0.2
Lower limbs	0 \times 0.4 = 0

2. Clinical signs (maximum possible for each area: 4 \times 3 = 12)

Head	Erythema (E): 2
Infiltration (I)	1
Desquamation (D)	2
Total	5

(continued)

Upper limbs	Erythema (E): 2
Infiltration (I)	3
Desquamation (D)	4
Total	9
Trunk	Erythema (E): 2
Infiltration (I)	2
Desquamation (D)	2
Total	6
Lower limbs	0
Total for head	0.5 \times 5 = 2.5
Total for upper limbs	0.9 \times 9 = 8.1
Total for trunk	0.2 \times 6 = 1.2
Total for lower limbs	0
Total PASI score	11.8

3 The Self-Administered Psoriasis Area and Severity Index

The Self-Administered Psoriasis Area and Severity Index (SAPASI) (Fleischer et al. 1994; Feldman et al. 1996) is a structured instrument for measuring the severity of psoriasis. It allows patients to assess the severity of psoriasis accurately.

Patients rate the color, induration, and scaling of an average psoriatic lesion using three modified visual analog scales.

As in the original PASI score, the SAPASI weights the involvement of the head, upper extremities, trunk, and legs as 10 %, 20 %, 30 %, and 40 % of the total body area, respectively.

$$\begin{aligned} \text{SAPASI} &= (0,1 \times A_H) + (0,2 \times A_U) \\ &+ (0,3 \times A_T) + (0,4 \times A_L) \times 4 \\ &\times (\text{VAS}_E + \text{VAS}_I + \text{VAS}_S) / \text{VAS len} \end{aligned}$$

where:

A_H : Head score

A_U : Upper extremity score

A_T : Trunk score

A_L : Lower extremity score

VAS: Visual analog scale

VAS_E : VAS erythema score (mm)

VAS_I : VAS induration score (mm)

VAS_S : VAS scale score (mm)

4 The Lattice System Global Psoriasis Score

The Lattice System Global Psoriasis Score (LS-GPS) (Ellis and Langley 2002) is a method for rating psoriasis. It correlates well with the PGA ($r > 0.8$). However, the LS-GPS is better defined and appears to be more reproducible.

The LS-GPS is proprietary, and there may be fees for its use.

5 The Evaluation for Prognosis with Average PASI

Evaluation for Prognosis with Average PASI (E-PAP). (Sugai et al. 1998) is derived from PASI. The authors modified PASI for evaluating clinical symptoms throughout the observation period by adding a time parameter (the number of days) to PASI.

The E-PAP value is calculated as follows. First the mean value of PASI for two consecutive observation days is calculated. The accumulated PASI for a short term (Apn) is determined by multiplying the mean PASI by the number of days in this short term. Then, all individually calculated Apn values during the entire observation period are summed. The accumulated Apn value is divided by the total number of observation days. The final value is the E-PAP value.

6 The Salford Psoriasis Index

The Salford Psoriasis Index (SPI) (Kirby et al. 2000) is derived from combining a score of current severity of psoriasis based on the PASI, a score indicating psychosocial disability, and a score based on historical information (Ellis and Langley 2002). The resultant three-figure SPI (signs, psychosocial disability, interventions) is a paradigm similar to the TNM classification for cancer staging.

The first figure of the SPI transforms the PASI into a number from 0 to 10, with each number corresponding to a band of PASI values.

PASI	Extent Score
0	0
0.1–3	1
3.1–5	2
5.1–8	3
8.1–11	4
11.1–14	5
14.1–18	6
18.1–23	7
23.1–29	8
29.1–36	9
>36	10

The second figure indicates the psychosocial impact of psoriasis on each patient using a 0–10 visual analog scale (VAS). Patients are asked to mark on the scale (10 = completely affected, and 0 = not at all affected) the extent to which they perceive that their psoriasis is affecting their day-to-day life at the time of assessment.

The third figure reflects historical disease severity as judged by the need for systemic treatment or admission to hospital and by the number of episodes of erythroderma.

Calculation of historical disease severity scores for the Salford Psoriasis Index

- 1 point for each individual systemic treatment including PUVA
- 1 extra point for each treatment received for >1 year
- 1 extra point if patient has received >200 treatments or >1000 J/cm² of PUVA
- 1 point for every five hospital admissions for the treatment of psoriasis
- 1 point for every episode of erythroderma

7 The Dermatology Index of Disease Severity

The Dermatology Index of Disease Severity (DIDS) (Faust et al. 1997) focuses on two factors: the percentage of involved BSA and functional limitation, in forming a five-stage scale ranging from stage 0 to stage IV.

0	No evidence of clinical disease
I	Limited disease
II	Mild disease
III	Moderate disease
IV	Severe disease

Acne vulgaris • Acne scars • Score • Grading system • Lesion counting • Photographic scales • Ideal scoring system • Quality of life scales

1 Introduction

Research on acne vulgaris, a common dermatosis encountered by dermatologists worldwide with significant individual and societal impact, is hindered owing to the absence of a universal, consistently applied standard for acne severity. Optimal patient care in the field of dermatology which predominantly relies on the clinical evaluation of patient necessitates a validated outcome measure which objectively monitors the disease severity over time without much inter- or intraobserver variability. As far as assessing the severity of acne vulgaris is concerned, more than 25 different grading systems exist in literature till date, indicating the lack of consensus on this issue resulting in the absence of a global standard grading system (Tan et al. 2013; Ramli et al. 2012). The difficulty in assessing acne severity and the presence of multiple assessment systems could be attributed to the polymorphic nature of acne vulgaris, its varied extent of involvement, and variations occurring during the natural course of the disease (Adityan et al. 2009). This limitation is likely to have an impact on patient care by hindering the translation of results from interventional studies

and epidemiologic research to clinical practice (Tan et al. 2013).

Cutaneous diseases have a significant impact on the quality of life (QOL) which can be as complex as those from more debilitating and life-threatening diseases, and acne vulgaris has been described to cause more psychic trauma and suffering than does other cutaneous diseases. Hence QOL measures which are not reflected in measures of skin disease severity, like psychologic stress, embarrassment, stigma, physical discomfort, etc., need to be assessed while assessing disease severity (Anderson and Rajagopalan 1997; Koo 1995). In addition, both active disease and damage from burnt out disease can cause significant patient morbidity. Hence scoring systems are essential for both acne vulgaris and its sequelae – post-acne scarring.

2 Classification of Scoring Systems in Acne

The scoring systems in acne can be classified into the following six types (Ramli et al. 2012; Faure et al. 2009; Barratt et al. 2009; Witkowski and Parish 2004):

- Qualitative scales – degrees of severity: minimal, moderate, and severe
- Semiquantitative scales – numerical score: ranging from 0 to 10
- Quantitative scales – based on lesion counting
- Photographic scales
- Acne-specific quality of life scales
- Post-acne scarring scoring system

Carmen Thomas of Philadelphia was the first person who used a scoring system for acne vulgaris by using lesion counting in the 1930s (Witkowski and Parish 1999). The various scoring systems for acne vulgaris published in literature are summarized in Tables 1, 2, and 3, and the scoring systems for acne scars are summarized in Table 4. The various quality of life (QOL) scales specific for acne vulgaris which can be

used to monitor change during therapy include the following (Barnes et al. 2012):

- Acne Disability Index (ADI)
- The Cardiff Acne Disability Index (CADI)
- The APSEA (Assessment of the Psychological and Social Effects of Acne) from Leeds
- The acne QOL

3 Advantages and Disadvantages of Various Acne Scoring Systems

3.1 Grading System

Grading is based on observing the dominant lesions, evaluating the presence or absence of inflammation, and estimating the extent of involvement. It is simple, reproducible, and quick to use during serial clinic visits. It estimates the full extent of involvement and also allows the clinician to observe the dominant lesions and to evaluate the presence/absence of inflammation. It has also been suggested that an overall grading system can replace spot counting but it may not be so in the setting of therapeutic trials where lesion counting, a more sensitive method, would be preferred. The subjective nature and presence of multiple variables may result in interobserver variability with the grading system. In addition, grade assessment is complicated by the presence of erythema and scaling which might be attributed to the side effects of topical treatments rather than the worsening of acne per se. Some grading techniques use photographic standards as reference scales which have their own drawbacks which will be discussed later (Adityan et al. 2009; Barratt et al. 2009; Burke and Cunliffe 1984).

3.2 Lesion Counting

Lesion counting being an objective measure and a more sensitive technique by distinguishing small effects in therapeutic response far better than an

Table 1 Grading systems based on the description of lesions

S. no	Authors	Grading			
1.	Pillsbury et al. (1956) (Ramli et al. 2012)	Grade	Description		
		1	Comedones and occasional small cysts confined to the face		
		2	Comedones with occasional pustules and small cysts confined to the face		
		3	Many comedones and small and large inflammatory papules and pustules, more extensive but confined to the face		
2.	James and Tisserand (1958) (Ramli et al. 2012; Witkowski and Parish 2004)	Grade	Description		
		1	Simple noninflammatory acne comedones and a few papules		
		2	Comedones, pustules, and a few pustules		
		3	Larger inflammatory papules, pustules, and a few cysts; a more severe form involving the face, neck, and upper portions of the trunk		
3.	Pochi et al. (1991) – Report of the Consensus Conference on Acne Classification	Grade	Papules/pustules (papules – inflammatory lesions <5 mm in diameter; pustules – visible central core of purulent material)	Nodules (inflammatory lesions ≥5 mm in diameter)	
		Mild	Few to several	None	
		Moderate	Several to many	Few to several	
		Severe	Numerous and/or extensive	Many	
4.	Doshi et al. (1997) – Global acne grading system (GAGS)	The face, chest, and back divided into six areas and assigned a factor based on size			
		Each type of lesion is given a value depending on severity			
		The score for each area is the product of the most severe lesion, multiplied by the area factor			
		Total score = sum of individual scores			
		Location	Factor	Severity	Local score
		Forehead	2	0 Nil	Factor X Severity
		Right cheek	2	1 Comedone	Mild 1–18 Moderate 19–30 Severe 31–38
		Left cheek	2	2 Papule	
Nose	1	3 Pustule			
Chin	1	4 Nodule	Very severe >39		
Chest and upper back	3

(continued)

Table 2 (continued)

S. no	Authors	Scoring	
6.	Burke and Cunliffe (1984) – Leeds technique	Lesions divided into inflamed and noninflamed are as follows	
		<i>Noninflamed lesions</i> – blackheads and whiteheads (intermediate lesions counted according to their major component)	
		<i>Inflamed lesions</i> – superficial (papules and pustules) or deep (nodules, cysts, and deep pustules)	
		(i) <i>Superficial papules and pustules</i> – 0.1 cm (with minimal erythema) to 0.5 cm (with a marked macular flare). Smaller less inflammatory lesions were classified as “less active papules or pustules,” the larger erythematous lesions as “active papules or pustules.” The lesions were assigned according to its major component	
		(ii) <i>Deep inflamed lesions</i> – predominantly nodules 0.5 cm or larger	
		(iii) <i>Macules</i> – resolving phase of either superficial or deep lesions and were either large or small	
		Used for detailed work in therapeutic trials to distinguish between active and less active acne lesions	
7.	Lucky et al. (1996)	Counted each type of acne lesions, and then recorded on a special facial template that was divided into five segments, which are the right and the left forehead, the right and left cheek, and the chin	
		Hairline- and jawline-defined perimeters of the face and the nose area were excluded	
		Grade	Description
		Very mild	Just a few comedones
		Mild	More comedones and few papules and pustules
		Moderate	Many papules and pustules
		Severe	Many papules and pustules with a few nodules
		Very severe	Several comedones, papules, pustules, and nodules
8.	Dreno et al. (1999) Echelle de Cotation des Lésions d’Acné (ECLA) or “Acne Lesion Score Scale”	Semiquantitative method	
		Three factors of severity considered based on the extent of involvement and scarring	
		Involvement of the face – based on the count of comedones (scored 0–5), papulopustules (scored 0–5), and inflamed nodules/cysts (counted not scored)	
		Involvement of other areas (the neck, chest, upper and lower back, and arms) – based on acne grading (comedones and papules/pustules all taken together) as 0, none; 1, mild; 2, moderate; 3, severe and counting inflamed nodules/cysts	
		The presence or absence of scarring is noted on the entire acne area	
		Advantages: entire acne-prone area covered, good intra- and interinvestigator’s reliability, less time taken, can be used in clinics	
		Limitations: prior training mandatory	
9.	Lehmann et al. (2002)	Grade	Description
		Mild	<20 comedones, <15 inflammatory lesions, or total lesion count <30
		Moderate	20–100 comedones, 15–50 inflammatory lesions, or total lesion count 30–125
		Severe	>5 cysts, total comedo count >100, total inflammatory count >50, or total lesion count >125
10.	Tan et al. (2007) Comprehensive Acne Severity Scale (CASS)	Grade	Description
		Clear	0 No lesions to barely noticeable ones. Very few scattered comedones and papules
		Almost clear	1 Hardly visible from 2.5 m away. A few scattered comedones, few small papules, and very few pustules

(continued)

Table 2 (continued)

S. no	Authors	Scoring		
		Mild	2	Easily recognizable; less than half of the affected area is involved. Many comedones, papules, and pustules (0–5 papules-pustules)
		Moderate	3	More than half of the affected area is involved Numerous comedones, papules, and pustules (6–20 papules-pustules)
		Severe	4	The entire area is involved. Covered with comedones, numerous pustules, and papules, a few nodules and cyst (21–50 papules-pustules)
		Very severe	5	Highly inflammatory acne covering the affected area, with nodules and cyst present (>50 inflammatory lesions)

variables such as assessor's visual acuity and office lighting (Adityan et al. 2009; Barratt et al. 2009; Burke and Cunliffe 1984).

3.3 Photography

The major advantages of photography include a permanent record of acne severity and reliable recording of changes with time. Fluorescence and polarized light photography have some advantages over normal color photography in estimating the number of comedones and emphasizing erythema, but their major drawback is excessive time involvement and the need for more complicated and expensive equipment. Photography is associated with technical problems requiring constant lighting, constant distance between the patient and camera, and constant developing procedures which are difficult to standardize and maintain accurately. Moreover, photographs can never detect the small inflammatory lesions and comedones adequately and may not reflect disease activity. Residual erythema, pigmentary changes, tanning, and redness from natural or artificial light exposure and excoriations are minimized especially when the patient has additional pigment. Finally, photography being two dimensional can never replace palpation, resulting in errors in distinguishing deep lesions from active superficial lesions or macules (Adityan et al. 2009; Barratt et al. 2009; Burke and Cunliffe 1984).

3.4 Quality of Life Scales

Quality of life is considered an important outcome measure of treatment which guides treatment selection by both patients and physicians. With acne being a disorder associated with significant psychosocial issues, the improvement in quality of life should be considered a major outcome measure as they assess what the patient experiences (Anderson and Rajagopalan 1997; Koo 1995). But studies (Kokandi 2010; Dreno et al. 2007b; Ilgen and Derya 2005; Aktan et al. 2000) have shown that acne severity scores failed to correlate with the QOL scales, indicating that clinical severity alone does not affect quality of life and many other factors might play a role. Hence, each patient should be treated individually, taking into consideration that mild disease does not mean little effect on the quality of life, and scoring systems should include QOL measures also to assess response to treatment. In order for quality of life measures to be used more frequently in the routine clinical work, they need to be easy to use, meaningful, and readily accessible (European Dermatology Forum 2013).

4 Precautions to Be Followed

Whatever is the method used, certain precautions need to be followed while scoring the severity of acne in a patient. These include (Burke and Cunliffe 1984):

Table 3 Scoring systems based on photographic references and newer imaging modalities

S. no	Authors	Grading	
1.	Cook et al. (1979)	Grade	
		0	Up to small scattered comedones and/or small papules are allowed
		2	Very few pustules or three dozen papules and/or comedones; lesion are hardly visible from 2.5 m away
		4	There are red lesions and inflammation to a significant degree; worth treating
		6	Loaded with comedones, numerous pustules; lesions are easily recognized at 2.5 m
		8	Conglobata-, sinus-, or cystic-type acne; covering most of the face
		Both sides of a patient’s face photographed on a single exposure using a front-surface mirror	
Five reference photographs used			
Proposed for use in larger clinical trials			
2.	Wilson (1980)	Elaborated on the scoring system devised by Blaney and Cookin 1976 and perfected at the 1978 American Academy of Dermatology meeting by inviting about 800 dermatologists to try his method for office application	
3.	Allen and Smith (1982)	A photonumeric method – both grading using lesion counting and photographic standards	
		Grade	Description
		0	The facial skin need not be perfectly clear. A few scattered comedones or papules may be present but should be visible only on close examination
		2	One fourth of the facial area involved, with small papules (about 6–12) and comedones (a few pustules or large prominent papules may be present)
		4	Half of the facial area involved, with small papules and large or small comedones. A few pustules or large prominent papules are usually present. (If lesions are generally large, then “grade 4” severity, even if less than half of facial area involved.)
		6	Three fourths of the facial area involved, with papules and/or large open comedones. (Lesser facial area of involvement is permissible if inflammatory lesions are large.) Numerous pustules are usually present, some of which may be large
		8	Whole facial area involved, with lesions. Large prominent pustules are usually visible. Lesions are usually highly inflammatory. Other types of acne (such as conglobata, including sinus and cystic types) may be present
		Grading scale for comedones	
		Grade	Description
		0	No comedones
		2	Mild comedonal acne
		4	Obvious comedonal acne
		6	Severe comedonal acne
8	Extremely severe comedonal acne		

(continued)

Table 3 (continued)

S. no	Authors	Grading	
4.	Gibson et al. (1982) (Gibson et al. 1984)	1. A 0–10 visual-tactile grading system – quick but thoughtful clinical assessment, overall impression of the clinical picture, both the types of lesions present, area of the skin involved are taken into account and given a score	
		2. Lesion counting – a careful count of less active and active papules, less active and active pustules, deep pustules, nodulo-cysts, and macules	
		3. Patient self-assessment – worse, no change, fair, good, excellent	
		4. Photographs (black and white and colour slides)	
		(1) Severity of acne according to a 0–4 scale with half point ratings	
		Grade	Description
		0	No acne
		1	Minimal acne
		2	Mild acne
		3	Moderate acne
		4	Severe acne
		(2) Change in acne severity using scoring system	
		Grade	Description
		–2	Much worse
		–1	Worse
		0	No change
		1	Minimal improvement
		2	Fair improvement
3	Good improvement		
4	Excellent improvement		
	Observed good correlation between lesion counts and the severity of acne as judged by both photographic methods and clinical grading		
	Lack of correlation between the photographic assessments and clinical grading with regard to the change in acne severity		
	Concluded that well-thought-out clinical grading system is the best overall method as it provides a meaningful assessment with speed and reasonable accuracy		
5.	Burke and Cunliffe (1984) – Leeds technique	Graded acne lesions on a scale of 0 (no acne whatsoever) – 10 (the most severe acne) and compared the results with reference photographs	
		Subdivided 0–2 into 7 subgroups – 0.25, 0.50, 0.75, 1, 1.25, 1.5, 1.75	
		Physiological acne or “acne minor” – 0.25–1	
		Clinical acne or “acne major” – ≥ 1.5 (1.5–10 subdivided into 0.50 subdivisions)	
		Three sites graded – the face including the chin and neck anterior to the stern mastoid muscles; the chest in men from the waist upward, but in women only the skin between the breasts and above the bra; back in both sexes from the waist upwards. Shoulders were included for both the back and chest assessment, but the arms were excluded	
	Accurate, reproducible, rapid, and suitable for use in the routine clinic		

(continued)

Table 3 (continued)

S. no	Authors	Grading			
6.	Samuelson (1985)	Graded based on a set of nine reference photographs			
		Both the patient and physician assessed the severity based on the reference on a nine-grade scale			
		The face, chest, and back are included			
		Degree of change	Description		
		Excellent	There was a decrease of three or more grade numbers with reduced redness and tenderness		
		Good	There was a decrease of two grades with reduced redness and tenderness		
		Moderate	There was a decrease of one grade with reduced redness and tenderness		
		None Worse	There was no change There was an increase of one grade or more or an increase in redness or tenderness with the same grade		
7.	Lucchina et al. (1996)	Fluorescence photography – Two filters were used for fluorescence photography for UVA transmittance and elimination of infrared light			
		Severity of comedonal acne assessed based on a four-point scale			
		Excluded the chest and back			
		Grade	Scale		
		0	None		
		1	Mild		
8.	Phillips et al. (1997)	Polarized light photography – the polarizing filter on the camera was oriented at a right angle with respect to the linear polarizer on the ring flash			
		Counts of comedones and inflammatory acne assessed			
		Enhanced visualization of the skin features, color, and lighting and framing made comedo counts easier			
9.	O'Brien et al. (1998) – The Leeds Revised Acne Grading System	Provides a photographic standard for acne grading of the face, back, and chest – representations selected over 1,000 photographs by an expert panel of three dermatologists and four acne assessors			
		12 grades for the face and 8 grades for the upper chest and back			
		Body part	Mild	Moderate	Severe
		Face	Grade 1–grade 4	Grade 5–grade 8	Grade 9–grade 12
		Upper chest and back	Grade 1–grade 3	Grade 4–grade 5	Grade 6–grade 8
10.	Rizova and Kligman (2001)	Parallel-polarized and cross-polarized photography with video microscopy and sebum production measurement			
		Since multiple modalities are used, it cannot be used for real-time analysis			
11.	Hayashi et al. (2008)	Standard photographs and lesion counting			
		First, acne classified based on the number of inflammatory eruption of half the face			
		Second, the lesions were counted and divided into four groups			
		The judgments on severity grades were then compared with those of an expert panel of three dermatologists, who evaluated half-face photographs of the same patients			
		Total number of lesions	Group		
		6–20	Moderate		
21–50	Severe				
>50	Very severe				

(continued)

Table 3 (continued)

S. no	Authors	Grading		
12.	Do et al. (2008)	Computer-assisted alignment and tracking of acne		
		Combined digital photography with photoediting software with alignment capabilities		
		Region of interest (ROI) with the most clinically major acne lesions selected – up to seven ROIs		
		The lesions were counted in each ROI and classified either as open or as closed comedones, papules, pustules, and nodules		
		From the first appearance, numbers were assigned to each new lesion after tracking inflammatory lesions		
		Lesion growth monitored every 2 weeks for 12 weeks		
		This technique eliminated photographic inconsistencies such as variability of camera angle and framing		
13.	Fuji et al. (2008)	Multispectral imaging (MSI) – 16-band multispectral camera		
		The spectral information for various types of acne skin lesions, acquired from the MSI of the lesion used		
		Combination of several linear discriminant functions (LDFs) used for acne lesion classification		
		Three Fisher LDFs and three threshold values used to consider three classes to classify acne types		
		The Fisher LDFs were calculated from both reddish papule and pustule, both pustule and scar, and both reddish papule and scar, respectively		
		The threshold values for these LDFs were determined experimentally. MSI and the LDF classifier were able to differentiate several skin lesions such as comedo, reddish papule, pustule, and scar based on color image		
14.	Bae et al. (2008)	Multimodal facial color imaging modality for objective analysis of skin lesion		
		Used a conventional color image, parallel and cross-polarization color images, and a fluorescent color image		
		Proposed fluorescent image analysis methods for the quantitative evaluation of sebum-related parameters such as pattern, area and density, average size and diameter of spots		
15.	Dreno et al. (2011) Global Evaluation Acne (GEA) scale for France and Europe	Photographic and clinical assessment		
		Grade	Description	
		0	Clear. No lesions	Residual pigmentation and erythema may be seen
		1	Almost clear. Almost no lesions	A few scattered open or closed comedones and very few papules
		2	Mild	Easily recognizable. Less than half of the face is involved. A few open or closed comedones and a few papules and pustules
		3	Moderate	More than half of the face is involved. Many papules and pustules; many open or closed comedones. One nodule may be present
		4	Severe	The entire face is involved, covered with many papules and pustules, open or closed comedones, and rare nodules
5	Very severe	Highly inflammatory acne covering the face with the presence of nodules		

(continued)

Table 3 (continued)

S. no	Authors	Grading
		Simple and practical tool designed for everyday use in routine clinical practice as well as in clinical trials Good inter- and intraobserver reliability Limitation validated for a homogeneous population of polymorphous juvenile acne of the face
16.	Choi et al. (2012)	3D image analysis system Skin surface roughness and volume of acnes protruding on the skin surface analyzed quantitatively Volume of acne lesions may provide more reliable criteria for the topographic classification of acne lesions because acne lesions usually have irregular shapes, and hence their diameter in any specific direction may not represent their size correctly 3D image analysis system may supplement the counting or grading system of acne lesions Provides novel opportunities to address topographical changes of the skin from the cosmetic point of view Clinically less relevant than acne scoring based on pathological severity – could underestimate severe nodular and cystic acne if they show minimal protrusion above the level of the surrounding skin Requires additional methods including visual assessment, spectrophotometric determination and pathological examination

- The patient should be seated comfortably so that the observer can move around him easily to count each area.
- In addition to good background fluorescent lighting, Brighton 1001 fluorescent lamp, which can be easily moved to illuminate both sides of the patient during the examination, is recommended.
- In the entire acne-prone area including the face, chest, back and in each site, the total area needs to be examined. When counting, the face should be divided into the right and left sides, and both sides need to be counted. In some patients, the lesions are clustered around the midline, making a right-left division difficult; in such cases, the forehead, the cheeks, and the chin should be counted separately and finally combined.
- Cosmetics should be removed at least 30 min prior to assessment as erythema due to washing needs to settle.
- Palpation (without stretching the skin) is mandatory in counting methods to enable detection of all comedones and nodules. Though stretching of the skin and use of magnifying lens would increase the number of visible whiteheads and blackheads, they are not permitted as the degree of stretching might vary.
- If a lesion is impalpable and not obvious with good lighting, then such a vague lesion should be best ignored.
- In clinical trials, baseline scoring is essential which should be after at least 3 months of washout period of the previous treatment.
- Trials should not be conducted in summer to avoid the anti-inflammatory effect of sun rays as ultraviolet radiation will camouflage the noninflamed lesions and make the inflamed lesions look less inflamed.
- All scales require a minimum observer training especially for counting methods as the secret of lesion counting is practice.
- Prior to clinical trials, the assessor's reliability needs to be checked – the novice assessor should select 30 patients and in groups of 10 should count the lesions (under standard conditions) on 1 day and then 24 h later. The more spot counting performed, the more spots will be seen until a plateau is reached. When this plateau is achieved, then comparison of

data collected on two consecutive days should give a correlation with a minimum value of 0.80. Only at this stage the physician will be considered ready to count spots in a clinical trial.

- Acne scores or grades are distributed on ordinal scale, and absolute counts are distributed on an interval scale, and these interval scales would be better for statistical analysis.

5 Problems Encountered

- Prominent follicles are likely to be confused with noninflamed lesions especially around the nose and on the chin, especially in mid-teenagers. Hence, in therapeutic trials, it is recommended that noninflamed lesions are not counted either on the nose or around the edge of the nose.
- Sandpaper acne covering the forehead (usually ≥ 100) are very superficial lesions, which are impossible to be classified correctly, and such patients should be excluded from clinical trials.
- Long, uncut hair may mask noninflamed lesions, and hence counting around the hairline should be avoided. However, there is usually no difficulty in recognizing inflamed lesions in this area.
- Growing mustache or beard during the trial would complicate the results, and these patients may develop low-grade folliculitis on the chin and neck as a result of shaving trauma. However, the papules and pustules associated with a folliculitis are much less easily felt than acne lesions. Patients should shave daily, preferably at a constant time, as stubble can affect the interpretation of all lesions.
- Other dermatoses like sycosis barbae which may occur in association with acne and low-grade seborrhoeic eczema may simulate a primary irritant dermatitis which can be seen commonly with treatments with benzoyl peroxide (Burke and Cunliffe 1984).

6 Ideal Scoring System

The essential components and features for ideal acne global grading scale (AGGS) have been currently established by consensus from clinical and investigative experts in acne by an online Delphi process (Tan et al. 2013, 2012). These include four clinical components and four features as follows:

6.1 Clinical Components

- Primary lesions (no inflammatory and inflammatory, evaluated separately)
- Quantity of lesions (evaluated through counting and numerical range)
- Extrafacial sites of involvement (specifically the chest, back, neck, and shoulders)
- Extent of involvement (evaluated using proportion descriptors such as one third or less)

6.2 Features

- Clinimetric properties (validity, reproducibility, discriminatory capacity, and responsiveness)
- Efficiency (easy for clinicians, researchers, and nursing staff to use and easy to teach)
- Acceptability (by researchers, clinicians, and regulators)
- Categorization of severity (through descriptive text and/or photographic examples)

7 Future Prospects

Novel emerging techniques like computerized morphometric analysis of acne lesions and spectrophotometric dermoscopy to determine disruption of the dermal-epidermal junction and assess quantities of melanin, collagen, and blood within specific layers of skin to assess acne lesions may also help in assessing acne severity (Barratt et al. 2009).

Table 4 Scoring system for acne scars

S. no	Authors	Grading																			
1.	Friedman et al. (2002)	Optical three-dimensional in vivo skin measurement device – grading device that focus on 3-dimensional grid-based mapping of lesions and molded skin replicas for comparison examination Demonstrated a substantial correlation between subjective clinical assessment and objective 3D in vivo imaging Not applicable in practical, daily use by the average physician																			
2.	Dreno et al. (2006) (Dreno et al. 2007a) – ECCA grading scale (échelled’évaluation clinique des cicatrices d’acné)	Built on the model of the ECLA grading scale for acne. It is composed of six types of scar described and associated with a quantitative score (ranging from 0 to 4) and a weighting factor (ranging from 15 to 50) This weighting factor is based on clinical approach and is based on the severity, the evolution, and the morphological aspect of the scars and hence is directly correlated with the clinical severity Number of scars – semiquantitative estimation by a 4-point scale: 0 = no scar, 1 = a few scars (<5), 2 = limited number of scars (between 5 and 20), 3 = many scars (>20) Grading of the different kinds of scars = product of the semiquantitative score and the weighting factor V-shaped atrophic scars (weighting factor 15): diameter of <2 mm and punctiform; U-shaped atrophic scars (weighting factor 20): diameter of 2–4 mm with sheer edges; M-shaped atrophic scars (weighting factor 25): diameter of >4 mm, superficial and with irregular surface; Superficial elastolysis (weighting factor 30); Hypertrophic inflammatory scars (weighting factor 40): <2 years of age; Keloid scars (weighting factor 50): hypertrophic scars, >2 years of age Subgrading 1 – grading of the first 4 items Subgrading 2 – grading of the last 2 items Global score = subgradings 1 + 2 – varies between 0 and 540 Good interinvestigator reliability																			
3.	Goodman and Baron (2006a, b)	Quantitative grading system: based on counting of scar type and severity (Goodman and Baron 2006a) Reasonably accurate and reproducible with good interinvestigator reliability <table border="1" style="width: 100%; border-collapse: collapse;"> <thead> <tr> <th>(Grade) type</th> <th>Number of lesions:</th> <th>Number of lesions:</th> <th>Number of lesions:</th> </tr> </thead> <tbody> <tr> <td></td> <td>1 (1–10)</td> <td>2 (11–20)</td> <td>3 (>20)</td> </tr> <tr> <td>Milder scarring (1 point each)</td> <td rowspan="3">1 point</td> <td rowspan="3">2 points</td> <td rowspan="3">3 points</td> </tr> <tr> <td>Macular erythematous or pigmented</td> </tr> <tr> <td>Mildly atrophic dish-like</td> </tr> <tr> <td>Moderate scarring (2 points each)</td> <td rowspan="2">2 points</td> <td rowspan="2">4 points</td> <td rowspan="2">6 points</td> </tr> <tr> <td>Moderately atrophic dish-like</td> </tr> </tbody> </table>	(Grade) type	Number of lesions:	Number of lesions:	Number of lesions:		1 (1–10)	2 (11–20)	3 (>20)	Milder scarring (1 point each)	1 point	2 points	3 points	Macular erythematous or pigmented	Mildly atrophic dish-like	Moderate scarring (2 points each)	2 points	4 points	6 points	Moderately atrophic dish-like
(Grade) type	Number of lesions:	Number of lesions:	Number of lesions:																		
	1 (1–10)	2 (11–20)	3 (>20)																		
Milder scarring (1 point each)	1 point	2 points	3 points																		
Macular erythematous or pigmented																					
Mildly atrophic dish-like																					
Moderate scarring (2 points each)	2 points	4 points	6 points																		
Moderately atrophic dish-like																					

(continued)

Table 4 (continued)

S. no	Authors	Grading			
		Punched out with shallow bases small scars (<5 mm)			
		Shallow but broad atrophic areas			
		Severe scarring (3 points each)	3 points	6 points	9 points
		Punched out with deep but normal bases, small scars (<5 mm)			
		Punched out with deep abnormal bases, small scars (<5 mm)			
		Linear or troughed dermal scarring			
		Deep, broad atrophic areas			
		Hyperplastic papular scars	2 points	4 points	6 points
		Hyperplastic	Area <5 cm ² 6 points	Area 5–20 cm ² 12 points	Area >20 cm ² 18 points
Qualitative grading system – simpler for quick, daily use (Goodman and Baron 2006b)					
		Grade	Level of disease	Characteristics	Examples of scars
		1	Macular	Erythematous, hyper- or hypopigmented flat marks visible to patient or observer irrespective of distance	Erythematous, hyper- or hypopigmented flat marks
		2	Mild	Mild atrophy or hypertrophy that may not be obvious at distances of ≥50 cm and may be covered adequately by makeup or the normal shadow of shaved beard hair in males or normal body hair if extra facial	Mild rolling, small soft papular

(continued)

Table 4 (continued)

S. no	Authors	Grading				
3.	Goodman and Baron (2006a, b)	3	Moderate	Moderate atrophic or hypertrophic scarring that is obvious at ≥ 50 cm and is not covered easily by makeup or the normal shadow of shaved beard hair in males or body hair if extra facial, but is still able to be flattened by manual stretching of the skin	More significant rolling, shallow “boxcar,” mild to moderate hypertrophic or papular scars	
		4	Severe	Severe atrophic or hypertrophic scarring that is obvious at ≥ 50 cm and is not covered easily by makeup or the normal shadow of shaved beard hair in males or body hair (if extrafacial) and is not able to be flattened by manual stretching of the skin	Punched out atrophic (deep “boxcar”), “ice pick,” bridges and tunnels, gross atrophy, dystrophic scars significant hypertrophy or keloid	
Global acne scarring classification by area of involvement and major scar type (Goodman and Baron 2006b)						
		Grade	Description	Subgroup	A, focal, 1 cosmetic unit	B, discrete, 2–3 cosmetic units
		1	Macular	Erythematous	1A	1B
				Hyperpigmented		
				Hypopigmented		
		2	Mild	Atrophic	2A	2B
				Hypertrophic		
		3	Moderate	Atrophic	3A	3B
				Hypertrophic		
		4	Severe	Atrophic	4A	4B
				Hypertrophic		
4.	Chapas et al. (2008)	3D optical profilometry				
Valid and reliable method for assessing improvement in acne scarring						
Highly operator-dependent and may produce a variety of artifacts						
5.	Tan et al. (2010)-SCAR-S (2010)	Six-category global severity scale				
For assessment of acne scarring at each of the face, chest, and back						
Practical, validated, global system for acne scar evaluation						
Clinically relevant in overall severity grading of acne						

Similarly, various methods and techniques developed for skin analysis can also be used as potential computational methods for acne grade assessment quantitatively. These include the following (Ramli et al. 2012):

- Xu et al. (1999) – automatic method for the segmentation of images of skin lesions
- Schmid-Saugeon et al. (2003) – computer-aided diagnosis system for skin lesion boundary detection and quantification of diagnostic features, the classification into different types of lesions, the visualization, etc.
- Masood et al. (2008) – unsupervised color segmentation procedure for skin lesion classification

Skin detection refers to a common preprocessing step for analyzing images or videos of humans aiming to track the human body for further recognition which includes face detection and recognition, image content classification, etc., and these include the following (Ramli et al. 2012):

- Skin color thresholding
- Neural network classifier
- Maximum entropy classifier
- Bayes classifier

The descriptions of these techniques are beyond the scope of this chapter. Readers may assess those papers to find the details.

8 Conclusion

A validated standard acne scoring system is essential to maintain objectivity in observations while evaluating the severity of acne, to monitor the response to therapy, and to evaluate the efficacy of new drugs. No universal standard exists for grading acne severity till date. In the absence of such a score, new therapies cannot be systematically assessed, and clinical trials conducted

without such standardized outcome measures produce less reliable results. Essential clinical components and features for an ideal scale have been identified, and the current acne global scales can serve as foundations upon which an ideal standard can be developed.

1 Introduction

Optimal treatment of acne vulgaris depends on the accurate severity assessment (Rizova and Kligman 2001). Due to the polymorphic nature and varied involvement of acne, a simple evaluation is not easy (Adityan et al. 2009). Assessment has relied on text descriptions, lesion counting, and photographic methods. Clinical trials require valid and consistent measures, but with no universal method, trials rely on subjective assessments that complicate intertrial comparison (Barratt et al. 2009). An ideal grading system would be accurate and reproducible. Ease of use as well as time and monetary cost should also be considered. Photography approaches such a system and has a place in the measurement of acne severity (Tables 1 and 2).

2 Results**2.1 Photographic Standards**

Photography has various uses in evaluating acne, from having a photographic standard for categorizing acne severity to using a patient's photographs to visualize their acne condition.

Cook et al. (1979) proposed an innovative and useful acne grading method: the first photographic standard. Lesion counting is not as simple a method as it sounds since size and redness of lesions are not considered and variance can be great. Even if lesion types are individually counted, classification still requires subjective judgment. To develop a user-friendly, precise, intergrader consistent grading system capable of documentation for retrospective verification, Cook proposed an overall acne severity scale of 0–8 with reference photos and text descriptions illustrating grades 0, 2, 4, 6, and 8. Both sides of the face were photographed on a single exposure by positioning the face parallel to a front-surface mirror. A 35-mm single-lens reflex camera fitted with lens of 85–105-mm focal length is placed 45° from the mirror. A strobe flashlight source above the camera provided sufficient depth of field to bring into focus both real and reflected images. A set of five reference photos that elicited the most consistent 2–4–6 response was selected from numerous patient photographs by trained graders and panelists.

This grading scheme was used by two judges in a trial involving treatment groups, each composed of 20 subjects: (1) placebo capsules and topical placebo, (2) oral tetracycline and topical placebo, and (3) topical tetracycline and placebo capsules. The greatest correlation between the judges was for overall severity grades for 1 week prior to treatment and after 8 weeks of treatment with coefficients 0.785 and 0.891, respectively. A similar earlier trial (Blaney and Cook 1976) was conducted with 75 subjects divided into groups: (1) topical active mixture and oral lactose capsules, (2) topical placebo and oral lactose capsules, and (3) topical placebo and oral tetracycline hydrochloride capsules. Three sets of five reference photos each were used to grade subjects. In addition, both sides of the face were photographed at each visit with the camera mirror setup described above. Other trials confirmed that grading overall severity provided a measurement of efficacy consistent between graders and more sensitive to differences between treatments than

lesion counts. However, for studies on experimental drugs, affected lesions types should be defined and counted for precise results. For example, tetracycline has a greater effect on inflammatory lesions than comedonal acne. After initial efficacy trials, overall severity grading may be used for large-scale trials to save time. Cook concluded that photographic standards were useful and reliable, aiding consistency between sessions and graders. In addition, photographic documentation creates a regradable record for verification. Results showed that a 1.5 grade change constituted a clinically important difference. Since images are less powerful than on-site impressions, 1 grade change for photos was determined to be an important difference.

Through the years, Cook's photographic standard has been utilized and expanded on.

In 1980, Wilson (1980) commented on Cook's method revised at the 1978 American Academy of Dermatology meeting with a new set of chosen reference. Recording objective descriptions for later evaluation is often difficult, especially for acne with various lesion types. Patients improve more rapidly in certain areas than others, and if not observed for weeks, opinions on improvement may differ between physician and patient. Wilson found that while applying the system in clinic, grading agreed closely with the patient's opinion. In conclusion, Wilson praised Cook's method as a quick and accurate acne grading system in practice.

In 1985, Samuelson (1985) elaborated on Cook with a 9-grade scale of nine reference photos and descriptions. This scale was used to evaluate 62 patients in a 12-week study with half receiving minocycline and the other half tetracycline. Every 2 weeks, both the patient and on-site investigator evaluated patient condition, and patient photos were taken. Two reviewers retrospectively graded the photos twice: group 1 slides were completely randomized and group 2 slides were randomized for each patient. At baseline, the investigator and patients assigned comparable grades, but reviewers assigned grades averaging 1–2 units lower. By week 12, all grades agreed

Table 1 Photographic standards for grading acne severity

Author Reference	Method	Comment	References for trials testing methods
Cook et al. (1979)	Plain concave mirror (both sides of patient's face photographed on a single exposure)	Provided strong objective data, placebo versus active, permanent and regradable record, and documentation for verification	(Blaney and Cook 1976; Wilson 1980; Allen and Smith 1982; Leyden et al. 2005)
	Photonumeric 0–8 grading scale, standards given for grades 0, 2, 4, 6, 8	Standards aid consistency from session to session and from grader to grader	
		Allowed detection of 1-unit grade change	
		Cook's scale and lesion counting are at least equally reproducible grading methods	
Samuelson (1985)	Facial acne 1–9 grading scale with nine photographs and descriptions	Reasonable agreement within one grade unit between investigator, patients, and two independent retrospective reviewers	
	Color transparency of three-quarters left profile against surface mirror obtained	Disagreement seen for lower ratings by retrospective reviewers in early stages of study and agreement was best after 12 weeks of therapy	
	Strobe light adjusted to permit equal lighting of the reflected and opposite sides of the patient's face		
Burke and Cunliffe (1984)	Leeds technique: overall assessment of acne severity in area grade 0–10 scale. Graded sites include the face, back, and chest	Useful for routine clinical assessment	(Gibson et al. 1984; Bergman et al. 2009)
	Example black and white photographs of one side of face given for facial grades 0.5, 0.75, 1.0, 1.5, 2.0, 3.0, 5.0, and 8.0	Intraductor correlation was good, especially for the face and back	
		Interdoctor correlation was numerically lower but still good, indicating importance of having the same rater evaluate a patient throughout a study or treatment	
		Meaningful assessment with speed and accuracy	
O'Brien et al. (1998)	Leeds revised: color photographs include a wide range of acne severity	Pictures easily demonstrate impact of inflamed lesions	(Tan et al. 2012a)
	Reference photographs for each grade in facial grades severity 1–12, back grades 1–8, and chest grades 1–8. Note for facial photographs that only right side is shown, and chest photographs are only of male subjects	Scale not suited to score noninflamed lesions, although photographs for a grading system 1–3 for noninflamed acne is introduced	
	Lighting necessary when assessing acne, especially with noninflamed lesions	Grading system is not all encompassing, for example for patients with disproportionately localized acne and sporadic and asymmetrical large nodular lesions

Table 1 (continued)

Author Reference	Method	Comment	References for trials testing methods
		Photographic grading cannot compensate for palpation to assess depth, but this pictorial assessment is still useful for standardization	
		Photographs inadequately represent milder acne grades; still a need for images that correspond to a categorical acne scale for the face, back, and chest	
Hayashi et al. (2008a)	Four rankings: mild, moderate, severe, and very severe. Photographs for half of the face taken at 70° angle from front	Standard photographs make adjustments for difference of judgments between estimators, increasing inter-rater conformity and precision	(Hayashi et al. 2008b)
	Nomination of standard photographs selected matched the counting-based classifications		
	Divisions of number inflammatory eruptions included in classifications for counting conversion to global estimation		

closely. Due to the difference in baseline grades, improvement was greater according to the investigator and patients. Investigator and reviewer grades were substantially different between groups 1 and 2, possibly since reviewers could not retain visual impressions. However, according to Samuelson, complete randomization for group 1 was an unreasonable test anyway. Samuelson concluded that the scale is a useful research tool, and disagreement between reviewers and investigator was caused by investigators having a 3D view, whereas reviewers had a flat perspective.

