“This textbook is dedicated to the memory of its creator, Professor Pierre Agache, whose fingerprints are visible in every page”.

Foreword

We live in a world of rapidly increasing information. The journalists and academicians often speak about this in a negative sense – utilizing the word “overload.”

Many readers understand the overload phenomena and its impact on their daily life and work. Few of us can master the rapidly increasing data of the Information Age.

The Googles of the universe have aided us greatly in dealing with information overload.

It is divided into the pre- and post-computer age and has been expedited greatly by electronic searching and indexing. The Google world is attempting to ameliorate unmet need-indexing and electronic availability of the world’s book collections.

In spite of all of these electronic advances and aids, we remain indebted to the rare scholar – in this case the late Pierre Agache – for his seminal contributions in the previous edition of this book.

Professor Agache was a dedicated, thoughtful, and disciplined scholar – making the previous edition one of the most valuable reference textbooks for anybody working in the dermatologic space, including the skin, hair, nails, and their other organ involvements.

This edition builds upon the work of Pierre’s work.

We have in this edition – the current edition – a technology that Pierre did not have available.

The Springer organization has arranged so that this book will be updated – almost on a daily basis – when needed. The reader is now able to get updates in both electronic and print-on-demand versions.

We greatly appreciate the creativity and assistance of Dr. S. Klemp for making this available. We also thank the Springer team for their skilled assistance in their editorial process.

Your editors appreciate corrections and suggestions and can be readily reached by email and telephone.

Howard I. Maibach

Preface

Measuring the Skin: A New Look in Dermatology

Measuring the skin succeeds now to looking at the skin or inspecting the skin.

Many clinicians limited their diagnosis in dermatology on the only description of skin signs and skin lesions. The fundamental functions of the skin were not considered except through the aspect of the skin. For example, loss of barrier function was deduced of the dryness pattern of the skin. The development of cosmetology with new active ingredients which are enable to modify the skin physiology by targeting cell and their nucleus functions, has led the biometrologists to create the new instrumental devices to accurately assess the imperceptible modifications of the skin.

Since the skin is an organ which can be easily analyzed by looking, touching and smelling to evaluate some of its patterns such as roughness/smoothness, dryness/moisture, Stiffness/sagging, elasticity, extensibility, resistance, radiance/dullness, temperature and etc., it is now appreciated to be able to assess quantitative measurements, to visualize through the skin and inthe skin different structures such as dermis, vessels, appendages, etc.

The real development of methods to measure the skin took place during the 1970s. Indeed, in the last fifty years, the knowledge on the skin physiology and anatomy has been significantly developed in such a manner we are not able to imagine correctly the problems existed many years ago.

Up to these last years, histology remained the gold standard for morphological investigation of the skin, although biopsy may alter the original morphology. Advances in ultra-sound and optics provide nowadays a true in vivo analysis of the skin with precise and accurate signification, leading to the non-invasive optical biopsies. These progresses have many clinical applications in different fields of the medicine such as cancer diagnosis.

Thus a new semiology was born, requiring to be familiar with new patterns and signs. Healthy images at different anatomic sites as well as pathological data regularly appear in the field of biometrology, and need to be known by young researchers and dermatologists.

The data and images given by new technologies could be now available for the practitioners and physiologists which were reserved only to engineers and researchers in the past,. These methods give the possibility of repetitive histometric measurements of the same skin site.

Inflammatory diseases, blistering dermatosis and skin tumors are easily explored using new sophisticated methods, and the treatment effects can be evaluated. Since biometrology permits to follow the effects of such active principles, it is necessary to enter in the field of cutaneous pharmacology.

Another domain which interests the pharmacists, cosmeticians, doctors, researchers and also the people is skin aging. Indeed, skin appearance is changing with age, not only in terms of wrinkles and loss of elasticity, but also in terms of its moisture and radiance. Biometrological assessment allows to determine the mechanisms between intrinsic and extrinsic factors which are involved in skin aging process. The quality of the barrier function of the skin is assessed by numerous methods more and more sophisticated, allowing to have knowledges on the skin hydration in different levels. Further, new technologies such as RAMAN method helps to determine the qualitative and quantitative constitution of the skin; The non-invasive imaging technologies significantly improve the diagnosis and also clinical management of skin conditions while giving the dermatologist and closely related specialists, the new ways for assessing and exploring the skin in its unknown and invisible parts.

The aim of this new edition of *Measuring the skin* is to provide the doctor, the researcher, the cosmetician and all person who is involved in assessing the skin, with the tools and their usefulness to characterize the skin. In none of other field of medicine does such a book exist. Indeed, due to its superficial location and simple approach the skin is the target of every measure, every device, and all of its function have been explored. When written for the first time by Prof. Pierre Agache and myself in 2004, we didn't imagine at that time that a new edition will bring so many new information, and disclose so new fields of investigation.

This book has vocation to be the professional basic book of each of you, who wants to know how to characterize such skin property, and wants to know more on new skin physiology developments. In memory of my mentor, I am proud to follow him in this skin specialty he contributed to create and to develop.

Philippe Humbert

Acknowledgments

We would never have been able to finish this work without the help of our colleagues.

The authors would like to express their deepest gratitude to the persons listed below for their valuable help and support:

- Adeline Jeudy, Thomas Lihoreau, Sophie Mac-Mary, Jean-marie Sainthillier, Alexandre Guichard and Ahmed Elkhyat for their help to update the table of contents and the new authors according to the recent publications.
- Dr. Makan Rahshenas for his great help to carry out the correspondance with authors
- Isabelle Bruey for her assistance in bibliography
- Agnès Fontaine and Brigitte Boissenin for their precious help to organise the work meetings.
- Elisabeth Homassel for her valuable help in english translation of some chapters.
- Dr. Hui Xiaoying and Tita F. Reyes and other colleagues of Pr. Maibach in San Francisco who helped us a lot in updating process.
- Deep thanks to the Springer team who followed the redaction process patiently and efficiently.
- In memory of Pr. Xuemin Wang, Vice-Chairman of Shanghai Skin Disease Hospital, who has written two wonderful chapters on microbiology of the skin in this edition. Unfortunately he expired on February 2016 without having the opportunity to see the outcome.
- Special thanks to Mr. Emmanuel Leclerc, editorial director and Mrs. Sylvie Cortes, Edition Department assistant at « Lavoisier » editing house in Paris who dedicated the all legal autorisations to Springer for the upcoming edition of this textbook.
- Finally a no-name appreciation to all secretaries, colleagues, collaborators and medical and university staffs who helped the authors/co-authors during this long project.

Phillippe Humbert
Ferial Fanian
Howard I. Maibach

Introduction

Ferial Fanian

Readers of the previous edition of this book have relied on it to aid them in measuring all parameters of the skin through the appreciable work of Pierre Agache and Philippe Humbert. After the heart-rending death of Pierre Agache in 2003, the first edition was published on 2004 by Springer which was a modified complete translation of the french version edited by him and published in 2000 by Lavoisier (Physiologie de la peau et explorations fonctionnelles cutanées).

Unfortunately the second version was delayed according to several administrative reasons till I have been asked on 2011 to start this big project. Although it was a noticeable major job, it was my great honor to work with the well known authors and also the two great editors, Howard Maibach and Philippe Humbert who always made me the fruitful suggestions and were my enthusiastic supporter through out this long project.

I would like to appreciate all of the respected authors and editors and also all of my friends and colleagues which are named in acknowledgment.

I would like to express my special thanks to Doctor Aude Agache, the esteemed daughter of Professor Agache who did kindly help the team to carry out all administrative steps successfully.

At the end, I would like to dedicate this work to my mother and father, Saeideh Bashirazami and Mohamadali Fanian, which are my first and permanent encouraging teachers to study more and more, to my dear Professors, Yahya Dowlati and Alireza Firooz who gave me the scientific view and motivated me always to go on even in the hard moments, and finally to my husband, Massoud Salari, who was always at my side cheering me up and supporting me through the happy and unhappy moments and also my son, Sepanta Salari, who understood patiently my busy time during this hard project.

Procedure

The table of the contents was modified in order to add the most updated technologies in skin physiology, biometrologie, biophysics, imaging and clinical scoring. The authors have been selected according to the most recent published articles in each field.

Comparing to the first edition with 84 chapters and 784 pages, this new edition contain 160 chapters and 1652 pages which can cover the most of the researchers' needs in this domain.

Fortunately, this volume has been selected to become part of the Springer-Reference portfolio, which now comprises over 400 major reference works and almost 500,000 entries/chapters online. This means it will not only be a static printed book, but it will have a "living" update version online which is very important for this book because of its gadget like nature.

Contents

In the first section, we have considered an anatomic approach for the chapter titles : you will start with the surface of the skin and then you will go deeper by leafing the pages. Then you would discover the different measuring techniques according to the functional approach : Mechanical, Photoprotection and sensory function of the skin. Furtherly, you will find the standard scoring scales (which will be more completed for the next edition) and the book finishes with skin maps.

We have kept most of the precious chapters of Pierre Agache whose scientific value still remain intact even after 10 years.

All of the reader's precious comments are welcome.

On behalf of the editors, I would like to invite all of the researchers who are interested to introduce the new methods in the global domain of "Measuring the Skin", to contact the editors.

Contents

Volume 1

1 The Human Skin: An Overview	1
Pierre Agache, Thomas Lihoreau, Sophie Mac-Mary, Ferial Fanian, and Philippe Humbert	
2 Measurements of the Human Skin: Why and How?	5
Pierre Agache	
3 Chronobiology of the Skin: Cutaneous Clocks and Biorhythms	15

About the Editors

Philippe Humbert

Department of Dermatology
University Hospital of Besançon
Besançon, France

Professor Humbert has been elevated to the grade of Professor of University in 1993, at the age of 34 years. Specialist in Dermatology as well in internal Medicine, Allergology and clinical Immunology, and skin oncology, he performed a Ph.D. in cutaneous Pharmacology.

During his position of head of the Department of Dermatology in the University Hospital of Besançon from 1993 to 2015, he developed a clinical department with all the specialties of Dermatology, i.e., Allergology, Surgery, Laser, Internal Medicine, Oncology, pediatric Dermatology, Photobiology, Biometrology.

During the same period, he created the Laboratory of Cutaneous Biology in which news skin models are developed as well as cell cultures (keratinocytes, fibroblasts, melanocytes. . .) which are used as pharmacological models.

On a clinical point of view, he created the CERT (Center for Investigation and Research on the Skin) in which, with a team of engineers, doctors, pharmacists, technicians, he performs clinical studies for evaluation of cosmetics or drugs.

In this field of biometrology, he was elected as President of the ISBS (International Society for Bioengineering and Imaging of the Skin) from 2005 to 2010 (he organized indeed the International Meeting of ISBS in Besançon in 2009), as well as President of the International Society of Cutaneous Pharmacology. He was President of ESCAD in 2011.

His bibliography includes more than 350 publications and five books.

Professor Philippe Humbert received the Award of the French Society of Dermatology, of the French Society of Dermatological Research, as well the French Society of Cosmetology.

Known for his humanism and generosity, Professor Philippe Humbert welcomes many students or professors coming from abroad, and he was proud to contribute to teach six famous Chinese Professors. He collaborates with many universities over the world. Believing in the creativity of his students, he helped them to assess three innovative start ups in the domain of skin biometrology (Skinexigence^R), skin biology (Bioexigence^R), and skin pharmacology (Proviskin^R).

Student of Pr Agache, his Editor position is the way to honor his mentor, and to contribute to his artwork.

Ferial Fanian

Center for Study and Research on
the Integuments
Department of Dermatology
University Hospital of Besançon
Besançon, France

Ferial Fanian is a French-Persian dermatologist working in Research Centre of Department of Dermatology of Besançon, France (CERT). She has a remarkable experience on laser applications in dermatology while she was always working as a researcher in biometrology of the skin.

She is also familiar with optical Biopsy methods particularly with in vivo Confocal Microscopy and that is why she is the board member of ICNI group (Non-Invasive Cutaneous Imaging thematique Group) at French Society of Dermatology. She was working on melanocytes activity and morphology through her PhD thesis. She has also obtained two academic fellowship in « Laser and Cosmetic Dermatology » and also « Innovative Chronic Wound Healing » in 2012 and 2013 in France.

Actually, she is the reviewer or invited author for several English and French scientific journals in the field of dermatology, aesthetic medicine and biometrology such as JEADV, Archives of Dermatology, Journal of Cosmetic Dermatology, Case Reports in Dermatological Medicine, Medical Staff Dermatologie, Réalités Thérapeutiques en Dermato-Vénérologie.

Research Interests

Advances and Emerging Techniques in Dermatology
 Anti-Aging
 Cosmetic Dermatology
 Invasive and Non-Invasive Methods in Dermatology
 Investigative Dermatology

Howard I. Maibach
 Department of Dermatology
 School of Medicine
 University of California
 San Francisco, CA, USA

Present Title: Professor

EDUCATION	DEGREE
Tulane University, New Orleans, LA	A.B.
Tulane University, New Orleans, LA	M.D.
USPHS, Hospital of the University of Pennsylvania	Resident/Fellow

HONORARY DEGREES	DEGREE	YEAR
L'Universite de Paris-Sud, France	Ph.D.	1985
Université Claude Bernard Lyon 1, France	Ph.D.	2008
University of Southern Denmark	M.D.	2010

Dr. Howard Maibach joined the University of California Faculty in 1961 as Assistant Professor, and is currently Professor of Dermatology.

Dr. Maibach, an expert in contact and occupational dermatitis, sees patients at the Environmental Dermatoses Clinic, which is part of the Dermatology Clinic at UCSF. His most active fields of research are dermatopharmacology, dermatotoxicology, and environmental dermatoses. He has been doing human subject research for 45 years.

He has been on the editorial board of more than 30 scientific journals. His bibliography includes more than 2790 publications and 100 books.

He is member of 19 professional societies, including the American Academy of Dermatology (AAD), San Francisco Dermatological Society (SFDS), North American Contact Dermatitis Group (NACDG), American Contact Dermatitis Society (ACDS), International Contact Dermatitis Research Group (ICDRG), Society of Toxicology (SOT), European Environmental and Contact Dermatitis Research Group (EECDRG), and the Internal Commission on Occupational Health. He is a consultant to government, academia, and industry worldwide.

Dr. Howard Maibach was honored as the 2013 recipient of The Master Dermatologist Award by The American Academy of Dermatology's 71st Annual Conference held in Miami, Florida. This prestigious award recognizes an Academy member's significant contributions to the field of dermatology and to the American Academy of Dermatology.

In March 2015, The International League of Dermatological Societies (ILDS) awarded Dr. Maibach their 2014 ILDS Certificate of Appreciation in recognition of his outstanding contribution to dermatology, both nationally and internationally, through his work, research, publications, and teaching in the USA and over 60 countries.

Human skin • Body temperature control • Chemical barrier • Elasticity • Hydration • Immune function • Mechanical protection • Microcirculation • Self-maintenance and self-repair • Sensory function • Sexual function • Skin appendages • Topographical variations

1 A Few Figures About the Skin

Area: 1.8 m²

Average thickness: 1.2 mm

Average volume: 3.5 dm³ = 0.035 m³

Weight with blood: 4.7 kg

Weight without blood: 4.2 kg

Ratio area/thickness = 150,000

The skin participates in many physiological and pathological events and processes of the human organism, owing to its large area of contact with the internal milieu, but also to its volume and variety of tissues. The cutaneous expression of internal diseases is frequent, varied, and often specific.

2 Skin Structure

The general structure of the skin is a stratified tissue whose four layers are, from the top to the bottom, the stratum corneum (8–20 μm thick, could go up to 1.5 mm on palms and soles), the viable epidermis (30–80 μm), the dermis (1–2 mm), and the hypodermis or subcutis (0.1 to several cm) (Fig. 1). Each of these layers has its own physiology, functions, and evolution along life.

2.1 Annexes

The skin is a heterogeneous organ (dead tissue, epithelium, connective tissue, muscles, etc.), and furthermore it harbors four types of independent mini-organs, also called skin appendages:

- The nails, growing at a speed of 3 mm/month on hands and 1–1.5 mm/month on feet, with

Fig. 1 A vertical section of the plantar skin. *dr* reticular dermis. *ds* superficial dermis. *e* viable epidermis, *h* hypodermis and adipose tissue, *sc* stratum corneum. *Stars* coiled part of sweat glands (both secretory segment and lower duct). *Arrows* sweat ducts. Note the large skin thickness (1.8 mm, in other sites it would be close to 1 mm), the absence of pilosebaceous follicles, the large thickness of the stratum corneum, and the great number of sweat glands. In vivo dimensions were about 15 % larger. Bar = 200 μm (From Degos and Civatte 1977)

this speed decreasing with age (Scher and Daniel 2007)

- The pilosebaceous follicles and hair: between 90,000 and 130,000 on the scalp, with a terminal hair diameter of 40–120 μm, depending of the phototype; 60–100 hair fall per day, and they grow at a speed of 0.35–0.44 mm/day, (1 cm/month, 12 cm/year) (Blume-Peytavi 2008; Guichard et al. 2013)
- The eccrine sweat glands (three millions)
- The apocrine sweat glands (armpit, perineum)

2.2 Variations

Topographical variations in its structure and functions are considerable: the scalp, the skin of the face, the dorsal skin of the hands and feet, the

palms and soles, the armpits, and the perineum have their own anatomy, functions, and reactivity (Tagami 2008; Sandby-Møller et al. 2003; Waller and Maibach 2006).

To briefly give some examples, in usual temperature and hygrometric atmosphere conditions (20–22 °C, 40–60 %), skin sebum excretion could vary from 0 (arms, legs, etc.) to more than 200 µg/cm² (greasy subjects forehead), and hydration index could go from 10 (dry skin on the legs) to 100 (well-hydrated skin on the forehead, without unity).

Aging (intrinsic or extrinsic) is obviously modifying skin structure (Lévêque and Agache 1993):

- Hydration presents maximum values between 20 and 40 and then regresses.
- Elasticity is the mechanical property that better reflects skin aging: it decreases and becomes oriented with age, is sun exposure dependent, and more important on women, and its values decrease from head to feet.
- Skin microrelief, roughness, and wrinkles are not involving on the whole body in the same manner, again depending on topology (gravity, expressions, etc.) or environmental factors (sun, tobacco, etc.), along life (Guinot et al. 2006);
- Microcirculation: capillary density, structured at the beginning even if variable in density in different body areas (mean of 60–70/mm²), could worsen until a disorganized (orientation), heterogeneous (size, shape of the capillaries) network, characterized by a density of 30/mm² or less.

The skin characteristics are also function of **sex** and **ethnicity** of the subject; it could even be dependent on the **side of the face** (Mac-Mary et al. 2010) or **environmental factors** (season, weather, etc.) (Fanian et al. 2013).

Due to these important variations, parameters previously cited appear in publications in comparison before and after a treatment, rather than compared to “normal” or “pathologic” values.

3 Skin Functions

3.1 Specific

- Self-maintenance and self-repair (but there is no repair of appendages)
- Mechanical protection: resistance to frontal and tangential shocks, attenuation of external pressures, body external shape maintenance through reversible deformations, adhesion of the palms and soles to objects in the hand and on the ground
- Chemical barrier: limitation of foreign substances penetration, prevention of water and endogenous fluid loss
- Protection against ultraviolet rays
- Protection against environmental pathogenic microorganisms
- Social and psychological function through the physical aspect and mimic

3.2 Exerted in Cooperation with Other Organs

- Sensory function: tactile senses, perception of temperature and pain and even of light (popliteal region) (Campbell and Murphy 1998)
- Body temperature control: especially regulation of heat gains and losses
- Immune function: the skin is the first line of information and defense in the process of immunity, especially “delayed immunity”
- Ossification: synthesis of provitamin D (vitamin D is responsible for the intestinal absorption of calcium)
- Sexual function: conversion of testosterone into more active dihydrotestosterone

Keywords

Gaussian distribution • Good measuring practice • Interval scales • Comparative measurements • MKSA system • Nominal scale • Nongaussian series • Ordinal scale • Parametric evaluation • Sequential analysis • Standard deviation • Taguchi designs

In experimental sciences, measuring phenomena is a key point, since it is through the quantitative evaluation of an effect related to a given cause that the law of phenomena can be founded. (Bernard 1984)

1 The Relevance of Measurements

Metrology is the science of measurement, of evaluation of its requirements, limitations, and interpretations. The primary reason for using metrology in cutaneous noninvasive investigations is its role as a major source of progress, not only because impressions are replaced by objective facts and qualitative descriptions by quantitative assessments, but also because new situations are unveiled. Even the simplest phenomenon becomes complex when measured; one starts from one fact and then discovers its possible components and variations, which induces new hypotheses and opens a pathway for new knowledge. Physics in the past could only progress through the development of measurement methods. The remarkable advances in human physiology during the nineteenth century, which preceded modern medicine and allowed it to progress, came about because of a double process of discovery and quantification. Skin metrology provides many examples. The measurement of sebum secretion with a view to correcting the removal of lipid from the surface quickly showed that the measured phenomenon was not the one expected, but rather the partial emptying of a follicular reservoir, the existence of which had previously been ignored. The measurement of epidermal turnover in psoriasis provided a leap forward in understanding the disease.

Biological phenomena are changeable and difficult to quantify. At first glance, observation may prevail over measurement, but the notion of dimension is required to investigate a structure and the magnitude of change. The pathologist must decide whether, in the visualized skin section, the tissue components are modified in dimension and number by a pathological process. Furthermore, normal characteristics vary depending on the anatomical site, which has not yet been quantified; consequently, the pathologist remains unable to reach a conclusion unless major changes are seen. When the noninvasive anatomical or functional investigations are quantitative, they provide a measure with low subjectivity. The clinician evaluating a new medication would like to rapidly and accurately assess treatment efficacy; this goal can be reached only by quantification of clinical symptoms. Accordingly, it is necessary to know whether the measure is accurate (degree of precision and variability) and if it truly reflects the targeted phenomenon.

Numerical results of blood sample examinations is standard practice. It is likely to be the same for most clinical symptoms in the years to come. This is possible today in the detection and substantiation of subtle changes (e.g., aging (Escoffier et al. 1989; Larnier et al. 1994)) or the effect of a therapy on a chronic disease such as scleroderma (Humbert et al. 1993). The last decade of progress in molecular genetics has emphasized the considerable benefit that the collection of data provided by everyday medical practice might generate, and in years to come practitioners will certainly be involved in collecting and processing this data. Such information requires classification, substantiation, and treatment using statistical parameters. A few nondermatological specialties also utilize skin measurements, e.g., in physiology (endocrinology, body temperature regulation, immunology, etc.), where the skin is an effector organ readily examined noninvasively because of its accessibility. It is also the case for cosmetology research, where innocuousness and efficacy criteria may become visually unattainable because of their subtlety, and require instrumental measurements for assessment.

2 Types of Measurements

Before choosing an appropriate evaluation method, it is necessary to look at the nature of the data. If they relate to individuals or categories, hence with no possibility of converting them into numbers, the evaluation mandates a nominal scale. If the data can be translated into numbers, but on a scale where intervals are unknown or uneven, they can only be ranked. Finally, if the variation is measured on a continuous scale with even intervals, then the traditional evaluation is used: the so-called parametric evaluation (Siegel 1956).

2.1 Nominal Scale

This is the only means of measuring categories, facts or states, named by a word or an expression, and not put into numbers, for example, aggravation, desquamation, over 60-year-old subjects, etc. The nominal scale uses a number or the percentage of a total. If the measured category is part of a series, it can be replaced by a number for easier presentation, but without ranking.

A percentage should be presented with its uncertainty margins, thus its standard deviation (SD). The latter is calculated by the formula $SD = [p(1 - p)/n]^{1/2}$, where p is the percentage (from 0 to 1) and n the total number of data. The confidence interval for an occurrence by chance of less than 5 % is that between two standard deviations on each side of p . Tables of 5 % confidence intervals can be found in statistics textbooks. A close evaluation can be obtained using an abacus (Fig. 1).

2.2 Ordinal Scale

The ordinal scale provides only a ranking. This type of scale should be selected for two reasons: either the data are part of a discontinuous series, thus one cannot apply a number to them, or they come from a continuous series, but on an unknown scale on which it is not known if the distances

between the measured objects are equal or proportional: only the rank is identified. For instance, nonexistent, slight, good, and very good improvements can be rated 0, 1, 2, 3, knowing that 3 does not mean that the improvement was 3 times better than 1. To describe series of this type, the adequate parameters are the median and the extreme values. Graduated scales should be avoided (especially when the series is made up of averages) because they may be mistakenly used for parametric measurements instead of being more accurately applied to ranking measurements. This type of classification is particularly indicated in psychosensorial evaluations in which the phenomenon under study varies discontinuously, or continuously but with unknown intervals.

2.3 Interval Scale

Interval scales are most commonly used in evaluation for numbers in a continuous series. Units may be changed if the scale is the same (e.g., temperature in the same series can be converted from Celsius into Fahrenheit degrees and vice versa). If the data have a gaussian (or normal) distribution, they can be described by the mean and its standard error (i.e., the standard deviation of the mean); otherwise the adequate parameters are the median and the extreme values. If it is previously known that the studied parameter has a gaussian distribution, one can surmise that the means of samples equal to or greater than 30 are also normally distributed. In a comparative evaluation, it is often possible that each subject is its own reference; this avoids the interindividual source of variation (important in biology) and makes it possible to use statistical tests for matched pairs.

2.3.1 Opposition Method

The opposition method, also called the zero method, is used to obtain a higher degree of precision than a direct measurement. The rationale is to measure only the difference between the unknown quantity and another very close and already precisely known value. The measure of

Fig. 1 Confidence interval of a percentage when the probability of a greater or lower number occurring by chance only is limited to 5 %. As shown, if the sample size is 120, the 5 % confidence interval of 30 % is 22–39 %. If the sample size is 40, the 5 % confidence interval of 30 % is 18–47 %

the difference can be more precise because it deals with a much smaller quantity. Consequently its precision, related to the initial value to be measured, becomes more accurate. For instance, to weigh sebum laid on a glass slide, the slide is placed on one pan of a pair of scales and a standard mass of a similar weight known with great precision (e.g., a glass slide without sebum) is placed on the other. Then a weight is added on the lighter side to make up the difference and this difference is then measured. The International Bureau of Weights and Measures has scales designed for this type of differential weighing.

2.3.2 Psychosensorial Evaluations

For the psychosensorial evaluations in which the studied phenomenon is believed to vary in a continuous and uniform way (equal intervals), a nongraduated linear scale is used for each measurement. Generally this measurement consists of a 10-cm-long horizontal line, with zero on the left end and ten on the right; the measurement is indicated by a small vertical stroke. Graduated scales are less suitable because they tend to distort the scoring by favoring values close to the graduations, with the operator influenced by the value indicated. However, operators should be well

aware of the scale extremes (zero and ten), which sets the limits of the measure; consequently its variability is lessened. Another way to decrease variability is to replace the absolute measurement by a comparative measurement: the objects to be compared are placed next to each other so that they are perceived almost simultaneously; the nearer they are in time and space, the more accurate the measurement is. Operator training is also important.

3 Selecting the Suitable Unit

The units can be either arbitrary (e.g., millimeters on the linear scales used for psychosensorial measures), or arbitrarily linked to international physical units (e.g., skin blood flow measured in volts by the Doppler), or absolute (e.g., skin blood flow measured by the epicutaneous xenon clearance in milliliters per minute per 100 g soft tissue). Physical units are always better than arbitrary units, and absolute units are preferred to those of other associated physical phenomena (e.g., measuring stratum corneum water depletion in milliliters per square centimeter per hour, as compared to decreased electrical impedance). Creating dermatological or biological units should be avoided when it is possible to use internationally approved units so that skin structure and properties remain within the physics of all other materials for easier comparison and the opportunity to use the laws of physics and chemistry for interpretation, thus considerably increasing the benefit of the measurements, also necessary for scientific progress.

We recommend measurements in units of the *Système International d'Unités* (SI), also called the MKSA system, the four fundamental units of which are the meter (m), the kilogram (kg), the second (s) and the ampere (A). Skin area is commonly measured in square centimeters, its thickness in millimeters, etc. For the derived units, the conversion between the centimeter-gram-second (CGS) system, MKSA, or other systems is often a source of error. See conversion tables in [▶ Chap. 160, "Correspondence Between International System Units \(MKSA\) and CGS Units."](#)

4 Data Presentation

Faced with a variation or a distribution, the first step to prepare is a graphic representation: a curve or a histogram. The eye appreciates at once a series of features necessary for the interpretation and the processing of the information, for example, the gaussian or nongaussian characteristic of a distribution, the linear or nonlinear character of a relation, and the absolute level of a measure. Misunderstandings often stem from skipping this step.

When studying a histogram, the first question is "Does it fit a well-known distribution?" because the processing and interpretation of the data is then easier. A gaussian distribution, bell-shaped and symmetrical, means that data are independent of each other and that the distribution most probably results only from their summation. A distribution with two peaks may correspond to two interpenetrated gaussian curves. To rapidly check if a distribution is gaussian, the use of gaussometric graph paper (or gaussologarithmic if the abscissa is in logarithms) is suitable: it provides a quick calculation of the adjustment to this type of distribution. An asymmetrical histogram may indicate a binomial distribution. A substantial asymmetry suggests a Poisson distribution (a particular case of binomial distribution). An asymmetrical distribution can sometimes be transformed into a gaussian one by using the logarithm of the data.

Showing a variation through a mathematical function (of time or any other parameter) indicates major progress in data interpretation, if the variable has an anatomical or functional meaning. This makes it possible to use the function in other situations, sometimes to generalize its use, with further progress in knowledge. However, a purely descriptive mathematical model (i.e., when variables are devoid of biological meaning) is of minimal interest. The linear function speaks for itself and is one of the most profitable functions through the calculation of the slope and intercepts with the axes. It can be deduced from an exponential function by taking the logarithm of the data, and from any other function by replacing x on the x -axis with a power of x (e.g., for $y = a + b/x$, $1/x$ is put on the x -axis).

5 Precision of Measures

In a common parametric measurement, the highest level of accuracy is desirable, even if ultimately the decimals are rounded for convenience. Only the significant figures must be mentioned. Sampling uncertainty should always be mentioned, together with the observed variation.

5.1 Calculation of the Maximum Experimental Error in Measurements

To predict the maximum possible error in a measure of combined quantities from the separate measure of each quantity, the standard rules are:

- The absolute error Δy on a sum $y = u + v$ is the sum of the errors on each component $\Delta y = \Delta u + \Delta v$.
- The absolute error Δy on a difference $y = u - v$ is the sum of the errors on each component $\Delta y = \Delta u + \Delta v$.
- The absolute error Δy on a product $y = uv$ corresponds to the formula $\Delta y = u\Delta v + v\Delta u$. The relative error $\Delta y/y = \Delta u/u + \Delta v/v$.
- The absolute error Δy on a quotient $y = u/v$ corresponds to the formula $\Delta y = (u\Delta v + v\Delta u)/v^2$. The relative error $\Delta y/y = \Delta u/u + \Delta v/v$.

Note that these errors (Δu , Δv , etc.) are experimental errors on crude data and have no relation to statistical errors which are dealt with in the following paragraphs.

5.2 Variation in a Gaussian Distribution

In a gaussian distribution, the mean (m) must be presented with its uncertainty limits (i.e., either standard deviation and number of data, or standard error of the mean). The standard deviation (SD) must be mentioned with the number of observations (n) because the confidence interval it indicates

(95 % confidence interval ranges between two standard deviations on each side of m) differs with the number of measurements. The standard error could either be mentioned (SD divided by the square root of the number of observations), as in the error bars of a graph of means. If the data are logarithmic, the mean must be geometrical (n^{th} root of the product of n data). In the case of a percentage, both the SD and the number of data should be mentioned.

5.3 Variation in an Atypical Distribution

If the histogram does not show a gaussian distribution, it should be described using the median instead of the mean, i.e., the value under and above which 50 % of the observations are found. The variability around this value is indicated in the quartiles, which are the values under which 25 %, 50 %, and 75 % of the observations are made. One can also mention the centiles (or percentiles), the 80th centile being the value under which 80 % of the data are found.

The constant search for precision must not be sterilizing. An isolated mean, a separate percentage, a graph with no mention of variation are only indicators, but are always preferable to the text alone.

6 Comparative Measurements

One purpose of a measurement is to compare the obtained value to others, to ascertain whether the observed difference is true, or rather to calculate the probability that it might originate from chance alone. The methods chosen vary according to the type of measurement.

6.1 Comparison of an Isolated Value (x) to a Gaussian Series of More than 30 Numbers

Its distance to the mean of the series determines the probability for the value x to belong to this reference population by chance alone. For a

distance of 1 SD, the probability is 15.9 %, for two SDs 2.3 %, and for three SDs 0.13 %. The exact probability is the total area (=1) under the Gauss curve minus the part of that area beyond x on the x -axis. It can be found in gaussian curve tables, where it has to be divided by 2 since the value of x is located on one side of the mean (one-tailed test).

6.2 Comparisons of Two Series of Measurements

6.2.1 Gaussian Series or Series Larger than 30

Use the test of comparison of variances (statistics manuals: F tables), followed by the usual parametric tests of comparison of means.

Series with Variances (s^2) Not Significantly Different

- Independent samples n_a and n_b are ≥ 30 ; use the formula:

$$\epsilon = (m_a - m_b) / (s_a^2/n_a + s_b^2/n_b)^{0,5}$$

with degree of freedom (df) = $n_a + n_b - 2$

- Independent samples n_a and n_b are < 30 ; use the formula:

$$t = \frac{m_a - m_b}{\sqrt{\left(\frac{1}{n_a} + \frac{1}{n_b}\right) \frac{s_a^2(n_a - 1) + s_b^2(n_b - 1)}{n_a + n_b - 2}}}$$

with df = $n_a + n_b - 2$

- Matched samples: the calculation is made on the paired differences (n pairs): use the formula:

$$t \text{ (or } \epsilon) = m.n^{0,5}/s, \text{ where}$$

$$df = n - 1 \text{ and}$$

$$m = \text{the mean of differences.}$$

The parameter (distance to the mean, calculated in standard deviation) is the same for the three situ-

ations, but it is called ϵ or t depending on the size of each sample (30 or < 30 , respectively).

Series with Significantly Different Variances (s^2)

The same formulas are used but the number of degrees of freedom used to refer to the probability table must be modified according to the formula of Welch's G test,

$$\frac{1}{ddl} = \frac{1}{n_a - 1} \left[\frac{s_a^2}{n_a s^2} \right] + \frac{1}{n_b - 1} \left[\frac{s_b^2}{n_b s^2} \right]$$

the global variance s^2 , calculated by the equation:
 $s^2 = s_a^2/n_a + s_b^2/n_b$

The threshold value of parameter t depends on the risk α and the one-tailed or two-tailed character of the hypothesis to be checked.

6.2.2 Nongaussian Series

Nonparametric tests should be used, for example:

- Comparison of two nominal-type series: χ^2 test
- Comparison of two independent ordinal-type series: Mann and Whitney test
- Comparison of two matched ordinal-type series: Wilcoxon's matched pairs signed-ranks tests
- Comparison of two independent interval-type series: randomization test for two independent samples (Siegel 1956)
- Comparison of two matched interval-type series: randomization test for matched pairs (Siegel 1956) (the most powerful nonparametric test)

6.3 Simultaneous Comparison of Several Sets of Measurements

- Gaussian series: one-way variance analysis (ANOVA)
- Nongaussian series:
 - Nominal type series: $\#\chi^2$ test
 - Independent ordinal- or interval-type series: Kruskal-Wallis variance analysis (Siegel 1956)
 - Matched ordinal- or interval-type series: Friedman's variance analysis (Siegel 1956)

7 Minimizing the Number of Measurements

7.1 Sequential Analysis

When observing the sequential *chance* occurrence of two types of events in order to know if one type is more probable than the other, intuitively one feels the most probable is the one that happens more often. Indeed, when the difference in occurrences increases, at one point it becomes statistically significant at the 5 % probability level (or any level chosen in advance). On a graph showing the sequence of events, each one marked by an oblique dash in a specific direction (e.g., upward for one series, downward for the other), a broken line is obtained, the global direction of which leans toward the direction of the most probable event. The limits the line would cross when the difference is significant can then be drawn on each side of the central line. As soon as this happens, the experiment can be stopped (Fig. 2) (Whitehead 1997).

Fig. 2 Sequential trial. In the first patient, compound A was more effective than compound B, thus the first *vertical box* above the *black* one was checked. In the second patient, compound B was more effective than compound A, thus the next *horizontal box* was checked. In this example, the exit lies between the two wings of the grid, indicating no significant difference in effectiveness between the two compounds. Significance would be indicated by an exit at the exterior side of the wings

These limits can be computed using mathematical formulas which can be found in the book of Armitage et al. signalled at the end of this chapter.

7.2 Taguchi Designs

Taguchi designs are the most widely used experimental plans aimed at reaching the desired result with a minimum of experiments Taguchi and Wu (1980). For example, for the study of the effect of three parameters, each having two possibilities, it is possible to carry out four experiments instead of eight corresponding to the possible combinations. Among the categories of plans, the main types are:

- Designs with two parameters, each having two modes (L4 designs)
- Designs with three to five parameters, each having two modes (L8 designs)
- Designs for parameters with three modes (L9 designs)
- Designs allowing the combination of one parameter with two modes with parameters with three modes (L18 designs)
- Crossed designs, i.e., combining controlled parameters (as in the above designs) with so-called external parameters that are not under control.

8 Good Measuring Practice

Any measurement, especially in biology, has a degree of uncertainty, due to the nature of the measured phenomenon, as well as the measuring device and the operator. The reliability of a measurement can only be obtained if these last two factors are under control.

Equipment on the market must comply with technical standards. However, with time, performance may weaken, due to climatic, magnetic or other factors; we recommend placing the equipment on a test bench at regular intervals (for instance every year) in order to check the accuracy of its technical performance. For example, when a

device uses several pressures, are the displayed pressures correct? Does a cast meant to last several years lose its shape with time? It may be wise to check the device completely every year by measuring the equivalent skin standard. For example, the reliability of an ultrasound imaging device is checked by measuring the thickness of the layers of a stratified material. These methods are rarely used but should become common practice. Indeed, it is difficult to find standard materials that are reliable over prolonged periods. Manufacturers should assist users on this matter.

Most errors are caused by the operator and not the equipment. They tend to occur if the operator does not systematically ask: Have I read thoroughly and understood the instruction manual? Have I followed the recommendations? It is not possible to be a good operator instantly; patience, a critical mind, and experience are necessary.

The second question is related to the conditions in which the measurement is taken. Environmental conditions: temperature and relative humidity of the room must always be noted. Other conditions are specific to the type of measurement (e.g., for thermography). Physiological conditions related to the subject should be respected: minimum of 15 min acclimation to the room temperature, rest, relaxation (made easier when the test is noninvasive), thermal comfort, absence of sweating. A third question arises when subjects are their own controls: is the test site appropriate? Symmetry is no guarantee (Treffel et al. 1994), neither is proximity (Panisset et al. 1992). The random permutation of control and active sites obviates this problem. Finally a mandatory procedure is to always write down the date and hour, the environmental conditions, and an identification mark of the tested subjects, including the control subjects. Good practice in metrology implies that a manual or computerized logbook be kept with each device.

A rational catalog of possible errors sources is (Serup 1994):

1. Study design (strategic error)
2. The measuring device (technical error)
3. The use of the device (performance error)
4. Measuring conditions (inadequate laboratory facilities)

5. Selection and preconditioning of test subject (subject-related error)
6. Data acquisition, storing, and handling (data error)
7. Reporting and publication policies (explanatory mistake)

Even when these rules are observed, it is useful to know the results obtained by others. It often happens that the values given by a device in a laboratory group are not exactly the same as those given by similar equipment in another group. When new equipment is implemented, the operating team should check the reliability of their measurements on the same subjects, and know the variation coefficient (standard deviation/mean) of the measured parameters in a sample of at least 30 people. This is also essential in order to forecast the number of subjects (belonging to the tested sample) that will have to be recruited in comparative studies using this method.

For two independent samples, this number is given by the formula:

$$N \geq 2[(\epsilon_{\alpha} + \epsilon_{\beta})s/\Delta]^2$$

where ϵ_{α} is the accepted limit probability for considering as true a difference Δ that does not exist (risk α): usually one takes $\epsilon_{\alpha} = 1.96$ for a $\leq 5\%$ risk of error. And ϵ_{β} is the risk of ignoring a real difference Δ (risk β): usually the chosen figure is: $\epsilon_{\beta} = 1.28$ for a $\leq 10\%$ risk of error.

If the samples are matched (i.e., if subjects are their own controls) the formula is:

$$N \geq [(\epsilon_{\alpha} + \epsilon_{\beta})s/\Delta]^2$$

Misinterpretation is forgivable. Mistakes are often made because of ignorance of what is actually measured. Upon obtaining results, the operator must ask the following two questions:

1. Beyond the object that is officially measured, what is the real phenomenon, e.g., the so-called sebum excretion rate? Possible answers are:
 - The follicular reservoir excretion rate
 - The sebaceous gland secretion rate

- The absorbing paper absorption rate
 - The stratum disjunctum absorption rate
 - or what is the measuring method rationale, e.g., skin thickness measurement by ultrasound. The possible answer is the time for the ultrasound to go forward and backward divided by its *assumed constant* speed.
2. What is the measurement unit and why? For example, the cutaneous blood flow is measured in volts by the Doppler because an absolute calibration of the device has not been possible. A bias in the measurement technique may also alter the interpretation. It can be caused by subject and/or operator subjectivity or biased sample selection. The former problem is circumvented by using a single- or double-blind protocol, the latter by randomization of the sample or the sites so as to cancel unknown physiological variation (always use an algorithm-generated list of random numbers).

9 Conclusion

The following procedure should be followed by the operator:

1. Ascertain the reliability and accuracy of the equipment.
2. Meticulously follow all the manufacturer's instructions for using the equipment.
3. Set up the laboratory so that the material and physiological conditions of a precise measurement are routinely ensured.
4. Systematically record the above-mentioned elements on a specific logbook.
5. Determine the variance of the equipment's measures, preferably before the method is used routinely.

Acknowledgments The author thanks Mrs. Mariette Mercier, Professor of Statistics at the Faculty of Medicine and Pharmacy of Besançon (France), who kindly revised this chapter and provided the information about Welch's test.

1 Introduction

Cognizance of time and its influence on the recurring behavioral patterns of plants and animals dates back many centuries (reviewed by Reinberg and Smolensky 1983; Moser et al. 2006; Halberg et al. 2001). The study of the rhythmic time-based relationships found in biological systems has been coined chronobiology – the science of investigating and objectively quantifying phenomena and mechanisms of the biological time structure, including the rhythmic manifestations of life (American Association for Medical Chronobiology and Chronotherapeutics, www.aamcc.net/glossary.htm). Chronobiological rhythms have a profound influence on organisms by providing the temporal structure for biological processes. To “tell time,” most living organisms use timekeeping mechanisms known as “biological clocks.” These “clocks” coordinate our physiological and behavioral functions, thereby optimizing the adaptations to and interactions with our environment. In the last decades, hundreds of different clocks/cycles have been identified sparking renewed interest in chronobiology. In addition, the awareness of the implications of chronobiological effects has increased, and it is now

Fig. 1 Schematic representation of typical chronobiological rhythms and the clocks influencing them

recognized that these have true mechanistic and therapeutic implications (e.g., chronotherapy; reviewed by Kaur et al. 2013; Librodo et al. 2012). A short description of typical chronobiological rhythms is depicted in Fig. 1.

While the underlying science of biological oscillators is intricate and complex and therefore not entirely understood, our master clocks are most likely set according to the world's most reliable timekeeper: the sun. The circadian rhythm, the daily cycle, is probably the most pronounced and therefore the best researched. Light is assumed to be the most important zeitgeber, the external stimuli which entrain the rhythms and govern the synchronization of the circadian rhythm. Circadian timekeeping systems in mammals are organized into a complex hierarchical network of oscillators with the suprachiasmatic nucleus (SCN) of the hypothalamus acting as the principal pacemaker. The SCN receives light signals from specialized cells in the retina, the retinal ganglion cells, which entrain the SCN to light-dark cycles via glutaminergic innervation and/or photoreceptive systems based on melanopsin. This in turn triggers circadian rhythms, e.g., via

the release of the hormone melatonin or adrenocorticotropic hormone (ACTH; Berson et al. 2002; Hastings et al. 2003; Luboshitzky 2000), which influences the peripheral clocks ubiquitously found in human cells. Although the exact functions are not yet well elucidated, it is reasonable to assume that the peripheral clocks are then responsible for the physiological fine-tuning leading to optimized responses to environmental and internal occurrences and processes. Biological periodicities can also be governed by other environmental cues, e.g., by the lunar cycle, but also by daily social rhythms, e.g., work. Interestingly, if left undisturbed, the "free-running" circadian rhythm in humans is approximately 25 h (possibly reflecting lunar influences as secondary synchronizers as this time period corresponds to the orbit time of the moon and with it, the tidal peaks that occur every 12 h and 25 min). One aspect that should not be forgotten is that life itself is a biological rhythm. Malfunctions of the biological clocks can lead to various disorders, including hypertension, sleep, psychosomatic disorders, and a number of chronobiological rhythms most likely out of phase in the elderly population

(Mishima et al. 2000; Pagani et al. 2011; Chang and Guarente 2013).

Skin is the interphase of the body and its environment. As such, it plays a critical role in the adaptation of processes to maintain the body's homeostasis. Although seasonal variations and phases inherent to life also play a role (e.g., reviewed by Mehling and Fluhr 2006), in the following, an overview will be given on chronobiological effects found in the skin with the main focus being on circadian rhythms (in this context including ultradian rhythms, etc.) and skin clocks.

2 Functional Chronobiological Rhythms of the Skin

Among the initial systematic and comprehensive studies actually focusing on the natural "healthy," chronobiological effects found in the skin function were the studies conducted by Yosipovitch et al. (1998) and Le Fur et al. (2001). Yosipovitch et al. conducted a study comparing the rhythmicity of the skin surface parameters: skin pH, skin surface moisture, skin barrier function (via transepidermal water loss, TEWL), and skin temperature. Measurements were conducted at four different locations (forehead, forearm, upper back, and shin) on seven women and nine men at 2-h intervals over a period of 24 h under well-controlled conditions. Discernible rhythms for TEWL, temperature, and pH were observed at most sites. Using TEWL as a measure of skin barrier function, the skin barrier showed an improved status in the morning which decreased toward the evening. This was not correlated with an increase in skin temperature, although skin temperature was also elevated at night. No significant differences were observed for skin hydration although capacitance was slightly higher around 4 p.m. In a later study, Yosipovitch et al. (2004) also investigated the effects of cortisone treatment of irritated and nonirritated skin on the circadian rhythms of blood flow, skin temperature, and TEWL. Blood flow exhibited circadian and ultradian rhythms with a significant correlation found to skin temperature but not TEWL. Blood

flow was highest in the late afternoon/early evening and before onset of sleep and lowest in the morning.

Le Fur et al. (2001) studied time-dependent rhythms of the face and volar forearm skin over a time span of 48 h every 4 h under standardized environmental conditions. In addition to the skin parameters reported by Yosipovitch et al., sebum secretion was also measured. Salivary cortisol levels as surrogate markers for plasma cortisol were assessed to ensure that the volunteers were synchronized. In general, these results corroborated those found by Yosipovitch et al. Circadian rhythms were detected for sebum excretion (face), transepidermal water loss (face and forearm), skin temperature (forearm), pH (face), and capacitance (forearm). In addition, ultradian rhythms with periods of 8 h were found for sebum excretion, of 8 and 12 h for transepidermal water loss (face and forearm), and of 12 h for skin temperature (forearm). Skin pH was highest in the morning, sebum secretion peaked around midday, skin temperature of the forearm (but not face) was lowest around midday and exhibited two peaks at 4:00 p.m. and 4:00 a.m., and skin barrier function (cheek) as assessed by TEWL was lowest at 8:00 a.m. and 4:00 p.m.

Denda and Tsuchiya (2000) investigated the recovery of the skin barrier function (via TEWL measurements) of the volar forearm skin at various time points in the course of a day (30 h). Skin surface temperature peaked at 2:00–3:00 a.m. and remained slightly elevated throughout the morning. Following skin barrier disruption via tape stripping, recovery rates assessed via TEWL and measured 1 h after tape stripping exhibited time-dependent effects with decreased recovery rates found between 20:00 and 23:00 h in comparison to measurements made at other time points. During this time, there was no significant correlation to skin temperature. The basal TEWL values were observed at about 03:00 h (33.6 °C and 0.30 mg/cm²/h) indicating that the time-dependent differences in cutaneous barrier repair are independent of changes in skin temperature.

"Out-of-sync" clocks have also been implicated in atopic dermatitis, psoriasis, contact

hypersensitivity, and skin cancer (Wood and Hrushesky 1996; Gelfant et al. 1982; Li et al. 2013; Takita et al. 2013; Gaddameedhi et al. 2011; Cermakian et al. 2013; Muñoz-Hoyos et al. 2007). Cutaneous immune responses to allergens differ throughout the day, e.g., Reinberg et al. (1965) observed that there is a circadian variation to the reactivity to skin tests. Zak-Nejmark et al. (2006) et al. studied skin reactivity of healthy and atopic individuals to histamine and observed that healthy individuals have the lowest reactivity at night. In contrast atopic individuals exhibit the highest reactivity at night. Histamine binding to lymphocytes and neutrophils also displayed variations between day and night. As atopics tend to suffer more from itching at night and asthma is also increased at night, this may have implications for chronotherapeutic approaches. Circadian processes may play a role in the exacerbation of skin cancer. Mice exhibited a fivefold increase of invasive squamous cell carcinoma when irradiated with UVB at 4:00 a.m. than at 4:00 p.m. Low-dose UVB has been reported to downregulate clock genes and to alter their expression, thereby modulating circadian rhythms (Kawara et al. 2002). Maintaining the proper balance between light and dark and the resulting beneficial (e.g., vitamin D production) or damaging effects (e.g., photodamage) of UV (reviewed by Desotelle et al. 2012) may have a pronounced impact on cellular functioning and susceptibility to skin cancer. Downregulation of clock genes has been observed in skin tumor biopsies indicating a possible role in protective role in cutaneous tumorigenesis (Lengyel et al. 2013), possibly attributable to aberrant cellular responses to DNA damage, including repair, checkpoints, and apoptosis. Clock genes play a role in hair cycling, beard hair follicles have endogenous clocks lined to PER1 and PER3, and clock gene dysfunction may play a role in age-related alopecia (Watanabe et al. 2012; Geyfman and Andersen 2010). These are but a few examples of chronobiological rhythms playing a role in cutaneous processes.

Differences in the circadian rhythms of skin function have been observed. These may be attributable to the time intervals used to assess the

parameters. In some studies, parameters were measured every 2 h, in others every 4 h, etc. Depending on the sampling time, and the circadian rhythms exhibited by the organism, ultradian rhythms can be identified or certain circadian rhythms being missed. Other parameters, such as ambient temperature and humidity as well as season, may also lead to masking of the natural biorhythms or to different entrainments. Gender (e.g., menstrual cycle of women), age (children tend to have longer sleep phases, whereas aged people most likely have defective clocks), etc., may also play a role.

3 Cutaneous Clocks

Although circadian rhythms are entrained by the external time cues that are primarily governed by the solar day, circadian oscillations are also generated at the cellular level and occur in most cells of the body. These molecular clocks are not always directly linked to the cues given by the SCN, and cell autonomous clockworks can be found. These may be linked to physiological and metabolic processes that are not directly associated with the solar day, e.g., metabolic processes linked to food uptake or temperature variations as potential zeitgeber. The orchestration of the oscillations is governed by an intricate network of transcriptional and translational feedback loops. Among the most prominent examples are the positive transcriptional regulator genes *Clock* (Circadian Locomotor Output Cycles Kaput) and *Bmal1* (brain and muscle aryl hydrocarbon receptor nuclear translocator-like protein-1) which drive the expression of the target genes such as the *Period* (*Per*) 1–3 genes and the genes *Cryptochrome* (*Cry*) 1 and 2. Autoregulatory negative feedback loops occur via the formation of PER/CRY protein complexes which in turn block the transcription factor CLOCK/BMAL1 and thereby inhibit their own transcription. How does this occur? The positive arm of the regulatory feedback loop is formed by the heterodimer CLOCK/BMAL1 which binds to the E-box sequences of targets genes such as *Per*, *Cry*, *ROR* (retinoid-related orphan receptor), and

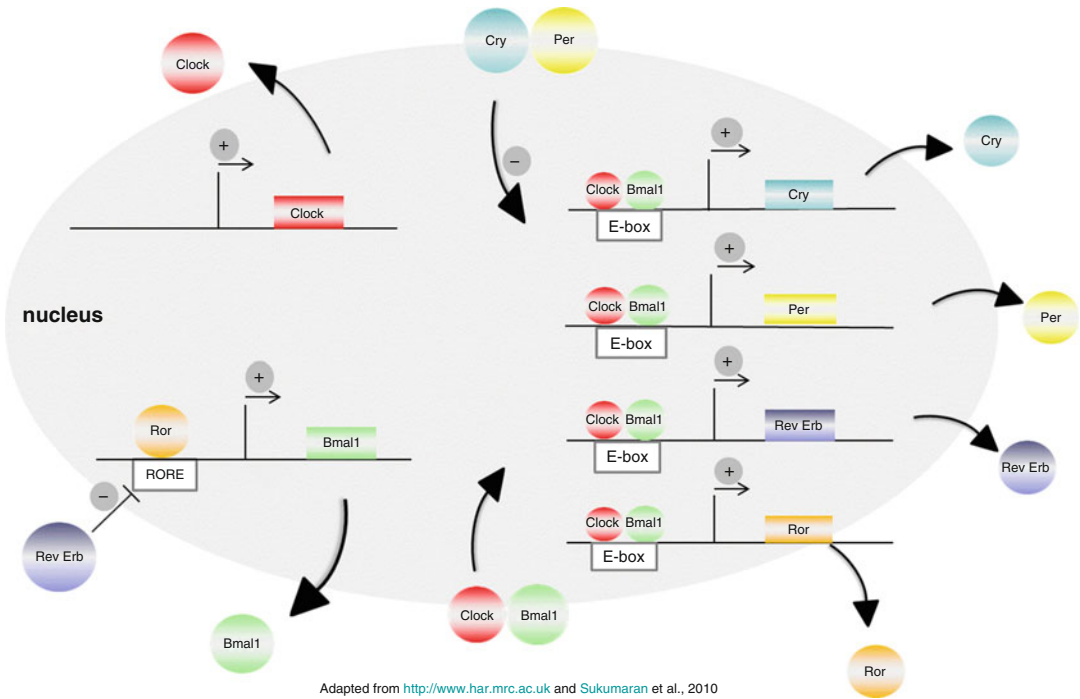

Fig. 2 Example of feedback mechanisms regulating cellular rhythms. In the cytoplasm, Clock and Bmal1 associate as a heterodimer before their translocation to the nucleus where they are able to bind to the E-box sequences of target genes such as PER, CRY, ROR and REV ERB in order to stimulate their transcription. CRY and PER are transcription factors which form the negative regulatory loop. They are able to heterodimerize in the

cytoplasm before their translocation in the nucleus where they are able to inhibit the action of CLOCK/BMAL1 complex. Moreover, the nuclear receptor transcription factors ROR and REV-ERB have opposite control on *Bmal1* gene. In turn ROR up-regulates and REV-ERB down regulates the expression of *Bmal1* by binding to the RORE element present in the upstream region of the *Bmal1* gene

REV-ERB (orphan nuclear receptor), thereby stimulating their transcription. The gene products, CRY and PER, can then form heterodimers which subsequently function as repressive transcription factors by inhibiting CLOCK/BMAL1 induced transcription, thereby forming the negative arm of the regulatory feedback loop. Further “oscillation” is achieved in that the expression of *Bmal1* is regulated by the nuclear receptor transcription factors ROR and REV-ERB. ROR upregulates and REV-ERB downregulates the expression of *Bmal1* by binding to the RORE element present in the upstream region of the *Bmal1* gene (Fig. 2). In addition, TIM (timeless protein) can control PER stabilization in the cytoplasm by binding to specific domains in order to coregulate their subcellular localization and to protect PER from degradation or to activate the

repression of CLOCK/BMAL1 function (Sukumaran et al. 2010). Cellular clockworks such as these are also found in the skin, and it is estimated that up to 10 % of the genes exhibit a circadian rhythmic expression (Desotelle et al. 2012).

Expression of the human clock genes, *Clock*, *Tim*, *Per1*, *Cry1*, and *Bmal1*, is found in both the oral mucosa and skin and is typically aligned with the circadian profiles controlled by the SCN. The patterns are strongly correlated with the expression patterns found in mice suggesting that the skin itself may be an additional pacemaker in circadian rhythms (Bjarnason et al. 2001). The expression of the genes *Per1*, *Cry1*, and *Bmal1* peaks in the morning, late afternoon, and at night. In addition, the expression of the cell cycle proteins of the mucosa

coincides with the expression of some clock genes, e.g., with *Per1* expression occurring at the same time as the G₁ phase, indicating an interaction of the gene products. Cultured human skin cells, e.g., keratinocytes and fibroblasts, as well as the keratinocyte cell line HaCaT and the melanoma A375 have been shown to exhibit expression of the circadian clock genes *Clock* and *Per1* (Zanello et al. 2000). HaCaTs have robust circadian expression patterns which correlate well with those found in vivo as does the murine fibroblast cell line NIH3T3. In a recent study, Spörl et al. (2011) investigated the effects of temperature cycles on the rhythmicity of the cutaneous clocks. As Yosipovitch et al. (1998) already reported for human skin, temperature is an effective zeitgeber for the cellular clocks, e.g., *Per2* (both primary keratinocytes and cultured cell lines), thereby linking them to the physiological influences given by environmental cues. Rhythmic PER2 expression has also been described by Tanioka et al. (2009) who observed an essential role of this protein in generating circadian oscillations in the peripheral clocks. Temperature can even be used to entrain the cells. Interestingly, a circadian transcription of *Insig2a* was also observed. This gene is pivotal for cholesterol homeostasis and with it for keratinocyte differentiation, cornified envelope development, and skin barrier function. If there is a cholesterol deficiency, sterol regulatory element binding proteins (SREBPs) are released and activate de novo synthesis of cholesterol (e.g., via *Hmgcr*) or enhance its uptake (e.g., via *Ldl* receptor gene products), whereby both genes also intriguingly exhibit circadian rhythms. The same group recently employed genome-wide transcriptional profiling in which whole genome microarrays were used to characterize gene expression profiles in human suction blister epidermis during the course of a day (Spörl et al. 2012). Over 300 genes exhibited diurnal daytime-dependent expression, many of which were also found in vitro. Among these, Krüppel-like factor 9 (*Krf9*) exhibited a profound circadian rhythms which was cortisol dependent and linked to keratinocyte differentiation and proliferation.

The proliferation HaCaT cells has also been reported to be influenced by melatonin – the secretion of which has a pronounced circadian rhythm itself (Hipler et al. 2003; Fischer et al. 1999). Clock gene expression in HaCaT cells is modulated by low-dose UVB irradiation (Kawara et al. 2002) suggesting that expression in circadian clock genes in keratinocytes is influenced by solar irradiation via melatonin-independent mechanisms. These studies give further indication that skin processes follow chronobiological patterns and exposure of the skin to UV irradiation and/or light may possibly be involved in the circadian rhythm regulation via modulation of clock gene expression. The observation that skin cancer is also controlled by circadian rhythms, e.g., as nucleotide excision repair genes follows circadian patterns (Gaddameedhi et al. 2011; Sancar et al. 2010), further points to the important role chronobiological processes have on organisms.

4 Conclusions

The skin barrier function is essential in protecting the body against water loss, pathogens, and xenobiotics. The studies described above suggest that skin has a pronounced circadian rhythm. An interpretation of the observed time-dependent patterns is that they are suggestive of skin adapting to boost its protective functions during the day to ward off environmental threats; during evening and night processes are then directed at regeneration. As skin seems to be more reactive and permeable toward late afternoon and evening, these effects can possibly be used to optimize delivery and efficacy of both cosmetic and medical actives. Clocks are found on the cellular/molecular level in cells throughout the body indicating a profound importance for the fine-tuning needed to maintain the body's homeostasis when adapting multitude of different environmental and cellular cues. The concepts of chronopharmaceutics and chronocosmetics are not just obscure imaginings – they have a justified role in designing more efficacious and targeted approaches to pharmaceutical and skin care regimens.

The skin surface is an ecosystem: its ground is the desquamating uppermost stratum corneum (the *stratum disjunctum*) and the living part is the resident bacterial and mycotic flora, continuously proliferating in a complex environment made of lipids of sebaceous and epidermal origin, desmosomal and intercellular enzymatic protein degradation, transepidermal water, and sweat. The part played by physicochemical phenomena (surface tension, electrochemistry) is considerable. This ecosystem constantly regenerates and remains stable in spite of the daily sloughing out of one *stratum disjunctum* layer, i.e., about a third of the ecosystem thickness. Its part in the skin physiology is essential and subject of lots of works in the last years, involving experts in dermatology, microbiology, immunology, and molecular and genomic fields.

1 Skin Relief

The relief of the skin surface (also referred to as microrelief, microtopography, skin surface texture, skin roughness) varies according to the anatomic site and their own characteristics. It is formed by the association of the furrows, the follicular orifices or sweat pores, and the slightly

Fig. 1 Volar forearm skin surface. *Thick arrow*: first-order furrow. *Middle-sized arrow*: second-order furrow. *Small arrows*: third-order furrows. In between furrows are easily recognized the bumps made by corneocytes (corneocyte pavement). Scanning electron micrograph (Courtesy of Dr Boleslav Turek)

Fig. 2 Volar forearm skin surface. Sweat duct orifices are seen on some plateaus. Scanning electron micrograph (Courtesy of Dr Boleslav Turek)

protruding corneocytes (Fig. 1). On most sites, the main furrows, called primary lines (Wolf 1940; Hanusova 1938; Tring and Murgatroyd 1974), are 70–200 μm deep and follow two directions at least and delimit plateaus of variable shapes according to the area (Chinn and Dobson 1964; Sarkany and Caron 1965). The follicular orifices are located at the junction of these furrows, whereas the eccrine sweat pores (Figs. 2 and 3) are preferentially on the plateaus (Johnson et al. 1970) or in more superficial furrows, called secondary lines, and 20–70 μm deep. The third type of furrows roughly separates groups of corneocytes and is inconstant.

This network of furrows is present at birth (Tchernoff 1985) and its depth increases with age until puberty (Makki et al. 1984). In adults, it is less deep in women (Makki et al. 1984). On the face, small wrinkles (depth 0.2–1 mm) and deeper wrinkles (depth >1 mm) appear with age. On other zones, the deepest furrows increase, the small furrows disappear, and the skin surface becomes distended (Makki et al. 1984; Corcuff et al. 1983; Zahouani and Vargiolu 2004). The main function of the furrows is mechanical. By (partly) smoothing out they allow the extension of the skin surface and the epidermis. Their anatomical distribution

reflects at each site the direction of the mechanical constraints sustained by the skin. On the volar forearm, the resistance to this smoothing action represents approximately 50 % of the resistance of the whole skin to stretching (Panisset et al. 1993). The furrows also act as channels for the sebum and sweat flowing and retention. They preferentially trap and keep the substances applied on the skin: they are possibly preferential sites of percutaneous absorption.

On the palms and soles, the furrows draw curvy shapes which form the dermatoglyphs. The plateaus are replaced by concentric ridges on top of which sweat pores are located at regular intervals (Fig. 4). This type of relief seems specifically adapted to the need to adhere to the ground and objects. This is achieved by three factors: the dermatoglyphic drawing, the constant moisturizing of the crests by a slow although continuous sweat secretion which considerably increases the friction coefficient (Highley et al. 1977), and finally the sudden sweat secretion of the palms and soles in the event of a psychological stress (psychogenic sweating). This function was crucial for primitive humans who lived naked in the savanna. For a probably similar reason, the palms and soles have no pilosebaceous follicles: the sebum, like any fatty substance, and the hairs reduce the friction coefficient (Elkhyat et al. 2014).

Fig. 4 Finger pad skin surface. Orthophtaldialdehyde-dyed sweat orifices are located on the concentric ridges (Laboratory of Skin Biophysics, Besançon)

2 Microbiology of the Skin Surface

One major aspect of the skin surface ecology is the presence of a resident bacterial (more than 10^{10} bacteria living on our skin), mycotic (and probably viral) flora; its presence and normal behavior are essential to ensure a healthy skin (Kloos 1981). Numerous researches focus on understanding the role of these microbes in human health and

Fig. 3 Sweat duct orifice. Scanning electron micrograph of a Silflö replica. X 2000. (Laboratory of Skin Biophysics, Besançon)

diseases; this field of research received support from institutions such as US National Institutes of Health that initiated in 2007 the Human Microbiome Project (HMP, www.hmpdacc.org) and use now advanced and high-level technologies, like metagenomic sequencing for genetic characterization of skin microbiota (Schloss 2014) or molecular gene profiling to identify the species or phylotypes (Dekio et al. 2005).

2.1 Skin Flora Behavior

Research over the last years has provided data on the nature and the taxonomy of the resident species (Table 1). Most of these microorganisms live in colonies adhering to the squames, mainly in the furrows of the skin surface, in the pilosebaceous infundibula, and inside the *stratum disjunctum*.

The permanently *resident* character of the typical skin flora (micrococci, *P. acnes*, aerobic corynebacteria, *Pityrosporum*) implies its continuous proliferation in situ, regulated by the nutrients found in the area (especially lipids), humidity, pH, and probably other factors such as temperature, partial oxygen and carbon dioxide pressure, and exposure to ultraviolet rays. The bacterial spectrum depends primarily on local factors. For example, the density (number of microorganisms per surface unit) is almost constant. It reproduces itself quickly after scratching, bathing, or washing and even after disinfection (Johnston et al. 1987). A bath a day or no washing for 3 weeks will not make any difference (Hartmann 1990).

The *temporarily resident* character (transient flora) applies to potentially pathogenic (*S. aureus*, *C. minutissimum*, Gram-negative bacteria (*Proteus*, *Klebsiella*, *Pseudomonas aeruginosa*, *Escherichia coli*), non-lipophilic yeast (*levure*) (*C. albicans*), dermatophytes) microorganisms. They either come from the environment or invade the skin from adjacent areas (nasal vestibules, rectum). They do not proliferate, except if local or immune conditions are favorable. Accordingly their preferred location is in folds (armpits,

Table 1 Bacteria found on healthy skin

1. Gram+ cocci

They produce a catalase which differentiates them from streptococci. There are two main genera:

Staphylococci, able to ferment glucose under anaerobic conditions. They include mainly *S. albus* (coagulase negative) with its 9 species: the main species are *S. epidermidis*, *S. hominis*, and *S. saccharolyticus*, distinguished by their phenotype and their DNA (Kloos 1981). They are ubiquitous, i.e., found almost everywhere on the integument

S. aureus (coagulase +) is sometimes found steadily on healthy skin, especially in nasal vestibules (nasal carriage). It belongs to the transient resident flora

Micrococci (strictly aerobic) have 8 species, distinguished by their phenotype, their possible genetic transformation, and partly by their DNA (Kloos 1981; Marples 1981). They are ubiquitous

2. Aerobic corynebacteria (Tring and Murgatroyd 1974; Pitcher and Jackman 1981)

These are club-shaped sticks, are Gram+, and do not produce spores. Cultures under UV light emit a coral fluorescence. They are also characterized by the presence of arabinose and corynemycolic acid in their wall. On the skin some are responsible for a sour pungent smell. There are two categories:

Non-lipophilic in vitro (perineum, axilla):

C. minutissimum

C. xerosis

Brevibacterium epidermidis (responsible for the unpleasant foot odor due to the production of CH₃SH)

Lipophilic in vitro:

C. lipophilicus (toe webs, perineum, axilla)

C. jeikeium (also called *Corynebacterium JK*) and *C. urealyticum* (also called *Corynebacterium D2*) are part of the transient resident flora

3. Propionibacteria

These are anaerobic corynebacteria in vitro. They are lipophilic as well as lipolytic and are found on the seborrheic areas and in the pilosebaceous follicles

P. acnes = *C. parvum* (immune enhancer)

P. granulosum

P. avidum (proteolytic)

4. Gram-negative bacteria (Somerville and Noble 1970)

Acinetobacter calcoaceticus (axilla, toe webs)

The transient resident flora includes *Pseudomonas*, *Proteus*, and *Klebsiella*: located in the axilla, nostrils, groin, perineum, and toe webs

5. Yeasts

Pityrosporon (*P. ovale* = *P. orbiculare* = *Malassezia furfur*), lipophilic and lipolytic, is abundant on seborrheic areas

(continued)

Table 1 (continued)

Non-lipophilic yeasts of rectal origin (*Candida*, *Rhodotorula*, *Torulopsis*, *Cryptococcus*) belong to the transient resident flora of the perineum

6. **Dermatophytes**, transiently resident, come from the environment : *Trichophyton rubrum*, *T. interdigitale*, *Epidermophyton floccosum*, *Microsporon*

perineum, between toes), and they are found in some individuals only and in diseased skin. They are generally few in number (“*S. aureus* carriage” applies if density is over 10^6 bacteria/cm²). In some cases, the skin *transient flora* comes from the environment (contamination in hospital wards, sinks); for example, Gram-negative bacilli are abundant in vases and flower pots; group B streptococci may be of pharyngeal or rectal origin.

The neonate skin is colonized through vaginal contact, and then within the next 3 days following birth, the flora diversifies (*S. epidermidis* especially appears), due to the transition from an aqueous and sterile environment of the womb to a gaseous one, characterized by constant microbial interactions and bacterial colonization (Capone et al. 2011). Infant and young children skin harbors mainly micrococci, white staphylococci, corynebacteria, frequently Gram-negative bacteria, streptococci (during the period of hyposeborrhea between the ages of 6 months and 6 years), and *S. aureus* (colonization of the nasal vestibule), these proportions evolving over the first years; early microbial colonization is important for the development of skin barrier and immune functions and widely for the systemic immune system. In older people there is a global flora decrease, especially of propionibacteria.

2.2 Topographical Variations

The major importance of the environment in the proliferation of microorganisms is shown from topographical variations. Even among healthy individuals, differences in location and quantity of microbes have been described (ethnicity, skin pH, age, BMI); these fluctuations are not being yet fully explained, even if diet, hygiene,

environment, host physiology, genetics, and early microbial exposure are implicated (Schommer and Gallo 2013; Grice and Segre 2011; Grice et al. 2008). Thanks to genomic and molecular recent approaches, relying on sequence analysis of the 16S ribosomal RNA gene (present in all bacteria and archaea), it seems that not dominant but low-abundance organism’s composition could allow to better differentiate each individual (Schloss 2014).

The skin is confronted to an important diversity of parameters that could influence its surface characteristics; furthermore and depending on the body site, a wide variety of cell types can be encountered (Sanford and Gallo 2013).

Three types of habitat for microbes are distinguished. The *fatty habitat* (scalp, face, shoulders, thorax) is marked by the importance of the sebum secretion, triglycerides being necessary to the development of propionibacteria and Pityrosporum. Thus the density in *P. acnes* varies in parallel with the “sebum excretion rate” changes with age or isotretinoin treatment (Leyden et al. 1991). The sebaceous lipids inhibit *Streptococcus pyogenes* and hydrophilic species (Tables 3 and 4); thus, surprisingly, occlusion on the scalp does not alter the flora nor increase the bacterial density (Leyden et al. 1991). The *humid habitat* applies to the body creases where the transcutaneous water loss cannot be evacuated and the easier corneocyte degradation facilitates supply of protein, which is the selective nutrient of dermatophytes. The other hairless sites correspond to the *dry habitat*, where dryness is responsible for a low bacterial density. To these three habitats should be added the nostrils (*nasal vestibule*) which play an important role in the skin colonization.

The distribution of the main species on the main body sites is presented in Tables 2, 3, and 4. This is only an outline, since differences can be found on quite close sites and depend on skin thickness, folds, density of hair follicles, and glands. For example, inside the sebaceous follicle, Pityrosporum are found at the ostium, white staphylococci at the supra-infundibulum level, and anaerobic propionibacteria (*P. acnes*) in the infra-infundibulum.

2.3 Proliferation

Continuous proliferation is mandatory for the resident flora because of the stratum corneum desquamation which daily removes approximately one cell layer. The *stratum disjunctum*, daily preserved through the decay of one stratum compactum layer, and especially the pilosebaceous infundibula constitute the reservoir.

Table 2 Topographical variations of the skin flora

1. Oily habitat (seborrheic)	
Scalp: Pityrosporum > propionibacteria (<i>P. acnes</i> > <i>P. granulosum</i> > <i>P. avidum</i>) > white staphylococci (<i>S. epidermidis</i> , <i>S. hominis</i>)	
Other areas : propionibacteria > Pityrosporum > white staphylococci	
2. Wet habitat	
Axilla: aerobic corynebacteria, <i>P. avidum</i> > <i>P. granulosum</i> , <i>P. acnes</i> , white staphylococci (<i>S. epidermidis</i> , <i>S. hominis</i>), <i>Acinetobacter calcoaceticus</i> (Chinn 1964), ± <i>S. aureus</i> , Gram-negative bacilli	
Groin: aerobic corynebacteria, <i>P. avidum</i> , white staphylococci ± Gram-negative bacilli	
Perineum: white staphylococci ± <i>S. aureus</i> , Gram-negative bacilli, group B streptococci	
Interdigital: <i>P. avidum</i> , aerobic corynebacteria, <i>Acinetobacter calcoaceticus</i> (Johnston et al. 1987), ± Gram-negative bacilli, <i>C. minutissimum</i>	
3. Dry habitat	
Upper limbs: white staphylococci (<i>S. epidermidis</i> , <i>S. hominis</i> , <i>S. haemolyticus</i>), lipophilic corynebacteria	
Lower limbs: white staphylococci	
Hands (impossible to sterilize): white staphylococci ± <i>S. aureus</i> (in dermatologists), corynebacteria of the JK group (in oncologists), Gram-negative bacilli, candidas	
4. Nasal vestibules:	
<i>P. avidum</i> , <i>Staphylococcus epidermidis</i> , aerobic corynebacteria ± <i>S. aureus</i> (20 % of permanent carriers), Gram-negative bacilli	

The main growth factors are the available nutrients, humidity, and heat. This explains the high microbiological density increases (Tables 3 and 4). A 24-h occlusion increases by 1,000 the bacterial density: an increased number of staphylococci and micrococci appear first and then non-lipophilic diphtheroids and Gram-negative bacilli. Moisture is essential for the development of *C. albicans*. In the tropical jungle environment, non-lipophilic corynebacteria and Gram-negative bacilli proliferate. However seasons have little effect in temperate countries. For premature babies, the high relative humidity and temperature of incubators imply a risk of proliferation of *P. aeruginosa* on the umbilical stump.

Unfavorable or selection factors are also present. The sweat, through its lactic acid, inhibits some colonies of micrococci and staphylococci. *P. acnes* (and acne) proliferates through a small increase of the skin surface pH (from 5.5 to 6.0), but staphylococci do not (Korting and Schmid 1995). A pH ≤5.0 inhibits *Brevibacterium epidermidis* (Korting and Schmid 1995). There are specific substrates for each bacterial adhesin (e.g., *S. aureus* adheres to fibronectin and fibrinogen by teichoic acid and protein A).

Some bacteria inhibit the proliferation of exogenous microorganisms (bacterial interference). Pityrosporum (by production of phenylethyl alcohol) and aerobic corynebacteria inhibit most of the Gram-negative bacteria. *S. epidermidis* inhibits *S. pyogenes* and some colonies of micrococci. The eradication of the resident flora favors the prolonged life of *S. aureus*, however without any effect on *Candida albicans*, *S. pyogenes*, and *P. aeruginosa*. Dermatophytes produce penicillin and streptomycin (hence the selection of resistant

cocci). Bacteria of the *Brevibacterium* genus inhibit the dermatophytes (by production of methanethiol).

What is the effect of skin cleansing (Brandberg and Andersson 1981)? Absence of washing, even for a week, does not increase the total number of microorganisms. Excess washing has little or no effect either. A shower causes a local and transient reduction in microbial count on denser areas and an increase in density on the lower ones, probably through colony breaking and dispersion. Washing with an antiseptic can induce an apparently total disappearance of the flora, but it does not last. One possible mechanism of this resistance is the formation of bacterial clusters covered by a protecting film (biofilm). Testing the efficacy of washings, antiseptics, and disinfectants has been addressed recently by Kramer (1999).

2.4 Role of Skin Flora?

– The resident skin flora plays a fundamental part as a barrier against colonization by pathogenic or harmful species. This effect is enhanced by the physiological desquamation: squamous conditions favor the carriage of pathogenic bacteria. Microorganisms may also have a role in the immune system by educating the billions of T cells found in the skin (Grice and Segre 2011) or helping protect against allergy or inflammation (Fyhrquist et al. 2014).

- Propionibacteria transform the sebum triglycerides into free fatty acids – one of the characteristics of the physicochemical environment of the skin surface. They contribute to its acidity and its low surface energy.
- *Propionibacterium acnes* is an immunity enhancer. In the 1970s, under the name *Corynebacterium parvum*, it has been used to improve the late hypersensitivity in melanoma patients. It is possible that this effect be exerted through percutaneous absorption of some bacterial products which modulate the cytokine production by skin viable tissues.

2.5 Pathology

Abnormal high or low rates, absence, deregulations, or presence of new resident species in skin flora could have pathological consequences not only on the skin but also widely on the whole organism.

“Dysbiosis” is the dedicated term for an imbalance of microorganisms and exists in much pathology, but it is not clear whether and in which proportions this phenomenon is a cause or a consequence of the concerned disease (Schommer and Gallo 2013; Grice and Segre 2011; Grice et al. 2008), more so because of complex and dynamic interaction networks between microorganisms and host.

In this context and in a more or less accurate and well-known way, diseases related to

microorganism ecosystem dysfunction have been described (Zeeuwen et al. 2013):

- In atopic dermatitis, flares are associated with colonization and infection by *S. aureus* but also with defects in some epidermal functions as well as environmental factors.
 - In seborrheic dermatitis (“dandruff” on the scalp), the presumptive target of fungicides that are efficient against the pathology is *Malassezia* spp. (that is however also found in healthy skin) and *M. restricta* and *M. globosa* for dandruff.
 - No microorganisms have been directly linked to chronic plaque psoriasis, especially given that genetic factors are known to be implied; however, potential differences have been detected in the microbiome between psoriatic and normal skin (diversity and staphylococcus (Fry et al. 2014a, b)), probably due to a breakdown – not yet identified – in the immune tolerance to the skin microbiome.
 - Acne inflammatory disorder is associated with damage caused by *P. acnes* bacterium (one of the lipophilic microorganisms that are increased at puberty) in the pilosebaceous unit, and it appears that pathological follicles contain *P. acnes*, *Staphylococcus epidermidis*, and *Corynebacterium* (*P. acnes* only in healthy follicles) (Murillo and Raoult 2013).
 - A mite named *Demodex*, existing on healthy skin, is significantly increased on the skin of papulopustular rosacea patients. *Demodex* could take an advantage of microbiome ecosystem shift due to genetic but also immune and age variations and express some antigen inducing the inflammatory immune response (Yuan et al. 2014; Lacey et al. 2007).
 - *S. epidermis* is usually commensal but in some cases uses the indwelling medical devices to cause nosocomial infection and disease.
 - Infections in chronic wounds could also be due to commensal microorganisms (species implicated not being well identified), taking the opportunity to invade the skin presenting defects in its barrier function and participating in healing difficulties (Canesso et al. 2014).
- Current works are also studying the role of microbiome in sensitive skin syndrome, herpes viruses, or specific areas like scalp microbiome (alopecia areata, seborrheic dermatitis dandruff, pediculosis capitis).

Thus, a better knowledge of skin microbiome and interactions with many other factors is still necessary to understand and identify the skin disorders associated with an imbalance and to adapt new diagnostic or therapeutic approaches, including manipulation of skin microbes. For in vitro research, skin substitute will have to take into account microbiome of the tissue it claims to replace, as well as antiaging medicine is interested in understanding the role of microbiome in sagging or wrinkle development.

3 Chemicophysical Status

3.1 pH

The skin surface acidity, discovered by Heuss in 1892, was later highlighted by Schade and Marchionini (1928) who underlined its protection feature and called it the “acidic mantle.” By the way, it controls the resident flora to a great extent and prevents the skin colonization by pathogenic species (Marchionini and Hausknecht 1938; Korting et al. 1987). It may also favor corneodesmosome decay and desquamation because the stratum corneum hydrolases have an optimal pH of 5.6 (Öhman and Vahlquist 1993). The value of the skin pH is between 4.2 and 6.1 and its distribution between these values is Gaussian, except on the forehead (Braun-Falco and Korting 1986; Zlotogorski 1987). Findings related to difference with gender are contradictory (Zlotogorski 1987; Dikstein and Zlotogorski 1989; Elhers et al. 2001). Diurnal variation was advocated, with a peak about midday (Yosipovitch et al. 1998), but it may be related to climatic influence (Elhers et al. 2001) (see Annex 4, circadian rhythms).

There are “physiological holes in the acidic mantle” (Marchionini and Hausknecht 1938), where the pH is closer to 7. These sites are the axilla, perineum, interdigital areas, toe webs, and

legs. Even on the uncovered body most of which are acidic, local pH differences contribute to the existence of a particular flora. On the forehead, it is slightly lower than on the cheeks (Zlotogorski 1987; Dikstein and Zlotogorski 1989). In a cross-over comparative study on the effect of the prolonged use of alkaline soaps and acidic detergents on the forehead pH and flora, Korting et al. (1987) and Schmid and Korting (1995) showed that a small increase in pH (from 5.5 to 6.0) activated the proliferation of *P. acnes* without changing that of staphylococci and at the same time exacerbated acne. Inversely, a similar pH decrease would improve acne significantly ($p < 0.00001$).

The origin of the skin acidity depends on the content in free fatty acids of the surface ecosystem (Ansari 2014). Any cleansing of the skin, even with a soap with a higher acidity than the skin, increases the pH (Korting et al. 1987; Gfatter et al. 1997). Stratum corneum stripping is associated with a steep pH rise (Öhman and Vahlquist 1998). In newborn babies, the skin pH lies between 6 and 7 and the skin surface free fatty acid content is lower than in adults (Braun-Falco and Korting 1986; Gfatter et al. 1997; Behrendt and Green 1958; Beare et al. 1960). On day 1 pH was found higher than in adults in all body sites (soles, back, abdomen, palms, forearm, forehead): mean 7.1 ± 0.17 versus 5.7 ± 0.16 , respectively ($n = 44$). By the second day the pH decreased although keeping statistically different from adult values (Beare et al. 1960). The latter was attained only by the fourth day of life. Can sweat (pH between 4.0 and 6.8) be responsible in part for the surface acidity? It seemingly has no influence on the basal level; the sites with higher pH are those of continuous sweating.

On the buccal mucosae, pH is usually close to 7, with a maximum on the hard palate (see ► Chap. 156, “Main Skin Biological Constants”) (Yosipovitch et al. 2000).

3.2 Skin Surface Tension

The formation of droplets, or conversely the spreading of a liquid over a surface, depends on liquid-solid interfacial energies (Fig. 5). When the droplet remains stable, its contact angle θ obeys Young’s equation: $\Gamma_{sv} = \Gamma_{sl} + \Gamma_{vl} \cos\theta$, where Γ_{sv} , Γ_{sl} , and Γ_{vl} are respectively the interfacial energies solid-vapor, solid-liquid, and vapor-liquid. Generally the vapor element is the air and is not mentioned, hence the simplified formula $\Gamma_s = \Gamma_{sl} + \Gamma_l \cos\theta$, where Γ_s is the surface energy of the solid, Γ_l the surface tension of the liquids, and Γ_{sl} the interfacial energy solid-liquid. When $\Gamma_s < \Gamma_l + \Gamma_{sl}$, no droplet is formed, but the liquid spreads out over the solid, up to making (theoretically) a single molecular layer. In this case, it is considered that $\cos\theta = 1$. The hydrophobicity or hydrophilicity of a surface is mainly connected to the interfacial energy Γ_{sl} .

The overall skin surface is hydrophobic. As such, a water droplet placed on the volar forearm (wettability of the skin test (Elkhyat et al. 2014)) persists over 15 min. This property, long known (Jacobi 1949), is characterized by a low surface wetting critical tension (i.e., the maximal surface tension of a liquid still able to completely spread out over that surface) 27.5 ± 2.4 dyn/cm on the volar forearm (water has a surface tension of 72.8 dyn/cm and olive oil 32 dyn/cm) (Elkhyat et al. 1996). In that respect, the skin surface is

Fig. 5 A theoretical profile of a drop at equilibrium on a solid surface. Vectors are those of interfacial energy. By definition, the contact angle is always inside the drop. ϑ_{sv} ,

ϑ_{sl} , and ϑ_{vl} are the solid-vapor, solid-liquid, and vapor-liquid interfacial energies, respectively

similar to plastic substances. Its surface free energy on the forearm is $38.7 \pm 6.4 \text{ mJ/m}^2$, somewhat higher than that of plastic substances, with an apolar component of $35.6 \pm 5.8 \text{ mJ/m}^2$, a basic polar component of $4.2 \pm 3.0 \text{ mJ/m}^2$, and an acidic polar component of $0.8 \pm 0.7 \text{ mJ/m}^2$. The skin surface, from an electrochemical viewpoint, is therefore mainly monopolar basic (Mavon et al. 1997).

On seborrheic areas the skin surface is less hydrophobic, its wetting critical tension being beyond 50 dyn/cm. This higher value is related to the high amount of sebum; a cleansing of the forehead with ether reduces it to 29 dyn/cm (Elkhyat et al. 1996). Similarly, on the forehead the surface free energy ($42.5 \pm 3.9 \text{ mJ/m}^2$) is higher than on the forearm because of the greater part of basic polar component (28.3 mJ/m^2) in turn linked to the high amount of free fatty acids in the sebum (Mavon et al. 1997). Degreasing and dehydrating the forehead with ether decrease both the surface free energy and the basic polar component.

The skin hydrophobia contributes to its low permeability. Thus the sweat has enough time to evaporate and so play its role in thermoregulation. In profuse sweating, the sweat in excess drips down but does not form an emulsion with the sebum. Even in more stable and prolonged conditions, and in vitro, no sebum-sweat emulsion could be shown, although the surface tensions of both liquids are close (less than 2 dyn/cm apart), and the interfacial tension is only 1.1 dyn/cm (Mavon 1997).

Finally surface tension, because of the enormous forces it generates, has a major role in the adherence of microorganisms to their support (corneocytes, hairs), in the spontaneous sebaceous excretion, and in skin surface regreasing after cleansing (► Chap. 13, “Sebaceous Physiology”).

4 Social and Cultural Function

Although it has often been overlooked in publications because of its “non-organic” nature, the social and cultural function of the skin is considerable. It involves ethnic, racial, age-related, and

“apparent health” considerations and influences the psyche of each individual. It participates in self-consciousness and in the image which is projected toward the others. This function relies on the skin relief, optical properties, color, and mechanical properties. Desquamation on dry skin is much more visible than on oily skin. The stratum corneum translucency softens an irregular surface relief or small wrinkles (Creidi et al. 1994), hence the higher reliability of instrumental measurements of this relief. In the same way, to reduce wrinkle visibility, an oily cosmetic is better than an opaque makeup. The translucence of the whole stratum corneum also contributes to a better visibility of the underlying bloodstream and favors a radiant complexion. Furthermore, the variations in the mechanical behavior of the stratum corneum depend on the hydration of its superficial layers; in this area, microfractures due to very dry conditions generate an unpleasant tight feeling in healthy subjects and pruritus in atopic subjects.

1 Introduction

The color of the skin is a commonly used parameter to assess different aspects and conditions of the skin. It depends mainly on its pigment content, on the spectrum of the illuminating light, and on the quality of the cutaneous surface. When light impinges on the skin, a few percents are directly reflected by the surface (specular reflection) whereas entering photons are either absorbed or scattered by different molecules and structures present in the cutaneous layers. The pigments of the skin, also called chromophores, are mainly represented by melanin in the epidermis and by hemoglobin in the dermis. Other molecules such as bilirubin, amino acids, nucleic acids, porphyrins, and carotenoids (endogenously produced) may participate at different levels to the absorbing and reflecting process of the light. The pigmentation of the skin is related to the melanin amount in the keratinocytes. The various contents of melanin in the keratinocytes produce the wide spectrum of human skin color found in the different human races. Two classes of melanins are found in humans: the eumelanins which are brown to black pigments and the pheomelanins which are yellow to reddish-brown (Fitzpatrick et al. 1979). Melanin absorbs in a decreasing manner from ultraviolet (UV) (highest absorption) to visible light domain. On the other hand, hemoglobin in the dermal microvasculature contributes to the overall skin color with a red dominant for oxygenated hemoglobin and bluish red for reduced

hemoglobin. Here again, the hemoglobin contribution to the skin color depends on the melanin amount in the keratinocytes which acts as a neutral filter; it is readily visible in fair-skinned people, and practically not observable in deeply melanized skin (Stamatas et al. 2008; Diffey and Robson 1992).

The need for assessment of the skin color and pigmentation extends from the dermatocosmetology domain (including sunscreens, skin pigmentsing or depigmenting products, antiaging agents, and makeup evaluations) to the clinical dermatology for the characterization of the various types of skin pigmented lesions. Although the human eye is able to distinguish between hundreds of colors, the results of visual assessment remain subjective and qualitative with a poor reproducibility in time.

Since the last decades, several objective methods and technologies have been developed (Taylor et al. 2006; Takiwaki et al. 1994; Fullerton et al. 1996) to measure skin color and some were proposed as commercially available devices. Two main types of skin color investigation systems are coexisting. One is based on different approaches of analysis of reflected light by the skin which gives only spectral information. The second is based on the skin imaging technologies which offers, besides the color and spectral aspects, spatial information taking into account, for example, the lesion borders or heterogeneity on a large skin area (e.g., the whole face). The first and oldest type of systems is based on the spectrophotometric analysis of the reflected light by the skin, the illuminating light being either a continuous spectrum (white light) (Andersen and Bjerring 1990; Lock-Andersen et al. 1998a) or single bands specific of absorption of melanin and hemoglobin (Lock-Andersen et al. 1997; Feather et al. 1988). The reflectance tristimulus CIE colorimetry (Weatherall and Coombs 1992; Piérard 1998) allows expressing the color of the skin in a three-dimensional space. These objective methods are easy to use but have the inconvenience to produce color information only on small areas (0.5–1 cm²). They are very useful in skin pharmacology where only the information on skin

erythema and pigmentation intensities are needed on small test surfaces.

With the progress of the optical instrumentation, of the digital imaging techniques, and the development of dedicated image analysis processing, the spatial component of the skin color can be integrated in the measurement (Alghamdi et al. 2012; Liu et al. 2012). Recent development of dermoscopy has been shown to improve the diagnostic accuracy of pigmented skin lesions (Celebi et al. 2009). Some of these techniques, such as the multispectral imaging taking into account the combination of spectral and spatial information, aim to determine the severity of skin pathologies. Finally, thanks to the improvement of digital image processing technology and to the high quality of the available video camera, techniques of epiluminescence microscopy such as dermoscopy and reflectance confocal microscopy (RCM) (Smith and MacNeil 2011) represent very promising tools allowing the dermatologist to perform a very accurate noninvasive diagnosis of pigmented skin lesions.

2 Visual Assessment of Skin Color and Pigmentation

The eye is the first diagnostic tool for the dermatologist. Color perception is the result of radiant electromagnetic radiations in the “visible” wavelength range 400–700 nm collected by the eye and interpreted by the brain. Thus, color perception includes physical and psychophysiological aspects. The human eye is known to have a high power of discrimination between colors including shades and hues (Wassermann 1971; Bornstein 1968). The evaluation of skin pigmentation by visual examination depends not only on the subjective perception of colors by the observer but also on the nature of the illuminant and on the geometric position of the observer relative to the skin surface. Moreover, visual memory concerning colors is not stable in time making repetitive evaluations not reliable.

Various scales and indexes have been developed to reduce potential interobserver variability

and enable more objective assessment of skin pigmentation. For example, in the case of melasma, the severity index of melasma MASI (Kimbrough-Green et al. 1994) is calculated on the basis of area (A) of involvement, darkness (D) of melasma, and homogeneity (H) of the hyperpigmentation.

Using a standardized environment and grading skin color with either standard color references such as Munsell standards or very precise rating scales or color charts (Taylor et al. 2006; de Rigal et al. 2007) may lead to reliable visual color assessments.

3 Reflectance Tristimulus CIE Colorimetry

Colorimetry tristimulus system is based on the following two principles: the first is that each color can be matched by a suitable mixture of three selected light radiations; the second is that if two colors are matched by three radiations, the mixture of these two colors is found additive by suitable optical means. In 1931, the “Commission Internationale de l’Eclairage (CIE)” standardized the color mixture characteristics of an “average observer” and developed a standard framework for a color specification. The standard observer is represented by functions which were determined from data obtained from series of observers matching the color at each wavelength from 400 to 700 nm with appropriate mixtures from three primary light sources. In this system, each color is defined with a set of three tristimulus primary values (X: red content, Y: green content, Z: blue content). The drawback of the CIE 1931 color system is that equal distances in the chromaticity diagram do not represent equal differences in color as perceived by the human eye. This was corrected in the CIE 1976 $L^* a^* b^*$ color system which more closely represents the human eye sensitivity to color. The L^* , a^* , b^* coordinates are also calculated from the X, Y, and Z tristimulus primary values. In the $L^* a^* b^*$ color space, L^* is the lightness ranging from 0 (black) to 100 (white), a^* is the balance between

red (positive values) and green (negative values) and b^* is the balance between yellow (positive values) and blue (negative values).

Based on the accumulation of numerous measurements of skin color using colorimetry (Chardon et al. 1993; Chardon et al. 1991) have shown that all the different types of basal skin color (stable state) for a selected body site (the back, for example) are located inside a vertical arched volume in the $L^* a^* b^*$ color space (Fig. 1). In this volume, the points of color are distributed from top to bottom as a function of the natural melanic pigmentation intensity with the nonmelanized skin (albino) at the top and very dark skin at the bottom. The points constitute the melanization axis which structure the volume along its longer axis and are distributed in its section as a function of the hue and chroma afforded by the natural skin pigment mixing (melanin, hemoglobin, carotenoids, etc.). Figure 1 indicates also that the direction of color changes in the volume depends of the skin pigment involved in the reaction related to the skin color variation. For example, following a UVA irradiation, the induced Immediate Pigment Darkening (IPD) does not follow the melanization axis but a different direction due to the fact that IPD is the bluish coloration generated by photo-oxidized melanins already present in the skin. This bluish color is expressed by a decrease of the b^* component. On the other hand, the induction of an erythema translates the skin color point outside the melanization axis toward the colorimetric coordinate of hemoglobin ($L^* \approx 45$, $a^* \approx 45$, $b^* \approx 18$).

Since the Caucasian skin has a yellow/orange aspect, the constitutional pigmentation is well described in the L^* versus b^* plane. Thus, sectors of skin color categories have been delineated (Chardon et al. 1991) to correspond roughly to the skin phototypes (Fitzpatrick 1988). The sectors are delimited by radii originating from $L^* = 50$ and $b^* = 0$ and constitute defined angles with the b^* axis. Therefore, a subject can be characterized by the so-called individual typology angle (ITA°) which is calculated by

$$ITA^\circ = \text{Arctangent} \left((L^* - 50) / b^* \right) \times 180 / \Pi$$

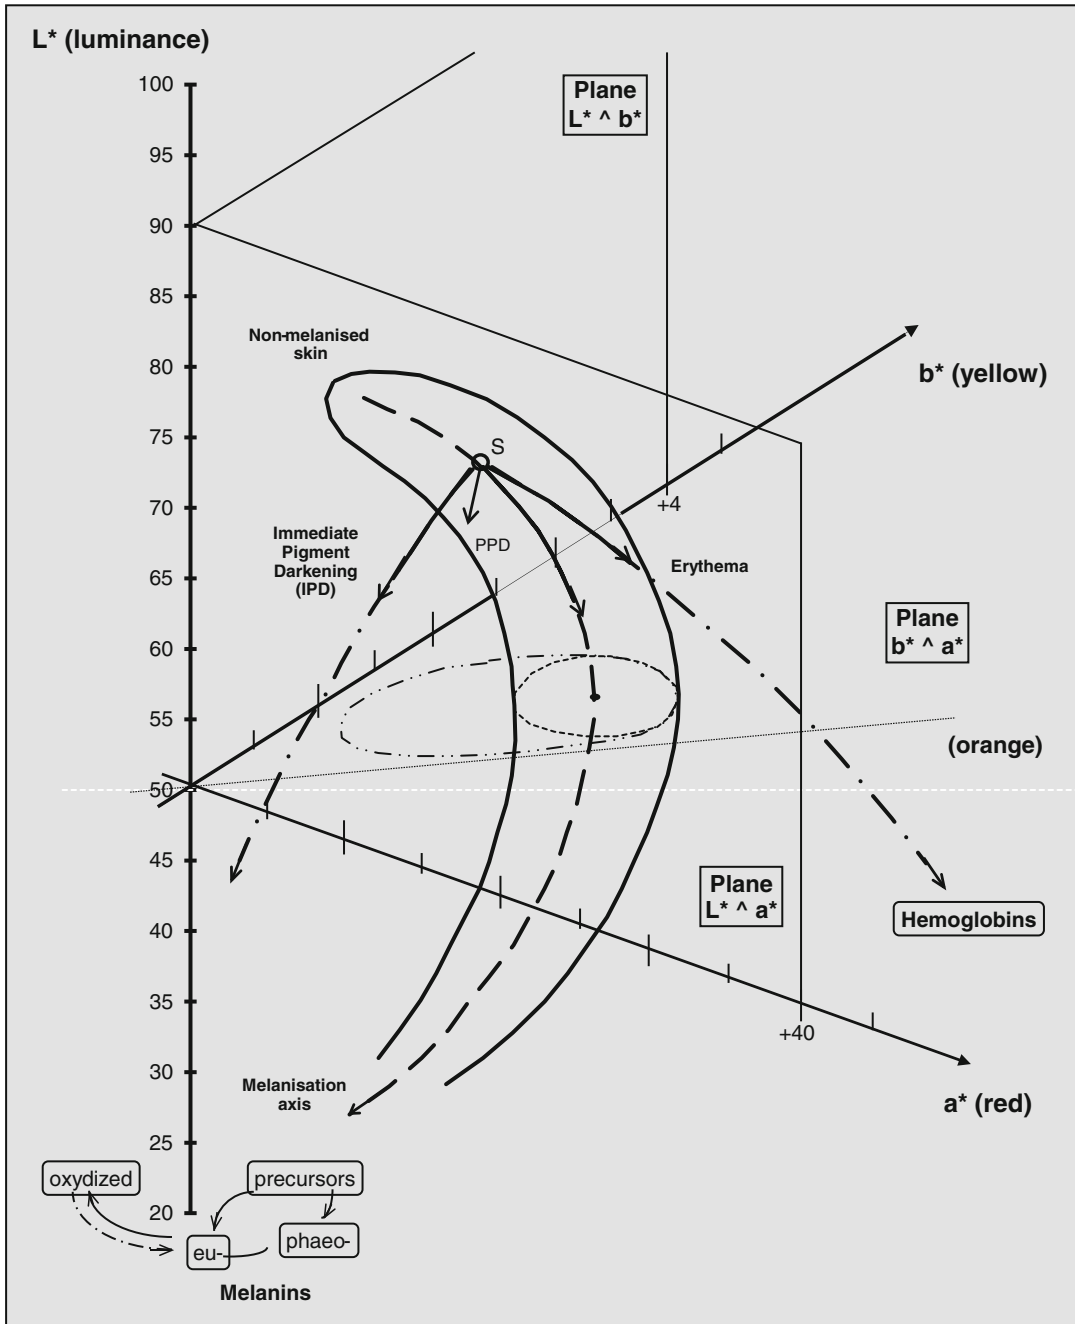

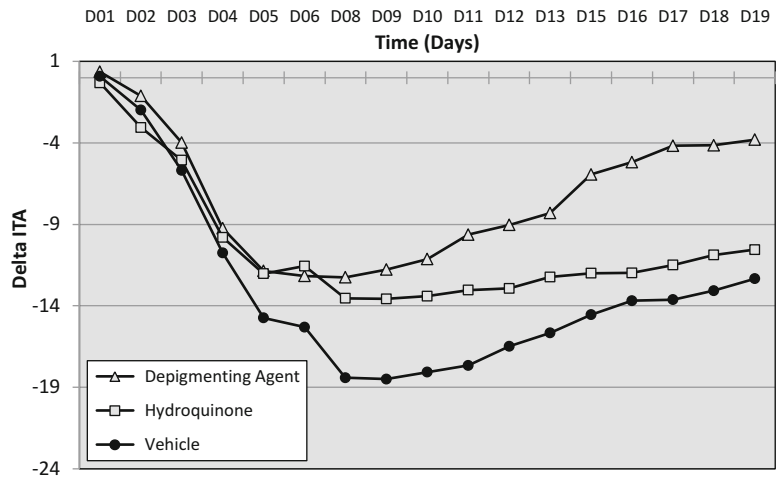

Fig. 1 The skin color volume in the CIE L^* , a^* , b^* color space (With permission of A. Chardon et al. (1991))

The values proposed for the angles of skin category boundaries were

Very light skin $> 55^\circ$ $>$ Light skin $> 41^\circ$ $>$ Intermediate skin $> 28^\circ$ $>$ Tanned skin $> 10^\circ$.

It has been shown (Masson et al. 1992) that the use of ITA allows to determine the range of ultraviolet doses needed to induce a minimal erythema (Minimal Erythema Dose determination without prior irradiation).

Fig. 2 Evolution of ITA angle (normalized to baseline before UV exposure) on UV induced pigmentation (UV exposure from D01 to D04, doses range 0.75–1.5 MED). Effect of a depigmenting agent compared to Hydroquinone and Vehicle (With courtesy of GALDERMA R&D Laboratories)

Colorimetry has been extensively used to assess the process of UV-induced hyperpigmentation (Park et al. 1999), skin typology (Roh et al. 2001), and photoprotection factors (Andreassi et al. 1990; Ferguson et al. 1996; Chardon et al. 1988; Moyal et al. 2000). Figure 2 illustrates the depigmenting treatment effect measured by the ITA angle on skin UV-induced pigmentation (4-day exposure with dose range 0.75–1.5 MED).

4 Reflectance Spectrophotometry

4.1 Reflectance Spectroscopy

The scanning reflectance spectroscopy (Andersen and Bjerring 1990; Stamatas et al. 2004) analyzes the spectrum of light reflected by the skin, typically between 400 and 700 nm, and allows to measure skin color in order to obtain information on skin chromophore content. The optical properties of the skin are determined by the spectral absorption, reflection, and scattering of the light as it strikes and penetrates the different cutaneous structures. The scanning reflectance spectrometers are built to measure the diffuse reflectance of the light, i.e., the part of the light which is modified by the absorption, reflection, and scattering processes inside the skin, and which is re-emitted from the skin. This technique is also

called diffuse reflectance spectroscopy or DRS (Stamatas et al. 2004). The instrumental setup consists of: a light source such as a xenon short arc lamp or a tungsten halogen lamp, a measuring head which is an integrating sphere, an optical system (monochromator or equivalent) to decompose and analyze the light re-emitted by the skin, and a photodetector to measure the light intensity in the different bands of wavelength. A system of optical guides (bundles of optical fibers) conducts the light from the source to the skin and from the skin to the monochromator and the photodetector. In some handheld instruments (e.g., Minolta 2600d, Osaka, Japan), the distance between the light source and the skin surface is shorter (about 10 cm) and the reflected light is diffracted by a dual beam monochromator and measured by a photodiode array.