In 1984, Burke and Cunliffe (1984) presented the Leeds technique that included a clinical scale of 0–10 for the overall assessment of acne severity in particular areas: face, back, and chest. Grading between 0 and 2 was divided into 0.25 increments. Reference black and white facial photos were given for grades 0.5, 0.75, 1.0, 1.5, 2.0, 3.0, 5.0, and 8.0. However, the authors noted that black and white photos do not accurately reflect clinical assessment. Intra- and interdoctor comparisons were made for two physicians assessing patients with Pearson's coefficient correlation. Intra- and interdoctor was good with r-values for each of the doctors: face 0.92 and 0.94, back 0.89 and 0.89, and chest

0.81 and 0.94. Correlations between doctors were lower but still good with r-values: face 0.89, back 0.87, and chest 0.80. Three drawbacks of photography were mentioned: First, difficulty in maintaining constant lighting, distance to camera, and developing procedures; second, difficulty in detecting small noninflamed lesions; and third, because photos are 2D, difficulty in distinguishing deep lesions from active superficial lesions or macules. Grading is also complicated by erythema and scaling. The authors suggest that although Leeds is quick, reproducible, and suitable for clinical use, an overall grading system still cannot replace the counting technique that better distinguishes small differences, especially for trials. When patients have noninflamed and few inflamed lesions, inter- and intra- and interdoctor correlation is poor, and counting is a better assessment choice. However, Leeds is useful in clinic as it requires less practice, and if individual grading is consistent, interdoctor differences are of little concern.

In 1998, Cunliffe et al. (O'Brien et al. 1998) Leeds revised to include reference photos for each grade of facial 1–12, back 1–8, and chest 1–8. Standards were selected from 1,000 photographs

Table 2 Advanced methods for acne assessment

Author	Method	Comment	References
Lucchina et al.	Fluorescence photography	Fluorescence corresponds to protoporphyrin IX production by Propionibacterium acnes in open comedones, follicles, and inflammatory lesions	(Lucchina et al. 1996; Pagnoni et al. 1999)
Pagnoni et al.		Not sensitive enough to detect modest changes but is reliable when variation is clinically relevant	
		Culture still necessary when modest changes in P. acnes cannot be detected with fluorescence	
		Reliable, quick, and easy way to estimate suppressive effects of antibacterial agents on P. acnes	
Phillips et al.	Perpendicular (cross)-polarized and parallel-polarized light photography	Perpendicular-polarized photography enhances subsurface features to better visualize subtle features of acne that are often missed with clinical evaluation alone, such as small comedones, hyperpigmentation, and erythema, which is important for distinguishing inflammatory from noninflammatory lesions	(Rizova and Kligman 2001; Phillips et al. 1997)
Rizova and Kligman		Parallel-polarized photography enhances visualization of surface features such as greasiness, scaling, and degree of lesion elevation	
		Mean Leeds score from perpendicular photographs higher than scores from clinical assessments and flash photographs, indicating increased sensitivity for more accurate severity assessment	
Do et al.	Picture Window Pro 4.0 program	Used to align and track lesions, monitoring development of open/closed comedones, erythematous macules, papules, pustules, and nodules over time	(Do et al. 2008)
		The technology tracks effects of acne medication on lifespan of lesions and characterize natural history of acne	
Choi et al.	PRIMOS Compact 3D image analysis system	Skin surface measurements before and after treatment gave quantitative analysis of skin roughness and lesion volume	(Choi et al. 2012)
		While acne is usually classified by diameter, authors argue that lesions are often irregularly shaped. Thus, volume provides more reliable criteria for classification	
		Disadvantage: severity can be underestimated if lesions only have minimal protrusion	
Fuji et al.	Extraction method for lesion classification	Since inferior color reproduction provided by RGB cameras causes visual differentiation of lesion types to be difficult, in this computer-aided diagnosis system, detailed spectral features are acquired by multispectral images (MSIs) and lesion types such as papule, pustule, and scar are classified by applying a combination of linear discriminant functions (LDFs)	(Fuji et al. 2008)
Bae et al.	Multimodal imaging modality and objective image analysis methods	Independent modalities standard, parallel- and cross-polarized, and fluorescent photographs integrated into one modality to maximize clinical utility	(Bae et al. 2008)

(continued)

Table 2 (continued)

		Each image emphasizes different morphological and functional skin information, to more reliably evaluate severity	
		Polarized images used to analyze skin texture and compute erythema index and melanin index to evaluate vascular and pigmented lesions, respectively	
		Fluorescent images used to quantitatively evaluate sebum characteristics such as pattern, area and density, and average size and diameter of spots	

by the three authors and four assessors. Severity grading was based on inflammation, size of lesions, and erythema. Although the system is not for scoring noninflamed lesions, a 1–3 photographic scale for noninflamed acne was introduced. Other conditions such as irritant dermatitis or retinoid-induced dermatitis may complicate grading. Lighting is also important so as to not undergrade, especially noninflamed lesions. Photographic grading more easily demonstrates the impact of inflamed lesions but cannot easily assess lesion depth. However, the authors believe that the system's attempt at quantitative assessment of acne is useful in clinic and recommend that it complement counting.

In 2008, Hayashi et al. (2008a) established a photographic standard that matched lesion counts and text descriptions with the following categories: mild, moderate, severe, and very severe. Three dermatologists graded 390 half-face photographs. Complete accord among grades was observed for 176 faces (45.1 %). Two hundred sixty-eight faces (68.7 %) had identical classifications by at least two dermatologists. One thousand one hundred seventy photographic evaluations were also compared: 770 decisions (65.8 %) showed conformity, and 1,165 decisions (99.6 %) were within one grade difference. After the comparison of counting lesion types and classification, counting was limited to inflammatory eruptions, papules, and pustules. Distribution of counts was analyzed and divisions were decided:

0–5 mild, 6–20 moderate, 21–50 severe, and 50 plus for very severe on half of the face. Standard photos that satisfied lesion counting-based classifications were selected and were believed to make classification more precise and adjust for differences between graders. Hayashi et al. (2008b) evaluated the validity of this method by calculating conformity for before and after grades. Eighty-seven members at the 104th meeting of the Japanese Dermatological Association and 82 members at the 11th Hunchun Symposium in Seoul were asked to participate, first grading six patient photos. After presenting the severity classification and reference photographs, the same six photos were presented in different orders for grading. The conformity rate rose from 67.0 % to 88.9 % in Japan and 68.0–79.8 % in Korea. A reference was made to Leeds revised (O'Brien et al. 1998) having an approximate conformity rate of 50 %. However, it was noted that Leeds grades into 16 groups rather than 4, so comparison cannot be easily done. The authors conclude that conformity data shows adequacy of their system and believe it is a candidate for acne severity classification at least for Asian patients.

2.2 Photographic Uses and Improvements

There have been many extensions of Cook's method using retrospective assessment of photos

and choosing parameters for grading and ways to increase accuracy of photographic methods.

In 1982, Allen and Smith (1982) used Cook's method in two acne treatment studies. One hundred ninety male college students participated in a first 12-week study, and 141 male college students enrolled in a second 10-week study. Three judges evaluated participants every 2 weeks, grading overall severity by Cook's method, papule count, pustule count, and comedo grade. Photos were taken every 4 weeks for documentation. Pearson's correlation coefficient was used to evaluate correlation of inter-judge evaluations and between the different grading methods. For the first study, severity grade versus papule count had high mean correlation coefficient of 0.84. Severity grade versus pustule count and severity grade versus comedo grade had correlation coefficients of 0.64 and 0.54, respectively. High mean correlation coefficients between graders were obtained for severity grade with 0.82 and papule count with 0.77. For the second study, severity grade versus papule count had high mean correlation coefficient of 0.89. Severity grade versus pustule count and severity grade versus comedo count had correlation coefficients of 0.59 and 0.67, respectively. High mean correlation coefficients between graders were obtained for severity grade with 0.82 and papule count with 0.86. The authors conclude that Cook's scale and counting are at least equally reproducible grading methods. Experience gained from study 1 improved correlation between judges for study 2. The authors believe that overall grading scales, with its ease of use and high reproducibility, are superior to laborious lesion counts for clinical evaluation of acne severity.

In 1984, Gibson et al. (1984) assessed correlation between clinical and photographic methods for assessing facial acne. Forty-five patients were evaluated clinically with Leeds (Burke and Cunliffe 1984) and lesion counting and retrospectively with photos from each visit. Retrospective assessment was conducted on a 0–4 scale with 0.5 increments and change in severity on a scale of –2 to 4. Correlation for clinical grading versus counts, correlation between the three judges

grading photos, correlation for severity judged by photos versus clinical grading, and correlation for severity judged by photos versus counts were all significant ($p = 0.01$). Lesion counting appears objective but is tedious, whereas clinical grading can reflect disease severity more meaningfully but can lack objectivity. Photographic methods allow for a permanent record but lack palpation during retrospective assessment. The authors conclude that Leeds provides meaningful assessment with speed and accuracy.

In 2005, Leyden et al. (2005) presented findings from a retrospective photographic assessment study of topical retinoids for acne. Photos of 577 patients were collected from multiple trials comparing topical retinoids: tazarotene 0.1 % gel, adapalene 0.1 % gel, tretinoin 0.1 % microsphere, tretinoin 0.025 % gel, and tazarotene 0.1 % cream. Complete sets of right, front, and left view of patient photos before (week 0) and after treatment (week 12 or 15) were evaluated by five investigators. Overall severity was assessed with a 7-point modified version of Cook's method. 1 grade change indicated clinically meaningful, and grade change 2 or more indicated clearly clinically significant. This study showed intrainvestigator consistency with no significant differences. Interinvestigator consistency was also shown with correlation coefficients between investigators ranging from 0.648 to 0.836. The authors note that irritation in early phase of studies could not be observed since photos were only taken at the beginning and end of trials, implying that if photos were taken more frequently, a more complete record of results could be obtained.

In 2009, Bergman et al. (2009) conducted a study where 300 digital images from 20 patients were evaluated by two dermatology residents using total inflammatory lesion count (TILC) and Leeds (Burke and Cunliffe 1984). A set of front, right, and left views were taken by either subjects themselves or staff and reviewed for adherence to standardization. To test reliability, Pearson's coefficient correlation was calculated for TILC and κ -score for Leeds. Intra-rater reliability was excellent for TILC with $r = 0.989$ and 0.908, and Leeds $\kappa = 1.0$ and 0.879 for raters

A and B, respectively. Inter-rater reliability was high for TILC $r = 0.871$ but low for Leeds $\kappa = 0.381$. However, when agreement within 0.25 unit was considered for Leeds rather than absolute agreement, $\kappa = 0.74$. Although TILC was indicated as the best measure, since TILC reliability decreased with greater number of lesions and the patients studied had mild to moderate acne, a study evaluating a broader range of severity might indicate a better performance for Leeds. Inter-rater reliability was also less than intra-rater for all methods, reflecting the importance of having the same rater evaluate a patient throughout a study or course of treatment. The authors conclude that digital images can reliably be evaluated for diagnostic purposes and remotely monitor patient progress.

In 2012, Tan et al. (2012a) believed that text descriptions and photographs combined could accurately describe severity categories and would be more practical and time efficient than lesion counting in practice. The scales presented by Cook et al. (1979) and Hayashi et al. (2008a) included photos and text descriptions but are limited to facial acne. Therefore, the authors matched two acne scales that incorporated evaluation of the chest and back in addition to the face, assigning images from Leeds revised (O'Brien et al. 1998) to text description grades from the six-category comprehensive acne severity scale (CASS). Twenty-three dermatologists graded 56 photos of the face, chest, and back using CASS. Photographs included 25 patient photos and the set of 31 photographs from Leeds revised. Rater consensus was achieved for Leeds facial inflammatory 2 with CASS 3, 4 with CASS 4, 6 with CASS 4, and 9–12 all with CASS 5. Consensus was also obtained for Leeds facial comedonal A with CASS 2, Leeds chest 7 and 8 both with CASS 5, and Leeds back 7 and 8 both with CASS 5. The authors found that photos in Leeds revised inadequately represented milder CASS grades 1 and 2 for facial acne and all CASS grades of the chest and back except 5 for very severe. Thus, there is still a need for images that correspond to a categorical acne scale for the chest, back, and face.

2.2.1 Fluorescence and Polarized Photography Have Increased Accuracy of Acne Evaluation

In 1996, Lucchina et al. (1996) studied fluorescence photography for evaluating acne, as fluorescence corresponds to protoporphyrin IX production by *P. acnes* in open comedones, follicles, and inflammatory lesions. Thirty-two patients completed a 12-week study in which subjects applied either clindamycin 1 % topical or vehicle twice daily. Clinical evaluation with counting and Leeds (Burke and Cunliffe 1984) and evaluations of flash and fluorescence photographs were obtained at baseline and weeks 4, 8, and 12. Flash photographs were assigned a Leeds score at baseline and week 12. Fluorescence photographs were evaluated at baseline and week 12 for facial areas: overall, the nose only and face excluding nose. Each area was assigned a fluorescence score within 0–3 and an improvement score within –1 to 4. The treatment group had less fluorescence compared to baseline and statistically significant larger decreases in evaluations than the vehicle group. Fluorescence photography can evaluate acne therapy efficacy by charting the course of acne treatment.

In 1999, Pagnoni et al. (1999) also studied fluorescence photography as a quick and simple method to demonstrate *P. acnes* population. Fourteen subjects, of which five were controls, participated in a study where 10 % benzoyl peroxide was applied twice daily for 7 days to measure efficacy. Fluorescence photos of the cheek and nose and cheek scrub culture samples were taken at baseline, day 3, day 7, and day 16. The area of fluorescence in the nose and cheek regions was calculated by Optimas 6.2 software. A decrease in fluorescence paralleled a decrease in cultured *P. acnes* with treatment. The recolonization of *P. acnes* after stopping treatment matched the reappearance of porphyrins. Correlation in the treatment group, mean = 0.80, between *P. acnes* and fluorescence was good, whereas correlation for control was poor. Fluorescence photography is not sensitive enough to detect modest changes but is reliable when variation is clinically relevant, at least one order magnitude. Thus, culture may still be necessary when modest changes in *P. acnes*

cannot be detected with fluorescence. The authors conclude that fluorescence photography is a reliable, quick, and easy way to estimate suppressive effects of antibacterial agents on *P. acnes*.

In 1997, Phillips et al. (1997) introduced the use of perpendicular polarized light photography (originally a method for enhancing subsurface features in photoaged skin) as a method to enhance visualization of acne. With standard photos, small comedones may be missed, and macular and elevated lesions cannot be differentiated. Features may also only change slightly during a 12-week trial. Polarized photography enhances visualization of features such as erythema, important for distinguishing inflammatory from noninflammatory lesions. Thirty-two subjects were treated with clindamycin 1 %, and clinical assessment using Leeds (Burke and Cunliffe 1984) was performed at baseline and after 12 weeks. Standard and perpendicular polarized photographs were also taken and retrospectively graded using Leeds. Because reproducible photographs were required for reliable retrospective evaluation, the authors concentrated on keeping consistent color, lighting, and framing with anatomic landmarks. Advantages of perpendicular polarized photos include enhancing visualization of subsurface erythema and hemoglobin-related structures and better identifying inflammatory lesions and open comedones by removing glare and surface topography. The mean Leeds score from perpendicular photos was higher than scores from clinical assessments and flash photos, indicating increased sensitivity. The difference in mean Leeds scores after 12 weeks for polarized photos was similar to clinical assessments but significantly higher than flash ($p = 0.03$). The authors conclude that clinical evaluations match retrospective grading with perpendicular more than with flash photos.

In 2001, Rizova and Kligman (2001) used polarized light photography as a noninvasive and reliable method to assess acne and track lesion development. Visual assessment is compromised by viewer subjectivity and is dependent on consistent standards. Although standard photography with consistent technique can be used for more objective assessment, visualization of small

comedones and subtle cutaneous characteristics is inconsistent, and inflammatory lesions are difficult to differentiate from hyperpigmented macules. Polarized light photography can increase accuracy of acne evaluation. Five volunteers enrolled in a 16-week study with the following phases: 4-week pretreatment phase to track the natural progression of lesions, 8-week treatment with adapalene gel 0.1 %, and 4-week follow-up after ending treatment to evaluate lesion evolution. Parallel- and cross (or perpendicular)-polarized photographs were taken at each visit to record lesion evolution. Parallel-polarized photography enhances visualization of surface features such as greasiness, scaling, and degree of lesion elevation, while cross-polarized photography improves visibility of subsurface erythema, hyperpigmentation, small lesions, and inflammation. The authors believe that serial photographs using polarized techniques to track lesions can provide more data for treatment efficacy and the changing landscape characteristic of acne.

2.2.2 Computational Methods Have Also Been Used to Improve Acne Evaluation

In 2008, Do et al. (2008) studied the program Picture Window Pro 4.0 used to align and track images of the night sky. Even with standardization, position inconsistencies are possible between photos. By manually selecting alignment points for anatomic landmarks such as the nose tip, successive photos could be superimposed to decrease angle and framing inconsistencies. Observations such as inflammatory lesions rising from comedones with a time course of 2–12 plus weeks were determined by monitoring development of lesion types open/closed comedones, erythematous macules, papules, pustules, and nodules. The authors conclude that such technology can track effects of acne medication on the lifespan of lesions and characterize the natural history of acne.

In 2012, Choi et al. (2012) used a 3D image analysis system (PRIMOS Compact) to evaluate skin texture and acne lesions objectively. From the successful use of 3D analysis to monitor wrinkles, the authors applied the method to quantify skin

surface roughness and acne volumes before and after 4 weeks of anti-acne cream (acure clarifying marks eraser[®]). Skin surface measurements before and after treatment using the 3D image system gave quantitative analysis of roughness and volume of lesions. Roughness was assessed by parameters: Ra average of values, Rmax maximum peak-to-valley value, Rz average of peak-to-valley values, and Rp maximum peak. Lesions were analyzed by total number and average volume. Results indicated that skin texture significantly improved after treatment with Ra, Rmax, Rz, and Rp, decreasing by 6.25 %, 7.50 %, 7.00 %, and 7.70 %, respectively. Volume of lesions decreased by 19.54 % after treatment, although lesion count was unchanged. While acne is usually classified by diameter, the authors indicate that volume provides more reliable criteria for the classification of lesions with irregular shapes. 3D analysis can supplement counting and grading systems. However, image analysis is less clinically relevant than grading based on severity since severity can be underestimated with minimal protrusion. Image-based analysis provides opportunities to address topographical changes in the skin and should be used with additional visual assessment methods to grade severity.

In 2008, Fuji et al. (2008) proposed an extraction method to classify lesion types such as comedo, reddish papule, pustule, and scar. Acne should be classified and counted for accurate grading, but this takes time. Inferior color reproduction of cameras causes visually detecting and differentiating lesion types to be difficult. Instead, accurate color reproduction of multispectral images (MSIs) is better. In the computer-aided diagnosis system, detailed spectral features are acquired by MSI, and lesions can be classified by applying linear discriminant functions (LDFs). Three LDFs were calculated from papule and pustule, pustule and scar, and papule and scar. Results of MSI and LDF classifier on clinical images showed viability of this method.

In 2008, Bae et al. (2008) introduced a multi-modal imaging modality and objective image

analysis methods. Independent modalities standard, parallel- and cross-polarized, and fluorescent images were integrated into one modality to maximize clinical utility. Each image emphasizes different morphological and functional skin information, and the images can be utilized to more reliably and efficiently evaluate severity. Polarized images are useful for analyzing skin texture, pigmentation, and vascularity and computing erythema index and melanin index to evaluate vascular and pigmented lesions, respectively. Fluorescent images are useful for quantitatively evaluating sebum characteristics such as pattern, area and density, and average size and diameter of spots.

There are also existing skin analysis methods that can be applied to quantitatively assess acne severity. In 1999, Xu et al. (1999) presented a segmentation method for images of skin cancer and pigmented lesions. Lesions are detected in an image to compute qualities such as diameter, color variation, etc. In 2003, Schmid-Saugeon et al. (2003) presented a computer-aided diagnosis system to assist physicians in analyzing pigmented skin lesions, such as lesion boundary detection, visualization, quantification of texture, shape, and color, and classification as benign or malignant. In 2008, Masood et al. (2008) introduced a segmentation procedure for lesions in atopic dermatitis. Improving accuracy of lesion boundary detection is important for obtaining objective evaluation of lesions through quantitative attributes and monitoring lesion evolution. Computerized analysis of position, size, shape, color, and other features can categorize lesions.

3 Conclusion

The photographic standard introduced by Cook et al. (1979) is precise, is easy to use, and has inter-grader consistency. Cook's method has been expanded in various ways, from including the back and chest evaluation to matching lesion counts with severity grades. Photography also documents progress for retrospective verification.

With lesion tracking, the natural history of lesion development can be determined. In addition, photographic methods have expanded from flash to fluorescence and polarized, to improve visualization and increase accuracy of assessing acne severity.

However, drawbacks of photography include not allowing palpation to determine depth and minimization of small lesions, comedones, and erythema. Photographs of patients with pigment are also difficult to evaluate (Witkowski and Parish 2004). Maintaining consistent settings such as lighting, distance to camera, framing, and angles can also be problematic (Burke and Cunliffe 1984). Although many agree that Cook's photometric method has good inter- and intra-rater reliability, some criticize that the method is inaccurate because photographic evaluation is inherently more subjective than lesion counting (Doshi et al. 1997). Pigmentation changes from healing lesions or tanning can affect grading. Dark skin tones also complicate the visualization and assessment of lesions (Witkowski et al. 1980). Some praise lesion counting as more objective and accurate, despite being tedious and time consuming.

Even so, there has been much support for a photographic standard, with trials showing reliability of such assessment and applicability to clinical practice. In addition, patient photos can be transferred to other physicians for a second opinion to ensure accurate assessment. As supported by Samuelson (1981), who concurrently used two methods of evaluation, there is a close correlation between lesion counting and overall assessment of photographs. While lesion count evaluations differed by as much as 20 %, the photographic method only had a 5 % difference, showing that the photographic method provides a more accurate evaluation of change. In addition, change in counts is meaningless if overall severity remains the same. With counting, a quantitative measure, statistical evaluation, must be handled carefully as a count of 10 reducing to 5 does not necessarily indicate 50 % severity reduction. Discrepancy between raters also increases as count

rises (Bergman et al. 2009), indicating reliability issues as severity worsens. As evaluated in a survey conducted by Tan et al. (2012b), severity was selected as the most important clinical feature. In clinical practice, acne severity assessment must be time efficient, and although lesion counting is important, it is largely impractical in practice. Thus, severity is often measured by qualitative methods. Numerical range of lesions for severity categories with descriptive text and photographic standards are more appropriate for clinic use.

Methods such as fluorescence and polarized photography also offer more information about dermatological conditions than noticeable by clinical observation alone. Computer alignment, imaging modality, segmentation, quantitative analysis, and 3D analysis methods expand the use of images to track lesions and measure objective characteristics such as the extent of erythema and lesion attributes. Computational methods also address issues of inter- and intra-rater reliability, which can lead to effective acne treatment and contribute to existing grading systems (Ramli et al. 2012).

Since the introduction of Cook's standard, other photographic extensions and analysis techniques have helped improve accuracy of diagnosis. Photography is (1) an objective and usable technique for measuring acne and (2) a valuable technique for training and qualifying graders. Because of its reproducibility, the method can also help decrease subject sample size in research. Taken together, the combined experience summarized here strongly promotes the use of the photographic method – at least as an auxiliary method in phase 1 and 2 clinical trials. The small definitive intra-subject documentation achieved by Cook represents a major savings in resources.

Androgenetic alopecia • Male • Female • Clas-
sification • Hair loss scoring

Hair is a major visual demonstration of the human body, especially in social and sexual communications. Androgenetic alopecia (AGA) is the most common form of alopecia, affecting up to 80 % of men and 50 % of women in the course of their life (Piraccini and Alessandrini 2014; Shapiro et al. 2000; Blume-Peytavi et al. 2008). Today, hair loss is a common complaint in clinical dermatology. Hair growth assessment is based on the clinical experience and trichological knowledge of the assessor. Careful clinical examination is required in order to establish the differential diagnoses, which will then inform the choice of assessment technology made (Shapiro et al. 2000; Blume-Peytavi et al. 2008). The use of specific and reproducible scoring systems for scalp hair by the physician is best approached, as it facilitates the diagnosis and differential diagnosis with other diseases, allows staging of severity, and monitors the progress of the disease in time and response to treatment (Piraccini and Alessandrini 2014).

1 AGA Classification

The most well-known grading systems are those described by Hamilton-Norwood (for male) and Ludwig (for female) (Messenger

Table 1 Different scalp hair assessment scores in androgenetic alopecia

Author	Year	Classification
Beek	1950	This study was done on 1,000 Caucasian with two aspect (frontal and front vertical baldness (Beek 1950)
Hamilton	1951	A classification based on the report of eight aspects and three subgroups for male pattern hair loss and further comparison of the incidence of baldness for Caucasians and Chinese (Hamilton 1951)
Ogata	1953	Fifteen types of baldness were distinguished from 20 different aspects and classified them to six groups (Ogata 1953)
Feit	1969	A more detailed classification than Hamilton version. He characterized 12 different varieties of 16 categorizes aspects (Feit 1969)
Setty	1970	A simplified three-group version of Hamilton's version: (1). Totopilosis (relates to Hamilton type I). (2). Indentato-pilosis (Hamilton type II–V). (3). Indentatocirculopilosis (more or less Hamilton VI–VII; confluent/nonconfluent) (Setty 1970)
Ebling and Rook	1972	Classification which differentiates alopecia into 5°: for grades I–III medical treatment is appropriate; for grade IV, surgical therapy; for grade V, no solution is available (Ebling and Rook 1972)
Rook and Dawber	1975	A classification of five evolving stages (Rook and Dawber 1982)
Norwood	1975	Norwood modified Hamilton classification, added more details for male pattern baldness, and described as Hamilton-Norwood classification (Fig. 1) (Norwood 1975)
Bouhanna and Nataf	1976	A simplified classification in three stages of evolution with or without vertex balding (Bouhanna and Nataf 1976)
Ludwig	1977	Ludwig classification (Fig. 3) (Ludwig 1977)
Blanchard and Blanchard	1984	Classification distributed into five stages of evolution by measuring the distance of fixed landmarks with the borders of alopecia (Blanchard and Blanchard 1984)
Camacho	1988	A classification of AGA which involves the hair loss pattern. Male AGA (MAGA.I–V) and male pattern female AGA (FAGA.M.I–V) are judged with the Ebling classification. Female AGA (FAGA.I–III) and female pattern male AGA (MAGA.F.I–III) are rated with the Ludwig classification (Camacho 1988)
Savin	1992	The Savin scale is a photographic depiction of gradations of scalp hair loss in women as determined by parting width. The patient's hair is compared with eight computer-generated pictorial representations of the central scalp hair parted in the middle (Savin 1992)
Bouhanna	2000	A presurgical method to determine the extent of bald and hairy areas, measured by five distances on the scalp: median sagittal distance, left and right paramedian distances, transverse supra-auricular distance, temporal anterior spacing distance (Bouhanna 2000; Camacho 1988).
Koo et al	2000	Classified the type of male pattern baldness into six types according to the English alphabetical letter shape of the bald area (Lee et al. 2007; Koo et al. 2000)
Sinclair	2004	Described more grade than the Ludwig scale (Fig. 4) (Messenger 2008; Sinclair et al. 2004; Gan and Sinclair 2005)
Olsen et al.	2004	The scalp is divided in four regions: frontal (F), bitemporal (T), midscalp (M), and vertex (V). These regions are each assigned a 7-point density scale of 0–6, with 0 being no loss and 6 being total or near-total terminal hair loss (Fig. 1) (Olsen et al. 2004)
Lee et al.	2007	Basic and specific (BASP) classification. There are four basic types (L, M, C, and U) and two specific types (F and V). The final type is decided by the combination of the assigned basic and specific types (Fig. 2) (Lee et al. 2007)

2008). However, various classifications for assessing hair loss score have been proposed for AGA (Table 1) (Blume-Peytavi et al. 2008; Lee et al. 2007; Olsen 2003; Thaysen-Petersen et al. 2015).

1.1 AGA in Men

In the majority of men, AGA involves the fronto-temporal and the vertex areas, and hair loss progresses to end-stage blading in 50–60 % of men

Fig. 1 Hamilton-Norwood classification of male balding (Drawing by Ali Rajabi Estarabadi based on Male pattern baldness classification published by Norwood) (Norwood 1975; Blume-Peytavi et al. 2011)

by age of 70 years (Fig. 1) (Hamilton 1951; Norwood 1975). This process may start at any time following puberty or sooner. The most widespread use classification method for male AGA is the one that described by Norwood in 1975, with refining Hamilton's classification (Blume-Peytavi et al. 2008; Lee et al. 2007; Norwood 1975). In some instances, however, men develop diffuse thinning of the crown with retention of the frontal hairline with a pattern that resembles the Ludwig type observed in women (Blume-Peytavi et al. 2011).

The basic and specific (BASP) classification is a new scoring method of hair loss which was introduced by Lee et al. in 2007. BASP was designed based on the pattern of hair loss, including four basic types (the shape of the anterior hairline) and two specific types (the density of hair on the frontal and vertex areas). The final

type is decided by the combination of the basic and specific types (Fig. 2) (Lee et al. 2007).

1.2 AGA in Women

Female pattern hair loss (FPHL) is the most common hair loss disorder in women and has a complex mode of inheritance. The etiopathogenesis of FPHL is largely unknown; however, it is hypothesized that FPHL and male pattern baldness share common genetic susceptibility alleles (Nuwaihdy et al. 2014). It results from a progressive reduction in the ratio of terminal hairs to shorter, thinner vellus hairs, which is known as follicular miniaturization (Bouhanna and Nataf 1976; Blume-Peytavi et al. 2011). This miniaturization follows usually a pattern distribution. In women, FPHL typically presents as a diffuse reduction in hair density over the

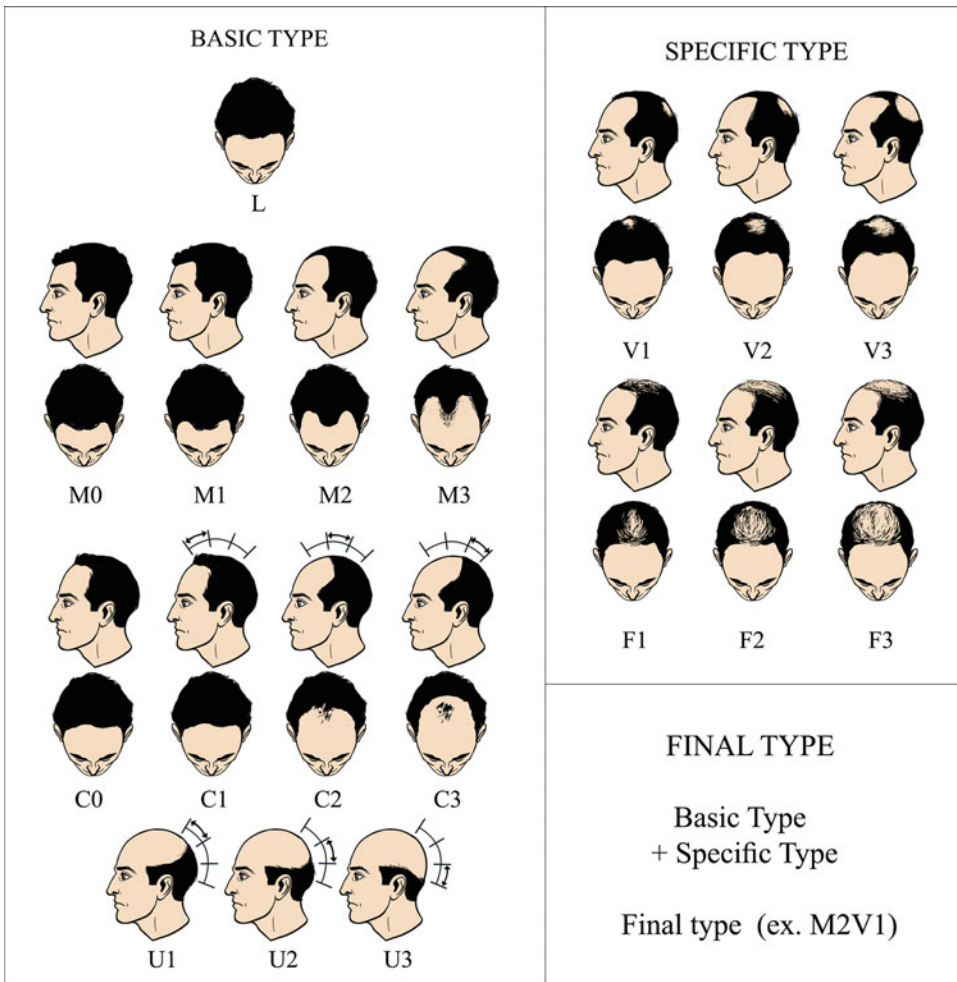

Fig. 2 The basic and specific (*BASP*) classification system. Four basic types (L, M, C, and U) and two specific types (V and F) are used in the *BASP* classification. The final type is defined by a combination of the basic and

specific type (Drawing by Ali Rajabi Estarabadi based on *BASP* classification published by Lee and et al.) (Lee et al. 2007)

frontal and vertex areas, but parietal and occipital regions may be involved (Bouhanna and Nataf 1976; Blume-Peytavi et al. 2011). So FPHL may have three different patterns which is a term for decreasing in different regions of scalp hair density (Blume-Peytavi et al. 2008; Pragst and Balikova 2006):

1. Diffuse thinning of the crown region with preservation of the frontal hairline. There are two scales that describe this pattern: the commonly used 3-point Ludwig scale and the 5-point Sinclair scale (Blume-Peytavi et al. 2011).

The Ludwig classification uses three stages to describe female pattern genetic hair loss: type I (mild), type II (moderate), and type III (extensive). In all three Ludwig stages, there is hair loss on the front and top of the scalp with relative preservation of the frontal hairline. The back and sides may or may not be involved (Fig. 3) (Ludwig 1977; Olsen 2001, 2008).

2. Thinning and widening of the central part of the scalp with breach of frontal hairline described by Olsen scale: Christmas tree pattern (Fig. 5) (Olsen 2003, 2008). Olsen

Fig. 3 Ludwig pattern of hair loss-3-point (Drawing by Ali Rajabi Estarabadi based on Classification of alopecia in female published by Ludwig) (Ludwig 1977; Blume-Peytavi et al. 2011)

Fig. 4 Sinclair scale (5-point) for grading of female pattern hair loss (Drawing by Ali Rajabi Estarabadi based on the Sinclair scale) (Sinclair et al. 2004; Gan and Sinclair 2005)

Fig. 5 Olsen scale: Christmas tree pattern in female pattern hair loss (Drawing by Ali Rajabi Estarabadi based on Female pattern hair loss published by Olsen) (Olsen 2008; Blume-Peytavi et al. 2011)

proposed that frontal accentuation (or the “Christmas tree” pattern) be considered another pattern of hair loss in women, which helps to distinguish hair loss from other potential hair loss mimickers in women (Lee et al. 2007; Olsen 2003; Vujovic and Del Marmol 2014).

3. Thinning associated with bitemporal recession the same as male hair loss pattern (Hamilton-Norwood type, Fig. 1) (Olsen 2003; Hamilton 1951; Norwood 1975).

Norwood-Hamilton’s classification for male pattern of hair loss and Ludwig’s classification

for female pattern of hair loss are the most commonly used classification methods for assessing AGA worldwide (Blume-Peytavi et al. 2008, 2011; Gan and Sinclair 2005).

Hirsutism scoring system-Ferriman • Gallwey scale

1 Introduction

Hirsutism is a condition where a female develops a male pattern growth of thick, pigmented androgen-dependent terminal hair. This is to be differentiated from overgrowth of nonsexual (vellus) hair, which is the fine, lightly pigmented hair covering most areas of the body during the prepubertal years and is known as hypertrichosis. Although hirsutism is generally thought to affect 5–10 % of women of reproductive age, it is important to bear in mind that the incidence is highly affected by location and ethnicity being higher in those of African or Mediterranean descent (Metwally 2012).

The first semiquantitative assessment method was developed for the of body hair growth by *D. Ferriman* and *J.D. Gallwey*, published in 1961 by *D. Ferriman* and *J.D. Gallwey* in the *Journal of Clinical Endocrinology*. Five gradings based on densities and areas involved (0–4) were determined for each of 11 sites: upper lip, chin, chest, upper back, lower back, upper abdomen, lower abdomen, upper arms, forearms, thighs, and legs

Fig. 1 The modified Ferriman-Gallwey scoring model for quantifying the extent and severity of hair growth in women. Hair growth is graded using a scale from 0 (no terminal hair) to 4 (maximal growth) in nine different areas. The maximum score is 36. A score more than 8 could

be considered as hirsutism and indicated the hyperandrogenic state (Reproduced from Hatch R, Rosenfield RS, Kim MH, Tredway D. Hirsutism: implications, etiology and management. *Am J Obstet Gynecol* 1981; 140: 815. Copyright ©1981 Elsevier)

Table 1 Suggested cutoffs for the mFG hirsutism score according to the 95 percentile in different unselected populations of premenopausal women (Escobar-Morreale HF et al. Hum Reprod Update. 2012) (Escobar-Morreale et al. 2012)

^aAs defined by the 95th percentile of an unselected population of premenopausal women (Escobar-Morreale et al. 2012)

(Ferriman and Gallwey 1961). In 1981, Hatch et al. provided the modified FG scoring model with nine zones by eliminating forearms and thighs and legs (Hatch et al. 1981) (Fig. 1).

2 Cutoff Score for Defining Hirsutism

According to the different studies, the women with the score of more than 8 are considered to be hirsute (Hertweck et al. 2012; Hassa et al. 2005; Rosenfield 2005); however, the Rong Li et al. considered 4 as the cutoff score for nonhirsute/hirsute women (Li et al. 2012). Escobar-Morreale et al. suggested a table of cutoffs for the modified FG hirsutism score according to the 95 percentile in different unselected populations of premenopausal women based on their systematic review published on 2012 (Table 1) (Escobar-Morreale et al. 2012).

3 How Modified Ferriman-Gallwey Scale is Applicable?

Although the Ferriman-Gallwey scale is a useful clinical scoring system, there are a number of potential limitations, one of which is the fact that the existing scoring system does not take into account the fact that abnormal amounts of hair growth may be confined to only a few areas without exceeding the cutoff value in total hirsutism score. Also it does not include areas such as the neck, sideburns, and buttocks/perineum where increased hair growth may be a concern in some women. Moreover, it is also less prominent in adolescents and older women and regresses as women age (Azziz 2004). Hassa et al. in 2005 showed that the areas not considered in FG scale like buttocks/preneum, sideburn, and neck have a high score in accordance with the hyperandrogenic state (Hassa et al. 2005). They

also revealed that the upper arm, upper back, and upper abdomen have a low impact on the total hirsutism score. Although the study population was too small, the author believes the existing scoring is open to intra- and interobserver variations and he proposed to include these three zones in the visual scoring of hirsutism (Hassa et al. 2005).

4 Is It Any Concordance Between Clinicians' and Patients' Self Scoring?

According to the study of *Espinós J* et al. in 2010 (Espinós et al. 2010), patients' self-scoring of hirsutism using the mFG system showed a mean (SEM) score of 15.1, compared with 12.0 for clinicians' scoring ($P = .01$). For the most androgen-sensitive areas, patients' scores were also significantly higher than clinicians' scores (9.4 vs. 8.1; $P = .04$). A relationship between patients' scores and clinicians' scores was observed ($r = 0.502$, $P < .007$), with a stronger relationship occurring when only the most androgen-sensitive areas were considered ($r = 0.599$, $P < .001$). In the logistic regression analysis, clinicians' scores of clinical hirsutism were significantly associated with BMI and TFI. In contrast, patients' self-scoring of hirsutism were not associated with any of the analyzed parameters. In the multivariable analysis, clinicians' scoring of hirsutism was the only independent variable significantly associated with increased total plasma T levels, with an area under the ROC curve of 0.939 (95 % confidence interval, 0.851–1.028) and a sensitivity of 100 % and specificity of 82.6 % for a mFG score > 13 (Espinós et al. 2010).

Skin scoring • Modified skin-weighted severity score • mSWAT • Cutaneous T-cell lymphoma • CTCL • Mycosis fungoides • Sézary syndrome

1 Part I: Primary Cutaneous T-Cell Lymphoma

Primary cutaneous T-cell lymphoma (CTCL) is typically an indolent lymphoma. Mycosis fungoides is the most common form of CTCL and 70 % of patients present with patches and plaques limited to the skin (stage I). Within 10 years from diagnosis, approximately 40 % of patients will progress to more advanced stages (stage II–IV) with development of skin tumors, erythroderma, or lymphadenopathy (Whittaker et al. 2003). Thirty percent present with advanced disease and have a poor prognosis with a median survival of 1-5 years. Sézary syndrome is a leukemic form of CTCL which presents with a triad of erythroderma, lymphadenopathy, and circulating atypical lymphocytes (Sézary cells).

In mycosis fungoides and Sézary syndrome, the skin is staged T1-T4 where T1 is defined by patches or plaques covering less than 10 % of the body surface area (BSA), T2 as patches and/or plaques covering greater than 10 % of BSA, T3 as presence of skin tumors, and T4 denotes erythroderma where greater than 80 % of BSA is involved. This staging system is used with staging

Table 1 Bunn and Lamberg staging system (Bunn and Lamberg 1979)

Stage	Tumor (T)	Lymph node (N)	Metastasis (M)
IA	T1: patches/plaques over <10 % of body surface	N0: no palpable nodes or histological evidence of MF	M0: no visceral involvement
IB	T2: patches/plaques over >10 % of body surface	N0	M0
IIA	T1 or T2	N1: palpable node; no histological evidence of MF	M0
IIB	T3: tumors	N0 or N1	M0
III	T4: erythroderma	N0 or N1	M0
IVA	T1–T4	N2, no palpable nodes but histological evidence of MF, or N3, palpable nodes and histological evidence of MF	M0
IVB	T1–T4	N0–N3	M1: histological visceral involvement

of lymph nodes (N0-3), and the presence or absence of metastasis (M0–1) to produce a TNM stage which is used to calculate a Bunn and Lamberg stage I-IVB (Table 1) (Bunn and Lamberg 1979). This staging system has been shown to have prognostic significance (Table 2) (Scarisbrick et al. 2014). The TNM staging has recently been revised by EORTC to include a blood stage (B0-B2) as well as to differentiate patches and plaques (T1a/b and T2a/b where “a” denotes patches and “b” plaques) and to record T-cell receptor clonality in blood and lymph node (where “a” denotes polyclonality and “b” monoclonality) (Table 3) (Olsen et al. 2007a). When more than one T rating might be applied, the highest is used for staging purposes, but in situations where both tumors and erythroderma exist simultaneously, both T ratings should be recorded (e.g., T4(3)). This provides a means of tracking patients with erythroderma plus tumors that may impact a poorer prognosis.

To skin score in MF/SS, the lesion type must be clearly defined prior to calculating BSA involved with each lesion type.

surrounding uninvolved skin. A patch must be flat and barely palpable but there may be light scaling (Figs. 1 and 2). The presence/absence of scale, crusting, poikiloderma (Fig. 3), and/or of hypo- or hyperpigmentation (Fig. 4) should be noted.

2.2 Plaque

Plaque disease is defined as any size lesion which is indurated, scaly, and possibly excoriated and includes keratoderma which is raised above the surface of the skin. It should be palpable with induration but without vertical growth or deep infiltration. Plaques are typically pink or red and maybe scaly (Fig. 5). Presence or absence of scale, crusting, ulceration, and/or poikiloderma should be noted. Histological features such as folliculotropism or large-cell transformation (25 % large cells defined as $>4\times$ diameter of normal lymphocytes), CD30+ or CD30–, and clinical features such as ulceration are also important to document.