Different skin modeling simulations have been used to analyze spectral data (Häggblad et al. 2010; Meglinski and Matcher 2003). For example, the reflectance spectra of the human skin in visible and near-infrared (NIR) spectral region have been calculated using the Monte Carlo technique (Wang et al. 1995), and the specular and internal reflection on the medium surface is taken into account. Skin is represented as a complex inhomogeneous multilayered highly scattering and absorbing medium. The model takes into account variations in spatial distribution of blood, index of blood oxygen saturation, volume fraction of water, and chromophore content.

An example of skin DRS reflectance spectra (presented as absorption spectra) is illustrated in Fig. 3. On this figure, compared to the normal skin spectrum, the differences of a heavy pigmented skin lesion (lentigo) spectrum and a deeply vascularized lesion (raised red spot) are clearly observable. The amounts of melanin, oxy-Hb, and deoxy-Hb can be calculated from the DRS spectra using different models and algorithms. Pigmentation and erythema indexes can be also derived from these calculations. Figure 4 shows the melanin concentration obtained from reflectance spectra obtained in the same study as Fig. 2 using a tristimulus spectrophotometer (Konica Minolta CM 700d).

Wallace et al. (2000) aimed to document the optical reflectance (range 320–1100 nm) characteristics of pigmented skin lesions in order to evaluate their potential for improving the differential diagnosis of malignant melanoma from benign pigmented skin lesions. Characteristic differences in spectra from benign and malignant lesions were studied and showed significant differences between lesion groups classified by histology. This simple objective technique appeared to perform as well as the expert dermatologist and

could improve the diagnostic accuracy of nonspecialists such as trainees and GPs.

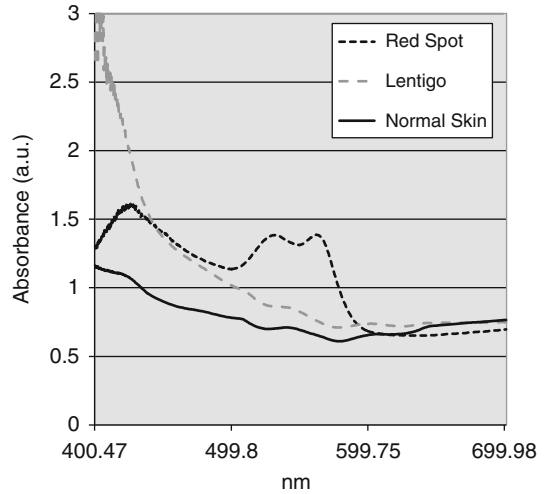

Fig. 3 DRS absorbance spectra (arbitrary unit) of three types of skin area: a pigmented lentigo (shape of typical melanin absorbance curve), a raised red spot (shape of typical hemoglobins absorbance curve, absorption peaks of oxyhemoglobin visible at 542–577 nm) and a normal skin area. Measurements performed with a Diffuse Reflectance Spectrometer (Canfield Scientific system, Fairfield, NJ, USA)

agent compared to Hydroquinone and Vehicle (With courtesy of GALDERMA R&D Laboratories)

4.2 Narrow-Band Reflectance Spectroscopy

The reflectance spectrophotometers are known to be expensive, cumbersome, and not well adapted for the routine clinical uses. Since the spectrophotometric measurements result often in the analysis of some specific narrow bands or peaks of spectra corresponding to the absorption bands of the main chromophores of the skin, the use of simpler and cheaper devices based on narrow-band analysis was developed.

The Mexameter MX16[®] (Courage-Khazaka, Eleelectronik, Köln, Germany) is equipped with 16 light-emitting diodes (LED) arranged circularly and emitting at 568 nm (green), 660 nm (red), and 880 nm (infrared). The positions of emitter and receiver guarantee that only diffuse and scattered light is measured. As the quantity of emitted light is defined, the quantity of light absorbed by the skin can be calculated. The system is based on the principles described by Diffey and coworkers (1984). The melanin index (mx) is measured at two wavelengths (660 and 880 nm). These wavelengths have been chosen in order to achieve different absorption rates by the melanin pigments. For the erythema index (ex), two different wavelengths are used to measure the absorption capacity of the skin. One of these wavelengths corresponds to the spectral absorption peak of hemoglobin (568 nm) and the other wavelength (660 nm) has been chosen to avoid other color influences (e.g., bilirubin). The measuring area is 5 mm in diameter (0.2 cm²). Other types of narrow-band spectrophotometers such as the DermaSpectrometer (Cortex Technology, Hadsund Denmark) are based on two LEDs whose bands are centered in the green (568 nm) and in the red (655 nm). The erythema index is also calculated from the ratio of red to green reflected light intensities. The melanin index is obtained from the inverse of reflected light intensity.

Several studies (Clarys et al. 2000; Tian et al. 2011) have been performed to compare narrow-band spectrophotometers to tristimulus colorimeter. The results showed both kinds of instruments are able to detect very small changes

in skin color. The correlation between the instruments were found to be moderately good between L* and the melanin indexes and good between a* and the erythema indexes. A recent study performed on scars (Van der Wal et al. 2013) showed that the Mexameter, the Colorimeter, and the DSL II colorimeter provided reliable color data on normal skin and scars.

Various type applications of assessment of the cutaneous pigmentation by narrow-band spectrophotometers were performed including, for example, UV-induced pigmentation (Lim et al. 2008; Seitz and Withmore 1988), efficacy of depigmenting agent (Yoshimura et al. 2001; Hurley et al. 2002), and protection of vitiligo (Gniadecka et al. 1996; Park et al. 2006). Skin typology (Hermanns et al. 2001; Lock-Andersen et al. 1998b) and epidemiology (Lock-Andersen et al. 1998c) produced numerous subjects of works. In the retrospective skin cancer case-control studies, there are major difficulties to estimate sun exposure during lifetime of subjects because no suitable objective measurements are available.

5 Dermoscopy and Skin Imaging Systems

Dermoscopy (dermatoscopy, epiluminescence microscopy, incident light microscopy, skin surface microscopy) has become one of the major in vivo noninvasive diagnostic techniques used in the diagnosis of melanoma and other pigmented skin lesions (Celebi et al. 2009; Park et al. 2006). With the progress of both handheld optics and digital imaging techniques, recent development of dermoscopy has been shown to improve the diagnostic accuracy of pigmented skin lesions.

The technical setup consists of a magnifying optical system (surface microscope, stereomicroscope, handheld scope) allowing magnification of the lesion image. The lesion is covered with an immersion oil or any kind of liquid including water and alcohol in order to eliminate surface reflections of the illuminating light. This makes the stratum corneum translucent,

enabling the visualization of pigmented structures of the epidermis and of the dermal-epidermal junction and superficial papillary dermis which are impossible to observe with the naked eye. The vessels of the superficial vascular plexus can be also observed.

Various diagnostic systems have been proposed for assessing dermoscopic images. All systems take into account local and global features. For example, in the ABCD system used for the melanoma diagnosis, the investigator has to score asymmetry (A), borders (B), colors (C), and number of different dermoscopic structures (D). For all the diagnostic systems, the color aspect of the pigmentation of the lesion is crucial, including number of different colors, aspect of pigment networks, distribution of pigments, and shape margin of pigmented areas.

However, the use of dermoscopy is limited to experienced and trained dermatologists who show no more than 85 % of skin lesion detection rate. Since the last decade, numerous computerized image analysis models have been proposed in order to maximize the diagnostic accuracy, in particular in the field of lesion border detection (Celebi et al. 2009; Abbas et al. 2013; Garnavi et al. 2011), color quantification (Lee et al. 2012; Shakya et al. 2012), and pattern classification (Abbas et al. 2012).

Finally, the classical photography technique performed in Wood's light is also a useful method to visualize skin pigmentation (Fulton 1997; Garcia and Fulton 1996; Asawanonda and Taylor 1999). This technique is based on the filtering of the light emitted by the flash using UVA band pass filter. The hyperpigmented skin areas such as solar lentigos appear darker on the black-and-white image compared to "normal skin" due to the fact that melanin absorbs heavily in the UVA domain. On the other hand, depigmented lesions such as vitiligo macules are displayed as white areas on the skin (Paraskevas et al. 2005). Here again, the processing of that kind of images by dedicated gray levels analysis software could increase the objective quantification level of this technique.

6 Reflectance Confocal Microscopy: A New Tool to Measure Skin Color?

Reflectance confocal microscopy (RCM) is a recent skin imaging technique that allows in vivo, noninvasive, real-time, and almost histological visualization of the skin (Hofmann-Wellenhoff et al. 2012). Confocal microscopy is a technique that enables virtual optical sections through an object of interest. Confocal microscopy was first used in biology to visualize cellular organelles, and it was adapted recently for clinical practice, especially in dermatology. Reflectance means that the images are obtained by reflection of a laser by endogenous molecules. Since melanin is the strongest contrast agent in the skin, RCM is particularly suitable to investigate skin pigmentation. Paradoxically melanized structures look very bright on RCM images, a feature that can be easily seen on RCM sections of the dermal-epidermal junction, where bright (pigmented) keratinocytes surround dark (nonpigmented) dermal papilla (Fig. 5). Interestingly, based on morphological criteria, RCM can discriminate between the different pigment cell populations in the skin (Busam et al. 2001). The interest of RCM for the diagnosis of pigmented lesions, especially pigmented tumors, has largely been reported (Kang et al. 2010a). RCM is also interesting for the evaluation of pigmentation disorders such as vitiligo (Kang et al. 2010b, and Fig. 6) or melasma (Kang et al. 2010c). Regarding normal pigmentation, it was reported recently that RCM may help to quantify variations of skin pigmentation (Lagarrigue et al. 2012). One of the objectives of this work was to identify RCM parameters able to quantify in vivo epidermis pigmentation potentially applicable in clinical studies. The study included 111 healthy female volunteers with phototypes I–VI. The authors proposed an index called "papillary contrast" and defined as the difference in brightness between the cellular ring around the papilla zone and the central dermal papilla zone. The mean papillary contrast (PC) was estimated according to the following function (Figs. 5 and 6):

Fig. 5 RCM evaluation of normal pigmentation. Confocal images ($500 \times 500 \mu\text{m}$) at the dermal epidermal junction presenting differences in the brightness of peri-papillary

cells between skin phototypes II (a), III (b), and V (c). Scale bar: $125 \mu\text{m}$. DP dermal papilla. Abdomen skin, non-exposed. Coll. P. Bahadoran

Fig. 6 RCM evaluation of pigmentation in vitiligo. Confocal images ($500 \times 500 \mu\text{m}$) at the dermal epidermal junction showing increasing brightness of peri-papillary cells in

vitiligo lesion (a), perilesional skin (b), and distant normal skin (c). Scale bar: $125 \mu\text{m}$. DP dermal papilla. Abdomen skin, non-exposed (Adapted from: Kang et al. (2010b))

$$PC = \frac{\sum (\overline{B_{ring}} - \overline{B_{center}})}{Nb_{pap}}$$

where PC, papillary contrast; B_{ring} , brightness of the ring papilla; B_{center} , brightness of the central dermal papilla; and Nb_{pap} , number of papillae.

PC measured at the dermoepidermal junction appeared to be a reliable marker of epidermis pigmentation and showed a strong correlation with skin pigmentation assessed clinically using the Fitzpatrick's classification. However, additional studies comparing RCM with established methods of skin color measurement such as colorimetry are needed in the future to confirm the interest of this approach. Another limitation worth

considering is the price of the RCM device $\sim 100,000$ euros, though it can be used for other purposes. Despite these limitations, RCM represents a significant advance in the field of pigment measurement since it might allow a quantification of melanin along with a morphological identification of melanized cells.

7 Spectral Imaging and Image Processing

Spectral imaging is the integration of spectroscopy with spatial measurement thus it extends the image into spectroscopy by allowing

measurement of the spectrum at each point of the image. As described before (see Sect. 5), spectroscopy yielded quantitative information and extended understanding of skin pigmentation. Images give morphological information such as lesion texture, borders, area. Spectral imaging of skin surface is then a way to extract both of these two crucial aspects of pigmented lesions.

The information captured by spectral imaging is similar to that acquired by the clinician. So spectral imaging provides global and sufficiently rich information to support diagnosis. In addition, this information is quantitative, objective, and reproducible. The spectral information is more detailed than information provided by human eye or contained in color images.

The human eye, like the dermatoscope (see Sect. 5), only has the capacity to capture in three spectral bands with its sensors for red, green, and blue (RGB). Multispectral imaging (MSI) can capture spectral information in wavelengths from several tens up to one hundred for Hyperspectral Imaging (HSI). The high definition of the skin spectral response which can be out of the visible light range offers a new possibility for identifying and quantitatively characterizing a cutaneous lesion leading to a more precise and robust diagnosis.

Even if different types of spectral imaging measurement are used, most of them imply a sequential capture.

Spectral imaging methods can be divided into four different methods. The wavelength-scan methods using preferentially variable filters measure the images one wavelength at a time. The spatial-scan methods using either a grating or a prism measure the whole spectrum at a time line by line. Time-scan methods are based on measuring interference of light. Interference is obtained using a Michelson system or other interferometer. At the end of the acquisition, the data is transformed to the actual spectral image by the Fourier transform. The fourth method measures the whole spectral image simultaneously, but compromises on spectral and spatial resolution. It consists of separating the CDD (charged coupled device) digital camera surface into several blocks, each of them capturing different

wavelengths (Garini et al. 2006). The selection of the most appropriate method depends on the capture constraints (e.g., time, sample movement, resolution need). The larger the number of wavelengths or the higher the spatial resolution, the longer will be the capture.

Multispectral technology has been applied to dermatology mainly for noninvasive diagnosis of melanomas. It has also been proposed for analysis of bruised skin (Randeberg et al. 2006), vascular lesions, (Kuzmina et al. 2010), acne vulgaris (Fujii et al. 2008), and various pigmented lesions including melasma, (Prigent et al. 2012), naevi, and pigmented skin cancers (Diebele et al. 2012a).

For noninvasive melanoma diagnosis, band selection in spectral imaging has been tested.

Some authors have used a predefined set of bands (Dhawan et al. 2009; Kuzmina et al. 2010; Diebele et al. 2012b; Elbaum et al. 2001). However, these sets differ among publications (Elbaum) and could be debatable as they are based on the spectral information supposed (melanin and hemoglobin absorption spectra) and not actually contained in the spectral image capture without taking into account the global information provided by multispectral technology. Other authors have applied methods and algorithms derived from the image processing field (Garini et al. 2006).

The synthesis of multispectral information consists in reducing the quantity of data while keeping all pertinent information. The most favorable approach will be based on the analysis of the spectral information contained in each skin lesion capture. The proposed method consists of identifying the most relevant features allowing the description of the captured data.

The features can be estimated as a linear combination of the different wavelengths that can be assimilated to a "spectral print."

The most currently used method is the independent component analysis (ICA) introduced in computerized skin analyses by Tsumura et al. (1999). The aim was to isolate the spectral components linked to melanin and hemoglobin chromophores using ICA. The principle was to obtain the spatially independent spectral components of the image expecting that some of these

independent features would correspond to certain molecules present in the skin.

Melanin and hemoglobin, the two principal chromophores involved in skin spectrum, are independently distributed. Tsumara et al. proved that the two features obtained by ICA correspond to these two skin chromophores representing the healthy skin spectral print.

ICA is commonly implemented to multispectral imaging seeking specific characterization of skin pigmented pathology, for example, for melasma diagnosis (Prigent et al. 2012).

A high number of different approaches have been proposed in the literature: implementation of statistical method based on Blind Source Separation (BSS) as Non-Negative Matrice factorization (NMF) to quantified melanin and hemoglobin (Galeano et al. 2012), band selection based on machine learning algorithms Support Vector Machine (SVM) (Quinzán et al. 2013), geometric method.

Although further investigation is expected, multispectral imaging is an effective tool for capturing the information useful in dermatology.

8 Conclusion

Skin color and pigmentation can be assessed using a wide variety of techniques. The choice depends on the objectives of the investigator. Two main families of methods can be identified: the first is related to the measure of skin color and pigmentation as a whole, i.e., as it can be needed in clinical pharmacology, for example, where only the information on skin erythema or pigmentation intensities are needed on small test surfaces. The associated technologies are based on different approaches of analysis of reflected light by the skin and gives only spectral information. The second family concerns the diagnostic assessments of pigmented skin lesion in which the accurate measurement of hue and chroma of the substructures of the pigmented lesion are very important with integration of morphological components in the assessments. In that sense, dermoscopy has been shown to improve the diagnostic accuracy of pigmented skin lesions and

some other techniques such as the multispectral imaging, taking into account the combination of spectral and spatial information, are still in development. Finally, thanks to the improvement of digital image processing technology and to the high quality of the available optics, techniques of epiluminescence microscopy such as dermoscopy and reflectance confocal microscopy represent very promising tools allowing the dermatologist to perform a very accurate noninvasive diagnosis of pigmented skin lesions.

Skin color • Skin melanin content • Chromameter • CIE XYZ color space • CIELAB • CMYK model • Dermacatch • Dermaspectrophotometer • Mexameter • RGB color space • Skin colorimetry

The color of human skin is determined by its melanin content, its oxy- and deoxy-hemoglobin contents, and the amount of endogenous or exogenous pigments such as bilirubin and carotene (Andreassi et al. 1999). The measurement of skin color is of the utmost importance for many researchers and clinicians involved in dermatologic as well as cosmetic fields. The noninvasive measurement of epidermal melanin content is necessary for in vivo studies that implicate skin depigmentation and repigmentation. Skin erythema values are considered as an index of inflammation and dermal vascularity/vasodilatation and are utilized in the evaluation of therapeutic outcome in several dermatologic treatments. The first quantitative evaluation of skin color was accomplished in 1939 by Edwards and Duntley, who obtained colorimetric data specific for different types of skin pigmentation (Edwards and Duntley 1939). Other authors subsequently utilized similar instruments to evaluate the skin color of different ethnic groups. In the 80s, the calorimetric technology evolved greatly and sophisticated instruments suitable for dermatologic use became available (Andreassi et al. 1999).

e-mail: behroozkasraee@yahoo.com

It is important to note that although the *in vitro* color measurement can be reliably done by several colorimetric devices, the quantification of skin color “evolution” *in vivo* appears to be more complex, as *in vivo* fluctuations in erythema can affect melanin values and vice versa (Baquie and Kasraee 2014). Knowing that melanin absorbs light in a large range of wavelengths (including green, red, and near-infrared light), the confusion over the discrimination between melanin and erythema can easily occur by colorimetric devices.

To discriminate melanin from skin erythema, different technologies have been developed with a variable level of reliability. Some colorimeters are based on scanning reflectance spectrophotometry (Andreassi et al. 1999), and others rely on tristimulus (i.e., three specific wavelengths) colorimetry, such as Chromameter (Minolta) (Andreassi et al. 1999), or narrow-band simple reflectance colorimetry, such as Mexameter (Courage-Khazaka, Germany) (Andreassi et al. 1999; Baquie and Kasraee 2014).

In order to understand the different color measurement technologies, it is essential to know the different existing color models.

1 The RGB Color Space

The name of the model comes from the initials of the three additive primary colors, red, green, and blue. This is an additive color model in which red, green, and blue lights are added together in various ways to produce a broad array of colors. Today, the main purpose of the RGB model is the representation and display of images in electronic devices such as computers. It has also been used in conventional photography. Before the electronic age, the RGB color model already had a robust theory behind it, based on human perception of colors (International Color Consortium 2006).

RGB is a *device-dependent* color model, that is, different devices reproduce or detect a given RGB value differently, since the color elements and their response to the individual R, G, and B levels might differ from one manufacturer to

another, or even in the same, device over time. Thus, RGB values do not define the same *color* across different devices (International Color Consortium 2006).

2 The CMYK Model

This is a subtractive color model in contrast to the additive RGB color model.

This model works by partially or entirely masking colors on a lighter, usually white, background and is the model used in color printing. The colors are cyan (C), magenta (M), yellow (Y), and key (K; black). The CMYK model is a device-dependent model (International Color Consortium 2006).

3 CIE- $L^*a^*b^*$ (CIELAB)

This is the most complete color space specified by the International Commission of Illumination (French *Commission Internationale de l'éclairage*). It describes all the colors visible to the human eye and was created to serve as a device-independent model to be used as a reference (International Color Consortium 2006).

The three coordinates of CIELAB represent the lightness of the color ($L^* = 0$ yields black and $L^* = 100$ indicates diffuse white), its position between red/magenta and green (a^* , negative values indicate green while positive values indicate magenta), and its position between yellow and blue (b^* , negative values indicate blue and positive values indicate yellow) (Andreassi et al. 1999; International Color Consortium 2006).

4 CIE XYZ

The CIE XYZ color space encompasses all color sensations that an average person can experience. It serves as a standard reference against which many other color spaces are defined. The human eye has three kinds of cone cells, which sense

light, with spectral sensitivity peaks in short (*S*, 420–440 nm), middle (*M*, 530–540 nm), and long (*L*, 560–580 nm) wavelengths. These cone cells underlie human color perception under medium- and high-brightness conditions. The CIE model capitalizes on this fact by defining *Y* as luminance. *Z* is quasi-equal to blue stimulation, or the *S* cone response, and *X* is a mix (a linear combination) of cone response curves chosen to be nonnegative. The XYZ tristimulus values are thus analogous to, but not equal to, the LMS cone responses of the human eye (Andreassi et al. 1999; International Color Consortium 2006).

5 The Basis of Skin Colorimetry

The basis of investigation of optical properties of an object is recording the intensity of light which is reflected from its surface at many narrow-band wavelength(s) throughout the spectra of visible light (400–700 nm), namely, the reflectance spectrophotometry (Takiwaki 1998). The CIE- $L^*a^*b^*$ values are most commonly used for the quantification of skin color (Weatherall and Coombs 1992). There are several other formulas that are proposed and used by other authors (Dawson et al. 1980; Kollias and Baqer 1985; Feather et al. 1989; Andersen and Bjerring 1990) for the conversion of reflectance data into different indices that show relative amounts of epidermal melanin pigment as well as oxy- and deoxy-Hb in the superficial vascular plexus of the dermis (Takiwaki 1998). These indices are read according to the Dawson's theory, by calculating the reflectance or absorbance values of the skin measured at several wavelengths that are determined in order to enable the abstraction of information about the quantity of the targeted chromophore (Takiwaki 1998). In practical use, a reflectance spectrometer is expensive and cumbersome, as it necessitates the connection to a computer. Several portable opto-electronic instruments have thus been designed and become widely available (Serup and Agner 1990; Westerhof 1995; Takiwaki and Serup 1995; Feather et al. 1988; Pearse et al. 1990; Kopola et al. 1993).

6 Chromameter[®]

Chromameter (Minolta, Osaka, Japan) is a tristimulus colorimetric instrument based on scanning reflectance spectrophotometry. It contains a xenon lamp as the light source, photodetectors, a microcomputer, and colored filters that match the CIE colorimetric standard observer curves (Westerhof 1995). Color values in accordance with the CIE color systems ($L^*a^*b^*$, or XYZ) are calculated automatically with these instruments. To obtain data, the probe head is placed onto the skin and the shutter button is pushed gently. The results ($L^*a^*b^*$, XYZ or melanin index in more recent chromameters) are instantly displayed on the screen (Takiwaki 1998).

Chromameter has the following disadvantages:

- Skin color is easily influenced by pressure on the skin and orthostatic position of the device (Takiwaki et al. 1994; Queille-Roussel et al. 1991; Takiwaki and Serup 1994). To avoid the influences of differences in the manner of measurement, standardized guidelines for skin color measurement with these instruments have been proposed by Fullerton et al. (1996).
- The color of an object smaller than the opening of the probe head (8–11 mm) cannot be measured exactly (Takiwaki 1998).
- The evaluation of the pattern or distribution of skin color in a test area is not possible (Takiwaki 1998). The values obtained by chromameter indicate an average of the total test area. These problems may be solved by computer-assisted image analysis of digitized color pictures of an object (Takiwaki 1998). However, as the color of an object depends on the illumination and the characteristics of the device used to record the image such as a CCD (charge coupled devices), the color values obtained with software for image analysis are not absolute but should be considered as relative data, which are comparable only with those obtained using the same system and under the same situations (Takiwaki 1998).
- To the best of our knowledge, there are no data available at present to show whether or not the

melanin values obtained by chromameter can be falsely affected by changes in the levels of skin erythema and vice versa.

7 Derma-Spectrophotometer[®]

Derma-Spectrophotometer (DSM; Cortex Technology, Denmark) is a narrow-band skin colorimeter with a high intensity white LED as the light source. DSM can display skin color in L*a*b, RGB, CMYK, and XYZ color models and can also display melanin and erythema values. For ease of operation, the probe is equipped with a guiding light that illuminates the target prior to reading. The effect of pressure on color measurements is minimal due to the probe head design. However, as an important disadvantage, the environmental light can affect the measurements. It is not known whether changes in erythema can falsely affect melanin values measured by Derma-Spectrophotometer and vice versa. The device is more ergonomic than chromameter.

8 Mexameter[®] (Courage-Khazaka, Germany)

This narrow-band simple reflectance colorimeter analyzes an area of 20 mm², that is, a disk of 5 mm in diameter. The device contains 16 diodes positioned at the periphery of the photodetector (Baquie and Kasraee 2014). Diodes emit at 568, 660 and 880 nm, which respectively correspond to green, red, and infrared light. Photodetection of the reflected light after emissions in the green and red allows computing cutaneous hemoglobin content (i.e., erythema value with arbitrary units), while analysis of reflected light from wavelengths in the red and near-infrared provides values of skin melanin content (i.e., melanin value also with arbitrary units). L*a*b, RGB, or CMYK values are not displayed (Baquie and Kasraee 2014).

The color measurement is automatically performed when the probe head is placed on the skin surface and removed. A vertical and gentle movement is necessary to reassure a correct

measurement (Baquie and Kasraee 2014). The disadvantages of Mexameter include the followings:

- Measurements can be affected by environmental light. Color measurements should therefore be done in a dark place.
- If the probe is not vertically placed on the skin surface or removed too rapidly, measurement accuracy can be affected.
- Measurements are affected by the pressure applied by the probe to the skin (Baquie and Kasraee 2014).
- A recent extensive study on Mexameter sensitivity and specificity confirmed that changes in skin erythema levels can falsely affect melanin values and vice versa (Baquie and Kasraee 2014).

A few clinical studies have compared the tristimulus and narrow-band colorimetric devices. Shriver and Parra found a strong correlation between the melanin index (MI) and L* value and concluded that both types of devices provide accurate measurements of skin and hair color in persons of European, Asian, and African-American ancestry (Shriver and Parra 2000).

In a comparison of the tristimulus chromameter and the narrow-band spectrophotometers and the Mexameter and the Derma-Spectrophotometer for the evaluation of various skin color changes (erythema, irritation, blanching, artificial, and UV tanning), it was found that the sensitivity and reproducibility of all devices were acceptable. The Mexameter showed the weakest sensitivity, but the day-to-day repeatability of melanin measurements was better for the narrow-band spectrophotometers (Clarys et al. 2000).

9 Dermacatch[®]

Dermacatch is a new colorimetric device recently developed by the Swiss company Colorix. Dermacatch is a visible-spectrum reflectance colorimeter that is made of a diode emitting in the “full visible light spectrum” (Baquie and Kasraee 2014). The photodetector measures the globally

reflected light to compute erythema as well as melanin values (with arbitrary units that differ from the Mexameter's units). The measured area covers a disk of 5.5 mm in diameter, that is, 24 mm².

An extensive *in vitro* and *in vivo* study, involving 18,000 measurements aimed at comparing the reproducibility, sensitivity, and specificity of Dermacatch versus Mexameter, showed that Dermacatch values were significantly more reproducible than Mexameter (Baquie and Kasraee 2014). Dermacatch was also shown to be more sensitive and specific than Mexameter in measuring melanin and erythema values *in vivo* (Baquie and Kasraee 2014). Changes in erythema levels did not affect melanin values and vice versa, that is, unlike Mexameter, Dermacatch could precisely discriminate the two parameters (Baquie and Kasraee 2014). It is claimed that the environmental light does not affect Dermacatch measurements; this, however, was not evaluated in the above-mentioned study. Disadvantages of Dermacatch are the followings:

- Measurement data are only displayed on the screen and cannot be printed out or automatically transferred to the computer.
- The color of an object smaller than the opening of the device (D: 5 mm) cannot be measured.

Recently bought by “Delfin technology”, this device has been recently upgraded and commercialized to “SkinColorCatch”.

10 Conclusion

Skin colorimetry remains a complex subject. Although the *in vitro* measurement of color (e.g., in color charts) by most colorimeters provides reproducible and reliable results, color measurement in biologic materials such as skin, in which parameters such as pigmentation, skin roughness, and especially skin erythema can readily change, is much more complicated. Taking into account that changes in each parameter can significantly, and falsely, affect the values

obtained for other parameters, one should note that data obtained for skin color “evolution” in two different time points should be interpreted with considerable caution. New, more specific colorimeters that permit a more precise discrimination between melanin and erythema might help to resolve this problem.

1 Introduction

Defining skin color and monitoring its modulation under the influence of varying types of stimuli (such as drug or light test/treatment, exposure to irritants) is a highly indicative method in dermatocosmetic research as well as in day-to-day practice. However, quantification of skin color evolution appears to be complex, as in vivo fluctuations in erythema can affect melanin values and vice versa. Knowing that melanin absorbs light in a large range of wavelengths (including green, red, and near-infrared light), the confusion over the discrimination between melanin and erythema (i.e., redness of hemoglobin) can easily occur by colorimetric devices.

To discriminate melanin from skin erythema, different technologies have been developed with a variable level of reliability; some colorimeters are based on scanning reflectance spectrophotometry (Bjerring 1995; Anderson and Bjerring 1995; Wilhem and Maibach 1995; Clarys et al. 2000; Biniek et al. 2012), others rely on tristimulus (i.e., three specific wavelengths) colorimetry (such as Chromameter[®], Minolta) (Clarys et al. 2000; Westerhof et al. 1986; Seitz and Whitmore 1988; Queille-Roussel et al. 1991; Chan and Li Wan Po

1993; Waring et al. 1993; Westerhof 1995; Takiwaki and Serup 1995; Elsner 1995; Rubegni et al. 2002) or narrow-band simple reflectance colorimetry, e.g., Mexameter[®] (Courage-Khazaka) (Clarys et al. 2000; Farr and Diffey 1984, 1985; Diffey et al. 1984; Diffey and Farr 1991; Takiwaki et al. 1994; Anderson 1995; Erythema Meter 1999; DermaSpectrometer 1999; Mexameter MX 16 1999; Courage W, Khazaka G, 1999, Calculation of the melanin value and erythema value for the Mexameter, personal communication; Gabard et al. 1993; Draaijers et al. 2004). Recently, has been released a new colorimeter, Dermacatch[®] (Colorix), which uses the entire visible-spectrum reflectance. It is claimed to better discriminate between melanin and erythema. To evaluate its potential, Dermacatch[®] was compared with Mexameter[®], one of the mostly used colorimeters in dermatological research. Sensitivity, specificity, and reproducibility of the respective erythema/melanin values of the two devices were first evaluated on standardized color charts. Then, the parameters were also analyzed on human volunteers before and after targeted exposure to different UVB doses and/or modulation of cutaneous erythema (through the application of topical vasodilator and vasoconstrictor agents).

2 Material and Methods

2.1 Instruments

2.1.1 Mexameter[®] M X16 (Courage-Khazaka, Germany)

This narrow-band simple reflectance colorimeter analyzes an area of 20 mm², that is, a disk of 5 mm in diameter. The device contains 16 diodes positioned at the periphery of the photodetector. Diodes emit at 568, 660, and 880 nm, which respectively correspond to green, red, and infrared light. Photodetection of the reflected light after emissions in the green and red allows computing cutaneous hemoglobin content (i.e., erythema value with arbitrary units), while analysis of reflected light from wavelengths in the red

and near-infrared provides values of skin melanin content (i.e., melanin value also with arbitrary units).

2.1.2 Dermacatch[®] (Colorix, Switzerland)

The visible-spectrum reflectance colorimeter is made of a diode emitting in the full visible spectrum. The photodetector measures the globally reflected light to compute erythema as well as melanin values (with arbitrary units that differ from the Mexameter's units). The measured area covers a disk of 5.5 mm in diameter, that is, 24 mm².

2.2 In Vitro Measurements

The two colorimeters were tested on 67 colors of the widely used Natural Colour System (NCS) color chart from the Scandinavian Colour Institute (Stockholm, Sweden). The selected colors covered notably the grey (i.e., from white to black), pink (i.e., from light pink to dark pink), red (i.e., from light red to dark red), beige (i.e., from light beige to dark beige), and brown (i.e., from light brown to dark brown) scales: NCS S 0300-N, NCS S 0500-N, NCS S 1000-N, NCS S 8000-N, NCS S 8500-N, NCS S 9000-N, NCS S 4000-N, NCS S 4500-N, NCS S 5000-N, NCS S 0505-Y20R, NCS S 1005-Y20R, NCS S 2005-Y20R, NCS S 3005-Y20R, NCS S 4005-Y20R, NCS S 5005-Y20R, NCS S 6005-Y20R, NCS S 7005-Y20R, NCS S 8005-Y20R, NCS S 8505-Y20R, NCS S 0505-Y50R, NCS S 1005-Y50R, NCS S 2005-Y50R, NCS S 3005-Y50R, NCS S 4005-Y50R, NCS S 5005-Y50R, NCS S 6005-Y50R, NCS S 7005-Y50R, NCS S 8005-Y50R, NCS S 0505-Y80R, NCS S 1005-Y80R, NCS S 2005-Y80R, NCS S 3005-Y80R, NCS S 4005-Y80R, NCS S 5005-Y80R, NCS S 6005-Y80R, NCS S 7005-Y80R, NCS S 8005-Y80R, NCS S 8505-Y80R, NCS S 3560-Y30R, NCS S 4550-Y30R, NCS S 3560-Y40R, NCS S 4550-Y40R, NCS S 3560-Y50R, NCS S 4550-Y50R, NCS S 3560-Y60R, NCS S 4550-Y60R, NCS S 3560-Y70R, NCS S 4550-Y70R, NCS S 0580-Y80R, NCS S 1080-Y80R, NCS S 0585-Y80R, NCS S 1085-

Y80R, NCS S 0580-Y90R, NCS S 1080-Y90R, NCS S 1085-Y90R, NCS S 1080-R, NCS S 6010-Y90R, NCS S 2565-R80B, NCS S 2565-G, NCS S 2070-G70Y, NCS S 0520-G80Y, NCS S 0530-G80Y, NCS S 0540-G80Y, NCS S 0550-G80Y, NCS S 0560-G80Y, NCS S 0570-G80Y, NCS S 0575-G90Y). On each color square, ten measures were collected with both colorimeters.

2.3 In Vivo Measurements

2.3.1 Analysis of Different Fitzpatrick Skin Colors

In vivo tests were performed on three groups of volunteers with, respectively, phototype II, III, and IV to validate the reliability of both devices. The analyzed area consisted of the proximal volar arm that was unexposed to UV light; ten measures were collected with both colorimeters.

2.3.2 Analysis of Cutaneous Erythema and Pigmentation

Twelve male volunteers of Fitzpatrick skin type III were recruited with an average age of 23. Approval from the local ethics committee as well as informed consent from the volunteers was collected prior to any experiment. Exclusion criteria were any sign, prior or during the experiment, of photosensitivity (e.g., drug-induced photosensitivity, diseases such as solar urticaria or auto-immune diseases), allergies to agents used during the tests, infection or inflammation of the skin, involvement in additional clinical test in parallel or within the preceding 3 months, or exposure to ultraviolet irradiation or intensive sunlight within 4 weeks before or during this study. All experiments were performed in the same room under controlled ambient conditions (temperature at 23 °C and relative humidity at 40 %). While each volunteer was acclimatized for 15 min prior testing, the skin area of interest was thoroughly cleansed with a neutral lotion and then rehydrated with an open application of Excipial cream (Spirig laboratories, Switzerland). For each time point and condition, measurements with both colorimeters were collected ten times on

each specific skin area of interest. In parallel, images were taken with a dermatoscope (Handyscope, Fotofinder) at each site for expert visual assessment.

2.3.3 Erythema Induction on the Forearms

For each of the 12 volunteers, a skin area of 40 mm in diameter was treated on the volar aspect of each forearm with 5 mM methyl nicotinate cream (MNC) for 30 s under occlusion at 3 mg/cm². MNC cream was prepared through dissolution of methyl nicotinate (Sigma-Aldrich) in ethanol 70° following the dispersion of the solution in Excipial cream to obtain a final concentration of 5 mM MNC. Two control areas, selected on each volar forearm, were similarly treated with Excipial cream alone. No skin site was closer than 40 mm to the antecubital fossa or to the wrist. After the exposure time of 30 s, excess of the cream was removed. Measurements were collected before treatment (i.e., 0 min) as well as after 5 and 10 min. At each time point, 10 measurements were performed on each area with each colorimeter.

2.3.4 UVB Exposure on the Back

On each side of the volunteer's back at the level of vertebra L1, three squares of 20 mm in width were exposed to UVB at 450, 600, and 750 mJ/cm², respectively, through a unique treatment by Excimer Laser (Xtrac, Photomedex). Measurements by Dermacatch as well as Mexameter were done before treatment (i.e., day 0) as well as after 2, 7, and 14 days. For each treated area, a contiguous unexposed skin area was considered as the respective control site.

2.3.5 Erythema Reduction on the Back

Seven days after UVB exposure, one of the two skin areas exposed at 750 mJ/cm² as well as its contiguous unexposed site was treated with a dermocorticoid (0.05 % clobetasol propionate, Dermovate cream) at 3 mg/cm² for 18 h under occlusion. After the exposure time, excess of the cream was removed. Measurements were collected before treatment (i.e., 0 h) as well as after 18 h of exposure.

2.3.6 Erythema Induction on the Back

Fourteen days after UVB exposure, one side of the back was treated with 5 mM MNC for 30 s under occlusion at 3 mg/cm². UVB-exposed as well as contiguous unexposed skin areas were similarly treated. Measurements were collected before treatment (i.e., 0 min) and after 10 min. The rest of the protocol was identical to the experiment of erythema induction on the forearms.

2.4 Calculation and Statistics

Coefficient of determination (R^2) was considered in the case of the *in vitro* analysis when visually assuming that the darkening and reddening of the standard colors gradually increased and remained constant, respectively.

Correlation ratio (CR) to compare the values of the two colorimeters relied on the Pearson correlation.

Coefficient of variation (CV) was calculated as follows: (Mean value after treatment – Mean value before treatment)/Mean value before treatment \times 100. Mean values corresponded to the average of the 10 repetitive measures from the same specific skin area at the same time point.

Multiple ANOVA analysis with Bonferroni correction was used to define the significance of the changes between conditions and time points.

3 Results

3.1 In Vitro Experiments

To define the reliability of the two colorimeters, initial tests were performed on an international standard, the NCS color chart. Colors of the chart were selected to visually show a gradual increase in darkness and a constant redness. When analyzing any type of colors, erythema values of Dermacatch remained constant, while those of Mexameter significantly fluctuated (Fig. 1a, c, and e). Regarding melanin values, Dermacatch values increased in a similar proportion to visual perception, while the increase of the

Mexameter values was not consistent (Fig. 1b, d, and f). Therefore, the limited range of sensitivity of Mexameter triggered a weak correlation between the two devices (Table 1). However, the repeatability of values was high for both colorimeters (standard deviation values–SD–of Table 1) and was below the official SD mentioned by the providers (i.e., \pm 10 arbitrary units of the value for both devices).

3.2 In Vivo Experiments

3.2.1 Analysis of Different Fitzpatrick Skin Colors

Contrary to the *in vitro* results that showed a poor specificity of Mexameter, the *in vivo* values of the two colorimeters provided a similar pattern of the three examined Fitzpatrick skin phototypes (i.e., type II, III, and IV) and were consistent with visual perception. However, the reproducibility of the data was slightly weaker with Mexameter even though the SD was below the official value (Fig. 2 and Table 2).

3.2.2 Erythema Induction on the Forearms

To determine if an increase in erythema was detectable by the colorimeters, forearms were treated with topical 5 mM MNC, a vasodilator. MNC was known to only induce a transient increase in redness; therefore, melanin values were expected to remain constant before and after MNC application, despite the homogenous increase in skin erythema. After 5 min of exposure, skin redness increased and reached a plateau according to both colorimeters and dermatoscopic evaluations. Noteworthy, Mexameter falsely measured a significant decrease in pigmentation that was inversely proportional to the increase in cutaneous redness. Thus, the melanin measurement with Mexameter appeared to be biased by the induced erythema modulation. In parallel, analysis of data from Dermacatch showed that its melanin values were not affected by this specific induced skin erythema (Fig. 3 and Table 3).

Fig. 1 Comparison of melanin and erythema values of the two colorimeters on the NCS color chart. Examples of erythema values (a, c, e) and melanin value (b, d, f) on colors ranging from white on the left side of the graph to

black on the right side (a, b), light red to dark red (c, d), and light beige to dark beige (e, f). Mexameter values are depicted as a dashed line and Dermacatch values as solid line

3.2.3 UVB Exposure on the Back

According to visual perception through dermatoscopic images, skin erythema reached its maximum at day 2 following the UVB exposure

on the volunteer’s back and then gradually decreased. Moreover, the intensity of erythema seemed to be proportional to the applied UVB dose. Interestingly, both devices showed the

Table 1 In vitro reliability of melanin and erythema values of both colorimeters

same pattern for erythema values, and this pattern was proportional to the applied dose of UVB.

In the case of melanin quantification, visual assessment considered an increase in pigmentation up to day 7, which appeared to be a plateau

up to day 14. Dermacatch detected a slight increase in melanin values already at day 2, while Mexameter showed a false but significant decrease in melanin values at the same time point for the conditions at 600 and 750 mJ/cm²

Fig. 3 Erythema induction on the forearms. Erythema (a–b) and melanin values (c–d) were provided by Dermacatch (a, c) and Mexameter (b, d) after a vasodilatation treatment of the forearm

of UVB. Some melanin values of Mexameter were thus consistently and significantly biased by the increase in skin erythema (Fig. 4 and Table 4).

3.2.4 Erythema Reduction on the Back

The following experiment consisted in analyzing the impact of a redness reduction on the melanin values. Seven days after UVB exposure, when the UVB-treated skin areas were already hyperpigmented but still erythematous, an UVB-exposed (i.e., 750 mJ/cm²) as well as an

unexposed portion of the back was treated with the vasoconstrictor Dermovate cream. After the exposure time of 18 h, skin erythema was slightly reduced according to both devices, which was confirmed by dermatoscopic images. The rate of erythema decrease measured by the two colorimeters was significantly similar regardless of the prior exposure of the skin to 0 or 750 mJ/cm² of UVB. Noteworthy, it appeared that Mexameter erroneously detected a significant reduction of pigmentation on the skin that had been previously exposed to UVB. However, such

Fig. 4 UVB exposure on the back. Erythema (a–b) and melanin values (c–d) were collected by Mexameter (a, c) and Dermacatch (b, d) after a treatment of increasing doses of UVB (450, 600, and 750 mJ/cm²) on the back

Table 4 In vivo reliability of both colorimeters after UVB exposure on the back

pigmentation reduction was not significant in the case of the skin not exposed to UVB. Finally, reproducibility of Mexameter values was found to be lower than that of Dermacatch (Fig. 5 and Table 5).

3.2.5 Erythema Induction on the Back

To further evaluate the false influence of skin erythema on melanin values, the UVB-exposed areas of the back as well as the adjacent unexposed regions of the back were treated with

Fig. 5 Erythema reduction on the back. Erythema (a–b) and melanin values (c–d) were collected by Mexameter (a, c) and Dermacatch (b, d) after a vasoconstriction treatment on the back

the vasodilator MNC on the 14th day following the UVB exposure. As confirmed by dermatoscopic images, melanin values remained constant before and after MNC application, despite the homogenous increase in skin erythema. Results from Mexameter showed that melanin values were significantly affected by the

increased erythema. The incorrect diminution in pigmentation was inversely proportional to the degree of pigmentation of the tested area. In the case of Dermacatch, the increase in skin erythema did not affect melanin values. The latter remained constant before and after erythema induction regardless of the pigmentation status of the

Fig. 6 Erythema induction on the back. Erythema (a–b) and melanin values (c–d) were provided by Mexameter (a, c) and Dermacatch (b, d) after a vasodilatation treatment of the back (exposed or not to the different doses of UVB)

studied area. Moreover, when quantified by Dermacatch, it appeared that the rate of erythema increase was significantly identical (based on the provider's criteria of the SD: ± 10 units) between the skin areas previously exposed to 0, 450, 600 or 750 mJ/cm² of UVB (increase of 20 units ± 5 units). Regarding Mexameter, some of its erythema values did not show a significantly similar rate of erythema increase (increase of 109 units ± 19 units when the provider's SD corresponded to ± 10 units). Finally, taken together Mexameter values showed a SD above the officially accepted value, which indicated a limited reproducibility of the device. In the same circumstances, Dermacatch SD was always below the limit defined by the providers (Fig. 6 and Table 6).

4 Discussion

Due to a partial overlap in wavelengths, colorimetric measurements of melanin can be falsely biased by a fluctuation in skin erythema and vice versa. Thus, an optimal skin colorimeter needs to be able to precisely discriminate between cutaneous melanin and erythema. The present study compared the new colorimeter Dermacatch with the reference device Mexameter in regard to (i) sensitivity to erythema and melanin detection as well as (ii) specificity of detecting changes in erythema or melanin, and (iii) reproducibility of melanin/erythema measurements.

Table 6 In vivo reliability of both colorimeters after erythema induction on the back

	mJ/cm ²	Melanin values		Erythema values	
		Dermacatch	Mexameter	Dermacatch	Mexameter
CV	750	0.2	-12.3	5.4	35.2
	600	0.1	-10.5	4.4	28.5
	450	0.1	-13.8	4.3	36.9
	0	0.6	-12.5	5.8	47.9
SD		5.0	11.6	3.2	14.3
CR	750	-1		1	
	600	1		1	
	450	-1		1	
	0	-1		1	

CV coefficient of variation, SD standard deviation, CR correlation ratio

In vitro evaluations showed a high level of reproducibility of both devices, which was in accordance with the technical data from the providers. However, the narrow-band technology of Mexameter showed a limited reliability especially in quantifying the darkening of the colors (e.g., from light pink to dark pink or light beige to dark beige).

In vivo, both colorimeters could reliably distinguish the different skin phototypes to the same extent. Moreover, a specific modulation in skin erythema, regardless of the pigmentation status, showed that Mexameter and Dermacatch erythema values were in accordance with visual perception. However, in the case of Mexameter, the rate of erythema increase after MNC treatment appeared to be erroneously influenced by its pigmentation status. In addition, Mexameter's melanin values were falsely affected by the erythema induction in all the three sets of experiments (i.e., vasodilatation of the normal skin, UVB exposure, and vasodilatation of the UVB-treated hyperpigmented skin). Mexameter showed significantly lower melanin values each time that the skin erythema was increased, and such a false decrease in melanin values was inversely proportional to the pigmentation level of the tested area. On the contrary, Dermacatch could reliably discriminate between skin erythema and melanin without any cross contamination.

Finally, the fact that Mexameter was at least two times less reproducible than Dermacatch increased the risk of a potential confusion over

the detection of erythema or melanin fluctuations when using Mexameter.

Taken together, the analysis of more than 18,000 measurements performed in the present study showed that the sensitivity of both colorimeters was high. However, Dermacatch appeared to be a more reproducible device as well as a more specific colorimeter to discriminate pigmentation from cutaneous erythema.

1 Introduction

The traditional approach treated the skin in the same way for at least 50 years. The skin is a protective membrane, a carpet that puts us in contact with the universe and provides information on possible attacks. All components of the skin are now clearly identified. The skin is made of palisade epidermal cells in ranks to better ensure our protection, below with a thick dermis to strengthen defenses (Fig. 1). But the dynamic aspects of the skin have been totally neglected.

As a plastic surgeon, I've always been very intrigued by simple phenomena, but still not very well explained and summarized under the term of ELASTICITY, SUPPLENESS, PLIABILITY, and FLEXIBILITY. How do all these elements adapt and link on each other during the movement, how does the skin move? (Fig. 2).

The skin, indeed, outside the traumatic event, always returns to its original state extemporaneously.

2 Materials and Methods

We will discuss from video observations realized during surgical procedures, under tourniquet. In order to clarify the comment, we will refer to the traditional anatomical layers distribution (Fig. 3).

Fig. 1 Diagram of the skin as it is proposed in classical histological books

This study is done using a video endoscope and borescope contact magnifying, respectively, 25 and 80 times Karl Storz camera Image One connected to a fiber optic Tricam 221,030 and associated with a cold light source Xenon Nova 201,315 (Fig. 4). The sequences were recorded with a video recorder KIPRO AJA HDV 10^E.

For in vitro studies made by Prof. JP Delage (INSERM), the skin fragments were fixed by immersion in a 10 % solution of formaldehyde for 5 days and then rinsed in the water for 5 days. Then they were subjected to maceration (NaOH) using the technique described by Passerieux et al. (2006). They were macerated in 5 N NaOH solution at 18° for 5 days and then rinsed in the water again for 5 days. This technique allows the maintenance of the main collagen (Type 1). The preparation is then frozen, dehydrated, and pigmented at the gold and examined under a Philips electron microscope.

The classic description is that there is a thin epidermis consisting of cornified and stratified thick epithelium cells. The dermis is more fibrous and houses glands, blood vessels, follicles, and nerve endings or specialized sensory receptors.

Fig. 2 (a–d) When we lift up the skin, we feel a little resistance to traction but the skin does not tear, and then, when we let go, it returns to its initial position, as if from memory (a, b, c, d)

Fig. 3 Use of endoscope during surgery

Aside from acting as a barrier to dehydration, infection, and physical damage, the skin has a major role in metabolism, sensation, and thermoregulation. But even if the cutaneous constitution is perfectly well defined, the following question remains: how does the skin move?

How do all these elements adapt and link on each other during movement?

3 Surface of the Epidermis

3.1 The Diversity of the Forms

The first observation which leads us to the main feature which is the skin morphology is varied (Fig. 5).

It is fascinating to see that the surface of the epidermis has many forms, and all of them come from the same basic polyhedric pattern.

The color can be very varied too. Skin color also exhibits many different tones: from white to very dark; the skin comes in many gradations.

But the diversity doesn't only concern color and pilosity. In the same person, depending on the anatomical zones, we can notice that these pseudopolyhedric forms can change into squares, into parallel cylinder ridges reminding us of sandhills, or into diamond-shaped pannels that look like waves.

Fig. 4 Subcutaneous endoscopic exploration with a fiber optic and cold light

These forms can glow with youth or sag with age, wrinkle with the weather, or get thinner when people have lost weight.

We can see changes due to the person's activity, like in the palm of a heavy worker or the arch of the foot of a jogger, and inner intrinsic influences like dermatosis digging deep lines, nevus coloring pigmenting the surface, or stretch marks, fractures of the dermis that occur during pregnancy.

3.2 Polyhedrons with Different Shapes

The skin is varied but always remains woven by this polyhedric drawing framework, irregular, fundamental, simple, and yet rarely described in the literature (Fig. 6a, b).

Therefore, questions should be asked:

Why is the skin surface made of polyhedron shapes?

Why isn't the cutaneous surface perfectly smooth?

The epidermis, the most superficial layer, is a surface printed with these small, changing polyhedrons, all of them irregular and different, limited to three, four, or five sides, each side about $500\ \mu$ length, with lines about $50\ \mu$ wide between the polyhedrons.

Not one polyhedron looks like its neighbor, and its distribution is very irregular.

Fig. 5 (a-f) Different shapes of the skin surfaces X2. (a) Shoulder skin surface (b) Palm of the hand (c) Pulp finger (d) Abdomen. Strecht marks (e) Thigh skin surface (f) Foot plantar surface

Fig. 6 (a, b) X3 Irregular polyhedrons at the skin surface. Each polyhedron is made of smaller polyhedrons which adjusts to its neighbour inside the bigger one

3.3 Complex Mosaic Pattern of Irregular Polyhedrons

These polyhedrons move in the three-dimensional space, and during their movements, we can notice changes even on their surface.

When the skin stretches and creases during everyday activities, these small polyhedrons move; their shape and aspect change, and when the forces are removed, they return to their initial state.

All the moments of our everyday lives induce these unperceivable yet unnoticed changes. Yet on closer observation, we do see those lines of force which change from vertical to horizontal and then blur out to appear again according to the strength of the pressure exerted.

These lines of force have got a physical reality. This diversity becomes more impressive as we draw the operating microscope closer, but then, it becomes more difficult to photograph and visualize because the depth of field is reduced, and the patient's fine movements from breathing and pulsations at rest are amplified.

Nevertheless, with careful study, we can see these changes, through video capture, especially by high magnification and filming in slow motion.

First, let's see the movement magnified ten times (Fig. 7a–d).

The polyhedrons are directed to the right. Let's press on the left, and they all move rapidly, apparently in a disordered manner; their forms change and the lines of force move to the left.

The response to the constraint, to the physical force applied, is obvious. The gymnastics agility of the polyhedrons, the apparent mechanical faculty ability to change forms and orientations, needs further investigation.

The shape of polyhedrons changes under the mechanical constraint. Lines of force are subject to stress.

The next sequence will clarify these movements, by drawing the microscope closer with 25 times magnifying power (Fig. 8a–d).

At rest, let's examine polyhedrons A, B, C, and D.

Let's pull downward lightly on the framework without changing the depth of field of the camera.

Fig. 7 (a–d) The response to the constraint, to the physical force applied, is obvious. The gymnastics agility of the polyhedrons, the apparent mechanical faculty ability to change forms and orientations

Fig. 8 (a-d) X3. Between a rest situation (a) and a local constraint to the right, polyhedrons shapes are changing and new lines are appearing

The elements B, C, and D are moving downward. The separation lines are only stretched.

But A remains rather static.

Then, as the traction exerted becomes stronger, new lines of force, E, F, and H, emerge, oriented in the direction of constraint, passing through existing structures. Then, as the traction becomes stronger, new lines appear colored in pink even slightly modifying the initial structural lines. Increasing constraint creates new lines here in green. The distance from A to C has increased by 15 %.

So we see stretching in the direction of the applied force with successive appearance of new lines of force added to the original ones, which look different and change the general shape.

3.4 Polyhedrons Are Fractalized

Moreover, inside each polyhedron, we can observe other subunits with varied dimensions and forms, which remain inactive until the tension overwhelms the fibers and give rise to their final shape (Fig. 9).

We get the impression that there is a dynamic environment which has a higher organization with structural latent solutions. It is certainly a

Fig. 9 Moreover, inside each polyhedron, we can observe other subunits with varied dimensions and forms, Polyhedrons are fractalized

fractalization that makes the dispersion of the force easier. We are reminded of the phenomenon we have described in the sliding tissue around tendons.

These dynamic compartments based on fractal organization are a very fascinating phenomenon and can be easily observed in heavily exposed skin, like the skin of the palm, where the wrinkles are particularly visible.

Inside these polyhedrons, measuring 500 μ on each side, we can observe sub-polyhedrons of 50 μ , substructures, perfectly individualized on

the mechanical morphology and mechanical behavior, because each small polyhedron adjusts to its neighbor inside the bigger one.

Finally, these sequences show that, although these polyhedrons stretch and are transformed, their ridges move very little. We can already assume there are anchor points with the depth of the epidermis.

The hypothesis that each apex could be reinforced by fibrils like a pillar or a column is wrong, but one can get the impression that the shape of the epidermis depends on elements existing deep inside.

There is an intimate fibrillar morphodynamic architecture in the epidermis. This epidermis architecture is linked with and depends on elements existing deep inside.

Our epidermis is not like an even tile but like a chaotic mosaic.

So the cutaneous architecture is not inert; it is living under constraint.

4 The Cutting of the Epidermis and Dermis

4.1 The Skin Is Under Tissular Tension

This tissue tension is also obvious when we cut the skin, either the dermis or the aponeurosis (Fig. 10). There is an intrinsic, pre-existing constraint tissue tension as revealed by observation.

The edges of the skin spontaneously draw apart a few millimeters as soon as the surgeon makes an incision.

Fig. 10 (a-b) Tissue tension is also obvious when we cut the skin, either the dermis or the aponeurosis

We are going to continue the exploration but this time using a contact endoscope.

This is an endoscope magnifying 25 times with simultaneous recording. An analysis of the sequences will be done at the same time, in order to keep the impressions of the moment intact.

Cutting through the epidermis and a part of the dermis enables us to confirm our early hypothesis and observations from the very beginning. We can find deep inside the dermis the fibrils which undoubtedly with their biomechanism infiltrate the extracellular matrix of the dermis. They penetrate it (Fig. 11).

Fibrils penetrate the dermis, and they exert a morphological influence on the shape of the skin surface of the epidermis.

But let's focus on our investigation. How do these microfibrils coming from the depth of the subcutaneous tissue turn into irregular polyhedrons at the surface of the skin?

The transverse cross section of the epidermis gives us a different impression with a view according to the lines of relief on the surface.

Sometimes they look like roman tiles (Fig. 12). Sometimes there are no lines of strain, but we can notice immediately as an obvious marker the limit between the epidermis and the dermis, at the level of the basement membrane, and the small vertical papillary vessels (Fig. 13a, b).

The epidermis is homogeneous, from its bottom to its surface, and the stratum corneum, its last element, also participates in its dynamic behavior which is global.

Fig. 11 Deep inside the dermis, the fibrils undoubtedly, with their biomechanism infiltrate the extracellular matrix of the dermis

So the epidermis moves, but in addition, if we look closer, we can observe at the center of the epidermis a slightly convex network which curves downward as if attracted by something.

Thus, our original observations on the surface may have been confirmed by cutting the skin.

Fig. 12 The transverse cross section of the epidermis gives us a different impression with a view according to the lines of relief on the surface. Sometimes they look like roman tiles

The form of the epidermic surface is dictated deep inside, by tethers whose direction is random, but which is nearly vertical in this particular case.

Fibrils cross the lamina densa and the stratum basale and shape the epidermis and its surface. This physical link between the dermis and epidermis is evident with video. Moreover in this continuity, there is a slight time lag on the papillary crest line. The interrelationships are more complex than expected (Fig. 14a, b).

We have been able to identify these intraepidermic fibrous tethers.

So there are different axes which cross the epidermis, split it, and, by intersecting in space, make movement possible.

4.1.1 Back Home

But before going further, let's recapitulate.

The surface of the skin is made of polyhedrons fractalized into smaller units (Fig. 15).

Each polyhedron has got a shape determined, deep inside, by tethers whose organization is irregular, without visible order, but which tends to be vertical.

The epidermis is formed of a network of fibrils where the cells are situated in attractivity comfortably within these pseudopillars (Fig. 16a, b).

Fig. 13 Inter-polyhedrons grooves are in correspondence with converging lines deep to the dermis. Observation of the surface and of the cross-section (X50) of the epidermis

highlights the harmonious relationship that exists between the cellular structures and the structures linking the furrows of the epidermis and the dermis

Fig. 14 (a, b) Fibrils cross the lamina densa, the stratum basale and shape the epidermis and its surface. This physical link between dermis and epidermis is evident with a video

Fig. 15 The surface of the skin is made of polyhedrons fractalised into smaller units

At this level, everything is mobile, under tension, without disruption but without any blood vessels.

We will find the vascularization in the dermis.

5 Junction Between the Epidermis and Dermis

The dermis is not easy to film because with the tourniquet on, it is white and inexpressive (Fig. 17). And after reperfusion, it is entirely red and highly bleeding.

Cutting through the epidermis and a part of the dermis allows us to confirm our initial observations and the hypothesis that deep inside, microfibrils penetrate and infiltrate the matrix of the dermis where they exert a morphological influence on the shape of the dermis. How do these microfibrils, rooted as they are in the depths of the subcutaneous tissue, give rise to irregular polyhedrons at the surface of the skin?

In certain cross sections of the epidermis and dermis, you can see obviously the fibers which pass through the dermis, the basement membrane, and the epidermis and extend into the furrows between the epidermal polyhedrons. The dermis and the epidermis are shaped by these fibers (Fig. 18a–c).

Fibrils cross the lamina densa and the stratum basale and shape the epidermis and its surface. This physical link between dermis and epidermis is evident with video.

Bleeding occurs at the level called papillary dermis.

This zone is full of vessels which seem to end in small vertical loops, but which, in fact, form a real network under the epidermis (Fig. 19a, b).

The notion of papillary crests can thus be explained. At the surface of the dermis, it seems that the papillary vessels and their multifibrillar texture bump against the Malpighian layer and push it a little.

Fig. 16 (a, b) X50 Diagram explaining the fibrillar network of the epidermis framing the skin surface (a), linked with the dermis and embedding the epithelial cells (b)

Fig. 17 The dermis is not easy to film because with the tourniquet on, it is white and inexpressive

The distribution of the papillary crests is irregular and occasionally in relation with the surface of the epidermis above (Fig. 20a, b).

What is the most surprising is that this vascular network coming from the dermis is moving with the depth of the epidermis, perfusing the undersurface.

Actually, if we watch these sequences carefully, we can see movements between the dermis and the epidermis.

Moreover in this continuity, there is a slight time lag between the papillary crest line and the surface of the epidermis. The interrelationships

are more complex than expected. This is amazing, particularly when one takes into account the notion of a real tissue continuity, and if you focus now on the red spot, you can see the epidermis moving with the dermis with about half a second's delay (Fig. 21).

These crests papillae can be visible if the epidermic surface is rough, but they can sometimes be less prominent. There is a difference in mobility between the top of the papillary crest and the bottom inside the dermis (Fig. 22a-c).

6 The Dermis

So these framing fibers which model the shape of the epidermis also shape the surface of the dermis.

The same print with polyhedrons and lines will be observed, but it won't be an exact replica because the repartition of the axial fibers is irregular in the space (Fig. 23a, b).

The lines imprinted on the surface of the dermis as well as the epidermis also show close relationships with structures deeper than the dermis.

Thanks to the work of JP Delage, working with INSERM, after performing cross sections on the surface of the dermis every millimeter, we can reveal that these print ridges disappear when they are over 2 mm deep.

Fig. 18 (a) X25, (b, c) X20. Dermis cross section with evidence of the continuity of these fibers irregular in shapes and distributions

Fig. 19 (a, b) Papillary dermis. This zone is full of vessels which seem to end in small vertical loops arborizing (a), but which, in fact, form a real network under the epidermis perfusing the undersurface (b)

Beyond this depth, it seems that the extracellular matrix takes a different form (Fig. 24a, b). The mechanism structure of the medium central part of the dermis is difficult to explore since the structures are imbricated. Fibril repartition of

collagen and elastin, which looks very chaotic, plays a leading part.

Yet other sections of the dermis also show the presence of tissue axes, apparently less scattered (Fig. 25a, b).

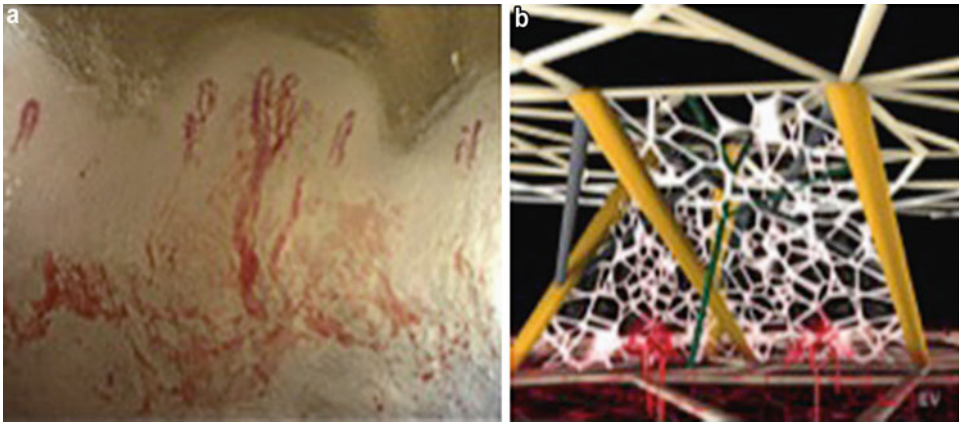

Fig. 20 (a, b) At the surface of the dermis, it seems that the papillary vessels and their multifibrillar texture bump against the Malpighian layer. (b) Diagram of the papillary zone

Fig. 21 (a, b, c) if you focus now on the red spot, you can see the epidermis moving with the dermis with about half a second's delay

These more axial fibrils could be the continuity of these microfibrillar and microvacuolar systems, which rise from the hypodermis and climb up to the dermis.

Sometimes, fibers are gathered in looking like balls or a basket-weave formation.

This suppleness, this mobility and possibility to recover the initial form, this fibrillar mechanism, obeys to the same rules as those observed

in the tendon gliding system and simultaneously nests in its framing network epidermic cells, fibroblasts, all cellular constituents in this network thus linked all together.

We perceive a world of great mobility. What impresses us most is the general suppleness of the epidermis and the dermis, which can be folded and manipulated with no stratification and no separation in total tissular continuity and in this

Fig. 22 (a, b, c) Cross section of the dermis in vivo. This vascular network coming from the dermis is moving with the depth of the epidermis

Fig. 23 (a) Dermis surface framed as the epidermis surface In vitro (Delage preparation) X25 (b) In Vivo after trauma

Fig. 24 (a, b) Cross sections on the surface of the dermis, every millimetre, we can reveal that these prints ridges disappear when they are over 2 mm deep

Fig. 26 Diagram. Dense and irregular fibrillar organisation of the dermis linking epidermis and hypodermis

Fig. 25 (a, b) The mechanism structure of the medium central part of the dermis is difficult to explore since the structures are imbricated. (a) Diagram (b) in vivo cross section

interwoven maze where nerves and vessels could all exist (Fig. 26).

Then, the sequences showing the choreography of the polyhedrons, their connection to the depth of the dermis and agility, make sense.

7 The Hypodermis

Once the dermis and epidermis have been crossed, the connection to the hypodermis happens simply.

Again, there are no stratified and separate layers of the tissue between the reticular dermis and hypodermis layers. Fat lobules under tension rapidly bulge out between the superficial veins and emerge between the sectioned edges of the reticular dermis (Fig. 27).

The fat lobules are inlaid in the reticular dermis in total physical continuity through the fibrillar continuous network (Fig. 28).

Greater mobility of structures within the hypodermis is evident. The fat lobules are situated

Fig. 27 Fat lobules under tension rapidly bulge out between the superficial veins and emerge between the sectioned edges of the reticular dermis

Fig. 29 Fibrillar and vascular continuity between the reticular dermis and the hypodermis is total X10

Fig. 28 The fatty lobules are inlaid in the reticular dermis in total physical continuity through the fibrillar continuous network. There are not separated layers

Fig. 30 Fatty lobules are of very different dimensions and shapes X15

between the blood vessels, below the dermis (Fig. 29), and look like little olive-shaped balloons, with widely variable dimensions ranging from approximately $100\ \mu$ to 1 cm in diameter. Their height varies from several millimeters to several centimeters. Although the size of the lobules varies considerably, they have a consistently smooth appearance and rounded shape (Fig. 30).

These lobules, containing millions of adipocytes, flatten, dilate, turn, and twist within the spaces that contain them, without separating or dissociating from each other. Fatty lobules display

great mobility and tend to slip from the grip of the surgical forceps.

The fibrils that leave the dermis are continuous with those that enter the lobules – there is total fibrillar continuity. Fibrils are found between the lobules (Fig. 31a, b). They ensure mobility between them, penetrating them and merging with the intercellular structures.

They extend toward the superficial fascia. This influences the functional and morphological properties of the fatty tissue.

In this way the fibrils contribute to, and help to determine, the form of the lobules, framing the cells within them (Fig. 32).

The mobility of the adipocytes within the lobule during externally applied movement is fascinating. There is complete and total harmony between the cells.

Fig. 31 (a, b) Fibers frame completely the shape of the fatty lobule. (b) Tissular continuum is total X45

Fig. 32 Fibers penetrate the fatty lobules, helping to the adipocytes arrangements X60

Fig. 33 Fatty lobules even close to each other can be with different colors X45

The adipocytes are not all exactly of the same color. Adipose tissue can be white in certain areas in some patients (Fig. 33). It also displays different shades of yellow, from pale yellow to bright buttercup, to tawny. From our study of tissue

samples under the scanning electron microscope, it would seem that the brown cells are in fact immature multifunctional cells with big nuclei, which are also capable of producing collagen. We are only at the dawn of our understanding of this cellular diversity.

Situated within the hypodermis and continuous with the fibrillar system extending from the dermis, we find the superficial fascia. Very often, it is difficult to distinguish the superficial fascia from the hypodermis or to separate them surgically. The superficial fascia can be described as a fibrillar reinforcement and a densification of the fibrillar network, but it should not be thought of as a sheet separated from other structures. Some authors, a long time ago, have observed this continuity and have taken a more nuanced view of the concept of separate tissue layers within the body (Richet 1877).

Tissue continuity with adjacent structures is total. Its role could be to maintain stability of form by holding the rest of the hypodermis under tension. Cutting into this tissue leads to a marked widening of the gap formed by incision of the dermis.

Then what are the relationships with the subcutaneous area (Fig. 34)?

Relations with the subcutaneous have already been described in previous reports. The skin covers the slip system that we called the Multifibrillar Collagenic and Microvacuolar Absorbing System (MCVAS), namely, fibrillar system, encompassing microvacuoles and thanks to fibrillar and water movements can to

ensure the damped structural mobility without discontinuity in transmission of information and energy.

7.1 The MCVAS

We can say that these polyhedral forms of the cutaneous surface mirror the multifibrillar microvacuolar organization underneath, that the fibrillar continuity toward the surface thus shaped

Fig. 34 Evidence of tissular and fibrillar physical continuity between, the hypodermis and the subcutaneous area

by the deep structures completely builds the architecture of the dermis and the epidermis.

7.2 A Pattern Emerges (Fig. 35) (2, 3)

The cell belongs to this system; it is in this system, from the DNA nucleic helix to the cytoskeleton including the links to the integrins and neighboring cells directly or through this fascinating tissue.

Everything is in continuity; everything is connected; everything moves to fit; everything moves and always comes back to its previous position; everything moves and can be replaced; everything moves within the tissue continuity.

Therefore, the form can be described and interpreted.

Now, let's stitch suture the skin back but let's keep in mind that, from now on, nothing will be accounted for without considering this fractal and dispersed pattern tissue organization that can be found in lots of other fields all around us and which introduces the fact that mobility and adaptability in biology do not depend on order and proportionality.

Fig. 35 The skin is part of the globality of the living matter and cannot and must not be regarded as a separated surface layer. We have to rethink the traditional layered vision

8 Conclusions

Skin is actually the area with the outside world report of a living matter. It is its component protection and its area information and exchange.

It is part of the globality of the living matter and cannot and must not be regarded as a separated surface layer.

1 Introduction

The interactions of light with human skin are controlled by the intrinsic optical properties of this remarkable biological surface. In the case of visible light, these interactions result in attributes, such as hue and glossiness, that characterize its appearance. From a tissue optics perspective, it is difficult to find a material more complex than human skin, which explains the wide range of variations in skin appearance observed in the world population.

Light impinging on the skin surface can be reflected back to the environment or transmitted to its internal layers. The amount of reflected light is associated with the probability of reflection, which, in turn, depends on the local refractive index differences and the angle of incidence of

the incoming light with respect to surface normal vector. The larger the angle of incidence and the local refractive index of the skin surface, the higher the probability of light being reflected.

Once light is transmitted into the skin tissues, it can be further attenuated by their constituents such as cells, fibers, and organelles. The mechanisms of light attenuation, namely, scattering and absorption, alter the spatial and spectral profiles of the light traveling within the various skin layers. Eventually, a portion of the traversing light may be propagated back to the environment.

In this chapter, we examine the optical properties of healthy human skin from a first-principles point of view. We focus on the main light-attenuation structures, or agents, acting within the cutaneous tissues. These agents can be loosely divided into two groups, namely, scatterers and absorbers. In the next sections, we review the roles of these agents with respect to their spatial and spectral action domains and discuss their interplay through light sieve and detour effects. We also concisely describe the roles of key light-emission (fluorescence) agents found in the skin tissues. The chapter closes with an overview of practical challenges related to the advance of research on skin optical properties.

2 Scattering Agents

The three main types of scattering occurring within the skin layers are reflective-refractive scattering, Mie scattering, and Rayleigh scattering (Baranoski and Krishnaswamy 2010). The occurrence of these forms of scattering is associated with different tissue constituents. The reflective-refractive scattering, or geometrical scattering, is largely controlled by the refractive index differences between large structures (e.g., cells) and the surrounding medium. For the most part, this type of scattering can be described using ray or geometrical optics. The Mie and Rayleigh scattering occurring within the skin tissues have been associated with the presence of small-scale light-scattering agents such as collagen fibers (Jacques 1996). In these types of scattering, the agents

have dimensions on the same order of magnitude of the wavelength of the impinging light, or smaller in the case of Rayleigh scattering (McCartney 1976). The mathematical description of these forms of scattering is usually more involving, and it takes into account wave optics phenomena to determine the attenuation of the propagated light. In the case of Rayleigh scattering, shorter wavelengths are preferably attenuated, i.e., the light attenuation is inversely proportional to the fourth power of the wavelength of light (McCartney 1976).

The dry mass of the most superficial part of the skin, the horny layer or stratum corneum, is dominated by the presence of keratin (Swanbeck 1959). Keratin is a protein produced by the keratinocyte cells located in the epidermis (van de Graaff 1995). This process, known as keratinization, starts in the lower epidermal layers. Upon its completion, the keratinocytes have migrated to the stratum corneum, where they become dead cells, termed corneocytes, filled with keratin fibrils. Since the keratin fibrils are birefringent, i.e., their refractive index depends on the polarization and direction of propagation of the impinging light (Feynman et al. 1964), the skin surface can also present some degree ($\sim 20\%$) of birefringence (Swanbeck 1959). In addition, the internal orientation of these fibrils within the corneocytes can asymmetrically affect the propagation of light by these cells (Swanbeck 1959).

The light reflected on the skin surface may be further spatially perturbed by the presence of microrelief structures and mesostructures (e.g., wrinkles) (Magenat-Thalmann et al. 2002; Sandoz et al. 2004; Sohaib et al. 2013). The rougher the skin surface, the closer the distribution of the reflected light resembles that of a perfect Lambertian reflector. In addition, the presence of these structures can result in some adjacent points on the skin surface being blocked from the impinging light (shadowing effect) and others being blocked from view (masking effect). It is also worth noting that the presence of lipids, including native oily sebum, may reduce the apparent roughness of the skin surface and increase its glossiness.

Fig. 1 Cumulative fractions of ultraviolet and visible light scattered by stratum corneum and epidermis samples of Caucasian subjects. **(a)** Stratum corneum. **(b)** Epidermis. Scattering data was measured by Bruls and van der Leun (1984) considering perpendicular irradiation and assuming azimuthal symmetry with respect to distribution of the scattered light

Below the stratum corneum, we find the epidermal tissues: stratum lucidum, a thin clear layer found only in the epidermis of the palms and soles (van de Graaff 1995), stratum granulosum, stratum spinosum, and stratum basale, the deepest epidermal layer. Scattering measurements by Bruls and van der Leun (1984) on Caucasian skin specimens resulted in a forward scattering behavior being observed for the stratum corneum and the epidermis of these specimens (Fig. 1). Although the portion of light going from one layer to another may be affected by the internal arrangement of the cells and their refractive index differences, one has also to take into account the scattering caused by other structures such as the

melanosomes. These membranous organelles are packed with melanin, the most important photoprotective pigment present in human skin (Kollias et al. 1991). Accordingly, it is directly associated with the level of pigmentation of an individual (e.g., lightly, moderately, and heavily pigmented). Typically, the volume fraction of the epidermis occupied by melanosomes varies from 1.3 % for lightly pigmented specimens to 43 % (for darkly pigmented specimens) (Jacques 1996), with the melanin content of the melanosomes varying from 17.9 % to 72.3 % (Kollias et al. 1991).

The melanosomes, like other relatively small biological structures (Latimer 1984), can cause small angular deviations in the direction of light

propagation, which are associated with wave optics phenomena. It has been observed (Chedekel 1995) that as their size decreases from approximately 300 nm to a degraded particle form, known as melanin dust (Kollias et al. 1991), they go from a predominantly forward scattering to a more symmetrical scattering behavior. It is worth mentioning that some amount of melanin dust may be also present in the stratum corneum (Kollias and Baqer 1986), notably following physiological changes in the skin pigmentation due to exposure to ultraviolet radiation (Kollias 1995).

The skin melanosomes are usually found in the long filaments of the melanocyte cells and within the keratinocyte cells (Toda et al. 1972). Although these organelles are predominantly located in the stratum basale (Olson et al. 1973), under different stimuli, notably exposure to ultraviolet radiation (UVR), they can migrate to the upper layers (Kochevar et al. 2008) as part of a process of induced pigmentation commonly known as tanning (Lin and Fisher 2007). Besides an increase in the biosynthesis of melanin (melanogenesis (Chedekel 1995)), the tanning process may also result in a temporary thickening of the skin tissues (Lopez et al. 2004).

Below the epidermis, one finds another skin layer with different histological characteristics, namely, the dermis. The boundary between these layers is characterized by the presence of interdigitations of the dermis, known as dermal papillae, into the epidermis. The roughness of this epidermis-dermis interface is typically greater than the skin-air roughness (Federici et al. 1999). Due to the high-roughness condition of this interface, it has a significant impact in the scattering profile of light traveling between these layers.

The dermis can be further subdivided into two structurally distinct layers: the papillary dermis and the reticular dermis. These layers are essentially composed of irregular connective tissue with nerves, lymphatic vessels, and blood vessels, the larger ones occurring in the reticular dermis. This connective tissue, in turn, is mostly formed by collagen fibrils organized into fibers. Collagen is a protein molecule that makes up about 70 % of the dry weight of the dermis, and it is also

birefringent (Anderson and Parrish 1982). Besides the collagen fibers, reticulum and elastin fibers can also be found in the dermis. Although these structures are believed to be responsible for Mie and Rayleigh scattering occurring within the dermis, the sources of these types of scattering, especially for Rayleigh scattering, have not yet been clearly identified.

Since the papillary dermis is characterized by the presence of small-scale collagen fibers and fibrils, while the thicker and more fibrous reticular dermis is characterized by the presence of large-scale collagen fibers, the working hypothesis is that Rayleigh scattering is more likely to be caused by the papillary structures (Jacques 1996). Despite open questions regarding the sources of these types of scattering in the dermal layers, their compound effect is the deeper penetration of longer wavelengths into the dermal layers (Anderson and Parrish 1981). Moreover, although scattering measurements by Jacques et al. (Jacques et al. 1987) on isolated dermis samples of Caucasian individuals revealed a forward-directed light traversing these samples (Fig. 2), it has also been observed that after a number of interactions, collimated light traveling within this tissue quickly becomes diffuse.

Eventually, the light traversing the dermis may reach the hypodermis. This adipose tissue consists mostly of fat cells that contain a number of smooth droplets of lipids whose size is large than that of typical tissue scatterers (Bashkatov et al. 2005). Nonetheless, light remission by large cellular structures in the hypodermis can further contribute for increasing the scattering of light within the dermis.

3 Absorption Agents

Once light is transmitted to the skin tissues, it is also attenuated by different absorbers present in these tissues. The amount of light absorbed in a given skin layer with respect to the spectral domains of interest, notably ultraviolet (100 to ~380 nm), visible (~380 to ~780 nm), and infrared (~780 to 3,000 nm) (CIE 2011; McCluney 1994), depends on the quantity, distribution, and

light extinction (absorption) spectra of the absorbers present in that layer. Although the occurrence of most absorbers found in human skin cannot be narrowed to a single layer, the absorption profile of each layer is usually associated with the presence of a specific set of absorbers. For example, in the stratum corneum, the absorption of light is mainly connected to the presence of keratin (Kölmel et al. 1990), uranic acid (Olivarius et al. 1997; Young 1997), and beta-carotene (Lee et al. 1975). Both keratin and uranic acid are characterized by a strong absorption behavior in the

ultraviolet domain (Fig. 3), while beta-carotene is characterized by a more pronounced absorption behavior in the visible domain (Fig. 4).

In the epidermal layers, the absorption of light is mainly associated with the presence of two classes of melanin: eumelanin and pheomelanin (Chedekel 1995; Thody et al. 1991). These pigments are the main absorbers acting in the ultraviolet and visible domains (Chedekel 1995) and have a strong impact on the color of the skin surface (Alaluf et al. 2002c; Thody et al. 1991). Both are characterized by a relative broad

Fig. 2 Distribution of light (632.8 nm) scattered by dermis samples of various thicknesses obtained from Caucasian subjects. Scattering data was measured by Jacques

et al. (1987) considering perpendicular irradiation and assuming azimuthal symmetry with respect to distribution of the scattered light

Fig. 3 Absorbers of light in human skin acting primarily in the ultraviolet domain. (a) Absorbance of keratin over a distance of 4 μm (Bendit 1966). (b) Absorbance of 50 μg/

mL of DNA and 15 μmol/L of urocanic acid over a distance of 1 cm (Clendening 2002; Oudhia 2012; Sutherland and Griffin 1981; Young 1997)

Fig. 4 Absorbers of light in human skin acting in the ultraviolet domain and visible domains. **(a)** Molar extinction coefficients of eumelanin and pheomelanin (Jacques 2001). **(b)** Molar extinction coefficients of functional hemoglobins (Prahl 1999). **(c)** Molar extinction

coefficients of beta-carotene and bilirubin (Prahl 2001). **(d)** Molar extinction coefficients of dysfunctional hemoglobins (Randeberg et al. 2004; Siggaard-Andersen et al. 1972; Yarynovska and Bilyi 2006)

absorption spectrum (Fig. 4), with higher values for shorter wavelengths. Although, as mentioned earlier, melanin may be also found in the stratum corneum in the form of granules (“dust”) under normal conditions (Kollias 1995; Kollias et al. 1991), the melanin absorption level is primarily associated with the amount of this pigment found in the epidermal layers (Jacques 1996).

The epidermal melanin pigmentation can be classified into two types: constitutive (determined by genetic factors) and facultative (induced to external stimuli, particularly UVR) (Anderson and Parrish 1982). The ratio between the volumetric concentration of pheomelanin and eumelanin present in human skin varies from an individual to another (Kollias and Baqer 1986; Parsad

et al. 2003). The volumetric concentrations of eumelanin and pheomelanin, in turn, depend on the concentrations of these pigments in the melanosomes, which vary for different skin phototypes (Alaluf et al. 2002b; Hennessy et al. 2005).

Besides the melanins, the absorption profile of the epidermal layers with respect to shorter wavelengths may be also affected by the presence of beta-carotene (Alaluf et al. 2002a), keratin formed during the keratinization process (van de Graaff 1995), and DNA found in the epidermal cells (Sutherland and Griffin 1981; Young 1997). However, while the contribution of beta-carotene to light absorption is more significant in the visible domain, the contributions of keratin and DNA are practically exclusive to the ultraviolet domain (Fig. 3).

The volume fraction of blood in human tissue can vary from $\sim 0.2\%$ to $\sim 7\%$ (Flewelling 1995; Jacques 1996). In blood-perfused tissues, such as the dermis and hypodermis, spectral responses in the ultraviolet and visible domains are associated with variations in the concentration of blood-borne pigments, notably hemoglobin. Most of the oxygen carried by blood is reversibly bound to hemoglobin molecules stored in the erythrocytes (red blood cells). The oxygenated and deoxygenated states of hemoglobin correspond to its two functional forms, namely, oxyhemoglobin (O_2Hb) and deoxyhemoglobin (HHb), which tend to have a more pronounced effect on the absorption profile of human skin within the visible domain (Fig. 4).

An increase in the volume fraction of blood in the dermal tissues accentuates the influence of blood-borne pigments on the spectral responses of human skin. Such spectral variations may result from erythema, a condition in which a dilation of the dermal blood vessels caused by external stimuli induces a “redness” appearance around the stimulus site (Baranoski and Krishnaswamy 2010). Although different types of stimuli (e.g., mechanical, chemical, electrical, thermal) can trigger erythema, it has been most extensively investigated as an acute response to UVR (Diffey 1980).

In addition to the functional forms of hemoglobin, dysfunctional forms of hemoglobin that do not bind oxygen reversibly can also be present in the erythrocytes, namely, carboxyhemoglobin (COHb), methemoglobin (MetHb), and sulfhemoglobin (SHb) (Baranoski et al. 2012). Similar to their functional counterparts, the dysfunctional hemoglobins can contribute to the absorption of light within the visible domain (Fig. 4), albeit at a lower level. Normally, only small traces ($<2\%$) of COHb and MetHb are found in human blood (Cunnington et al. 2004; Haymond et al. 2005; Yarynovska and Bilyi 2006), while SHb is absent (Gharahbaghian et al. 2009; Yarynovska and Bilyi 2006). However, certain pathological conditions are associated with the presence of excessive amounts of dysfunctional hemoglobins in the bloodstream. In these cases, one of the symptoms is a “bluish” skin color (cyanosis), which is more apparent in the body extremities of individuals with a relatively low level of melanin pigmentation (Gopalacharand et al. 2005; Haymond et al. 2005).

Besides the different forms of hemoglobin, other blood-borne pigments, such as bilirubin (Rolinsky et al. 2001; Saidi 1992) and carotenoids, such as beta-carotene, alpha-carotene, lutein, zeaxanthin, and lycopene (Alaluf et al. 2002a; Sthal and Sies 2004), can also contribute to light

Fig. 5 Absorbers of light in human skin acting primarily in the infrared domains. (a) Specific absorption coefficient of water (Palmer and Williams 1974; Pope and Fry 1997).

(b) Specific absorption coefficient of lipids (Altshuler et al. 2003; Prahl 2004; van Veen et al. 2004)

absorption in the dermal layers, especially in the visible domain (Fig. 4). Bilirubin is a pigment derived from the degradation of hemoglobin during the normal and abnormal destruction of red blood cells, and it is normally filtered out of the blood by the liver (Baranoski et al. 2012). If this organ is not working properly, an excessive quantity of this substance may be present in the bloodstream, resulting in a “yellowness” in the skin, a condition known as jaundice or hyperbilirubinemia (Rolinsky et al. 2001; Saidi 1992). Excessive amounts of carotenoids may also give the skin a “yellowness” appearance (Sthal and Sies 2004). Among the carotenoids found in human skin, beta-carotene and lycopene occur in larger quantities. They have similar absorption spectra, with a slight shift toward the red end of the light spectrum in the case of lycopene (Darvin et al. 2005).

In the infrared domain, the absorption of light in the skin layers is controlled by the presence of lipids (Williams et al. 1988) and water (Jacquez et al. 1955b). Both materials are characterized by broad absorption spectra in this domain (Fig. 3). Reflectance measurements by Jacquez et al. (1955a, b) illustrate the different skin spectral signatures that can be detected in the ultraviolet, visible, and infrared domains (Fig. 6). They depict some of the main spectral features of the skin surface. For example, one can observe that a low level of melanin pigmentation tends to make

the characteristic “omega” shape around 500 nm (caused by the presence of oxyhemoglobin) more prominent. In addition, one can observe spectral features in the infrared domain that are directly associated with the bands of absorption maxima of lipids and water in that domain.

4 Detour and Sieve Effects

Although the spectral responses of human skin can be analyzed with respect to the different contributions of its scattering and absorption agents, such responses are in fact the result of their combined actions. For example, the skin spectral responses in the visible domain are largely determined by how much light is absorbed by melanin and hemoglobin. In their native state, these pigments are usually found in organelles (melanosomes) and cells (erythrocytes), respectively, which also scatter light. In addition, when light traverses a turbid medium such as human skin, refractive index differences between these structures and the surrounding materials may cause multiple external and internal reflections that increase the light optical path length. This phenomenon, referred to as detour effect (Fukshansky 1981; Rabinowitch 1951), increases the probability of the traversing light to interact with the pigment of interest. Conversely, light traversing

Fig. 6 Reflectance spectra of lightly pigmented and darkly pigmented skin specimens measured by Jacquez et al. (1955a, b) considering an angle of incidence equal to 16.75°

a turbid medium may not encounter a pigment-containing structure, a phenomenon referred to as sieve effect (Fukshansky 1981; Rabinowitch 1951).

While the detour effect increases the probability of light absorption by the pigment of interest (notably in bands of absorption minima (Butler 1964)), the sieve effect reduces the probability of light absorption (notably in bands of absorption maxima (Latimer and Eubanks 1962)) in comparison with a homogenous solution with equal concentration of this pigment (Lovell et al. 1999; Pittman 1986). The net result of these two effects depends on several factors such as the distribution and volume fraction of the pigment-containing structures in the medium and the pigment concentration within these structures (Fukshansky 1981; Kramer et al. 1951; Pittman 1986; Rabinowitch 1951). For example, the sieve effect tends to dominate in whole blood samples with a low hematocrit (cellular volume fraction), while the detour effect tends to dominate in samples with a high hematocrit (Lovell et al. 1999; Pittman 1986; Yim et al. 2012). In the case of human skin, sieve and detour effects are more prominently associated with the presence of the melanosomes. For this reason, in the remainder of this section, we briefly review the main factors affecting their size, shape, and distribution within the cutaneous tissues.

Under normal physiological conditions, the size, shape, and distribution of the melanosomes depend on the biophysical characteristics of the skin specimen. While darkly pigmented individuals present larger, longer, wider, and denser melanosomes (Olson et al. 1973; Szabó et al. 1969) individually dispersed (Hawk and Parrish 1982; Szabó et al. 1969; Toda et al. 1972), lightly pigmented individuals present smaller melanosomes (Olson et al. 1973; Szabó et al. 1969) that appear in groups, or aggregates, surrounded by a membrane-bound vesicle (Hawk and Parrish 1982; Szabó et al. 1969; Toda et al. 1972). A mixture of single and aggregate complexes of melanosomes may also be found in moderately pigmented individuals (Hawk and Parrish 1982; Olson et al. 1973). Observations by Olson et al. (1973) indicate that the presence

of melanosome complexes is inversely proportional to the size of individual melanosomes.

Differences in the size and shape of skin melanosomes have been also associated with the class of melanin present in these organelles (Liu et al. 2005). Liu et al. (2005) have observed that eumelanin-containing melanosomes (eumelanosomes) found in black hair can usually have a shape of an oblate ellipsoid, while pheomelanin-containing melanosomes (pheomelanosomes) found in red hair can have a shape of an ellipsoid or closer to a perfect sphere, and they are generally smaller than those isolated from black hair. Experiments by Alaluf et al. (2001) involving heavily pigmented skin specimens have resulted in the same observation for skin pheomelanosomes, with their sphericity (given in terms of their long-to-short axis) ranging from 1.0 (perfectly spherical) to 6.0 (oblate, rod-shaped).

5 Fluorescence Agents

When electromagnetic radiation propagating at a certain wavelength is absorbed by a material, it may excite the orbital electrons of the atoms or molecules of this material to a higher quantum state. Upon return of these electrons to their ground state, they emit photons of light at another (usually longer) wavelength (Hunter and Harold 1987). This process, known as fluorescence, has a timescale of approximately 10^{-8} s or shorter (ANSI 1986). Endogenous materials that produce fluorescence upon excitation are called fluorophores. The key fluorescence properties of a fluorophore are its excitation and emission spectra, and the maxima of these spectra give the excitation-emission pair that characterizes that fluorophore (Kollias et al. 1998).

Within the human skin, we find mainly ultraviolet-induced fluorescence agents. These fluorophores include reduced nicotinamide adenine dinucleotide (NADH), keratin, collagen, elastin, aromatic amino acids (tryptophan and tyrosine), flavins, and porphyrins (Na et al. 2000, 2001; Sinichkin et al. 1998). The occurrence of fluorescence in human skin is associated with the main fluorophores present in its layers, namely, keratin (stratum corneum and epidermis), NADH

(epidermis), and collagen (dermis). Experiments by Ehlers et al. (2006) show that the fluorescence observed in the epidermal layers, notably in the stratum spinosum and stratum basale, has a slower decay characteristic than the keratinous stratum corneum and the collagen-rich dermis. Ehlers et al. (2006) have attributed this behavior to the presence of living cells in the former two skin layers.

Collagen is considered to be the main fluorophore contributing to the ultraviolet-induced autofluorescence of human skin (Sinichkin et al. 1998), with an excitation-emission maxima lower than excitation-emission maxima of keratin and NADH (Gilles et al. 2000; Na et al. 2000). Accordingly, the skin ultraviolet-induced autofluorescence is more pronounced within the dermal tissues (Anderson and Parrish 1982). It is worth noting that although melanin is a relatively low quantum yield fluorophore in the ultraviolet domain, experiments by Huang et al. (2006) indicate that natural melanins can exhibit significant fluorescence emission under near-infrared light excitation.

6 Challenges and Perspectives

Despite the importance of human skin and the advances in measurement technology, the current understanding of the optical properties of human skin is far from complete. Arguably the main obstacle is the lack of reliable and openly available measured data. For instance, the most useful measured dataset with respect to the scattering profile of the epidermis was obtained by Bruls and van der Leun (1984) in 1984 for specimens with similar biophysical characteristics (Caucasians) and considering a small set of illumination conditions. Since then, as examined by Baranoski et al. (2004, 2005), it has been often unduly generalized to represent the scattering of these tissues for skin specimens with different pigmentation levels and under a wide range of illumination conditions. Similar observations apply to the scattering of the dermis samples measured by Jacques et al. (1987).

Other significant examples of data barriers include the absorption spectra of the different absorbers present in the human skin. These datasets are obtained under *in vitro* conditions. Hence, they are bound to present significant qualitative and quantitative differences with respect to their *in vivo* counterparts. These differences are related not only to sieve and detour effects outlined earlier but also to experimental constraints such as the use of solvents during the preparation of dilute solutions of these absorbers for spectrophotometric measurements (Sardar et al. 2001). These procedures may alter the size and optical properties of the absorbing particles (Riesz et al. 2006). Currently, the chemical structure of key pigments, such as melanin, is still object of investigation, which makes the whole process of measuring their absorbing spectra even more difficult. In addition, the available measured absorption spectra for several absorbers found in the skin tissues are usually limited to specific spectral domains. Other examples of data scarcity include the refractive indices of different tissue constituents, which, when available, are usually provided as a single value measured at a specific wavelength.

Investigations of skin fluorescence are also impaired by data availability issues. For example, there are many fluorophores in human skin whose excitation-emission and quantum efficiency spectra are still object of investigation. This type of data is difficult to obtain since the fluorescence signal can be masked by the absorption of light by pigments such as melanin and hemoglobin (Na et al. 2001; Sinichkin et al. 1998). Moreover, fluorescence measurements may be further disturbed by environmental and physiological changes that may alter the molecular structure of the fluorophores and their spatial distribution (Na et al. 2000; Sinichkin et al. 1998).

In the last decades, a large body of work based on computer simulations have attempted to advance the current understanding of the optical properties of skin surfaces (Baranoski and Krishnaswamy 2010; Tuchin 2007). However, these simulations themselves are often limited by the scarcity of measured data to characterize the

scattering and absorption of different skin specimens. Furthermore, in order to be used in a predictive manner, these simulations need to be evaluated, which, in turn, requires comparisons of modeled data with measured data. Besides being also scarce, these datasets (e.g., reflectance and BRDF curves) rarely include characterization information (e.g., thickness, refractive indices) for the specimens employed in the measurements, which further impairs the proper evaluation of the simulations. It is important to note that the measurement of these specimens characterization parameters also involves sizable hurdles, not only under *in vivo* conditions (e.g., differences in water content from physiological levels to environmental levels (Chan et al. 2007)) but also under *in vitro* conditions (e.g., crystallization from freezing the tissue (Schaaf et al. 2010)).

Although one should not dismiss the contributions of computer simulations to the current understanding of skin optical properties, such computational efforts can lead to more substantial advances in skin tissue optics if paired with actual measured data. Hence, we believe that it is essential to strengthen the experimental basis in this area by enhancing quantitatively and qualitatively the measurement and dissemination of fundamental biophysical data associated with the optical properties of the skin tissues.

1 Introduction

The human skin is the largest organ of the human body. It protects the underlying tissues and plays an important role as a frontline defense system against invading pathogens and external environmental factors. It is colonized by a unique and complex microbial ecosystem, including bacteria, fungi, and bacteriophages, some of which could become pathogenic under certain conditions. The skin microbiome is very complex. Hundreds of different microbial species reside on the whole surface of the skin. Its composition and distribution are uniquely different from the flora of other organs. There are always differences among different people and different areas of the skin on the same person. Recent 16S rRNA-based methods revealed the similar situations.

Skin flora are usually nonpathogenic. They are not harmful to their host and offer benefits. The benefits bacteria can offer include preventing transient pathogenic microorganisms from colonizing the skin surface, either by competing for nutrients, secreting chemicals against them, or stimulating the skin's immune system. The microbial composition and distribution of the human skin microbiota have been associated with multiple

skin diseases, including atopic dermatitis (AD), acne vulgaris (AV), psoriasis vulgaris (PV), rosacea, dandruff, seborrheic dermatitis, etc.

2 The Skin Flora

The human skin flora, more properly referred to as the skin microbiome, are the microorganisms which reside on the whole human skin. Most of studies have been upon those that reside upon the 2 m² of human skin (cf. the human microbiome). Many of them are bacteria of which there are around 1,000 species from 19 phyla upon the human skin. The total number of bacteria on an average human has been estimated at one trillion. Most are found in the superficial layers of the epidermis and the upper parts of hair follicles.

Staphylococcus epidermidis and other coagulase-negative staphylococci were used to have been regarded as the primary bacterial colonizers of the human skin (Grice and Segre 2011). Other microorganisms that are generally regarded as skin colonizers include coryneforms of the phylum Actinobacteria, for example, the genera *Corynebacterium*, *Propionibacterium*, and *Brevibacterium* and the genus *Micrococcus*. Gram-negative bacteria, with the exception of some *Acinetobacter* spp., are generally not isolated from the skin, but are thought to arise in cultures owing to contamination from the other organs, such as the gastrointestinal tract (Roth and James 1988). Non-bacterial microorganisms have also been isolated from the skin. The most commonly isolated fungal species are *Malassezia* spp., which are especially prevalent in sebaceous areas. The *Demodex* mites, such as *Demodex folliculorum*, *Demodex brevis*, etc., are regarded as part of the normal skin flora. The living of *Demodex* mites depended on the amount of sebum. They are much more prevalent following puberty and reside at sebaceous areas of the face. *Demodex* mites may also feed on epithelial cells lining the pilosebaceous unit or even on other microorganisms (such as *Propionibacterium acnes*) that inhabit the same space. The role of commensal viruses has not been published, and investigations are limited by the available

molecular and microbiological means to identify and characterize viruses. Historically, culture-based approaches have been the standard for characterizing microbial diversity. It is now evident that only a minority of bacteria are able to thrive in isolation (Dunbar et al. 2002). Furthermore, hair follicles and sebaceous glands are the typical anoxic environments where some of anaerobic microorganisms reside.

2.1 Healthy Skin

The skin represents an interesting human habitat in which lifestyle and environmental factors shape the microbial community of different specific body sites. No taxa are ubiquitously present in every subject and body site, although targeted studies reveal that specific body sites are generally dominated by certain defining taxa.

The human skin is mainly comprised of Actinobacteria, Proteobacteria, and Firmicutes, some studies finding that more than 90 % of the microbiota of the forearm belonged to these phyla (Gao et al. 2007). The volar forearms of different subjects were found to only share 2 % of species-level operational taxonomic units (OTUs) (Gao et al. 2007), whereas the hands share 13 % of OTUs (Fierer et al. 2008). Estimates of species-level OTUs for skin sites include 246 for the volar forearm (Gao et al. 2007), more than 150 for the palms, and 113 for the inner elbow (Fierer et al. 2008). More than 50 % of sequences obtained from arm skin sites belong to *Propionibacterium*, *Corynebacterium*, *Staphylococcus*, *Streptococcus*, and *Lactobacillus* species (Grice et al. 2008).

2.2 Special Area Skin

The skin microbial community also plays an important role in the formation of body odor in, for instance, the vulva, axillae, etc. Few molecular-based researches were done on the axillary microbiome. Callewaert et al. (2013) detected the axillary microbiome of a group of 53 healthy subjects. A profound view was obtained of the

interpersonal, intrapersonal, and temporal diversity of the human axillary microbiota. Denaturing gradient gel electrophoresis and next generation sequencing on 16S rRNA gene region were combined and used as extent to each other. Two important clusters were characterized, where *Staphylococcus* and *Corynebacterium* species were the abundant species. Females predominantly clustered within the *Staphylococcus* cluster (87 %, $n = 17$), whereas males clustered more in the *Corynebacterium* cluster (39 %, $n = 36$). The axillary microbiota was unique to each individual. Left-right asymmetry occurred in about half of the human population.

The inter- and intraindividual differences in bacterial flora on the vulvar skin are known to exist. Aly et al. (1979) used a cultivation method to show that microbial counts are higher on the vulvar skin than on the forearm skin and that *S. aureus* normally inhabits the vulvar area. Brown et al. (2007) detected bacteria, such as *S. epidermidis*, *S. aureus*, *P. acnes*, *Lactobacillus* spp., *Prevotella* spp., etc., identified on the vulvar skin using the 16S rRNA gene-based clone library method. The number of total bacteria and the predominant species, such as *S. epidermidis* and *Lactobacillus* spp., were higher in the labia than those at other sites. There were only 60 % of subjects with *S. aureus* detected. *Prevotella* spp. were more predominant in the labial skin than in the vaginal skin (Mikamo et al. 1998). The species of the genus *Lactobacillus* are predominant in the labia minora of Japanese women, identified using the 16S rRNA gene-based clone library method (Shiraishi et al. 2011). *Prevotella* spp. were detected in the labia and groin of 95 % of Japanese subjects by another study (Miyamoto et al. 2013), so it is indicated that *Prevotella* spp. play a key role in vulvar skin conditions.

3 Skin Diseases

3.1 Atopic Dermatitis

Atopic dermatitis (AD) is a common, multifactorial, fluctuating, chronic inflammatory skin disease with a genetic predisposition. AD is often associated

with atopic conditions such as asthma and IgE-mediated food allergy, which can be triggered by different allergens and various environmental factors. The relevance of the colonization of the skin with bacteria, such as *S. aureus*, and fungi, such as *Malassezia furfur*, *Pityrosporum orbiculare*, and *Candida albicans*, to AD has been controversial over the past few decades. Children with AD often have infective exacerbations which are treated with antibiotics and/or antiseptics.

The most common infective cause is *S. aureus* with a trend toward antibiotic resistance. *S. aureus* is one of the important microorganisms of normal skin flora. Bacterial skin flora of patients with AD differ from that of healthy people.

AD skin provides a favorable environment for colonization and proliferation of *S. aureus*. Skin colonization with *S. aureus* is more in the lesional skin than in nonlesional skin and is minimal in the skin of healthy children. All of these published data have shown that there are significant differences between *S. aureus* in the lesional skin and nonlesional skin ($P < 0.01$) (see Table 1).