2 Part II: Defining Patch, Plaque, and Tumor Disease in MF

2.1 Patch

A patch disease is defined as flat erythema. A patch may be any size lesion without induration or significant elevation above the

2.3 Tumors

Tumors are any solid or nodular lesion greater than 1 cm in diameter with evidence of deep infiltration in the skin and/or vertical growth. Ulceration may occur with significant loss of superficial skin, including the entire epidermis and some portion of the upper dermis. Tumor

Table 2 Prognosis in mycosis fungoides and Sézary syndrome (Scarisbrick et al. 2014)

Stage	IA	IB	IIA	IIB	III	IVA	IVB
OS at 5 years	91–100 %	72–86 %	49–73 %	40–65 %	40–57 %	15–40 %	0–15 %
OS at 10 years	80–100 %	58–75 %	45–49 %	20–39 %	20–40 %	5–20 %	0–5 %
DSS at 5 years	96–100 %	96 % (81 % ^a)	68 %	52–80 %	52 %	25–40 %	0 %
DSS at 10 years	92–98 %	83 % (36 % ^a)	68 %	39–42 %	39 %	13–20 %	0 %
Median survival	35.5 years	12.1–26 years	10–15.8 years	2.9–4.7 years	3.6–4.7 years	13–25 months	13 months

IB^a Indicates DSS at 5 years and 10 years for stage IB patients with folliculotropic MF

Table 3 Revised TNMB staging for mycosis fungoides and Sézary syndrome (Olsen et al. 2007a)

Stage	Tumor (T)	Lymph node (N)	Blood (B)	Metastasis (M)
IA	T1: patches/plaques over <10 % of body surface	N0: no palpable nodes or histological evidence of MF	B0: <5 % peripheral blood lymphocytes atypical	M0: no visceral involvement
	T1a patches only	N0a clone negative	B0a clone negative	
	T1b plaques only	N0b clone positive	B0b clone positive	
			B1: >5 % of peripheral blood lymphocytes are atypical but <1,000/ μ l	
			B1a clone negative	
IB	T2: patches/plaques over >10 % of body surface	N0	B0–1	M0
	T2a patches only			
	T2b plaques only			
IIA	T1 or T2	N1: no histological evidence of MF (dermatopathic)	B0–1	M0
		N1a clone negative		
		N1b clone positive		
		N2: early involvement with MF, aggregates of atypical cells with preservation of nodal architecture		
		N2a clone negative		
	N2b clone positive			
IIB	T3: tumors, lesions >1 cm diameter with deep infiltration	N0–2	B0–1	M0
IIIA	T4: erythroderma >80 % BSA involved	N0–2	B0	M0
IIIB	T4: erythroderma	N0–2	B1	M0
IVA1	T1–T4	N0–2	B2: >1,000/ μ l circulating atypical lymphocytes (Sézary cells)	M0
IVA2		N3: lymph nodes involved with effacement of normal architecture	B0–2	M0
IVB	T1–T4	N0–N3	B0–2	M1: histological visceral involvement

lesions are often dome-shaped. There may be loss of epidermotropism and no scale (Fig. 6).

The total number of lesions, total BSA of lesions to include the largest size lesion, and region of body involved may be noted, but the significance of this finding is not known.

Histological evidence of large-cell transformation and CD30 positivity is encouraged.

The distinction between patch and thin plaque lesions and between thick plaques and tumors is subjective (Olsen et al. 2007a; Oliver et al. 1978; Lamberg et al. 1984). Whether there should be a

Fig. 1 Patch of mycosis fungoides

Fig. 3 Poikilodermatous MF – patch stage showing dyspigmentation, telangiectasia, and atrophy

Fig. 2 Patches of mycosis fungoides over the buttocks

minimum histological depth of infiltrate to distinguish plaque from tumor in order to corroborate this important assignment of T stage based on a single lesion has not been yet been determined.

2.4 Erythroderma

The ISCL criteria of erythroderma (T4 skin classification) is at least 80 % BSA involvement with

patch/plaque disease (Fig. 7). In erythroderma the extent of skin tumor burden may be assessed with macular erythema equivalent to patch stage MF, erythema with induration/edema equivalent to plaque, and the presence of tumors noted.

3 Part III: Assessment of BSA Involvement in Dermatological Disease

Estimating BSA has been used in the assessment of burns for more than 60 years. Burn surface area determines fluid resuscitation volumes and allows triage of patients to specialist burn units. Accurate measurement of burn BSA is therefore critical for burn assessment.

There are various methods of calculating BSA which act as guides to assess the percentage of the

total body surface area affected. The three commonly used methods of estimating BSA are (1) palmar surface (Kirby and Blackburn 1981), (2) Wallace's "rule of nines" (Wallace 1951), and (3) the Lund and Browder chart (Lund and Browder 1944).

Fig. 4 Patches of hypopigmented MF over legs

Fig. 5 Plaque of mycosis fungoides

3.1 Palmar Surface

Palmar surface assessment uses the palmar surface area of the patient's hand as an estimation guide (Kirby and Blackburn 1981). The surface area of the patient's palm including the fingers is assumed to be 1.0 % of the total body surface area. This method is useful to estimate relatively small affected BSA (less than 15 % of the total surface area) or larger areas (greater than 85 % when normal skin is counted), but in the middle ranges, this method is less accurate, because if the hand alone is used to assess the BSA affected, this may be overestimated as actual palmar surface is typically less than 1 % (Lee et al. 2007). This method is liable to further inaccuracies as textbook teaching of the definition of the palm or palmar surface varies (palm +/- fingers +/- thumb) and is assigned between 0.5 % and 1.5 % of the total body surface area.

This technique may be used to calculate affected skin or in a subtraction method by calculating the unaffected skin.

3.2 Wallace's "Rule of Nines" (Wallace 1951)

The "rule of nines" initially defined by Pulaski and Tennison in 1947 and published by Wallace in 1951 divides BSA into regions of 9 % or multiples of 9 %, leaving 1 % for the genitalia/perineum. The

Fig. 6 Tumors of mycosis fungoides

Fig. 7 Erythroderma defined as skin involvement greater than 80 % BSA

percentage of involved skin for each body part is recorded, and the sum of affected areas is calculated. This tool is convenient when estimating BSA involvement in an adult, but is less applicable in young children because of proportion differences.

3.3 The Lund and Browder Chart (Lund and Browder 1944)

The Lund and Browder chart consists of two body diagrams, one of the anterior and one of the posterior body, to allow mapping of the affected skin. The percentage SA of body parts are shown on a table that varies according to age to reflect body parts affected by growth. This chart provides comprehensible and accurate estimation for both children and adults (Hettiaratchy and Papini 2004).

Measuring BSA is subjective and vulnerable to errors due to inaccurate percentages assigned to body parts or errors in calculation of body surface area affected. The latter has been shown to be particularly vulnerable due to inconsistencies in published methods of measuring BSA. The palmar method of calculating BSA has proven preferable in many studies because of the relative speed of calculations. However, review of the literature shows discrepancies exist over the percentage BSA of the hand/palm. The original Lund and Browder publication designated each surface of hand as 1.5 %; this was later reduced in the modified Lund and Browder detailing each surface of hand as 1.25 %. The palmar method defines the surface of the hand to equal 1 %.

While UK teaching has been that the patient's palm represents 1 % of BSA, definition of the palm is lacking (Jose et al. 2004). The Advanced Trauma Life Support (ATLS) guidelines define the palm to exclude fingers and equal to 1 % (American College of Surgeons 1993) which

contradicts UK teaching where the distal wrist creases to top of the finger tips (palm plus digits is equal to 1 %) (Kirby and Blackburn 1981).

Planimetry involves using an instrument to measure the area of a plane figure. Planimetry may be used to measure hand/palmar surface area. A review of the literature (Scarisbrick and Morris 2013) identified several planimetry studies investigating palm surface area and found the palm alone to be consistently 0.5 % men, although may be affected by stature and is relatively smaller in women (0.4 %) and larger in children (~0.6 %), and there is also variation with race and BMI. The palmar surface plus fingers is approximately 0.8 %, while palm alone is 0.5 %. Using the palm and fingers to equate to 1 %, BSA will result in overscoring and inaccurate calculation of BSA which will be accentuated by a weighted scoring system as used in CTCL.

Even with a constant BSA assessment method, there is significant inter-user variability in scoring. Constant scoring methods are required for future studies. Where possible the same scorer should score any individual.

4 Part IV: Skin Scoring in Dermatology

Measuring BSA affected by skin diseases has allowed various methods of skin scoring to be developed in dermatological diseases. These skin scoring methods have been developed to aid assessment of disease severity and for use in clinical trials to measure disease response. Scoring systems for inflammatory diseases such as psoriasis and atopic eczema have been developed. The PASI (Psoriasis Area Severity Index) was first published in 1978 for quantifying skin disease in psoriasis (Fredriksson and Pettersson 1978). The body is divided into four sections (head, trunk, arms, and legs). The percentage involvement of each of these areas is scored by itself, and then the four scores are combined into the final PASI. The Atopic Dermatitis Severity Index (ADSI) (Bahmer et al. 1991) involves mapping disease onto body diagrams and evaluating using grid-point counting (this involves mapping areas of

affected skin onto diagrams and is time-consuming). SCORAD (SCORing Atopic Dermatitis) is a clinical tool used to assess the extent and severity of eczema (Scorad Index 1993). The sites affected by eczema are shaded on a drawing of a body and the rule of nines is used to calculate the affected area.

4.1 Skin Scoring in MF/SS

Distinction between stage T1 and T2 disease is dependent on the involvement of more than 10 % of BSA, while T4 is defined as greater than 80 % involvement. In T3 there is no minimum BSA involvement and the presence of one tumor >1 cm diameter defines disease. Skin scoring provides adjuvant information to staging in mycosis fungoides and Sézary syndrome by determining BSA involved with patch, plaques, and tumor. Skin scoring utilizes the measurement of affected BSA and type of skin lesion (patch, plaque, or tumor) and is used to allow quantification of skin tumor burden. Stevens et al. (2002) published a severity-weighted assessment tool (SWAT) which has been modified to produce the mSWAT which is now the preferred method of skin scoring in mycosis fungoides and Sézary syndrome. The mSWAT calculates BSA involved with patch, plaque, and tumor separately and then weights patch $\times 1$, plaque $\times 2$, and tumor $\times 4$ to produce a numerical value out of 400.

The overall mSWAT may not correlate with survival as a patient with widespread patches may have a high-percentage body surface area involved but a normal life expectancy, whereas tumors may be small 1-2 cm and cover a much smaller surface area but portray a poor prognosis and median survival of 3-5 years. However, the mSWAT score does allow responses to treatments to be quantified which is essential in clinical trials.

4.2 Lesion Weighting

For mSWAT calculations, the BSA of patch lesions are weighted $\times 1$, while BSA of plaque

lesions are weighted $\times 2$ to reflect the heavier dermal infiltrate in plaques and higher skin tumor burden. Tumor BSA is multiplied by $\times 4$. However, the thickness of the dermal infiltrate of tumors is far greater than four times that of patches (Rieger et al. 1989). However, multiplication $\times 4$ was agreed because of the variability of investigators in assigning a lesion to plaque versus tumor (Olsen et al. 2011). Thus, any change in tumor BSA may be underscored in the total mSWAT compared to changes in patch and plaques. A skin scoring for erythroderma may also be calculated using the mSWAT with summation of BSA involvement with macular erythema $\times 1$, equivalent to patch, plus erythema with induration/edema $\times 2$, equivalent to plaque, and the BSA of tumors $\times 4$. In this way the mSWAT may quantify extent of tumor burden in erythroderma while maintaining the ability to simultaneously track any tumors that may be present but does not track fissures or scale/exfoliation separately (Olsen et al. 2011).

4.3 SWAT

The original paper by Steven et al. in 2002 mapped clinical disease onto body diagrams distinguishing patch, plaque, and tumor. A 1 cm grid was randomly placed on the drawing, and the number of grid intersections overlying each lesion was counted to produce the percentage total BSA for each type of lesion (a method known as grid-point counting). Multiplication of patch $\times 1$, plaque $\times 2$, and tumor $\times 3$ produced a numerical value or SWAT out of 300. This method was verified in a study of 1,194 records from 323 (Stevens et al. 2002).

4.4 mSWAT

This SWAT has been modified (modified SWAT or mSWAT) in a number of studies using assessment of BSA by rule of nines or Lund and Browder charts as opposed to grid mapping, and multiplication of tumors has been used as $\times 4$ in some papers (Olsen et al. 2001, 2007b). This higher

value for tumors is suggested as the infiltrative depth of a tumor is relatively greater than ratios 1:3 patch or 2:3 plaque, but higher than $\times 4$ may further increase any discrepancies in BSA calculation. This modified SWAT is recommended as the skin scoring tool of choice to provide a global skin assessment of BSA weighted to skin lesion type and suggests the palmar method as the preferred method of calculating BSA. However, the total BSA of the hand in the modified Lund and Browder charts used is 5 %. If the palmar surface is taken as 1 % to represent palm plus fingers minus thumb, then each thumb would account for 0.5 % which is disproportional and may make this calculation invalid. Ensuring an accurate and robust measure of BSA is essential particularly as this scoring system is weighted and will multiply inconsistencies.

The mSWAT may be calculated using a chart (Fig. 8) showing the % BSA for the body regions. The BSA for patch, plaque, and tumor is calculated separately and then multiplied by the weighting factor.

It is recommended that in clinical trials mSWAT calculations should be performed by the same investigator at all time points to eliminate interobserver variability for a given patient (Olsen et al. 2011). If the same investigator cannot perform all the assessments, then all personnel grading the same patient must have completed prior training, ideally before study initiation. Standardized photographs of the skin are recommended to document the appearance of skin lesions at baseline and times of response/progression.

The recent international consensus paper from the EORTC (European Organisation for Research and Treatment of Cancer Cutaneous Lymphoma Task Force) and International Society for Cutaneous Lymphoma (ISCL) provides end points and response criteria for CTCL and recommends the mSWAT as the preferred method for determining skin tumor burden for both mycosis fungoides and Sézary syndrome (Olsen et al. 2011).

An iPhone application (CL-App) has been developed with Guy's and St Thomas' NHS Trust (2012) to aid skin scoring in CTCL by providing interactive body diagrams to score BSA involved as opposed to standard charts.

Body region (%BSA)	Patch*	Plaque*	Tumor*
Head (7 %)			
Neck (2%)			
Anterior trunk (13%)			
Arms (8%)			
Forearms (6%)			
Hands (5%)			
Posterior trunk (13%)			
Buttocks (5%)			
Thighs (19%)			
Legs (14%)			
Feet (7%)			
Groin (1%)			
Subtotal of lesion BSA			
Weighting factor	x1	x2	x4
Subtotal lesion BSA x weighting factor			
mSWAT score = summation of each column line above =			

Fig. 8 The body surface area of different body parts for calculating modified SWAT

This has the advantage over charts as mSWAT calculations are made electronically and this is likely to reduce user error. This application allows more rapid scoring of mSWAT within the clinical setting. The application also provides information on how to perform scoring. However, the availability requires access to an iPhone/iPad.

4.5 Discussion

In mycosis fungoides and Sézary syndrome, the mSWAT is the preferred method of skin scoring. The palmar surface of 0.5 % should be used as the measurement tool to skin score as this is relatively constant with age, stature, and different races (Scarisbrick and Morris 2013). A constant training method should be used to teach mSWAT calculations as there is significant inter-user variability. Where possible the same scorer should score any individual. Clinical photography is a useful adjuvant to represent skin involvement but skin scoring from photos is difficult.

The mSWAT should be used for skin scoring in mycosis fungoides and Sézary syndrome and may allow more accurate comparisons between centers which is essential for future clinical trials.

Overweight • BMI • Skin physiology • Epidermal water • Skin biomechanics

1 Introduction

The term “obesity” suggests several images that illustrate different personal, social, and/or professional impacts, explaining the diversity of definitions found for this disease (Longo et al. 2012). Obesity can be defined as a condition involving an excess of fatty tissue, which increases the risk of premature illness and mortality (Villareal et al. 2005). This definition requires the quantification of adipose tissue by the Quetelet index (weight/height²) kg/m² (Garrow and Welster 1985), commonly known as the body mass index (BMI) (Weigley and Adolphe 1976).

The available data on the prevalence of obesity is substantially affected by its definition, and the data is not always representative, often hindering comparison between different studies and groups (Wang et al. 2007). The most recent studies on the prevalence of obesity in the United States show that more than one third of adults and almost 17 % of children and adolescents were obese in 2009–2010 (Ogden et al. 2007, 2012). It is also suggested that differences in prevalence between men and women decreased between 1999–2000 and 2009–2010, with prevalence of male obesity reaching the same level of the female (Ogden et al. 2012). Regarding age, the prevalence of

Fig. 1 Prevalence of obesity in adults over age 20 in the United States (2009–2010), stratified by age and gender (Adapted from Ogden et al. 2007)

obesity was higher among older women compared with younger. These age differences were not detected in males. In children and adolescents, the prevalence of obesity was higher among adolescents than preschool children. According to this same study, no change in the prevalence of obesity was noted in recent years or even in the last decade for male (children and adults), but the same is not true for females (Ogden et al. 2012) (Fig. 1).

According to the WHO, in Europe in 2008, over 50 % of men and women were overweight, and about 23 % of women and 20 % of men were obese (WHO Europe 2012). Based on the latest European Union previews, up to 70 % of adults may be considered overweight, while obesity can reach 30 % in adults (WHO Europe 2012). The WHO estimates that the number of overweight children in Europe has increased steadily between 1990 and 2008, and over 60 % of children who are overweight before puberty will be overweight in early adult age (WHO Europe 2012).

Morbidity is well known and documented (Bray et al. 2009; Shipman and Millington 2011; Guida et al. 2010), and in most cases, obesity amplifies the effects of other pathologies such as skin diseases (e.g., ulcers and healing, or

infections). Specifically, beyond stretch marks, lymphedema, cellulitis, intertrigo, and lower limb stasis pigmentation, it has also been related to scleroderma, gangrene, and acanthosis nigricans (Shipman and Millington 2011). Nevertheless, it is not clear whether obesity per se is a cause of skin disease, although biomechanical and barrier modifications maybe present.

In general, the epidermal barrier is designed to prevent the loss of water and other components through the skin (Darlenski and Fluhr 2012; Venus et al. 2010). It is an essential property, especially dependent on the outermost layer, the stratum corneum (SC). Due to its constitution, the stratum corneum is also responsible for the mechanical strength of the skin. Thus, this barrier function seems to be closely related to the “envelope” function, and it has been demonstrated that when the skin barrier function is compromised, the biomechanical properties of the skin are also altered (Pederson et al. 2006) (Table 1). From the structural point of view, this biomechanical behavior allows the definition of the body contour even during dramatic shape variations such as in pregnancy, or when a marked increase or loss of weight occurs (Darlenski and Fluhr 2012). These properties illustrate a complex anisotropic

Table 1 Relationship between variables representing the “envelope” and the epidermal “barrier” functions

	Barrier function	Envelope function
TEWL	— — —	* * *
Epidermal hydration	+++	* * *
Biomechanical properties	* * *	+++

TEWL transepidermal water loss, +++ positive influence, — — — negative influence, *the published data determine a connection – see text

viscoelastic behavior that determines a nonlinear response when submitted to a force (physiological or not, such as the application of suction) (Darlenski and Fluhr 2012; Wu et al. 2006).

These properties change with age or gender, and also with many different pathological conditions. However, regarding obesity, modifications of skin physiology are still poorly described. TEWL changes have been related to the BMI in obese patients (Darlenski and Fluhr 2012; Guida et al. 2010; Löffler et al. 2002). A relationship between obesity and skin hydration (xerosis), increased TEWL, and sweat activity has been reported (Wu et al. 2006). However, most of these studies still provide insufficient information, and the information is difficult to compare when applying different methodologies and individuals. Therefore, in the present study, the focus is centered in comparing skin behavior of normal and overweight individuals in regard to these two basic properties of in vivo skin – barrier function and biomechanical behavior.

2 Material and Methods

2.1 Subjects

A convenience sample of 30 healthy female volunteers aged between 29 and 46 (36 ± 4) years old, was selected after informed consent, in accordance with previously established inclusion criteria. The applied protocols were in full compliance with all ethical standards set by the Declaration of Helsinki and its amendments (World Medical Association declaration of Helsinki 2004).

In order to minimize individual variability and to make the sample as homogeneous as possible, noninclusion criteria regarded pregnancy or lactation, cutaneous signs, pigmentation or scarring in the experimental area, history of allergy, any skin treatments and regular practice of sport.

Restrictions were also imposed to reduce external interference:

- Application of cosmetics on the skin areas involved
- Washing the study areas with soap or shower gel on the day of laboratory measurements
- The use of tight underwear or any cause of friction in the area under study
- Oral and/or topical medication potentially interfering with measurements (mandatory to inform the investigator about any dermatological and/or ongoing pharmacological treatments)
- Sporadic utilization of antihistamines or vitamins (vitamin A) preceding the study and during its course
- Vaccination in the 3 weeks prior to the study
- Exposure to water via sauna/Turkish bath or immersion in an ocean/pool in the 2 days before the study
- Intense sun exposure in the 2 weeks before the study
- Consumption of coffee and/or tea in the 48 h prior to the study

2.2 Instrumentation

Taking into account the announced objectives, the “barrier” function was characterized by the TEWL, obtained with the Tewameter TM300 (CK electronics, FRG), expressed in $\text{g}/\text{m}^2/\text{h}$, and by the epidermal hydration, measured by the Moisture Meter SC (Delphin Technology D) system, which is based on the measurement of the “capacitance” and expressed in AU (arbitrary units). The “envelope” function was measured by the Cutometer CM575 systems (in mm) (Rodrigues and EEMCO 2001; Seidenari et al. 2006; Darlenski et al. 2009) from CK Technologies, FRG by several utility

descriptors. The chosen descriptors were the full recovery of the deformation at the end of the stress period (U_a), total elasticity of the skin (U_a/U_f , including pulse stretching and recovery), total elasticity or elastic function (U_r/U_e), and the viscoelastic ratio (U_v/U_e , e.g., the relationship between the elastic and the viscoelastic extension).

2.3 Experimental Design

This study was conducted at the Research Centre in Biosciences and Health Technologies (CBIOS from Universidade Lusófona) and the Plastic Surgery Department of the Hospital S. José, in collaboration with the service of General Surgery from the same hospital.

The sample was divided into three groups – Group I with BMI between 19.9 and 24.9 kg/m², Group II with BMI between 25 and 29.9 kg/m², and Group III with BMI between 30 and 39.9 kg/m².

After confirming all inclusion and noninclusion criteria, volunteers were submitted to the evaluations required for the quantitative description of the respective “barrier” and “envelope” function characterizations. Volunteers were allowed to acclimatize for a period of about 20 min to ensure full adaptation of their skin functions to ambient conditions. All evaluations were conducted in the laboratory under controlled temperature and humidity (21 ± 1 °C, 45 ± 5 %), in the absence of heat sources and forced convection, according to methodology and previously published recommendations (Rogiers and EEMCO Group 2001; Piérard 1999).

2.4 Statistics

Statistical analysis (descriptive and comparative) was performed using the SPSS (v 20.0) software by univariate analysis with calculation of measures of central tendency and dispersion. Pearson and Spearman tests were also applied, according to the (normal or non-normal, respectively)

distribution of variables, confirmed via the t-student and Mann-Whitney tests, and a 95 % confidence level was adopted. An adjustment for age was also applied.

3 Results and Discussion

3.1 TEWL and Epidermal Hydration

Some studies indicate that TEWL increases with BMI, while others suggest that TEWL decreases in obese individuals, although not stratified by classes (obese and overweight individuals including class I and II, and morbidly obese individuals) (Guida et al. 2010; Löffler et al. 2002; Nino et al. 2012; Sotoodian and Maibach 2012). In our experimental conditions, overweight and obese individuals have shown lower TEWL values than individuals with a normal body mass (Table 2). Until now, the lack of studies with sample stratification by BMI class has not allowed comparisons, but our results seem to favor related previously published data in this direction (Guida et al. 2010; Nino et al. 2012; Yosipovich et al. 2007; Millington 2012; Hidalgo 2002; Brown et al. 2004; Boza et al. 2012). These individuals (overweight and obese) also show higher epidermal hydration values than individuals with lower (normal) BMIs.

Dry skin is a well-known common problem in obese patients, necessarily related to a poor epidermal hydration (Nino et al. 2012; Yosipovich et al. 2007). However, our results have consistently shown that individuals with a BMI between 25 and 39.9 kg/m² had higher values of epidermal hydration. It appears that increased TEWL values always correspond to lower values of surface hydration. Since higher TEWL values correspond to greater water loss through the skin, this seems also to reflect lower water retention capacity and thus lower epidermal surface hydration.

Potentially related, a recent study demonstrated for the first time a clear influence of dietary habits, in particular the consumption of water, on skin hydration and elasticity (Palma et al. 2012a, b).

3.2 Biomechanics

Previous studies allowed us to consider variables U_a and the ratios U_a/U_f , U_v/U_e , and U_r/U_e , as well as the most relevant descriptors of the skin biomechanical condition. Some of these studies correlate these descriptors with weight variation and with subcutaneous adipose tissue. These seem to be better fitted to approach the ability of the skin to distend and retract in an immediate or

delayed form, allowing an overview of its mechanical condition and also a quantitative description of its plastic, elastic, and viscoelastic characteristics (Krueger et al. 2011; Ryu et al. 2008; Verhaegen et al. 2010; Xin et al. 2010; Paye et al. 2007; Ezure and Amano 2010).

Table 3 shows the results for the registered biomechanical descriptors. U_a corresponds to the maximum contractile recovery of the skin

(in mm), showing higher values for the normal weight individuals. Skin adapts to a new body contour following weight increase, apparently denoting greater distensibility. Therefore, we would expect that this recovery could be also higher in groups corresponding to a higher BMI. However, in our sample, values obtained in higher BMIs are lower than those from the normal weight group. This might imply some loss of resilience, given that the strain skin has been subjected for so long. In any case, our results agree with a previously published study (although performed in mice), suggesting a negative correlation of U_a with weight (Ezure and Amano 2009).

Concerning the ratios U_a/U_f , corresponding to biological elasticity (given by the correlation between the recovery and the maximum extensibility of the skin), and U_r/U_e , corresponding to the elastic function variables (the ratio between the immediate recovery U_r and immediate distension of the skin U_e), we normally consider for both

ratios. The higher the ratio, the better its biomechanical behavior. Our results have shown higher values for the normal weight group for both ratios.

An inverse correlation between the U_a/U_f ratio and sagging has been described in obesity (Krueger et al. 2011; Ryu et al. 2008; Verhaegen et al. 2010; Xin et al. 2010; Paye et al. 2007; Ezure and Amano 2009, 2010; Barbenel 2006; Blaak et al. 2011). According to these authors, the larger the value, the lower the sagging and hence higher firmness and better biomechanical behavior of the skin.

Another study identified a decrease of U_r/U_e in obese mice previously subjected to a high-fat diet, and this parameter correlated well with the degradation of the biomechanical behavior (Xin et al. 2010).

With weight gain, a better biomechanical behavior of the skin is expected, in view of the adaptability to new body contour. Here there is a negative change in biomechanical behavior with increasing weight.

Regarding the viscoelasticity, e.g., the ratio between the immediate and the delayed distension U_v/U_e , the higher its value, the better the ability of the skin to react after stretching, and therefore, the better its viscoelastic behavior. It would be expected that the skin's ability to react after stretching, i.e., its viscoelastic behavior, might improve with the weight gain as a consequence of the skin's progressive adaptation, to a new body contour. However, our results have shown that the viscoelastic behavior decreases with the weight gain.

Previous studies identified statistically significant differences among different age groups and as well as different anatomical areas (Krueger et al. 2011; Ezure and Amano 2010; Wa and Maibach 2010). The age adjustment performed helps to avoid the influence of this factor. Furthermore, our results are consistent with those studies referring significant differences among anatomical sites. Nevertheless, our results do not identify any significant statistical difference between the BMI groups for most of the anatomical areas. This is likely due to sample size limitations.

4 Conclusions

Our study clearly demonstrates that excess body weight alters the *in vivo* epidermal barrier function, superficial hydration, and biomechanical behavior of the skin, depending on the considered anatomical area. The magnitude of excess body weight seems to determine different changes – more pronounced deterioration of the skin biomechanical condition is registered with higher BMI, which also corresponds to higher TEWL. This might be related with the variety of dermatoses and other related skin problems observed in obese individuals when compared to normal weight individuals. Further studies involving wider populations, with all classes of BMI, are needed to better understand the pathophysiological impact of this condition on the skin's normal physiology.

1 Introduction

1.1 Occupational Skin Health Surveillance

Occupational skin diseases are very common and some occupations have a far higher risk than others. Occupational contact dermatitis (OCD) of the hands is the most common form and

M.F.C. Steiner (✉)
GO Health Services, NHS Grampian, Aberdeen, UK
e-mail: m.steiner@abdn.ac.uk; m.steiner@nhs.net

accounts for about 80 % of all cases (Andersen 2003). The economic consequences due to days lost at work from absenteeism and related costs for industries are significant. Brown summarized the strategies for prevention of OCD in the workplace following the hierarchy of control to minimize or eliminate exposure hazards: elimination, substitution, engineering controls, administrative controls, and personal protective equipment (Brown 2004). Despite the lack of supporting evidence, health and safety legislation requires that employers offer regular skin surveillance for their staff where the hazard cannot be eliminated or adequately controlled (HSE 2011). This includes workers exposed to chemicals (e.g., solvents), wet work, biological agents, and physical agents such as low humidity, cold, or heat. The current UK recommendation is to screen the workforce at risk on a regular basis (annual or more frequent depending on the likelihood of adverse health outcomes) using regular questionnaire surveys or visual inspection by a responsible person such as a supervisor or line manager (HSE 2008).

Both approaches have their limitations:

- Despite the widespread use of questionnaires asking about both skin symptoms in the past and current symptoms, these have not been validated against clinical assessment. Both recall bias and the individual's perception of their health status and what is normal skin make these instruments open to misclassification and under- or overreporting. In some industries, workers see changes in their skin as "something that comes with the job" and consider these changes as normal, and so they are not reported.
- On the other hand, there is also no validation of screening the workforce by a responsible person. Ideally, this would be done by an occupational health professional with the appropriate resources, but in most cases this is done by someone with no health background. We don't know how valid such screening programs are, and whether underreporting to protect colleagues from unwanted job changes or loss of job occurs.

1.2 Tele dermatology

Telehealth (long-distance professional health education, public health, and health administration) and telemedicine (long-distance clinical health care for diagnosis and treatment) (Gershon-Cohen and Cooley 1950; Strehle and Shabde 2006; WHO Group Consultation on Health Telematics 1998) have evolved and gained widespread use since their origins around 1910 (Romero et al. 2008; Senel 2010; Preston et al. 1992). Nowadays, the change from analogue to digital technologies allows fast transmission and storage of clinical data around the world. Tele dermatology has been shown to give accurate results with concordant results of between 80 % and 90 % when compared to face-to-face consultation (High et al. 2000) but do not always reduce costs compared with traditional face-to-face consultations with dermatologists, when using expensive videoconferencing systems (Loane et al. 2001; Hailey et al. 2002).

Tele dermatology implements three different approaches of telemedicine:

- Store-and-forward technology (S&F) where digital photographs are taken and sent (with clinical information) to a specialist for assessment at a convenient time. This method only requires a digital camera (or even mobile phone with camera) and an internet connection to transfer the images.
- The second approach uses a real-time videoconferencing link (VC) between patient or local health professional and a dermatologist. This method is far more resource intensive in terms of the equipment needed; however, recent technical developments have reduced equipment costs considerably. This method would now be feasible in any practice with a PC and internet connection. However, this method requires that both patient and/or local health professional and the specialist are available at the time of consultation with the requirement of scheduled appointments. On the positive side, the direct interaction between patient and specialist makes it possible to obtain clinically useful information for diagnosis and management (Loane et al. 2000).

- The third approach applies both approaches, S&F and VC, where photographic images are transferred before or during a VC consultation so combining the advantages of both systems.

In recent years studies looking into the feasibility, acceptance by patients and specialists, cost-effectiveness, and reliability of teledermatologic assessments and treatment outcomes have been published. These studies were in settings providing support to rural areas where direct consultation is time consuming and expensive (Loane et al. 2001; Baba et al. 2005; Bergmo 2000; Burgiss et al. 1997; Finch et al. 2007; Finch 2008; Du Moulin et al. 2003; Eminovic et al. 2010; Chambers et al. 2012). However, they have had their emphasis on specific skin condition like psoriasis, melanoma, or other skin tumors (Kroemer et al. 2011; Singh et al. 2011; Warshaw et al. 2009a, b, 2010), or looking into the treatment success in other specific conditions (e.g. treatment of leg ulcers) (Binder et al. 2007). Other studies were conducted in settings where a multitude of different skin conditions were seen.

Recent studies in these areas suggest a good agreement between clinical face-to-face examination and S&F teledermatology, reporting a kappa – the chance-corrected agreement between two modalities – of 0.71 and 0.86 for S&F teledermatology (Edison et al. 2008; Rubegni et al. 2011). Parsi et al. reported cost reductions in teledermatologic care of psoriasis patients of 1.7 times less compared to face-to-face consultations (Parsi et al. 2012), and Moreno-Ramirez et al. reported a similar cost reduction of 1.6 times for skin cancer patients (Moreno-Ramirez et al. 2009).

All these conditions were looking into clinically ill patients for various dermatological conditions, examining the reliability to make the correct diagnosis and/or to monitor treatment progress and outcomes. Only one study was identified looking into the diagnostic accuracy of teledermatologic assessment of dermatitis and skin rashes, a condition probably closest to what one would expect to see in an occupational health clinic. Heffner et al. reported the diagnostic concordance in 137 pediatric patients with skin rashes

between direct visual assessment and teledermatologic assessment with history and digital images alone by a board-certified dermatologist. The intra-rater concordance by the primary dermatologist was 82 % with a kappa of 0.8 (95 %-CI, 0.73–0.88); the inter-rater concordance between two dermatologists was reported for photographs only and photograph versus inpatient assessment with 73 % respective 69 % and a kappa of 0.69 (95 %-CI, 0.61–0.77) respective 0.65 (95 %-CI, 0.58–0.73). Clinically relevant disagreement occurred in 12–16 % of cases depending on modality. However, this study included many different diseases and aimed to make a correct differential diagnosis for these conditions.

2 Results

In occupational medicine and specifically in occupational health surveillance for skin diseases, the signs for skin lesions are often minor, but their recognition is important to avoid progression to more severe or chronic disease. The early detection of workers with damaged skin can also support the health and safety processes in a company to identify areas and work tasks with an increased risk and implement preventive measures according to the hierarchy of risk control. Apart from many examples of telemedical applications in an occupational context, especially in the maritime environment (Schlaich et al. 2009), teledermatologic applications are almost nonexistent.

However, two recent studies have been identified using a teledermatologic approach to occupational health surveillance (Steiner 2011; Baumeister et al. 2009). Both studies were looking into the early detection of occupational hand dermatitis.

Baumeister et al. reported teledermatological skin examinations using digital images in 100 metal workers. All workers were assessed for hand dermatitis in their workplace by a physician including completing an initial interview-based questionnaire related to working conditions, the use of protective equipment, and

medical history. The skin was then examined and classified into four categories no, discrete, moderate, or severe skin change. Subsequently the skin was assessed using a quantitative scoring system developed by the authors (Weistenhofer et al. 2011) where 54 areas of the hands were scored for several primary (erythema, vesicles, papules) and secondary skin changes (scaling, erosions, fissures, lichenification) and the corresponding severity between 0 (absent) and 3 (severe). The hand eczema score for occupational screenings (HEROS) has been validated in a separate study for its intra-observer and inter-observer validity and shown to have a comparable reliability to three other scoring systems for distinct hand eczema, namely, the hand eczema severity index (HECSI) (Held et al. 2005), the Osnabrueck hand eczema severity index (OHSI) (Skudlik et al. 2006), and Manuscore (John 2001). After the examination digital photographs using an Olympus SP-350 camera mounted on a tripod against a green background were taken of the dorsal and palmar aspect of both hands. After several weeks, the digital images were analyzed by two physicians using the same scoring system. The results in their study showed that the mean scores were significantly higher in the teledermatological examination (16.3) compared to the face-to-face examination (13.1) with a predominance of higher scores for secondary skin lesions. No difference was found for the primary lesions. Mean scores for the four subjective categories of skin damage were reported as 5.6 in the face-to-face examination respective 6 in the teledermatologic assessment for no skin changes, 14.6 respective 16.7 for discrete changes, and 33.8 respective 9 (only one case) for moderate skin damage. No assessment of concordance and reliability for the agreement in the subjective categories “no skin change,” “discrete,” “moderate,” and “severe” between the two modalities of face-to-face examination and teledermatologic assessment, but a calculation from the numbers provided in the paper the kappa (quadratic weighted kappa) was 0.1 (95 %-CI, -0.09–0.23) providing only a poor intra-agreement between both modalities.

The second study in the field of teledermatologic assessment of occupational skin diseases has been conducted by this author and was looking into the development of a toolkit taking standardized photographs regardless of environmental influences and its assessment for diagnostic accuracy and reliability using calibrated equipment (Steiner 2011). Despite proven reliability and technical advances, the reasons teledermatology is not widely practiced are (Armstrong et al. 2010, 2011):

- Lack of appropriate training in taking photographs to high standards
- Costly and inefficient software platforms
- Need for better integration in existing practice systems
- Lack of reimbursement for telemedical services but also cost-attractive implementation models

This study aimed to address the first two points with the development of a cost-effective photographic tool for taking standardized photographs without the need for specialist training.

Elimination for the need of user interaction controlling camera settings and taking reproducible photographs independent of time, location, and operator in workplaces where no control over lighting conditions was guaranteed led to the development of a toolkit under the following premise:

- Easy to transport, robust, and set up as the toolkit was for use in different workplaces
- Use of standard components to keep the costs low
- A compact digital camera which could be remotely controlled by a laptop or PC (tethered shooting)
- Give reproducible lighting condition and reduce environmental influences from other light sources
- Assessment of the digital images using a standardized setup with color-calibrated equipment avoiding differences in classification of skin damage and scoring results due to technical issues

Standardized lightning conditions were achieved by a setup blocking out environmental light sources and using a reproducible light output of defined light quality (camera flash). The camera was controlled via tethered shooting in the following aspects: (a) live preview of the picture on the PC, (b) zoom control, (c) autofocus, (d) flash output control, and (e) full control over the exposure settings (ISO, shutter speed, aperture, and white balance). Figure 1 shows the final toolbox in its dismantled and fully setup stage.

For the second objective to assess the diagnostic validity and reliability between face-to-face and teledermatologic assessment in occupational skin health surveillance, a web platform was developed presenting the photographs on color-calibrated monitors. Four occupations at increased risk of hand dermatitis (Forrester and Roth 1998; Meyer et al. 2000) were selected: health-care workers in an intensive care unit (ITU), engineering workers from engineering workshops in the Aberdeen area, hairdresser apprentices from several colleges in North East Scotland, and due to anecdotal evidence of increased hand dermatitis, nursery nurses from

several children's nurseries in the region were included.

Next to a qualitative assessment into "normal skin," "dry skin," or "dermatitis," the quantitative hand eczema severity index (HECSI) (Held et al. 2005) was used.

The participants were examined during their working hours so the time for the face-to-face assessment had to be kept short, and the quantitative HECSI and qualitative assessment was blinded to additional information. Arrangements were made to examine the participants on a monthly basis over a 7-month period if available.

Three pictures of the hands were taken at each time point from every participant: (1) dorsal aspect of the hand, (2) palmar aspect of the hand with fingers stretched out, and (3) fingers lifted to see the fingertips. Toward the end of the study, a fourth picture (4) was added displaying the inner lateral aspect of the fingers. Figure 2 gives an overview over the four positions of the hands which took only about 1–2 min including checking and entering the participant identifier. A standard reference color card (Gretag Macbeth Color Checker Mini-Chart, X-Rite Inc.) was used

Fig. 1 Photographic toolbox used for taking standardized photographs in the workplace

Fig. 2 Example of photographs taken from each participant at each session

regularly to permit checking of the photographs for correct exposure settings (with regard to color casts).

Overall 1,217 face-to-face assessment in 332 participants were available for analysis of intra- and inter-observer agreement. The teledermatologic assessment was based solely on the visual appearance of the hands in the photographs without additional supporting information. Analysis for agreement between face-to-face inspection and teledermatologic assessment for the subjective categories “normal skin,” “dry skin/minor dermatitis,” and “dermatitis” using unweighted kappa gives intra-rater agreement of 87.8 % with a kappa of 0.79 (95 %-CI, 0.76–0.82) and an inter-rater agreement between the physician and the dermatologist of 57.2 % with a corresponding kappa of 0.16 (95 %-CI, 0.12–0.21). Using quadratic weighted kappa, the intra-rater agreement increases to 95.1 % with a weighted kappa of 0.82 (95 %-CI, 0.78–0.85) and respective 80.1 % with a weighted kappa of 0.27 (95 %-CI, 0.20–0.33). HECSI scores were only complete for the intra-rater assessment and

showed a spearman correlation of coefficient of 0.76 HECSI discriminated well between the three categories of skin health independent from factors like occupation, age, or sex. Overall this study has shown a very good intra-rater agreement between face-to-face and teledermatologic assessments in occupational skin surveillance for hand dermatitis but presented a poor inter-rater agreement.

3 Discussion

Teledermatology has been established and widely used in clinical settings supporting the general practitioner in rural areas with dermatology input, reducing costs and times for patients and specialists specifically when using S&F technology. Teledermatology has also shown a good diagnostic agreement between face-to-face consultation and teledermatologic assessment for several skin conditions, mainly skin tumors, melanomas, or psoriasis, and to monitor treatment success in specific disease conditions (Pak et al. 2007). Baumeister et al. presented a case

study where teledermatology was successfully used supporting an occupational physician to make a diagnosis and identify the probable source for an inflammatory condition in six railroad workers (Baumeister et al. 2007) and later tested the performance and correlation of two hand eczema scoring systems for early hand eczema in teledermatological settings (Baumeister et al. 2010). Only two studies to date have used teledermatology in the setting of occupational health surveillance despite its potential attractiveness to offer a method which is quick and wouldn't disturb the work process. The results from both studies are inconclusive as one showed a poor intra-rater reliability (Baumeister et al. 2009), the other promising results in terms of intra-rater agreement, but a poor inter-rater reliability (Steiner 2011). What are the potential reasons for these results and how can they be addressed? Diagnostic concordance in other studies between dermatologists in face-to-face consultations is about 78 % (Ribas et al. 2010), and one would expect that teledermatology would offer a similar reliability.

The first study doesn't report if the settings for taking photographs have been standardized and if precautions had been taken to avoid misclassification due to technical issues. This can be a major issue in failing an accurate assessment in a teledermatological setting. Figure 3 shows an example of the same photograph presented on the same monitor when viewed at different angles and illustrates the importance to standardize every step in the pathway using teledermatology for occupational screening for skin conditions.

The second study addressed all possible issues around the standardization taking hand photographs and the assessment, and similar suggestions can now be found in the practice guidelines for teledermatology published by the American Telemedicine Association (Krupinski et al. 2008). The study was able to show a very good agreement between face-to-face and teledermatologic assessment but showed only a poor to moderate inter-rater agreement between clinical RF and the dermatology consultant. Both trained the scoring for hand dermatitis in a clinical outpatient setting on patients with distinct hand dermatitis. The presentation of the photographs was randomized and blinded, and bias was reduced to a possible minimum. Two probable reasons for the disagreement between both assessors are likely (a) the dermatologist scored only participants when subjectively identified with hand dermatitis and therefore relied on the first overview of the hands not looking closer for specific signs and (b) different threshold when assessing patients with minor skin changes or skin damage between specialties. The dermatologist consultant only sees patients in the clinic with moderate to severe hand dermatitis, and rarely patients present with minor skin changes on the hands which would require clinical treatment. In contrast the clinical RF and occupational physician is confronted with workers where the hands show only minor skin changes, which need to be addressed to avoid their deterioration with possible time off work or job loss and to suggest preventive measures for the workforce. This makes it likely that both assessors had a different view

Fig. 3 Appearance of the same photograph under minimal changes of the viewing angle on a calibrated laptop screen

according to the settings in which they normally work. Another drawback in the performance of the teledermatologic method is the fact that some skin lesions might be too subtle to be easily recognized in photographs. This is true to some extent for minor scaling as presented, for example, in occupations exposed to wet work. Such skin changes are only recognized by experienced assessors and can easily be missed. The provision of additional occupational and clinical data is likely to increase the accuracy in the assessment of such minor changes.

Both studies showed that skin conditions are scored worse in the teledermatological setting compared to the face-to-face inspection. A likely reason for this might be the ability to zoom into the picture into greater detail than possible by visual inspection, and minor changes are studied in more detail with more time in the digital images. This does lead to higher scores in using established scoring tools but didn't have an effect on the subjective assessment for dermatitis in the second study.

Based on the very good intra-rater agreement using standardized equipment, teledermatology offers an attractive method for occupational skin surveillance for signs of hand dermatitis, with the advantage that it wouldn't take much of a workers time (minutes only) or disrupt working processes and that it can be done at convenient times for the worker and employer. It also offers the advantage that the assessment can be done at convenient times by a health professional without blocking valuable clinical times and that the progress of preventive measures or treatments can be monitored over time and documented using a reproducible method. The easy standardized setup allows to produce photographs which are repeatable and which can be integrated in the documentation process of occupational skin surveillance but also allows frequent follow-up in the clinical setting or clinical studies in the treatment of hand dermatitis.

For the assessment of hand dermatitis, several scoring systems are available and validated, and despite some of these were developed to monitor clinical treatment progress of distinct HE (HECSI, Manuscore), the studies have shown

that they are able to distinguish also for minor skin changes like their alternatives (HEROS, OHSI). The methods for taking photographs and for the remote assessment however have to be standardized all the way through to allow for reproducible results. Further studies into the inter-rater reliability of teledermatologic occupational skin surveillance should be initiated to identify further shortcomings or prove the validity of this concept.

Important factors for a toolkit to be used for occupational skin surveillance are:

- A setup that does not need user interaction controlling camera settings and lighting conditions for reproducible photographs
- An assessment environment using standardized workstation settings and calibrated equipment
- Assessors which are sufficiently trained in recognizing minor skin damage; later might be best achieved in assessment centers with trained staff, regular training, and cross-validation of random samples between assessors

Future developments of such toolkits might include:

- (a) A setup where staff cards can be used to start up the system for the specific staff member without further user input and real-time user instructions as to how to position their hands for a set of four photographs
- (b) The use of polarized light sources to allow a more detailed inspection of either surface structures (e.g. for scaling using parallel-polarized photographs)

Due to the fact that all camera manufacturers discontinued compact camera models which allow tethered shooting, new alternatives are necessary: either one could make use of more expensive digital SLR cameras which would increase the costs for the teledermatologic tool or the development of a solution using a credit card-sized computer (Raspberry Pi) with a camera module or a mobile phone app making the use of

a dedicated laptop for controlling the camera and storing the photographs obsolete.

1 Introduction

Although extensively studied (Agner 1992), sodium lauryl sulfate (SLS) has been rarely used on the face to investigate mechanisms of irritation (Cua et al. 1990).

Because of the particular skin sensitivity of the face and the neck and because of the regional and age-related variabilities detected in these areas to compounds inducing contact urticaria (Shriner and Maibach 1996; Marrakchi and Maibach 2006), we conducted this study with SLS 2 % under occlusion for 1 h.

Because baseline TEWL has been speculated as a predictive parameter to skin susceptibility to SLS (Tupker et al. 1989) and changes in hydration of superficial epidermis suspected to be responsible for the seasonal variability of skin irritation induced by SLS (Agner and Serup 1989), we measured the baseline TEWL and capacitance before SLS application and studied their correlation with changes in TEWL (∂ TEWL), 1 h and 23 h after patch removal (Agner 1992).

2 Material and Methods

2.1 Subjects

Two age groups were examined: ten young subjects, aged 25.2 ± 4.7 years ranging from 19 to 30, and ten older subjects, aged 73.7 ± 3.9 years ranging from 70 to 81.

2.2 Methods

Eight areas of the skin (forehead, nose, cheek, nasolabial and perioral areas, chin, neck, and volar forearm) were studied.

After 15 min of rest, necessary to suppress excess water evaporation, baseline TEWL was measured using an evaporimeter, Tewameter TM 210* (Courage + Khazaka, Cologne, Germany), and baseline capacitance was measured with a Corneometer CM 820 PC (Courage + Khazaka, Cologne, Germany).

Sodium lauryl sulfate (Sigma, St Louis, MO) 2 % (w/v) in water was then applied to each of the eight areas for 1 h under occlusion using a saturated absorbent filter paper disk (0,8 cm diameter) in Finn Chamber aluminum disks (Epitest Ltd Oy, Finland). On the contralateral side, water was applied in the same conditions as control.

To assess skin irritation, TEWL was measured 1 h and 23 h after patch removal.

Transepidermal water loss values of the areas tested were corrected according to the changes in the control areas:

$$\text{TEWL} = \text{TEWL measured} - \partial\text{TEWL H}_2\text{O}$$

where TEWL measured is the measured TEWL in the tested area at 1 h or 23 h and $\partial\text{TEWL H}_2\text{O} = \text{TEWL control} - \text{baseline TEWL H}_2\text{O}$ where TEWL control is the measured TEWL value in the control area at 1 h or 23 h.

The skin reactivity to SLS was assessed by the changes in TEWL ($\partial\text{TEWL} = \text{TEWL} - \text{baseline TEWL}$)

2.3 Statistical Analysis

To compare the skin reactivity (∂TEWL) of the regions within each group, the two-tailed Student *t* test for paired data was used. The two-tailed Student *t* test for unpaired data was used to compare the two age groups.

Simple linear regression and correlation analysis between basal TEWL and skin irritation (∂TEWL) and between baseline capacitance and ∂TEWL for each skin location combining the data of the two age groups was used. ∂TEWL was considered as the dependent variable.

3 Results

3.1 Skin Reactivity

Sodium lauryl sulfate 2 % under occlusion for 1 h induced in most of the cases a subclinical irritation and sometimes minimal erythema.

The absolute TEWL values taken after 1 h and 23 h did not show significant differences. Since the 23 h measurements demonstrated lower standard deviation values, only the irritation assessed at 23 h will be considered.

3.1.1 Comparison Between the Regions

In the young group, all the areas reacted to SLS except the forearm. Skin irritation induced by SLS and assessed by ∂TEWL was greater in the cheek and chin when compared to the neck and forearm ($p < 0.05$).

The highest ∂TEWL mean values were found in the cheek and chin (Table 1), but no statistically significant differences with the remaining regions of the face were detected.

All the other regions except the forehead showed a significantly higher irritation than the forearm.

In the old group, all regions reacted to SLS except the nose, perioral area, and forearm. The cheek and chin showed the highest ∂TEWL mean values (Table 1). Significantly ($p < 0.05$) higher

reactivity of these two areas was found when compared to the forearm and when the chin is compared to the forehead.

3.1.2 Comparison Between the Two Age Groups

The mean ∂ TEWL values were higher in all the areas studied in the young than in the older group (Table 1). Only in the chin ($p = 0.035$) and nasolabial area ($p = 0.005$) were the differences significant.

4 Correlation Study

4.1 Correlation Between Baseline TEWL and ∂ TEWL

Table 2 summarizes the correlations in each area between baseline TEWL and ∂ TEWL 23 h after patch removal.

The forehead and the neck showed the strongest correlations ($r = 0.6474$, $p = 0.002$ in the forehead; $r = 0.6273$, $p = 0.003$ in the neck).

Table 1 Reactivity of regions in the young and old group

Area	∂ TEWL (Mean \pm SD) g/m ² h		<i>p</i> value
	Young group	Old group	
Cheek	15.1 \pm 12.8	6.8 \pm 7.3	0.093
Chin*	13.5 \pm 9.9	6.0 \pm 3.3	0.035

Areas which reacted to SLS: statistically significant ($p < 0.05$) difference baseline TEWL and TEWL 23 h after patch removal

r coefficient of correlation

p significance (significant correlation when $p < 0.05$)

The nose and chin did not demonstrate a significant correlation between basal TEWL and TEWL changes induced by SLS. The forearm was not studied since this area did not react to the surfactant.

4.2 Correlation Between Baseline Capacitance and ∂ TEWL

The baseline capacitance was not correlated to the skin irritation induced by SLS in any area studied.

5 Discussion

Sodium lauryl sulfate, an anionic surfactant, is widely used to study the sensitivity of the skin to irritants. Little information on the susceptibility of the face to SLS is available (Cua et al. 1990).

It has also been demonstrated that SLS could greatly increase the capacity of rigid nanoparticles to serve as transdermal drug carriers (Lopez et al. 2011).

In this study, we investigated the influence of age and regional variability on SLS irritation with a focus on the skin of the face.

We considered only TEWL 23 h after patch removal because of the lower SD when compared to the 1 h values. This difference in SD might be explained by the “transient damage to the water barrier of the skin” described by Agner and Serup (1993) and induced by exposure to water. This transient increase of TEWL not related to SLS nor to the evaporation of additional water lasts between 1 and 3 h after patch removal.

Considering the increase of TEWL after SLS exposure (∂ TEWL), the young group had a higher irritant response than the old group in the chin and nasolabial area. In the remaining regions including the neck, ∂ TEWL mean values were higher in the young group although the differences were not significant. This lack of significant differences might be explained by the high SD values (Table 1) in these regions. Previous studies (Cua et al. 1990; Elsner et al. 1990) investigated the influence of age on the susceptibility to SLS and

reported a decrease of the sensitivity in the elderly which is in concordance with our results.

Various protocols (concentrations, application time) use SLS in water solution to induce skin irritation (Wilhelm et al. 1989; Van Neste and De Brouwer 1992). In our study, since the face was suspected to be more sensitive than the remaining regions of the body, and for a practical purpose, SLS 2 % was applied only for 1 h under occlusion. This protocol was sufficient to induce subclinical irritation in most of the areas of the face but not in the forearm confirming that the face is more sensitive than the forearm.

Although the cheek and chin showed the highest ∂ TEWL mean values, no regional variations were detected between the various regions of the face in both age groups, but the cheek and chin were more sensitive than the neck in the young group. This lack of significant differences between regions might be explained by the high SD observed in ∂ TEWL values.

To see whether significant differences in skin irritation induced by surfactant exist between the regions of the face, higher SLS concentrations should be tested as well as repeated open applications which may better reflect the common use of potential irritants on the face.

The correlation study showed a significant correlation between basal TEWL and ∂ TEWL in five of the seven areas which have reacted to SLS (Table 2).

The correlations between baseline TEWL and TEWL 23 h after patch removal were more obvious. All the areas which reacted to SLS (all the areas studied except the forearm) showed a strong correlation coefficient varying between 0.76 and 0.88 with a highly significant p value < 0.001 .

However, we think that the correlation between basal TEWL and the absolute TEWL value after irritation does not imply that higher basal TEWL values predispose to higher skin sensitivity, but only the correlation between baseline TEWL and the changes in

TEWL after irritation (∂ TEWL) may have this significance. Even if for different basal TEWL values, the changes in TEWL are the same, a positive correlation could be found because

TEWL is considered as a stable parameter (Oestmann et al. 1993).

The tendency that reactivity of the human face to SLS decreases with age is sustained by findings in the literature that TEWL measured in the face of a large group of Asian volunteers decreases with age (Tagami 2008).

Not only the face but also volar forearm, a seemingly homogeneous skin area, demonstrated regional variability to react to SLS (Bock et al. 2007).

Further studies are needed to detect the participation, with baseline TEWL of biophysical, biochemical, or anatomical parameters in the susceptibility of the face to irritants.

1 The Risk Factors Associated with Foot Blister Creation

Foot blisters can form in people of all ages and activity levels, but those at increased risk are athletes (Institute for Preventative Foot Health [Internet]. National Foot Health Assessment; [cited 2014]; Brennan 2002), hikers (Kogut and Rodewald 1994), those wearing incorrect footwear and hosiery (Dai et al. 2006) and military staff (Akers and Sulzberger 1972; Mailler-Savage and Adams 2006; Sian-Wei Tan et al. 2008). Moreover, the formation of blisters during endurance training can be the cause of further injury (Van Tiggelen et al. 2009; Bush et al. 2000). The primary risks associated with foot blisters are local sepsis and consequent cellulitis (Hoeffler 1975; Knapik et al. 1995).

There are a range of suspected (but not fully verified) factors that place foot skin at increased risk of blister. Some of these factors can be manipulated in order to reduce the risk; others are intrinsic to the nature of the skin (Table 1). Proactive measures to reduce the risk of blistering can be successful to a degree, the primary target being that of moisture reduction within the shoe and

sock and consequently the surface of the skin. A number of other risk factors have been referred to in the literature but have not yet been tested in the context of foot skin blister, such as skin elasticity and thickness.

The majority of foot blister research studies have focused largely on prevalence and severity of blisters in response to specific activities as the sole outcome measure. Such studies have not been conducted in controlled conditions, but “in the field,” for example, obtaining blister counts from groups of people after military training exercises or at the end of hiking sessions. Due to the practical nature of these studies, and the consequent methodological limitations, the physiological events (and the causes) that take place prior to the visible appearance of the blisters are overlooked. As a result, advances in the development of effective, preventative interventions are stunted. There are some seminal pieces of work in the field of tribology that have contributed to a greater understanding of how foot skin might respond to specific external forces. The next section describes the early works that formed the foundations of knowledge in this area.

2 Early Work on the Measurement of Skin Trauma Due to External Forces

It was the detrimental impact of foot blisters on military staff that motivated the research conducted by Naylor and Sulzberger in the 1950s and 1960s (Naylor 1955; Sulzberger et al. 1966). Naylor reported an inverse relationship between the number of ‘rubs’ required to form a blister and the frictional force applied (Naylor 1955). Sulzberger and associates generated a large body of evidence that corroborated and added to Naylor’s findings (Akers 1977). Both authors conducted laboratory-based research on anterior shin, forearm, and palmar skin sites (in vivo), by systematically rubbing the skin to the point of pain, blister, and/or abrasion. Akers and Sulzberger (1972) further explored the effects of temperature and moisture on blister formation on these skin sites using strain gauge technology to allow for the precise quantification of forces applied to the skin. The apparatus used a system of weights and pulleys to apply a loading probe that could be moved

Fig. 1 The friction measurement devices designed by (a) Naylor (1952) and (b) Sulzberger et al. (1966)

manually in a linear direction across the surface of the skin allowing for the simultaneous measurement of friction loads at the interface of the probe and the skin (Fig. 1). The elegance of this work involved altering the frictional loads while maintaining constant normal (or perpendicular) loads. This was achieved by systematically applying substances to the skin that would alter the coefficient of friction (CoF), for example, oil or talcum powder. Their results showed that a greater number of load cycles were required to cause tissue trauma, using these substances, compared to skin without any substance being applied. Conversely, Naylor found that increased skin surface moisture caused an increase in CoF (Naylor 1955), and El Shimi (1977) later found that dry skin has a relatively low friction response (Shimi 1977). On closer inspection of Naylor's data, it is plausible to suggest that a reduction in CoF of approximately 30 % could increase the number of load cycles required to cause skin trauma by threefold. He therefore demonstrated that by keeping the compressive forces constant and manipulating only the friction loads, skin damage could still occur.

This early work paved the way for the science of tribology, where a range of motorized, laboratory-based devices were developed that primarily involved the application of a controlled normal load to a skin site on the body and the detection of the resistance of the skin to the movement of that applied load. The direction of the load movement of these devices tended to be either

linear (Comaish and Bottoms 1971; Koudine et al. 2000; Asserin et al. 2000; Sivamani et al. 2003a, b) or rotational (Shimi 1977; Highley et al. 1977; Prall 1973; Cua et al. 1990; Elsen et al. 1990). During this time the focus of research shifted from testing skin on the lower limb to sites elsewhere on the body, mainly skin on the forearm. In fact, published work of this nature on foot skin is rare, and many blister prevention interventions are informed by the work conducted on skin other than on the foot.

3 The Application of Knowledge in Tribology and Tissue Mechanics to Foot Skin Function and Blistering

In the 1970s, the basic principles of friction in relation to skin were beginning to be challenged. According to Amonton's law, the dynamic friction coefficient, generated when two relatively stiff materials (with smooth surfaces) pass across one another, remains constant despite changes in normal load and velocity of the relative movement. However, in the case of a stiff material in contact with viscoelastic skin, at the contact phase between the two materials, there is a nonlinear deformation of the skin with increasing load transfer to the deeper tissues. This load is referred to as shear load (Fig. 2). Several investigators have tested this behavior of the skin and have concluded that it does not follow Amonton's law

Fig. 2 Diagram illustrating the generation of shear loads in response to compression and friction forces

(Shimi 1977; Comaish and Bottoms 1971; Koudine et al. 2000). This scenario of increased shear forces within the skin places the dermoepidermal junction vulnerable to physical rupture. It follows that increased friction can lead to increased shear forces in the deeper tissues. This is even more relevant in the case of foot skin where the friction and shear components of contact loading are influenced by the repetitive forces generated not only between the shoe and foot skin during walking but also between the contoured bony prominence (of the heel or metatarsal head) and the adjacent subcutaneous tissue. It is these additional factors that influence friction and shear forces to reach a critical level causing abrasion, blistering, or ulceration of foot skin.

During walking, each area of the skin on the foot (in particular plantar and posterior heel skin) is subjected to a combination of perpendicular and parallel loads. The generation and decline of these loads relate to the changes in the gait cycle as well as the nature of the soft tissues that respond to these loads. These loads vary greatly from site to site on the foot and between different stages of the gait cycle. The peak compression and shear loads do not necessarily take place at the same time. The majority of the research focusing on the reduction of skin trauma from repetitive loading has concentrated on peak compression levels only. However, it is clear that the true nature of repetitive loading involves a friction and shear element, for example, low, repetitive peak loads are damaging

when a significant component of the load is parallel to the surface of the skin. An example of this is chaffing of the skin. When this shear component is large, damage to the skin can take place relatively early (i.e., after a few load cycles). Conversely, when the friction component is small, it takes more load repetitions to cause skin damage. The level of friction loads is governed by the CoF and the direct contact pressure. To add to this complex picture, there is considerable variability in CoF measures within the general population, i.e., the skin of one person may respond to loads differently to that of another.

With these factors in mind, Hashmi et al. (2013) designed a series of experiments on posterior heel skin (in vivo), where the incidence of foot blisters is most common, and the architecture of the underlying bone is likely to influence tissue damage (Hashmi et al. 2013). The authors generated 30 heel blisters from a population of healthy adults, using a device that applied a standard, intermittent load/unload pattern on the skin that mimicked the contact between the posterior heel skin and the counter of the shoe during walking (Fig. 3). The degree of tissue trauma during load application was monitored and quantified using medical thermography (Fig. 4). This acted as a surrogate measure for trauma due to friction and shear loads. The experimental design was similar to those of other devices used in tribological studies but with a focus on effectively applying load to the contoured, bony surface of the

posterior aspect of the heel while being able to visually inspect and measure the degree of inflammation in response to tissue trauma. The results

showed that the initiation of friction heel blisters took place at a temperature of approximately 5 °C above the normal skin temperature of the foot.

Although understanding the architecture of the foot and its relationship to the biomechanical properties of soft tissues is vital, the common factor that increases the susceptibility of skin to blistering on any site on the body is that of increased moisture. Therefore, in the context of foot blistering, the interaction between the skin and footwear materials and the accumulation of moisture within the shoe is an important consideration when implementing clinical solutions.

Fig. 3 Load application mechanism for applying intermittent normal and friction loads to the posterior aspect of the heel (Hashmi et al. 2013)

4 The Effect of Hydration on Foot Skin Friction and Shear Forces

Water on the surface of skin has the effect of making the skin more pliable when in contact with the loading surface. This in turn allows for closer contact between the skin and the material

Fig. 4 Thermal images of four different heels at the point of blister creation. Each image depicts a ‘hot spot’ (in red) representing the area where the blister has formed

and therefore increases the CoF. The converse is the case with dry skin in that the loading surface does not achieve as much contact with the skin and slides more easily over the surface. This has been tested in skin dried using isopropyl alcohol (Sivamani et al. 2003a) and in patients with clinically dry skin (Lodén et al. 1992). However, the maintenance of constant moisture on the skin surface under experimental conditions is difficult to achieve, therefore producing varied CoF results (Shimi 1977; Sivamani et al. 2003a; Highley et al. 1977; Nacht et al. 1981).

A similar observation was made by Kirkham et al. (2014), who hydrated foot skin using a water foot bath and subjected the skin to the same compression and friction loads, as reported by Hashmi et al. (2013). These data were compared to the skin on contralateral feet that were not hydrated and showed that the time taken to achieve skin trauma (akin to a preblistered state) was significantly less in the hydrated foot skin compared to the relatively dry skin. Contrary to the data generated from other skin sites, Kirkham et al. found no significant, positive correlation between heel skin hydration and elasticity (Kirkham et al. 2014). This is not surprising as the measurement of elasticity was conducted using suction pressure; therefore, the inclusion of the dermis in the measure could not be avoided, whereas the hydration readings were that of the superficial skin layers. Also, it may be reasonable to assume that the evaporation of the water from the surface of the skin may occur relatively quickly compared to the time taken to conduct the experiment, as well as water being absorbed into the deeper layers of the skin. The changes in hydration of foot skin during exercise have not been reported; therefore, the work by Kirkham cannot be put into the context of the behavior of skin within the shoe.

In addition, a clearer understanding of how the friction, compression, and shear forces act collectively on the skin around bony prominences of the foot is necessary. Researchers in the field of prosthetics and orthotics have tried to address this question in the context of pressures applied at the interface between a limb stump and a prosthetic. The most notable research in this area is that conducted by Sanders and colleagues (1992, 1993,

1997, 1998, 2004; Sanders and Daly 1993), who designed shear load sensors that quantified shear/friction forces at various prosthetic socket wall locations. This technology has allowed peak friction loads on “at-risk” locations to be varied by making known changes in the interface CoF at those locations using a variety of common cushioning materials with known CoF (Sanders et al. 1998, 2004). From their data, a number of material combinations could be selected, representing a significant range of CoF values. It would be helpful to apply these methods to exploring the interaction between the foot and shoe in order to understand and interpret foot skin mechanics during walking. It is only when translation of this knowledge is achieved that the development (based on scientific evidence) of efficacious prevention treatments for blisters, calluses, and ulcers can truly be successful.

5 Hydration and the Inshoe Environment

Skin trauma as a result of changes in the microclimate within the skin – clothing system and the transfer of heat and moisture within it – has been extensively reviewed (Zhong et al. 2006); however, minimal work has been generated with regard to the inshoe microclimate and foot skin irritation. The degree of foot skin hydration is largely influenced by two factors: inherent susceptibility to the production of sweat and the accumulation of moisture within the shoe. Therefore, the appropriate choice of footwear, socks, and topical preventative therapies is imperative for those who are prone to hyperhidrosis and blistering. The few papers published in this area have concentrated on measuring the prevalence and size of blisters in response to different types of sock materials. For example, the outcomes of a double-blind study by Herring and Richie showed that acrylic fiber socks reduced the prevalence and size of foot blisters after long-distance running (Herring and Richie 1993). Knapik et al. (1996) conducted a similar study on military trainees and found that the denser sock materials increased the prevalence and size of foot blisters (Knapik et al. 1996), the implication being that the denser the material, the greater the

potential for accumulating moisture within it. Others have attempted to test the effects of antiperspirants on the incidence and severity of friction foot blisters (Reynolds et al. 1995; Knapik et al. 1998). These works showed no positive effects of preventing blisters after hiking activities. In fact, an increased rate of irritant dermatitis was reported. Despite these works, the prevalence and severity of blisters in response to activities and preventative treatments are poorly understood. This will remain the case until a more detailed identification of the specific changes in the functional behavior of foot skin in different microclimates is made. In short, more sensitive measures of change in skin are required to counteract the variations seen between people.

There are several approaches that can be implemented to combat the challenges of predicting inshoe responses of foot skin to changes in microclimate and force generation during walking. In the absence of designing controlled laboratory studies and the presence of multiple variables, finite element modeling (FEM) may be the future direction for research in this field. An example of one such work is that conducted by Dai and colleagues, who used FEM to understand the effects of specific sock materials on friction forces at the skin to sock and sock to shoe interfaces (Dai et al. 2006). These researchers found that wearing a sock with low friction against foot skin was more effective in reducing plantar shear force than on the skin than with a sock with low friction against the insole of the shoe. This is valuable knowledge when considering the motion of the foot within the shoe. As the philosophy behind the design of blister prevention treatments focuses on the reduction of moisture at the skin material interface, it would be valuable to develop models to test this and further apply the results to predicting the efficacy of blister prevention treatments.

6 Conclusions and Future Directions

The importance of hydration as a risk factor for friction blisters is evident. What is agreed among all researchers in this field is the multifarious

etiology of foot blisters and the limitations that these place on study designs. It must be acknowledged that the work conducted to date, by researchers in all scientific disciplines, has endorsed the impact of hydration on foot blister risk. However, it is evident that the data generated from these studies may now have reached a saturation point, and in order to be able to translate these data to have meaningful clinical impact, the use of modeling technology may be the logical progression. Incorporation of existing clinical study data into specific foot skin models may bring us closer to predicting the efficacy of interventions. Advances in this direction may also prove fruitful avenues for investigating the role of friction and the potential value of friction management in reducing foot ulceration and excessive callus formation.

Keywords

Retinoids • Connectivity map • Organoculture
• Skin • Gene array

Abbreviations

A-A-A	Acetyl aspartic acid
Cmap	Connectivity map
COLIV	Collagen IV
CYPs	Cytochrome P450-dependent enzymes
DEJ	Epidermal–dermal junction
ECM	Extracellular matrix
HRIPT	Human repeat insult patch
MMPs	Matrix metalloproteinases
RA	All-trans retinoic acid/tretinoin
RALDH	Retinol dehydrogenases (RDH) and retinal dehydrogenases
RAR	Retinoic acid receptors
RHE's-SkinEthic model	Human reconstructed epidermis
ROI	Region of interest
RXRs	9- <i>cis</i> -retinoic acid receptors

1 The Use of the Connectivity Map in Drug Development

In 2006, an innovative method, named the “connectivity map” (Cmap), was reported by Lamb et al. (2006). The investigators created a large public database containing hundreds of gene expression profiles, called “reference gene signatures,” of cultured human cells treated with >1,000 bioactive small molecules, attached to a pattern-matching tool.

The most recent version contains 7,056 gene expression profiles from 1,309 bioactive compounds, representing 6,100 individual treatments in five different human cell lines.

Researchers can access that database via the Internet and can compare gene signatures of

interest with the Cmap database. The pattern-matching software scores and ranks similarities between the researcher's and the reference signatures and can lead to unexpected connections between the researcher's gene profiling data and small molecules and therefore lead to new treatment strategies in a number of diseases.

2 Applications of Cmap in Drug Discovery

In this section, we discuss some of the applications of Cmap in the context of therapeutic research. With the use of this method, novel agents have been identified mainly for use in the treatment of cancer (Sirota et al. 2011; Chen et al. 2011; Yang and Agarwal 2011; Siu et al. 2008; Claerhout et al. 2011; Hassane et al. 2008; Wang et al. 2011; Reka et al. 2011). Recently agents have also been identified for drug development within Gaucher disease (Chen et al. 2011), pain management (Chang et al. 2010), muscle atrophy (Kunkel et al. 2011), inflammatory bowel disease (Dudley et al. 2011), smoking cessation (Boyle et al. 2010), and Alzheimer's disease (Chen et al. 2013) (as outlined in Table 1). Within the dermatology field, however, there is only one study published so far on the use of connectivity mapping. The Shiseido research group has identified a potential repurposing opportunity for the promiscuous antipsychotic drug, fluphenazine, to be used as a novel hair-growth inducer candidate by means of Cmap analysis (Ishimatsu-Tsuji et al. 2010).

3 The Use of Retinoids as an Antiaging Strategy

One of the most studied classes of skin-targeted compounds is all-trans retinoic acid (RA) also referred to as tretinoin. RA and its synthetic or natural derivatives (retinoids) affect epidermal

Table 1 Drugs identified and key findings through gene arrays with corresponding connectivity mapping and the disease that these drugs could be used as a treatment

Disease	Drug identified	Key finding	Validation	Reference
Muscle atrophy	Ursolic acid	Identified opportunity to repurpose ursolic acid to, for example, muscle atrophy	In vitro and in vivo (rodent)	(Kunkel et al. 2011)
Lung cancer	Cimetidine (an antiulcer drug)	Predicted new indications for the 164 drugs in the Cmap and validated cimetidine as a candidate therapeutic for lung adenocarcinoma	In vitro and in vivo (rodent)	(Sirota et al. 2011)
Hepatocellular carcinoma (HCC)	Chlorpromazine and trifluoperazine	Identified therapeutic candidates for HCC, with in vitro anti-tumor activities validated for 28 drugs and in vivo for 2 drugs (Chlorpromazine and trifluoperazine)	In vitro and in vivo (rodent)	(Chen et al. 2011)
Hair growth	Fluphenazine (an antipsychotic drug)	Identified a list of candidate agents with mimic patterns to the hair growth inducer cyclosporine and validated fluphenazine in vivo	In vivo (rodent)	(Ishimatsu-Tsuji et al. 2010)
Osteoarthritic pain	Phenoxybenzamine (an antihypertensive drug)	Predicted analgesic activity for phenoxybenzamine	In vivo (rodent)	(Chang et al. 2010)
Inflammatory bowel disease	Topiramate (an anticonvulsant drug)	Predicted new use option for topiramate as a drug to treat IBD	In vivo (rodent)	(Dudley et al. 2011)
Lung cancer	Polyphyllin D (a potent cytotoxic saponin)	Predicted polyphyllin D as a potential endoplasmic reticulum stress inducer to be used for anticancer treatment	In vitro	(Yang and Agarwal 2011)
Breast cancer (tamoxifen resistant)	Phenothiazines (antipsychotic and antihistaminic drugs)	Identified and validated three compounds from phenothiazine family as potential therapeutics for drug-resistant breast cancers	In vitro	(Siu et al. 2008)
Gastric cancer	Vorinostat (for cutaneous T-cell lymphoma)	Identified vorinostat as a candidate drug for gastric cancer	In vitro	(Claerhout et al. 2011)
CNS injury	Piperazine (antipsychotic drug)	Identified piperazine as promoters of CNS neurite growth	In vitro	(Johnstone et al. 2012)
Acute myelogenous leukemia (AML)	Celastrol and 4-hydroxy-2-nonenal	Predicted and discovered new agents that can effectively improve AML	In vitro	(Hassane et al. 2008)
Smoking cessation	Geldanamycin (HSP90 inhibitor)	Predicted that geldanamycin may suppress smoking-induced transcriptome changes as an antiemetic of tobacco	In vitro	(Boyle et al. 2010)
Cancer	Terpineol (a bioactive component from essential oil extract)	Elucidated cytotoxicity and potential antitumor utility and mechanism of NF-kappaB inhibition for terpineol	In vivo	(Hassan et al. 2010)

(continued)

Table 1 (continued)

Disease	Drug identified	Key finding	Validation	Reference
Lung cancer	HDAC inhibitors, HSP90 inhibitors, PI3K inhibitors, and others	Predicted HDAC inhibitors such as 17-AAG among several other compounds as potential candidates for treating lung cancer	In vitro	(Wang et al. 2011)
Cancer metastasis	LY294002, 17-AAG, rapamycin	Identified potential epithelial–mesenchymal transformation inhibitors of rapamycin, 17-AAG, LY294002 that may be used in preventing metastasis	In vitro	(Reka et al. 2011)
Gaucher disease	Comparison of signature from microarray profiling of spleen and liver cells obtained from GD1 and wild-type mice	Use of Cmap to query signature to yield a hierarchical list of novel compounds that share common mechanisms with GBA1	In vivo rodents	(Zhao et al. 2012)
Colon cancer	Mebendazole (anthelmintic drug)	Repositioning of the anthelmintic drug mebendazole for the treatment for colon cancer	In vitro	(Nygren et al. 2013)
Alzheimer's disease	Comparison of different brain regions in AD and the corresponding gene signatures	Identified small molecules, such as histone deacetylase (HDAC) inhibitor, may be candidate drugs in the treatment of AD	In vivo rodents	(Chen et al. 2013)

growth and differentiation (Eckert and Rorke 1989). Synthetic retinoids are today used widely in the treatment of psoriasis and other disorders of keratinization (Saurat 1999; Pavez Lorié et al. 2009a). Acne has been widely treated with various forms of natural and synthetic retinoids for more than 40 years (Kligman et al. 1986; Titus and Hodge 2012). Retinoids have also been used in the treatment of hyperpigmentation disorders such as post-inflammatory hyperpigmentation and melasma (Griffiths et al. 1993). Separate from the effect of retinoids in skin disease, Kligman and Willis were the first to introduce retinoids for use as anti-photoaging agents (Kligman and Willis 1975). After its application, the authors noticed improvement of skin depigmentation and rejuvenation (Kligman et al. 1984, 1986). Today, retinoids are extensively used for this indication (Babamiri and Nassab 2010; Bellemère et al. 2009).

Further studies have shown that RA's clinical effects include improvement of wrinkles, surface roughness, mottled pigmentation, and skin appearance as a whole when used on photodamaged skin (Kang et al. 1997; Liu et al. 2009). At a cellular

level, retinoids are known to modulate the proliferation and differentiation of epidermal keratinocytes (Fuchs 2007; Fuchs and Green 1981; Asselineau et al. 1989) by binding to nuclear retinoic acid receptors (RAR) and 9-*cis*-retinoic acid receptors (RXRs) which results in upregulation or downregulation of the transcription of target genes (Ghyselinck et al. 2002).

RA is the biologically active form of vitamin A (retinol). Endogenous production of RA by epidermal keratinocytes involves the uptake of preformed vitamin A from the surroundings followed by a series of metabolic activation steps involving retinol dehydrogenases (RDH1, RDH4, RDH10, and DHRS9) and retinal dehydrogenases (RALDH1, RALDH2, and RALDH3) (Kurlandsky et al. 1996; Vahlquist 1999; Napoli 2012).

While endogenously produced or exogenously applied, RA is transported through the cytoplasm by specific intracellular retinoic-binding proteins (CRABP2) (Bellemère et al. 2009).

Once synthesized, the cellular levels of RA are controlled by several cytochrome P450-dependent enzymes (CYPs), CYP26A1, B1, and C1, which

metabolize RA into 4-hydroxy-RA, 4-oxo-RA, and 18-OH-RA (White et al. 1997; Taimi et al. 2004). CYP26B1 is known to be expressed higher than both CYP26A1 and CYP26C1 in human keratinocytes (Pavez Loriè et al. 2009b).

Over the last quarter century, 532 genes have been validated to be regulated by RA (Balmer 2002). In some cases this control is direct, driven by a liganded RAR:RXR heterodimer bound to a DNA response element; in others, it is indirect, reflecting the actions of intermediate transcription factors, nonclassical associations of receptors with other proteins, or even more distant mechanisms.

Cell cultures have been studied extensively to characterize and prophesy the effect of retinoids on epidermal differentiation and growth (Fuchs and Green 1981; Asselineau et al. 1989; Eckert and Green 1984; Gilfix and Eckert 1985; Varani et al. 1989; Asselineau and Darmon 1995).

In addition, a selection of genes using RT-PCR has been studied in full-thickness skin treated with retinoids.

Today, recent gene array techniques allow the characterization of the mRNA expression status of

a large number of genes in cells or tissues after retinoid treatments with more than 170 studies conducted.

Some studies using gene arrays to evaluate the effect of RA have also been carried out on reconstructed epidermis and human epidermis in vivo (Bernard et al. 2002). In 2013, the first gene arrays were conducted investigating the effect of RA in organocultures of human skin (Gillbro et al. 2014).

4 Retinoic Acid as a Lead Compound to Find New Active Antiaging Ingredients

Due to the well-known and studied activity of RA, this has been used as a lead compound to identify new active ingredients for antiaging purposes (Gillbro et al. 2014).

To investigate the effect of RA on 30,000 genes with corresponding Cmap analysis, an organoculture of human skin was firstly conducted (Fig. 1). Briefly, the skin from surgical waste material from breast reductions was

Fig. 1 Establishment of a skin organoculture. Briefly, the skin from surgical waste material from breast reductions was collected directly after surgery and immediately put in DMEM (a). All subcutaneous fat was removed with a scalpel to ensure full diffusion nitrification of the tissue. Eight millimeter punch biopsies were taken from the skin and referred to as full-thickness skin explants. Thereafter, the explants were put on Millipore Millicell culture plate inserts (12 mm Ø) (b)

collected and immediately put in DMEM at 8 °C (Gillbro et al. 2014). All subcutaneous fat was removed with a scalpel to ensure full diffusion nitrification of the tissue. Eight millimeter punch biopsies were taken from the skin and referred to as full-thickness skin explants. Thereafter, the explants were put on Millipore Millicell culture plate inserts (12 mm Ø) (Millipore Corporation, Stockholm, Sweden). Inserts containing skin explants were put in six-well plates (one insert/well) and supplemented with keratinocyte medium (M154) (Life Technologies, Stockholm, Sweden) to allow survival of the explants. Cream containing RA (tretinoin) (0,05 %) (Aberela®, Janssen-Cilag) at a concentration of 5 mg/cm² was applied topically on each explant, using positive displacement pipettes. Five milligram per square centimeter is a typical finite dose applied on skin penetration tests and considered as a nonocclusive dose (*OECD guidance notes on dermal absorption 2010*; *Scientific committee on consumer safety SCCS Basic criteria for the in vitro assessment of dermal absorption of cosmetic ingredients 2010*). The study was vehicle controlled with a cream containing all ingredients except for RA, referred to as placebo.

The explants were incubated with the RA cream for 24 h at 37 °C in 5 % CO₂ humidified air. At the end of the incubation period, two Ø 3 mm biopsies were taken from each explants for RNA extraction. Total RNAs were extracted from skin samples using QIAzol Lysis Reagent (Qiagen) according to the manufacturer's protocol. Two-hundred fifty nanograms of total RNA from each sample was used to prepare biotinylated fragmented cRNA according to the GeneChip® 3' IVT Express Kit Manual (Affymetrix Inc., Santa Clara, CA). Affymetrix GeneChip® expression arrays (Human Genome U133 Plus 2.0) were hybridized for 16 h in a 45 °C incubator, rotated at 60 rpm. The arrays were washed and stained using the Fluidics Station 450 and finally scanned using the GeneChip® Scanner 3000 7G (Affymetrix).

Subsequent analysis of the gene expression data was carried out in the freely available statistical computing language R (<http://www.r-project.org>) using packages available from the Bioconductor project (www.bioconductor.org). The raw data was normalized using the robust multi-array average (RMA) method (Irizarry et al. 2003; Li and Wong 2001). In order to search for the differentially expressed genes between the X sample and the Y sample groups, an empirical Bayes moderated *t*-test was then applied using the "limma" package (Smyth 2004). To address the problem with multiple testing, the *p*-values were adjusted using the method of Benjamini and Hochberg (Benjamini et al. 2001). The enrichment analysis was performed to determine the probability that gene ontology groups are specifically overexpressed in RA-treated skin as compared to vehicle-treated skin. For this analysis investigators are often using DAVID bioinformatics database (<http://david.abcc.ncifcrf.gov/>). The enrichment score of each gene is determined by calculating the relative expression in the RA-treated skin compared to placebo-treated skin (Gillbro et al. 2014).

To do subsequent enrichment analysis, researchers normally compare gene expression between control and experimental cells with fold changes $2 \geq$ and *p*-values ≤ 0.05 for selection (Huang et al. 2009).

5 The Identification of Genes and Biological Groups Affected by RA in an Organoculture of Human Skin

Microarrays simultaneously measure the levels of 22,000 mRNAs. We showed that 93 genes were significantly regulated by RA. Out of these 93 genes, 60 genes were upregulated and 33 downregulated (Gillbro et al. 2014). The clusters with the smallest *p*-value ($p < 0.05$) which were retrieved after 24 h stimulation with RA are presented in Fig. 2 and Table 2.

Fig. 2 Heat map of hierarchical clustering of 93 genes in RA-treated explants compared to placebo. Hierarchical clustering was performed using the Genesis software, with default settings (e.g., Euclidean distance, average linkage) of genes differentially expressed more than

twofold, i.e., 93 genes. *Green* indicates reduced expression, *black* indicates the unaltered expression, and *red* indicates increased expression in RA-treated as compared to placebo-treated explants ($n = 3$). The *color scale bar* is shown at the top of each figure

When summarized, the functional categories of the genes upregulated by RA were found to be more than 30 % within one of the following ontological

categories: clusters (lipid, hormone, and retinoid metabolism) and in development (organ, tissue, and epithelial development) (Gillbro et al. 2014).

Table 2 The corresponding genes to the clusters shown in Fig. 2, with gene name, gene symbol, gene ID, and fold change compared to placebo

6 The Identification of New Novel Cmap Compounds Mimicking the Gene Profile of RA Treatment in an Organoculture

As for the identification of new compounds stimulating hair growth using cyclosporine as lead compounds (Ishimatsu-Tsuji et al. 2010),

the gene signatures of the RA-treated skin were queried in the Cmap database to identify novel antiaging actives. Agents that were highly ranked in Cmap were identified as potential antiaging ingredients. Solely compounds of natural origin were selected for further analysis. One example of an identified agent through this approach was quercetin (unpublished

data). The use of quercetin as an antiaging compound has also been noted previously, but RA mimicking action has not been investigated (Chondrogianni et al. 2010; Casagrande et al. 2006).

7 Identification of New Novel Cmap Compounds Mimicking the Gene Profile of Topical RA Treatment in a Clinical Study on Nine Female Subjects

In addition, the gene profile of RA treatment was investigated in an in vivo study conducted on nine healthy Caucasian female volunteers aged 56.78 ± 6.87 (Mean \pm SEM) exhibiting moderate to severe photodamage on their lower outer forearms. Tretinoin (Retin-A[®], 0.025 %) and placebo were applied once daily on randomly assigned left or right forearm test sites for 7 days (Gillbro et al. 2015a).

Topical stimulation of nine females for 7 days with RA resulted in less significant gene alteration compared to the explant study on three subjects.

Eighteen genes were upregulated and one downregulated according the selection criteria. As for the study on topical application of RA in an organoculture (Gillbro et al. 2014), the in vivo study showed genes overrepresented in development process (Fig. 3 and Table 3).

Within the cluster of development process, KRT4 was highly upregulated.

Interestingly, genes involved in retinoid metabolism such as CYP26 were not induced in the clinical study as for the study in organocultures (Gillbro et al. 2015a). This could be due to greater variance between the subjects in the clinical in vivo study compared to the study in organocultures. Another explanation could be that mRNA levels of CYP26 are induced after acute short-term treatment and not after long-term treatment.

The gene signature of this in vivo study was then queried in the Cmap database.

8 Cmap Analysis Connects the Gene Signature of RA-Treated Skin to Acetyl Aspartic Acid (A-A-A)

The genes that were significantly upregulated (18 genes) or downregulated (1 gene) more than twofold were entered into the Cmap. Forty-eight compounds (data not shown) were highly ranked as comparable to the RA gene signature. Importantly, tretinoin (RA) was ranked highest (1) in the Cmap list with highest specificity (p -value 0,00002) which was an important proof that the gene expression profile for RA in the tested cell lines was similar for RA-treated skin in this study. Interestingly, also compounds with antibiotic character were listed among the identified compounds. This is in line with recent discoveries on inhibition of retinoid catabolism/metabolism by antibiotic drugs (Regen et al. 2015).

In total, six natural compounds were identified out of in total 48 RA mimicking agents.

Once we had identified the RA gene signature in photodamaged human skin, we conducted corresponding Cmap analysis which revealed six natural compounds showing similar activity on the gene level compared to the applied RA. These were tomatidine, cyanocobalamin (vitamin B12), docosahexaenoic acid ethyl ester, riboflavin (vitamin B2), *N*-acetylmuramic acid (peptidoglycan), and *N*-acetyl-L-aspartic acid (A-A-A).

Further restrictions on low molecular weight (<500 g/mol), chemical properties, and potential sourcing resulted in selection of *N*-acetyl aspartic acid (A-A-A) with the enrichment score 0,673 (p -value 0,02) (Table 4).