Haslund et al. (2009) confirmed the important role of colonization with *S. aureus* as an aggravating factor in AD, as there was a significant correlation between the severity of AD and *S. aureus* skin colonization. The results of their study were in agreement with other results (see Table 2).

Several studies demonstrated that the colonization of the skin with superantigen-producing *Staphylococcus aureus* is associated with increased severity of AD. It has been shown that AD may be aggravated by the direct biological

Table 1 The colonization of *S. aureus* in AD skin (%)

Reference	Lesional skin	Nonlesional skin
Miyamoto et al. (2013)	65.0	30.0
Gomes et al. (2011)	57.0	43.0

Guzik et al. (2005)	100.0	0

Table 2 The relationship between severity of AD and skin colonization (%)

Severity	Gomes et al. (2011)	Haslund et al. (2009)
Mild	46.0	48.0
Moderate	73.0	52.0
Severe	100.0	77.5

action of bacteria or their products or by an immunological reaction to bacterial antigens or superantigens.

The studies (Hill 2011; Gomes et al. 2011; Pezesk et al. 2007; Guzik et al. 2005) had shown association between lesional skin *S. aureus* colonization rates with increasing age. The colonization rate in this study was 41.4 % (12 out of 29) in the youngest group, 81.8 % (18 out of 22) in the second group (>2–12 years), and 100 % (9 out of 9) in the third group (>12 years).

Malassezia species are confirmed to be involved in the development of skin lesions in AD; sometimes the response of adult AD to anti-inflammatory treatments is poor. Takahata et al. (2007) collected scale samples from skin lesions of 58 patients with AD in the head and neck regions (28 males and 30 females; 31 children and 27 adults), and fungal DNA was extracted from the samples directly. The number and identities of the *Malassezia* species were analyzed with high accuracy using a polymerase chain reaction-based culture-independent method. The in vivo level of anti-*Malassezia* IgE antibody was also assayed. The results had shown that *Malassezia restricta* was the predominant species in the children with AD, while both *M. restricta* and *M. globosa* predominated in the adults. The increased sensitization in terms of anti-*Malassezia*-specific IgE responses in the sera to both *M. globosa* and *M. restricta* from adults was comparable to that from children. There are some differences of the cutaneous *Malassezia* flora between adults and children with AD.

AD skin lesions are characterized by a Th-2 cell-mediated response to environmental antigens (Baker 2006). The increasing prevalence and severity of atopic diseases including AD over the last three decades have been attributed to

decreased exposure to microorganisms during early life, which may result in an altered Th-1/Th-2 balance and/or reduced T cell regulation of the immune response. The patients with AD exhibit defects in innate and acquired immune responses resulting in a heightened susceptibility to bacterial, fungal, and other microorganism colonization, most notably colonization by *S. aureus*. Toxins produced by *S. aureus* exacerbate disease activity by both the induction of toxin-specific IgE and the activation of various cell types including Th-2 cells, eosinophils, and keratinocytes. Allergens expressed by the *Malassezia furfur* have also been implicated in disease pathogenesis in some of AD patients. Microorganisms play an influential role in AD pathogenesis, interacting with disease susceptibility genes to cause initiation and activation of disease activity.

The relevance of specific IgE antibodies for AD is still under discussion. Several experimental studies focus on a link between allergens and AD by IgE-independent mechanisms (Isolauri and Turjanmaa 1996). There is increasing evidence of a relationship between microorganisms and the deviation of immune responses. A high correlation between a positive patch test with milk and delayed-onset reactions due to milk provocation tests in children was found, while milk-specific IgE antibodies were relevant only for immediate-type reactions. Some clinical studies had shown that the IgE-mediated sensitization to *P. ovale* for the prediction of a therapeutic effect of ketoconazole in the treatment of AD using patch tests with *P. ovale* may be more useful. Positive patch test reactions to *P. orbiculare* have been demonstrated in atopic patients (Lindner et al. 2000). In the case of positive patch test results with food and mite allergens, patients may find relief by avoiding allergen exposure. The treatment of children with AD with specific probiotic bacteria strains reduces the eczema severity.

Allen et al. (2008) found that some clinical features are the special features of AD, such as miliaria of AD, which causes the itching, the most common symptom of this dermatitis, which occurred in areas of sweating, even in areas where patients did not realize they perspired. The epidemiological study results found that

sweating was a significant factor in exacerbating eczema. Miliaria arises from blockage of the eccrine sweat ducts. The material causes the blockage of duct. It is the film-like materials, which contain film-producing *S. epidermidis*, extracellular polysaccharide substance, and filaggrin-deficient stratum corneum. So the sweating and sweat retention are the important information of flare factors (Mowad et al. 1995). The subclinical miliaria provoked by film-producing *S. epidermidis* as part of a “double-hit” phenomenon (Serra et al. 1997) fits well in the pathogenesis of AD.

The microbiology of AD skin is dealt with the causes, mechanism, treatment, and prevention. This is the new insight to help us research and formulate the treatment strategy for AD.

3.2 Acne Vulgaris

Acne vulgaris (AV) is the most common, multifactorial, chronic inflammatory follicle disorder affecting much more individuals all over the world. It is a global disease that has no predilection for a specific race or gender. More than 60 % of the population suffers from AV at some point in their life. Four basic mechanisms contributing to acne are hormones, increased sebum production, changes inside hair follicles, and bacteria. The most commonly cited theory regarding the pathogenesis of acne states that increased sebum production leads to alterations in the lipid composition of hair follicles (Cunliffe 2002). Then *P. acnes* is a species of bacteria that implicated frequently and acts as the key player of the acnegenic microbes (Bruggemann et al. 2004). P acne is not only eliciting inflammatory lesion response but also the important pathogenesis of whole mechanism of disease. *P. acnes* can be recovered from skin surface as well as follicles on both normal and acne skin (Bruggemann et al. 2004). There is also no correlation between the number of *P. acnes* within a lesion and the clinical features of acne, both the types of lesion and severity of disease. But *P. acnes* is able to metabolize triglycerides into free fatty acids and glycerol, which is an immunological stimulant

and/or a cytotoxic agent that leads to breakage in the follicular epithelium (Higaki et al. 2000). Other proposed *P. acnes* virulence factors include enzymes that are involved in adherence and colonization of the follicle (Cunliffe 2002). Another bacterial species detected frequently from pilosebaceous units and acne lesions are *S. epidermidis* and *Propionibacterium* species (*P. granulosum*). They are often significantly less abundant than *P. acnes* in acne lesions, but its abundance appears to correlate with clinical severity of acne. In addition to bacterial species, another microbial group is the fungal genus *Malassezia*, which has been implicated in the pathogenesis of seborrheic dermatitis and dandruff (Ro and Dawson 2005); their link to acne remains far more speculative.

3.3 Psoriasis Vulgaris

Psoriasis vulgaris (PV) is a common, chronic, relapsing/remitting, immune-mediated skin disease characterized by red, scaly patches, papules, and plaques, which usually itch. The skin lesions seen in psoriasis may vary in severity from minor localized patches to complete body coverage. The prevalence of psoriasis is around 2–4 % of the general population. The clinical characteristics are red, scaly patches on the skin. The manifestation of psoriasis includes hyperkeratosis, hyperproliferation of keratinocytes, infiltration of the skin by immune cells, and angiogenesis. The most commonly affected skin areas are elbows and knees.

Several bacterial species, including *S. aureus* and *Streptococcus pyogenes*, have been suggested to play a role in the pathogenesis of psoriasis. Fungi, including *M. furfur* and *Candida albicans*, have also been linked with the development of psoriatic skin lesions and play a role in the pathogenesis of PV.

The overall bacterial diversity of the microbiota in the psoriatic lesions is greater than in normal skin samples. There are significant differences in the distribution of the three major bacterial phyla in the human skin biota: Actinobacteria, Firmicutes, and Proteobacteria. Firmicutes are overrepresented in the lesion

Table 3 Distribution of dominant bacterial phylum in patient with PV (%) (Gao et al. 2008)

Bacteria	Nonlesional skin	Psoriatic lesional skin
Actinobacteria	47.6	37.3
Firmicutes	39.0	46.2
<i>Propionibacterium</i>	21.9	11.4

whereas the other two are underrepresented. The distribution of dominant bacterial phylum in lesional skin and nonlesional skin of patient with PV (%) is shown in Table 3.

3.4 Others

The genus *Malassezia* (*Pityrosporum*), recognized as a member of microbiological flora of the human skin, has been recently revised to include *Malassezia* species. The pityriasis versicolor (PV) is one of the common skin diseases caused by the *Malassezia* infection. The results of Salah's (Salah et al. 2005) study had shown *Malassezia globosa* was the predominant species in lesional skin of PV (65 %). It was isolated alone in 47 % of cases and associated in 18 % with *M. furfur* (13 %) or *M. sympodialis* (5 %). In the healthy skin, *M. globosa* was found alone in 7.77 % and associated in 15.54 % with *M. furfur* (4.44 %), *M. sympodialis* (4.44 %), *M. restricta* (3.33 %), and *M. slooffiae* (1.11 %). *M. globosa* presents the main species implicated in the pathogenicity of PV and *M. furfur* as the second agent of importance.

The vulvar skin is the special area of female. The bacterial population of vulvar skin is characterized by a high density of microorganisms that are related to flora of the vagina and urethra, such as *Lactobacillus* spp., or are common on other areas of the skin, such as *Staphylococcus epidermidis* and *Staphylococcus aureus*. Miyamoto et al. (2013) studied the vulvar skin of healthy Japanese women and understood microbes of the stratum corneum. A total of 40 subjects were quantified. The detection ratio and number of skin bacteria at the three test sites, labia and groin, mons pubis, and inner thigh,

were taken. The labia and groin had significantly (>10-fold) more bacteria than the other sites. *Lactobacillus* spp. and *S. epidermidis* were the predominant species at all sites, followed by *S. aureus*. *Propionibacterium acnes* was present in almost all subjects but was less abundant than *S. aureus*, which was present in about 50 % of subjects. *Prevotella* spp. were detected in the labia and groin in almost all subjects but not in other sites.

Gardnerella vaginalis is one of the common skin diseases at the genital area. Myhre et al. (2002) took the samples from 278 (99 boys and 179 girls) out of 3,773 children, with a mean age of 5.63 years (range, 5.13–6.73), and found that at least one bacterial species was isolated from the genitals of 59 (33.9 %) girls. Most isolates (39 out of 99) were bacteria representing skin flora (staphylococci and coryneform organisms), with viridans streptococci and related organisms as the second most common group of isolates (31 out of 99). *S. anginosus* was the single most frequent bacterial species identified (17 isolates). *Streptococcus pyogenes* was isolated from the genitals of two girls, *Streptococcus pneumoniae* from one girl, and *Haemophilus influenzae* from eight girls. *G. vaginalis* was not isolated from the genitals in any girl, but the organism was isolated from the anal canal in three children. The results had shown that a large number of different aerobic organisms from children were identified from the genital area. *G. vaginalis* was rare and only isolated from the anal canal.

The skin flora is influenced by some system diseases (Arun and Palit 2003). Mean colony-forming units were 160.6, forearm, and 229.4, sternum ($P < 0.000$). In logistic regression analysis, patients in the medical intensive care unit were significantly more likely to have high counts on the arm (odds ratio, 2.48; 95 % confidence interval, 1.34–4.43; $P = 0.004$), and blacks were significantly more likely to have higher counts on the sternum when compared with other ethnic groups (odds ratio, 1.92; confidence interval, 1.18–3.11; $P = 0.009$). No differences were noted between inpatients or outpatients in prevalence of methicillin-sensitive *Staphylococcus aureus*, but inpatients were more likely to carry

methicillin-resistant *Staphylococcus aureus* (arm, $P = 0.007$; sternum, $P = 0.02$). Outpatients had a higher prevalence of micrococci and gram-negative bacteria at both skin sites (all $P < 0.01$) and yeast at the sternal site ($P = 0.007$). This comparison provides data to differentiate between effects of hospitalization and effects of chronic illness on skin flora.

4 Skin Flora Influence by Skin Surface pH

The acidic pH of the horny layer, measurable on the skin surface, has long been regarded as a result of exocrine secretion of the skin glands (Rippke et al. 2002). The “acid mantle” was thought to regulate the bacterial skin flora and to be sensitive primarily to skin-cleansing procedures. The pH of the deeper layers of the stratum corneum changes, as well as on the influence of physiological and pathological factors. The central role for the acidic milieu as a regulating factor in stratum corneum homeostasis is now emerging. This has relevance to the integrity of the barrier function, from normal maturation of the stratum corneum lipids to desquamation. Changes in the pH and the organic factors influencing it appear to play a role, not only in the pathogenesis, prevention, and treatment of irritant contact dermatitis but also of atopic dermatitis and ichthyosis and in wound healing. On the basis of these findings, a broader concept, exceeding the superficial “acid mantle” theory, has been formulated.

Microbiology of skin surface deals with skin health care and skin disease treatment and prevention. So healthy skin, abnormal skin and skin diseases, and the skin microbiome and its diversity all are being the hot topics of dermatology.

1 Introduction

The microorganisms, such as bacteria, fungi, etc., on the skin have been identified mostly by culture based on the sampling methods. The composition and distribution of the microorganisms on the skin were not extensively described until culture-independent molecular methods have been used now. The main techniques in sampling the skin microorganisms include impression methods, swabbing methods, and washing methods and punch biopsy. Both swabbing and taping are simple, quick, and noninvasive. Other two methods are scraping and punch biopsy which are applied under certain situation. Scraping usually comprises significant amount of skin cells. Punch biopsy is invasive, and it can cover all layers of the skin microbiota. There are two kinds of specific sampling techniques for follicle of the skin. Each category included several techniques. For example, the impression methods included contact plates, pads, sellotape stripping, etc. The washing methods included the detergent scrub technique and the sterile bag technique. About these three different sampling techniques, such as swabbing, scraping, and punch biopsy, the

results were shown that there was no difference of detection at all depths of the skin (Grice et al. 2008). There are special methods for follicular sampling methods. They are comedone extractor and cyanoacrylate glue.

2 Methods of Sampling

There are several sampling methods for microorganism of skin surface (Tiffany and Michael 2014). How to choose the method for applying it is depending on the numbers and types of bacteria (Grice et al. 2009).

For all surface sampling methods, adequate time must be needed after sample collection to allow the bacterial flora to reestablish before a further sample can be taken from the same site. Another way is sampling bacteria from adjacent sites or from identical sites on the right and left side.

2.1 Impression Methods

2.1.1 Contact Plates

The contact plates are specialized Petri dishes that are filled with different appropriate culture media until the agar surface is slightly concaved. The different bacteria should be under different culture conditions in suitable media. The common culture medium is fresh blood agar.

The contact plates are pressed firmly onto the skin to remove surface bacteria. One study was used to sample the medial surface of the forearm and midsternum because they are representative of the “dry” areas of the skin surface that are readily accessible and in contact with the environment (Larson et al. 2000). These are also frequent sites of intravenous (IV) catheterization (arm) or surgery (sternum). Generally the dominant arm was sampled, but in inpatients, attempts were made to avoid obtaining cultures near IV sites. When a mediastinal incision was present, the upper back was sampled rather than the sternum.

It is limited to one recovery medium. The facilitated colony counting is mainly a method to

assess the results of this test. It only gives the estimation of the number of the microcolonies. The number of colonies (colony-forming units, CFU) is counted with a grid printed or glued on its base. It is not a quantitative way because there is no dispersal step to break down aggregates of cells into smaller colony-forming units.

However, these have severe limitations and should only be used if a specific organism is being sought or if low numbers of bacteria ($\leq 10^6$ cm²) are expected and they can all be cultured on the same medium. The method is suitable for isolating *S. aureus* from suspected infected eczema.

It is easy and quick to use on intact and broken skin. The method of contact plates can be employed for routine patient sampling. But it is not quantitative. Since these colonies are not dissociated, the density of CFUs obtained does not correspond to the density of bacteria on the skin.

2.1.2 Pads

The velvet pads are used to remove bacteria from the skin surface. The main advantage of it is that the sufficient microorganisms are removed to serially inoculate a number of different culture media. The method is very inefficient too, and only a small proportion of microorganisms are successfully transferred from the pad to the medium. Since mechanical rinsing could improve bacterial recoveries, the pads are no longer used directly to inoculate culture media. The quantitative estimate of bacterial numbers could be obtained.

2.1.3 Tape Stripping

Tape stripping is a common method for skin microbiological study since it could sample not only skin surface but also aerobic bacteria residing in the upper part of the epidermis. Mostly all areas of the skin contain numerous pilosebaceous follicles. Some microorganisms are pulled out from the upper portion of each duct so that the numbers of bacteria may not decline in subsequent strips, as they do in areas with few pilosebaceous units. The tape strips are inverted onto the surface of the culture medium. If the tape is removed, not all microorganisms are transferred to the culture media successfully. The combination of tape

stripping and contact plates is often used for skin sampling. The tape is used to remove successive sheets of epidermal cells, and the contact plates are used to remove the exposed bacteria.

2.2 Swabbing Methods

The swabbing methods included dry swabs and moist swabs. The dry swabs are associated with poor recoveries of viable organisms. The moist swabs are among the most versatile of skin sampling techniques. Normally the swab, fixed to an applicator, is soaked in phosphate buffer saline containing 2 % Tween 80 and 0.3 % lecithin or Williamson-Kligman washing fluid. A template delimiting the sampling area is put on the skin. The swab is vigorously rubbed inside the template. Then the buffer is inoculated to appropriate culture media. The number of colonies in each culture can be counted. If CFU density is too high, it makes counting impossible, and serial dilutions are done before inoculation. The sensitivity limit is 4 CFUs per template. The accurate quantitative results cannot be obtained by the swabbing methods.

There is no doubt that moist swabbing is the method of choice for skin surface sampling. It remains the most commonly used method for routine sampling of patients with diseases, infections, or wounds of the skin. It can detect the unknown pathogen of the above skin disease. They are semiquantitative. But the method can be used when few microorganisms are present or when the swabbed area can be accurately defined and the bacteria of interest are known to reside superficially. In other words, it inoculates several culture media with a single swab and thus makes it possible to detect the entire range of skin flora present, and finally bacterial counting is possible since the original colonies have been dissociated by shaking in the buffer and flora collection has been improved by the friction. Usually skin swabs could be collected both from skin lesions and non-lesional areas from patients with skin diseases (e.g., AD) and also from healthy control skin (Petry et al. 2014). Two skin swabs were taken from each patient for culture and sensitivity, one

from the worst area of atopic dermatitis and the other from non-lesional skin. Also 15 skin swabs were taken from the skin of healthy children. Specific swabs for this method exist in various materials, such as polyvinyl alcohol foam, cotton, rayon, calcium alginate, etc. And they are commercially available. There are severe limitations, and for seeking the specific microorganism or the lower numbers of bacteria ($\leq 10 \text{ cm}^2$), they can be cultured on the same medium. They depend on the types of swab used, and the procedures are used to transfer microorganisms to the culture media. Several recovery media can be inoculated immediately, both in the clinic or laboratory. All types should be moistened by phosphate-buffered saline. The area of the sample site can be standardized by holding a template onto the skin surface. The swabs rub the studied area of skin surface firmly and repeatedly for several seconds to ensure adequate removal of microorganisms. For semi-quantitative work, the swabs transfer to 1 ml of half-strength wash fluid and decimally diluted in the same. A fixed volume (usually 100 ml) of each dilution and the undiluted sample is then plated onto one or more suitable recovery media and spread with a sterile glass spreader. The correct use of swabs is the best or only possible methods of skin sampling. They are used for routine clinical or research sampling from any sites, e.g., the back, chest, forehead, shoulders, etc. The inoculum is put on the suitable medium for culture.

For research the swabbing techniques can be standardized, whether in intertriginous areas or on damaged skin whichever is interesting. It can be an identification of components of the aerobic skin flora of premature neonates.

2.3 Washing Method

2.3.1 The Detergent Scrub Technique

The detergent scrub technique is the most widely used for research purposes since this method could be standardized, quantitative, reproducible, and efficient (i.e., removes over 95 % of the aerobic bacteria present at the sample site). Several modifications and adaptations have appeared in different studies. A metal ring is held firmly

against the skin surface and the procedures are standardized, including the wash fluid, the amount, the time of rubbing, the collection of wash fluid, etc. There are several features of the scrub wash technique that are worthy of further comment. The wash fluid contains a mild detergent in order to facilitate dispersal of clumps of bacteria. Various modifications for the survival of different skin bacteria in wash fluid with inconclusive results. It is best for individual investigators to estimate for themselves the survival time in wash fluid of those organisms of special interest to them. The sample site is chosen because the subungual space harbors large numbers of bacteria and is one of the most difficult sites to disinfect. Several recovery media can be employed.

The detergent scrub technique is more efficient in terms of number of microorganisms recovered or in reproducibility. For research purposes, and when quantitative data are required, the detergent scrub technique should be chosen. The major limitation of this technique is that it is fairly aggressive and cannot be used on sensitive or damaged skin, although several groups have used it to sample bacteria from eczema lesions. It is suitable for determining the proportion of the resident staphylococcal flora resistant to an antibiotic.

3 Follicular Sampling Methods

Until now, many researchers are still interested in the pathogenesis of pilosebaceous follicle for the living organisms. The methods that will be described below can be used to sample noninflamed lesions only and are not suitable for use with normal follicles or inflamed lesions.

3.1 Comedone Extractor

Open comedones are removed nontraumatically using a comedone extractor. It is the best method of sampling intrafollicular bacteria. Microcomedones are more common, but it is not easier than rapidly polymerizing cyanoacrylate glue. Both open comedones and microcomedones

can be obtained noninvasively. This method for damaged follicles is not similar as the method for normal follicles. The standard procedure is as follows. The first step is sterilizing the skin surface with an isopropanol swab. Then the entire comedone is removed by the extractor. It is transferred by a sterile needle into a preweighed microcentrifuge. The amount of wash fluid is pipetted into the tube and the bacteria are dispersed from the comedone with the micro tissue grinder. The fluid according to the different treating procedure is then plated onto one or more selective or nonselective media as required. Bacteria can be counted and expressed as CFU per milligram wet weight of comedonal material. The detection limit is 4 CFU/comedo. However, it should be ensured that the whole of the comedone is removed from the skin because the distribution of bacteria in follicular ducts varies with depth. The density and composition of the microflora at the face could be tested. It is simple and quick procedure. It can study microflora of a single pilosebaceous unit. It can inoculate several recovery media.

3.1.1 Cyanoacrylate Glue

Rapidly polymerizing cyanoacrylate glue is used to remove thin sheets of stratum corneum. It could be quickly realized that follicular plugs are extracted from pilosebaceous follicles as the glue being pulled away from the skin surface. This method is very easy. It is not used for normal follicles. One drop of the glue is spread over an area of the skin and left to polymerize for 1 min. The second step is pressed on this glass slide over for 1 min and then the slide is slowly removed from the skin. It is then applied on top of the area of the skin and spread uniformly by inverting a glass slide over it and pressing down firmly. After several minutes, the slide is removed from the surface of the skin with the adherent sheet of both adhesive and follicular casts, which represent the contents of microcomedones and consist of a mixture of corneocytes, sebum, and microbes. The more standardized procedure uses a sterile glass sampler of known surface area instead of a slide and a sterile Teflon ring to delineate the

target area, which is extracted twice with glue. It can inoculate several recovery media.

Normal pilosebaceous follicles cannot be studied by either of these two methods, but only microdissected follicles from biopsies. It can collect the entire comedo or cyst because the flora of the follicular duct varies according to depth. It can count or analyze several samples because the flora can be very different from one follicle to another.

One commercial kit, such as Exolift[®], included a patented dermal tape and cyanoacrylate glue. It is easier to use than glass slides or samplers, but is much more expensive. Whichever procedure is followed, only follicular bacteria will be enumerated since surface organisms are sequestered between the glue and the thin sheet of stratum corneum. The main problems with the use of cyanoacrylate glue are the high frequency of incomplete takes, when the glue fails to polymerize properly over part of the sample site, and the uncertainty of removing entire follicular casts. For obvious reasons, the method should not be used near the eyes.

3.1.2 Impact Factors

There are some important factors in determining the choice of sampling method, location of bacteria, type of the skin, type of bacteria, choice of sample site, efficacy of technique, reason for sampling, etc. The different growth media are suitable for recovery of resident skin bacteria and primary pathogens. For example, the *brain heart infusion* or *reinforced clostridial* agar containing 6 mg/l furazolidone is suitable for *Propionibacteria*; *heated blood* agar for *coagulase-negative staphylococci*; *mannitol salt* agar and *cysteine lactose electrolyte deficient (CLED) medium* for *S. aureus*; *fresh blood* agar containing 0.2 % w/v glucose, 0.3 % w/v yeast extract, 0.2 % v/v Tween 80, and 6 mg/l furazolidone for *aerobic coryneforms*; and *fresh blood* agar containing 0.0002 % crystal violet or 7.5 mg/l nalidixic acid and 17 units/ml *polymyxin B* for *group A beta-hemolytic streptococci*. Antibiotic sensitivity test can be done according to the Clinical and Laboratory Standards Institute (CLSI, 2011), using

vancomycin, erythromycin, gentamicin, penicillin, ampicillin, fusidic acid, and flucloxacillin antibiotics (r1).

3.1.3 Application of New Techniques

Recently the molecular characterizations of the human surface skin microorganisms based on 16S ribosomal RNA analysis have been carried out on a large scale (Gao et al. 2007). For the fungi, such as yeast, the specific techniques of culture are used and the 18S ribosomal DNA analysis has been done. Molecular analyzing was used for some studies, not only qualitative but also quantitative. The polymerase chain reaction-restriction fragment length polymorphism method (PCR-RFLP) of *Malassezia* species, a part of the skin microflora of neonates, was applied. The results supported that neonates acquire *Malassezia* flora through direct contact with their mothers or hospital personnel (Mourelatos et al. 2007a). For quantitative analysis of *Malassezia*, the real-time polymerase chain reaction (PCR) assay could be used also (Mourelatos et al. 2007b). The dominant operational taxonomic units (OTUs) conducted often are captured by all these methods although the rare OTUs are different. Commensal bacteria play a crucial role in the development of the immune system in humans (Zomorodain et al. 2008).

The objectives of the evaluation of skin surface flora are to study the pathogenic flora carriage in patients, the effects of antibiotics and antiseptics on skin flora, the efficiency of skin disinfection methods, and the physiology of resident skin flora under different environmental conditions. So understanding the methods of evaluation, knowing its impact factors, and applying new techniques are the goals of achieving the aims.

1 Core Messages

- Skin surface is characterized by acidic pH
- The acidic milieu is important for sustaining skin physiology namely epidermal barrier homeostasis, stratum corneum integrity and antimicrobial defence
- Among variety of methods for skin surface acidity investigation, the flat glass electrode remains the gold standard and most practical for in vivo measurement of cutaneous pH
- Subject-, instrument- and environment-related variables influence skin surface acidity measurements

2 Introduction

The skin separates the inner part of our body against the potentially harmful environment. The skin barrier protects the human body against many external stressors namely physical stress (mechanical, thermal, UV radiation e.g.), chemical stress (tensides, prolonged water exposure, solvents e.g.) and environmental conditions (Elias and Choi 2005). The concept of acid mantle of the skin was introduced more than 80 years ago by Schade and Marchionini (1928). Today there is a growing body of evidence that the acidic nature of the outermost skin layers is a key factor in regulating epidermal barrier homeostasis, stratum corneum (SC) integrity and cohesion, as well as antimicrobial defence (Schade and Marchionini 1928; Fluhr et al. 2010; Fluhr and Elias 2002).

The striving for quantification and qualification dates since the ancient societies. Nowadays a demand for standardizing and unifying evaluation procedures in biomedical research is widely accepted. Different non-invasive methods for the *in vivo* investigation of the skin surface acidity have been developed in the past decades (Darlenski et al. 2009). Here we summarize the different measurement techniques for skin pH and we discuss the potential factors that influence pH measurements.

3 Role of Skin Surface Acidity for Epidermal Functions

The acidic pH of SC is essential for the formation of intact skin barrier. Although basal permeability barrier function is competent at birth (Behne et al. 2002), skin surface pH is neutral at birth both in humans and in various animal models (Fluhr et al. 2004a; Hardman et al. 1998; Visscher et al. 2000). Following acute barrier disruption by either tape stripping or acetone treatment, barrier recovery was markedly delayed in the newborn rats (Fluhr et al. 2004a). Further animal studies excluded a variety of exogenous and endogenous mechanisms previously thought to be implicated in

post-natal SC acidification (Fluhr et al. 2004b). The results proved the central role for two endogenous mechanisms, the secretory phospholipase A2 pathway and sodium-proton exchanger, in the generation of the postnatal acid mantle. The functional consequences of neutral pH of SC included abnormal permeability homeostasis and defects in SC integrity, attributed respectively to the reduced beta glucocerebrosidase (β -Gluc Cer'ase) and increased serine proteases activity directly after birth (Fluhr et al. 2004a). Exogenous acidification of SC normalized barrier recovery kinetics and improved SC integrity (Fluhr et al. 2004a).

SC acidity is essential for the epidermal barrier recovery, the latter being delayed at a neutral pH, due to disturbance in processing secreted extracellular SC lipids, while lipid secretion remains unimpaired (Mauro et al. 1998). The impairment of the barrier homeostasis was attributed to the acidic pH optima of the key lipid-processing enzymes, i.e., β -Gluc-Cer'ase and acidic sphingomyelinase. Rising of the pH resulted in perturbations of lipid processing and in an impairment of the barrier homeostasis. Later it was shown that prolonged increase of pH leads to degradation of these enzymes by sustained serine proteases activity (Hachem et al. 2005). It was further demonstrated that prolonged increase of pH not only delays barrier recovery, but also increases basal transepidermal water loss (TEWL) (Hachem et al. 2005). It has been proposed that an acidic pH directly impacts lipid-lipid interactions in the SC extracellular lamellar bilayers (Bouwstra et al. 1999).

The acidity of the skin surface is also involved in the regulation of the corneocyte desquamation, respectively SC integrity and cohesion. The main enzymes, regulating the integrity/cohesion, kallikrein 5 (previously known as SC trypsin-like enzyme, SCTE) and kallikrein 7 (previously known as SC chymotrypsin-like enzyme, SCCE) exhibit normal-to-alkaline pH optima (Komatsu et al. 2005; Egelrud 2000). A superbase-induced elevation in SC pH resulted in reversible increase of the activity of these enzymes (Hachem et al. 2003). Moreover, these changes are followed by degradation of desmoglein 1 and reduction of the corneodesmosome-density, thus stimulating the process of desquamation (Hachem et al. 2003).

Acidification of skin surface results in improved lipid processing and inhibition of the degradation of corneodesmosomes (Hachem et al. 2010)

The acidic buffer system of the skin is essential for performing an unspecific antimicrobial protection as well as the regulation of the innate immunity (Drake et al. 2008). Elevation of the pH values is beneficial for growing pathogens on the skin surface, such as *Staphylococcus aureus* and *Candida albicans*, while normal flora predominantly grow best at acidic environment (Korting et al. 1990; Schmid-Wendtner and Korting 2006). The absence of an acidic SC at birth has been associated with an increased risk of bacterial and yeast infections in neonates (Leyden and Kligman 1978). The clinical importance of these findings is reflected in the pathophysiology of diaper dermatitis. The incomplete acidification of the SC, together with the ammonia-induced alkalization activates stool enzymes (trypsin, lipase), causing irritation and further perturbation of the skin barrier. Additional data on the role of skin surface acidity for antimicrobial protection can be found in the chapter on skin surface acidity of this book.

4 Measuring Methods

A variety of measuring methods for investigating skin surface acidity exist. The pioneering studies were performed by gas chain bell electrode (Schade and Marchionini 1928). Nowadays the most widely used devices are based on flat glass electrode (Fig. 1).

4.1 Flat Glass Electrode

Different companies have developed planar electrodes specialized for skin measurement. Any commercialized pH meter device fitted with a planar electrode can be used for the measurement of skin surface pH (Ehlers et al. 2001a). The contact site between the electrode and the skin covers an area of approximately 10 mm in diameter, and its use is considered as non-invasive. The flat glass

Fig. 1 Measurement of skin surface pH with flat glass electrode device Skin-pH-meter PH 905 (Courage and Khazaka electronic GmbH, Germany)

electrode measurements are widely used and considered as simple, non-cumbersome, and reproducible (Darlenki et al. 2009). The following practical consideration should be taken into account when performing the measurement:

- The electrode face (membrane) should not be brought into contact with hard objects. During short intervals between measurements, the electrode (or rather the electrode face) is best immersed in a KCl solution or in distilled water.
- Any kind of contamination of the electrode (e.g., by lipids or proteins) should be avoided or eliminated.
- Regular device calibration is advised.
- Before application to the skin, the electrode must be dipped into distilled water to moisten the surface. Then, the flat electrode top is placed on the skin with slight pressure during the measurement.
- Excessive pressure on the probe should be avoided.
- Ambient temperature and sweating may affect the pH measurements. It is desirable to perform

measurements under controlled conditions (e.g., 20–22 °C) and the relative humidity between 40 % and 60 %.

- Volunteers should be relaxed and acclimatized to the measuring environment for 15–20 min.
- No cosmetic residue or excessive sebum should be left on the surface of the skin. In both cases, gentle dry wiping is advised for the removal. Cleaning must be avoided as it will greatly affect pH measurements (even pure water).
- A minimum period of 3–6 h should be awaited between the personal hygiene procedures of the subject and the measurements.

4.2 pH-sensitive Dyes

Certain dyes have a color that changes according to pH, e.g., bromthymol blue and carboxy-SNARF-1 marking (Wagner et al. 2003). Limitation include that pH spectra of some dyes are not adjusted to the acidic nature of SC as well as potential *in vivo* toxicity. Values obtained by flat glass electrode assessment were concordant with the ones estimated by fluorescent dye marking (Wagner et al. 2003).

4.3 Experimental Methods

Two-photon fluorescence lifetime imaging (FLIM) assess SC acidity by using fluorophore 2',7'-bis-(2-carboxyethyl)-5-(and- 6)-carboxyfluorescein with a pH-dependent lifetime in the range of the expected values within SC (Hanson et al. 2002). It was shown that SC pH increases with depth. The authors hypothesized that the acid mantle results from the presence of aqueous acidic pockets within the lipid-rich extracellular matrix of SC (Hanson et al. 2002).

In vivo Raman confocal microscopy offers the possibility to measure quantitatively constituents within the depth of SC (Fluhr et al. 2010, 2012; Darlenski et al. 2009). Early studies showed that this method can detect urocanic

acid isomers within the epidermis (Caspers et al. 2001). As discussed in detail in former chapters of this book, the histidine-to-urocanic acid pathway is one of the endogenous mechanisms for skin surface acidification. Lactic acid can be monitored by Raman spectroscopy *in vivo* and certain differences between newborns and adults exist in the profile of lactate (Fluhr et al. 2012). A pseudo-pH measurement is possible with *in-vivo* Raman microspectroscopy.

5 Variables Influencing the Measurement

A wide number of variables influence the skin pH measurement and should be taken into account e.g., anatomical site, age, gender, race and circadian rhythms (Fluhr and Elias 2002; Darlenski et al. 2009; Darlenski and Fluhr 2012).

5.1 Age

Skin surface pH changes over age with the neonatal period being the most dynamic. We have shown that even in full-term neonates surface pH is around 6.5 and decreases within the first days after birth (Fluhr et al. 2012). This is in accordance with other publications (Schmid-Wendtner and Korting 2006; Ali and Yosipovitch 2013; Yosipovitch et al. 1998). A schematic overview on skin surface acidity differences within selected age groups (infants vs. adults) is presented in Fig. 2 (adapted from (Fluhr et al. 2012)). Acidification progresses throughout the first months, independently from the baby's birth weight. Being stable throughout the greater period of the lifespan, in elderly an increase in skin surface pH is observed. Subjects over 80 years of age have half a unit higher SC pH on both, the forehead and the cheek, than in younger adults (Zlotogorski 1987). A positive

Fig. 2 Skin surface acidity in different age groups

correlation between age and pH was reported by other groups (i.e., higher pH at older age) (Thune et al. 1988).

5.2 Gender

No gender differences were noticed at the forehead and the cheek in a controlled study (Zlotogorski 1987). Other groups found higher values on the volar forearm of females (Yosipovitch et al. 1993a, b; Ehlers et al. 2001b). It is tempting to hypothesize that pH is under sex hormone regulation.

5.3 Race

Data on racial variances in skin surface acidity is controversial. The majority of studies show lower pH values in darker skin subjects at least in the upper parts of the SC (Berardesca et al. 1998; Gunathilake et al. 2009). Lower pH was associated with enhanced epidermal barrier function and higher SC integrity, linked to increased lamellar body density and epidermal lipid content (Gunathilake et al. 2009).

5.4 Circadian Rhythm

Diurnal variation in skin surface pH has been documented. Yosipovitch et al. reported SC pH maxima between 2.00 and 4.00 p.m. (Yosipovitch et al. 1998). Lowest pH values were witnessed around 4.00 a.m. with a plateau during daytime (Le Fur et al. 2001). A control under glucocorticoid hormones can be assumed.

5.5 Anatomical Site

Higher pH values at the intertriginous areas (axillae and inguinal region) were noted in 1938 and named “physiological gaps” in the acid mantle (Marchionini and Hausknecht 1938). Since then a lot of studies were performed on the anatomical variations in skin surface acidity. We have recently published a full body mapping of skin surface pH (Fig. 3) (Kleesz et al. 2012). No difference between the left and right arm was detected (Ehlers et al. 2001a; Treffel et al. 1994).

The role of other external factors such as skin cleansing, application of cosmetics and

Fig. 3 Anatomical site variations in healthy adults. Abbreviations: *R* right, *L* left, *C4* region corresponding to the fourth cervical spine

concomitant skin disease has been discussed in detail in the chapter, devoted on skin surface acidification, of this book.

6 Conclusion

Measuring skin surface pH is possible in vivo by non-invasive and reproducible methods. Different variables influence pH values and should be taken into consideration prior to initiating skin physiology studies. Novel techniques such as Raman confocal microscopy should be challenged in a multicenter way in order to be introduced routinely in practice.

1 Sebaceous Glands and Sebocytes

The sebaceous gland is a holocrine system made of multiacini. Palms and soles are the only parts of the skin which do not have sebaceous glands. Sebaceous gland development is related to epidermis and hair follicles (Benfenati and Brillanti 1939; Montagna 1974; Thody and Shuster 1989; Deplewski and Rosenfield 2000).

2 Embryology

By week 13–15 of fetal development, it is possible to distinguish a gland arising from a hair follicle in a cephalocaudal direction. At 17 weeks, the gland has started making lipids and lipid droplets can be seen in the center of the gland (Fujita et al. 1972; Sato et al. 1977). The acini of the gland will attach to the common excretory duct; this duct begins as a cord composed of sebum-containing cells which will eventually rupture, forming the first pilosebaceous canal. The new acini will then

originate from the peripheral parts of the canal (Tosti 1974). Not all the acini in a unit are in the same stage of differentiation (Serri and Huber 1963).

3 Histology

In sebaceous glands, the most external layer is the basal layer and includes mitotically active small, flattened, or cuboidal cells comprising about 40 % of the gland. This layer is called the peripheral zone. The next layer is the maturation zone which also comprises about 40 % of the gland. Here, cells are larger and contain lipid droplets. Toward the center, there is the necrosis zone which comprises about 20 % of the gland. Its cells have stopped dividing and there is lipid accumulation; cells lose their subcellular structures, and when they reach to the duct, they are at their terminal differentiation so they rupture and release their content into the duct. The mechanism of lysis and rupture may include release of lysosomal enzymes. Desmosomes and tight junctions attach sebocytes to their surroundings. It takes about 21–25 days for sebocytes to renew (transit time) (Plewig and Christophers 1974). This transit time for the sebum which is in the canal is 14 h (Downing and Strauss 1982). The gland is surrounded by trabeculae of collagen-rich connective tissue. Those glands that are not associated with hair follicles are called free sebaceous glands. They include Meibomian (eyelids), Montgomery's (nipples), Tyson's (genitals), and ceruminous (ears) glands and Fordyce spots (oral epithelia) which secrete their contents directly to skin surface. Most of the sebaceous glands in humans are associated with hair follicles (Schneider and Paus 2010).

The most common ways of identifying sebocytes are using lipophilic dyes Oil Red O, Sudan IV, and Nile Red and also using immunostaining against lipid-associated proteins such as perilipin and adipophilin. They can also be detected using staining for fatty acid synthase, keratin 7, or other markers (Schneider and Paus 2010).

4 Physiology

A few hours after birth, sebum secretion increases and reaches a peak during the first week (Agache et al. 1980; Henderson et al. 2000). In humans, sebum is a major component of the vernix caseosa. In fetal and neonatal periods, sebum development is regulated by various factors including maternal androgens, steroid synthesis, growth factors, cell adhesion molecules, extracellular matrix proteins, intracellular signaling molecules, other hormones, cytokines, enzymes, and retinoids (Deplewski and Rosenfield 2000; Niemann et al. 2003). There is a correlation between maternal and neonatal sebum excretion rates which will be lost in the following weeks after the birth. The sebum level per unit of skin is in the same range as adults and the sequence of sebaceous transformation is identical to postnatal life. It seems that maternal hormones play an important role on glands. Androgens stimulate sebum secretion before birth (Agache et al. 1980; Henderson et al. 2000). After a slow reduction in the rate of sebum excretion, another increase happens with adrenarche (about the age of 9 years) and continues until the age of 17 years when it reaches adult range (Pochi et al. 1977). Contrary to the cycling growth of hair follicles, sebaceous gland growth is continuous. But in mice it has been shown that there are functional fluctuations such as changes in sebocyte apoptosis and also changes in the volume of sebaceous glands. These fluctuations are dependent upon hair cycle (Lindner et al. 1997).

The number of glands remains approximately constant throughout life, though their size increases as one ages (Fenske and Lober 1986; Zouboulis and Boschnakow 2001). The quality of glands is the same in normal adults and prepubertal and hypogonadal males, but the glands are bigger in normal adults (Serri and Huber 1963). It takes more than a week for sebocytes to synthesize and secrete sebum. As one gets older, sebaceous gland turnover will be slower (Plewig and Kligman 1978). Therefore, facial sebaceous glands undergo hyperplasia in older ages. There are some cofactors for sebaceous gland

hyperplasia such as immune suppression, ultraviolet radiation, and overexpression of aging-associated gene Smad7 and parathormone-related protein. On the other hand, c-Myc overexpression is associated with enhancement in sebum production. There are also differences between males and females in terms of their circulating levels of GH, IGF-1, 17 β -estradiol, progesterone, DHEA, and testosterone (Makrantonaki et al. 2006; Zouboulis and Makrantonaki 2006). In women, sebum level tends to decrease after menopause. In males, no significant change occurs until the eighth decade (Zouboulis and Boschnakow 2001).

Sebocytes are components of sebaceous glands which synthesize and store lipid (Hong et al. 2008). Two of the signals for sebocyte development are β -catenin and lymphoid enhancer factor-1 (Lef-1). Stem cell progeny chooses the lineage according to the level of β -catenin (Niemann et al. 2003; Takda et al. 2006). Low levels stimulate epidermis and sebaceous gland formation, while high levels make the stem cell go toward making hair follicles. There are intracellular signaling molecules which control lineage differentiation. Examples of these molecules are transcription factor 3 (Tcf3), Lef-1, Indian hedgehog (IHH), and sonic hedgehog (SHH). SHH is needed for terminal hair lineage differentiation (Fuchs et al. 2001; Merrill et al. 2001; Nicolaides 1974; Niemann et al. 2002). IHH along with other molecules is involved in the development of sebocytes (Allen et al. 2003).

Sebaceous glands have different functions; they produce sebum, regulate cutaneous steroid synthesis and local androgen synthesis, interact with neuropeptides, synthesize certain lipids having antimicrobial effects, and have anti-inflammatory and pro-inflammatory effects (Zouboulis et al. 2002, 2003; Zouboulis 2000, 2001; Fritsch et al. 2001; Thiboutot et al. 2003; Wille and Kidonius 2003a; Böhm et al. 2002). In humans, sebum contributes to maintain a functional epidermal barrier. Other exact roles of sebum in humans (such as protection against UV-B radiation and being a source of antioxidants especially vitamin E, anti- and pro-inflammatory substances, and antimicrobial peptides and

pheromones) remain to be completely understood (Proksch et al. 2008; Zouboulis et al. 2008; Smith and Thiboutot 2008). There is some evidence suggesting that dietary factors may alter the output of sebocytes. Increased amount of fat or carbohydrate in the diet may increase sebum production, while decreased caloric intake might have the reverse effect. Variations in carbohydrates might also affect sebum composition (Llewellyn 1967; MacDonald 1964, 1967; Downing et al. 1972; Pochi et al. 1970).

5 Sebocytes Versus Adipocytes

The similarities of these two cells are as follows: large amounts of lipid accumulation, similar types of receptors, and partially similar enzymes involved in lipid production (Smith and Thiboutot 2008). The differences are as follows: lipid production, composition, and secretion differ in them. Besides, their origins are different: hair follicle keratinocytes for sebocytes and mesenchymal cells for adipocytes (Schneider and Paus 2010; Schneider et al. 2009).

6 What Is Sebum?

In mammals, sebaceous glands produce a mixture of relatively nonpolar lipids. It acts as a heat insulation layer and also a hydrophobic protection against overwetting. In many mammals sebaceous glands produce and deliver pheromones. In furry mammals it is also used for thermoregulation. It has different ingredients and functions in different species (Montagna 1974; Nikkari 1974; Pochi 1982; Wheatley 1956; Thody and Shuster 1989). For instance, sebaceous gland secretions of hamster skin lack squalene and wax esters found in human skin sebum (Ito et al. 1998). Sebum density at 4 °C (gcm^{-3}) is 0.90 ± 0.01 and its freezing point is between 15 °C and 17 °C (Burton 1970). Melting point of free fatty acids and triglycerides is between 20 °C and 30 °C (Dünner 1946). Sebum surface tension (mN m^{-1} or dyne/cm) is 24.9 ± 2.6 between 26.5 and 31.0 °C. The sebum

viscosity 0 (*poise*) is 0.552 at 38 °C and 0.664 at 36 °C (Butcher and Coonin 1949) and about 0.5 at 30 °C (at about 30 °C some components become viscous and the sebum viscosity increases irregularly) (Burton 1970).

Human sebum is a mixture of sebaceous lipids and cell debris. It is made of wax esters (made from fatty acids and fatty alcohols), glycerides, squalene (an intermediate in cholesterol synthesis made through fusion of two molecules of farnesyl pyrophosphate by squalene synthase), cholesterol, cholesterol esters, and free fatty acids (Pappas et al. 2002). Their contribution to human sebum is as follows: triglycerides, diglycerides, and free fatty acids 57 %, wax esters 26–30 %, squalene 12–20 %, cholesterol esters 3–6 %, and cholesterol 1.5–2.5 %. This differs significantly from epidermal lipid components which are as follows: glycerides 30–35 %, free fatty acids 8–16 %, wax esters and squalene 0 %, cholesterol esters 15–20 %, and cholesterol 20–25 % (Schneider and Paus 2010; Smith and Thiboutot 2008; Picardo et al. 2009).

Squalene and some of the fatty acids are solely made by sebaceous glands (Pappas et al. 2002). In the human body, squalene and wax esters are only found in sebocytes (Schneider and Paus 2010). In vitro synthesis of squalene, wax esters, and cholesterol esters is less than their in vivo synthesis. However, this can be enhanced by using arachidonic acid (AA) and linoleic acid (LA) (Sanders et al. 1994; Zouboulis et al. 1998). Squalene may be a marker of sebocytes' terminal differentiation (Zouboulis et al. 1998). The squalene is a linear intermediate in the cholesterol synthesis pathway. It is not converted into lanosterol and this stops the completion of cholesterol synthesis and leads to accumulation of squalene; the reasons which might explain this are not crystal clear; however the possibilities may be overexpression or increased activity of the enzyme squalene synthase or decreased level or activity of other enzymes in the cholesterol synthesis pathway (Smith and Thiboutot 2008).

β -Oxidation of LA is a sebocyte-specific process and is related to the level of sebocyte differentiation (Pappas et al. 2002). Branched-chain

fatty acids and lipids which are desaturated in a particular way are unique characteristics of sebum. The enzyme which catalyzes the sebocyte-specific desaturation is called $\Delta 6$ desaturase (fatty acid desaturase-2). This enzyme is mainly found in sebocytes which are differentiated. These cells are found in the suprabasal layers of sebaceous glands. Therefore, this enzyme can be regarded as a functional marker for activity and differentiation of sebocytes (Ge et al. 2003).

Palmitoleic (sapienic) and sebaleic acids are predominant fatty acids and are unique in humans (Nicolaidis 1974; Pappas et al. 2002; Ge et al. 2003; Stewart et al. 1986a). $\Delta 6$ desaturase converts palmitic acid (16:0) to sapienic acid (16:1, $\Delta 6$). Sapienic acid represents about 25 % of total fatty acids. Sapienic acid can be further elongated by a 2-carbon unit and its further unsaturation produces sebaleic acid (18:0, $\Delta 5,8$). The ratio between $\Delta 6$ and $\Delta 9$ unsaturated fatty acids is suggested as an index for sebocyte maturation and their associated metabolic processes (Ge et al. 2003; Zheng et al. 1999). Palmitoleic acid has antibacterial activity against gram-positive bacteria like *P. acnes* (Wille and Kidonius 2003b). Animal studies have suggested a new role for the sebocytes associated with the ability to secrete antibacterial proteins and sterol regulation (Nagai et al. 2005).

Sebum is abundant on the head, face, neck, shoulders, back, and anterior thorax except breasts. Around female nipples there are large sebaceous glands. On external genitalia, the amount of sebum is less and other areas have very few sebum. Palms and soles do not have any sebum (Emanuel 1938). Sebum lipid composition changes with age or the activity of the glands (Nikkari 1974; Ramasastry et al. 1970; Stewart and Downing 1985; Jacobson et al. 1985). There are differences in proliferation of sebaceous glands in different locations regarding their response to androgens, and this is due to their different sensitivities to androgen effects (Akamatsu et al. 1992).

The amount of surface sebum is expressed as casual level (CL) which is the amount of sebum

per unit of skin surface area (Agache 2004; Kim et al. 2006). Skin is classified into three different skin types in terms of individuals' subjective feelings being oily, normal, and dry. However, it has been proposed that people usually regard their skins drier than what is objectively measured on their facial skin. Therefore, simple subjective classification of skin type is not a useful method of classification (Youn et al. 2002). The maximum amount of CL is on the forehead (having usual values between 100 and 200 $\mu\text{g}/\text{cm}^2$ in adults with normal sebum secretion) and on the scalp. Hyposeborrhea is defined as CL less than 50 $\mu\text{g}/\text{cm}^2$ and hyperseborrhea is CL of more than 500 $\mu\text{g}/\text{cm}^2$ which is due to both more sebum production and higher density of sebaceous glands (Greene et al. 1970; Pierard 1987).

CL shows daily fluctuations: at night, there is a 6–7 % reduction which returns to the previous level in the morning (Mavon 1997). There are also seasonal fluctuations with about 30 % higher CLs at the beginning of the summer compared to autumn (Constans et al. 1985). This is not due to the increase in the number of secreting sebaceous glands (Piérard-Franchimont et al. 1990). Temperature also affects CL: at an external temperature of 40 °C, the sebum is very fluid and the CL and re-fattening rates are high, while at 10 °C, the sebum is solid and the CL is very low (Dünner 1946). Most of the sebum will probably undergo cutaneous absorption, with part of its components (especially squalene) being used by keratinocytes (Blanc et al. 1989).