A-A-A is a derivative of aspartic acid. The actual chemical name is (2S)-2-acetamidobutanedioic acid; cas number is "997-55-7," with a formula of C₆H₉NO₅ and a molecular weight of 175 g/mol, and a log P of -1.1. In the Cmap, the dose which other scientists worldwide have used to get the expression profile was also revealed (i.e., 23 μ M). Therefore we continued using a range of 2,3–230 μ M for further activity testing in vitro.

Fig. 3 Heat map of hierarchical clustering of 19 genes in nine RA-treated volunteers compared to placebo. Cluster analyses of genes encoding genes involved in development genes (*blue arrows*). These subsets of genes were clustered hierarchically on the basis of the similarity of their expression profiles (cluster 1: enrichment score 2.0). *P* placebo, *RA* retinoic acid treatment. Table 2 shows the corresponding genes to the clusters shown in Fig. 3

Table 3 The corresponding genes to the clusters shown in Fig. 3, with gene name, gene symbol, gene ID, and fold change compared to placebo

Table 4 The connectivity scores for RA and A-A-A identified through Cmap, through the transcriptional activity to RA in a clinical study of nine healthy Caucasian female volunteers

Cmap name	Connectivity score (enrichment)	<i>P</i> -value
Tretinoin (RA)	0,512	0.00002
A-A-A	0,673	0.02

The next step was to investigate whether A-A-A could be used as a cosmetic ingredient. In vitro studies showed relief of the fibroblast stiffness marker (F-actin) together with increased keratinocyte regeneration and inhibition of matrix metalloproteinases (MMPs) (Gillbro et al. 2015b).

Safety studies were conducted (see section below on “Safety Testing of A-A-A”) as well as testing the skincare benefits in terms of skin firmness. Skin firmness was used as a testing parameter since RA is known to increase skin firmness (Ho et al. 2012), and RA was used as the lead compound in the Cmap studies described herein.

9 Safety Testing of A-A-A

The first stage in the safety assessment of A-A-A was a complete literature review of its toxicological profile. There was sufficient data in the literature to give a complete picture of its hazard potential with the exception of skin irritation and skin sensitization.

An in vitro skin irritation study on human reconstructed epidermis (RHE’s-SkinEthic model) according to OECD Guideline 439 was

therefore conducted in the first instance. After application of the test substance (pure) on RHE’s for 42 min and a 42 h posttreatment incubation, cellular viability was measured by the transformation of MTT into blue formazan crystal. Under the conditions of the assay, the test substance tested pure was classified as nonirritant.

The lack of sensitization potential of A-A-A was confirmed in a Human Repeat Insult Patch (HRIPT) study after review of structurally similar materials. The study was a single-center, evaluator-blinded, within-subject randomized patch application study. The objective was to confirm, in a panel of healthy adult subjects, that the application of A-A-A tested neat, under maximizing conditions of exposure, did not induce delayed contact sensitization (Daly and Moran 2015).

Healthy men or nonpregnant women ages 18–68 of Caucasian origin with skin phototypes I–III were screened to enroll a sufficient number to achieve a minimum completion rate of 100, a sample size standard for these studies (Jordan and King 1977).

The methodology used was an adaptation of that described by Marzulli and Maibach (1976). The volunteers were treated with neat A-A-A under occlusive patch nine times to the same site (induction site) over a period of 3 consecutive weeks followed by a challenge phase after a minimal 2-week rest period, under patch, to the induction site and to a virgin site for 48 h.

In conclusion, under the experimental conditions adopted, the repeated application of A-A-A, tested neat, under occlusive patch on a panel of 107 test subjects with all types of skin on the body, induced no allergic reaction. The studies were conducted in accordance with the Declaration of

Helsinki and good clinical practice (GCP) guidelines.

10 Clinical Testing of the Antiaging Effect of A-A-A

As a first effort to investigate the antiaging effect of A-A-A, a clinical study on 16 Caucasian healthy female volunteers age range 55–75 years (mean age 64) with visible signs of moderate photodamage on the skin of the lateral forearms was conducted (Gillbro et al. 2015c).

The study was designed as a placebo-controlled, assessor-blinded, within-subject comparison of 12-day treatment phase of three test sites under occlusion (Finn Chambers 12 mm in diameter). One site was a blank chamber that was used as negative control.

Two extracellular matrix (ECM) proteins, collagen IV (COLIV) and fibrillin-1 were investigated using histological analysis of the 3 mm Ø punch biopsies taken from the sites. One of the ECM proteins, COLIV, expressed in the epidermal–dermal junction (DEJ) is important for dermal support to protect against wrinkle formation (Uitto 1986; Mays et al. 1995; Boisnic et al. 1999). Fibrillin-1 is a glycoprotein and shown to be important for the formation of elastic fibers (Sakai et al. 1986).

After 12-day topical application with A-A-A, both ECM proteins, COLIV and fibrillin-1, were statistically significantly increased compared to placebo and untreated skin, visualized by immunohistochemical stainings using diaminobenzidine (DAB) in brown (Fig. 4a). A-A-A treatment increased COLIV protein expression with 13,2 % versus placebo and 17,6 % versus untreated skin. Fibrillin expression increased with 6,4 % compared to placebo-treated skin (Fig. 4b).

COLIV was primarily expressed in the DEJ which separates the epidermis from dermis. Fibrillin-1 showed strong staining in DEJ as well as throughout the dermis. The DEJ was defined as region of interest (ROI) in the analysis of COLIV, and for fibrillin-1, DEJ plus 200 µm in dermis was defined as ROI.

Since the lead compound RA is known to improve skin firmness (Ho et al. 2012; Tucker-

Samaras et al. 2009), we investigated the effect of the identified Cmap compound, A-A-A, on skin firmness using a Cutometer MPA580 (Courage + Khazaka Electronic GmbH, Cologne, Germany) on the inner forearm of 12 healthy female volunteers aged 50–65 years. In this double-blind vehicle-controlled study, three products were tested. All products were based on the same simple formulation only further characterized by the addition of A-A-A (1 %) in Product A and of retinol (0.1 %) in Product B. Product C was the vehicle (no active compound). Retinol was chosen as the cosmetically used precursor of RA, i.e., retinol (Tucker-Samaras et al. 2009).

In preparation of the study, volunteers followed a strict washout phase for 7 days during which no topical products could be used on the forearms. That restriction was observed for the whole length of the study.

On the first day of the study, four standard sites were identified and marked on the forearms of each volunteer (two on each forearm), leaving one site as untreated control. The assignment of each test products to a particular test site was randomized via a standard procedure prior to the start of the study. A baseline measurement of skin firmness was performed on all sites after a 30 min acclimatization in controlled conditions (T° : 21 ± 1 °C; RH 50 ± 5 %). Subsequently to the baseline, measurement products were applied at an approximate dose of 2 mg/cm², twice daily for 28 days. Final Cutometer measurements were performed on all test sites at the end of the study.

The Cutometer enables the investigation of the viscoelastic properties of the skin via the principle of repeated cycles of suction and release of the skin through the aperture of the probe (2 mm). It is an established standard technique for the measurement of skin firmness and elasticity (Barel and Courage 1995). The F4 area parameter represents skin firmness, i.e., the resistance of the skin to suction over the set of repeated cycles (20 in total). A decrease in F4 corresponds to an increase in skin firmness.

Changes in F4 after 28 days of product application in the treated areas were compared to the changes in the untreated control (shown in Fig. 5).

Fig. 4 a Application of A-A-A resulted in increased expression of COLIV, the basement membrane of the dermo-epidermal junction of photoaged skin (c) compared to vehicle (b) and untreated skin (a). Arrows indicate the location of the presence of this staining. Fibrillin-1 expression was also increased after 12-day treatment with A-A-A (c) compared to vehicle (b) and untreated skin (a).

(b) Quantification of immunostaining in (a) represented in graph. A-A-A treatment increased COLIV protein expression by 13.2 % vs vehicle and 17.6 % vs untreated skin. Fibrillin-1 expression increased by 6.4 % compared to vehicle-treated skin. Statistical analysis using paired *t*-test; **p* = 0.02, ***p* = 0.004, mean ± SEM

Both retinol- and A-A-A-containing products were found to enhance significantly skin firmness after 28 days of treatment, whereas the vehicle did not. Further comparison of the active products with the vehicle showed that A-A-A significantly increased skin firmness compared to placebo after 28 days of treatment. This effect was comparable to retinol (Gillbro et al. 2015c).

11 General Conclusion

The studies presented in this chapter show the Cmap approach is highly functional to identify novel antiaging ingredients. This chapter described studies using Cmap to identify new compounds of medical and cosmetic interest. To our knowledge,

Fig. 5 Increase of skin firmness (associated with a decrease of F4) corrected to baseline after the use of the test products. Statistical analysis using paired *t*-test, ****p* < 0.0001; **p* = 0.0104. Mean ± SEM

Oriflame Cosmetics is the first company using the Cmap approach to identify new ingredients for antiaging purpose. Organocultures of human skin and a preclinical clinical study on photoaged skin of human forearm were used to identify new compounds with antiaging benefits. A-A-A was identified and based on our criteria continued in in vitro screening where it was shown to have activity on both keratinocytes and fibroblasts. In vitro irritation study confirmed A-A-A to be nonirritant and HRIPT testing confirmed lack of sensitization potential. Furthermore, A-A-A was clinically tested in a vehicle-controlled study and shown to significantly increase protein expression of two ECM proteins, COLIV and fibrillin-1, which was translated in improved skin firmness in a similar manner to retinol using Cutometer assessment on human forearm.

In conclusion, Affymetrix® gene arrays with corresponding connectivity mapping have been proven to be a useful method to identify new lead compounds with antiaging activities.

1 Introduction

Active and passive cellular biomechanics based on the stability provided by the cytoskeleton impact many essential cellular functions such as motility, division, and mechanosensitivity (Bereiter-Hahn et al. 1994; Fletcher and Mullins 2010). Previous studies have shown that biomechanical properties are connected to cell functions that are regulated by mechanical forces (Ingber 1997; Janmey and Weitz 2004). Individual cells are able to sense mechanical signals and transduce them into a biochemical response. There is a link between the fibroblasts' collagen production and mechanical forces acting on the cells when comparing the cells' synthesis activity in stressed versus relaxed collagen gels (Kessler et al. 2001; Fluck et al. 2003). Moreover, it has been shown that a functionally intact cytoskeleton is crucial to build up contraction forces in a three-dimensional collagen lattice (Kolodney and Wysolmerski 1992; Brown et al. 1996). All these cell functions are essentially needed for the homeostasis of the skin.

Considering the importance of cellular biomechanics for correct physiologic functioning, the mechanical behavior of isolated skin cells is accessible by new sophisticated biotechnological tools.

2 Biomechanical Characterization of Cells

Different types of measurement techniques have been developed to quantify the mechanical properties of biological cells and to investigate the relation between structural response and cytoskeletal composition. The majority of these studies imply a correlation of cellular stiffness to cell status.

In general, a defined force or stress is applied to the cells and the resulting deformation is analyzed. Most techniques deform local regions of the cell, while only a few methods are capable of assessing the cells' whole structural response (global deformation techniques). One of the most common methods is the micropipette aspiration (Hochmuth 2000) that works by applying locally a negative pressure to adherent cells while measuring the linear extension into the pipette. Using this method, it was shown that malignantly transformed fibroblasts are significantly softer than their normal counterparts (Ward

et al. 1991). In addition micropipette aspiration was used to determine the elastic properties of polymer gels (Boudou et al. 2009) and cell adhesion forces (Sung et al. 1996). A more recently developed technique is scanning-force microscopy (SFM) that allows the measurement of biomechanical properties of cells, tissues, and even molecules (Rotsch and Radmacher 2000). Besides imaging biological samples at nanometer resolution, an SFM is capable of probing cellular elasticity by using a hard indenter to measure the relation between applied force and local deformation of adherent cells. Thereby, defined forces are exerted to the cell membrane by a fine tip that is attached to a flexible cantilever. When in contact with the sample, the cantilever deflection is detected by a laser beam reflected from the back of the cantilever to a photodiode detector (Fig. 1a). Figure 1b shows a typical force-distance curve measured by a SFM. The cantilever tip is pushed into the cell (approach) and then retracted again, while recording the height and deflection. Based on a theoretical model developed by Heinrich Hertz, which analytically describes the elastic deformation of two homogeneous spheres pressed against each other (Hertz 1881), the cell's local Young's modulus can be calculated if the force constant of the cantilever is known. The SFM technique has been improved by attaching micron-sized beads to the cantilever tip that prevent penetration of the plasma membrane and

Fig. 1 Elasticity measurement by scanning-force microscopy. (a) The SFM basically consists of a flexible cantilever that is deflected by the sample. The reflected IR laser beam changes its position, which is detected by the photodiode. (b) The force exerted by the cantilever can be

calculated from the deflection signal. Fitting the measured data of applied force and sample indentation with an appropriate analytical model allows for extracting cell elasticity

assures a well-defined geometrical shape (Mahaffy et al. 2000). Since the Hertz model assumes linear elastic materials and does not consider the cells' cytoplasmic viscosity, it was extended by Mahaffy et al. to obtain information about the frequency-dependent viscoelastic response.

Using the so-called force mapping mode, the SFM can provide two-dimensional elasticity maps of a sample by scanning the cantilever over the cell and measuring a force-distance curve for each point of the map. A disadvantage of this method is the high measurement duration.

In case of magnetic bead microrheology, the viscoelastic properties of adherent cells are measured by exerting forces via micron-sized magnetic beads that are coated and bound specifically to integrin receptors at the cell membrane (Fabry et al. 2001). The microbeads are twisted by an external homogeneous magnetic field that is varying sinusoidally in time. Analysis of the bead displacement allows to calculate viscoelastic material properties. Optical tweezers can also be used for cell deformation experiments when beads with appropriate optical properties are bound to the membrane and serve as handles for the force application (Sleep et al. 1999). Besides an active deformation of the sample, there are also passive methods where the cytoskeleton is interspersed by fluorescent beads. Here, the Brownian motion, which is influenced by the mechanical properties of the polymer network, is measured. A disadvantage that all bead experiments have in common is the fact that it cannot be known if and how the beads are attached to the sample. In case of active deformation techniques, differences in contact area would cause a varying mechanical stress. In addition, coating of the beads with antibodies makes these methods tedious and cost intensive. Another critical point, which also applies for the micropipette aspiration technique, is that the displacement of microspheres can provide inaccurate measurement data if the plasma membrane detaches from the cytoskeleton during deformation.

While the already mentioned methods probe cell elasticity predominantly over a relative small area of the surface (local deformation), the

mechanical response of whole cells can be assessed by microplate manipulation, where the rheological properties of cell monolayers are measured by shear experiments (Fernandez et al. 2007). Nevertheless, these measurements can only provide an average value rather than the true single cell behavior and suffer from artifacts due to the influence of cell-cell and cell-substrate adhesion.

The optical stretcher is a recently developed technique that permits measuring large numbers of individual cells without any mechanical contact (noninvasively). Deformation experiments by direct contact can cause problems due to an unsymmetric stress distribution or not predictable active cell reactions. The microfluidic optical stretcher is an optical trap that allows trapping and controlled deformation of single suspended cells by using two counter-propagating laser beams (Guck et al. 2000). Cellular extension is caused by a momentum transfer acting on the cell surface. The applied global stress permits the measurement of whole cell elasticity that characterizes the integral effects of molecular changes on the cytoskeleton. A disadvantage of this technique is that probing rheological properties of cells in suspension may be considered as unphysiological, because of the lack of cellular contact to the extracellular matrix. Nevertheless, the symmetric shell-like structural design, the broad and continuous distribution of stress over the cell surface, and the avoidance of artifacts due to mechanical contact are the reasons for the low variability within the measured properties of the cell populations and the reproducibility of this method. The use of optical deformability as a sensitive cell marker has already been demonstrated for the characterization of individual dermal fibroblasts at different donor ages (Schulze et al. 2010).

3 Optical Cell Stretcher

Optical traps have been used to exert forces and manipulate dielectric particles for quite a long time (Ashkin 1970). Soon, the great potential to use optical techniques like optical tweezers to

noninvasively analyze biological samples was realized (Ashkin et al. 1987). The forces that can be exerted on biological matter by light are in the range between pico- and nanonewtons, which might appear small compared to other micromanipulation tools like SFM. However, these forces are perfectly suited to noninvasively hold and manipulate individual biological cells without causing damage and contamination. The optical stretcher is a recently developed two-laser beam trap that uses two counter-propagating divergent beams integrated into a microfluidic system to probe the viscoelastic behavior of suspended cells. Since the laser beams are not focused, there is no problem with radiation damage, which minimizes the light flux through the cells in comparison to other optical traps.

In this paragraph, first the basic working principle of stretching dielectric particles with light is introduced, followed by the experimental setup of the optical stretcher and a description of data analysis.

3.1 Basic Principle

When light hits the surface of an object with higher optical density, forces are generated that act normal to the surface and point away from the optical denser medium. This physical effect can be used to exert forces on single biological cells in suspension to analyze their deformation behavior. The optical stretcher basically consists of two laser beams with Gaussian intensity distribution that form a symmetric trap geometry. The cells are typically deformed by a constant stress profile causing a characteristic, passive, viscoelastic response. The surface forces can be attributed to a transfer of momentum at the interface between the cell (high refractive index) and surrounding medium (low refractive index) according to Newton's second law. The theoretical description of the interaction between laser radiation and small dielectric particles strongly depends on the ratio of particle size and the used wavelength λ . In case of optical traps, the wavelength is usually in the range of 600–1200 nm, whereas the cell diameter

d is an order of magnitude larger $d > 20 \mu\text{m}$. For that reason the surface forces can be quantitatively explained using the Mie regime, which is also called ray-optics regime. The approach in this regime is to decompose the laser beam into individual rays that propagate in a straight line and are described by geometric optics. The theoretical explanation in case of $d \approx \lambda$ is highly nontrivial and requires the exact solution of the Maxwell equations, whereas problems in the limit $d \ll \lambda$ are specified by the Rayleigh regime.

At first, one might expect that a soft dielectric particle hit by two counter-propagating laser beams is rather compressed than stretched. In the Mie regime, the ability of light to exert forces on dielectric samples can be explained by simple momentum transfer. To illustrate the basic principle of cell stretching, the following section outlines changes of momentum when a light ray passes at normal incidence through an optically denser object. For each ray or photon with the energy $E = h \cdot \nu$ the relativistic energy-momentum relation predicts the momentum p as (Ashkin and Dziedzic 1973)

$$p = n \cdot \frac{E}{c_0} \quad (1)$$

where n is the refractive index of the medium, c_0 is the speed of light in vacuum, h is the Planck constant, and ν is the frequency. Since the momentum is directly proportional to the refractive index, the light gains momentum as it enters the object. According to the law of conservation of momentum, the same amount of momentum change is transferred to the surface in the opposite direction. As the light exits the optical denser medium, it loses momentum which causes a transfer of momentum to the surface at the back in the direction of light propagation. Further, at both interfaces, a fraction of light is reflected, which leads to additional transfer of momenta in the direction of light propagation. In case of biological cells interacting with an infrared laser, the fraction of reflected light is less than 0.5 %. Therefore, the contribution of reflected light to the surface forces is considerably smaller. The resulting forces acting on the front and back

Fig. 2 Schematic of a light ray incident on a spherical object with refractive index n_{cell} , which is refracted and reflected at the intersurfaces according to Snell's law

surface are directed in opposite directions and will cause a stretching of soft objects.

In this example the asymmetry between both surface forces would cause a net force acting on the center of mass and pushing the cell away from the laser source (so-called scattering force). A second light ray passing through the object from the opposite site would compensate this net force, so that only surface forces are left, which are additive.

If a light ray with momentum $p_i = n_{\text{medium}} \cdot E/c_0$ hits the surface of a spherical object like a cell under arbitrary angle of incidence, it has to be considered that not only the absolute value of momentum but also its direction changes (Fig. 2). This is described by Snell's law:

$$n_{\text{medium}} \cdot \sin \alpha = n_{\text{cell}} \cdot \sin \beta \quad (2)$$

where n_{medium} and n_{cell} are the refractive indices and α and β the angles of incidence and refraction. The angle of reflection is identical to the angle of incidence.

The momenta of the reflected light ray p_r and the refracted (transmitted) light ray p_t are given by

$$p_r = \frac{n_{\text{medium}} \cdot E}{c} \cdot R(\alpha) \quad (3)$$

$$p_t = \frac{n_{\text{cell}} \cdot E}{c} \cdot (1 - R(\alpha)) \quad (4)$$

where $R(\alpha)$ is the reflection coefficient, which represents the ratio of reflected and incident intensity and can be calculated by Fresnel's equations.

The magnitudes of momentum at the backside of the cell are accordingly given by

$$p_{i2} = p_t \quad (5)$$

$$p_{r2} = p_t \cdot (1 - R(\beta)) \quad (6)$$

$$p_{r2} = p_t \cdot R(\beta) \quad (7)$$

Taking the vector nature of momentum into account, the resulting momenta transferred to the surfaces calculate as

Fig. 3 (a) Rotational symmetric stress profile acting on a cell trapped in a two-laser beam geometry with Gaussian intensity distributions. (b) When the cell is out of the center of the trap, restoring gradient and scattering forces will move it back

$$\Delta \vec{p}_1 = \vec{p}_i - \vec{p}_r - \vec{p}_t \quad (8)$$

$$\Delta \vec{p}_2 = \vec{p}_{i2} - \vec{p}_{r2} - \vec{p}_{t2} \quad (9)$$

A dual beam laser trap, such as the optical stretcher, consists of two counter-propagating, divergent Gaussian laser beams that function as stable optical trap where cells can be held between the two beams and stretched along the laser beam axis at increasing power. Based on this simple ray-optics model, the total stress profile $\sigma(\alpha)$ acting on the surface of the object can be calculated by considering the total transferred momentum of the incident beam (Guck et al. 2000) (Fig. 3):

$$\begin{aligned} \sigma(\alpha) &= \frac{F(\alpha)}{A} = \frac{\Delta p(\alpha)}{\Delta t \cdot A} = \frac{\Delta p(\alpha)}{E} \frac{E}{\Delta t \cdot A} \\ &= \frac{\Delta p(\alpha)}{E} \cdot I(z, r, \alpha) \end{aligned} \quad (10)$$

where $\Delta p(\alpha)$ is the total momentum transferred on a single surface element, $I(z, r, \alpha)$ is the local light intensity that can be calculated at distance z from the source fiber as follows, and r is the radius of the particle:

$$I(z, r, \alpha) = \frac{2P}{\pi \omega(z)^2} \exp\left(-\frac{2(r \sin \alpha)^2}{\omega(z)^2}\right). \quad (11)$$

Here, P is the total power of the laser beam and $\omega(z)$ is the beam width. The latter describes the circumstance that the beam diverges as it exits the optical fiber with increasing distance and can be calculated by

$$w(z) = w_0 \sqrt{1 + \left(\frac{\lambda z}{n_{\text{medium}} \pi w_0^2}\right)^2} \quad (12)$$

with the beam waist at the exit of the optical fiber ω_0 . The peak stress σ_0 acting along the laser beam axis can be calculated by insertion of $\alpha = 0$:

$$\sigma_0 = \frac{n_{\text{medium}} I}{c} (R^2 - R - 2) \left(\frac{n_{\text{cell}}}{n_{\text{medium}}} - 1\right) \quad (13)$$

The shape of the stress profile and the magnitude of peak stress depend on the ratio between beam width ω and sphere radius r , as well as the ratio of refractive indices $n_{\text{cell}}/n_{\text{medium}}$. Figure 3 shows the total stress profiles for a cell that is stable trapped between the two divergent beams and a cell that is displaced from the beam axis. All forces act normal to the surface. In the first case, the profile has rotational symmetry with respect to the beam axis and the total force on the center of mass is zero. When the cell gets displaced, the symmetry is broken and it experiences a restoring net force perpendicular to the axis (so-called gradient

force). The gradient force pulls the cell in direction of the highest light intensity at the center of the beam.

3.2 Experimental Setup and Data Analysis

In typical optical stretcher experiments, suspended cells are trapped by the opposing laser beams at low power (i.e., 0.1 W per fiber) and stretched by increasing the laser power to 1.0–1.4 W per fiber. The setup basically consists of the fiber laser, a microfluidic

delivery system, an inverted microscope, and a charge-coupled device (CCD) camera to monitor the deformation over time. As infrared laser light source, an ytterbium-doped single-mode fiber laser can be used emitting at a wavelength of $\lambda = 1064$ nm. At this wavelength, light is barely absorbed by proteins. The two fibers of the laser are integrated into a microfluidic system that guides the cells serially into the trap through a microfluidic flow channel (Fig. 4). The microfluidic chamber is positioned on the stage of a phase contrast microscope where a digital CCD camera is connected via C-mount adapter recording the stretching experiments.

Fig. 4 Microfluidic chamber. Using photo-lithographic structures (SU-8), the optical fibers are aligned perpendicular to a glass capillary that has an inner diameter of 80 μm.

Suspended cells are trapped at low laser power and can be deformed along the laser beam axis by increasing the power

The setup can be automated using a computer-controlled microfluidic pump and image-processing software that allows for live detection of cells in the trapping region of the flow chamber. Automated optical stretcher setups enable trapping and stretching of about 150–300 cells per hour.

In order to quantify cellular deformation, it is necessary to detect the cell boundaries by image processing. When the time development of the cell boundaries is given in an analytical form, the relative deformation along the laser beam axis $\Delta x/x$ can be derived (Fig. 5). During a “step stress” experiment, the cell is stretched for 2 s at constant laser power, followed by a relaxation phase, when the laser is switched back to trapping power. The temporal development of strain can be further analyzed to extract

physical material properties. The mechanical behavior of biological cells under stress can be quantified using a simple model that illustrates the viscoelastic response of the cell to external forces, as they arise in the optical stretcher. The stress-strain behavior can be explained by a mechanical analogon that combines elastic and viscous components and describes the deformation of the cell under stress to a sufficient approximation (Wottawah et al. 2005a, b). This model implies that the deformation and relaxation is passive and due to a transiently cross-linked isotropic actin cortex, which is only given for a relative small strain (linear viscoelastic regime) and short times of applied stress. Any active cell behavior like actomyosin interactions as well as the glassy material properties and metastability of

Fig. 5 Viscoelastic deformation of a fibroblast (black). The cell is trapped at a laser power (red) of 0.1 W per fiber and then stretched for 2 s at 1.2 W per fiber. When the

laser is switched back to trapping power, the cell’s relaxation behavior can be observed

the polymer network (Kollmannsberger and Fabry 2009; Semmrich et al. 2007) is not considered in this simple model. Based on the three-element model described by Wottawah et al., the relation between applied stress and resulting strain can be described by the constitutive equation:

$$\sigma + \frac{\eta_0 + \eta_1}{E_0} \dot{\sigma} = \eta_1 \dot{\gamma} + \frac{\eta_0 \eta_1}{E_0} \ddot{\gamma} \quad (14)$$

where η_0 , η_1 and E_0 are the viscosities and Young’s modulus of the mechanical elements (Fig. 6a). Solving this differential equation for a constant stress σ between $t_0 = 1$ s and $t_1 = 3$ s gives the temporal development of extension and relaxation:

$$\gamma(t) = \frac{\sigma}{E_0} \left(1 - e^{-\frac{E_0}{\eta_0}(t-t_0)} \right) + \frac{\sigma}{\eta_1} (t - t_0) \quad (15)$$

for $1 \leq t \leq 3$

$$\gamma(t) = \frac{\sigma}{E_0} \left(1 - e^{-\frac{E_0}{\eta_0}(t_1-t_0)} \right) e^{-\frac{E_0}{\eta_0}(t-t_1)} + \frac{\sigma}{\eta_1} (t_1 - t_0)$$

for $3 \leq t$

(16)

Fitting these equations to the strain data (Fig. 6b) allows for the calculation of several physically relevant values. When the analytical expression of the compliance $D(t) = \gamma(t)/\sigma$ is known, the time-dependent Young’s modulus $E(t)$ can be derived (Wotottawah et al. 2005b) using the substitutions:

$$b_1 = \frac{(\eta_0 + \eta_1)}{E_0}, \quad a_1 = \eta_1, \quad \text{and} \quad a_2 = \frac{\eta_0 \cdot \eta_1}{E_0}. \quad (17)$$

Young’s modulus can be calculated by

$$E(t) = \frac{a_1 b_1 - a_2}{b_1^2} e^{-\frac{t}{b_1}} + \frac{a_2}{b_1} \delta(t). \quad (18)$$

Fig. 6 (a) Scheme of the three-element model used to fit optical stretcher data. (b) Fitting of the strain function to the measured cell extension. The parameters can be used to

calculate the cells’ viscoelastic properties such as the time-dependent relaxation modulus $E(t)$ (c) and the frequency-dependent Young’s modulus $E^*(\omega) = E'(\omega) + i E''(\omega)$ (d)

Fourier integration gives the frequency-dependent complex Young's modulus describing the behavior in case of an oscillatory deformation:

$$E^*(\omega) = E'(\omega) + iE''(\omega) \quad \text{with} \quad (19)$$

$$E'(\omega) = \omega \int_0^{\infty} E(t) \sin(\omega t) dt$$

$$= \frac{\omega^2(a_1 b_1 - a_2)}{1 + \omega^2 b_1^2} \quad \text{and} \quad (20)$$

$$E''(\omega) = \omega \int_0^{\infty} E(t) \cos(\omega t) dt$$

$$= \frac{\omega a_1 + \omega^3 a_2 b_1}{1 + \omega^2 b_1^2} \quad (21)$$

E' , which is also called storage modulus, is a measure for the part of energy stored during a periodic strain and corresponds to the elastic part of the stress response. E'' describes the part associated with the viscous dissipation of energy and is called loss modulus. Typical results obtained for the dynamic material properties are shown in Fig. 6c, 6d. Equations 19 and 20 allow for the calculation of characteristic rheological parameters like the plateau Young's modulus at high frequencies:

$$E_p = \lim_{\omega \rightarrow \infty} E'(\omega) = \frac{a_1 b_1 - a_2}{b_1^2} \quad (22)$$

and the steady-state viscosity:

$$E_{sts} = \lim_{\omega \rightarrow 0} \frac{E''(\omega)}{\omega} = a_1 \quad (23)$$

1 Introduction

Our skin is surrounded by reactive oxygen species (ROS) and other free radicals. This is due to environmental hazards such as UV irradiation (Thiele et al. 2001), ozone gas, air pollutants, xenobiotics, or microorganisms (Sander et al. 2004; Vermeij et al. 2011) but also endogenous radical formation, e.g., by the mitochondrial respiratory chain (Berger 2005), antimicrobial mechanisms of leucocytes, and inflammatory responses (Sander et al. 2004; Berger 2005). Reactive oxygen species occur during important physiological processes, e.g., immune defense and cell signalling (Vermeij et al. 2011; Vermeij and Backendorf 2010). If an unbalance of oxidants and antioxidants appears in the skin, oxidative stress is the consequence, and the excess production of ROS can cause severe cell damage associated with skin carcinogenesis and accelerated skin aging (Sander et al. 2004; Richelle et al. 2006; Packer and Valacchi 2002). Therefore, antioxidants are of high importance for the maintenance of skin health. The skin provides a variety of enzymatic and nonenzymatic antioxidants (Thiele et al. 2001; Richelle et al. 2006).

juergen.lademann@charite.de

Superoxide dismutase, catalase, and glutathione peroxidase are examples for enzymatic antioxidants. Important nonenzymatic antioxidants in the human body and the skin are carotenoids (beta-carotene, lycopene, lutein); coenzyme Q10; glutathione; and the vitamins A, C, E, and D (Thiele et al. 2001; Shindo et al. 1994). These antioxidants form protective chains, i.e., they protect each other against the destructive effects of free radicals (Valko et al. 2007; Wrona et al. 2003). Most of these antioxidants cannot be produced in the human body but have to be taken in with food, especially with a diet rich in fruit and vegetables.

Darvin et al. showed that women of comparable age (around 50 years) with a high concentration of lycopene in the skin have less wrinkles and furrows compared to women with low values (Darvin et al. 2008). For the prevention of skin aging and cancer development, a diet rich in antioxidants is important. So far the antioxidant status can be measured in blood samples (Tong et al. 2013). These invasive investigations only give information about the short-term antioxidant status, because blood clearance is fast for most antioxidants. In the skin, antioxidants such as carotenoids can be stored over a longer time period (Meinke et al. 2010). For routine investigations, noninvasive methods that measure the antioxidant status of the skin are more suitable. One noninvasive method is resonance Raman spectroscopy, which measures cutaneous carotenoids. Carotenoids can be used as a marker substance of the exogenous skin antioxidants (Haag et al. 2011), if the nutrition is well-balanced and no acute changes in nutrition or life style (e.g., sudden stress) appeared. Should the endogenous antioxidants be of interest, electron paramagnetic resonance (EPR) spectroscopy can be applied to measure the antioxidant status of the skin, effects of nutrition, or topically applied antioxidants and the effect of stress can also be studied.

The EPR spectroscopy is a method, which can detect paramagnetic species such as free radicals in the skin. Therefore, it can be used to investigate the radical scavenging activity of the skin. This can be performed in two ways:

1. Direct reaction of antioxidants with a topically applied test radical
2. Radical formation induced by irradiation or other forms of stress

In the first method, a test radical is applied, whereby the cutaneous antioxidants react with the test radical and the EPR signal decreases over time. Regarding the second method, another test radical, which does not react directly with the cutaneous antioxidants, is applied and a stress is induced to form short-lived radicals. These short-lived radicals cannot be measured directly. They react with the applied test radical and decrease its initial signal. Existing cutaneous antioxidants can also neutralize induced short-lived radicals and act as a competitive mechanism.

The two methods can provide information about:

- Antioxidant potential of the skin
- Sun protection properties
- Lifestyle (nutrition, sleeplessness, smoking, etc.)
- Topically applied antioxidants

These properties can be measured in vivo without an intervention but also to determine the effect of supplements, creams, or possible stress effects such as irradiation in the UV, visible, or near-infrared spectral range.

In this chapter, the application of EPR spectroscopy will be shown to investigate the effect of supplements containing a fruit and vegetable extract. Moreover, topically applied antioxidants are evaluated with regard to their protection properties against stress such as sunlight.

2 Materials and Methods

2.1 Electron Paramagnetic Resonance (EPR) Spectroscopy

EPR spectroscopy is based on the resonant absorption of microwave radiation by paramagnetic species exposed to a magnetic field.

Microwave absorption occurs when the applied radiation matches the energy difference of the spin state, so that characteristic absorption spectra are obtained from specific substances (Haag et al. 2011).

The measurements were performed with the L-Band EPR spectrometer LBM MT 03 (Magnettech, Berlin, Germany) using the following EPR parameters: microwave frequency (1.3 GHz), central magnetic field (46 mT), sweep width (8 mT), sweep time (10 s), and modulation amplitude (0.15 mT).

2.1.1 Direct Reaction of Antioxidants with a Topically Applied Test Radical

In vivo EPR investigations of the direct radical scavenging activity was performed using the spin probe TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy; Sigma-Aldrich, Steinheim, Germany). Using a 30 mM TEMPO solution, the spectral shape is optimal for intensity evaluation by measuring the height of the central line, as previously described by Haag et al. (Haag et al. 2011). A typical spectrum of the nitroxide in the skin is shown in Fig. 1.

Measuring spots were chosen from the middle third of the inner forearm. All measurements from one volunteer were performed on the same arm. The measurement area was prepared by carefully

clipping off all terminal hairs and cleaning the skin with an ethanol-soaked cotton pad. TEMPO solution (50 μ L) was applied onto a filter paper (diameter 11 mm; Epitest Ltd Oy, Tuusula, Finland) and occluded with a Finn Chamber (Epitest Ltd Oy, Tuusula, Finland) for 10 min. The Finn Chamber and filter paper were then removed, and the skin was wiped with a paper towel. The arm was placed on a splint in the EPR and lifted up to the surface coil with soft pressure. A thin cover glass (Menzel-Gläser, Braunschweig, Germany) separated the skin from the surface coil. To increase the signal-to-noise ratio, four scans per minute were recorded for a total of 20 min and the mean spectrum of eight scans covering 2 min of reaction time was evaluated. The intensities of the central lines were plotted over time as exemplified in Fig. 2 and fitted by the equation $I = I_0 \exp -kt$, whereas k represents the rate constant of the function, which characterizes the individual radical scavenging properties of the skin. The exponential decay was normalized to the baseline EPR signal height (Fig. 2). On each visit, measurements were performed in duplicate.

2.1.2 Radical Formation Induced by Irradiation

For the determination of radical formation, the nitroxide 3-carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxy (PCA; Sigma-Aldrich) was

Fig. 1 Typical EPR spectrum of the nitroxide TEMPO after penetration into the skin

Fig. 2 Peak-to-peak intensity decay of TEMPO in the skin over time following a first order exponential decay

used. Compared to TEMPO, PCA hardly reacts with the skin's antioxidant system at the concentration used (Haag et al. 2010). However, PCA reacts well with short-lived free radicals, e.g., irradiation induced radicals, which transform the EPR marker to EPR-silent. This reduction in EPR signal intensity can be correlated with free radical formation (Darvin et al. 2010; Herrling et al. 2003). Preparation of measurement areas on the right inner forearm was performed as described above, for the section regarding the determination of radical scavenging capacity. PCA solution (100 μL) (43 mM, water:ethanol, 1:1, v:v) was applied to the skin on two paper filter disks (Epitest Ltd Oy), occluded with a Finn chamber (Epitest Ltd Oy) and allowed to penetrate the skin for 40 min. Subsequently, the arm was placed in the EPR spectrometer and measurements were started without irradiation for 10 min. Since the reduction of PCA was below 5 % without irradiation, the same measurement spot was used for the irradiation experiment. A solar simulator (Low Cost Solar Simulator, LS0104, LOT-Oriel Group, Darmstadt, Germany, wavelength: 420–2000 nm; output: 120 mW/cm^2) was used for in situ irradiation of the skin. Measurements were continued during irradiation for a further 10 min. To increase the signal-to-noise ratio, four scans per minute were recorded and the mean spectrum of eight scans covering 2 min

of reaction time was evaluated. PCA intensity was derived from the central line of the spectrum. Measurements were performed in duplicate on each volunteer.

Measurements After Topical Application

In Vivo

The volunteers applied the verum and placebo cream to either one of the inner forearms twice daily for a period of 4 weeks. One-third of the placebo cream-treated forearm remained untreated. The last application of the test creams was, on average, 8.5 h (range 5–12 h) prior to the measurements, in order to avoid optical influences of the creams due to occlusive layer development or different penetration behavior of placebo and verum cream.

The measurements were performed as described above.

Ex Vivo

Comparable to the in vivo measurements, the following samples were prepared from each pig ear: two samples each without any cream applied, treated with placebo cream or with verum cream. The pig ears were first washed, shaved, and cleaned with ethanol.

Afterwards, the skin samples ($d = 19$ mm), fixed onto glass slides, were treated as in vivo

with slight modifications (50 μL PCA solution, 20-min penetration time, no glass slide) in order to achieve similar EPR intensities as in vivo. Thereafter, the cream, if any, was applied (2 mg/cm^2 according to the Colipa standard) and measurements started one hour after penetration.

Measurements without irradiation were performed for 20 min and subsequently for 20 min under NIR/VIS irradiation. All measurements were performed in duplicate.

3 Results and Discussion

3.1 Cutaneous Antioxidant Status Before and After Supplementation

3.1.1 Supplementation of Water Soluble Antioxidants

In this study, vitamin C (calcium ascorbate) or chokeberry extract (Aronia energy, Privatinstitut Galenus, Berlin, Germany) was taken by 33 healthy volunteers. Aronia energy is a powder, which consists of dextrose, Aronia berry peel extract, Topinambur extract, and calcium ascorbate (<3 %). The major antioxidant part is the chokeberry peel extract (>70 %). For the vitamin C sample, calcium ascorbate was prepared in dextrose, and as placebo, pure dextrose was taken. All samples were randomly numbered.

The placebo controlled double blind study consisted of three groups with 11 volunteers in

each group of placebo, vitamin C (Vit C), and Aronia (Meinke et al. 2012a).

The antioxidant activity of the samples of the vitamin C and the Aronia group was adjusted to the same radical protection factor (RPF, 3600×10^{14} radicals/mg) (Herrling et al. 1998). This resulted in approximately 100 mg vitamin C per day.

All volunteers were measured before (visit 1) and after 28 days with supplementation (visit 2). The volunteers were measured by EPR spectroscopy on the inner forearm.

Each volunteer was instructed to take the study powder by dissolving one spoonful of the powder in water twice daily, in the morning and in the evening. After 14 days, nine volunteers of the vitamin C group were investigated in addition to the visits 1 and 2. The nine volunteers had been selected by the study coordinator, whereby the investigator was not informed as to which group the volunteers had been allocated, in order to ensure double blindness.

The radical scavenging of the skin was enhanced after supplementation, the decrease in TEMPO is faster and the rate constant increases. Although the individual values of rate constant differ strongly in all groups, with the exception of placebo, significant differences after the intake of the antioxidants were obtained. Significant differences could be found between the differences in rate constants before and after the intake of both verum groups compared to placebo (Fig. 3)

Fig. 3 Rate constants after a 4-week intake of the different products related to the initial values before intake; taken from (Meinke et al. 2012a)

No significant differences could be found between Aronia and Vit C. The relative increase is 23 % for Aronia and 20 % for Vit C.

Additionally, cutaneous carotenoids were measured but no significant change could be observed. Nine volunteers from the Vit C group were measured after 14 and 28 days with supplementation. The rate constants increased significantly after 14 days, whereas no further significant increase appeared after 28 days.

This indicates that both vitamin C and chokeberry extract increase the antioxidant status of the skin. The appearance in the skin is within 14 days, perhaps even faster and did not increase with further intake.

The intestinal absorption capacity for ascorbate is limited by the amount of transporters present. In healthy adults almost maximal absorption is achieved by a single 200 mg dose (Levine et al. 1996); vitamin C bioavailability decreases after further increasing oral doses. The amount of 125 mg per day vitamin C in two portions can be considered to be a moderate dose. This amount is already sufficient to considerably enhance the radical scavenging capacity in the skin.

Furthermore, the natural extract, with the same RPF consisting of different polyphenolic compounds also increases the antioxidant capacity to the same amount, although the absorption of dietary polyphenols is, in general, very low (plasma concentrations of total metabolites are in the nM to low μ M range) and the time to reach maximum concentration ranges between 30 min and several hours, depending on the site of absorption (Manach et al. 2003). However, EPR spectroscopy does not provide the identity of the antioxidants, which are responsible for the increased radical scavenging activity. It could be demonstrated that polyphenols from chokeberry contribute to the radical scavenging effect in the skin.

3.1.2 Supplementation of Lipophilic Antioxidants

In the following study, the effect of a curly kale extract was investigated (Meinke et al. 2013a). The supplements were provided for a time period of 8 weeks. The verum capsules LutexskinTM

(BioActive Food GmbH, Bad Segeberg, Germany) consist of a curly kale extract (*Brassica oleracea* convar. *acephala* var. *sabellica* L.), sea buckthorn oil (*Hippophae rhamnoides* L.), and olive oil, containing a high amount of carotenoids. The dosage for 1 day provided the following moderate amounts of carotenoids: 2200 μ g lutein, 1000 μ g beta carotin, 50 μ g alpha carotin, 400 μ g lycopin, 700 μ g zeaxanthin, and 100 μ g cryptoxanthin. As a control, a placebo capsule containing olive oil with almost no antioxidants was given.

Twenty-four healthy volunteers were recruited. The study included four visits and lasted 20 weeks. As starting time, autumn was chosen in order to reduce a possible influence of the sun. The volunteers took the supplements for a time period of 8 weeks. On visit 1 the volunteers were randomly assigned to either the verum group or to the placebo group. Supplementation started in the evening of visit 1. The second visit took place after 4 weeks, the third visit 8 weeks after administration of the supplements. After a further 12 weeks without supplementation, the fourth and final visit took place.

The following measurements were performed at each visit: (1) Resonance Raman spectroscopy was conducted to determine cutaneous carotenoids. (2) By means of EPR spectroscopy the radical scavenging capacity of the skin was determined. (3) Determination of radical formation in the VIS/NIR spectral range in order to acquire information about the photoprotection of the skin against oxidative stress.