7 Immortalized Sebocyte Lineages

SZ95 sebocytes are human sebaceous gland cell lines used for research involving the sebaceous gland. They are immortalized cell lines of sebocytes which can be cloned and have major characteristics of normal human sebocytes and can subsequently undergo apoptosis (Wróbel et al. 2003; Zouboulis 1992; Zouboulis et al. 1991, 1999). CCAAT/enhancer-binding protein transcription factors, galectin-12, resistin, and

sterol regulatory element-binding protein 1 (SREBP1) are lipogenic factors which have been found in SZ95 sebocytes (Harrison et al. 2007). Another lineage of immortalized sebocytes is called SEB-1. They also have characteristic proteins of human sebaceous glands. Their cytoplasm can induce Oil Red O-positive lipid droplets (Thiboutot et al. 2003). E6E7 is another immortalized sebocyte lineage. Like the SZ95 lineage, E6E7 expresses k7 and involucrin and they respond to chemicals in a similar way (Lo Celso et al. 2008).

8 Sebocyte Receptors

Peptide hormones and neurotransmitter receptors are CRH receptors 1 and 2, melanocortin 1 (regulates inflammation) and 5 (marker of differentiation) receptors, μ -opiate receptors (bind β -endorphin and stimulate lipogenesis), VPAC receptors (bind vasoactive intestinal peptide), neuropeptide Y (NY) receptors (cytokine synthesis), calcitonin gene-related peptide (CGRP) (localized with substance P), cannabinoid receptors 1 and 2 (sebocyte differentiation), histamine-1 receptor (squalene synthesis regulation), insulin-like growth factor (ILGF)-1 receptor (lipid accumulation in sebocytes), and growth hormone (GH) receptors (increased differentiation and increased DHT effect on lipogenesis) (Zouboulis et al. 2002; Böhm et al. 2002, 2004; Deplewski and Rosenfield 1999; Dobrosi et al. 2008; Krause et al. 2007; Makrantonaki et al. 2004; Pelle et al. 2008; Seiffert et al. 2000; Ständer et al. 2005; Zhang et al. 2006).

Nuclear receptors (bind a hormone-specific hormone response element) include androgen receptors (increased proliferation) and other types of receptors. Androgen receptors have been found in sebaceous glands, eccrine glands, and hair follicle mesenchymal cells. In human skin, these receptors have been found with highest density on sebaceous glands. Both basal and differentiating sebocytes have androgen receptors and this shows that androgens play a role in sebocyte proliferation regulation and also in lipogenesis. Other nuclear receptors include

progesterone receptors (nuclei of basal sebocytes), estrogen receptors α (basal and early differentiated sebocytes) and β (basal and partially differentiated sebocytes) (increased polar lipids), retinoic acid receptors (RARs) α and γ (proliferation regulation), retinoid X receptor (possibly regulates lipogenesis), vitamin D receptor (proliferation regulation and cell cycle regulation, lipid content regulation, IL-6 and IL-8 secretion modulation), PPARs (increase lipogenesis and PGE2 release, increase cyclooxygenase-2 synthesis and IL-6 secretion), and liver X receptors (increase lipogenesis, decrease proliferation, decrease cyclooxygenase-2 and nitric oxide synthase) (Hong et al. 2008; Bläuer et al. 1991; Choudhry et al. 1992; Liang et al. 1993; Akamatsu et al. 1993; Alestas et al. 2006; Fimmel et al. 2007; Kim et al. 2001; Makrantonaki and Zouboulis 2007; Pelletier and Ren 2004; Reichrath et al. 1997, 2000; Russell et al. 2007; Schmuth et al. 2005; Schuler et al. 2005; Thornton et al. 2003, 2006; Tsukada et al. 2000; Zouboulis et al. 2007).

The vanilloid receptor is present in sebocytes which are differentiating and its ligand (capsaicin) decreases differentiation (Tóth et al. 2005).

9 Hormones and Sebaceous Glands

Sebocytes produce hormones including corticotropin-releasing hormone (CRH), androgens, estrogens, atRA, cortisol, vitamin D3, and eicosanoids (prostaglandins (PGs), prostacyclins, leukotrienes (LTs), and derivatives of AA) (Zouboulis 2000, 2005; Zouboulis et al. 2008). The skin has a corticotropin-releasing hormone (CRH)/proopiomelanocortin (POMC) system which can deal with signals with the potential to damage cells (Solminski et al. 2000). Nerves in the dermis and different cutaneous cells including sebocytes synthesize and release CRH in response to pro-inflammatory cytokines. CRH has receptors in sebocytes and when these receptors are activated, they lead to regulation of nonpolar lipids and expression of 3β -hydroxysteroid dehydrogenase- Δ (Deplewski and Rosenfield 2000)

isomerase (Zouboulis et al. 2002). CRH stimulates the secretion of α -melanocyte-stimulating hormone, and this in turn reduces interleukin (IL)-8 synthesis in sebocytes in vitro (Böhm et al. 2002). In sebocytes, CRH directly upregulates conversion of dehydroepiandrosterone (DHEA) into testosterone using the enzyme 3β - Δ (Deplewski and Rosenfield 2000)-hydroxysteroid dehydrogenase (3β -HSD). Also, synthesis of neutral lipids and IL-6 and IL-8 is stimulated with CRH (Fritsch et al. 2001; Zouboulis et al. 2002; Krause et al. 2007). Different hormones including testosterone, estrogen, growth hormone, and others regulate expression of the abovementioned receptors. Adrenocorticotrophic hormone induces cortisol secretion (Stewart et al. 1986b). All enzymes which are needed to transform cholesterol to steroids and adrenal precursors including dehydroepiandrosterone (DHEA) sulfate and DHEA are found in the skin (Zouboulis 2000; Thiboutot et al. 2003). Testosterone gets converted into 5α -dihydrotestosterone (DHT) using the enzyme 5α -reductase. The type I of this enzyme is the predominant type in sebaceous glands, sweat glands, and the epidermis. The highest activity is found on the sebaceous glands of the face and scalp (Luu-The et al. 1994; Thiboutot et al. 1995; Chen et al. 1998).

Animal studies have suggested that for terminal differentiation of sebocytes, DHT and peroxisome proliferator-activated receptor (PPAR) ligands should both be present (Rosenfield et al. 1998). PPARs in human sebocytes have a regulatory role on different lipid metabolic genes in sebocytes, mitochondria, peroxisomes, and microsomes (Fritsch et al. 2001; Zouboulis et al. 1998; Chen et al. 2003; Brun et al. 1996). Glucocorticoids can affect sebaceous glands. Patients suffering from adrenal insufficiency have reduced amounts of sebum secretion. Decreased levels of androgens might be an explanation for the mechanism of glucocorticoid action (Pochi et al. 1963; Goolamali et al. 1974). Estrogens show inhibitory effects on sebaceous activity, possibly through their inhibitory role on gonadotropin secretion or enhancement of binding between testosterone and its binding globulin

(Montagna 1974; Zouboulis and Boschnakow 2001; Zouboulis 2000; Strauss et al. 1962; Guy et al. 1996). Cortisol, estrogen, and atRA decrease differentiation while increasing proliferation and decreasing intracellular accumulation of neutral lipids (Wróbel et al. 2003; Harrison et al. 2007; Chen et al. 2006). Prolactin can affect sebaceous glands indirectly through its effect on increasing adrenal androgen production (Glickman et al. 1982). In the logarithmic phase of cell growth and differentiation, vitamin D3 is antiproliferative in SZ95 sebocytes. Also, in hamsters, it decreases lipogenesis (Sato et al. 2001; Schreiner et al. 2003). Lipogenesis can be regulated by all-trans retinoic acid and androgens in sebocytes of both hamsters and humans. Fibroblast growth factor (FGF), transforming growth factor (TGF)- α , and epidermal growth factor (EGF) have shown to be mitogenic in sebocytes of hamsters. TGF- α and FGF act as anti-lipogenic agents (Zouboulis et al. 1999; Sato et al. 2001; Akimoto et al. 2002). Inflammatory signals can be induced by eicosanoids in human sebocytes (Alestas et al. 2006). In patients with acne, nerves around sebaceous glands express substance P, though in acinar peripheral regions, undifferentiated sebocytes produce substance P inactivator neutral endopeptidase (Makrantonaki et al. 2004). Also in these patients, UV-induced fluorescence on the face has been reported to be correlated with casual sebum level. Distribution of fluorescence changes as age of onset differs and as the patient ages. The number and distribution of acne lesions are associated with amount and distribution of UV fluorescence (Choi et al. 2012).

Skin surface lipid • Sebum • Sebaceous gland • Assessment • Sebum excretion rate • Casual level

1 Utility

Many conditions can affect the function of sebaceous glands, so assessment of sebaceous function can be useful for evaluation of the pathogenesis of skin diseases, diagnosis of some diseases (such as hypoandrogenic syndromes), efficacy of skin and hair care products, and medical treatments.

2 What Can Be Assessed?

2.1 The Composition of Skin Surface Lipid (SSL)

The composition of the secreted sebum is an individual characteristic and depends on the person's age, his/her hormonal system, and function of body region (Wójcik et al. 2011). The SSL is composed of lipids originated from sebum and also lipids with epidermal origin (keratinocyte intercellular spaces). Lipids produced by the epidermal cells are an insignificant fraction of the total extractable surface lipid on areas rich in sebaceous glands. Lipids of epidermal origin fill the spaces between the cells, like mortar or cement. The sebaceous lipids are primarily nonpolar lipids as triglycerides, wax esters, and squalene, while epidermal lipids are a mixture of ceramides, free fatty acids, and cholesterol (Pappas 2009).

The sebaceous lipid mixture is highly complex and consists of triacylglycerols, diacylglycerols, and free fatty acids, which together account for 50–60 % of its composition. SSL also contains 20–30 % wax esters (WE), 10–16 % squalene, and 2–4 % cholesterol esters (Picardo et al. 2009). It is believed that free fatty acids which are present on the skin surface appear as a result of partial hydrolysis of triglyceride (Downing et al. 1969). Also the relative composition of sebum depends on the

sampling method used. In particular, if the major components of sebum, triglycerides, are sampled before or after their modification by bacteria (which hydrolyze them to free fatty acids and glycerol) (Pappas 2009).

2.2 The Quantity of Sebum Excretion

2.2.1 Sebum Casual Level

The natural skin lipids spread as a nonuniform thin layer on the skin surface. This spontaneous layer is known as the “casual level” of skin surface lipids, expressed in $\mu\text{g}/\text{cm}^2$ (Rode et al. 2000a). It ranges from 100 to 700 $\mu\text{g}/\text{cm}^2$ on the forehead of normal adults. It is a static parameter, expressing the amount of SSLs present on an untreated skin surface (Clarys and Barel 1995). Sebaceous glands are scattered all over the body except for palms, soles, and the dorsum of the feet (Smith and Thiboutot 2007). The greatest number of the glands and the amount of sebum is on the face (T-zone, especially the forehead), back, and chest, and it may range from 400 to 900 glands/ cm^2 (Thody and Shuster 1989). The number of active sebaceous glands and the amount of sebum per unit skin surface area (casual level) are different in different people, but the shape and distribution in a human body seem to remain constant during the life; however, their size changes – it grows with age (Pierard 1986; Zouboulis and Boschnakow 2001).

2.2.2 The Refatting Rate

Because of this thin layer of lipids, dirt and cell debris may stick to the skin. This contamination makes real-value sebum excretion measurements almost impossible. The dirt, cell debris, and droplets of excessive lipid can be removed from the skin surface with solvents. By removing the surface lipids, the skin is degreased or defatted, creating an opportunity for a real impression of the rate of sebum excretion. Refatting time is the time from defatting until casual level is reached. Washing gently with a detergent solution and then performing three wipes with alcohol is optimal

for degreasing the forehead, nose, and chin. For the cheek and upper back, it is sufficient to use a mild soap. Casual level is reached after 2 h in all seborrheic areas, irrespective of level of oiliness (Rode et al. 2000a).

2.2.3 The Secretion Rate

Measuring sebum secretion is the focus of constant attention of dermatologists, cosmetologists, and pharmacists as well as after cosmetic producers. We can do it with various methods which were already used in the past. Measurement of sebum excretion rate (SER) is tedious and time-consuming. It is now possible to measure SER 1 h after degreasing with a 70 % ethanol solution. The skin surface lipids (SSL) collected during this time have similar composition to those collected for up to 7 h. A qualitative and quantitative study of sebaceous excretion showed that the refatting kinetics obeyed the same mathematical law, independent of the subjects' individual SER (Saint-Leger and Cohen 1985).

2.2.4 The Sebum Replacement Time

The time required to recover CL after cleaning the sebum from the skin surface is called sebum replacement time. It is a time taking measurement and so difficult to manage which makes it less frequently used (Agache 2004).

2.2.5 The Density of Sebum-Rich Reservoirs

The number of spots over a plastic film is related to the density of sebum which exists in rich follicular reservoirs.

2.2.6 The Instant Sebum Delivery

This parameter presents the unpremeditated secretion of sebum from follicular reservoirs. It can be obtained using Sebuffix tape on the skin surface for a few seconds.

2.2.7 The Follicular Excretion Rate

This measurement has been presented to estimate the delivery rate of sebum from follicular reservoirs.

2.3 Glandular Parameters

Glandular parameters include density, distribution, and level of activity of active sebaceous glands (Agache 2004).

3 Methods for Collecting Sebum

Various methods have been developed for collecting the SSL on the human skin, and although these were used in the past, these are still practical and operative.

3.1 Solvents

The technique is based on the solubility of the SSLs in solvents. For the measurement of SSL of hairless skin, it can be collected by scrubbing the skin surface with a degreased cotton pad, a polyurethane sponge, or a swab and then extracted with a solvent.

The cup method should be used for assessment of the amount of SSL per unit surface area (CL). In this method a hollow cylinder made of metal, glass, or plastic is placed on the skin. Then an exact amount of a solvent is poured into a cylinder and is collected after 1 or 2 min. Finally, the solvent is evaporated and the lipids weighted. Also the amount of the sebum collected through this method can be evaluated by high-performance thin-layer chromatography or densitometry (Piérard et al. 2000).

For collecting SSL from hairy skin, the best method is to rinse the hair with a solvent (e.g., ether). For separating the hairs and squames, it is filtered by using Whatman paper and then evaporated.

Unfortunately, in this method there is no control of the amount of sebum collected from follicular reservoirs which may have an influence on the results. On the other hand, the application of these solvents can alter the physiology and structure of the stratum corneum (SC); hence, this method is no longer recommended for assessing the amount of SSLs (Piérard et al. 2000).

The solvents most commonly used in studies are shown in Table 1. It seems the most

Table 1 Solvents for collecting SSL and their features

Solvents	Features
Ether (diethyl ether)	The most convenient, widely used, moderately polar
Ether-ethanol mixture	Extracts nearly all known lipids
Ethanol (EtOH)	Well tolerated
Petroleum ether	Leaves the polar group of free fatty acids and water
Hexane	Leaves the polar group of free fatty acids and water
Acetone	Difficult solving of waxes
Carbon tetrachloride	–
Methanol-chloroform mixture	Too aggressive for in vivo studies, produces epidermal damage

convenient and the best option is ether (Agache 2004).

3.2 Absorbent Paper Pads

One of the most widely used methods for measurement of sebum secretion rate is the cigarette paper which was introduced by Strauss and Pochi and improved by Cunliffe and Shuster (1969). This method has been applied for measuring sebum secretion rate and sebum glandular parameters (Agache 2004). The absorbent capacity of papers differs, and it is necessary to check that the saturation point will not be reached and the paper absorbs the different components equally.

For this purpose, the paper can be checked by using artificial sebum (Agache 2004; Blanc and Agache 1980). Artificial sebum has been used for studies on properties of the skin and hair. One study showed that a mixture of 17 % fatty acid, 44.7 % triglyceride, 25 % wax monoester (jojoba oil), and 12.4 % squalene is very similar to human sebum. It is stable on exposure to the atmosphere at 32 °C for at least 48 h, and it is also stable on storage at 4 or –20 °C, either dry or in chloroform/methanol solution for at least 6 months. This synthetic sebum could be useful in studies on cosmetic properties of the skin surface or hair, on penetration of chemicals into the skin, or in development of standardized tests of laundry detergent performance (Wertz 2009).

The skin is first cleansed to remove surface lipids. A previously extracted cigarette paper is then placed against the skin and held in place with an ace bandage. After a 3-h collection period, the cigarette paper is removed. Lipids

are extracted from the paper using ethyl ether and quantified either by weighing or by quantitative thin-layer chromatographic analysis (Sisalli et al. 2006; Downing et al. 1982). When samples are extracted for quantitative analysis, an internal standard (e.g., methyl nervonate) can be added to the extraction solvent (Clarys and Barel 1995).

A combined method for cigarette absorbent paper is interposing the paper between the skin and a UV-light video camera (Visioscan VC 98, C + K Electronic, Cologne, Germany). After defined collecting time (45 s or more), pictures of the lipid droplets are analyzed by computerized image analysis.

3.3 Bentonite Gel

Bentonite has been used to adsorb sebum. Bentonite gel is a water suspension of 15.5 % bentonite clay and 0.2 % carboxymethyl cellulose (Collison et al. 1987; Jacobsen et al. 1985a). After washing the skin with soap and water and swabbing with an ethanol-soaked gauze pad, a thin layer of bentonite gel is applied to the skin. In initial studies, two 1.8-mm diameter circular disks of Dacron mesh were pressed into the bentonite, and these were covered with additional bentonite. At 3-h interval thereafter, the Dacron disks and adhering bentonite were replaced and sampling continued for 24 h. The amount of sebum adsorbed per disk over 3 h decreases steadily for about the first 12 h, after which the rate of sebum secretion becomes constant. The excess sebum secreted during the initial 12 h of

collection is interpreted as a reflection of a follicular reservoir. Only after this reservoir is depleted is the sustainable sebum secretion rate measurable (Harris et al. 1983).

This sustainable secretion rate is equal to the rate of synthesis in the glands. In later studies, bentonite was applied to the skin, and a rectangular piece of Dacron mesh large enough to cover most of the skin was pressed into the gel and covered with additional bentonite. After 7 h, the Dacron mesh on the forehead was replaced, and after another 7 h (to deplete the reservoir), the rectangular Dacron was replaced with two circular disks of Dacron for a final 3-h collection period, reflecting the sustainable rate of sebum secretion. The lipids were extracted from the bentonite into ethyl ether and analyzed by quantitative thin-layer chromatography. In a variant on this method, the final collection period after depletion of the follicular reservoir was extended to 9 h, and the extracted sebum was quantified gravimetrically (Harris et al. 1983).

The bentonite clay method seems to be sensitive to collect sebum in very low sebum conditions, but its major drawback is the fact that it takes at least 12 h for collecting the SSLs, making it the most cumbersome and time-consuming method (Stewart and Downing 1985).

3.4 Frosted Glass

Schaefer and Kuhn-Bussius demonstrated that sebum secretion could be measured by collecting it on a slide of frosted glass which was applied for 30 s on the skin and measuring the transparency. As sebum is adsorbed on the rough surface, it spreads and fills the microscopic pockets. This smooths the surface and will result in less light scattering when the plate is illuminated with a beam of light. The relationship between the amount of adsorbed lipid and light transmission was quantified and shown to be nonlinear. Subsequently, several instruments based on this principle have become commercially available. The first of this is the Lipometer introduced by L'Oreal (Aulnay-sous-Bois, France). More recently, the Sebumeter has been

made by Courage + Khazaka Electronic (Köln, Germany). These instruments allow measurement of the amount of sebum on the skin surface or the sebum secretion rate, which can be made easily within a few minutes. The important advantage of this method is that it bears no risk of uneven retrieval of the components. However, calibration can be difficult, and unless the sebaceous reservoir has been depleted, this will be the least accurate means for measuring sebum secretion rates (Saint-Leger et al. 1979). This method has been suggested for use in specific temperature and humidity. Also the surface of the glass must be cleaned and degreased before using. The skin surface temperature must be at least 30 °C because in lower temperatures some sebum components become semisolid and induce a change in optical density (Wójcik et al. 2011; Saint-Leger et al. 1979). This method is time-saving and highly reproducible and needs no trained scientific staff compared with previous techniques.

3.5 Plastic Film

3.5.1 Sebutape

The Sebutape[©] (CuDerm Corp., Dallas, Texas) consists of a hydrophobic polymeric white film (Kligman et al. 1986) and is used to measure the sebum secretion (Dobrev 2007; Clarys and Barel 1996) and evaluate the distribution of skin pores (Pierard 1986; Nordstrom et al. 1986). There are innumerable, tiny air cavities, and the surface is coated with a lipid-porous adhesive which enables the tape to be sealed to the skin during the period of collection. The film absorbs the sebum originating from the follicular openings. As sebum reaches the skin surface, it is rapidly absorbed into the film. As the air within the microcavities is displaced by sebum, the lipid-filled cavities become transparent to light. The output from each follicle forms a sharply defined spot; the size corresponds to the volume of the droplet. Sebum absorption by Sebutape is slow and perhaps incomplete because of the barrier of the glue (Saint-Leger and Cohen 1985).

First, the skin surface is ordinarily prepared by soap and water washing to remove debris and lipids. For greater accuracy, complete defatting can be obtained by wiping with a gauze pad soaked in hexane. The film is placed on the forehead for 1–3 h and then a computer image analysis is conducted. In the places where the sebaceous secretion has been absorbed, the film becomes transparent. Thanks to the placing of the film on the dark background, we can receive the pore patterns. These patterns can be assigned to one of five categories, referring to images provided by the manufacturer: prepubertal, pubertal, acne, mature, or senescent (Clarys and Barel 1995). Lipids which are examined with this method can be also extracted and then analyzed with thin-layer chromatography (Sisalli et al. 2006; Nordstrom et al. 1986).

The self-adhesive application of the Sebutape omits the difficult procedures encountered in the cigarette paper method and the former extraction methods. Moreover, the area under investigation is covered during the procedure, resulting in a more standardized collection. Compared with the cigarette paper technique, the Sebutape requires a shorter collection time, as most of the parameters can be determined after 1 h of collection and also, most of the evaluation methods described can be carried out on the same Sebutape: kinetic color measurement during the collection period, image analysis after the collection period, and quantitative and qualitative analysis after extraction of the lipids from the tape.

3.5.2 Sebufix F16

The Sebufix instrument is also commonly used. Here, like in the Sebutape, we use a polymer film to measure the activity of the sebaceous glands. The film is image analyzed with a UV-light video camera (Visioscan[®] VC 98, C + K Electronic, Cologne) device (Dobrev 2007). The Sebufix is thus very similar to the Sebutape; the only difference is the fact that in the case of the Sebutape, the film is placed on the selected area for 1–3 h and in the other for 30 s (Clarys and Barel 1996). Therefore, the Sebufix allows for measuring sebum secretion within a shorter period of time.

The method is not really quantitative because the relation between the surface of a spot and the quantity of sebum it contains is not known and several spots can rapidly coalesce. Accordingly, it cannot measure the CL, but it may provide an estimate of the refatting rate. It can display the distribution of the active sebaceous gland and the individual refatting rate of each gland (Saint-Leger and Cohen 1985).

3.5.3 Sebumeter SM 810

This device facilitates objective measurement of sebum from the skin surface areas and can be used to determine the level of sebum on the skin surface or the rate of its secretion (Knaggs et al. 1999; Tagami 2003; Schaefer and Kuhn-Bussius 1970; Bergler-Czop and Brzezińska-Weisło 2010; Biro et al. 2003). It cannot, however, determine the state of the sebaceous glands (Son et al. 2008). In order to gather sebum secretion, the film is pressed to the skin or hairy skin or other areas of the body for 30 s. Then the film with the sebum gathered is subjected to a photometric analysis and gives the sebum index. The Sebumeter is a simple device, easy to operate, which can be used to make an objective classification of dry, normal, or oily skin (Nouveau-Richard et al. 2007; Youn et al. 2005; Kim et al. 2006) as well as to evaluate “the biological age” of the skin (Jacobsen et al. 1985b; Marrakchi and Maibach 2007; Firooz et al. 2012).

Nevertheless, one study has shown that a statistically significant difference was present between the oily and dry skin types. However, there were no statistical differences between oily and normal, and normal and dry skin types. So subjective skin type does not match the amount of sebum secreted. Thus, this simple and subjective classification is of very limited use and it should be reevaluated by using an objective and standardized measuring tool (Yong et al. 2002).

Compared with Lipometer[®] (L’Oreal, Aulnay-sous-Bois, France), the Sebumeter is more user-friendly and there is no need to clean the probe at each assessment. Thanks to its integrity, reproducibility, commercial availability, easy handling and operating, short measuring time, and numerical

values, the Sebumeter is now used in most of the sebum evaluation studies (Ambroisine et al. 2007; Lee et al. 2006; Cheng et al. 2007, 2009; Stinco et al. 2007; Akhtar et al. 2010).

3.5.4 Sebumeter SM 815(Cassette)

The measurement is based on grease-spot photometry. The Sebumeter cassette contains a mat synthetic tape, 0.1 mm thick. A special tape becomes transparent in contact with the sebum on the skin surface. For sebum determination, the measuring head of the cassette is inserted into the aperture of the device, where the transparency is measured by a light source sending light through the tape which is reflected by a little mirror behind the tape. A photocell measures the transparency. The light transmission represents the sebum content on the surface of the measuring area and is displayed in units from 0 to 350. The measuring time of 30 s is controlled by a clock set in the device. The measuring head of the cassette exposes a 64 mm² measuring section of the tape. For a measurement, the tape is moved forward by a trigger at the side of the cassette to expose a new section of tape. The used tape is rewound inside the cassette. The accuracy of this tool is about $\pm 5\%$. It would be the best choice for assessment of SSLs on hairy skin and scalp skin.

3.5.5 Applications of Sebumeter

1. To objectively classify skin type as dry, normal, or oily (Firooz et al. 2007; Davari et al. 2008; Seirafi et al. 2009; Davoudi et al. 2010)
2. To study the effectiveness of hair and skin cosmetic products
3. To study sebaceous gland activity in different diseases
4. To assess the effectiveness of different kinds of treatment on skin diseases

3.6 Skin Surface Cast

This absorbing material is a mixture of plaster of Paris and water which gives a smooth paste. After degreasing of the skin surface by a solvent, it is

spread over the skin and after 20 min will become solid. It is easily evaluated using a staining product. Osmic acid is a good material which has been used for this purpose (Sarkany and Gaylarde 1968).

4 Global Assessment of the SSL Casual Level

The casual level is a static parameter, expressing the amount of thin layer of SSLs when the skin surface remains untouched for several hours. The basis of global assessment of the SSL casual level is to sample the SSL on the skin surface in its spontaneous phase, at least 5 h after defatting and at least 24 h after application of a cosmetic product (Kligman 1963). If

Two methods have been defined for measurement of casual level.

4.1 Gravimetric Method

In case of sampling the sebum with solvent, the latter is evaporated under a nitrogen flow and the remaining sebum will be weighed. To ensure reliable outcomes, strict situation and precision are needed:

1. Sensitivity of scale: up to 0.01 mg
2. Clean field: protected from drafts
3. Field: placed on a special table or concrete base or a stone
4. Reduction of static electricity: by using aluminum containers
5. Stability: thermal stability and reduced relative humidity in the room and inside of the scale (where it is controlled by silica gel)

If the skin surface sebum is collected with filter paper, the initial and original method, which includes immersing the paper in a solvent for several hours, is used to extract lipids. Then the solvent is evaporated and the remaining lipid weighed. All the precision steps must be followed as above and also any contact with fingers must be avoided (Saint-Leger and Cohen 1985).

4.2 Photometric Method

All materials used for sampling the SSL (glass slide, Sebutape, Sebufix F16, Sebumeter tape) have a different sampling modulus, so they can collect only a part of the SSL. Their modulus depends on three main factors:

1. Capacity of the material for absorbing
2. The available area on the sensor
3. Skin surface lipid viscosity

Two factors influencing on the absorbing capacity of the material and the available area on the sensor include roughness and cleanliness of the slide. The main factor which influences on the SSL viscosity is temperature. It seems that repeated sampling on the same area avoids the feature bias in measurements.

5 Refatting Rate

5.1 Free Refatting Rate

The level of skin surface sebum 1 h after degreasing is called free refatting rate or sebum replacement rate. When the skin surface lipids are removed, the time which is needed to recover the entirety of sebum is about 3–4 h, although the half of it reforms in 30 min. But for this purpose, the initial rate which can be assessed during the first hour is applied as the free refatting rate (Agache 2004; Pie'rard-Franchimont et al. 2010).

5.2 Sebum Excretion Rate (SER)

Sebum excretion rate (SER) is a dynamic parameter expressing the speed of production of sebum in $\mu\text{g}/\text{cm}^2/\text{min}$. This rate is an indicator and quantifier of the activity of the sebaceous glands (Rode et al. 2000b). The duration of the definitive collection period is important because SER in the first hour after degreasing the skin is equal to the free refatting rate, and then it progressively decreases over the first hours to become stable after 9 h. SER of the first hour sampling usually ranges from 0.5 to 2.5 $\mu\text{g}/\text{cm}^2/\text{min}$ on the forehead (Pie'rard-Franchimont et al. 2010). The measurement of SER can be done with filter paper, clay gel, Sebutape, and Sebumeter.

6 Density and Activity of Sebaceous Glands

6.1 Osmic Acid (OsO_4) Staining

The main factor of this method is that when OsO_4 is encountered with unsaturated fatty acids, it is reduced to osmium which shows a black color on the field. In these kinds of studies, first sebum is sampled by using an absorbent paper and then it is placed in a flask containing wool and a few drops of OsO_4 . The follicular ostia, where the sebum is stored, are presented as black spots. The evaluation is achieved using densitometry or computerized image analysis (Lademann et al. 2001).

Table 2 The different parameters of sebaceous glands activity and the available methods for their assessment

Sebaceous gland parameter	Methods of assessment						
	Solvents	Absorbent pads	Bentonite clay	Sebutape	Sebumeter	Lipometer	Sebufix
Casual level	✓				✓	✓	
Sebum excretion rate	✓	✓			✓	✓	
Refatting rate							
Instant sebum delivery				✓			✓
Follicular excretion rate				✓			✓
Glandular parameter				✓			✓

6.2 Sebufix F16 and Sebutate

In this method, the sebum-loaded film is examined through the light. The available evaluation techniques for this purpose include densitometry, computerized image analysis, photometry, and colorimetry. Densitometry is the simple way to achieve the global quantification of transplant spots and is expressed in arbitrary units. All parameters related to glandular production such as the measurement of cumulated stained areas, the number of spots per cm², the average of the spots, and the distribution of the sebum spots versus their size are provided by computerized image analysis (Serup 1991).

The different parameters of sebaceous gland activity and the available methods for their assessment are summarized in Table 2.

1 Introduction

The presence of an adequate amount of water is an essential prerequisite for the maintenance of the normal structure and function of the stratum corneum. It has been known since many years that the electrical properties of the skin are related to the water content of the stratum corneum. Measurement of the total electrical resistance (impedance) of the skin to an alternating current of frequency F is the most widely used method for assessing the hydration state of the skin surface. The total impedance (Z) depends on two components, a resistance R and a capacitance C , as explained by a simple theoretical model where the skin is submitted to an electrical alternating circuit with a resistance in parallel with a capacitor (Lévêque and de Rigal 1983; Bernengo and de Rigal 2000; Tagami 2006; Barel and Clarys 2006; Gabard et al. 2006). As pointed out by many authors, the complex electrical impedance properties of the horny layer are dependent on the water content of this layer but also on a variety of other factors (ions, proteins, natural

moisturizing factors, etc.). Many physical factors may play a role in impedance measurements: design of the oscillating electronic circuit and frequency of the electrical current, geometry of applied electrode on the skin (micrometer or millimeter distance between the electrodes), measuring depth of the electrical field in the skin, direct galvanic contact or not with the skin surface, pressure of application of the electrode, etc.

Comparative studies about the measuring capabilities of the various electrical methods have been published (Gabard et al. 2006; Clarys et al. 1999, 2012; Fluhr et al. 1999; Xia et al. 2009).

It is the aim of the present chapter to give an overview of the available commercial instruments but equally to discuss some recently developed devices used for the assessment of skin surface hydration.

2 Commercial Electrical Instruments

2.1 Corneometer CM 825

The principles and characteristics of this capacitance-based instrument manufactured by Courage-Khazaka have been published by several research groups (Barel and Clarys 2006; Gabard et al. 2006; Clarys et al. 1999, 2012; Fluhr et al. 1999; Xia et al. 2009; Corneometer CM 825, 2013; Heinrich et al. 2003). The instrument has a flat measuring probe with an interdigitating grid of gold-covered electrodes. During the measurement there is no direct galvanic contact of the electrode surface with the skin since the interdigitating grid is covered with a low dielectric vitrified material. The pressure of application of the measuring probe is lower than 1 N as assured by a spring system triggering the capacitance measurements. The frequency shifts from 0.95 MHz for a hydrated medium to 1.15 MHz for a dry medium. The variable total capacitance of the skin surface is converted in arbitrary units (a.u.) of skin

hydration ranging from 20 (very dry) to 120 (well-hydrated) units. Skin penetration depth of the electrical current is about 45 mm.

2.2 DermaLab Moisture Unit

The instrument is based on skin conductance measurements and is manufactured by Cortex Technology (Gabard et al. 2006; Fluhr et al. 1999; DermaLab conductance instrument 2013), operating at a single frequency of 100 MHz and delivering impedance units between 0 and 10,000 μ S. There are two moisture probes available: a classical flat-faced electrode for normal skin surface and a pin probe featuring eight pin electrodes for very dry and scaly skin and for scalp measurements. There is galvanic contact between the electrodes and the skin surface. A spring system assures a constant pressure of application of the probe on the skin surface (0.9 N) and triggers the measurement of impedance.

2.3 Moisture Meter

These more recent instruments are manufactured by Delfin Technologies. The technical description of these instruments and their use has been published (Alanen et al. 2004; Moisture Meter 2013). There are three types of instruments: the classical model Moisture Meter D operating at a frequency of 300 MHz, a compact and wireless model of Moisture Meter D (same frequency), and the new Moisture Meter SC, operating at 1.3 MHz. The Moisture Meter D instrument can be equipped with four different probes with different diameters of the measuring head. As a consequence measuring depths between 0.5 and 5.0 mm are obtained. Both versions of the Moisture Meter D deliver hydration data expressed as relative dielectric constant units. The Moisture Meter SC, fully portable and with wireless data transfer capabilities, is also equipped with a variable application force system ranging from 0 to

1.81 N. The measuring depth is 2 mm. This instrument delivers arbitrary dielectric constant data which are converted in water content (in percent).

2.4 Nova Dermal Phase Meter

These instruments are manufactured by Nova Technology Corporation, and technical descriptions of the system have been published (Gabard et al. 2006; Clarys et al. 1999; Fluhr et al. 1999; Nova DPM 9003 2013). The instruments measure impedance of the skin at preselected frequencies up to 1 MHz. The final readout is given in arbitrary DPM units. Different sizes of measuring probes are available: DPM 9103 external diameter of electrode 8.76 mm, DPM 9105 diameter 5.08 mm, and DPM9107 diameter 3.81 mm. Constant pressure of application is assured by means of a sensor switch spring system. Recently a hand-held portable apparatus (Penguin) has been developed with a wireless transmission system of data. This model delivers also data concerning skin surface temperature and force of application of the probe.

2.5 Skicon 200 EX

This instrument is commercialized by ISB Company (Tagami 2006; Gabard et al. 2006; Clarys et al. 2012; O’Goshi and Serup 2007; co.jp, skicon 200 EX 2013). Technical descriptions of the most recent apparatus (Skicon 200 EX) have been published (co.jp, skicon 200 EX 2013). The Skicon 200 EX measures the impedance expressed in micro-siemens (μS) units, at a single frequency of 3.5 MHz. The measuring head consists of concentric interdigitating gold-covered electrodes with a gap of 200 μm between the electrodes. There is direct galvanic contact between the electrodes and the skin. Pressure application of the electrode on the skin surface is constant using a spring system (0.5 N) (Clarys et al. 2012).

3 Recently Developed Devices

Other more sophisticated experimental devices for measuring hydration and image hydration of the skin have been recently developed.

3.1 Opto-thermal Transient Emission Radiometry (OTTER)

This novel experimental infrared remote-sensing technology developed by Imhof et al. (1984) measures in vivo the opto-thermal emission at a wavelength of 13.1 μm . From the opto-thermal decay curves, a water distribution profile in the stratum corneum can be determined in vivo. However this rather expensive instrument has not been commercialized.

3.2 Skin Capacitance Imaging Systems

A nonoptical skin surface imaging system, based on the fingerprint-sensing technology, has been developed by the L’Oréal research group: skin capacitance imaging (SCI) (Lévêque and Querleux 2003). The sensor is composed of an array of capacitance microsensors. SCI images are acquired, and the capacitance values are transformed into a range of 256 gray levels to compose a nonoptical image. The mean gray level of the image represents the average skin surface hydration correlating well with the average capacitance values given by the Corneometer (Xhaufflaire-Uhoda and Piérard 2009). This device remains experimental and is not commercially available.

Aqualmarger, a contact imaging instrument using silicon fingerprint sensors, has been recently developed by Biox Systems. The device with 256×300 capacitance-sensing pixels (5 μm resolution) has shown potentials for skin hydration imaging and skin surface microrelief measurements (Xiao et al. 2011).

Finally the Moisture Map MM 100 instrument developed by Courage-Khazaka became recently commercially available (Moisture Map MM 100 2014). This instrument is a device featuring a capacitance sensor based on the recording fingerprint technology (patent of L'Oréal on skin chip (Lévêque and Querleux 2003)). The image of the Moisture Map sensor of the skin surface represents graphical information on the mean surface hydration distribution and also the microtopography of the surface.

3.3 Confocal Raman Spectroscopy

Raman instruments are becoming commercially available, and in the typical *in vivo* Raman spectra obtained, the respective contributions of keratins and water can be discriminated (Caspers et al. 1998). As a consequence the percentage of water in the skin in function of depth can be determined from Raman spectra (Van Der Pol and Caspers 2009). Unfortunately these Raman spectroscopy instruments are rather expensive and not used for routine measurements.

4 Conclusions

Taking into account the comparative performances and the high degree of correlation between the instruments, the possibilities of *in vitro* calibration, the range of sensitivity, the depth of measurement, and the low coefficient of intra-person variability, it can be concluded in this chapter that the Corneometer, DermaLab, Moisture Meter, Nova Dermal Phase Meter, and Skicon are validated electrical instruments for assessing the hydration state of the horny layer. The recently developed but not always commercially available instruments allow the determination of additional stratum corneum properties.

Acknowledgments The authors are grateful to Dr. Bernard Gabard for his contribution to this chapter.

1 Introduction

Optimum hydration is critical for stratum corneum (SC) function (Blank 1952; Gloor et al. 1998). Among the multiple functions affected by SC water content are desquamation, restoration of barrier integrity after wounding, acid mantle formation, microbial colonization, tactile discrimination, infection control, immunosurveillance, and protection against ultraviolet light and environmental irritants (Rawlings and Leyden 2009). Optimum hydration may be defined as the amount of SC water that achieves flexibility (biomechanics) while facilitating terminal differentiation, programmed cell death, and orderly corneocyte incorporation into the lower SC with balanced pH-dependent desquamation of the outer SC. Overhydration can cause maceration, disruption of the intercellular lipid bilayers, desmosomal degradation with creation of amorphous regions, corneocyte swelling, enhanced molecular transport, and increased permeability (Warner et al. 1999, 2003; Zimmerman et al. 1986), as well as irritation, inflammation,

and urticaria (Halkier-Sorensen et al. 1995; Hurkmans et al. 1985; Kligman 1996; Medeiros 1996; Rustemeyer and Frosch 1996; Willis 1973). Low hydration can cause dryness/scaling, aberrant desquamation via reduced enzyme activity, cracking, reduced flexibility, tightness, and itching. On balance, the SC water-handling properties must be sufficiently robust to respond to local, potentially disruptive forces, e.g., friction, heat, humidity, bathing, and topical product applications (Visscher et al. 2002). This chapter explores infant skin hydration for healthy full-term infants and premature babies and considers the factors that impact hydration after birth.

2 Fetal Skin Development

Water concentration varies throughout the SC (Warner et al. 1988) with lower hydration in the outermost layers, increasing with depth and decreasing at the lowest levels (Bouwstra et al. 2003). In vivo measurements with Raman spectroscopy indicate normal skin to be 25–30 % water, while hydrated SC is 45 % and dry skin ranging from 10 % to 15 % (Boncheva et al. 2009).

In contrast, the human fetus is immersed in a high-water environment of amniotic fluid during development. Epidermal cornification begins to occur around 23 weeks from head to toe and dorsal-ventral (25 week, abdomen) over the fetus and occurs in a programmatic fashion from head (initially, week 23) to toe and dorsal-ventral (week 25, abdomen) across the fetus, presumably under hormonal control (Hoath et al. 2006; Hardman et al. 1998). This is in contrast to skin cultures where cornification does not occur when the epidermis is covered with water and requiring dry conditions for SC formation (Supp et al. 1999). Vernix caseosa, a mixture of sebaceous gland secretions, lanugo, and desquamated epithelial cells, appears about the time of fetal cornification. It extrudes onto the epidermis through the hair shaft, spreads over the surface (Hardman

et al. 1998), and, presumably, protects the epidermis from exposure to amniotic fluid via formation of a hydrophobic layer (Youssef et al. 2001). Although the mechanism is yet unknown, vernix may create a sufficiently dry environment for cornification.

3 Full-Term Infant Skin Hydration

3.1 Birth

Within minutes to hours after birth, full-term infant skin hydration varies with body site (chest, back, forehead), time under the radiant warmer, and the presence of vernix (Visscher et al. 1999a, 2005). Despite prolonged exposure to water during gestation, low skin hydration is consistently observed in full-term neonates within the first day after birth (Visscher et al. 1999b, 2000, 2005; Fluhr et al. 2012). In 30 healthy full-term infants, hydration decreased markedly in the first day and then increased during the first 2 weeks, unlike the mother's skin where hydration was relatively constant (Fig. 1). Water-binding ability also increased during the first 14 days. Water-handling properties of the upper inner thigh and buttocks were evaluated in 19 healthy full-term infants at birth (day 3 or 7) and months 1, 3, 6, 9, and 12. SC hydration for the thigh increased over the first month and was relatively constant over 12 months and was lower than their mothers' values (Minami-Hori et al. 2014). Water holding capacity of thigh SC was higher for infants versus mothers, decreased during the first month and then remained constant.

These changes suggest that the SC is undergoing adaptive changes to the drier environment (Visscher et al. 2000). Abrupt humidity reduction in hairless mice increased DNA synthesis, decreased total free amino acids, and reduced filaggrin immunoreactivity, due to decreased epidermal keratohyalin granules induced by high

Fig. 1 Full-term skin hydration over the first month. In 30 healthy full-term infants, hydration decreased markedly in the first day and then increased during the first 2 weeks, unlike the mother's skin where hydration was relatively constant (Adapted from Visscher et al. 2000)

humidity and produced dry skin (Visscher et al. 1999b; Denda et al. 1998; Katagiri et al. 2003; Scott and Harding 1986). Low hydration may indicate an underdeveloped SC due to lack of transglutaminase activity (Rawlings and Matts 2005). However, this is unlikely since very low transepidermal water loss (TEWL) is consistently observed full-term newborn skin indicating a well-functioning epidermal barrier (Fluhr et al. 2012; Hammarlund et al. 1979; Ludriksone et al. 2014).

3.2 Vernix

Vernix covers newborn skin at birth and contains 80 % water. It is sometimes removed immediately after birth. Its potential hydrating effects were evaluated in parallel groups of full-term infants. Vernix was wiped off at delivery in one group and left on and allowed to rub in for another. The vernix-treated skin had significantly higher skin hydration at 4 h and 24 h after birth ($p < 0.05$) (Fig. 2a; Visscher et al. 2005). Skin pH values were lower in the vernix-treated group suggesting that vernix assists in acid mantle development

(Fig. 2b; Visscher et al. 2005). Visual erythema was lower immediately after birth for the vernix group and dryness tended to be lower ($p = 0.10$).

3.3 Adaptation and Time

The full-term infant skin was significantly drier than the skin of older infants (1, 2, and 6 months) and the mothers (Nikolovski et al. 2008). Low SC hydration and dryness during the immediate postnatal period may result from several interacting factors including a lack of water-binding natural moisturizing factor (NMF) in the upper SC, via extraction into the amniotic fluid in utero (soaking effect) (Visscher et al. 2002; Robinson et al. 2010a) and/or to delayed or impaired filaggrin proteolysis at high humidity (Scott and Harding 1986). About 40 % of NMF consists of free amino acids (FAA) that result from proteolysis of filaggrin. FAA levels were measured for high-performance liquid chromatography analysis of the surface SC collected from the skin surface of newborn infants. The levels were extremely low at birth (in the absence of vernix), increased over the first month but remained markedly lower than typical adult levels (Fig. 3a;

Fig. 2 (a, b) Effect of vernix on infant skin hydration. At birth, vernix was allowed to remain on the skin in one group of healthy newborns and removed from the other. The vernix-treated skin had significantly higher skin hydration at 4 h and 24 h after birth ($p < 0.05$) (a). Skin pH values were lower in the vernix-treated group suggesting that vernix assists in acid mantle development ($p < 0.05$) (b). From Visscher et al. 2005

Visscher et al. 2011). Vernix contains FAAs, and the relative amounts of histidine and glutamic acid were higher than expected from filaggrin proteolysis alone, indicating that vernix may contain other sources of soluble amino acids. Vernix-treated skin had significantly higher FAA levels 24 h after birth compared to skin with vernix removed, paralleling the higher skin hydration (Fig. 3b; Visscher et al. 2011). The higher FAAs in the vernix-treated skin are attributed to the vernix rather than to proteolysis of filaggrin in the upper stratum corneum secondary to a reduction in ambient humidity (Scott and Harding 1986).

To further examine the cause of low hydration, levels of FAA were measured across ten layers of neonatal foreskin and adult volar forearm skin.

Neonatal foreskin was used as an in vitro control for newborn skin because FAA levels could be determined as a function of SC depth. FAAs were significantly lower across ten layers of neonatal foreskin compared to adult volar forearm skin. The arginine/citrulline ratio is relatively high in filaggrin, i.e., 8:1 (McKinley-Grant et al. 1989). To facilitate proteolysis to FAA, the filaggrin arginine residues must be deaminated to citrulline to allow separation from the intracorneocyte matrix (Chavanas et al. 2006; Kamata et al. 2009). Despite the depth in the tissue, citrulline levels were diminished relative to adults, and the ratio of arginine to citrulline was higher in foreskin. This suggests that filaggrin proteolysis to form FAA had not occurred in the uppermost layers of foreskin SC and, perhaps, that the newborn infant is not yet producing water-binding amino acids to hydrate the SC.

Additional information about SC hydration has been determined among infants aged 3–12 months and compared with adults using Raman confocal microspectroscopy. Water levels were higher in infants to a depth of 26 μm versus the same depth in adults, with the greatest difference at a depth of 10–14 μm (Nikolovski et al. 2008). Compared with adults, SC NMF levels were lower in infants in the outer 12 μm . Water content (mass percent) measured by Raman confocal microspectroscopy was lower throughout the SC for full-term newborns aged 1–15 days than older infants and adults. The level in the SC of 60 % water saturation was deeper for the youngest infants (Fluhr et al. 2012). One explanation of the lower levels in infants is that sphingomyelinase and B-glucocerebrosidase are not able to function under the conditions of acidity and hydration, resulting in an SC lipid matrix that is not fully competent due to the absence of specific hydrophobic components. An examination of NMF levels at an SC depth of 1–2 μm by attenuated total reflectance Fourier transform infrared spectroscopy showed no significant differences from birth to 12 months in a cohort of healthy full-term infants for either the upper inner thigh or the buttocks (Minami-Hori et al. 2014).

Fig. 3 (a, b) Free amino acid levels in infant skin. The free amino acid (FAA) component of natural moisturizing factor was measured from surface SC collected from newborn infants. The levels were extremely low at birth (in the absence of vernix), increased over the first month, but remained markedly lower than typical adult levels (a). *Indicates all groups different from each other ($p < 0.05$). Vernix-treated skin had significantly higher FAA levels 24 h after birth compared to skin with vernix removed, paralleling the higher skin hydration (b). *Indicates higher for a vernix-treated skin ($p < 0.05$). #Indicates lower for a vernix-treated skin ($p < 0.05$) (Figure 3b reprinted with permission from John Wiley and Sons)

4 Premature Infant Skin Hydration

4.1 Relevance

Premature infants are at increased risk for infection, a leading cause of mortality, due to an underdeveloped epidermal barrier with few cornified layers (Evans and Rutter 1986; Cartlidge 2000). Reduction in mortality is a global health priority. Implementation of evidence-based strategies for catheter insertion and maintenance of very premature infants significantly reduced infections, but to a lesser extent than expected (Kaplan et al. 2011). Poor skin integrity may be a predisposing factor for sepsis.

4.2 Birth, Effects of Gestational Age, and Adaptation

At 23 weeks GA, TEWL values can be as high as 75 g/m²/h, and skin hydration is high as the SC is

nearly absent (Sedin et al. 1983). By week 26, a few cornified layers have formed (TEWL of ~45 g/m²/h), corresponding to a wounded skin surface (Evans and Rutter 1986; Cartlidge 2000). At 29 weeks, TEWL is 17 g/m²/h and markedly higher than values of 5–6 g/m²/h observed in full terms. To investigate the rate of SC maturation, hydration and TEWL were measured daily, over periods of up to 67 days, in ten very premature infants ranging from 23 to 32 weeks GA (most were <26–27 weeks) (Kalia et al. 1998) using low-frequency impedance spectroscopy to measure hydration (Fig. 4). Skin impedance was low in premature infants, indicating high levels of SC hydration and gradually decreased over time, i.e., ~70 days (Emery et al. 1991). Impedance values increased with increasing gestation. There was variability in the rate of change in hydration and TEWL, as shown for infants of 23 weeks' (Fig. 4a, b) and 26 weeks' GA (Fig. 4c, d), respectively. The time to reach normal (full-term) hydration (skin impedance of 200) was longer for the younger infant with increasing SC hydration and

Fig. 4 (a, b, c, d) Stratum corneum maturation in premature infants. Hydration and TEWL were measured daily in ten very premature infants ranging from 23 to 32 weeks GA. Skin impedance was low in premature infants, indicating high SC hydration, and gradually decreased over time. There was variability in the rate of change in hydration and TEWL, as shown for infants of 23 weeks (a, b)

and 26 weeks GA (c, d), respectively. The time to reach normal (full-term) hydration (skin impedance of 200) was longer for the younger infant with increasing SC hydration and decreasing TEWL over time. The profile differed for the 26-week infant as “normal” levels occurred more quickly (Adapted from Kalia et al. 1998)

decreasing TEWL over time. The profile differed for the 26-week infant as “normal” levels occurred more quickly. The time to complete SC maturation may be as long as 9 weeks postnatal age (Kalia et al. 1998; Harpin and Rutter 1983; Agren et al. 1998; Nonato et al. 2000).

SC hydration was inversely related to gestational age among 40 premature and full-term neonates (Okah et al. 1995). Skin hydration was measured daily from days 2–7 and then weekly for 7 weeks in 48 premature infants of 30–37 weeks GA (mean 34.4). Overall, hydration was constant over the period and higher for the abdomen and buttocks versus the leg and forehead

(Kanti et al. 2014). SC hydration was significantly higher for the most premature subgroup, aged 30.3–33.7 weeks, but decreased over time versus the older groups which were 34.0–34.8 and 35–36.7 weeks GA. Skin hydration for the leg increased over time for infants 35–36.7 weeks.

One day after birth, SC hydration was significantly higher for infants <30 weeks gestational age than infants >30 weeks due to high amounts of water passing through the skin. Hydration values did not differ for infants 32–24 weeks GA versus full-term neonates (≥ 37 weeks GA). Hydration values on day 5 were significantly lower than on day 1 for infants less than

Fig. 5 Stratum corneum hydration in premature infants. One day after birth, SC hydration was significantly higher for infants <30 weeks gestational age than infants >30 weeks due to high amounts of water passing through the skin. Hydration values did not differ for infants

32–24 weeks GA versus full-term neonates (≥ 37 weeks GA). Hydration values on day 5 were significantly lower than on day 1 for infants less than 26 weeks GA, and environmental conditions (isolettes) were constant throughout the period (Adapted from Okah et al. 1995)

26 weeks GA, and environmental conditions (isolettes) were constant throughout the period (Fig. 5). This finding suggests that SC maturation is rapid for very premature infants once they are exposed to a dry environment (Harpin and Rutter 1983; Okah et al. 1995) (Agren et al. 2006). Very premature infants frequently exhibit an abnormal desquamation several weeks after birth, indicative of a hyperproliferative SC (Okah et al. 1995; Bodak and Bodemer 2002; Visscher et al. 2009). Humidity affects filaggrin proteolysis to form NMF which, in term, hydrates the skin (Rawlings et al. 1994). NMF levels are likely to be quite low under the conditions of rapid skin development for premature infants in low-humidity settings, based on results of newborn animal studies (Scott and Harding 1986).

permeability (Imokawa et al. 1991; Ponyai et al. 2008; Weidinger et al. 2006). Uninvolved atopic skin exhibits subclinical inflammation, reduced hydration, increased TEWL, and increased SC turnover (Tagami et al. 2006). The skin hydration of uninvolved, non-lesional skin on the cheek, chest, back, forearm, and leg of infants <12 months of age was significantly lower than comparable sites in a cohort of nonatopic infants of the same age (Matsumoto et al. 2007). Decreased hydration was also found in older cohorts and infants between 1–2 years and 2–4 years, versus their nonatopic counterparts.

5 Infants, Atopy, and Hydration

Atopic dermatitis is characterized by a compromised barrier, reduced ceramides and mutations of the filaggrin gene, and increased barrier

6 Factors Influencing Infant Skin Hydration

Some of the “environmental” factors that impact infant SC hydration have been described above as the infant transitions from a wet environment during gestation to relatively drier surroundings after birth. Routine activities of daily living, such as water exposure (bathing), clothing (diapering),

and application of topical materials are expected to impact infant SC hydration as they do in adults.

6.1 Water Exposure: Bathing

With bathing, infant SC transitions from dry to wet and back to a dry environment, somewhat analogous to the transition from aqueous in utero conditions to much drier conditions at birth. Bathing in water for 10 min significantly decreased hydration, measured as the rate of moisture accumulation, friction, visual erythema, and visual dryness 15 min later (Visscher et al. 2002). The time of recovery to prebath hydration levels was not determined. Similarly, SC hydration decreased in adults who soaked for 10 min, and reductions in hydration persisted for more than 4 h (Visscher et al. 2003). Subsequent studies indicated that the reduction in SC hydration was associated with decreases in NMF measured in the upper SC (Robinson et al. 2010a, b). While the impact of water exposure on infant NMF has not been reported, similar findings are anticipated.

Fifty-seven healthy full-term newborns were either bathed with water or wiped with a water-soaked cloth twice weekly from days 7–28 weeks. SC hydration was higher on the abdomen and forehead for the bathing group than the water-wiped group, although SC hydration levels were lower than for older infants and adults (Garcia Bartels et al. 2009). However, it was not possible to determine whether the increases were due to adaptation or to the water exposure from each method. Healthy newborns ($n = 307$) were enrolled within 48 h of birth in a randomized trial to compare a cleanser versus water alone at least twice per week for 4 weeks. SC hydration did not differ for the two products over the study period (Lavender et al. 2013). The effects of bathing twice weekly with two liquid cleansers and water alone were determined among three parallel groups of infants ($n = 180$ total) aged 1 day to <12 months. SC hydration increased versus baseline for the cleansers versus water after 1 week but

returned to baseline levels at week two, with no evidence of dryness, erythema, or edema (Dizon et al. 2010). Infants and young children ($n = 125$), aged 1–36 months, used a liquid baby wash or a baby shampoo at least three times weekly or a baby lotion (and bathing) once daily over 4 weeks. Both the baby wash and baby lotion resulted in significantly increased SC hydration at weeks 1 and 4 (Coret et al. 2014). The increase was attributed to the skin care products although there was no untreated control to eliminate factors that could have increased hydration.

6.2 Diapers

SC hydration of diapered and non-diapered skin sites did not differ at birth (Visscher et al. 2000). Measurements were made 15 min after removing the diaper to avoid confounding effects of surface water. Diapered skin hydration increased significantly over the first two postnatal weeks and was higher than non-diapered skin on day 7, but the sites were not different by day 28. Diapered skin hydration increased from day 2–28 among 44 healthy newborns with values higher on the buttocks versus the leg (Garcia Bartels et al. 2012). Among 3–6-month-old infants, skin hydration was lower for diapered versus non-diapered skin 15 min after diaper removal, suggesting that the site difference continues over time (Visscher et al. 2002). Diaper SC hydration increased during the first month of life and then remained constant through the first year among 19 infants (Minami-Hori et al. 2014). The water holding capacity followed a similar pattern, diminishing in month one.

Disposable diaper technology has progressed significantly since it was first introduced, particularly with the development of water-vapor-permeable outer covers that reduce skin hydration and in diaper humidity (Counts et al. 2014). The severity of diaper dermatitis has decreased as a result of these advances (Oodio and Friedlander 2000; Runeman 2008).

6.3 Effect of Humidity: Premature Infants

Groups of hairless mice were kept at high (90 % RH) and low (10 % RH) humidity for 5 days following acclimation at 40–50 % RH. Epidermal DNA synthesis increased, beginning 12 h after exposure to low humidity, but did not change at high humidity, even though TEWL values were comparable. SC hydration was significantly lower for the low-humidity group, suggesting that the decrease in SC hydration caused an increase in DNA synthesis (Sato et al. 1998). The effect of environmental humidity on skin barrier development in 22 premature infants aged 23–27 weeks was determined by varying the incubator humidity after 7 days at 85 % relative humidity (RH). Infants were then exposed to either 75 % or 50 % RH until day 28. Barrier integrity, measured as TEWL, decreased significantly from about 62 g/m²/h at birth to about 33 g/m²/h on day 7. The decrease at day 28 was significantly more pronounced at 50 % RH with a mean TEWL of 13 g/m²/h versus 22 g/m²/h at 70 %. Although SC hydration was not measured, values would likely be reduced, given the findings from the animal study. The influence of decreasing humidity at birth on filaggrin was determined using a newborn rat model (Scott and Harding 1986). Proteolysis occurred immediately after birth, and filaggrin was found in the lower stratum corneum only (Scott and Harding 1986). Proteolysis depended on the humidity at birth and was observed at ranges of 80–95 % RH, but not at 100 % RH.

1 Introduction

Radiance, as an optical parameter defined by physics, can be measured in terms of the amount of light that is emitted from a particular object, such as light source. If we apply this definition to skin radiance, then when the skin reflects more incident light should look more radiant. However, skin radiance is more complex, is a psychophysical parameter, is the mirror of general health, both physical and psychological, and involves more than simply the quantity of light that is reflected from the skin (Matsubara et al. 2012; Petitjean et al. 2007a).

A gray skin, a “blotchy complexion,” may reflect bad looks because of great fatigue, weariness, hormonal status, emotional states (sadness, stress, etc.), illness (dysfunction of vital organs such as the liver), nutrition deficiency or excess, tobacco, alcohol, pollution, seasons, etc. (Purdue and Hunt 1986; Middleton 1968; Monfrecola et al. 1998; Koh et al. 2002; Besné et al. 2003).

Inversely “peachy-colored skin” reflects a smooth, pink, and velvety skin with good health status. The complexion plays essential psychological and social roles (Petitjean 2006).

Many articles showed that the perception of aging is highly influenced by the skin tone uniformity (Nkengne et al. 2008; Puccetti et al. 2011; Fink and Matts 2008; Matts et al. 2007; Fink et al. 2012).

According to the literature, no precise definition and quantifiable description exist for skin radiance. It is difficult to list all constituting parameters and their relative proportions; they involve quite complicated surface and internal qualities of the skin (Jeudy et al. 2014).

When the light meets the skin surface, a small quantity (about 5 % (Takiwaki et al. 1997)) is reflected directly, while the major part penetrates to the different layers of the skin. The specular light gives its luminous aspect, whereas the back-scattered light (Fig. 1) gives the complexion (peachy-color). In other words, specular reflection explains the glow (depending on the nature and state of the surface of the skin), absorption phenomena explain its hue (depending on the skin's chromophore content), whereas diffusion phenomena define its saturation (depending mostly on the collagen content).

The skin radiance seems to be a balanced mixture of (Petitjean 2006):

- **Color**, which is mostly influenced itself by the skin microcirculation and inner skin structures
- **Light reflection**

- More globally **of texture** of the skin surface

Therefore, the related studies imply the quantification of each mentioned components.

2 Color

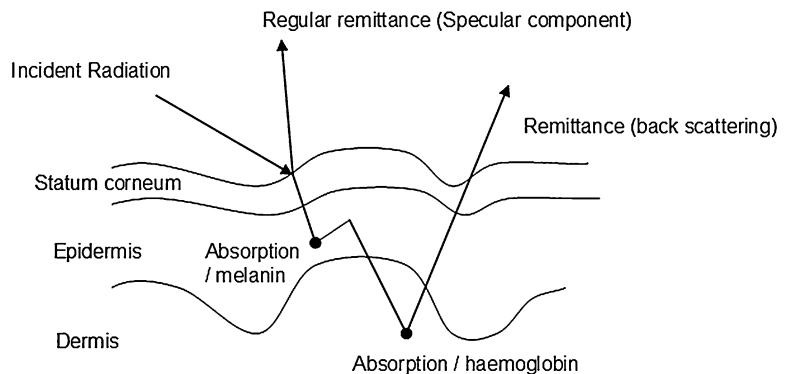

The skin color mainly depends on the melanin as well as the hemoglobin concentrations and their distributions; they absorb the light and affect sub-surface reflection (Kim et al. 2015).

The melanin (brown) absorbs all wavelengths, but this absorption decreases considerably from purple to red, which makes the melanin look like a mixture of gray (global absorption) and yellow (significant absorption of blue light).

Hemoglobin looks red because it absorbs selectively the green light and therefore retrodiffuses a light where this complementary color is missing.

The importance of the distribution of color was observed by Matts et al. (2007), who found that in female skin, melanin evenness had a stronger effect on perceived age, health, and attractiveness than hemoglobin. Similarly, Fink et al. (2012) found that hemoglobin distribution in males was associated more strongly with health and attractiveness perception, whereas the evenness of melanized features was a stronger marker for age perception.

Fig. 1 Optical pathways in the skin (The layer is so thin in the stratum corneum and the epidermis that its contribution to remittance other than specular is minimal over the entire visible and near-infrared regions (Anderson and Parrish 1981))

The hemoglobin plays an important role in the skin radiance, which is usually perceived as “pink” skin. An indirect way to assess the radiance is to study consequently the skin microcirculation.

2.1 Assessment of Skin Microcirculation

The hemoglobin transports the oxygen inside the red globules: if oxygen is not enough, the face will be gray and dull. If the microcirculation is effectively stimulated, the light will more easily reflect the red blood cells at the source of the skin color.

The skin microcirculation is therefore an important factor of the dull complexion:

- Under stress, catecholamines are delivered in the skin, inducing vasoconstriction (and thus produce skin pallor) (Purdue and Hunt 1986; Sainthillier et al. 2002; Altemus et al. 2001).
- With tiredness (lack of sleep and/or intensive activity), the body reacts by sending more blood to vital organs and the cutaneous microcirculation is “sluggish” (Besné et al. 2003).
- With pollution and smoking, the microvessels lose their colors (grayish aspect of the skin) (Monfrecola et al. 1998; Koh et al. 2002;

Besné et al. 2003; Petitjean et al. 2006; Raitio et al. 2004).

- With aging, papillar capillary loops disappear, inducing a loss in dermal nutritional vessel density and surface area for exchange (Li et al. 2006a).

Among the existing available techniques, capillaroscopy and videocapillaroscopy (Video Microscope Moritex Serie MS500, Perimed) allow direct visualization of the capillary network in vivo.

This optical device is made of a microscopic lens, a beam guide, and a CCD camera (Fig. 2).

The method used is based on the use of epiluminescence video microscopy. This device uses a halogen lamp as a light source. The light is conveyed to the target optical fiber. The incident light is generally lateral to increase the contrast, and on cold light.

The video microscope is connected to a computer with an operating system for the implementation of digital accurate quantitative measurements and a picture archiving.

Exploration is carried out directly on the skin after depositing a drop of oil to enhance skin transparency. An optical magnifying system is used to visualize its vascular network. Different levels of magnification can be used to assess the surface of the microvasculature structure as well

Fig. 2 Videocapillaroscopy device

Fig. 3 (a) (1.73 mm^2) magnification of $\times 200$ allows to quantify the vascularization network of the skin, whereas (b) (28 mm^2) a magnification of $\times 50$ allows to quantify the skin redness

as its color (Fig. 3) (Humbert et al. 2005; Sainthillier et al. 2005).

With this assay system, you can access various parameters such as capillary diameters, lengths, surfaces, density, and intercapillary space.

Various magnifications are available: The lenses of $\times 200$, $\times 100$, and $\times 50$ enable to explore of microcirculatory network for areas of $1\text{--}20 \text{ mm}^2$. The images are color coded and use RGB system (three layers red, green, and blue) and a resolution of 528×720 pixels.

The main advantage of this technique is its interactivity. The result of the capture and quality of the image can be checked immediately. Handling is easy thanks to the use of a computer, which is directly connected to the videocapillaroscope, and the whole data acquisition process is digitized.

2.2 Assessment of Skin Color

The most logical way to assess skin complexion is to study directly its color. In 2006, Taylor et al. described the different techniques available (Taylor et al. 2006). Among them, reflectance spectroscopy, chromameters, and narrowband reflectometers should be the most frequently used one. The latter are dedicated to the assessment of erythema or pigmentation (by measuring

more specifically the skin chromophores) (Agache 2004a, b).

The color variations of the skin surface can be measured by reflectance spectroscopy (spectrocolorimeter (CM2600D, Konica Minolta Sensing) or chromameter (CR400, Konica Minolta Sensing). These devices have sensitivities corresponding to those of the human eyes, but the measurements are performed in standardized conditions using the same light source. The International Commission of Illumination (Commission Internationale de l'Eclairage) (CIE) has defined the spectral characteristics of several types of typical illuminants (the D65 corresponds to average daylight and is usually used as the reference) (Precise color communication 1998):

2.2.1 Chromameter CR 200 (Minolta)

With this instrument, the skin surface is illuminated by a pulsed xenon arc lamp. The light reflected perpendicular to the surface is collected for a tristimulus color analysis at 450, 560, and 600 nm, using the $L^*a^*b^*$ color system, as determined by the CIE (Robertson 1990). The L^* parameter expresses color brightness (varying between a value of 100 for a white surface and 0 for a black surface).

The a^* parameter represents changes along a red/green axis with changes from +60 for a red surface to -60 for a green surface. The b^*

Fig. 4 $L^*a^*b^*$ color system

parameter changes from +60 for a yellow surface to -60 for a blue surface (Fig. 4).

The probe is applied on the skin surface simply by weight (651 g). With the standard equipment, the skin surface under the probe application is 1.77 cm² (diameter of 1.5 cm). The pressure of application on the skin is rather high, 368 g/cm². The instrument is calibrated using a white calibration plate (Clarys et al. 2000).

The skin radiance can therefore be described by a^* which corresponds to the redness and L^* which defines the luminosity.

However, additional information can be extracted, in order to qualify the skin color heterogeneity:

Color difference metric $\Delta E =$

$$\left[(L_1 - L_2)^2 + (a_1 - a_2)^2 + (b_1 - b_2)^2 \right]^{1/2}$$

(Haeghen et al. 2000)

and/or vividness:

– Chroma = $\left((a^*)^2 + (b^*)^2 \right)^{1/2}$ (Precise color communication 1998)

which are key factors in the problematics of dull complexion.

2.2.2 Mexameter M X16 (Courage-Khazaka)

The Mexameter (Courage & Khazaka MX18) measures the amount of melanin and hemoglobin in the skin.

In this instrument, 16 light emitting diodes circularly arranged emit light at three defined wavelengths 568 nm (green), 660 nm (red), and 880 (infrared). A photodetector measures the light reflected by the skin. The principle is based on the measurement of absorbed and reflected light at green and red wavelengths for hemoglobin and at red and near-infrared wavelengths for melanin. A melanin index is computed from the intensity of the absorbed and the reflected light at 660 and 880 nm, respectively. An erythema index is computed from the intensity of the absorbed and the reflected light at 568 and 660 nm, respectively.

The skin measuring area is 5 mm in diameter (surface 0.20 cm²). The probe is applied on the skin surface with constant pressure using a spring: pressure of application on the skin is 91 g/cm² (Clarys et al. 2000).

The skin radiance can be described by erythema index, which corresponds to the redness.

2.2.3 Derma-Spectrometer (Cortex Technology)

This instrument's light emitting diodes emit light at two defined wavelengths: 568 nm (green) and 655 nm (red). A photodetector measures the light reflected by the skin. It measures the absorbed and reflected light at green wavelengths for hemoglobin and at red wavelengths for melanin. A melanin index and an erythema index are computed from the intensity of the absorbed and the reflected light at 568 and 655 nm, respectively. The skin measuring area is 6 mm in diameter (surface 0.28 cm²). The probe is applied on the skin surface, simply by weight (640 g). The pressure of application on the skin is 158 g/cm². This instrument is calibrated using a black and white calibration plate (Clarys et al. 2000).

As Mexameter, the skin radiance can be described by erythema index which corresponds to the redness.

3 Reflection

The optical appearance of the skin such as radiance, glow, and shine can be quantified by determining the light-reflection profile of the skin. Understanding the optical-reflection characteristics by means of objective measurements is the first step in investigating these aspects of facial appearance.

The reflection of light from the skin is complicated by its multilayer structure. The stratum corneum, the outermost layer of the epidermis, is optically translucent and reflects partially incident light while allowing most of it to penetrate to deeper layers of the skin. As a result, the reflection from the skin is a mixture of specular surface reflection and diffuses subsurface reflection. It is therefore necessary to separate the surface and subsurface reflections from the skin to achieve a concept of the fundamental optical characteristics associated with its appearance (Matsubara 2012).

3.1 Assessment of the Skin Ability to Reflect the Light

The assessment of the light reflexion provides direct information on the skin radiance. It is generally admitted that radiant skin tends to act as a mirror, that is, to reflect rays in a specular manner, and dull skin tends to diffuse light more (Petitjean et al. 2007b).

3.1.1 Glossymeter

Courage and Khazaka had developed the **Glossymeter** to assess the quantity of specular and diffuse light reflected by the skin.

In the probe head containing parallel white light is created by the LEDs. Light is sent out at 0° and reflected by mirrors to 60° to the skin surface.

Part of the light is directly reflected in the same angle, so the angle of incidence is equal to the angle of reflection, and the other part of the light is absorbed by the surface and then scattered and reflected diffusely.

The Skin-Glossymeter GL 200 measures both the portion of directly reflected light, mirrored from the surface, which is related to the gloss and the scattered portion from the surface.

Two separate measurement channels measure the direct reflected light (again guided by a mirror in the same angle, i.e., at 120°) and the diffuse reflected (scattered) light degrees.

The scattered/diffuse reflected light is measured at 90° (completely vertically above the measured surface) under the assumption that light is scattered in the same way over all degrees.

The Skin-Glossymeter GL 200 is designed to assess the gloss of the skin surface. Skin, however, does vary not only in structure and brightness but also in color. With the DSC (Diffuse Scattering Correction), these facts are taken into account and the diffuse reflection light portion detected in the gloss measurement channel is eliminated, thus allowing to compare gloss measurements of different skin types.

3.1.2 SkinGlossMeter

The **SkinGlossMeter** is developed by Delfin Technology for measuring the specularly reflecting light from skin. In the SkinGlossMeter, the light beam reflects back at the same angle as it contacts the measured surface. This device does not measure scattered light.

As a light source, the instrument has a built-in 635 nm red semiconductor diode laser (superior reflective capabilities from the skin). The laser's spot size diameter at the surface level is 50 μm.

3.1.3 Brillanometer

Gillon et al. have also developed a specific contactless device (**brillanometry**) (Gillon et al. 2002). This device is for determination of both specular and diffuse light reflections continuously in numerous directions; it allows measurement of the skin gloss.

For skin optical measurements, an incident polarized-light beam is sent on the skin surface to be analyzed according to one direction, and the reflected beam is simultaneously measured in the same direction (Fig. 5). A small proportion of the light is reflected at the stratum corneum/air

Fig. 5 Presentation of the two components of skin reflected light measurement. Variation of optical head positioning in numerous directions (Gillon et al. 2002)

interface, due to specular reflectance, which keeps the same polarization as incident light; this manifestation gives shining skin radiance if well moisturized and tightened.

On the contrary, diffuse reflected light is depolarized. This optical property allows separating both components of the light (specular and diffuse light reflections).

3.1.4 Goniolux

Recently, the Orion concept developed **Goniolux**, a device that measurement of light intensities re-emitted in all directions of space.

Parameters are expressed as a volume or quantity of re-emitted light in different directions of space:

- Spec.Vol. = Specular reflection
- Diff.Vol. = Diffused light (specular diffusion and back-scattered light after its absorption by the skin – relationship with the skin relief or iridescence)
- Left or right Aniso.Vol. = Anisotropy of all reflections (for 2 directions = Left and right)
- Tot.Vol. = total quantity of light re-emitted by the surface

Results can be expressed as a ratio of these different parameters.

3.1.5 Translucymeter

Optical measurement of subsurface reflection can be acquired using translucymetre (TLS850,

Diastron Ltd, Andover, Hampshire, UK). TLS 850 is a contact translucency device in which light source has direct contact with the skin (Fig. 6). So it can measure only subsurface reflections (Kim et al. 2015).

A narrow beam from a RGB LED source illuminates the skin. Measurements can be performed using the “one color” mode of the LED, that is, either red, green, or blue.

Translucent materials like skin scatter light within deeper layers of the skin and a proportion of the scattered light are reflected back to the probe. The back-scattered light from the skin is collected by the fiber optic flathead (FOP).

The decrease in skin surface scattering increases light penetration into the deeper skin layers, resulting in an increase in skin transparency.

This collected light can be displayed in light levels on a PC depending on the distance of the sample illumination point.

The translucency value is composed of three parameters as follows: (Kim et al. 2015)

- The K value represents the amount of light detected by the probe as close to the light source as possible.
- The ALPHA value represents the rate of attenuation of the light level moving away from the source. A high ALPHA represents a rapid attenuation of light intensity.

Fig. 6 Principle of translucency meter

- The AREA value represents the total amount of light scattered into the material. relief (Lagarde et al. 2001; Nardin et al. 2002; Lee et al. 2008; Makki et al. 1979).

4 Relief

This is in agreement with Fink and Matts (2008), who showed in 2008 that the surface **topography** cues had a significant influence on facial age perception and that the absence of facial discoloration is a key indicator of health, two attributes that are probably most influential in the evaluation of human facial attractiveness.

The relief of the skin produces different image contrasts depending on the brightness level of the surface (the same relief appears more easily in the case of a bright surface). When the skin surface is irregular, it absorbs light with difficulty and reflects it in many directions. This is particularly typical of dry and scaly skin (Jeudy et al. 2014).

Radiant skin is usually considered as smooth and homogeneous, without imperfections. Although innate, the microtopography of the skin is affected by the environment as well as aging and undergoes changes in quantity, depth, and direction (Pierard et al. 2004; Li et al. 2006b).

Profilometry (mechanical, transparency, or optical), initially developed for microtechniques, has been applied for many years to study the skin

4.1 Fringes Projection

One of the most up-to-date methods for the 3D evaluation of skin topography in real time is the digital fringe projection method. This method consists of a projector unit used for a digital projection of a striped pattern in a defined angle onto the skin in vivo and a camera used as a recording unit combined with a processing analysis unit (Fig. 7).

By analysis of the distortions of the striped pattern, it is possible to reconstruct the 3D structure of the skin precisely in an objective and reproducible manner (Luebberding et al. 2014).

Interestingly this in vivo technique allows to study the skin imperfections via the assessment of the volume and depth of the wrinkles and in particular the roughness and heterogeneity of the microrelief (dilated pores, comedones, fine wrinkles, etc.) (Fig. 8).

Currently, two such devices are available on the market: PRIMOS[®] (GF Messtechnik GmbH, Berlin, Germany) and DermaTOP[®] (Breukmann, Teltow, Germany). The main difference between them is in how the fringe patterns are produced: the PRIMOS[®] uses micromirrors with different PRIMOS[®] models available according to sampling sizes, while

Fig. 7 Principle of fringe projection

Fig. 8 3-D reconstructions obtained from the cheek (20×20 mm area), allowing to detect dilated pores (a), or from hemi-face (60×80 mm area) (b) allowing to quantify the roughness/heterogeneity of its relief (Jeudy et al. 2014)

DermaTOP[®] uses a template for the shadow projection and offers the option of measuring different sized areas using the same device. Similar performances are reported by both systems (Tchvialeva et al. 2010).

4.2 VisioScan

Skin microrelief parameters can be evaluated by VisioScan (Courage and Khazaka). This device uses a special high-resolution video camera that

uses ultraviolet A light (proven to present no hazard to normal human skin) for uniform illumination of the skin and has been developed specially to study the skin surface directly, with SELS (Surface Evaluation of the Living Skin) software (Fig. 9).

The resulting images show the structure of the skin and the level of dryness, and the gray-level distribution of the image (in 256 grey levels) is used to evaluate the following skin microrelief parameters: maximum wrinkle depth (Rt), surface evaluation (SE) of skin

Fig. 9 Visio Scan and example of a resulting image

roughness (SE_r), skin smoothness (SE_{sm} ; proportional to width and format of the wrinkles), and the number and width of the wrinkles (SE_w) (Mercurio et al. 2013).

5 MultiFactors Assessments

5.1 Photography

Once calibrated and standardized, photography offers many applications to study skin complexion. It appears more appropriate to study texture or color heterogeneity than glowing aspect because of the influence of the light. The image can be easily disturbed by brightness induced by the flashlight or by the environment. The nature as well as the positioning of the light source and the posture of the subject are of major importance and must be taken into consideration to avoid visual artifacts (Raitio et al. 2004; Haeghen et al. 2000; Tanaka et al. 2008; Baret et al. 2006).

5.1.1 Polarized Photography

Polarized light photography provides more information than usual in terms of heterogeneity of structure.

For the measurement of skin-color or relief features, imaging systems equipped with two polarizing filters are widely used; the planes of polarization of the filters are oriented perpendicular or parallel to one another, and one

filter is located in front of the source of illumination and the other is located front of the camera lens.

With the cross-polarized-light photography technique, the surface-reflection component from the skin, known as specular reflection, is removed, and only the subsurface reflection component from the skin is captured in the resulting image revealing the complexion (skin redness or paleness, color heterogeneity, etc.) (Fig. 10).

With the parallel polarized-light photography technique, the specular reflections are included in captured images, and in this case, details of the surface are enhanced (wrinkles, shininess, scaling) (Fig. 10) (Matsubara 2012).

With parallel polarization (C), only the reflected polarized lights pass (revealing the shininess and relief of the skin (Photograph D)).

Imperfections, which can be revealed by parallel polarization in photography, can be directly assessed thanks to profilometry.

5.1.2 SAMBA (Bossa Nova Technologies)

The application of systems of polarization of the light currently used in photographs has given the opportunity to Bossa Nova Technologies (Los Angeles, CA, USA), to develop a system called SAMBA a few years ago (McMullen and Jachowicz 2003). This whole-face image-capture-and-analysis system was used to measure the surface and subsurface reflections from the skin.

Fig. 10 Simplified schema of the principle of polarized-light photography. (a) With cross-polarization, only the back-scattered light reached the lens (revealing the complexion (Photograph (b)))

Fig. 11 Diagram of the SAMBA face-imaging system

This system consists of two illumination units, a high-resolution digital camera and a head-positioning stand (Fig. 11). Each illumination unit is equipped with a linear polarizing filter. The digital camera is also equipped with a liquid-crystal polarizer that can electrically flip its polarization angle from a direction that is parallel to the plane of polarization of the polarizing filters on the illumination units to one that is at 90° to it (crossed orientation) (Matsubara 2012).

The frequency of the flip is 4 Hz, and therefore, facial images for the two polarization states can be

Fig. 12 VISIA complexion analysis system

captured in very rapid succession. The facial position and angle in the parallel (P) and crossed (C) polarization images is therefore identical, and the corresponding pixels in the two images can be compared with one another by image processing to extract the surface-reflection component (Matsubara 2012).

5.1.3 VISIA (Canfield Imaging Systems)

The VISIA Complexion Analysis System (Canfield Imaging Systems, Fairfield, NJ, Fig. 12) generates a series of photographs using standard, ultraviolet, and cross-polarized lighting.

The system also analyzes the photographs to quantify the skin complaint and count the number of lesions, such as brown spots or dilated pores. VISIA uses standard flash lighting to identify spots, rhytides, texture, and pore.

Ultraviolet lighting is used to generate an ultraviolet spot image and a porphyrin image. The ultraviolet lighting takes advantage of the selective absorption of ultraviolet light by epidermal

melanin in comparison with deeper melanin (Goldsberry et al. 2014).

5.2 Clinical Scoring

In 2006, Baret et al. organized a round table meeting with women (Baret et al. 2006). As a result of these exchanges, many items (including the skin grain, brightness, and color) were selected and studied in volunteers of different age groups from image analysis of video data of their face. Experts performed clinical scoring and then divided the volunteers in two groups: the young one, whose radiance was considered more dependent on skin luminosity and color (“rosy color”), and the old one, who was mainly characterized by irregular skin surface aspects and color variations.

These definitions corroborate the idea that radiance is multifactorial and naturally include an important subjective part.

DESCRIPTORS	ANTICIPATED OPTIMUM	SKIN EVALUATION
Red Pink	<p>Absence of red (unless the product contains an active ingredient to promote cutaneous micro-circulation)</p> <p>0% % of saturation 100%</p>	<i>+/- red skin</i>
Beige	<p>Medium beige (unless the product is a make-up foundation)</p> <p>0% % of saturation 100%</p>	<i>+/- clear complexion</i>
Olive	<p>Absence of olive</p> <p>0% % of saturation 100%</p>	<i>Less sallow complexion</i>
Light pink	<p>Optimal pinkness</p> <p>0% % of saturation 100%</p>	<i>Pinker complexion</i>
Luminosity	<p>Optimal luminosity</p> <p>Ref 0 Minimum Ref 10 Maximum</p>	<i>More luminous skin</i>
Brightness	<p>Optimal brightness</p> <p>Ref 0 Minimum Ref 10 Maximum</p>	<i>More uniform and regular skin</i>
Transparency	<p>Optimal transparency</p> <p>Ref 0 Minimum Ref 10 Maximum</p>	<i>More transparent skin</i>

Fig. 13 C.L.B.T. parameters defining the complexion

As previously mentioned for photography, it is of great importance to perform the scoring in controlled conditions. The subjects have to be seated between “daylight” lamps and to wear white clothes as well as a white paper cap to avoid any influence from extrinsic colors and to stay at rest in a temperature-controlled room (Musnier et al. 2004).

In 2004, Musnier et al. organized a brainstorming session with several beauticians to develop a model of sensory evaluation of the skin radiance (Musnier et al. 2004). One hundred volunteers

were also interviewed to self-appraise their complexion. The synthesis of the data allowed to determine four skin coloring descriptors and to construct a model “C.L.B.T.,” based on the visual perception of skin color (C), luminosity (L), brightness (B), and transparency (T). Recently, this score was adapted to the Asian skin (Périn et al. 2007).

The “red-pink,” “beige,” “olive,” and “light-pink” skin hues were determined to describe the various complexions’ coloring. Skin hues are due to chromophores found within the skin in the form

of melanin (brown and yellow hues), bilirubin (yellow hue), or hemoglobin (bluish red hue). The perceived color depends largely on both the concentration of the various pigments and their distribution throughout the skin's thickness.

The visual evaluation of skin coloring by trained assessors is undertaken with the help of structured visual color scales presenting the spectrum of the four main facial hues (red-pink/beige/olive/light-pink). Each hue is saturated at 100 % and its color gradations were shown. The results are expressed in terms of color saturation percentages.

Skin luminosity was defined as the intensity of the light areas reflected on the salient areas of the face, while skin brightness was the combined uniformity of skin coloring and skin texture, and skin transparency was the possibility of seeing the vessels beneath the skin. Figure 13 presents the interpretations attributed to the different descriptors after the application of a cosmetic product designed to improve "complexion radiance."

The visual evaluation of luminosity, brightness, and transparency (the LBT descriptors) is made using visual analogical scales that range from "no luminosity/brightness/transparency" (limit 0) to "maximum luminosity/brightness/transparency" (limit 10) (Musnier et al. 2004).

Clinical scoring offers the possibility to evaluate the different parameters implicated in the skin radiance.

6 Conclusion

Finally, no instrument can quantify today the skin radiance globally, but there are devices which allow to assess its different components.

With contrast to the color, the glow remains difficult to quantify. The development of simulation systems would perhaps be one solution (Minami et al. 2007). Many terms are usually employed to characterize the skin radiance: shininess, brightness, glow, glare, gloss, etc. Shininess, brightness, and gloss refer to the reflection of light to something and are more frequently used

to characterize seborrheic skin or to assess the effect of makeup on lips. Glare seems to evoke a shine with a dazzling light, whereas the glow associates an intense color with a slight shine. The glowing aspect of the skin has thus to be differentiated from its brightness, which is the characteristic of greasy skin and is inaeesthetic. If gloss is what women expect for their hair, glow is a better representation of radiant skin. All these notions show a real need to define the skin radiance more accurately (Jeudy et al. 2014).

The assessment of skin radiance implies the study of the geometry of the light reflection as well as the interaction between the light (interaction with surface-relief/glow) and the color (interaction within the skin/complexion) (Petitjean 2006).

1 Introduction

Although the skin is smooth, its surface is not even. Its relief is a succession of peaks and hollows organized in a relatively uniform pattern of deep and wide primary furrows (20–200 μm) and of finer and more superficial transversal secondary furrows (30–70 μm). Tertiary and quaternary lines are also observed but they can be studied only with high-resolution systems. The structure of microdepressions or microrelief forms the sides of more or less triangle-shaped plateaus on most of the body surface, except on the palms and soles (Fig. 1). This network has two roles: it gives the skin a protective mechanical stretching ability in the direction of the constraints the skin sustains and it is also useful for the evacuation and retention of sebum and sweat and to capture substances applied to the skin (Agache 2000; Agache and Humbert 2004; Bazin and Lévêque 2011).

The skin of the face has its own specificities: in addition to its microrelief, a locally more marked relief pattern is visible. It consists of a macrorelief made of fine wrinkles (depth between 0.2 and 1 mm) and wrinkles (>1 mm) which appear and develop with aging, more notably on the forehead (glabella wrinkle), the crow's foot area, and later on the cheeks. These wrinkles are the result of

structure alterations in the epidermis, the dermis, and the hypodermis (Bazin and Lévêque 2011; Zahouani and Vargiolu 2000; Piérard et al. 2004).

Both types of relief are neither measured nor quantified with similar procedures because of their different scales (from several microns to a few millimeters, i.e., up to a factor 100). Furthermore their exploration requires different approaches which must take into account their localization and the resolution necessary to measure them.

The assessment of both micro- and macrorelief is described below for use in clinical research and the description is centered on an accurate and polyvalent technique to perform measurements both *in vitro* (on replicas) and *in vivo*: optical profilometry by fringe projection.

2 Profilometry and Fringe Projection

The techniques available to assess a surface and carry out its 3D reconstruction can be listed in five main groups: optical systems (by detection of reflected light, depending on depth and angle of relief), mechanical systems, laser profilometry, optical systems by transmission, and optical profilometry by fringe projection (Lagarde et al. 2001; Stout et al. 2000).

Interestingly, 2D imaging allows to measure the relief indirectly (it is called pseudo relief).

The principle (either by camera or by photography) is to detect the contrast formed by the wrinkle and the adjacent skin. Generally the wrinkle appears dark inside a lighter area, and the intensity of the contrast corresponds to the depth and marked appearance of the wrinkle (Rosa Pena Ferreira et al. 2010; Russ 2007).

Mechanical profilometry was the first method developed and is based on a tactile detector able to measure a 2D profile or a 3D surface. It is mechanically connected to an inductive sensor which transforms the relief variations into an analogue signal.

Laser profilometry, based on dynamic focalisation or (simple or double) triangulation, uses the movement of a mobile lens or a spotlight reflected on a sensor to measure the height at each point of a sample surface.

Profilometry by transmission measures the variation of intensity of light shining through a replica. Applying the Beer-Lambert law, the absorption of light is linked to the transparency and therefore the thickness of the replica.

These systems are very different in terms of acquisition speed (from a few seconds to several minutes with mechanical systems), accuracy, and easiness of use. Laser profilometry and fringe projection profilometry are the only methods that can be used on the skin *in vivo*.

Profilometry by fringe projection is based on the principle of interferometry. It was originally

devised in the microtechnics industry and its application to the study of the skin was developed in the 1980s. From the 2000s, compact systems with specifically designed sensors and software were developed to study the skin relief. It became therefore possible to reduce the acquisition time, to remove or add some stages of processing and filtering while improving sensitivity.

The principle of fringe projection is to project structured light, i.e., a network of fringes, onto the investigated surface (Marsaut 2004). Fringes are deformed (modulated) by the relief. Several acquisitions with different phases of the projected network are recorded by a camera; after processing by a dedicated software, the tridimensional profile of the studied area is reconstructed within a few seconds (Takeda et al. 1982; Srinivasan et al. 1984; Hayashi et al. 1989). Two systems with CE certification are currently available: DermaTop Blue (Eotech in France) and Primos (GFM in Germany). Repeatability, reproducibility, and sensitivity of other very similar devices (Microtop) have already been shown (Lagarde et al. 2001).

The DermaTop device consists of a LED projector for the fringes and a CCD camera (Fig. 2). Three sets of objectives can be adapted to the system: an objective of great accuracy dedicated to the characterization of microrelief *in vitro*, an intermediary objective specifically designed to study facial wrinkles, and a wide-field objective for larger measurement areas of the nasogenian

fold, the lips, or the cheeks. A fair compromise must be found between the size of the investigated area (which increases) and the precision of the measurement (which decreases) in relation to these objectives. Most examples and images presented in this chapter are issued from this device and illustrate the possibilities offered by various objectives in relation to the investigations.

Although data acquisition by fringe projection is fast (a few thousandths of second), processing and 3D reconstruction are complex. The whole procedure involves several steps: all the raw data of each subject (in absolute coordinates) are loaded, solved (by calculating the deformation of fringes from the sensor's parameters), and straightened while taking into account the global shape of the area. The surfaces are then registered (in relation to the first measure, i.e., at T0) by using the surface itself or fixed anatomical marks (in wide-field imaging). A region of interest is defined (of variable size but always smaller than the exploration field), then filtered, and finally projected onto a reference plan. This final projection constitutes what is called 3D topography and is the basis for calculation (micro- and macrorelief). The topography defined vertically and horizontally (by lateral resolution determined according to the sensor used) is expressed by a matrix where each point corresponds to a single height (scale in z).

Fig. 2 Measurement of the cheekbone *in vivo* with Eotech system. The *blue* light covers the site where fringes are projected (left side of the subject's face). The sensor consists of a fringe projector (*black*) and a CCD camera (*green*) and is attached to a table where its position and the subject's position can be reproduced. Measurements are performed in a dark room to limit the influence of external light

3 Microrelief and Roughness

A rough surface is defined by its asperities and irregularities, uneven to the touch. Inversely a surface is deemed soft if its contact is pleasant because of its smoothness. Roughness is therefore linked to both sensorial and functional criteria: for example, a surface roughness accounts for its sensitivity to wear and tear or its adherence or sliding properties (Zani 2003).

Originally roughness is defined in two dimensions only. Standard measuring instruments developed from mechanical profilometry are contact systems composed of a mobile unit and a sensor that scans the sample according to predetermined direction and length. From the acquisition of a profile, various mathematical formulas are applied to extract parameters. It is difficult to apprehend roughness because it is a statistical parameter with a variety of possible definitions: means of heights of peaks, height of the highest peaks, wider amplitude between the height of a peak and the depth of a furrow, mean distance between several peaks, etc. No definition is actually more relevant than another and everything therefore depends on the intended application.

Paradoxically there is no standard to characterize surface states (roughness calculated directly in three dimensions on a surface). Calculation methods developed for profiles can however be adapted to surfaces by the addition of a supplementary dimension.

Based on our experience in this field, we have selected two robust and sensitive parameters: Sa and St. They are well-known, easy to calculate, and complementary because they allow for localized and global reading of the measured surface.

- **Sa** (in μm): arithmetic mean of the deviations of the surface to the mean plane
- **St** (in μm): dynamics = amplitude = difference in height between the highest peak and the lowest hollow of the surface

St is used to assess the quality of the calculated surface quickly and globally. Important variations of this parameter usually express acquisitions with noise, with the presence of aberrant points. Sa is a

parameter sensitive enough to detect a change in microrelief, even of low amplitude (between 5 and 10 μm). Of course, other parameters exist and have been used successfully in the study of the skin surface (Zahouani et al. 1985; Mignot et al. 1987; Mignot 1986; Makki et al. 1979, 1984).

The distribution/orientation of the furrows can also be calculated under the form of a compass rose. The density of orientation in a determined angle corresponds to the number of elements of the furrows having this orientation. With this method it is possible to quantify the rate of anisotropy of the relief which is defined in the interval 0–100 % (0 % expresses the anisotropy rate of a perfectly isotropic surface and 100 % of a perfectly anisotropic surface) (Zahouani and Vargiolu 2004; Zahouani et al. 1998; Lagarde et al. 2005).

4 Wrinkles and Macrorelief

In terms of topography a volume combines two complementary quantities: negative quantity located in depth (absence of matter) and positive quantity located in height (presence of matter). The separation plane between both quantities corresponds to the mean plane.

Mathematical measurement of the volume of a wrinkle consists therefore in the assessment of the negative matter located under the mean plan, by integrating the three dimensions of the image, i.e., height, width, and depth (in mm):

$$\text{Volume} = \text{height} \times \text{width} \times \text{depth}.$$

Several methods are available to calculate the volume of a wrinkle. These approaches all use the mean plane and quantify the volume located beneath it (Sainthillier et al. 2009). They are however different in the way they define the calculation zone and are therefore more or less adapted in relation to the nature of the relief.

The calculated parameters are usually linked to the morphology of the wrinkle (its surface, volume, mean depth, etc.). Other more elaborated parameters can be defined to quantify the slope

of the wrinkle, its splay, and its fragmentation. However, the relevance of these parameters depends on their application to surfaces free of any perturbation, noise, or artifacts.

On the forehead (Fig. 3), the relief is usually flat and not very marked but covers a large surface, with one or two horizontal wrinkles frequently discontinued at their centre. The top of the glabella is sometimes visible on the most marked foreheads. In the assessment of this area, the calculation of the global volume will be preferred, taking into account all the wrinkles and

fine wrinkles. This method is reliable only if the surface has absolutely no artifacts (they would distort the calculation).

On the crow's foot wrinkles (Fig. 4), the relief is more irregular and localized, with one or several independent wrinkles spreading like a fan from the eye canthus. Unlike evaluation on the forehead, the assessments of the crow's foot wrinkles are aimed at characterizing and following up a selected and clearly identified wrinkle, free of any artifact. A region of interest is defined in the shape of a polygon around the studied wrinkle or

Fig. 3 In vivo acquisitions before/after treatment (*top/bottom*) on the forehead (30×20 mm). The *top* end of the glabella is visible in the lower part of the images. A few non measured points appear in the lower *left* corner. The

calculated volume varies from 28.4 to 23.7 mm³. The decrease is the result of the evolution of both horizontal wrinkles which become narrow and discontinued. The maximal depth varies from 0.95 to 0.79 mm

Fig. 4 In vivo acquisitions of crow's foot wrinkles (20×20 mm). *Top*: original image taken by the camera. *Bottom*: 3D topography. Two fine and discontinued wrinkles are visible. The region of interest has been defined at a distance

from the eye canthus (the eyes were open during the acquisition process) and does not take into account the hair on the *right* and the eyebrows at the *top* of the image. The calculated volume is 7.7 mm^3 in this example

part of wrinkle. This polygon defines a binary mask inside which the volume is calculated. The polygonal shape is preferred to a rectangle in order to follow the curves of the wrinkle more accurately. Its geometrical characteristics and its position can be saved and applied to other surfaces in a perfectly comparable way at different times of measurement.

To quantify its volume, a relief is usually filtered (median filtering, Fourier transform, etc.), and a cutoff threshold may also be determined.

The aim of the filtering process is to separate the shape and the relief of the wrinkle from its intrinsic (micro)roughness. It is then possible to analyze separately both sets of data and to determine on which item the investigational ingredient or treatment is active.

Other areas such as the lips or nasogenian folds can be studied (Goldman et al. 2009). In this type of assessment, the main objective is not the measurement of the volume in itself but rather the comparison of shapes, by subtracting surfaces, by measuring local roughness, or by drawing profiles.

A complete acquisition of the lips can be made with a wide-field objective (Fig. 5). Imaging of this area is rather easy from the front but the repeatability of the measures can be an issue because the lips are naturally more or less contracted at the time of acquisition. Points which are not measured appear in the brightest

areas or at the junction between the upper lip or the lower lip. It is possible to isolate an area of interest on one of the lips and to calculate roughness parameters locally (Sa and St). It is also possible to draw vertical profiles regularly spaced on the whole surface and to compare their curvature radius during the various acquisitions.

The wide-field objective can also be used to quantify the depth or width of nasogenian folds (Fig. 6). This type of measurement is a very interesting tool in the follow-up of the effects of a filler or an injection on the relief of the area. The acquisition is performed from a three fourth view of the area of the face under the eye. Its morphology is characterized by profiles drawn in a fan shape from the cheek and crossing the nasogenian fold (e.g., in relation to the quantity of injected product or the dermatologist's gesture).

Other facial sites can also be studied such as eye bags or jaw ptosis but experience on this type of assessment is currently not sufficient. A multisensor system (two sensors – fringes + CCD camera – placed at 45° around the subject) dedicated to 3D measurements of the whole face is available (AEVA, Eotech) (Fig. 7). It is used to measure facial ptosis or the curve of the breasts.

Besides the assessment of features of the face, fringe projection is also an interesting technique in the study of cellulite. The sensor is placed on an

Fig. 5 *Top*: In vivo acquisition of lips (with camera texture) with wide field objective (80×60 mm). A few non measured points are visible in the lower part of the image, on the *right* and on the *left*. A small wound is visible on the

lower lip. *Bottom*: a 20×5 mm region of interest has been extracted from the centre of the lower lip. Its microrelief is clearly visible, as well as the wound

adjustable tripod. Measurements are performed on the thigh and the volume of the dimples is analyzed. For obvious reasons the exact localization of the tested area (especially its height) and the position of the subject are essential for the quality and repeatability of this type of measurement.

5 Acquisition from Replicas

The technique of replicas is a simple process to reproduce a surface and is also a practical means to study it independently from its support

(Lagarde et al. 2001). Replicas are made with silicon polymer (Silflo[®], Monaderm, Monaco) which polymerizes at room temperature in contact with a specific catalyzer. It is harmless for the skin and mucosa. The product flows in the hollow parts of the skin, follows its relief perfectly, and within a few minutes becomes a negative cast reproducing the relief of the skin very finely.

Replicas can be made directly on the skin (Fig. 8) or with a rigid support (Cuderm, Dallas, USA) of standard size which delimitates the cast site. Silflo[®] is then applied with a syringe or a spatula.

Replicas must be made by trained staff to reduce the risk of having artifacts such as holes

Fig. 6 In vivo acquisition of nasogenian fold with wide field objective lens (80×60 mm). On the *left*, image of the *right* side of the face, taken by the camera. On the *right*, in the corresponding 3D reconstructed image, non measured areas are visible (nostrils, lashes, lips folds) and appear like transparent tears (these points are not taken into account in calculation). These areas are located in dark zones that cannot be solved by the system. The section in white on

the camera view has been drawn manually from the cheek. From this section it is possible to determine locally the depth of the fold which gets wider very progressively in a gradual slope toward the upper lip (*bottom* graph). It is therefore more difficult to calculate its width. In this type of approach the coordinates of the section must be saved for future applications on the same site on the various topographies of the subject (for example before and after injection)

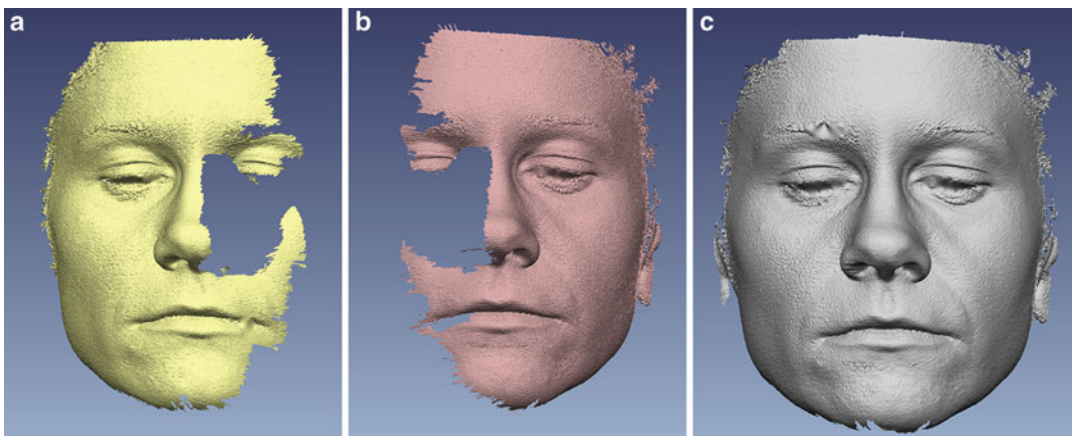

Fig. 7 Acquisition of the whole face with AEVA system. The final 3D reconstruction (*bottom*) results from the combination of 2 acquisitions of the *right* and *left* sides (2 images at the *top*). Side acquisitions are made one after the other, with the subject staying perfectly still. To ensure

a global reconstruction of quality, both views must have overlapping zones to facilitate registration. The resolution of the periphery of the face is poor (especially the ears, hair, chin). Interpolation has been carried out on the eyebrows and the eyes

Fig. 8 Preparation of replica (1) A few drops of catalyser are added to Silflo[®] and the mixture is homogenized immediately before application. (2) Silflo[®] is spread on the skin with a spatula. (3) After a few minutes wait, the

replica is gently removed. The negative relief of the subject's glabella (a very fine wrinkle in this example) is visible on the replica (4)

or bubbles. It is also necessary to check the subject's movements when the replica is produced. In theory, replicas can be made on any site on the body as long as the surface is relatively flat and without artifacts, but on the face the presence of many artifacts (hairs, vellus, pores, etc.) makes microrelief analysis rather difficult.

The accurate localization of the tested sites is essential to ensure that the same area is measured at each time of assessment according to the plan in the study protocol.

Microrelief is characterized using an objective with a high degree of precision, and the size of the region of interest is therefore reduced (10×10 mm). The replica is positioned on a flat surface under the sensor (its orientation is not relevant).

Replicas made with the help of a support require, during computer processing, the application of an occlusion mask adapted to its shape (either round or rectangular). During the calculation of the topography, this binary mask delimitates automatically the inside of the cast excluding the edges.