At visits 1 and 4, the volunteers completed a questionnaire in order to ensure that neither their life style nor their eating habits had changed.

Radical Scavenging Activity

In order to determine the radical scavenging activity of the supplement itself, the RPF value was determined using the highly reactive test radical 2,2-diphenyl-1-picrylhydrazyl (DPPH), which resulted in 180×10^{14} radicals/mg. However, the supplement did not react with the test radical TEMPO that is used for the determination of the skin radical scavenging capacity in a time frame of 6 h.

Fig. 4 *Left:* Cutaneous carotenoid concentration relative to initial value, *right:* rate constant relative to initial value, V1 – before intake, V2 – after a 4-week intake, V3 – after

an 8-week intake, V4 – 12 weeks after stop of intake; taken from (Meinke et al. 2013a)

Nevertheless, the radical scavenging capacity of the skin changed after the supplementation with the curly kale extract. A stronger decrease of the test radical TEMPO in the verum group was observed at V3 with an increase in rate constant (Fig. 4, right).

The bioavailability of the curly kale extract in the skin was measured using resonance Raman spectroscopy. Regarding the rate constants, as a measure of the antioxidant capacity determined by EPR spectroscopy, the data obtained show a similar behavior as the increase of the additionally measured cutaneous carotenoids; however, the differences were less pronounced. The increase in the rate constant of the verum group is 27 % after 4 weeks and significantly 48 % after 8 weeks; furthermore, the difference between the rate constants of verum and placebo groups at V3 is significant. After the end of supplementation, the k -values decreased significantly from V3 to V4 to their initial values at V1 within the verum group. Moreover, no differences between verum and placebo at V4 could be observed.

Prevention of Radical Formation

Radical formation after VIS/NIR irradiation can be reduced by topically applied antioxidants. The question was whether orally applied antioxidants, such as the administered curly kale extract, can

reduce the radical formation during a 10-min VIS/NIR irradiation.

Prevention of radical formation induced by VIS/NIR irradiation was observed after 8 weeks of supplementation at V3. After 10 min of VIS/NIR irradiation, the radical formation in the verum group was significantly reduced by 34 %. At other time points no significant differences between both groups were observed.

The estimation of the daily total carotenoid intake of all volunteers resulted in $2.13 \text{ mg} \pm 1.97 \text{ mg}$ (range: 0.25–6.39 mg).

The RPF value of 180×10^{14} radicals/mg is rather low compared to other values of antioxidants. This is due to the low reaction efficacy of carotenoids with the used test radical DPPH (Herrling et al. 1998). Carotenoids also do not react with the cutaneously used test radical TEMPO within 6 h. Nevertheless, the investigations could show that the topically applied TEMPO was reduced much faster in the verum group after supplementation with carotenoids for 8 weeks. Significance could also be achieved within the verum group between the k -values before the beginning and after the end of supplementation. This indicates that the radical scavenging activity of the skin is enhanced on the whole, implying that antioxidants interact with each other and that carotenoids in a natural matrix affect other antioxidants in such a way

that they increase the antioxidant properties of the skin.

The reduction in radical formation after irradiation in the VIS/NIR range is in agreement with the increase in the antioxidant capacity of the skin. Studies which applied the antioxidants topically have shown that radical formation was reduced after irradiation in the VIS/IR range (Meinke et al. 2011) Furthermore, this result corresponds to results from UV irradiation with reduced erythema or photodamage in cells after consumption of carotenoids or other antioxidants (Meinke et al. 2012b; Heinrich et al. 2003; Bayer et al. 2011) In this context, synergistic effect should be mentioned (Wölfle et al. 2013).

3.2 Antioxidant Status After Topical Application of Antioxidants

3.2.1 In vivo

The aim of these in vivo measurements was to evaluate a method that measures radical protection by a cream, containing the *Hypericum perforatum* extract (1.5 %), which is rich in hyperforin and known to reduce radical formation in the skin ex vivo after IR irradiation. The radical protection factor (RPF) of the verum cream was $425 [10^{14} \text{ radicals/mg}]$ and the verum cream without HP extract was $39 [10^{14} \text{ radicals/mg}]$. The investigated creams were applied in vivo several times by the volunteers, in order to detect the

long-term effect of the application. EPR measurements were performed during irradiation and the changes in radical formation of the in vivo investigations after 4 weeks of cream application are shown in Fig. 5 left (Arndt et al. 2013).

The increase in radical production decreases along with time. During the first 2 min, the radical production is maximal (Haag et al. 2013). A longer irradiation time than 10 min of the untreated skin did not increase the radical formation significantly (data not shown). Untreated skin shows the highest radical production followed by a significant decrease to $55.7 \pm 8.7 \%$ after a 12-min irradiation of placebo-pretreated skin and a further significant reduction to $24.9 \pm 8.7 \%$ when verum was applied.

The analysis of the questionnaires did not show any significant differences in stress, smoking, and intake of fruit and vegetables.

The topical application increases the neutralization of ROS in a more pronounced manner than the so far investigated oral application. A possible reason is that for topical applications the concentration could be much higher than the recommended physiological concentration for supplementation. So far no side effects of topically applied antioxidants have been reported (Darvin et al. 2006).

3.2.2 Ex vivo

Ex vivo, the measurements were performed 1 h after one single application of the creams.

Fig. 5 Changes in radical formation during VIS/NIR irradiation (120 mW/cm^2), on untreated, placebo, and verum-treated skin; left: in vivo on a volunteer's forearm, and right ex vivo on porcine ear skin; taken from (Arndt et al. 2013)

Untreated skin was used as control. In contrast to *in vivo* measurements, the measurement time can be extended to longer irradiation times. The *ex vivo* results on porcine ear skin are presented in Fig. 5, right. The radical production did not decrease within the performed time frame. The change in radical production could be fitted by a linear equation. This means that the production of radicals has a constant value over the irradiation time, however, this value differs, depending on pretreatment.

As with *in vivo*, the untreated skin produced the highest number of radicals. Taking the fitted values, placebo and verum reduced the radical production to $75 \pm 20\%$ and $26.3 \pm 8.5\%$, respectively.

A direct comparison of results after a 10-min irradiation of excised porcine ear skin and the forearm of the volunteers *in vivo* showed that the radical production, due to irradiation in the VIS/NIR range, is more pronounced *in vivo*. For the same irradiation time of 10 min *in vivo*, the radical production is 1.9 times higher compared to *ex vivo*. This difference can be reduced by a longer irradiation time *ex vivo*.

The results have shown that both verum and placebo cream applied *in vivo* or *ex vivo* protect the skin from VIS/NIR induced radicals. The effect of placebo could be due to the optical properties of the cream. Besides antioxidants, high scattering properties of the creams can reduce radical formation in the infrared region as shown for sunscreens applied *ex vivo* (Meinke et al. 2013b). This method is also applicable to the investigations of sunscreens from the UV to the NIR spectral range.

The fact that in human skin *in vivo* more radicals are produced in the first minutes compared to *ex vivo* in porcine ear skin can be explained by the oxygen supply in living tissue. Nevertheless, this should be investigated in more detail using excised human skin as comparison. The decrease in radical formation *in vivo* with time could be explained by an up regulation of the endogenous antioxidant network, which neutralizes induced free radicals (Thiele et al. 2001). This defense mechanism cannot be studied *ex vivo*.

4 Conclusion

The different investigations have shown that EPR spectroscopy is well suited to investigate the antioxidant status and stress of the skin. The investigation can be performed *ex vivo* as well as *in vivo*. The results have shown that during *in vivo* and *ex vivo* investigations the radical formation due to irradiation is different.

The uptake of hydrophilic and lipophilic supplements could be followed, with the result that both products increase the radical scavenging activity in the skin. This even occurs when the investigated product does not react directly with the test radical TEMPO, indicating that the cutaneous antioxidants interact and protect each other. It could be shown that compounds which increase the rate constant also provide protection against stress induced radicals as formed during VIS/NIR irradiation.

The effects of water soluble antioxidants were observed faster in the skin (a saturation is visible within 2 weeks) compared to carotenoids (saturation not visible after 2 months) which is plausible due to different transport mechanisms of water and lipid soluble vitamins.

In comparison to orally applied antioxidants in physiological concentrations, topical application of antioxidants in a cream provided higher protection against stress induced radicals as formed during VIS/NIR irradiation.

This leads to the conclusion that a moderate protection distributed over the whole body could be achieved by oral application of antioxidants, and for high protection on sun-exposed areas, an additional topical application of antioxidants can be recommended.

Acknowledgments This work was supported by the Federal Land of Berlin within the Program to Promote Research, Innovation and Technologies (ProFIT, grant n# 10142343 and 10149524) for granting subsidies from the innovation promotion fund, with cofinancing by the European Fund for Regional Development (ERDF). We would also like to thank the companies Privatinstitut Galenus, Bioactive Food, and Klosterfrau Healthcare Group for providing the investigated products containing the different antioxidants.

Artificial dermis • Skin substitute • Defects • Cancer • Negative-pressure therapy

1 Introduction

Artificial dermis is widely used in the treatment of excessive burn injuries and is also more and more used in reconstructive surgery. It is an excellent option for reconstructing defects created by tumor excision. After an overall description of the properties of DE, their relevance in the treatment of oncologic surgical defects is assessed through a review of the literature and our own experience.

2 Artificial Dermis

2.1 Presentation

Since the 1970s, various types of dermal skin substitutes have been developed and used as models in *in vitro* studies and for therapeutic use. Thanks to the development of techniques of cell culture, the reconstruction of the epidermis (Rheinwald and Green 1975) and the reconstruction of dermal equivalents (DEs) are now possible. DE can be cellularized, like the model by Bell et al. (1981) consisting of a matrix of collagen contracted by the fibroblasts it contains (Apligraf[®]), or constituted by a synthesized matrix and integrated by the fibroblasts themselves (TransCyte[®]). Other types of DE are in acellular form, such as the model developed by Yannas and Burke (1980; Yannas et al. 1980). The latter (Integra[®] (Integra LifeSciences[®])) is made of collagen supplemented with chondroitin-6-sulfate and is available in single layer or double layer types, covered by a silicone film. Integra[®] was the first dermal substitute on the market and remained the only product available for 10 years. Since 2007, new acellular dermal equivalents have been available in France: Matriderm[®] (Medical Z[®]) is made of a collagen and elastin matrix; Renoskin[®] (Perouse

Plastic[®]) consists of a collagen matrix covered with a silicone film; Hyalomatrix[®] (Addmedica[®]) is composed of esterified hyaluronic acid covered with a flexible elastomer film.

Whereas the implantation of the first products was performed in a two-stage procedure, substitutes allowing to perform the skin graft and the implantation of the dermal equivalent simultaneously have been developed (Integra[®] single layer, Matriderm[®] 1 mm). In research, models are continuously becoming more complex: either endothelialized reconstructed dermis, or immuno-competent substitute, or reconstructed skin including the hypodermis (Auxenfans et al. 2009). In this article, only acellular DE will be reviewed.

2.2 Mode of Action of Acellular Dermal Equivalents

The DE is implanted on a site where it is susceptible to be colonized by fibroblasts and the process of vascularization is possible. As a simplified model of the extracellular matrix of the dermis, it is integrated in the healing process in order to recreate the mechanical and nutritional support of the epidermis. Histological studies have showed four stages in the process (Moiemen et al. 2006):

- A phase of inhibition
- A phase of migration of the fibroblasts
- A phase of revascularization lasting 4 weeks (without associated negative pressure therapy)
- A phase of remodeling and maturation

The 3-D structure of the acellular DE acts like a frame in the process of connective healing with the *de novo* synthesis of a tissue similar to mature human dermis within a few weeks, without proliferation of the anarchic granulation tissue (Lakhel-Le Coadou et al. 2000). The colonized DE behaves like neodermis, not like scar tissue, thus accounting for aesthetic and functional results which are similar to the normal cutaneous layer and superior to those of an isolated split skin

Fig. 1 Histological section 1 year after application of dermis equivalent followed by a granulation phase and then a split-thickness skin graft (patient 2 of the series). *H* hypodermis, *DRT* dermal regeneration template, *GT* granulation tissue, *E* epidermis. Note the rich

vascularization and the cell infiltrate within the granulation tissue in contrast to the organization of the collagen fibers of the corresponding area on application of the dermal equivalent. Standard HES stain, objective X 2.5

graft (Dantzer and Braye 2001). From a histological point of view, the recolonized dermal skin substitute is distinct from the original dermis by the absence of pilosebaceous annexes, the absence of elastin fibers (absent in Integra[®], but present in Matriderm[®]), the absence of nerve ending, and a straight dermis-epidermis junction without the papilla (Fig. 1) (Moïemen et al. 2006). This accounts for the sensation of dryness sometimes reported by patients and the absence of superficial sensitivity. In histology it is however impossible to differentiate new collagen from collagen of the local dermis. Regarding the two most frequently used DE types in France, no evidence has been found of a difference between Integra[®] and Matriderm[®] in animals in terms of revascularization or integration of the substitute (Schneider et al. 2009).

When the implantation of a dermal equivalent is to be followed by a skin graft in a two-stage procedure, it is temporarily covered with a silicon film. This film limits liquid leaks by allowing gas exchanges and is also a barrier to bacteria. Dermal substitutes implanted together with a skin graft in a one-stage procedure are thinner (1 mm) to accelerate nutrition of the epidermis from the capillaries before the death of the keratinocytes.

2.3 Legislation

Dermal skin substitutes are medical devices (MD). In the French *Code de la Santé Publique* (Public Health Regulations) (Art L5221-1 and R5211-1), MD are defined as “any instrument,

device, piece of equipment, matter, product, [...] designed by the manufacturer to be used in humans for medical purposes and whose main intended action is obtained through neither pharmacological, nor immunological means, nor metabolism...” (Article L5211). Contrary to medicine, their commercialization does not need the authorities’ approval (*Autorisation de Misesur le Marché* – AMM), but requires CE marking which guarantees its conformity to essential exigencies in conception, manufacturing, performances, and safety. The main drawback of CE marking is the quasi absence of exigency in terms of efficacy demonstrated by clinical evaluation. CE marks are delivered by a certified organization or by the manufacturer’s self-certification for class I MD.

There are four classes of MD (I, IIa, IIb, III) corresponding to increasing levels of risks (Table 1). This classification is based on the product’s length of use (from temporary to implantable), its invasive or noninvasive characteristics, its surgical or nonsurgical features, its active or non-active characteristics, and the part of the body in contact with the MD. Dermal equivalents are class III medical devices (very serious potential risk). In addition, since dermal equivalents are considered implantable MD, they are submitted to compulsory sanitary traceability according to the procedures of the *Code de la Santé Publique* (Article R5212-36 to 5212-42). The aim is the rapid identification of patients exposed to risks from a specific batch or series and the identification of batches of MD used by a patient.

Table 1 Classification of medical devices and risks

Class	Type of device	Examples	Risk
Class I	Noninvasive device	Medical beds, wheelchairs	Low risk ↓ High risk
	Invasive device – continuous use for less than 1 h		
Class IIa	Invasive device – continuous use between 1 h and 30 days	Urinary catheter	
		Tracheal tube	
Class IIb	Invasive device – long-term use (>30 days)	Articular prosthesis, bone cements, non-resorbable sutures	
Class III	Invasive device – long-term use (implantable device) designed to be in direct contact with the heart, the central circulatory system, or the central nervous system, to have a biological effect, containing medicine or manufactured from tissue of animal origin	Vascular stents, bone cements with antibiotics, mammary prosthesis, etc.	

2.4 Technical Applications of Artificial Dermis

2.4.1 Dermal Equivalents and Burns

Integra[®], the first dermal substitute on the market, was initially developed to improve the management of acute burns (Burke et al. 1981). Its monopolist position and free availability in the management of burn injuries in many countries account for the vast amount of literature on this particular MD, even though recent articles also show the efficacy of other DE in the same indications, such as Matriderm[®] (Haslik et al. 2007; Ryssel et al. 2008; Kolokythas et al. 2008) and Hyalomatrix (Gravante et al. 2007).

In the management of severe burns, the free-of-charge availability of Integra[®] has been justified by its specific qualities (Heimbach et al. 1988, 2003):

- Reduced duration of hospitalization (Ryan et al. 2002)
- Advantageous replacement of allograft of the skin bank
- Association with split skin grafts allowing quicker healing of donor sites
- Better quality of skin grafts (texture, suppleness, glide space)
- Reduction of hypertrophic scars (Dantzer and Braye 2001; Branski et al. 2007; Clayman et al. 2006)

In the treatment of burn sequelae, the use of Integra[®] also allows the diminution of contractures and bridges (Chou et al. 2001; Groos

et al. 2005; Unglaub et al. 2005; Stiefel et al. 2009); however, usual prevention means by immobilization and pressure therapy are still necessary (Hunt et al. 2000; Haertsch 2002). In some cases, the use of DE avoids implanting skin flaps after exposure of structures without spontaneous healing potential (Boyce et al. 2009).

Patients with burns have reported the following problems:

- Sensitivity to infection with two peaks of frequency, on D3 (by accumulation of fluid and hematoma) and on D14 (Molnar et al. 2004). The rate of infection in burned patients varies between 16.3 % (Heimbach et al. 2003) and 40 % (Branski et al. 2007; Muangman et al. 2006). Infection is mainly due to one germ (83 %) with predominance of Gram-negative bacillus.
- The rate of Integra[®] integration is lower than with skin grafts (Molnar et al. 2004) and evaluated at 76.2 % in the largest series (Heimbach et al. 2003).
- The cost, which is approximately 5 €/cm² in France for Integra[®], and the absence of free-of-charge availability and valorization in some countries like France.

The infection risk must however be put in perspective. The bacterial ecosystem and the immunity of burned patients managed in specialist care centers are specific, and grafted surfaces are often large (Bargues et al. 2009).

However, it justifies the use of dressings with antiseptic properties in very rigorous asepsis conditions. The risk of complications can be reduced by two treatments which can be associated:

- Negative-pressure therapy (NPT)
- Skin grafting and DE implantation performed in a one-stage procedure

The possibility to implant the thin skin graft together with the DE in a one-stage procedure (DE (Matriderm[®] 1 mm, Integra[®] single layer) also has several advantages (Ryssel et al. 2008):

- Single surgical operation
- Reduced risk of bacterial contamination
- Reduced healing time

However, as in full-thickness skin grafts, the presence of dermis delays the nutrition of the epidermis from the capillaries and can be at the origin of a delay in the successful take of the skin graft. We were able to show this phenomenon in our investigations with perfusion laser Doppler imaging and capillaroscopy (Fig. 2).

2.4.2 The Use of Dermal Equivalents in Cases Other than Burns

The use of DE for loss of substance in plastic surgery in cases other than the treatment of burns is more recent. In France it is used in this indication only occasionally because of a problem of cost, since no study has shown the economic benefits of the products. The properties put forward to justify their prescription in plastic surgery are:

- Improvement of the quality of split skin grafts
- Possibility of glide plane in the mobile areas or in contact with tendons (Haslik et al. 2008; Aquilina et al. 2009; Yurugi et al. 2002; Wang and To 2000)
- Possibility of integration of DE implanted on tissue without granulation power such as bone without periosteum (bridge phenomenon)

The latter property makes DE a possible alternative to skin flaps, as a structure independent from the vascular network, and a good option in this indication. For some authors, DEs are already an alternative to skin flaps in civilian (Molnar et al. 2004; Pu 2008) and military (Helgeson et al. 2007) practice. Clinical cases have shown successful implants of artificial dermis to cover loss of substance in cases of skull exposure (Simon et al. 2008), after purpura fulminans (Besner and Klamar 1998; Pollard et al. 2008), on myelomeningocele (Nakazawa et al. 2005), on tendons (Wetzig et al. 2009), and after breast reconstruction (Namnoum 2009).

3 Artificial Dermis in Skin Cancer

3.1 Overview

DE can be used in skin cancer:

- To help understand cancer in research with in vitro models (Meier et al. 2000; Satyamoorthy et al. 1999; Berking and Herlyn 2001)
- To treat sequelae on donor sites of skin flaps used in cancer treatment, especially radial forearm free flap (Wax et al. 2002) and forehead skin flap (Wang and To 2000)
- To perform primary cover for loss of substance after excision of cancer lesions

In the latter case, DEs are used:

- To improve the quality of the skin graft
- As an alternative to a skin flap

Aside from any aesthetic consideration, cancer-related losses of substance have specific features:

- Elderly patients in most cases
- Multi-operated sites
- Lower risk of infection (compared to patients with burns)
- Absence of compromise with the excision margins that are sometimes important and necessity of total independence from reconstruction (except on the face in some cases)

Fig. 2 Patient 4 of the series: demonstration of distress of a split-thickness skin graft applied at the same time as a dermal substitute related to the inevitable delay in revascularization inherent to the presence of the DE (*dotted white lines* on D14). Patient with a squamous cell carcinoma with fungoid mycosis of the left leg. Skin excision covering the loss of substance (*dotted black line*) and application at the same time of a 2/10th millimeter split-thickness skin graft. The use of negative pressure therapy from D0 to D14 with a change of dressing on D8. As the laser Doppler perfusion imager (laser Doppler PerisScan PIM 3 imager, Perimed) visualizes the vascular flow at a depth of about 1 mm, it objectivates the delay in perfusion within the dermal substitute on D8 with a predominance of blue, the image being comparable to the appearance on D0. From D14, there is no obvious difference in vascularization between the dermal substitute and the skin graft applied directly to the muscle, with a comparable red color in both cases. Conversely, the delay in revascularization of the skin graft because of the presence of the DE explains the epidermolysis of part of the skin graft (*dotted white lines*). At the same time, capillaroscopy within the dermal substitute shows an increase in the number of capillaries within the substitute between D14 and week 6 (W6), so that it is comparable in terms of density to that of healthy skin

- Possibility of adjuvant or neoadjuvant radiotherapy, chemotherapy, and adjuvant immunotherapy requiring fast healing process so as not to delay treatment
- Possibility to have to differ covering of the loss of substance while waiting for results from anatomic-pathological analyses of edges and deep plane
- Non-recommendation of prolonged NPT (Labler et al. 2009; Jacobs et al. 2008)
- Possibility of local recurrence and relevance of early detection
- Significant psychological impact

The covering of loss of substance, depending on its extent, is performed by procedures that can be simple when it is possible or more complex when it is necessary: direct suture, skin graft, and local, regional, or free flaps. In all types of skin tumor, the skin graft, when it is necessary and possible, is an option as a cover and has many advantages:

- Low morbidity, especially in full-thickness skin graft procedure.
- Its thinness makes local follow-up easy.
- It can be removed and repeated if surgical revision is required for pathological excision margins.
- It does not induce an additional scar to the tumor site.

However:

- The bed that receives it must be able to revascularize it.
- Its thinness makes it sensitive to mechanical constraints, to adjuvant radiotherapy.
- It can be unaesthetic because of dyschromia or depression, depending on the location.

When full-thickness skin grafting is not possible, a skin flap is the obvious option, but its implantation can be difficult because of the patient's age and susceptibility, the presence of scars from previous surgery, or a history of previous radiotherapy. Furthermore, when it is

local or regional, it results in scars near the tumor site that can alter lymphatic drainage pathways. Finally it causes additional morbidity associated with the donor site morbidity that can justify the recourse to other covering procedures.

3.2 Review of Literature

Dermal substitutes can present the advantages of both skin graft and skin flap with the possibility to be revascularized in bridges in case of partial implantation on a poorly vascularized bed. In Tufaro's series (Tufaro et al. 2007), Integra[®] double layer was used without NPT for cancer-related losses of substance with skin grafts performed on D21. The mean age of the 17 patients was 54 years old and the defect surface was $172 \text{ cm}^2 \pm 260$ (20–1,080). In six cases, Integra[®] was placed on the bone and in seven cases on the periosteum, and in three cases the patients received neoadjuvant radiotherapy. The author does not report any complication except premature loosening of less than 10 % of the silicone film from the surface in two patients and the successful take of the skin graft superior to 97 % in all cases. Three patients out of five who underwent radiotherapy presented with phlyctenules (ophthalmic terme) for blistering and ulcerations of favorable evolution in controlled healing.

The Corradino's series (Corradino et al. 2009) refers to the cases of eight elderly patients (mean age 81.5) presenting with scalp tumors. A two-stage procedure of excision and skin grafting was performed under local anesthesia (average loss of substance = 143 cm^2). The success of the graft was very satisfactory in all patients without using NPT. Two local recurrences were found at an early stage because of the fineness of the layer and were treated successfully using the same procedure. In this series, no removal of the outer table of the skull was performed contrary to other authors' recommendations (Komorowska-Timek et al. 2005; Koenen et al. 2008).

Giant congenital nevi are particular cases. They are not actually malignant cutaneous tumors, but

the risk of degeneration, recently reevaluated at 0.7 % (Krengel et al. 2006), requires excision and poses the same problems of reconstruction in a younger population (Abai et al. 2004). Schiestl reports the cases of 12 children (mean age 3.8 years, extremes 7 months and 11 years) with giant congenital nevi representing 1–12 % of body surface treated with Integra[®] double layer (Schiestl et al. 2009). NPT was used in the last treated patients and biological glue was used in all cases. In two-third of children, the two-stage procedure was a success. In a third of the patients, implantation of Integra[®] was not successful, among them one patient with complete failure in a gluteal and perianal location treated without NPT. The benefits of NPT, colic preparation, and parenteral nutrition are herein reminded for gluteal and perianal sites.

In the literature the use of DE after excision of facial skin carcinoma in patients with xeroderma pigmentosum (Herlin et al. 2009) is also reported.

3.3 Preliminary Experience in Our Department

In our department, five patients could benefit from the use of dermal equivalents after excision of malignant or degenerative skin lesions: two melanoma, one Darier-Ferrand dermatofibrosarcoma, one spinocellular carcinoma, and one giant congenital nevus (Table 2) (Figs. 3, 4, 5, 6, 7, 8, 9, and 10). In four patients the lesions were located on the lower limbs and in one patient on the supraclavicular region. DE was selected as the appropriate option for the following reasons:

- To avoid the use of a skin flap because of bone or tendon exposure after excision (patients 1, 2, and 3)
- To improve the quality of the skin graft by the addition of dermis (patients 4 and 5)

The mean surface of losses of substance was 216 cm² (extremes 20 and 330 cm²). The patients are listed in Table 1 in chronological order of treatment in the department. This was our first experience of the use of DE in the department.

The first three patients received Integra[®] double layer without NPT and the last two Matriderm[®] 1 mm with split skin graft associated with NPT in a one-stage procedure. After implantation of DE, the patients without NPT were followed in an outpatient setting for the renewal of dressings three times a week. Patients with NPT were hospitalized for the whole duration of the treatment (15 days) because of circumstances impeding their follow-up at home. Although implantation of DE was not complete in two patients for both types of dermal substitutes, final healing was always obtained by controlled wound healing.

3.4 Discussion

Our preliminary series reveals the following issues:

- The management of DE in hospitals in France
- The complications of our series and the learning curve inherent in the acquisition of a new technique
- The relevance of the association with NPT

3.4.1 Dermal Substitutes in Hospital Practice

Hospital funding in France is based on T2A (*Tarification A l'Activité*: fees in connection with activity) defining GHS (*Groupe Homogène de Séjour*: homogeneous group of hospitalization) representing fees for all the costs associated with the patients' hospitalization defined by the GHM (*Groupe Homogène de Maladies*: homogeneous group of diseases). These fees include the costs of dermal equivalents except those described in the "list of implantable medical devices funded in addition to GHS fees."

The decision to cover these costs in addition to GHS fees and the funding of a medical device belongs to the Ministry of Health, based on:

- The medical and technical recommendations of the National Committee for the evaluation of medical devices and health technology (*Commission nationale d'évaluation des dispositifs médicaux et des technologies de santé* (CNEDiMTS)) (e.g., *Commission*

Table 2 Patients having received artificial skin for the cover of loss of substance after excision of skin tumors or giant congenital nevus

Patient	Age	Pathology	Comments	Exposure bone or tendon	Localization	Surface	Dermal substitute	Dressing	Integration of de	Integration of skin graft	Complications
Patient 1	48	Melanoma	Breslow 1,36 mm	Achilles tendon	Posterior aspect Lower third of leg	20 cm ²	Integra® double layer	UrgoTulSag®	100 %	100 %	NO
Patient 2	35	Achromic melanoma	Breslow 23 mm	Bone and tendon	Volar aspect lower third of leg	180 cm ²	Integra® double layer	UrgoTulSag®	100 %	100 %	Infection and removal of silicone film on D17
Patient 3	32	Darier-Ferrand dermatofibrosarcoma	Excision margin 3 cm (Mofis)	Bone	Supraclavicular	300 cm ²	Integra® double layer	UrgoTulSag®	90 %	95 %	Infection on D10, premature removal of silicone film, controlled wound healing
Patient 4	70	Spino-cellular carcinoma on mycosis fungoides		No	Leg	250 cm ²	Matriderm® single layer	TPN 15 days	100 %	85 %	Controlled healing

d'Evaluation des Produits et Prestations (CEPP) de la Haute Autorité de Santé (HAS))

- The medical and economic recommendations of the Economic Committee for Health Products (*Comité Economique des Produits de Santé (CEPS)*)

It is then listed in the List of Refundable Products and Services (*Liste des Produits et Prestations Remboursables (LPPR)*). The CNEDiMTS gives scientific and independent recommendations on the expected service

determined from the severity of the pathology, the disability and the quality of life, the ratio efficacy/risk, the place in the therapeutic strategy, and the interest for public health and on the improvement of the expected service. Among the skin substitutes currently marketed in France (Integra®, Matriderm®, Renoskin®, Hyalomatrix®), none is on the LPPR list. Only Integra® has had, since May 27, 2008, a positive recommendation by the CNEDiMTS with an expected service estimated to be sufficient and a moderate improvement of the expected service (ASA III) in severe burns when a classic skin graft (autograft or allograft) is not available, technically possible or presents important risks of failure and an absence of improvement of the expected service (ASA V) in the losses of total cutaneous substance (Haute Autorité de Santé 2008). In conclusion, to this day, the cost of all the dermal substitutes is included in the GHS.

In 2008, national funding was provided through the National Program in Favor of Innovating and Expensive Techniques (*Programme National de Soutien aux Techniques Innovantes et Coûteuses (STIC)*) for the medical and economic evaluation of Integra® in the cover of trauma-induced losses of skin substance of the lower limbs. At the University Hospital of Besançon, the funding of Integra® has been guaranteed since June 2009 by this STIC in the evaluation of treatments in post-trauma losses of

Fig. 5 Patient 2 of the series. Outcome at 12 months and locoregional recurrence with multiple cutaneous and subcutaneous lesions. Note the extension by contiguity of the melanoma within the DE and the quality of the skin graft

Fig. 6 Patient 3 of the series with neglected dermatofibrosarcoma protuberans of the supraclavicular region. Outline of the excision limits with 3 cm margins and exhaustive analysis of the edges using modified Mohs technique

cutaneous substances of the lower third of the leg and foot in comparison with the skin flap technique and by the GHS for the other indications. Funding of DE has also been obtained from the Department of Clinical Research and Innovation (*Département de la Recherche Clinique et de l'Innovation* (DRCI)) of the hospital in the treatment of cancer-related losses of substances

allowing the treatment of eight to ten patients each year in the department.

With regard to other countries, Integra[®] is funded in the United States of America, Greece, and Hungary for the treatment of burns. In Hungary, the government also provides funding for Integra[®] used in reconstructive surgery.

3.4.2 Our Series

Our experience of the use of dermal substitutes related in this article corresponds to our first patients treated with DE in our department. In all our patients, the objectives at the basis of DE indication have been filled, i.e., to avoid the use of skin flaps and to improve skin graft quality. However, the learning curve which is inherent to the acquisition of any new technique probably explains the high infection rate (2/5) found in the first treated cases and the use of controlled wound healing in some cases. Infection has however not been detrimental to the success of the implantation of DE when it occurred after revascularization (patient n°2). This differs from the results obtained by some authors who may already be experienced in the use of the product (Tufaro et al. 2007; Corradino et al. 2009). These infections are probably prompted by the absence of NPT in our first cases, with changes of dressings three times a week in an outpatient setting, and by the absence of knowledge of clinical follow-up for the detection and early treatment of infections and effusion. If a patient shows

Fig. 7 Patient 3 of the series. Loss of substance with exposure of the periosteum clavicle

Fig. 8 Patient 3 of the series. Application of an Integra® DL film to cover the exposed bone

Fig. 9 Patient 3 of the series. Premature application of silicone film on D15 for infection (*Pseudomonas aeruginosa*)

signs of local infection, the centers specialized in the treatment of severely burned patients recommend local care with dressings humidified with alcohol chlorhexidine (Bargues et al. 2009), local antibiotics such as neomycin and polymyxin B (Muangman et al. 2006), and irrigations of mafenide solution every 8 h (Bargues et al. 2009).

3.4.3 Interest of Negative Pressure Therapy

The combination of dermal substitute and NPT was suggested in 2004 (McEwan et al. 2004) and has several advantages (Sinna et al. 2009):

- Reduction of exogene bacterial contamination due to the reduced number of dressing changes (changed every 4 (Molnar et al. 2004) or even 7 days (Schiestl et al. 2009)) and the adhesive film which isolates the wound from the exterior environment
- Acceleration of revascularization inside the dermal substitute with split skin grafts possible between D4 and D11 for Integra® double layer (Molnar et al. 2004), whereas the manufacturer recommends grafting around the 21st day without NPT (Burke et al. 1981; Heimbach et al. 1988; Clayton and Bishop 1998; Sheridan et al. 2001)

Fig. 10 Patient 3 of the series. Outcome at 2 years

- Application of homogeneous “pressure” on the DE by depression on the whole surface of the DE with diminution of the risk of collection (recommended depression – 125 mmHg (Molnar et al. 2004))
- Possibility to organize NPT at home, hence shortened hospitalization

Some authors use biological glue, either isolated or combined with NPT (Tufaro et al. 2007; Schiestl et al. 2009; Greenhalgh et al. 1999; Currie et al. 2001; Jeschke et al. 2004).

The last two patients in our series received the association of DE and skin graft at the same time and NPT with excellent results and moderate results for gluteal and perianal locations; the problems related to these locations have already been mentioned (Schiestl et al. 2009).

4 Conclusion

DE is beneficial in skin cancer therapy and is well adapted to this type of pathology. It should not be substituted to full-thickness skin graft when it is possible but it can be an alternative to skin flaps. As is the case in the acquisition of knowledge of any new technique, it implies a learning curve. The simultaneous association DE, skin graft, and NPT seems to be the ideal solution, but the combination of the three techniques increases the cost

whose total amount is included in the GHS, thus limiting its indications.

Acknowledgments The author thanks the companies Skinexigence and Perimed, as well as the laboratory of anatomic-pathology, in particular Professor Kantelip and Dr Algros for their contribution to this article. There is no conflict of interest.

1 Introduction

1.1 Infrared Thermography

The skin emits infrared radiation as a result of physiological processes. Temperature distribution depends upon blood perfusion, metabolism, thermal conductivity, drug effects, sympathetic nervous system activity, and environmental conditions (Wu et al. 2007; Jones 1998; Fujimasa et al. 2000). Cellular metabolic activity is distributed at the skin surface as heat and may change as a result of physiological abnormality (Wu et al. 2007). In addition, heat exchange occurs between circulating blood and tissue. External factors, e.g., thermal energy, also impact skin surface temperature (Thomas et al. 2000). Skin lesions result from abnormal processes including increased cell proliferation, excess metabolism, and disordered structure and respond differently from normal, healthy tissue (Wu et al. 2007). Infrared thermography has been used to ascertain the physiology for tumors, lesions, vascular function, and vascular disease (Fujimasa et al. 2000; Garcia-Romero et al. 2014; Janicek et al. 2003; Saxena and Willital 2008). Surface temperature is influenced by tumor size, i.e., higher with increasing size, and depth, i.e., inversely with distance of the vasculature from the skin surface (Wu et al. 2007; Draper and Boag 1971; Deng and Liu 2004).

Infrared (IR) thermography records 7.5–13- μ m emitted radiation and provides an intensity map of thermal energy at the skin surface (Jones 1998).

Static IR captures steady-state conditions at a point in time. Dynamic IR applies a stress (e.g., cooling, heating, pressure) to the skin and alters the subsurface structures (vasculature). They respond and restore equilibrium. The patterns, such as time to prestress temperature, provide functional tissue information (Pirtini Çetingül and Herman 2011; Di Carlo 1995; Santa Cruz et al. 2009). As a result, dynamic IR provides information about metabolism, depth, structure, and circulatory effects, more information than can be obtained from static IR (Renkielska et al. 2006). The time course to return to initial conditions following a specific stress, reveals physiological abnormalities (Cetingul and Herman 2010; Jiang et al. 2005). The use of IR thermography in the dynamic mode eliminates environmental effects on the physiological response (Fujimasa et al. 2000).

Measurement of skin temperature over time in the dynamic IR mode has been used to quantify vascular and neurological conditions such as diabetic neuropathy (Jiang et al. 2005; Bagavathiappan et al. 2010; Lahiri et al. 2012). IR thermal imaging differentiated superficial from deep areas in pediatric burns and was used to estimate graft sizes needed for treatment (Medina-Preciado et al. 2013). Dynamic IR methods have been used effectively to determine burn depth and to predict which burns will heal within 3 weeks. The quantitative results were more accurate than clinical assessment of burn depth (Renkielska et al. 2014). Thermal imaging over time following skin prick testing has been evaluated for quantifying and understanding the mechanisms involved with allergic cutaneous responses (Rokita et al. 2011). Melanoma lesions exhibited higher temperatures during recovery from cold stress compared to benign lesions and healthy skin using dynamic IR (Pirtini Çetingül and Herman 2011; Ruminski et al. 2007; O'Reilly and Taylor 1992). Skin erythema resulting from boron neutron capture therapy for melanoma was detected as a more rapid

rewarming response to cold stress compared to normal tissue (Santa Cruz et al. 2009).

1.2 Infantile Hemangiomas

Infantile hemangiomas (IHs) are benign rapidly proliferating vascular neoplasms occurring in up to 12 % of births (Mueller and Mulliken 1999). They exhibit increased angiogenesis, disorganized structure, increased perfusion, and resultant higher temperatures than uninvolved tissue. They are most commonly located on the head and neck (60 %) (Adams and Lucky 2006). They appear shortly after birth and undergo rapid growth via endothelial cell proliferation for 8–18 months, followed by stabilization (plateau), then slowly involute with diminishing cellular activity, reduced blood flow, and fat deposition for 7–10 years (Marler and Mulliken 2005; Mulliken and Glowacki 1982). About 50 % have involuted by 5 years. Up to 24 % develop life- or function-threatening complications including ulcerations, infection, heart failure, vision impairment, airway obstruction, and disfigurement (Haggstrom et al. 2006; Holland and Drolet 2010). They are classified as superficial, deep, or mixed based on dermal involvement and exhibit wide heterogeneity. Superficial IHs are bright red, slightly elevated, and noncompressible reaching maximal size by 6–8 months. Deep IHs are soft, warm, and slightly bluish and may proliferate for up to 2 years (Drolet et al. 1999). Most IHs are both superficial and deep. They are diagnosed by history and examination of size, color, depth, tactile characteristics, and morphologic subtype (Beck and Gosain 2009; Chang et al. 2008).

In the clinic, IHs are examined visually and palpated for temperature and deformation. Color photographs may be used to judge color and size and treatment response. These are indirect measures of IH status as the extent of proliferation or involution must be inferred. Size, vasculature, and

direction of blood flow can be measured with gray-scale and color Doppler ultrasound (Verity et al. 2006), but experienced operators are required (Spierer et al. 2012). Magnetic resonance imaging and computed topography are rarely used due to risks of sedation and radiation exposure (Spierer et al. 2012; Dubois and Garel 1999; Baker et al. 1993; Burrows et al. 1998; Argenta et al. 2006). Conventional histology is impractical for most cases.

2 IR Thermography Methods

Subjects equilibrated to room conditions for at least 15 min prior to measurements. To quantify the characteristics of hemangiomas, or other cutaneous conditions of interest, IR images of the region of interest (ROI), including adjacent regions and uninvolved contralateral control sites, were taken at 60 cm and perpendicular to the site with an emissivity of 0.98 (Jones 1998). A FLIR T400 (FLIR Systems Inc., Wilsonville, OR, USA) was used for this work. The infrared range was 7.5–13 μm , and the camera used an uncooled microbolometer focal plan array detector, 320 \times 240 pixel resolution, sensitivity of < 0.05 $^{\circ}\text{C}$ at 30 $^{\circ}\text{C}$, and accuracy of ± 2 $^{\circ}\text{C}$ (< 2 %) in either the static or dynamic mode. To relate the thermal information to the IH as visualized clinically, a static IR image was co-registered with a high-resolution color image. Color images were taken 30 cm perpendicular to the site with a digital camera (Nikon D90, Micro Nikkor 60-mm lens, Nikon R1 Wireless Close-Up flash (Nikon Inc., Nikon Corporation, Tokyo, Japan)), standardized lighting, and color correction (Canning et al. 2009).

2.1 Static IR

The region of involvement (ROI) was extracted from the IR image with an algorithm to segment

Fig. 1 Static IR threshold determination. Histograms for a typical hemangioma and contralateral uninvolved control site are shown. A threshold of three standard deviations

above the control mean temperature was selected to isolate the thermal activity attributable to the IH

the region of higher temperature from uninvolved control skin (ExaminIR software). A threshold of three standard deviations above the control IR image mean temperature was used to isolate the IH features (Fig. 1) following an evaluation of multiple IHs and control sites.

2.2 Dynamic IR

In the dynamic IR mode, a cold stress was applied at 18 ± 0.2 °C for 30 s (Jack Frost™ insulated cold pack, Cardinal Health, McGaw Park, IL). The consistency and reproducibility of cooling were determined (subject coefficient of variation (%CV) of 0.49–1.27 % and cool pack %CV of 2.59 %). The cold stress was removed and rewarming temperature video recorded (7 frames/s) for 30 s. The behavior of the

uninvolved contralateral site and that of an area adjacent to the IH (within the cooled region) were similar ($n = 24$, cooled $32.5^\circ \pm 1.4$ °C; contralateral $32.7^\circ \pm 1.2$ °C; $p = 0.36$). Therefore, adjacent sites served as the control to minimize the number of cooling procedures (Pirtini Çetingül and Herman 2011; Hassan et al. 2004).

For extraction of quantitative outcomes, the ROI was the IH thermal area above the temperature of uninvolved tissue at the end of rewarming (30 s). This ROI was used for the analysis of all other time points during rewarming (ExaminIR software, FLIR). Distributions of thermal intensity and area were determined using Matlab® (R2012a, MathWorks, Natick, MA, USA). A threshold of the highest 10 % of thermal pixels immediately after cooling was selected (Janicek et al. 2003; Symonds et al. 2012; Wojciech et al. 2010). This procedure isolates the highest thermal activity

Fig. 2 Dynamic IR imaging outcomes. The dynamic IR imaging outcome measures are shown. In this example, the IH temperature prior to cooling for 30 s is higher than the control site (T_{static}), indicating greater thermal activity. The temperature decrease with cooling ($T_{cool} - T_{static}$) is greater for the control than the IH, resulting in a lower area under the curve (AUC_{cool}). The area under the curve during rewarming (AUC_{rw}) is greater for the IH, and T_{max} is reached about 20 s after the cool stress is removed

within the IH, segments it from surrounding uninvolved skin, and provides a better signal to noise ratio versus thresholds based on the control value. Video frames at baseline (cooling removed) and 5-s intervals for 30 s were used to generate rewarming curves (Meyer et al. 2013).

Quantitative outcomes were distribution maps of thermal area and intensity, temperature change with cooling (after cooling – static), area under the curve during cooling (AUC_{cool}), area under the curve during rewarming (AUC_{rw}), time to maximum temperature (T_{max}) during rewarming, and difference in cooling and rewarming (AUC_{cool}-AUC_{rw}) (Fig. 2). In this example, the IH temperature prior to cooling for 30 s was higher than the control site (T_{static}), indicating greater thermal activity. The temperature decrease with cooling ($T_{cool} - T_{static}$) was greater for the control than the IH, resulting in a lower AUC_{cool}. The AUC_{rw} is greater for the IH, and T_{max} is reached about 20 s after the cool stress is removed.

3 IR Thermography of Infantile Hemangiomas

Static and dynamic IR thermography coupled with color imaging was used to evaluate the features of IHs over time in a group of patients with superficial or mixed IHs.

3.1 Subjects

Twenty-five subjects were recruited from the patient population of the Hemangioma and Vascular Malformation Center of Cincinnati Children's Hospital Medical Center. This multidisciplinary clinic was composed of specialists from hematology/oncology, surgery, dermatology, pathology, cardiology, orthopedics, and radiology and is a national referral center. The Institutional Review Board approved the study, and parents/guardians provided written

informed consent. Clinic physicians determined the appropriate treatment as propranolol, topical timolol, or observation (untreated). The 25 subjects with 26 IHs were assessed at each clinic visit over 17 months. The mean age at enrollment was 7.4 ± 8.4 months (range 1.3–38.3) with six males and 19 females, reflecting the expected gender distribution. There were 59 evaluation sessions (mean 3.8 per subject, range 2–9). Rapid IH growth occurs from 6 to 9 weeks (Tollefson and Frieden 2012), early proliferation before 3 months, most growth before 5 months,

and on the plateau for ~ 7 months and involution takes place after 10–12 months (Chang et al. 2008). Therefore, the data were stratified by age at evaluation into four groups: 1–2 months, 3–5 months, 6–9 months, and 10–18 months.

3.2 Region of Involvement

An example of IR (A) and color images (B) of an IH is shown in Fig. 3a–e. Both images are from

Fig. 3 IR and color images of the same region. An example of IR (a) and color images (b) of an IH is shown here. Both images are from the same area on the patient. Areas of highest temperature are *white*, followed by *yellow*, *orange*, and *red* in the IR image. The color image shows the visible area of the lesion. The IR area of involvement extends beyond the visible borders in the color image. The IR

image has a larger area of elevated temperature as outlined by the *black dashed line*. The area visible upon inspection is outlined in *blue*. The thermal area of involvement selected with the IR software is shown in (c). Image processing creates a temperature distribution map (d). The map in (e) is for thermal pixels greater than the control mean plus 3SD threshold

the same area on the patient. Areas of highest temperature are white, followed by yellow, orange, and red in the IR image. The color image shows the visible area of the lesion. The IR area of involvement extends beyond the visible borders in the color image. The IR image has a larger area of elevated temperature as outlined by the black dashed line. The area visible upon inspection is outlined in blue (Fig. 3b). Figure 3c shows the thermal area of involvement selected with the IR software. Image processing creates a temperature distribution map (D). Figure 3e is the map for thermal pixels greater than the control mean plus three standard deviation (SD) threshold. The color area/IR area ratio for the 59 evaluations averaged $36\% \pm 19\%$, suggesting that the relevant information about the IH is not readily visible, i.e., upon clinical examination.

3.3 IH and Control Skin

For the study population, the IHs differed from uninvolved (control) skin for all of the dynamic IR outcomes ($p < 0.05$, data not shown). The behavior of the IH and control sites during cooling and rewarming (Fig. 2) is representative of the overall results for the 59 evaluations.

3.4 Dynamic IR Responses

An example of the dynamic response to a cold stress is shown in Fig. 4 for a mixed IH in a 6-month subject. The color and thermal images were co-registered (Fig. 4a). The IR temperature distribution maps are shown for the static image (before cooling) above threshold of mean + 3SD with an area of 353 pixels (Fig. 4b) and for the highest 10% of thermal pixels (Fig. 4c). Figures 4d, e, f and g show maps at 30 s, immediately after removal of the cold pack (area 325 pixels), 33 s (area 496), 36 s (area 932), and 39 s (area 1190), respectively. The area of thermal activity increases from 325 pixels after cooling to

1190 pixels 9 s later. Note that the highest temperature was at the top of the IH prior to cooling (Fig. 4c) but that the portion at the bottom responded more quickly (Figs. 4d, e, f, g). Specifically, the highest thermal activity is at the bottom, as indicated by the red color. The lowest temperature is in the center and regions of remaining thermal activity are toward the outside of the hemangioma.

The IH was then surgically excised. Histological evaluation showed involvement throughout the dermis but not into the subcutaneous tissue and closely packed capillary blood vessels lined with flattened or hobnailed endothelial cells (Fig. 5a) with pericytes in some regions. Medium-sized feeding vessels were noted in lower regions. There was nonuniform proliferation, some capillary vessel dilatation and slightly increased paucicellular fibrous stroma, both suggesting early involution. The response to the cold stress is shown in Fig. 5b and consistent with rapid rewarming, presumably due to capillary blood flow.

3.5 Dynamic Response – IH Changes Over Time

The mean strata ages were 2.2, 4.5, 8.0, and 12.8 months. The AUC_{rw} decreased over time ($p < 0.05$) indicating a slower response to cooling (Fig. 6). AUC was higher for subjects aged 1–2 months than all older groups and higher for infants of 3–5 months (mean 4.5) than 10–18 months.

The dynamic response over time (two visits) is shown for two subjects. Figure 7 shows an untreated mixed IH at 5.1 (Fig. 7a) and 22 months (Fig. 7f). There was a visibly detectable change. IH height from three-dimensional scans (data not shown) and decreased from 5.1 mm to 3.4 mm. At 5.1 months, the area increased from 359 pixels immediately after cooling (Fig. 7b) to 1100 pixels within 7 s (Fig. 7c). There were pixels at higher temperatures, i.e., $\geq 36.5^\circ\text{C}$, 14 s (area 1365, Fig. 7d) and 27 s (area 1482,

Fig. 4 IH dynamic response to cold stress. An example of the dynamic response to a cold stress is shown for a mixed IH in a 6-month-old subject. The color and thermal images were co-registered (a) The static IR temperature distribution maps are prior to cooling and show values above the mean + 3SD (b) and the highest 10 % of thermal pixels (area 353) (c). The maps in (d), (e), (f), and (g) are at 30 s, immediately after removal of the cold pack (area 496), 36 s (area 496), 36 s (area 932), and 39 s (area 1190). The area of thermal activity increases from 325 pixels after cooling to 1190 pixels 9 s later. Note that the highest temperature was at the *top* of the IH prior to cooling but that the region at the *bottom* responded more quickly. Specifically, the region of highest thermal activity is at the *bottom*, as indicated by the *red* color. The lowest temperature is in the *center* and regions of remaining thermal activity to be toward the outside

Fig. 5 Histology and dynamic IR outcomes. **(a)** Histological evaluation of the IH in Fig. 4 showed involvement throughout the dermis but not into the subcutaneous tissue. The IH had closely packed capillary blood vessels lined with flattened or hobnailed endothelial cells with pericytes in some regions. Medium-sized feeding vessels were noted

in lower regions. There was nonuniform proliferation, some capillary vessel dilatation and slightly increased paucicellular fibrous stroma, both suggesting early involution. The response to the cold stress **(b)** is consistent with rapid rewarming, presumably due to capillary blood flow

Fig. 7e) after cooling. The highest temperatures are generally outside the superficial portion (color image, Fig. 7a), suggesting they are from deeper components. At 22 months (Fig. 7f), the central areas were slowest to rewarm (Figs. 7g, h, i, j). The areas were 418 immediately after

cooling (Fig. 7g), 868 at 5 s (Fig. 7h), 1169 at 11 s (Fig. 7i) and 1579 at 24 sec (Fig. 7j). While the areas were similar, the temperatures were lower, i.e., indicated by yellow (35.5-36.5 °C) and green (34-35.5 °C) regions in Figs. 7g, h, i and j.

Fig. 6 Dynamic IR response over time. The AUC_{Crw} decreased over time indicating a slower response to cooling. AUC_{Crw} was higher for subjects aged 1–2 months than all older groups and higher for infants of 3–5 months (mean 4.5) than 10–18 months. * indicates different versus all other groups ($p < 0.05$). ‡ indicates different from mean age of 4.5 months ($p < 0.05$)

Figure 8 shows a mixed IH treated with propranolol. From 11.7 to 15.7 months, the height decreased from 10.3 to 6.5 mm and lightness increased (Figs. 8a, f). The thermal area increased from 769 immediately after cooling to 2047 at 2 sec (Fig. 8c), 4207 at 9 s (Fig. 8d) and 6358 pixels at 25 s (Fig. 8e), with the highest temperature in the lower portion (Fig. 8e). Four months later, the areas were much lower, i.e., 190 pixels immediately post cooling (Fig. 8g), 456 at 4 s (Fig. 8h), 728 at 11 s (Fig. 8i) and 1131 at 27 s (Fig. 8j). The highest activity was toward the center.

4 Summary

Dynamic IR thermography was used to investigate the physiological response to stress, namely, cooling, among subjects with IHs at varying ages. The slower recovery from this stress over time is taken to be due to a reduction in

perfusion, blood supply, and/or metabolic activity as proliferation decreases and involution occurs. A relatively small decrease in temperature and area after cooling suggests that sources of thermal activity are robust. IR thermography does not quantify blood flow as volume per time but may be correlated with it (Pascoe et al. 2007). The method provides physiological information about IH status that is not visible upon clinical inspection or with standard color imaging. Therefore, it shows promise as a viable tool for the quantitative evaluation of infantile hemangiomas and has potential application for other cutaneous conditions.

Acknowledgments This research was funded by the Society of Pediatric Dermatology, American Foundation of Pharmaceutical Education Pre-Doctoral Fellowship, Center for Clinical and Translational Science and Training, and Imaging Research Center. It was supported by the National Center for Research Resources and the National Center for Advancing Translational Sciences, National Institutes of Health, through Grant 8 UL1 TR000077-05. Body surface area (BSA) • Body height • Body weight • Dubois formula • Sendroy and Collision Chart

There are many equations available in order to calculate the body surface area (BSA) based on the height and weight (Sendroy and Collison 1966). Some of them are as follow:

$$BSA (m^2) = \frac{\sqrt{\text{height (cm)} \times \text{weight(kg)}}}{3600}$$

Dubois formula:

$$BSA (m^2) = 0.007184 \times \text{Weight}^{0.425} \times \text{Height}^{0.725}$$

$$BSA (m^2) = \frac{\sqrt{\text{Height (in.)} \times \text{weight (lb)}}}{3131}$$

In 1960, J Sendroy et al. constructed a chart for calculating the BSA based on the weight and height. This chart has been adapted for children shorter than 95 cm (Fig. 1) and the subjects as tall as 85–200 cm (Fig. 2) (Sendroy and Collison 1966).

1 Anatomical Constants (Averages)

1.1 Tissue Retraction Following Processing for Histology (Jouanny et al. 1993)

Young people	38–58 %
Aged people	12 %

1.2 Body Surface Area

- Standard figure in adults $\approx 1.8 \text{ m}^2$
- Du Bois and du Bois' formula $A = 71.84 \approx \text{Weight}^{0.425} \approx \text{Height}^{0.725}$ (Du Bois and du Bois 1916) (weight in kg, height in cm, and area in cm^2) Example: for 63 kg and 1.61 m the skin area is 1.66 m^2

When the body surface area is less than 0.6 m^2 , Boyde's formula would be more accurate (Pittet et al. 1979):

- Boyde's formula $A = 3.207 \times 10^{-4} \times \text{Weight}^{(0.7285-0.0188 \log \text{weight})} \times \text{Height}^{0.3}$ (Pittet et al. 1979) (weight in g, height in cm, and area in cm^2)
- Wallace's fractional distribution (Wallace 1951): Head and neck 9 %, each upper limb 9 %, each lower limb 18 %, anterior trunk 18 %, posterior trunk 18 %, genitalia 1 %
- Lund and Browder's fractional distribution (% of total body surface area) (Lund and Browder 1944):

Age (years)	Head	Trunk, neck, genitalia	Upper limbs	Lower limbs
0	19	34	19	28
1	17	34	19	30
5	13	34	19	34
10	11	34	19	36
15	9	34	19	38
Adult	7	34	19	40

At all ages palm area $\approx 1 \%$ of body area

Berkow's fractional distribution (Berkow 1931):

Body anterior aspect (total = 51%)	
Face	3 %
Anterior trunk (total = 20%)	
Neck + upper third	7 %
Middle third	6 %
Lower third + genitalia	7 %

(continued)

Upper limbs anterior aspect (total = 9%)	
Arms	3.5 %
Forearms	3.25 %
Hands	2.25 %
Lower limbs anterior aspect (total = 19%)	
Thighs	9.5 %
Legs	6.5 %
Feet	3 %
Body posterior aspect (total = 49 %)	
Head	3 %
Posterior trunk (total = 18 %)	
Neck + upper half	9 %
Lower half	9 %
Upper limbs posterior aspect (total = 9 %)	
Arms	3.5 %
Forearms	3.25 %
Hands	2.25 %
Lower limbs posterior aspect (total = 19 %)	
Thighs	9.5 %
Legs	6.5 %
Feet	3 %
Children (see also maps, ► Chap. 152, "Body Surface Area")	
Trunk	40 %
Head	6 % + (12 minus age) %
Lower limbs	38 % + (12 minus age) %

1.3 Special Areas

Scalp area, 400–500 cm²

Palm area (Mahler et al. 1983):

	Male (<i>n</i> = 22)	Female (<i>n</i> = 18)
Area (cm ²)	146 ± 14	118 ± 10
% Body area	0.76 ± 0.10	0.70 ± 0.07

Forefinger last phalange (ventral aspect) length
(Long and Finlay 1991):

Male	2.6 ± 0.15 cm (<i>n</i> = 16)
Female	2.4 ± 0.10 cm (<i>n</i> = 14)

1.4 Skin Volume In Vivo (Calculated for 18,000 cm² Body Area)

Male	3.8 dm ³	for 1.3 mm (mean skin thickness)
Female	3.2 dm ³	for 1.1 mm (mean skin thickness)

1.5 Skin Weight in Vivo (Calculated for 18,000 cm² Body Area)

Skin weight in vivo = [in vitro skin density ($d = 1.18$) \times volume] + blood density ($d = 1.06$) \times 500 ml

Male	5.0 kg	(of which 0.5 kg blood)
Female	4.3 kg	(of which 0.5 kg blood)

1.6 Skin Thickness

1.6.1 Ultrasound (20 MHz) Measurement (mm) (Black 1969)

Site	Male	Female
Forehead	2.19	1.79
Cheek	1.83	1.49
Neck	1.61	1.34
Nape	2.09	1.92
Site	Male	Female
Anterior chest	1.92	1.77
Abdomen	1.88	1.62
Back	2.62	2.33
Loins	2.21	2.09
Arm, anterior aspect	1.53	1.45
Arm, posterior aspect	1.21	1.05
Forearm, anterior aspect	1.31	1.12
Forearm, posterior aspect	1.42	1.36
Dorsum hand	1.50	1.26
Palm	1.48	1.50
Thigh, anterior aspect	1.59	1.42
Thigh, posterior aspect	1.51	1.46
Leg, anterior aspect	1.42	1.34
Leg, posterior aspect,	1.34	1.30
Ankle	2.01	2.08
Dorsum foot	1.74	1.49
Sole	1.60	1.53

	Males, 28.3 \pm 6.2 years ($n = 30$)	Females (Spalteholz 1927), 27.8 \pm 8.0 years ($n = 30$)
Forehead	1.78 \pm 0.14 (\pm SD)	1.55 \pm 0.20
Volar forearm	0.92 \pm 0.09 (\pm SD)	0.90 \pm 0.11

1.6.2 Xeroradiography (Black 1969) (mm)

Volar forearm

Male	1.3 mm
Female	1.1 m

1.6.3 Magnetic Resonance Imaging (Querleux et al. 2002)

Upper dorsal thigh	
Male	1.71 ± 0.24 (n = 23)
Female without cellulite	1.58 ± 0.21 (n = 20)
Female with cellulite	1.87 ± 0.39 (n = 21)

1.6.4 Neonates Skin Thickness (A-mode Echography) (n = 48) (Petersen et al. 1995)

Weight (g)	Abdomen (±SD)	Back (±SD)
1095	0.47 ± 0.05	0.52 ± 0.06
1810	0.55 ± 0.05	0.71 ± 0.04
1940	0.61 ± 0.09	0.65 ± 0.06
2900	0.65 ± 0.09	0.76 ± 0.05
3390	0.67 ± 0.08	0.78 ± 0.06
3890	0.67 ± 0.08	0.76 ± 0.09
4750	0.80 ± 0.08	0.85 ± 0.06

1.7 Skin Relief

First order furrows	70–200 µm
Second order furrows	20–70 µm
Small wrinkles	0.2–1 mm
Common wrinkles	>1 mm

1.8 Stratum Corneum

Thickness	8–20 µm	(Holbrook et al. 1974)
Volar forearm	16.8 ± 1.1 µm	(Corcuff et al. 1993)
Hip	11.8 ± 1.4 µm (SE) (Anderson and Cassidy 1973)	
Palms and soles	0.5–1 mm	

(continued)

Number of cell layers	19 ± 1.2 (SE)	(Anderson and Cassidy 1973)
Face	9 ± 2 (84) (Japanese) (M ± SD, n)	Holbrook et al. (1974)
Eyelid	9 ± 1 (8)	
Cheek	10 ± 3 (43)	
Nose	10 ± (2)	
Nasolabial fold	7 ± (2)	
Lip	10 ± (2)	
Ear	7 ± 2 (8)	
Periauricular	10 ± 3 (3)	
Scalp	12 ± 2 (12)	
Neck	10 ± 2 (5)	
Shoulder	13 ± 2 (3)	
Chest	13 ± 4 (9)	
Back	13 ± 3 (18)	
Abdomen	14 ± 4 (44)	
Buttock	12 ± 4 (20)	
Genitalia	6 ± 2 (9)	
Arm, outer	13 ± 4 (13)	
Arm, inner	14 ± (2)	
Forearm volar	16 ± 4 (4)	
Thigh	16 ± 4 (31)	
Leg posterior	18 ± 5 (5)	
Hand dorsum	25 ± 11 (10)	
Palm	50 ± 10 (8)	
Foot dorsum	30 ± 6 (7)	
Sole	55 ± 14 (12)	
Heel	86 ± 36 (5)	
Corneocytes number (volar forearm)	0.7 × 10 ⁶ to 1.5 × 10 ⁶ /cm ²	(Hunter et al. 1956)
Corneocytes thickness	0.3 μm	(Holbrook et al. 1974) (Plewig et al. 1983) (Ya-Zian et al. 1999)
Corneocyte diameter	26–45 μm	(Bartolone et al. 1991)
Corneocyte area	1000 μm ²	(Plewig et al. 1983)
Corneocyte thickness of keratin filaments	10–15 nm	
Intercellular spaces width	25 nm	(Lundström et al. 1994)
	0.1 μm	(Ya-Zian et al. 1999)
Corneodesmosomes		
Length	290 nm	(Lundström et al. 1994)
Thickness	25 nm	(Lundström et al. 1994)
Corneodesmosomes	Involved fraction of cell membranes, 6.8 %	(Lundström et al. 1994)

1.9 Viable Epidermis (Stratum Malpighi)

Thickness	30–80 μm	
Volar forearm	36 \pm 4 μm	(Corcuff et al. 1993)
Volar forearm (23–34 years)	64.2 \pm 4.9 ($n = 7$) (histology)	(Timar et al. 2000)
Volar forearm (44–54 years)	72.2 \pm 14.1 ($n = 7$) (histology)	(Timar et al. 2000)
Buttocks	69.6 \pm 10.2 ($n = 67$) (histology)	(Therkildsen et al. 1998)
Number of cell layers	5–10	
Volar forearm (23–34 years)	4.4 \pm 0.5 ($n = 7$) (histology)	(Timar et al. 2000)
Volar forearm (44–54 years)	4.6 \pm 0.4 ($n = 7$) (histology)	(Timar et al. 2000)
Epidermal cells number/ mm^2	73,952 \pm 19,426 (from 24 biopsies)	(Bauer et al. 2001)
Keratinocytes number/ mm^2		(Corcuff et al. 1993)
Stratum basale	7000	
Stratum spinosum	4000	
Stratum granulosum	1500	
Langerhans cells density	2–4 % of cells	(Banchereau et al. 1998)
	1/53 other epidermal cells (1.86 %)	(Bauer et al. 2001)
Langerhans cells number/ mm^2	460–1000	(Oxholm et al. 1987)
	1394 \pm 321 (breast, from 24 biopsies)	(Bauer et al. 2001)
Melanocytes	0.3–2.4 % of epidermal volume	(Zelickson and Mottaz 1968)
Cell diameter	30–40 μm	
Melanosome dimensions	$\sim 1 \times 0.4 \times 0.4 \mu\text{m}$	
Intercellular spaces	1.5–1.9 % of epidermal volume	(Zelickson and Mottaz 1968)
Histologic section: dermo-epidermal junction: length versus a straight line	1.1–1.2	(Frost and van Scott 1966)
Histologic section: epidermis area along 1 cm	44 $10^{-4} \mu\text{m}^2$	(Frost and van Scott 1966)
Histologic section: dermal papillae area along 1 cm	9 $\times 10^{-4} \mu\text{m}^2$	(Frost and van Scott 1966)
Keratinocyte nucleus average diameter	4.60 μm	(Barton 1988)

(continued)

Keratinocyte nucleolus average diameter	1.22 μm	(Barton 1988)
Desmosomes length		(Lundström et al. 1994)
Basal layer	0.13 μm	
Spinous and granular layers	0.26 μm	
Hemi-desmosomes	0.19 μm	
Desmosomes: involved fraction of cell membranes		(Lundström et al. 1994)
Basal layer	4 %	
Spinous and granular layers	11 %	
Dermo-epidermal junction length over a straight line (interdigitation index) (histology)		(Timar et al. 2000)
Volar forearm (23–34 years)	1.333 \pm 0.153 ($n = 7$)	
Volar forearm (44–54 years)	1.106 \pm 0.090 ($n = 7$)	

1.10 Dermis

Subpapillary dermis thickness	50–100 μm	
Peri-adnexial dermis thickness	20–70 μm	
Reticular dermis thickness	0.8–1.2 mm	
% Area of elastic fibers (by histology)		(Timar et al. 2000)
23–34 years ($n = 7$)	4.9 \pm 1.9	
44–54 years ($n = 7$)	11.6 \pm 1.6	
% Area of intercellular GAGs (by histology)	23–34 years ($n = 7$)	(Timar et al. 2000)
44–54 years ($n = 7$)	10.7 \pm 2.2	
Collagen fibers thickness	2–20 μm	
Collagen fibrils wavelength	3 μm	
Collagen fibrils thickness	50–70 nm	
Reticular dermis		
24 weeks fetus	\cong 50 nm	(Quaglino et al. 1996)
At birth	\cong 100 nm	
Adults	110–115 nm	
Beyond 60 years	\cong 100 nm	
Elastic fibers thickness	0.1–0.4 μm	(Pope 1998)
Oxytalan fibers	13–14 nm	(Pope 1998)
Fibrillin fibrils	1.0–1.3 nm	(Pope 1998)
Basement membrane thickness	50–100 nm	(Timpl and Brown 1996)
Dendritic cells	2–3 % of dermal cells	(Banchereau et al. 1998)

Table 1 Subcutaneous fat thickness, mm mean \pm 2 SE, skin fold (Carpentier and Maricq 1990)

Age group	Males Upper arm	Hip	n	Females Upper arm	Hip	n
5–9	5.4 \pm 0.7	14.8 \pm 1.8	17	6.7 \pm 0.8	18.4 \pm 2.2	9
10–14	5.5 \pm 0.6	16.3 \pm 1.9	24	8.3 \pm 1.0	26.4 \pm 3.2	17
15–19	5.8 \pm 0.6	10.0 \pm 1.2	22	10.9 \pm 1.2	30.5 \pm 3.8	25
20–29	6.3 \pm 0.7	9.7 \pm 1.1	42	10.9 \pm 1.3	31.3 \pm 3.5	53
30–39	6.2 \pm 0.7	8.6 \pm 1.0	22	10.4 \pm 1.2	31.5 \pm 3.9	21
40–49	6.3 \pm 0.7	9.1 \pm 1.1	27	10.6 \pm 1.2	31.6 \pm 4.0	20
50–69	6.4 \pm 0.9	9.4 \pm 1.0	13	11.1 \pm 1.4	29.1 \pm 4.1	14
70–91	5.8 \pm 0.8	8.3 \pm 1.0	13	9.1 \pm 1.1	13.3 \pm 1.8	22

1.11 Subcutis

Subcutaneous fat thickness, mm mean \pm 2 SE, skin fold (Lever et al. 1983) (Table 1):

Subcutaneous fat thickness at upper dorsal thigh (magnetic resonance imaging) (Uitto et al. 1989):

Males	6.64 \pm 3.16 (SE)
Females without cellulite	8.34 \pm 2.44 (SE)
Females with cellulite	34.02 \pm 5.42 (SE)

Neonate subcutis thickness (mm) ultrasound
A mode (n = 7) (Petersen et al. 1995):

Body weight (g)	Abdomen	Back
1095	0.65 \pm 0.07	0.77 \pm 0.10
1810	0.78 \pm 0.13	0.95 \pm 0.13
1940	1.52 \pm 0.20	1.53 \pm 0.16
2900	1.67 \pm 0.17	1.87 \pm 0.19
3390	1.80 \pm 0.16	1.74 \pm 0.23
3890	1.95 \pm 0 – 31	1.84 \pm 0.27
4750	2.90 \pm 0.22	2.45 \pm 0.24

Dermis-subcutaneous tissue irregularity index
(Querleux et al. 2002):

Males	1.91 \pm 0.24	(n = 20)
Females without cellulite	2.08 \pm 0.12	(n = 17)
Females with cellulite	2.29 \pm 0.32	(n = 16)

1.12 Blood Capillaries

Nail-fold		
Papillary loops number/mm	8.4 \pm 1 (n = 118)	(Jouanny et al. 1993)
	7.2 \pm 1.5 (n = 20)	(Gasser and Buhler 1992)

(continued)

Ascending loop internal diameter (i.e. of RBC column)	10.8 ± 30 µm (n = 396)	(Mahler et al. 1983)
Descending loop internal diameter (i.e. of RBC column)	12.0 ± 2.7 µm (n = 396)	(Mahler et al. 1983)
Ascending loop internal diameter (plasma, FITC-alb)	15.0 ± 2.5 µm (n = 396)	(Mahler et al. 1983)
Descending loop internal diameter (plasma, FITC-alb)	16.7 ± 3.0 µm (n = 396)	(Mahler et al. 1983)
Papillary loop		
Length	0.3–0.4 mm	(Spalteholz 1927)
Papillary loop width	62.6 µm	(Spalteholz 1927)
Papillary loop involved skin area	0.027–0.040 mm ²	(Spalteholz 1927)
Volar forearm capillaries number/mm ²		
Using capillaroscopy	31.2 ± 7.0 (n = 10)	
Using plasma, FITC-alb	28.9 ± 5.4 (n = 10)	
Subepidermal plexus vessels external diameter		
Horizontal capillaries	10–15 µm	
Ascending arteriole	17–26 µm	
Post-capillary venule	18–35 µm	
Deeper vessels (transfer vessels) external diameter		
Arterioles	30–150 µm	
Venules	50–300 µm	

1.13 Lymphatic Capillaries (Limbs)

Mean diameter	91 ± 22 µm	(Bollinger et al. 1981)
---------------	------------	-------------------------

1.14 Pilo-Sebaceous Follicles

Total number		(Ebling et al. 1979)
Whole body	5 × 10 ⁶	
Head and face	1 × 10 ⁶	
Scalp	1 × 10 ⁵	
Number/cm ²	(mean ± SEM)	(Cunliffe et al. 1976)
Forehead	330 ± 20	
Chest (medial)	59 ± 10	
Upper back (medial)	72 ± 2	
Upper back (lateral)	84 ± 4	
Hair density (per cm ²)		
Scalp		
Terminal hair	200–300	(Ebling et al. 1979)

(continued)

Vellus hair	5–15 %	(Guarrera et al. 1997) (Hayashi et al. 1991)
Forehead	439 ± 24 (±SEM)	(Blume et al. 1998)
Cheek (female)	416 ± 37 (±SEM)	(Blume et al. 1998)
Shoulder (male)	68 ± 5 (±SEM)	(Blume et al. 1998)
Chest	57 ± 3 (±SEM)	(Blume et al. 1998)
Back	85 ± 4 (±SEM)	(Blume et al. 1998)
Scalp terminal hair thickness		
Caucasians	50–90 µm (oval in section)	
Mongoloids	120 µm (round)	
Scalp vellus hair thickness	<30 µm	
Scalp hairs oval in section diameters' ratio	0.63–0.91	(Van Neste et al. 1985)
Scalp hair bulb volume		
Papilla	338 × 10 ³ µm ³	(Van Scott et al. 1958)
Matrix	3370 × 10 ³ µm ³	
Scalp hair daily growth	>0.2 mm/day	
Keratin production	0.2–0.3 g/day	

Body hairs

Mean length (Dawber et al. 1998):

	Males (mm)	Females (mm)
Thigh	17.0	5.5
Arm (outer)	9.0	6.0

Maximum length (Blume et al. 1998):

	15–20 years (mm)	25–30 years (mm)
	(±SEM)	(±SEM)
Forehead	2.0 ± 0.3	1.6 ± 0.5
Cheek (female)	4.1 ± 0.5	3.4 ± 0.4
Shoulder (male)	6.0 ± 0.4	4.3 ± 0.4
Chest	4.6 ± 0.2	3.9 ± 0.4
Back	6.2 ± 0.4	5.0 ± 0.4

Pilo-sebaceous duct exit size (mm²) (mean ± SEM), (Cunliffe et al. 1976):

Forehead	2.0 ± 0.1
Chest (medial)	4.3 ± 0.3
Upper back (medial)	3.0 ± 0.2
Upper back (lateral)	3.9 ± 0.2

Hair cells dimensions:

Cuticle	0.5–1 µm × 45 µm
Cortex	2–5 µm80 × 115 µm

Hair cortex internal components, (Atkins et al. 1974):

×Helix	1 nm
Protofibril	3–5 nm
Microfibril	8–15 nm
Macrofibril	200–500 nm

1.15 Nails

Total thickness at distal margin:

Fingers	0.3 mm (d5), 0.5 mm (thumb)
Toes	0.5 mm (d5), 0.8 mm (dl)

Nail thickness contributions (Achten and Parent 1983):

Upper dorsal nail	33 % of total nail thickness
Lower dorsal nail	66 % of total nail thickness

Big toe-nail (measurements on eight normal avulsed nails) (Johnson and Shuster 1993):

	Proximal end	End of lunula	Onychodermal band
% of total length	0	34.8	100
% of maximal thickness	27	19	100

Nail thickness contributions:

Nail bed	22 %
Matrix	78 %

Big toe-nail (measurements on 54 normal avulsed nails) (Johnson and Shuster 1994):

– Mean thickness:

Male	1.65 ± 0.43
Female	1.38 ± 0.20

	Proximal end	End of lunula	Onychodermal band
Thickness mean (mm)	0.37 ± 0.0004	1.08 ± 0.0008	1.38 ± 0.01
Thickness range	0.26–0.55	0.85–1.31	0.85–1.76

Onychocytes diameter, (Achten and Parent 1983):

Upper dorsal nail	2.2 µm
Lower dorsal nail	5.5 µm

1.16 Eccrine Sweat Glands

Total number: $3\text{--}4 \times 10^6$

Regional counts (Szabo 1962):

Soles	620 ± 120
Forehead	360 ± 50
Cheeks	320 ± 60
Dorsum foot	250 ± 5
Forearm	225 ± 25
Abdomen and groin	190 ± 5
Chest	175 ± 35
Back and buttocks	160 ± 30
Calf	150 ± 15
Arm	150 ± 20
Thigh	120 ± 10

Eccrine tube:

Length	5 mm
Diameter	0.02–0.05 mm

2 Chemical Composition

2.1 Whole Skin (% Abdomen Skin Dry Weight) (Weinstein and Boucek 1960)

Collagen (both sexes)	76.8 ± 9.1 (<i>n</i> = 83)	
Elastin		
Males:	4.45 ± 1.4 (<i>n</i> = 17)	
Females:	3.95 ± 0.9 (<i>n</i> = 10)	
Reticulin:	0.4 % skin dry weight	(Lundström et al. 1994)
Collagen content (g/cm ² skin)	234 ± 72 (SE)	(Shuster et al. 1969)

2.2 Sebum: Standard Composition (in Weight) (► Chap. 47, "Skin Wound Healing Assessment", Ref. 9)

Squalene	12.0 %
Wax esters	26.0 %
Glycerides and free fatty acids	57.5 %
Sterols (free and esters)	4.5 %

2.3 Skin Surface Lipids of Epidermal Origin (in Weight) (► [Chap. 47, "Skin Wound Healing Assessment", Ref. 9](#))

Glycerides and free fatty acids:	65 %
Cholesterol esters:	15 %
Cholesterol:	20 %

2.4 Stratum Corneum

Proteins (corneocytes)	$2.92 \pm 0.89 \mu\text{g cm}^{-2}$ (n = 6)	(Elias 1983)
Cystine	2.9 %	Fraser, in (Leveque 1994)
Other amino acids		see Fraser, in (Leveque 1994)
Lipids	10 %	(Leveque 1994)
Lipid fractions (of weight)		(De Rigal et al. 1992)
Cholesterol esters	15 %	
Cholesterol	32 %	
Saturated fatty acids	16 %	
Ceramides	37 %	
Water (for 20–60 % atmospheric relative humidity)		
35 % of volume		(Blank et al. 1984)
$0.05\text{--}0.15 \text{ g cm}^{-3}$		(Blank 1952)
$0.12 \pm 0.01 \text{ g cm}^{-3}$ (n = 6)		(Tagami et al. 1994)

2.5 Dermis

Reticular dermis (Quaglino et al. [1996](#)) (all figures represent percentages) (Table 2):

2.6 Subcutis

Composition: upper dorsal thigh, (magnetic resonance spectroscopy) (n = 67) (Querleux et al. [2002](#)):

Water	$4.7 \pm 5.6 \%$
Unsaturated lipids	$3.7 \pm 2.3 \%$
Saturated lipids	$85.3 \pm 5.9 \%$

Table 2 Reticular dermis (Quaglino et al. 1996)

	24 weeks fetus	At birth	Adults	Beyond 60 years
Collagen/tissue ratio	24	≈60	≈70	≈40
Elastic fibers/tissue	Absent	3–4	3–4	7–8
Mesenchymal cells	20	4	1.5	1.5
Type I collagen	80 % of total collagen			(Uitto et al. 1989)
Type III collagen	15 % of total collagen			(Uitto et al. 1989)
Collagen type I/type III	5:1 to 6:1			(Uitto et al. 1989)
Mature elastic fiber		(Braverman and Fonferko 1982)		
90 % elastin				
10 % microfibrils				
Interstitial fluid	2 % proteins			
Suction blister fluid				
4.2 % proteins	55 % albumin, 45 % globulins	(Stüttgen 1965)		
3.9 ± 0.4 g/dl (n = 6)	=54 % of concentration in plasma (Braun-Falco and Rupec 1964)			

Fatty acid ratio within lipids (gas liquid chromatography) (*n* = 22 obese women) (Timpl and Brown 1996):

	Arm	Thigh	Abdominal wall
Saturated fatty acids	39.4 ± 5.1 %	33.9 ± 4.3 %	35.9 ± 4.8 %
Unsaturated fatty acids	60.6 ± 4.7 %	66.0 ± 4.1 %	67.1 ± 4.6 %

Major fatty acids: % within lipids (gas liquid chromatography) (*n* = 22 obese women) (Timpl and Brown 1996):

	Arm	Thigh	Abdominal wall
12:0	6.7 ± 2.9	6.4 ± 2.9	8.4 ± 3.4
14:0	50.1 ± 10.6	44.7 ± 11.7	50.9 ± 9.6
15:0	5.1 ± 1.4	5.0 ± 1.4	4.9 ± 1.4
16:0	278.0 ± 40.0	245.5 ± 29.3	273.2 ± 32.4
16:1	80.3 ± 17.7	107.8 ± 21.9	82.3 ± 23.9
17:0	3.5 ± 1.1	3.0 ± 1.5	3.5 ± 1.1
17:1	4.3 ± 0.9	5.1 ± 1.3	4.6 ± 1.6
18:0	50.7 ± 12.2	34.1 ± 18.1	48.3 ± 16.6
18:1	464.8 ± 9.7	485.6 ± 31.7	465.5 ± 20.2
18:2	48.0 ± 30.9	51.9 ± 27.5	48.9 ± 25.5
20:1	8.4 ± 2.4	9.4 ± 3.6	9.4 ± 4.3

2.7 Hair

Standard composition (in weight)

Keratins	85–90 %	
Water	10–13 %	
Lipids	2 %	(Leveque 1994)
Trichochromes		
Cystine	7.6 %	Fraser, in (Leveque 1994)
Other amino acids		see Fraser, in (Leveque 1994)

2.8 Nails: Mean Composition

Cystine	7.4 %	Fraser, in (Leveque 1994)
Other amino acids		see Fraser, in (Leveque 1994)
Water	9–10 % of weight (in vitro big toe-nail, $n = 8$)	(Johnson and Shuster 1993)

Nota bene: Dehydration does not change nail thickness.

Relative humidity (%)	Water content (% of weight)	(Finlay et al. 1980)
15–20	5–6	
35–45	8–10	
60	13	
80	16	
90	17–21	
100	29	

Lipid (% of dry weight) (Helmdach et al. 2000):

	Male ($n = 31$)	Female ($n = 40$)
Cholesterol sulphate	1.45 ± 0.50	1.98 ± 0.72**
4–6 ceramides	6.12 ± 0.08	9.94 ± 1.96**
1–3 ceramides ^{a, b}	26.92 ± 5.78	25.60 ± 4.14
Cholesterol	8.93 ± 2.95	13.16 ± 2.83**
Free fatty acids ^a	30.83 ± 9.65	24.20 ± 6.53*
Triglycerides	7.34 ± 2.20	5.79 ± 1.53**
Sterol and wax esters	7.47 ± 1.08	8.44 ± 0.34**
Squalene	2.71 ± 0.48	1.50 ± 1.28**
Unidentified	7.56 ± 2.38	8.11 ± 3.08

Difference between males and females significant at 0.01 (*) and 0.001 (**) levels

^aInfants excluded (two males and four females)

^bInfants: 1–3 ceramides: mean = 4.59 %; free fatty acids: mean = 12.07 %

2.9 Sweat (► Chap. 76, "Scalp Sebaceous Function Assessment", Ref. 7)

Na ⁺ (mM)	<40
K ⁺ (mM)	4–20
Cl ⁻ (mM)	<20
CO ₃ H ⁻ (mM)	15–20
Ammonia (mM)	0.5–8
Lactates (mM)	10–15
Urea (mg/ml)	0.15–0.25
Glucose (:g/ml)	2–5
Proteins (mg/ml)	0.15–0.25

3 Functional Constants

3.1 Current Minimal Erythema Dose (MED) for Caucasians

UVB	30 mJ cm ⁻²
UVA	30 J cm ⁻²

3.2 Stratum Corneum Renewal

Daily production	1.15 ± 0.09 new layer	(Johannesson et al. 1978)
Desquamation		
Forearm	1309 ± 328 cells cm ⁻² h ⁻¹	(Edwards et al. 1995)
Forehead	2083 ± 481 cells cm ⁻² h ⁻¹	(Christensen et al. 1978)
Other body sites		See ► Chap. 25, "Stratum Corneum Desquamation", Sec ► 4
Daily protein loss forehead	12.1 ± 4.7 µg cm ⁻²	(Christensen et al. 1978)
Renewal time		
Overall	15 days	
Forearm	18.5 ± 4.6 days	(Roberts et al. 1980)
Forehead	6.3 ± 1.4 days	(Baker et al. 1967)
Abdomen	25.9 ± 5.4 days	(Roberts et al. 1980)
Other body sites		(Jansen et al. 1974)

3.3 Stratum Malpighi Renewal

Renewal time	15 days	
Basal cells distribution		(Mommers et al. 2000)
G ₀ phase	30 %	
Cycling	10 %	

(continued)

Number of mitoses in basal layer		
7.7 per cm length		(Frost and van Scott 1966)
1 out of 600 cells		(Fischer and Maibach 1971)
Mitotic index	1.59	(Fischer and Maibach 1971)
Proliferation index (thymidine or BrdU)	► Chap. 36, "Epidermal Physiology", Ref. 22	
Basal layer only	5–6 % of cells in S-phase	
Basal + 3 suprabasal layers	46 % of cells in S-phase	
Proliferation index (thymidine)		(Marks et al. 1987)
Sun unexposed sites	4.7 ± 2.2 (n = 19)	
Sun exposed sites	8.6 ± 2.1 (n = 19)	
Cell cycle duration		
G1 phase	7.6 h	(Mommers et al. 2000)
S phase	5.3–10.3 h	(Galand et al. 1989)
G2 + M phases	11 h	(Knaggs et al. 1994)
M phase	1.5 h	(Knaggs et al. 1994)
Whole cycle	50–282 h	(Knaggs et al. 1994)
28 h		(Mommers et al. 2000)
Transit time from basal layer to stratum corneum	6–27 days	(Knaggs et al. 1994)

3.4 Hair Follicle

Proliferation index, 11 % (Knaggs et al. 1994)

Scalp hair common stage formula: Anagen

80–90 %, telogen 10–20 %, catagen <1 %

Scalp hair stages:

	Male	Female	
Anagen with sheath	>55 %	>65 %	
Anagen without sheath	>20	>20	
Dystrophic anagen	<1,5	<1	
Catagen	<1	1 %	
Telogen	<25	<15	
% anagen hairs	Male (±SEM)	Female (±SEM)	
Body site (► Chap. 44, "In Vivo Magnetic Resonance Imaging of the Skin", Ref. 10)			
Forehead	49.5 ± 4.8	48.5 ± 4.5	
Cheek		46.4 ± 4.8	
Chest	34.7 ± 2.9	42.2 ± 2.4	
Shoulder	32.8 ± 2.2		

(continued)

	Male	Female	
Back	32.0 ± 2.0	30.9 2.5	
	Anagen	Telogen	
Stage duration			(Saitoh et al. 1970)
Scalp, terminal hair	3–7 years	3 months	
Scalp, vellus hair	4–26 weeks		(Ebling et al. 1979)
Arm	9 weeks	15 weeks	
Leg	16 weeks	22 weeks	
Dorsum finger	8 weeks	10 weeks	
Thigh(male)	8 weeks		(Saitoh et al. 1970)
Thigh (female)	3 weeks		(Saitoh et al. 1970)
Forehead	60.8 ± 4.9 days (±SEM)		(Blume et al. 1998)
Cheek (female)	78.6 ± 14.6 days (±SEM)		(Blume et al. 1998)
Shoulder (male)	51.2 ± 4.6 days (±SEM)		(Blume et al. 1998)
Back (female)	41.8 ± 1.8 days (±SEM)		(Blume et al. 1998)
Back (male)	49.4 ± 2.9 days (±SEM)		(Blume et al. 1998)
Chest	45.6 ± 1.9 days (±SEM)		(Blume et al. 1998)

Anagen duration (days) (► Chap. 44, "In Vivo Magnetic Resonance Imaging of the Skin", Ref. 12):

	Males	Females
Thigh	54	22
Arm (outer)	28	22

Daily growth (mm)

Scalp	0.3–0.5 mm	(Saitoh et al. 1970)
Thigh (male)	0.38 mm	
Thigh (female)	0.21 mm	
Chest	0.44 mm	
Beard	0.27 mm	
Back	0.134 ± 0.010 (SEM)	(Blume et al. 1998)
Forehead (male)	0.037 ± 0.005 (SEM)	
Forehead (female)	0.037 ± 0.005 (SEM)	
Cheek (female)	0.060 ± 0.007 (SEM)	
Shoulder (male)	0.119 ± 0.011 (SEM)	

Scalp: daily hair length production, 30–50 m
(i.e., 0.3–0.5 g)

Scalp: current (normal) daily hair loss, <70
(Kligman 1961)

Resistance to plucking (g):

Scalp hair	48 ± 18 (n = 10)	(Cunliffe et al. 1976)
Chest hair	71 ± 10 (n = 110)	(Chapman 1992)

3.5 Sebum

Casual level (forehead)	100–200 $\mu\text{g cm}^{-2}$	
Other body sites		see ► Chap. 13, “Sebaceous Physiology”
Casual level recover time	3–4 h; 50 % within 33 min	(Downing et al. 1981)
Infundibulum reservoir content	80 % of casual level	
Skin surface sebum spreading coefficient	1–10 mJ m^{-2}	
Maximal <i>spontaneous</i> sebum creep up the hair shaft	2 cm	
Sebaceous gland: cell transit time from basal layer to excretory canal	3 sem	
Sebaceous gland secretion rate	6–25 $\text{mg cm}^{-2} \text{h}^{-1}$	(Jani 1992) (Downing et al. 1981)

3.6 Nails

Daily linear growth:

Standard figures		
Hands	0.1 m	
Feet	0.05 mm	
Maximal rate (25 years)		(Orentreich et al. 1979)
Male	0.9 mm/week	
Female	0.7 mm/week	
Rate over life	0.5 % decrease per year, to 50 % reduction by 60 years of age, then stable	(Orentreich et al. 1979)
Temperature dependence	0.08 mm/week at 16 °C 2.0 mm/week at 32 °C	(Orentreich et al. 1979)
Circadian rhythm	5 $\mu\text{m h}^{-1}$ by midday 1 $\mu\text{m h}^{-1}$ by midnight	(Orentreich et al. 1979)

Thickness increase rate, (Johnson and Shuster 1993):

Lunula	0.13 mm/1.41 % length increment
Bed	0.02 mm/0.22 % length increment

3.7 Eccrine Sweat Glands

Fraction of active glands	50 %	(Knip 1969)
Sweat excretion frequency	0.3–12 min^{-1}	
Excretion rate per gland	4–28 nl min^{-1}	
Global sweating rate	1–3 $\text{mg min}^{-1} \text{cm}^{-2}$	(Cotter et al. 1995)
Heat loss per gland working as a heat pipe	9.68 $\times 10^{-6}$ W	
Sweating threshold	Max. by 18 h	(Crockford et al. 1970)

3.8 Skin Metabolism

Metabolic oxygen consumption at 37 °C	$2.6 \times 10^{-3} \text{ ml g}^{-1} \text{ min}^{-1}$	(Severinghaus et al. 1978)
Metabolic oxygen consumption at 45 °C (as in tcPO ₂ measurement)		
Normal skin	$3.7 \times 10^{-3} \text{ ml g}^{-1} \text{ min}^{-1}$	(Severinghaus et al. 1978)
Psoriasis (diseased skin)	$5.4 \times 10^{-3} \text{ ml g}^{-1} \text{ min}^{-1}$	(Ott et al. 1984)
Metabolic heat produced by epidermis		
Normal skin	$0.16 \text{ cal min}^{-1} \text{ cm}^{-2}$	► Chap. 58, “Transcutaneous Oxygen Pressure”
	(4 % increase per °C)	
Psoriasis (diseased skin)	$0.27 \text{ cal min}^{-1} \text{ cm}^{-2}$	(Ott et al. 1984)
Total heat loss ^a at rest and in thermal neutrality	$30 \text{ g h}^{-1} \text{ m}^{-2}$	

^aFrom skin and lung

Skin temperature (naked subject)
(► Chap. 123, “Skin Thermal Imaging”):

	At 20 °C	At thermal neutrality
Forehead	32.0 °C	34.8 °C
Forearm	27.7 °C	33.6 °C
Dorsum foot	20.0 °C	31.1 °C
Other body sites, see ► Sect. 2.1		

3.9 Skin Microbiology (► Chap. 4, “The Skin Surface Ecosystem: A Presentation”)

Microbial density at the skin surface (for details, see ► Chap. 4, “The Skin Surface Ecosystem: A Presentation”, Tables 3 and ► 4):

Scalp	$1.0 \times 10^6/\text{cm}^2$ to $1.2 \times 10^6/\text{cm}^2$
Forehead	$4.4 \times 10^6/\text{cm}^2$
Upper limbs (extremity)	$1.7 \times 10^3/\text{cm}^2$
Lower limb (extremity)	$4.4 \times 10^3/\text{cm}^2$
Axilla	$4.8 \times 10^3/\text{cm}^2$
Perineum	$4.3 \times 10^7/\text{cm}^2$
Toe webs	$1.4 \times 10^7/\text{cm}^2$
Staphylococcus aureus carriage,	$>10^6/\text{cm}^2$

3.10 Skin Blood Flow

Skin blood volume		(Martineaud et al. 1977)
At rest	9 % of total blood volume	
Vasodilated skin	12 % of total blood volume	
Global skin blood flow		(Martineaud et al. 1977)
At rest	0.5 l min ⁻¹	
Moderate exercise	0.9 l min ⁻¹	
Intense exercise + high outside temperature	7 l min ⁻¹	
Subpapillary dermis skin blood flow (volar forearm)	30–45 ml min ⁻¹ per 100 g tissue	
Resting skin blood flow (xenon clearance)		
Forearm	5.1 ± 1.7 ml min ⁻¹ per 100 g tissue	(Sejrsen 1969)
Lateral Malleola	6.2 ± 1.1 ml min ⁻¹ per 100 g tissue ^b	(Cardot et al. 1977)
Cheek with beard	15.2 ± 3.0 ml min ⁻¹ per 100 g tissue	(Sejrsen 1969)
Capillary perfusion pressure (nail-fold capillaries)		
Ascending limb	35.3 ± 6.5 torr	(Stüttgen et al. 1989)
Descending limb <?1>	20.8 ± 5.6 torr	(Stüttgen et al. 1989)
	16–21 torr	(Hahn et al. 1998)
Capillary pulse amplitude	2–5 torr	(Hahn et al. 1998)

^a100 g subpapillary dermis – 5000 cm² skin area (Coleman et al. 1986)

^b100 g skin tissue – 850 cm² skin area

Capillary perfusion pressure (forehead capillaries), (Agache et al. 1993) (Table 3):

3.11 Skin Lymphatics

Lymphatic flow rate (dorsum foot)	10.3 ± 4.1 μm s ⁻¹	(Franzeck et al. 1996)
Intralymphatic pressure (dorsum foot)		(Spiegel et al. 1992)
Subject lying	3.9 ± 4.2 torr	
Subject sitting	9.3 ± 3.0 torr	

3.12 Circadian Rhythms (Solar Time)

See Table 4.

Table 3 Capillary perfusion pressure (Tur et al. 1983)

	Children	Young adults	Elderly
Capillary systolic pressure (csp)	25 ± 4 torr	65 ± 8 torr	150 ± 10 torr
Ratio csp/arterial pressure (arm)	42 %	42 %	54 %
Diastolic pressure	15 torr	18 torr	16 torr
Arterioles compliance index (▶ Sect. 2)	6.0	3.5	1.8
Skin blanching pressure	30 torr		(Agache et al. 1993)
Red blood cells velocity (nail-fold capillaries)	0.7–1.1 mm/s		(Hahn et al. 1998)
At 23 °C	0.65 ± 0.27 (n = 20)		(Gasser and Buhler 1992)
After warming	0.87 ± 0.30 (n = 20)		(Gasser and Buhler 1992)
After cooling	0.21 ± 0.08 (n = 20)		(Gasser and Buhler 1992)
Vasomotion frequency	6–10 min ⁻¹ (∇ waves); 1–2 min ⁻¹ (∇ waves)		(Kastrup et al. 1989)
Cutaneous intravascular partial pressure (forearm, 44 °C)			(Hansen et al. 1980)
O ₂	64.3 ± 18.4 torr (n = 10)		
CO ₂	46.8 ± 3.6 torr (n = 10)		
Transcutaneous oxygen partial pressure (tcPO ₂) at 44 °C			▶ Chaps. 57, “Carbon Dioxide Transcutaneous Pressure” and ▶ 58, “Transcutaneous Oxygen Pressure”
Chest	80 torr		
Dorsum foot	72 torr		
Forearm	70 torr		
Other body sites, variation with sex and age			▶ Sect. 2.2
Transcutaneous oxygen index (TCI) = tcPO ₂ /PaO ₂			(Vermold et al. 1979)
Premature	–1		
Child	–0.9		
Adult	–0.8		
Mouth-skin (forearm) transit time			(Hansen et al. 1980)
O ₂	51 s		
CO ₂	61 s		
N ₂	94 s		
He	52 s		
tcPO ₂ decreasing rate under arterial occlusion (forearm)			
At 44 °C	130 torr min ⁻¹		
At 37 °C	90 torr min ⁻¹		(Severinghaus et al. 1978)
Cutaneous veins filling time (plethysmography)	35 ± 12 s		

Table 4 Circadian rhythms (solar time) of the skin biometrologic parameters

Event	Max. by	Min. by	Site	Reference
Stratum corneum renewal time	17 h	09 h	Forearm	(Takahashi et al. 1987)
Sweating threshold	18 h			(Crockford et al. 1970)
Growth of nails	12 h			(Orentreich et al. 1979)
TEWL	24 h	12 h	Forehead	(Clarys et al. 1997)
TEWL	18 h	06 h	Forearm	(Clarys et al. 1997)
TEWL (95 % c.i.)	6.00 ± 4.30 h		Forearm	(Le Fur et al. 2001)
TEWL (95 % c.i.)	11.38 ± 2.30 h		Face	(Le Fur et al. 2001)
Skin temperature	23 h	10 h	Forehead	(Le Fur et al. 2001)
Skin temperature (95 % c.i.)		0.48 ± 3.50 h	Forearm	(Le Fur et al. 2001)
Skin temperature	24 h	14 h	Forearm	(Le Fur et al. 2001)
Skin temperature	02 h	12 h	Shin	(Le Fur et al. 2001)
pH	14 h	02 h	Forearm	(Le Fur et al. 2001)
pH	11 h	24 h	Shin	(Le Fur et al. 2001)
pH	Morning	Afternoon	Axilla	(Burry et al. 2001)
Sebum casual level (95 % c.i.)	13.18 ± 3.30 h		Forehead	(Le Fur et al. 2001)
Sebum casual level	13.30–15.30 h	05.30 h	Forehead	(Downing et al. 1981)

Keywords

Chemicophysical constants • Connective tissue fibers in vitro • Corneocyte • Corneodesmosome • Dermis and subcutis • Elastic phase • Electrical constants • Hair • Mass density in vitro • Nails • Optical constants • Sebum • Skin • Stratum corneum • Sweat • Thermal constants • Ultrasound (25 MHz) attenuation • Ultrasound (25 MHz) impedance

• Ultrasound (25 MHz) velocity • Viable epidermis • Whole skin in vitro • Whole skin in vivo • Skin acoustic constants • Skin Mechanical constants • Skin optical constants • Skin thermal constants • Skin electrical constants • Skin chemicophysical constants

1 Mass Density In Vitro (kg/dm³)

Whole skin	1.176	Edwards (1988)
Epidermis	1.106	Edwards (1988)
Dermis	1.274	Edwards (1988)
Stratum corneum	1.30 and 1.20 ± 0.57 (±SEM)	Weigand et al. (1974) Anderson and Cassidy (1973)
Hair shaft	2.32 (60 % relative humidity)	
Nail	1.115	Orentreich et al. (1979)
	1.33	Finlay et al. (1980)
Sebum	0.910 ± 0.048	Butcher et al. (1949)
Subcutaneous fat	0.9007 at 37 °C	► Chap. 67, "Subcutis Metrology"
Sweat	<1,006	

2 Acoustic Constants**2.1 Ultrasound (25 MHz) Velocity**

Epidermis + dermis	-1600 m s ⁻¹	Edwards (1988), Escoffier et al. (1986)
Epidermis	1500 m s ⁻¹	Edwards (1988)
Dermis	1660 m s ⁻¹	Edwards (1988)
Adipose tissue	1450 m s ⁻¹	
Stratum corneum	-2600 m s ⁻¹	Agache and Humbert (2004)
Whole skin		
Forearm	1566 ± 26 m s ⁻¹	Guittet (1997)
Face	1598 ± 19 m s ⁻¹	Escoffier et al. (1986)
Breast	1640 ± 16 m s ⁻¹	Escoffier et al. (1986)
Whole nail	2459 m s ⁻¹	Jemec and Serup (1988)
Nail dorsal	3103 m s ⁻¹	Jemec and Serup (1988)
Nail ventral	2125 m s ⁻¹	Jemec and Serup (1988)

2.2 Ultrasound (25 MHz) Impedance

1 Rayleigh = $10^6 \text{ kg m}^{-2} \text{ s}^{-1}$		
Whole skin	1.863 Rayleigh	Edwards (1988)
(With respect to hydration)	Rayleigh 1.5–1.9	
Epidermis	1.659 Rayleigh	Edwards (1988)
Dermis	2.115 Rayleigh	Edwards (1988)
Stratum corneum	1.534 Rayleigh	Edwards (1984)

2.3 Ultrasound (25 MHz) Attenuation

Whole skin	$2.95 \pm 0.46 \text{ dB cm}^{-1} \text{ MHz}^{-1}$	Guittet (1997)
Dermis	$4 \pm 1 \text{ dB cm}^{-1} \text{ MHz}^{-1}$	Querleux (1994)

3 Mechanical Constants

3.1 Whole Skin In Vivo (Elastic Phase)

Elastic strain limit	25 %	
Volar forearm	10 %//and 27 % ζ Langer's lines	Ehring (1960)
Quasi-static Young's modulus in vivo (extension, calf)		
//to Langer's lines	1–4 MPa	Wijn et al. (1981)
ζ Langer's lines	0.06–0.25 MPa	Wijn et al. (1981)
Mechanical anisotropy coefficient (A)	16.0	Wijn et al. (1981)
Young's modulus at elastic limit (posterior calf)		
//to Langer's lines	0.22 MPa	Manschot et al. (1986)
ζ Langer's lines	0.6 MPa	Manschot et al. (1986)
Tangent modulus	3.0 MPa	Vasselet et al. (1987)
(extension 1 %/s, forearm)		
Tangent modulus (suction)	0.8 MPa	Panisset et al. (1993,1994)

	Male	Female	
Volar forearm	0.11 MPa	0.12 MPa	Barel et al. (1998)
Forehead	0.21 MPa	0.25 MPa	
Volar forearm	0.14 MPa	0.16 MPa	Tokumura et al. (1999)
Forehead	0.23 MPa	0.27 MPa	

Tangent modulus (torsion)	1.1 MPa	Escoffier et al. (1989)
Dynamic modulus	600 MPa	Takahashi et al. (1981)
Shear wave (5600 Hz) propagation velocity		Bader et al. (1983)
Volar forearm ($n = 34$)		
//arm axis	50 ms^{-1}	
ζ arm axis	$40\text{--}50 \text{ ms}^{-1}$	
Breast ($n = 20$)		
//breast contour	$62.0 \pm 2.2 \text{ ms}^{-1}$	
ζ breast contour	$36.6 \pm 1.4 \text{ ms}^{-1}$	
Shear modulus (volar forearm)	1–2 kPa	Bader et al. (1983)
Stiffness coefficient (E/σ) (calf)	0.244	Wijn et al. (1981)
Poisson's coefficient	0.3–0.4	see ► Chap. 95, "Skin Mechanical Function" sect. 2.4
Ballistometry		
Restitution coefficient		Tosti et al. (1977)
Forehead	0.5	
Dorsum of hand	0.6	
Thigh	0.7	
Absorption coefficient	0.4–1.1 with respect to age	Tosti et al. (1977)

3.2 Whole Skin In Vitro

In saline (► Chap. 95, "Skin Mechanical Function", Ref. 30)	
Elongation <40 % (elastic phase) Young's modulus	<7 kPa
Elongation 40 %–70 % yield phase modulus	510 kPa
Rupture: elongation 90 %	
In air (► Chap. 95, "Skin Mechanical Function", Refs. 32 and 33)	
Young's modulus:	7–50 MPa

3.3 Connective Tissue Fibers In Vitro

Young's modulus		
Elastic fibers	–0.3 MPa	Burton et al. (1968) Caro et al. (1978)
Collagen fibers	–100 MPa	Caro et al. (1978)
	–1000 MPa	Lapière et al. (1988), Burton (1968)

3.4 Stratum Corneum

3.4.1 Stratum Corneum

In vivo dynamic (sonic) Young's modulus	12.4–13.4 MPa	Weigand et al. (1974)
In vitro strain tangent modulus (volar forearm)	50–210 MPa	Koutroupi et al. (1990), Ferguson et al. (1980), Vasselet (1989)
In vitro strain elastic limit (volar forearm)	10 %	Agache and Humbert (2004)
Resistance to stripping (kPa)		Marks et al. (1972)

1. Surface layer

	Male	Female
Forearm	20.07 ± 3.20	17.15 ± 3.49
Wrist	22.23 ± 4.41	20.21 ± 3.94
Back	15.30 ± 2.18	15.30 ± 2.18

2. ≥18th strip: cohesion twice as strong

		Marks (1986)
Resistance to vertical peeling (1 m min ⁻¹) (Leveque 1994):		
	Force (N)	Pressure (kPa) as calculated for a 15 × 70 mm area
February	2.69 ± 0.15	2.56 ± 0.14
August	1.65 ± 0.16	1.57 ± 0.15

3.4.2 Corneocyte

In vitro (in water) elastic modulus (volar forearm)	450 MPa	Lévêque et al. (1988)
---	---------	-----------------------

3.4.3 Corneodesmosome

Stress at rupture (in water) (volar forearm)	26 GPa	Lévêque et al. (1988)
--	--------	-----------------------

3.5 Hair

Hair shaft mechanical parameters when elongated at a constant rate (25 %/min) at 20 °C (Pierard et al. (1993)) (Table 1):

Table 1 Hair shaft mechanical parameters when elongated at a constant rate (25 %/min) at 20 C (Pierard et al. 1993)

Relative humidity	Young's modulus (kPa)	σ at elastic limit (kPa)	ϵ at elastic limit (%)	σ at yield limit (kPa)	Post-yield modulus (kPa)	σ at rupture (kPa)	ϵ at rupture (%)
30 %	5100	51	1.02	110	416	196	40
60 %	4500	45	1	91	425	190	43
85 %	3300	30	0.93	65	442	186	48

σ , stress; ϵ , strain

3.6 Nails

Young's modulus (GPa)	Deflection method	Sound velocity method	Finlay et al. (1980)
//keratin fibers (i.e., \perp finger axis)	4.3 ± 0.6 ($n = 7$)	4.3 ± 0.4 ($n = ?$)	
ζ keratin fibers (i.e., //finger axis)	4.0 ± 0.7 ($n = 2$)	2.1 ± 0.3 ($n = ?$)	

4 Optical Constants

Non-specular reflection at the skin surface	$< 8\%$	Anderson et al. (1981)
Skin reflectance (for a perpendicular beam of any wavelength)	$4\% - 7\%$	Anderson and Parrish (1981)
Wavelength emitted by the skin at 32–36 °C	$\lambda \cong 10.5 \mu\text{m}$ (i.e., IR ray)	
Skin emittance (in IR)		
	$\epsilon = 0.97$ for $7 < \lambda < 12.5 \mu\text{m}$	
	$\epsilon = 0.7$ for $2 < \lambda < 5.5 \mu\text{m}$	
Refractive index		
Stratum corneum	1.52–1.54	Greger (1996), See ► Chap. 158, "Physical, Biological and General Constants of the Skin"
When strongly hydrated	1.33	Agache and Humbert (2004)
	Between 1.36 and 1.50 from	Knüttel et al. (2000)
	Optical Coherence Tomography	
Viable epidermis	1.39	Hulsbergen et al. (1977)
Scattering coefficient		Knüttel et al. (2000)
Stratum corneum	1–1.5	
Epidermis volar forearm	1.5–2	
Palm		
Basal layer	4–5	

(continued)

Granular layer	6–7	
Upper dermis	8–10	
Transmittance beyond dermis	1300 > λ > 600 nm, and <1 % of received light	Anderson and Parrish (1981)

5 Thermal Constants

Current skin temperature (Other body sites, (Agache 2004a))	32 °C (extremities) to 36 °C (forehead) see ► Chap. 123, “Skin Thermal Imaging” sect. 1.2, ► table 1	Houdas et al. (1977) Houdas et al. (1977)
Radiant fraction of the skin surface area (relative to body surface area)		► Chap. 119, “Thermal Exchanges in Man”
Sitting or squatting	0.7	
Standing	0.8	
Saturating watervapor pressure at skin temperatures	5.8–6.6 kPa	Houdas et al. (1977)
Energy produced by evaporation of 1 g sweat	2.42 kJ	
Thermal conductivity (K)		see ► Chap. 158, “Physical, Biological and General Constants of the Skin”
Of skin in vivo (volar forearm)	0.2–0.6 W m ⁻¹ °C ⁻¹	Dittmar et al. (1991)
	0.2 W m ⁻¹ °C ⁻¹ (ischemia by tourniquet)	Dittmar et al. (1991)
	0.9 W m ⁻¹ °C ⁻¹ (intense vasodilation)	Dittmar et al. (1991)
Of stratum corneum free water	0.6 W m ⁻¹ °C ⁻¹	see ► Chaps. 29, “Physical Methods to Measure Stratum Corneum Water Content In Vivo” and ► 30, “Stratum Corneum Dynamic Hydration Test”
Of stratum corneum bound water	0.18 W m ⁻¹ °C ⁻¹	see ► Chaps. 29, “Physical Methods to Measure Stratum Corneum Water Content In Vivo” and ► 30, “Stratum Corneum Dynamic Hydration Test”
Of adipose tissue	0.0278 W m ⁻¹ °C ⁻¹	
Thermal inertia (KDC)	cal ² cm ⁻⁴ °C ⁻² s ⁻¹	Houdas et al. (1977)
Skin	90 × 10 ⁻⁵ –400 × 10 ⁻⁵ with respect to the degree of vasodilation	
Skin (ischemia)	90 × 10 ⁻⁵	see ► Chap. 158, “Physical, Biological and General Constants of the Skin”

(continued)

Skin in vitro (see Annex 5)	55×10^{-5} (dry skin) to 75×10^{-5} (wet skin)	
Adipose tissue	22×10^{-5} – 32×10^{-5} (with respect to temperature)	
Thermal skin–atmosphere convection coefficient		Houdas and Guieu (1977)
No wind	3.7 – $6.0 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$	
Wind	$8.3 U$ $0.5 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$ (U is the wind speed)	
Thermal core–skin convection coefficient		Houdas and Guieu (1977)
By thermal neutrality	$12 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$	
In the cold state	$6.5 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$	
In the warm state	80 – $150 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$	

6 Chemicophysical Constants

6.1 Skin Surface

6.1.1 pH

Adults overall, 4.2–6.1 (► Chap. 4, “The Skin Surface Ecosystem: A Presentation” sect. 3.1)

Forehead	<i>n</i>	Median	5th–95th percentiles	Zlotogorski (1987)
Males	282	4.6	4.0–5.5	
Females	292	4.6	4.0–5.6	
Cheek				
Males	282	5.1	4.2–5.8	
Females	292	5.2	4.2–6.1	

Forearm (volar)	5.4–5.9		Braun-Falco et al. (1986)
	4.5 ± 0.2	<i>n</i> = 7	Öhman et al. (1998)
	4.87–5.44	<i>n</i> = 16	Yosipovitch et al. (1998)
Forehead	4.93–5.29	<i>n</i> = 16	Yosipovitch et al. (1998)
Back (upper)	5.14–5.50	<i>n</i> = 16	Yosipovitch et al. (1998)
Shin	4.8–5.5	<i>n</i> = 16	Yosipovitch et al. (1998)
Axilla		<i>n</i> = 20	Krönauer et al. (2001)
Morning	5.87 ± 0.23		
Evening	5.49 ± 0.23		
Tongue	6.65 ± 0.61	<i>n</i> = 32	Yosipovitch et al. (2001)
Bucca	6.68 ± 0.65	<i>n</i> = 32	Yosipovitch et al. (2001)
Palate	7.23 ± 0.88	<i>n</i> = 32	Yosipovitch et al. (2001)
Lip	6.61 ± 0.60	<i>n</i> = 32	Yosipovitch et al. (2001)
Neonates (first day)	7.08 ± 1.70	<i>n</i> = 44 (no difference between sites)	Yosipovitch et al. (2000)
Infants	6.6 ± 0.25	<i>n</i> = 40	Gfatter et al. (1997)

6.1.2 Surface Energy Parameters

Critical surface wetting tension

Volar forearm	27.5 ± 2.4 dyn/cm	see ► Chap. 4, “The Skin Surface Ecosystem: A Presentation” sect. 3.2
Forehead	>50 dyn/cm	see ► Chap. 4, “The Skin Surface Ecosystem: A Presentation” sect. 3.2
Free energy		
Volar forearm	38.7 ± 6.4 mJ/m ²	see ► Chap. 4, “The Skin Surface Ecosystem: A Presentation” sect. 3.2
Forehead	42.5 ± 3.9 mJ/m ²	see ► Chap. 4, “The Skin Surface Ecosystem: A Presentation” sect. 3.2

6.2 Viable Epidermis

Water content	88–99 %	Blank et al. (1984)
	86.4 % (48 mol)	Wilson et al. (1989)
	83 % (0.83 g ml ⁻¹)	Diridollou et al. (2000)
Resistance to transepidermal O ₂ diffusion		Versmold et al. (1979)
Term infants	1.59 ± 0.32 10 ³ atm ml ⁻¹ min cm ² (n = 7)	
Premature	0.58 ± 0.27 10 ³ atm ml ⁻¹ min cm ² (n = 7)	
Adults	1.67 ± 0.66 10 ³ atm ml ⁻¹ min cm ² (n = 10)	
O ₂ solubility “in skin” (assumed to equal that of water)		Severinghaus et al. (1978)
At 45 °C	0.0219 ml g ⁻¹ atm ⁻¹	
At 37 °C	0.0238 ml g ⁻¹ atm ⁻¹	
CO ₂ solubility “in skin” at 45 °C and 40 Torr:		Severinghaus et al. (1978)
1.48 ml g ⁻¹ atm ⁻¹ (estimated) (0.47 the value in blood, 3 times the value in water)		

6.3 Dermis and Subcutis

Mean water concentration	88 %	Blank et al. (1984)
Interstitial pressure (limbs)	0.18–0.27 Torr	McMaster (1946)
	1.10–1.67 Torr after	
	>15 min venous occlusion	
Suction blister oncotic pressure	4.70–6.84 Torr	Schwindt et al. (1998)

(continued)

Interstitial/blood partition coefficient (skin is likened to water)		Severinghaus et al. (1978)
O ₂	$\lambda = 0.90$	
CO ₂	$\lambda = 0.47$	
Xenon	$\lambda = 0.7$ (adipose tissue $\lambda = 10$)	Sejrsen (1969)
O ₂ and CO ₂ solubility "in skin"		See sect. 6.2

6.4 Stratum Corneum

6.4.1 Water Content

In vitro, dry stratum corneum: strongly bound water		
5 % of dry stratum corneum		Gournay et al. (1995), Gilard et al. (1998)
7 % of dry stratum corneum		Hansen and Yellin (1972), Leveque et al. (1987)
In vitro, saturated stratum corneum		
Total water	30–50 % of saturated stratum corneum	Warner and Lilly (1994)
Bound water	25–40 % of saturated stratum corneum	Warner and Lilly (1994)
	20–30 % of saturated stratum corneum	Walkley (1972), Inoue et al. (1986)
Increase in volume when in water:	>100 % (hair shaft: <5 %)	Fluhr et al. (2000)
stratum corneum		
In vivo		
Water content in uppermost stratum corneum	5.2 % (ambient air at 22 °C and 31 % RH)	Diridollou et al. (2000)
	22 % (ambient air at 31 °C and 40 % RH)	Wilson and Maibach (1989)
	10–30 % in the 1/3 upper layers (4–20 % in case of "dry skin")	Hensen et al. (1980)
Water content in the 2/3 deeper layers	30–35 % (20–35 % in case of "dry skin")	Hensen et al. (1980)
Mean water content during bathing	23.7 %	Pirot (1996)

6.4.2 Diffusion Parameters

Water partition coefficient at the skin surface		
Stratum corneum/air	0.413 (if 93 % relative humidity)	Blank et al. (1984)
Stratum corneum/water	0.9	Scheuplein (1980)

(continued)

Water partition coefficient at stratum corneum/viable tissue interface		
Stratum corneum/viable tissue	0.162 (if 60 % relative humidity)	Blank et al. (1984)
Stratum corneum intercellular lipid/viable tissue	0.06	Potts and Francoeur (1991)
Water diffusion coefficient	$2.15 (0.2-7.7) \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$	Schwindt et al. (1998)
	$3 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$	Liron et al. (1994)
Forearm	$6 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$	Scheuplein (1983)
Forearm	$2.54 \pm 1.2 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ ($n = 5$)	Burry et al. (2001)
Back	$2.34 \pm 0.82 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ ($n = 5$)	Burry et al. (2001)
Abdomen	$1.38 \pm 0.42 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ ($n = 5$)	Burry et al. (2001)
Thigh (Other body sites, see ► Chap. 101, "Skin Photoprotection Function", Table 1)	$2.37 \pm 1.6 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ ($n = 5$)	Burry et al. (2001)
Water permeability coefficient (If 60 % HR)	$500 \times 10^{-6} \text{ cm h}^{-1}$ $21.0 \times 10^{-8} \text{ cm s}^{-1}$, or $756 \times 10^{-6} \text{ cm h}^{-1}$	Scheuplein (1980) Horii et al. (1989)
Permeability coefficients for various products: see ► Chap. 106, "In vivo Skin Absorption and Skin", Table 2		
Ethanol in water permeability coefficient (Other permeability coefficients: see ► Chap. 106, "In vivo Skin Absorption and Skin", Table 1)	$500 \times 10^{-6} \text{ cm h}^{-1}$	Scheuplein (1980)
Resistance to transepidermal diffusion (i.e., 1/permeability coefficient) (forearm)		Wu et al. (1983)
O ₂	$1.79 \pm 0.92 \text{ atm cm}^2 \text{ min: l}^{-1}$	
CO ₂	$62.8 \pm 28.7 \text{ atm cm}^2 \text{ min ml}^{-1}$	
N ₂	$8.49 \pm 1.81 \text{ atm cm}^2 \text{ min: l}^{-1}$	
Resistance to O ₂ transepidermal diffusion at 44 °C (as in tcPO ₂ measurement)		Versmold et al. (1979)
Premature	$0.58 \pm 0.27 \text{ atm cm}^2 \text{ min } \mu\text{l}^{-1}$ ($n = 7$)	
Term infants	$1.59 \pm 0.32 \text{ atm cm}^2 \text{ min } \mu\text{l}^{-1}$ ($n = 7$)	
Adults	$1.67 \pm 0.66 \text{ atm cm}^2 \text{ min } \mu\text{l}^{-1}$ ($n = 10$)	

6.4.3 Transepidermal Water Loss

Adults			
Forehead	$20.1 \pm 4.8 \text{ g m}^{-2} \text{ h}^{-1}$	($n = 16$)	see ► Chap. 108, "Transepidermal Water Loss"
	10.34 ± 0.70	($n = 7$ males 20–30 years)	Torp et al. (1975)
	9.39 ± 0.73	($n = 8$ females 20–30 years)	Torp et al. (1975)
Post-auricular	8.35 ± 0.41	($n = 8$) (males 20–30 years)	Torp et al. (1975)
Chest	10.7 ± 1.3	($n = 16$)	see ► Chap. 108, "Transepidermal Water Loss"
	4.73 ± 0.26	($n = 8$) (males 20–30 years)	Torp et al. (1975)
Abdomen	9.9 ± 1.8	($n = 16$)	see ► Chap. 108, "Transepidermal Water Loss"
	4.40 ± 0.51	($n = 7$) (males 20–30 years)	Torp et al. (1975)

(continued)

Adults			
Arm (upper outer)	4.24 ± 0.35	(n = 8 males 20–30 years)	Torp et al. (1975)
	5.07 ± 0.23	(n = 8 males 45–55 years)	Torp et al. (1975)
	4.73 ± 0.45	(n = 7 males 65–80 years)	Torp et al. (1975)
	5.12 ± 0.35	(n = 7 females 20–30 years)	Torp et al. (1975)
Volar forearm	10.4 ± 3.1	(n = 16)	see ► Chap. 108, “Transepidermal Water Loss”
Elbow	2.50 ± 0.30	(n = 7) (males 20–30 years)	Torp et al. (1975)
Mid	4.00 ± 0.32	(n = 8) (males 20–30 years)	Torp et al. (1975)
Wrist	7.19 ± 0.39	(n = 7) (males 20–30 years)	Torp et al. (1975)
Back	4.51 ± 0.57	(n = 8) (males 20–30 years)	Torp et al. (1975)
Thigh	4.39 ± 0.32	(n = 7) (males 20–30 years)	Torp et al. (1975)
Calf	9.6 ± 1.8	(n = 16)	see ► Chap. 108, “Transepidermal Water Loss”
First day of life			Bork (1977)
Palms	31.3 ± 8.5		
Soles	16.8 ± 4.7		
Back	11.0 ± 2.9		
Abdomen	11.0 ± 3.4		
Forearm	27.5 ± 14.8	(n = 44)	
Children 1–6 years			Yosipovitch et al. (2000)
Volar forearm	6.2 ± 3.5 g m ⁻² h ⁻¹	(n = 44) (not different from their parents)	

6.5 Sebum

Surface tension	24.16 ± 1.29 dyn cm ⁻¹	Mathot et al. (1976)
Surface free energy	−34 N m ⁻²	Mavon (1997)
Freezing point	15–17 °C	Burton (1970)
Melting point of free fatty acids and triglycerides	20–30 °C	Dünner et al. (1946)
Viscosity at 32 °C	0.855 P	Butcher et al. (1949)
Between 38 °C and 31 °C	η = 4.969–0.047 °C (for details, See chapter 26 sect. 1.2 (Agache 2004b))	

6.6 Sweat

pH	5.0 (moderate sweating) to 7.0 (profuse sweating)	Sato et al. (1991)
	6.55 ± 0.32 (SE)	Shelley et al. (1953)
Osmolality (mOsmol/l)	154 ± 40	Dahlgren and Elsnau (1984)
Cryoscopic delta (°C)	−0.32	
Surface tension	32.2 ± 2.5 mN/m ⁻¹ (n = 6)	Mavon (1997)
Interface tension sebum-sweat	−1.5 mN/m ⁻¹	Mavon (1997)

6.7 Nails

Transonychial water loss			
Median	Range	<i>n</i>	
12.4 g m ⁻² h ⁻¹	7.9–18.7	10	Jemec et al. (1989)
75 %–25 % percentile interval	10.1–14.7	10	Jemec et al. (1989)
19.4 g m ⁻² h ⁻¹	11.7–33.5	21	Rougier et al. (2002)

7 Electrical Constants

7.1 Skin

DC resistance of stratum lucidum/corneum interface, 8700 ± 3500 Ω (*n* = 50), Zesch et al. (1972)

Current frequency (Hz)	10 ²	10 ⁴	10 ⁶	
Dielectric constant				Yamamoto and Yamamoto (1976)
Stratum corneum	31	15.5	6.8	
Viable epidermis	7700	930	80	
Resistivity ρ (Ωm)				Yamamoto and Yamamoto (1976)
Stratum corneum	50 × 10 ⁶	84 × 10 ⁵	79 × 10 ³	
Viable epidermis	680	680	170	
Stratum corneum dielectric constant at 10 ³ Hz				see ► Chaps. 29, “Physical Methods to Measure Stratum Corneum Water Content In Vivo”
Dry	–8			
Very hydrated	–80			

7.2 Hair

Resistivity	10 ¹² Ωm	Zviak et al. (1988)

At 37 °C	31.3 10 ⁻⁶ ml g ⁻¹ Torr ⁻¹
At 44 °C	28.8 10 ⁻⁶ ml g ⁻¹ Torr ⁻¹

1 Energy

Metabolic rate (basal) (= minimal energy production)	~50 Wm ⁻² ▶ Chap. 119, “Thermal Exchanges in Man”
Metabolic rate (resting)	59 Wm ⁻²
Oxygen originated energy (for a respiratory quotient 0.84)	5.6 Wl ⁻¹
Oxygen thermal coefficient (for a respiratory quotient 0.84)	20.27 kJl ⁻¹ ▶ Chap. 58, “Transcutaneous Oxygen Pressure,” Houdasy et al. (1977)

2 Thermal Constants

Thermal conductivity	Wm ⁻¹ °C ⁻¹
Air	25 × 10 ⁻³
Free water	624 × 10 ⁻³ at 37 °C ^a
Protein-bound water	180 × 10 ⁻³
Thermal inertia (KDC)	cal ² cm ⁻⁴ °C ⁻² s ⁻¹
Human tissues (with respect to temperature)	
Muscle	56 × 10 ⁻⁵ to 113 × 10 ⁻⁵
Bone	44 × 10 ⁻⁵ to 68 × 10 ⁻⁵
Materials	
Concrete	170 × 10 ⁻⁵
Oak	13 × 10 ⁻⁵
Steel	9 × 10 ⁻¹
Blood specific heat capacity	3.64 J °C ⁻¹ g ⁻¹

^a ▶ Chap. 2, “Measurements of the Human Skin: Why and How?,” Sect. 2.3

Thermal neutrality: subject naked in a room in which air and walls have the same temperature, close to 30 °C, relative humidity is below 50 %, and where air is barely in motion (0.1–0.2 m/s)

Saturating water pressure with respect to temperature (under 760 Torr atmospheric pressure) (Houdas and Guieu 1977): for given outside relative humidity (RH_{ext}), outside temperature (T_{ext}) and room temperature (T_{int}), the room relative humidity (RH_{int}) is calculated

as follows: $RH_{int} = RH_{ext} \times P_{sat_{ext}}/P_{sat_{int}}$, where $P_{sat_{ext}}$ is the outside saturating water pressure, and $P_{sat_{int}}$ is the room saturating water pressure.

Example: If $RH_{ext} = 30 \%$, $T_{ext} = 9 \text{ °C}$, and $T_{int} = 21 \text{ °C}$, then $HR_{int} = 30 \times 8.65/18.71 = 13.9$

Temperature (°C)	Saturating pressure (torr)	Temperature (°C)	Saturating pressure (torr)
-10	2.16	31	33.76
-9	2.34	32	35.72
-8	2.52	33	37.79

3 Acoustic Constants

Ultrasound (25 MHz) velocity in water	1480 m s ⁻¹
Ultrasound (25 MHz) acoustic impedance in water	1.48 Rayleigh ▶ Chap. 157, "Main Skin Physical Constants," Edwards et al. (1984)

4 Optic Constants

Stefan Boltzmann universal radiation constant	$\Phi = 5.6710^{-8}$ Wm ⁻² K ⁴
Refraction indexes	
Air	1.00
Glycerol	1.54
Acetic acid	1.54
Water	1.33
Irradiance: midday mean solar UV-A in summer (mediterranean countries)	3.5 mW cm ⁻²

Solar energy reaching the ground (normalized to equator):

Town	21 June	Equinox	21 December
Besaçon	91.5	68.0	33.5
Nice	93.9	72.6	39.6
Casablanca	98.4	83.5	55.0

Solar energy reaching the ground (normalized to a blue sky):

	Blue "milky" sky	Cirrus	Stratus	Stratocumulus
UVB	100	100	80	40
UVA	100	100	80	40
visible	100	95	80	30

(continued)

	Blue "milky" sky	Cirrus	Stratus	Stratocumulus
IR	95	80	60	10

Light reflection	
Snow	85 %
Sand and light colored soil or walls	17 %
Water	5 %
Grass	3 %
Absorption peaks	
Hb	415, 553 nm
HbO ₂	415, 543 and 577 nm
Light wavelengths seen by the human eye	560, 530, 420 nm (orange, green, blue, respectively)

Infrared main absorption bands

Wavelength		Stretched bonds	Measured substance	Reference
µm	cm ⁻¹			
9.65	1036	OH	Water	
8.94	1118		Protein	
6.47	1545 (amide II)	C-N	Protein	
6.10	1640	OH	Water	
6.08	1645 (amide I)	C=O	Protein	
5.85	1710	C=O	Free fatty acids	Brancaleon et al. (2001)
5.75	1740	C=O	Fatty acids esters	Brancaleon et al. (2001)
4.76	2101	OH	Water	
4.3	2326	CO ₂	Carbon dioxide	Thiele and Van Kempen (1972)
3.42	2920	CH ₂ asymmetrical	Lipids	Brancaleon et al. (2001)
3.51	2850	CH ₂ symmetrical	Lipids	Brancaleon et al. (2001)
3.03	3300	OH	Water	Brancaleon et al. (2001)
1.95	5128	OH	Water	

5 Biological Constants

Blood density	1.058–1.062
Plasma density	1.025–1.027
Plasma osmolality	302–308 mOsm l ⁻¹
Plasma cryoscopic delta	–0.56 to –0.57 °C
Blood pH	7.38
Plasma composition	
Na + (mM)	140
K+ (mM)	4–5
Cl – (mM)	103
CO ₃ H- (mM)	20–25
Ammonia (mM)	0.025–0.16
Lactates (mM)	<2
Urea (mg ml ⁻¹)	0.15–0.25
Glucose (:g ml ⁻¹)	700–1000
Proteins (mg ml ⁻¹)	70–80
Triglycerides density	0.92

Pierre Agache

Keywords

Pressure units • Bar • torr • MSW (metres sea water) • Atmosphere • Pascal

Presently or formerly popular pressure units include the following:

- Atmosphere (atm)
- Manometric units:
 - Centimeter, inch, millimeter (Torr) and micrometer (mTorr, micron) of mercury
 - Height of equivalent column of water, including millimetre (mm H₂O), centimetre (cm H₂O), metre, inch, and foot of water
- Imperial and customary units:
 - Kip, short ton-force, long ton-force, pound-force, ounce-force, and poundal per square inch
 - Short ton-force and long ton-force per square inch
 - FSW (feet sea water) used in underwater diving, particularly in connection with diving pressure exposure and decompression
- Non-SI metric units:
 - Bar, decibar, millibar
- MSW (meters sea water), used in underwater diving, particularly in connection with diving pressure exposure and decompression
 - Kilogram-force, or kilopond, per square centimeter (technical atmosphere)
 - Gram-force and tonne-force (metric ton-force) per square centimeter
 - Barye (dyne per square centimetre)
 - Kilogram-force and tonne-force per square meter
 - Sthene per square metre (pieze)

This chapter provides the correspondence between different standard pressure units.

The table should be read from left to right (Table 1). Example: 1 cm H₂O is equal to 0.7356 torr and equal to 10⁻³ kg-force cm⁻²

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

Correspondence between international system units (MKSA) and CGS units

Physical quantity	MKSA system	Ratio MKSA/CGS	CGS system
Length	Meter (m)	$=10^2$	Centimeter (cm)
Mass	Kilogram (kg)	$=10^3$	Gram (g)
Time	Second (s)	$=1$	Second (s)
Electric current	Ampere (A)	$=1$	Ampere (A)
Surface	m^2	$=10^4$	cm^2
Volume	m^3	$=10^6$	cm^3
Mass density	$kg\ m^{-3}$	$=10^{-3}$	$g\ cm^{-3}$
Speed	$m\ s^{-1}$	$=10^2$	$cm\ s^{-1}$
Acceleration	$m\ s^{-2}$	$=10^2$	$cm\ s^{-2}$
Force	Newton (N) = $kg\ m\ s^{-2}$	$=10^5$	dyne = $g\ cm\ s^{-2}$
Work	Joule (J) = N m	$=10^7$	erg = dyne cm
Power	Watt (W) = $J\ s^{-1}$	$=10^7$	erg s^{-1}
Pressure	Pascal (Pa) = $N\ m^{-2}$	$=10$	Barye = dyne cm^{-2}
Surface tension	$N\ m^{-1}$	$=10^3$	dyne cm^{-1}
Torque moment	N m	$=10^7$	dyne cm
Viscosity	Poiseuille = $kg\ m^{-1}\ s^{-1}$	$=10$	Poise = $g\ cm^{-1}\ s^{-1}$

1 kg force (=1 kg weight) = 10^3 g force = 9,81 N. It is the *force* exerted by gravity ($9,81\ m\ s^{-2}$) on a 1 kg mass