Replicas are used not only to study microrelief (Fig. 9) but also to cast the wrinkles of the face, such as crow's feet (Fig. 10) or glabella (Fujimura et al. 2007; Takema et al. 1997). To compare the evolution of wrinkles or fine wrinkles over a period of time, measurements must be superimposed with accuracy. In this process called registration (also found in acquisitions in vivo), the various acquisitions are compared and then aligned, with the first acquisition

Fig. 9 Examples of microrelief from replicas of the forearm of an old subject (*left*) and a young subject (*right*). *Top*: Camera images of the replicas. *Bottom*: Corresponding topographic images (10×10 mm) defined at the centre of the replica. The altitude of the surfaces has been inverted for illustrative purposes. However the roughness

parameters (S_a and S_t) are mathematically symmetrical. The microdepressionary network is clearly visible: coarse and anisotropic (*left*), or regular and isotropic (*right*). (*Left*: $S_a = 22.1/S_t = 253.8 \mu\text{m}$; *right*: $S_a = 14.4/S_t = 178.3 \mu\text{m}$)

(T_0) being used as a reference. Registration is a delicate automated process (if acquisition is of poor quality, its alignment and the alignment of the following acquisitions are perturbed or even impossible). Analysis may then become complex and difficult when the number of acquisitions increases (>5).

The assessment of relief from replicas is interesting because it gives the opportunity to carry out cost-effective multicentric studies (devices for 3D imaging and analysis are expensive). If the replicas are of good quality, they can be digitized in very high resolution since there is no movement during acquisition. Their fair color accentuates the contrast of fringes and optimizes 3D reconstruction. Another advantage is the possibility to store them for future analysis.

6 In Vivo Acquisition

The possibility to assess wrinkles in vivo is one of the main advantages of fringe projection because it is a fast matricial measurement without contact that can be performed directly on the skin.

In vivo measurements are not as easy as they seem and require strict acquisition conditions. They must take into account slight movements of the subject (shaking, breathing) as well as dark or too bright areas of the skin where the contrast of fringes is lost. Therefore the 3D sensor is systematically associated with a positioning table where the subject can be in a reproducible and stable position although it may be uncomfortable (Fig. 2). A ball joint fixed on a rail supports the sensor which can rotate around the subject for

Fig. 10 Replicas of crow's foot wrinkles. *Top*: topography (15 × 10 mm) from the central part of the replica. *Bottom*: the same topography after inversion of altitudes. A

few non measured points are visible at the start of the central wrinkle on the *left*. The calculated volume is 5.36 mm³

full face, three fourth view, or profile measurements.

The subject is asked to fix a point and keep their eyes open for measurement of crow's foot wrinkles or eyes closed for measurement of forehead wrinkles. The procedure takes place in a dark room to ensure that the contrast of fringes is not perturbed by light.

In vivo measurements are also limited by the morphology of the studied site and by the depth of field which depends on the lateral resolution of the selected objective (from 6 to 40 mm). Possibilities of evaluation will be restricted on areas with important differences of levels (the eye, nose, etc.). This accounts partly for the fact that the

use of a high-precision objective associated with low depth of field is not possible in vivo.

Noises present in in vivo acquisitions are materialized by aberrant or not measured points. They create breaches and more or less large distortions. Noises cannot always be detected during acquisition; they become really visible only when topography is processed. Adapted filtering (median filtering with large kernel) and filling by interpolation can compensate these perturbations to a certain extent.

The characterization of macrorelief in vivo opens very interesting perspectives in clinical evaluation. Associated with a positioning system (table or tripod), it is a reliable and polyvalent

measurement. Unlike replicas, several acquisitions can be carried out if a problem arises, on sites where it is not possible to make replicas (lips, for instance). Its main drawback however is that 3D acquisition in vivo generates more noises and requires more complex computer processing.

7 Conclusion

Fringe projection is a technique without contact to obtain accurate measurements of surfaces and it is therefore well adapted to the skin and its constraints. Added to the possibility to adapt the size of the measurement field to the studied object, it is a very interesting tool in clinical evaluation. Fringe projection is however not without drawbacks and restrictions. Like all methods of 3D digitization, it is still expensive and needs technical, practical, and computing competence.

3D digitization requires rigorous acquisition procedures to fix and document as exactly as possible the context in which the measurement is performed. The subjects are at the heart of the acquisition process by their position, attitude, posture, or expression which can strongly influence measurements.

 Quantificare: http://www.quantificare.com/index.php?q=LifeViz_EsthetiqueFR

The 3D LifeWiz system is made of a compact camera. It is based on stereovision which gives perception of depth. Two systems are available: a global system for large visualisation of the neck and face and a more accurate system for localised visualisation of wrinkles or scars.

Image processing by projected shadow

http://www.monaderm.com/Appareil_scientifique.php?appareil=quantirides

http://www.monaderm.com/Appareil_scientifique.php?appareil=quantiline

Quantirides and Quantilines systems have been developed to analyze, quantify and characterize wrinkles and microrelief from Silflo® replicas. The negative print of wrinkles is placed under oblique light (35°) which generates projected shadows behind each wrinkle. Acquisition of this image and its shadows is performed via high resolution digital camera. The image is then analyzed with dedicated software.

Profilometry by contact

<http://www.altimet.fr/fr/index.htm>

This company develops a range of equipment (Altisurf) for the metrology of surfaces, more specifically devised for the microtechnics industry (tests on varnishes, characterization of ink deposits, textile textures...) and nanotechnics industry (materials and substrates, corrosion, adhesive. . .)

1 Introduction

Water changes the properties of human keratin fibers existing in the skin, hair, and nails (Barba et al. 2010). Examples are the sorption of water by stratum corneum, the spreading of water and lipidic liquids which influences skin absorption, thermal loss, as well as transcutaneous pressure of water vapor, carbon dioxide, and oxygen (Agache et al. 2004). The production of a sweat/sebum emulsion can also be influenced by these interactions as well as the behavior and effect of topical drugs or cosmetics on the skin (Agache et al. 2004).

Frequent washing increases brittleness of the nail (Uyttendaele et al. 2003), and chronic wetting and drying of nails may cause lamellar dystrophy (onychoschizia) (van de Kerkhof et al. 2005). Brittle nails affect about 20 % of the population, and women are affected twice as frequently as men (Lubach et al. 1986). Hydrophobicity of soft tissue surfaces in the human body, including those of the human oral cavity, has been described for decades as playing an important role in many biological processes, like cellular adhesion (Barba et al. 2010), contact inhibition, elasticity (Agache et al. 2004), tissue

membranes functions, intracellular structures (Uyttendaele et al. 2003), and adhesion of infectious microorganisms (van de Kerkhof et al. 2005). Generally, tissues with absorption/exchange functions or, indeed, lubrication tend to be more hydrophilic. On the other hand, tissues requiring protection against pathogenic microorganisms or acids tend to be hydrophobic (Lubach et al. 1986).

From a fundamental point of view, wetting is an important phenomenon, because of its diverse applicability in everyday life. Friction and lubrication are intimately coupled to wettability.

In this chapter, we will first treat human skin wettability by showing effects of some treatments and applications on wettability parameters. Secondly, the skin friction coefficient will be studied through the effect of the surfaces hydrophobic/hydrophilic balance (Ho/Hi).

2 Human Skin Wettability

Wetting refers to the contact between a solid surface and a liquid; it depends on intermolecular interactions. The degree of surface wetting is evaluated through the measurement of contact angle. The wetting of the surface is the best, if it has the minimum contact angle (θ). When $\theta = 0^\circ$, the surface wets completely; the opposite corresponds to $\theta = 180^\circ$ (dewetting), and the partial wetting refers to θ ranging from 0 to 180° (Fig. 1).

Fig. 1 Solid wettability: $\theta = 0^\circ$: total wetting, $\theta = 180^\circ$: non wetting = dewetting, $0^\circ < \theta < 180^\circ$: partial wetting, $0^\circ < \theta < 180^\circ$: partial wetting

2.1 Theory

2.1.1 Contact Angle and Superficial Energy (Fig. 2)

Young’s equation (Eq. 1) (Young 1805) relates the surface tension between the liquid vapor (γ_{LV}), the solid vapor (γ_{SV}), and the solid-liquid (γ_{SL}) and the free surface energy by contact angle (θ). The general form of this equation for the solid-liquid-air system is

$$\gamma_{LV} \cos \theta = \gamma_{SV} - \gamma_{SL} - \pi_e \quad (1)$$

where π_e (external pressure) = 0 for low energy solids (Fowkes 1964).

2.1.2 Critical Surface Tension (γ_c) and Hydrophobic/Hydrophilic Balance (Ho/Hi)

Critical Surface Tension

γ_c (Fig. 3): The definition of γ_c is based on an empirical relationship between the cosine of the contact angle and the surface tension of a series of homologous liquid (Eq. 2) (Zisman 1964)

$$\cos \theta = 1 - b(\gamma_{liquid} - \gamma_c) \quad (2)$$

where γ_{liquid} , liquid surface tension (mJ/m^2). Note that a reduction of γ_c means an increase in the surface hydrophobia.

Fig. 3 Critical surface tension γ_c : total wetting condition ($\gamma_{liquid} \gamma_c$)

Hydrophobic/Hydrophilic Balance (Ho/Hi)

For decades, the surface hydrophobicity has been reported to play an important role in many biological processes, such as cellular adhesion, contact inhibition, elasticity, functionality of tissue membranes, functioning of intracellular structures, and adhesion of infectious microorganisms (Norris et al. 1999).

The skin hydrophobia balance (Ho/Hi) is quantified by a relationship between γ_c and the water surface tension (Eq. 3) (Elkhyat et al. 2001)

$$Hi = \gamma_c / \gamma_{H_2O} \quad (3)$$

where Hi is surface hydrophilia and Ho is surface hydrophobia.

This parameter is expressed by the ratio of its critical surface tension γ_c to the water surface tension γ_{H_2O} normalized by the latter.

Fig. 4 Contact angle visualization and measurement: tool rests on the use of a mirror directed 45° to the skin “Profile drop method”

Free Surface Energy FSE (γ_s)

Free skin energy is a topical parameter that determines most of the surface properties such as adsorption, wetting, adhesion, etc. The γ_s of the solids cannot be directly measured, because of the very weak mobility of the molecular atoms. It is necessary to resort to indirect methods such as study of the interactions between a solid and a liquid. The γ_s is derived from the measurement of the contact angle of pure liquids, with known surface tension parameters.

Several approaches are mentioned in the literature; the two most commonly used for the skin are described below:

Geometric mean approach (Owens and Wendt 1969): The γ_s proportional to the intermolecular energy is the sum of the dispersion component γ_s^d and the polar component γ_s^p .

Acid-base approach (Van Oss et al. 1988; Good and Van Oss 1992): The γ_s can be expressed as the sum of Lifshitz-van der Waals γ_s^{LW} and

acid-base γ_s^{AB} components $\gamma_s = \gamma_s^{LW} + \gamma_s^{AB}$. The acid-base components can be expressed as $\gamma_s^{AB} = 2(\gamma_s^+ \cdot \gamma_s^-)^{1/2}$; the γ_s^+ and γ_s^- components indicate, respectively, the electron-acceptor and the electron-donor components.

2.2 Contact Angle Measuring

For the visualization and the measurement of the contact angle, we developed a tool especially designed for the wettability *in vivo* measurements (Fig. 4). This tool is based on the use of a mirror directed at a 45° angle to the skin (profile drop method).

A drop of test liquid is deposited on the skin surface using a microsyringe and inflated up to a final drop volume of 5 μl . The advancing contact angle of test liquids corresponds to the maximum value of the contact angle when the drop is inflated without moving the contact line.

The drop’s image is recorded using a video camera (CDD-Iris, Sony, France) connected to a computer and mounted on a microscope (Wild Heerbrugg M650, Switzerland), with a magnification of $\times 16$, fitted with a slanted mirror. After visualization and storage of the drop profile, the contact angle is measured using a program which can determine θ from the tangents of both sides of the drop. The influence of roughness and skin temperature on the contact angle is treated in the literature (Wenzel 1936; Neumann and Good 1979; Mavon et al. 1997). The temperature effects on the liquid in contact with the skin are minimized with the nature of the deposit (advancing contact angle) and with shortening the time of deposit (15–20 s).

In order to allow every researcher to be able to assess the skin wettability, a new device has just been developed which stands for drop shape analysis (Fig. 5). With this measuring procedure, a drop of liquid (mostly water) dribbled on the inner side of the lower arm. According to the wettability of the sample surface, the drop will take on a form depending on the surface tension. In order to interpret this form into a conclusive

Fig. 5 Human skin wettability measurement: forearm rest with the new device

value for measurements, the drop's contact angle is determined.

This device has three basic components: (1) A black and white camera with a telecentric measuring lens adjustable with a small linear axes portal. (2) An arm rest with adjustable settling angle. The angle is set to position the lower arm on which the measurement is performed as horizontal as possible. This setting prevents the drop to run or disintegrate, and both sides of the contact angles are the same on each side of the drop if the contact area is positioned horizontally. (3) Software: The software allows the adjustment of the arm in a horizontal position, the calculation of the drop angle, and saving of pictures and data.

2.3 Data Analyses

2.3.1 Water Contact Angle θ_w

Water is an important factor for normal skin function. When the water content decreases, the skin becomes dry, itchy, and uncomfortable. The spreading degree of a water drop on the skin surface is an indication of its hydrophobic (Ho) or hydrophilic (Hi) properties.

Skin: Water spreads differently on skin. On the volar forearm, a poor site in sebum, water forms a semi hydrophobic contact angle ($\theta_w = 80^\circ - 91^\circ$) (Mavon et al. 1997; Elkhyat et al. 2004a, b; Schott 1971). On the forehead, rich site in sebum, water spreads over ($\theta_w = 57^\circ - 73^\circ$) (Afifi et al. 2006;

Fotouh et al. 2007; Mavon et al. 1998). A study of ten different sites (Afifi et al. 2006) was confirmed that the skin with poor sebaceous lipids is a hydrophobic surface ($\theta_w = 91^\circ - 102^\circ$). On the rich sebaceous zones, the skin becomes hydrophilic ($\theta_w = 60^\circ - 85^\circ$) (Fig. 6). Fotouh et al. (Fotouh et al. 2007) showed that the forehead skin wettability is significantly different ($p < 0.05$) between Black people (Africans or Caribbeans) ($\theta_w = 71^\circ$) and Mixed races (African or Caribbean) ($\theta_w = 67^\circ$) and Caucasians ($\theta_w = 67^\circ$). The water contact angle θ_w was recently measured on the forehead of 60 children (aged 7–11), and the results showed a $\theta_w = 87^\circ$ higher than adults indicating the skin is more hydrophobic than adults. Note that the sebum level measured on these children was particularly low ($17 \mu\text{g}/\text{cm}^2$) (Lodge 2007; Mac-Mary et al. 2012a).

Nail: The in vivo evaluation of the nails shows that human nail is a hydrophilic surface with a $\theta_w = 65^\circ$ (Fig. 7). No significant difference has been found between different ethnicities (France, China, Iran, Morocco) or different sexes (Elkhyat et al. 2010).

2.3.2 Critical Surface Energy γ_c and Hydrophobic/Hydrophilic Balance (Ho/Hi)

The skin hydrophobia increases by decreasing γ_c . Just like θ_w , the critical surface tension (γ_c) values show that in the presence of sebum, the skin is less hydrophobic. On the forearm, γ_c is about

Fig. 6 Human skin wettability: effect of sebum on hydrophobic/hydrophilic balance

Fig. 7 Nail: hydrophilic surface with water contact angle = 65°

26–27.5 mJ/m² (Rosemberg et al. 1973; El-Shimi and Goddard 1973; Ginn et al. 1968; Adamson et al. 1968; Elkhyat et al. 1996), and on the forehead, as a rich site in sebum, γ_c increases (33.2 mJ/m²) indicating an increasing of skin

wettability. According to Eq. 3, the percentage of hydrophobia H_o of the forearm is between 62 % and 64 %, while the presence of sebum on the forehead reduces the skin hydrophobia to 54 %.

2.3.3 Surface Free Energy (γ_s)

The surface wettability increases with increasing γ_s .

The γ_s value of the skin at the forearm is approximately 38.5 mJ/m² (Elkhyat et al. 2001; Mavon et al. 1997), while on the forehead, it ranges between 42 and 46 mJ/m² according to the skin type (oily, normal, dry skin) (Mavon et al. 1998). The use of the acid-base approach shows that the forehead (sebum-rich area) is a strongly monopolar basic surface ($\gamma_s^- = 26$ mJ/m²) and that the forearm (sebum-poor area) is a

weakly basic surface ($\gamma_s^- = 4 \text{ mJ/m}^2$) (Mavon et al. 1998). The γ_s increasing on the forearm is noticed by the increasing of the apolar component γ_s^{LW} (+10 mJ/m^2).

2.4 Effects of Some Treatments (Table 1)

The skin hydrophobia increases with the increase of θ_w and γ_c and decrease of γ_s (Elkhyat et al. 2001; Mavon et al. 1998).

2.4.1 Degreasing and Washing

Skin: Degreasing with organic solvents or washing with soap and water increases considerably the skin hydrophobia. This effect is observed by increasing the water contact angle θ_w (+10–15°) while reducing the free surface energy γ_s and the critical surface energy γ_c (Mavon et al. 1998). The initial skin hydrophilia of the forehead was found 2 h later after degreasing, time required for the reconstitution of the sebum current level (Mavon et al. 1998).

Nail: The degreasing of the nails with organic solvents also increases its hydrophobia ($\theta_w = +25^\circ$) (Fig. 8) (Elkhyat et al. 2010).

Hair: Virgin hair shows a mean thickness of 1.1 nm. The outermost layer of virgin hair surface is primarily made of a fatty acid called 18-methyleicosanoic acid (18-MEA), which strongly contributes to the hydrophobicity ($\theta_w = 103^\circ$) and lubricity of virgin hairs (Lodge 2007). Due to its hydrophobicity, the virgin hair surface is lacking of any water film, and therefore, the water film thickness measured on the surface is very low. Damaged hair, however, is slightly hydrophilic due to the removal of the fatty acid layer during damaging process ($\theta_w = 50^\circ\text{--}80^\circ$) (Lodge 2007).

2.4.2 Application of Moisturizers (Cream, Thermal Water)

Our skin needs an adequate daily fluid intake to replenish the water stock in the dermis (dehydration will induce the loss of skin elasticity and increasing the skin folds). On the other hand, the skin should renew the hydrolipidic film essential for the appearance and also for the barrier function of the epidermis. Applying a moisturizer on the face of 60 children for 1 week showed a significant decrease in θ_w angle (-10°) indicating an increase in skin hydration (+15 arbitrary unit) (Mac-Mary et al. 2012a, b).

Table 1 Human skin wettability

	Volar forearm		Forehead	
	No treated	Degreasing “ether”	No treated	Degreasing “ether”
θ_w	80° (Wenzel 1936); 84° (Neumann and Good 1979)	92° (Neumann and Good 1979); 101° (Fowkes 1964)	57–73° (Elkhyat et al. 2004b); 60° (Elkhyat et al. 2004a)	84° (Fowkes 1964)
	88° (Fowkes 1964); 91° (Mavon et al. 1997)		67–71° (Schott 1893–1895)	
γ_c	26 (Afifi et al. 2006); 26.8 (Fotoh C et al. 2007)	21.6 (Mac-Mary et al. 2012a)	33.2	22.4
	27 (Mavon et al. 1998); 27.5 (Lodge 2007; Mac-Mary et al. 2012a) 30.6 (Neumann and Good 1979)			
Ho	62 % (Elkhyat et al. 2001)	70 % (Elkhyat et al. 2001)	54 %	69 %
γ_s	38.5 (Fowkes 1964; Elkhyat et al. 2001)	32.4 (Fowkes 1964)	42–46 (Elkhyat et al. 2004b)	34.5 (Fowkes 1964)

θ_w : Water contact angle, Ho: Surface hydrophobicity; γ_c : Critical surface tension (in mJ/m^2); γ_s : Surface free energy (in mJ/m^2)

Fig. 8 Nail: degreasing effects: contact angle improvement (90°)

The effect of moisturizers is also noticed by increasing the critical surface energy (γ_c) and free surface energy γ_s . The application of thermal water reduces the skin hydrophobia by reducing the θ_w (-10°). This effect disappears 30 min after application (Elkhyat et al. 2004a).

2.4.3 Other Applications

Nutritional supplement provides comprehensive care of the skin envelope of the healthy individual and well-being as well. The effect of a nutritional supplement on the dryness in postmenopausal women has been shown with decreasing the contact angle which was initially hydrophobic (Humbert et al. 2005). The presence of mucus layer makes the surface of the pork tongue significantly more hydrophilic (more wettable). This effect is noted by decreasing the angle θ_w (-27°) and increasing the energy γ_s ($+11 \text{ mJ/m}^2$) (Ranc et al. 2006).

2.5 Discussion

The skin wettability study shows clearly the role of hydrolipidic layer on the skin hydrophobia. The suppression or the alteration of this layer increases the skin hydrophobia. This capacity of the cutaneous lipids to increase skin wettability was attributed to the free fatty acids, especially to those existing in the sebum. By increasing the amount of squalene and paraffin in sebum, skin wetting was found to be increased (Gloor et al. 1973).

The *in vivo* quantification of physicochemical parameters of wetting nails has a potential value in the field of researches. The practical interest of drug penetration through transungual barrier function places these studies increasingly at the center of attention. The choice of intermediate films, including antifungals and varnishes, depends on the knowledge of these parameters.

3 Human Skin Friction Coefficient

The frictional behavior of the skin in contact with different materials plays a critical role in the sensory perception of them. The friction is extremely important in our perception of cosmetic application such as antiaging cream and moisturizers (Gee et al. 2005). The consumer exposure of the wide majority of cosmetic products is limited to dermal contact. While touching an object, a contact happens between our skin and the object; then the tribological properties of such a contact influence how an object is perceived. Sensory perception is an important factor in the decision-making process of consumers (Bongaerts et al. 2007).

The friction coefficient is the measurement of the level of sliding between two surfaces. The initial force to start the slide is called the “dynamic friction coefficient,” while the force necessary to continue this is called the “kinetic friction coefficient.” A high friction coefficient represents a weak slide, while a low friction coefficient indicates a good slide.

The review of the published literature on the skin friction shows a wide range of measured values of μ (Table 2). These differences indicate that the assessment of the friction coefficient of the skin is a highly complex problem. It involves skin elasticity, skin anisotropy, micro-topography, anisotropy of the skin relief leading to variation in testing conditions, and individual differences in measuring techniques. This last point can divide the test apparatus into two types of designs: one called incorporate linear motion, wherein a probe is pressed onto the surface and dragged across the skin in a straight line, and the other design is rotational and consists of a probe pressed onto

Table 2 Human skin friction coefficient (μ) – literature data

and rotated against the skin surface. The friction coefficient does not vary significantly with gender but varies considerably among the anatomical sites of the body (Cua et al. 1990; Elsner et al. 1990; Sivamani et al. 2003a); the age effect was also measured (Asserin et al. 2000; Elsner et al. 1990; Sivamani et al. 2003a). The friction coefficient is influenced by load (Asserin et al. 2000; Sivamani et al. 2003a; Koudine

et al. 2000; Ramalho et al. 2007); however, it is increased due to water application (El-Shimi 1977; Asserin et al. 2000; Sivamani et al. 2003b). On the other hand, the application of petrolatum and glycerine on the forearm and on the hand decreases the friction coefficient immediately, and this effect lasts for at least 1 h after application (Ramalho et al. 2007). The application of isopropyl alcohol (Sivamani et al. 2003a) and

washing with soap (Egawa et al. 2002) will dry the skin and decrease its friction coefficient. The finger has a friction coefficient (μ) ranged from 0.27 to 0.70 and varying among individuals due to different states of skin hydration (Derler et al. 2007). Recently, our group (Fotoh et al. 2007) showed a significant difference ($p < 0.05$) of μ measured on the forehead depending on the ethnic affiliation. In 2004 (Elkhyat et al. 2004b), we showed the influence of the hydrophobic and hydrophilic characteristics of sliding and slider surfaces on μ . In this study, the wettability parameters for six surfaces (volar forearm, Teflon, silicone impression material [Silflo], vinyl polysiloxane impression material resin, steel, and glass) were measured, and their influences were compared to the friction coefficient μ .

The tribometer was developed and validated (Elkhyat et al. 2004b; Fotoh et al. 2007; Ranc et al. 2006; Asserin et al. 2000) to characterize the friction properties between skin in vivo and different sliding surfaces. A sliding ball of 10 mm diameter was pressed on the ventral forearm with a constant normal load (F_N) of 0.1 N and then moved at a constant velocity of 0.5 mms^{-1} . In order to maintain surfaces as flat as possible, a short sliding distance of 10–15 mm was selected.

In this study, we showed that if the skin is rubbed against a hydrophobic surface such as Teflon, the friction coefficient (μ) is lower than when rubbed against a hydrophilic surface such as glass or steel: so the hydrophobic surfaces have the lowest friction coefficient.

4 Discussion

Frictional properties of human skin depend not only on the skin itself including its texture, suppleness, smoothness, and its dryness or oiliness (Lodén et al. 1992) but also on its interaction with external surfaces and the outside environment (Zhang and Mak 1999).

In this chapter, we saw the role of the skin hydrophobia in the skin friction coefficient. The largest hydrophobicity of the abdomen explains its lowest friction coefficient compared to the

forehead measured by Cua et al. (1990). Water application decreases the skin hydrophobia and consequently increases its friction coefficient measured by Egawa et al. (2002) and Sivamani et al. (2003b). The decrease of μ after degreasing (isopropyl alcohol) (Sivamani et al. 2003a) or after washing with soap and water (Egawa et al. 2002) is quite normal; indeed, these treatments increase the skin hydrophobia (Table 1), while the increased skin hydrophobia with aging or in atopic skins leads to low μ as reported in the literature (Asserin et al. 2000; Lodén et al. 1992).

The role of the surface lipids was speculated as one possible factor contributing to the frictional properties of the skin, and the correlation between μ and the skin lipid content was evaluated: Cua et al. (1995) showed that the skin lipid content plays a role in the frictional properties of the skin. Moreover, in the skin, the friction resistance depends on hydrophilic and lipophilic elements present on the cutaneous surface. Fotoh et al. (2007) assumed that the hydrophilic/hydrophobic balance of the cutaneous hydrolipidic film is different between the different ethnic groups studied. Black women could have a decreased skin friction coefficient as well as an increased cutaneous hydrophobicity comparatively to Mixed-race and Caucasian women.

5 General Conclusion

The exploitation of these parameters should allow to classify the different types of the skin according to their affinity with water, which is of major importance in biology as in cosmetology. These data should also be possible to guide the cosmetic formulation to discriminate the emulsions which cannot spread properly on the skin. Investigation of skin frictional properties is relevant to several research areas, such as skin physiology, skin care products, textile industry, human friction-dependent activities, and skin friction-induced injuries (Zhang and Mak 1999). Friction of skin forms an integral part of tactile perception and plays an important role in the objective evaluation of consumer-perceptible skin attributes (Wolfram 1983).

6 Conclusion

In cosmetic researches, the structure and the physicochemical properties of the skin, the nail, and the hair are of great interest. Studies of physicochemical parameters of wetting the skin bring a new look at the interactions between the formulations and keratin (or skin).

Up to now, these parameters are known as a fundamental tool to orient better the formulations. An average of evaluating certain activities or medicated cosmetics and knowledge of the physicochemical parameters of wetting the skin surface can provide useful information in the field of hygiene, cosmetics, and topical medications.

To date, the study of bio-tribological properties of human skin has attracted much attention, which is attributed to its importance in human daily life. A good understanding of skin friction is generally believed to have not only the potential benefits for the performance of conducting tasks but also the prevention of pain and discomfort (for instance, a good understanding of the mechanism between skin and various materials could help in avoiding the chance of getting blisters on the foot) (Liu et al. 2013).

1 Measurement of Skin Friction Coefficient

The skin friction coefficient represents the skin resistance against the movement of an object on the skin surface. The coefficient of friction (μ) is calculated as the ratio of the friction force over the normal load. The normal load and friction force are expressed in newtons (N), and the coefficient of friction is dimensionless $\mu = F_{\text{friction}}/F_{\text{normal}}$ (Naz et al. 2014). Many devices, including a tri-axial quartz force plate (Kistler, Winterthur, Switzerland) (Derler et al. 2007; Gerhardt et al. 2008), Revolt SkinTribometer (Veijgen et al. 2013a, b), Frictiometer[®] FR 770 (Courage-Khazaka, Cologne, Germany) (Zhu et al. 2011; Neto et al. 2013), and Measurement Technologies Skin Friction Meter (Aca-Derm Inc., California, USA) (Zhang and Mak 1999), are available for the measurement of skin friction coefficients. The principle and methods of these devices are similar. For Courage-Khazaka Frictiometer[®] FR 770, the flat tip of the probe is made of Teflon. The tip surface area contacting the skin is 2 cm². The normal force level is 0.7 N and rotation speed is 255RPM. During measurement, the Frictiometer[®] FR 770 probe is connected to an MPA5 unit which is linked to a computer. The skin friction

coefficient will be displayed on a computer monitor upon placing the probe on the surface of the skin. The unit for skin friction coefficient is arbitrary unit (au).

2 Factors That Influence Skin Friction Coefficient

2.1 External Determinants of Skin Friction Coefficient

2.1.1 Material

As stated above, the skin friction coefficient represents resistance of the skin against the movement of an object on the surface of the skin. Thus, the type of material in contact with the skin can affect the skin friction coefficient. For instance, among bamboo viscose, polytetrafluoroethylene, and cotton/polyester (50%/50%), cotton/polyester yielded the highest friction coefficient (0.43 ± 0.04 for cotton/polyester; 0.38 ± 0.04 for bamboo viscose; 0.30 ± 0.04 for polytetrafluoroethylene) when sliding on the inner forearm at the normal load of 14.6 ± 1.3 N (Gerhardt et al. 2009). The skin friction coefficient on the fingertip pad is lower for aluminum in comparison with rubber hoses (0.6 for aluminum and 0.9 for hoses), especially at a lower level of normal force (Seo and Armstrong 2009). Among aluminum, nylon, silicone, cotton, and pelite, silicone induced the highest skin friction coefficient (Zhang and Mak 1999). The skin friction coefficient is positively correlated with the surface energy of the material against the skin (Veijgen et al. 2013b). The skin friction coefficient is also different between sheet and knitted materials (Comaish and Bottoms 1971).

2.1.2 Temperature

Regarding the impact of ambient temperature on skin friction coefficients, the results are controversial. Both static and dynamic skin friction coefficients were positively correlated with ambient temperature (Veijgen et al. 2013a, b). In contrast, another study demonstrated that skin friction coefficients on the porcine skin were higher at room temperature than that at 45°C (Hills et al. 1994). Nevertheless, these evidences suggest that the

ambient temperature can affect skin friction coefficients. Hence, it is necessary to maintain a consistent ambient temperature when measuring skin friction coefficients.

2.1.3 Normal Force

Several studies showed that the normal force had a negative impact on skin friction coefficient (Veijgen et al. 2013b; Seo and Armstrong 2009; Koudine et al. 2000; Bobjer et al. 1993; Sivamani et al. 2003). For example, when the normal force levels ranged from 1 to 1,000 g, both dynamic and static skin friction coefficients on the abdomen decreased as normal force increased (Comaish and Bottoms 1971). Another study demonstrated a sharp reduction in the static skin friction coefficient in the forearm when the normal force levels were increased from 10 to 100 mN, while the dynamic skin friction coefficient only slightly declined (Koudine et al. 2000). Further reduction of the normal force levels from 200 to 800 mN only induced a minimum reduction in both the static and dynamic skin friction coefficients (Koudine et al. 2000). Seo et al. (Seo and Armstrong 2009) reported that the skin friction coefficient on the fingertip pad in contact with aluminum was 0.6 ± 0.4 at the normal force level of 1.6 ± 0.7 N, while skin friction coefficient was 0.4 ± 0.3 at the normal force level of 10.8 ± 1.3 N. But a further increase in the normal force level to 19.6 ± 1.9 N did not cause an additional reduction in the skin friction coefficient (0.4 ± 0.2). A negative correlation of the skin friction coefficients with the normal force was also demonstrated on various body sites (Zhang and Mak 1999).

2.1.4 Contact Surface Area

The surface of the skin in contact with the material can also affect the skin friction coefficient. Generally, the skin friction coefficient in the normal skin increases as the contact area increases (Comaish and Bottoms 1971; Bobjer et al. 1993; Warman and Ennos 2009). But following topical treatment of the skin with either paraffin oil or lard, skin friction coefficient was negatively correlated with contact area (Bobjer et al. 1993). In addition, the type of material in contact with the skin influences the relationship between the skin

friction coefficient and the contact area. For example, the skin friction coefficient was positively correlated with the contact surface area when in contact with polythene, whereas the skin friction coefficient did not vary with the contact surface area when in contact with wool (Comaish and Bottoms 1971).

2.2 Internal Determinants of Skin Friction Coefficient

2.2.1 Age

The association of the skin friction coefficient with age is inconclusive. Although studies showed that both dynamic and static skin friction coefficients varied significantly with ages (Veijgen et al. 2013a, b), no differences in the skin friction coefficients between young and aged subjects have also been demonstrated (Cua

et al. 1990, 1995; Elsner et al. 1990). Our studies demonstrated that the skin friction coefficients in both males and females changed over their lifetimes, particularly in females (Fig. 1; Zhu et al. 2011). As shown in Fig. 1a, skin friction coefficient on both the canthus and the dorsal hand of females gradually increased before the age 40 years and then declined over lifetime, while on the forehead, skin friction coefficient positively correlated with age (Fig. 1a, $R^2 = 0.03506$, $p < 0.001$). In males, skin friction coefficient on the forehead and canthus did not change dramatically over the lifetime (Fig. 1b). But skin friction coefficient on the dorsal hand of males increased from age 0 to 40 and remained unchanged thereafter. Collectively, these data suggest that the association of the skin friction coefficient with age is body site and gender dependent.

Fig. 1 Skin friction coefficient varies with age and body sites (this figure is modified from previous publication (Zhu et al. 2011)). (a) In females; (b) In males. Significant differences between body sites are shown in the figures. $N = 300$ for males and $N = 333$ for females

2.2.2 Body Sites

It is generally accepted that the skin friction coefficient varies with body sites although some study showed no significant variation among body sites (Zhang and Mak 1999). On the upper limbs, both static and dynamic skin friction coefficients vary significantly among the midventral forearm, mid-dorsal forearm, index finger pad, and dorsal hand (Veijgen et al. 2013b). Both static and dynamic skin friction coefficients are higher on the index finger pad than on the dorsal forearm (Veijgen et al. 2013a). Our study showed that the canthus displayed a higher skin friction coefficient than the forehead (Fig. 1). The skin friction coefficients were lower on the forehead than on the dorsal hand (Fig. 1). But another study demonstrated that the forehead exhibited the highest skin friction coefficient (Fig. 2). Skin friction coefficients also vary among fingers (Warman and Ennos 2009). The variation of skin friction coefficient with body site is gender dependent (Fig. 1a vs. Fig. 1b).

2.2.3 Gender

The gender differences in skin biophysical properties including skin friction coefficient have been well documented (Zhu et al. 2011; Cua et al. 1990; Man et al. 2009; Choi et al. 2007; Marrakchi and Maibach 2007), although some studies showed no gender differences in skin friction coefficient on various body sites (Gerhardt et al. 2008; Veijgen et al. 2013a; Cua

et al. 1990, 1995). Our recent study in a large Chinese population showed that there were differences in skin friction coefficients between males and females (Fig. 3). The gender differences in skin friction coefficients are age and body site dependent. For example, on the forehead, there was no difference in skin friction coefficient between males and females (Fig. 3a). In contrast, on the canthus and the dorsal hand, skin friction coefficients in females significantly differed from males (Fig. 3b, 3c). The biggest differences between males and females occurred at 31–60 years old on the canthus (Fig. 3b) and at 20–30 years old on the dorsal hand (Fig. 3c). Skin friction coefficients on the dorsal hand of males aged 0–10 years were significantly higher than those in females (Fig. 3c). Thus, the discrepant results from different studies could be in part due to the differences in subject ages and body sites.

2.2.4 Stratum Corneum Hydration

The impact of stratum corneum hydration on skin friction coefficients has been extensively studied. Skin friction coefficients in both males and females were linearly correlated with skin stratum corneum hydration. Moisturization of the skin induced a more dramatic increase in the skin friction coefficient in females than in males (Gerhardt et al. 2008), suggesting that the influence of skin hydration on skin friction varies with gender. The impact of moisturizers on skin friction coefficient

Fig. 2 Variation of skin friction coefficient with body sites (this figure is modified from previous publication (Cua et al. 1995)). $N = 29$

Fig. 3 Comparison of skin friction coefficient between females and males (this figure is modified from previous publication (Zhu et al. 2011)). (a) Depicts the differences between males and females on the forehead, (b) on the canthus, and (c) on the dorsal hand. Significant differences are shown in the figure

varies with their properties. For example, skin friction coefficient increased immediately after the addition of water to the skin and returned to normal level within 10–15 min (Sivamani et al. 2003; Highley et al. 1977; Nacht et al. 1981). Skin friction coefficients were raised up to twofold following topical application of moisturizers (creams) and remained elevated for up to 4 h (Sivamani et al. 2003). Mineral oil,

petrolatum, and glycerin could cause an initial reduction in the skin friction coefficient, followed by a marked increase (Highley et al. 1977; Nacht et al. 1981). The relationship between skin friction coefficient and skin hydration varies with gender and body sites. One study showed that skin friction coefficients were positively correlated with skin hydration on the forehead and dorsal forearm, but not on the abdomen, upper back, and

Fig. 4 Correlation of skin friction coefficient with stratum corneum hydration. (a, b, and c) represent the correlation of skin friction coefficient with stratum corneum hydration

in females, while (d–f) are in males. Statistical significances are shown in the figures

postauricular area (Cua et al. 1990). Our study has demonstrated that the skin friction coefficients on the forehead were positively correlated with skin hydration in males, but not in females (Fig. 4a vs. Fig. 4d). In contrast, on the canthus, skin friction coefficients were positively correlated with skin hydration in females, but not in males (Fig. 4b vs. Fig. 4e). In subjects with atopic dermatitis, the correlation of skin friction coefficients

with skin hydration was only found on the volar forearm and lower back, but not on the dorsal hand (Lodén et al. 1992).

2.3 Other Determinants

Besides the external and internal factors described above, there are many other determinants that can

affect the skin friction coefficient. Studies have shown that air humidity can positively impact both static and dynamic skin friction coefficients (Veijgen et al. 2013a), while skin temperature, hair on the skin, and evening measurement have a negative effect on the skin friction coefficients (Veijgen et al. 2013a, b). Regarding the relationship of epidermal permeability barrier function measured by transepidermal water loss (TEWL) to skin friction coefficients, studies showed that TEWL levels were associated with skin friction coefficients on the thigh and the palm in normal subjects (Cua et al. 1990) and on the lower back in atopic subjects (Lodén et al. 1992). Topical application of 10 % sebum decreased static skin friction coefficient between the skin and polythene, but increased static skin friction coefficient between the skin and wool (Comaish and Bottoms 1971). In normal human, skin friction coefficient between the skin and Teflon (polytetrafluoroethylene-based product) was linearly correlated with skin surface sebum content (Cua et al. 1995). Sweat could increase the skin friction coefficient, too (Bobjer et al. 1993). In females, the skin friction coefficient on the forearm was significantly higher in premenopause than postmenopause (Elsner et al. 1990). Additionally, the movement speed of the object on the skin was positively correlated with skin friction coefficient (Zhang and Mak 1999).

3 Summary

Skin friction coefficients can easily be measured. Since there are many internal and external factors that can affect the value of skin friction coefficient, a consistent environment and measurement device would be required in order to obtain comparable results. Age, gender, body site, and skin condition should be considered in the interpretation and comparison of the results.

1 Introduction

Dermoscopy, also known as epiluminescence microscopy (ELM) or dermatoscopy, is the non-invasive examination of the skin with a device that permits improved visualization of surface and subsurface structures enabling the clinician to recognize morphologic features that are not perceived by naked eye examination (Argenziano et al. 1999, 2002). With the ability to visualize a new dimension of colors and microstructures, the dermatoscope increases the clinician's sensitivity and specificity when differentiating benign from malignant skin lesions and recently has been shown to improve the recognition of a growing number of skin diseases in general dermatology (Argenziano et al. 2009). ELM also forms a link between macroscopic clinical observation and

microscopic dermatopathology allowing the clinician to increase their confidence in clinical judgment (Argenziano et al. 2003). Dermoscopy maximizes early detection while minimizing the unnecessary excision of benign skin tumors proving that this modality can be used to both lower unnecessary healthcare expenditures and more importantly decrease mortality of melanoma (Alexandrescu 2009).

2 Tools

The dermatoscope is a handheld monocular optical system that enables magnification (10×) of the skin surface with the aid of an illumination system, either polarized or nonpolarized. Polarized devices allow for unobstructed viewing of vascular and chrysalis structures and do not require the use of immersion fluid such as mineral oil, alcohol, or water. Nonpolarized devices require immersion fluid and provide better viewing of pseudocysts, blue-gray dots, and blue-white veil/structures. Most current commercially available devices utilize LED illumination and provide the ability to switch between polarized and nonpolarized viewing (Argenziano et al. 2002; Wang et al. 2008; Liebman et al. 2012). Digital dermoscopy is the process of attaching a dermatoscope to a digital camera system that allows for easy photographic documentation, high-definition capture of lesions for enlarged view on a computer screen, and storage for patient follow-up (Argenziano et al. 2009, 2003; Soyer et al. 2012, 2001; Salemi et al. 2012; Niederkorn et al. 2011). Videodermoscopy aids in monitoring high-risk patients who present with a plethora of pigmented skin lesions that need to be followed up regularly and is also useful in the examination of hair disorders. Skin lesions can be magnified up to 120×, and mole mapping software allows for organized quantification and localization of lesions (Ross et al. 2006a). Both digital dermoscopy and videodermoscopy can take advantage of the ability to consult a second opinion via teledermatology (Malveyh and Puig

2002). Dermoscopy is also useful in aiding reflectance confocal microscopy (RCM) as the structures viewed in dermoscopy allow for determining mapping location in RCM, both with correlating histopathologic features (Bassoli et al. 2010).

3 Colors

Dermoscopy allows for in-vivo evaluation of colors of the epidermis, dermal-epidermal junction, and papillary dermis that are not easily viewed with traditional naked eye examination. Colors play a key role in the evaluation of skin lesions as the color perceived by the viewer is relative to the location of melanin (chromophore) and other pigment in the skin. Black correlates to melanin located in the stratum corneum and the upper epidermis, light to dark brown in the epidermis, gray to gray-blue in the papillary dermis, and steel-blue in the reticular dermis. Blue color represents melanin deposition deeper in the skin layers. Red color is associated with an increased number or dilation of blood vessels, trauma, or neovascularization. White color is a result of regression or scarring (Braun et al. 2005; Reisfeld 2000).

4 Structures

The use of dermoscopy permits the visualization of a variety of structures that aid the clinician in assessing both melanocytic and non-melanocytic lesions (Soyer et al. 2001, 2012). They include the presence or absence of pigment network, local features, and vascular structures (Stolz et al. 2002; Menzies et al. 2003; Braun et al. 2005; Reisfeld 2000; Malveyh et al. 2007; Ferrara et al. 2002; Haliasos et al. 2010). The six most common morphologic types of vascular structures include comma vessels, dotted vessels, linear-irregular vessels, hairpin vessels, glomerular vessels, and arborizing vessels (Table 1) (Zalaudek et al. 2010a, b).

Table 1 List of the main vascular pattern as seen in dermoscopy

Vessel type (new terminology)	Description	Diagnostic significance
Comma vessels (linear curved)	Coarse vessels that are slightly curved, barely branching, and variable in both size and caliber	Mainly in melanocytic nevi, especially dermal nevi
Dotted vessels (dots)	Tiny red dots densely aligned next to each other	Spitz nevi, sometimes in seborrheic keratosis, rarely in thin AHM
Linear irregular vessels (linear straight; linear serpentine)	Linear, irregularly shaped, sized, and distributed red structures	Pyogenic granuloma and melanoma
Hairpin vessels (linear looped)	Vascular loops sometimes twisted and bending, usually surrounded by a whitish halo when seen in keratinizing tumors	Common in seborrheic keratosis and melanoma
Glomerular vessels (linear coiled)	Tortuous capillaries often distributed in clusters mimicking the glomerular apparatus of the kidney	Bowen disease; intraepidermal carcinoma
Arborizing vessels	Stem vessels of large diameter branching irregularly into fine terminal capillaries. Vessel color is bright red	Frequently in BCC
Crown vessels (linear serpentine)	Groups of orderly bending, scarcely branching vessels located along the border of the lesion	Sebaceous hyperplasia

4.1 Melanocytic Lesions (Criteria)

4.1.1 Pigment Network

Pigment network is made up of pigmented network lines and hypopigmented holes, which correspond to the presence or absence of melanotic pigment in the cells of the basal layer of the epidermis. Network lines correlate histologically to rete ridges that are thick and contain an abundance of melanin. Network holes correlate histologically to the suprapapillary plate that is thinner and contains less melanin deposition. The pigmented network can be typical or atypical (Johr 2002). The network may not be visible if the rete ridges are short or less pigmented. Areas devoid of any network type corresponding to the flattening of rete ridges are called structureless areas.

The pigment network can be observed individually or in combination of the any of the following patterns: reticular pattern, globular pattern, homogeneous pattern, and starburst pattern. Reticular pattern is the most common global pattern found in melanocytic lesions. It appears as a grid of line segments, honeycomb-like, and in different shades of black, brown, or gray. Globular pattern consists of variously sized, round to oval structures. Homogeneous pattern is characterized by

diffuse, uniform, structureless color filling most of the lesions. Starburst pattern is characterized by the presence of pigmented streaks and/or dots and globules in a radial arrangement at the periphery of a melanocytic lesion (Soyer et al. 2012; Braun et al. 2005; Johr 2002; Argenziano et al. 1998, 2011a).

4.1.2 Broadened Network

Broadened network is defined as localized pigment network in which the line segments are thickened and irregular (Johr 2002).

4.1.3 Atypical Pigment Network

Atypical pigment network is described as black, brown, or gray thickened and irregular line segments anywhere in the lesion. In melanoma it typically presents as a sharp cutoff or demarcation of the pigment network at the periphery of the lesion. The term “atypical” network has been recently defined as the presence of different type of network within a given lesion (Soyer et al. 2012; Johr 2002; Argenziano et al. 1998, 2011a).

4.1.4 Dots

Dots are defined as small, round structures less than 0.1 mm in diameter which may be black,

light or dark brown, gray, or blue-gray (Stolz et al. 2002; Menzies et al. 2003; Malvehy et al. 2007). Black dots originate from pigment accumulation in the stratum corneum and the upper epidermis. Brown dots correspond to focal melanin accumulations at the dermo-epidermal junction. Blue-gray dots, also known as granules, dust-like dots, or “peppering,” are caused by accumulation of loose melanin or fine melanin particles in melanophages or free in the deep papillary or reticular dermis (Ferrara et al. 2002; Zalaudek et al. 2009; Soyer et al. 2000; Stoecker et al. 2011).

4.1.5 Globules

Globules are defined as symmetrical, round to oval, well-demarcated structures that may be black, brown, blue, or red. They are larger than dots and correspond histologically to nests of pigmented benign or malignant melanocytes, clumps of melanin, and/or melanophages situated usually in the lower epidermis, at the dermal-epidermal junction, or the papillary dermis (Stolz et al. 2002; Menzies et al. 2003; Braun et al. 2005; Reisfeld 2000; Malvehy et al. 2007; Ferrara et al. 2002; Zalaudek et al. 2009; Soyer et al. 2000). In benign lesions they have relatively homogenous size and shape with even distribution and generally central localization. In comparison, malignant lesions present with globules of varying size and shape with asymmetric peripheral localization (Stoecker et al. 2011; Kittler et al. 2000).

4.1.6 Streaks

Streaks are defined as dark linear structures of variable thickness found at the periphery of a lesion (Stolz et al. 2002; Braun et al. 2005; Malvehy et al. 2007). Histologically they represent linear, heavily pigmented, junctional nests of atypical melanocytes (Ferrara et al. 2002; Soyer et al. 2000). Streaks can be found in both benign and malignant melanocytic lesions. They are specific for melanoma notably when they are unevenly distributed at the periphery of a lesion. Symmetrical arrangement of streaks around the entire lesion periphery is commonly found in

Spitz nevi but can also be seen rarely in melanomas (Argenziano et al. 1999b).

4.1.7 Pseudopods/Radial Streaming

Pseudopods, also known as radial streaming, are defined as radially oriented or bulbous, fingerlike projections of pigment at the periphery of a lesion. They are either connected to the pigment network or directly connected to the tumor body (Soyer et al. 2012; Malvehy et al. 2007; Johr 2002). They correspond to intraepidermal or junctional confluent radial nests of melanocytes. Asymmetric pseudopod arrangement is one of the most specific features of superficial spreading melanoma subtype (Menzies 2001).

4.1.8 Blotches

Blotches, also known as black lamella, are defined as large concentrations of melanin pigment that obscure the visualization of other dermoscopic features of a given lesion. Blotches with irregular borders, sharp demarcation, and peripheral arrangement in a melanocytic lesion are very suggestive of a melanoma (Soyer et al. 2012; Malvehy et al. 2007; Massi et al. 2001a).

4.1.9 Blue-White Veil/Structures

Blue-white veil/structures is defined as an irregular, indistinct, confluent blue pigmentation with an overlying white, ground-glass haze that does not occupy the entire lesion (Soyer et al. 2012; Menzies et al. 2003; Braun et al. 2005; Reisfeld 2000; Malvehy et al. 2007; Argenziano et al. 2011b). It corresponds histopathologically to an aggregation of heavily pigmented cells or melanin in the dermis in combination with compact orthokeratosis (Massi et al. 2001b).

4.1.10 Regression

Regression is defined as a white scar-like depigmentation, lighter than the surrounding skin, or peppering (Braun et al. 2005; Malvehy et al. 2007). Histologically regression correlates to fibrosis, loss of pigmentation, and numerous melanophages in the papillary dermis (Ferrara et al. 2002). Regression is commonly found in melanoma, but also nevi can show a variable amount of regression although a different

distribution of regression and the variably association with white color helps in differentiating between the two entities (Zalaudek et al. 2004).

4.1.11 Atypical Vascular Pattern

An atypical vascular pattern is described as linear-irregular and/or dotted red vessels that are not seen in areas of regression. Moreover, the presence of polymorphous vessels is referred as atypical vascular pattern, and this can be found in malignant lesions either melanoma or squamous cell carcinoma. (Zalaudek et al. 2010a, b).

5 Special Site

5.1 Acral Lesions

Melanocytic acral lesions have specific patterns because of the presence of particular anatomic structures inherent to these locations on the palms and soles. The four main patterns of acral lesions are parallel furrow, lattice-like, fibrillar, and parallel ridge (Soyer et al. 2012; Malvey et al. 2007). The parallel furrow presents with multiple parallel linear pigmentation in the sulci, or furrows, of glabrous skin. The lattice-like pattern presents with linear pigmentation that follow and cross the sulci, demonstrating a rectangular network of brownish lines punctuated by several whitish dots, similar in appearance to a string of pearls. The fibrillar pattern is characterized by numerous short and thin brown lines that are parallelly arranged and run oblique to the ridges and furrows. The parallel ridge pattern, pathognomonic for acral melanoma, presents as pigmented bands on the ridges that are broader than the whitish lines in between. In addition to the four main patterns, a combination of globular, nontypical, transition, and globulostreak-like patterns can be observed less frequently (Kokgil et al. 2012; Miyazaki et al. 2005).

5.2 Facial Lesions

Melanocytic facial lesions present with difficult evaluation for naked eye examination and benefit

from the use of dermoscopy. Because of the specific anatomy of facial skin characterized by numerous folliculo-sebaceous units and an effaced epidermis, lesions on facial skin reveal specific dermoscopic features (Soyer et al. 2012). Benign lesions typically present with pigmented follicles and pseudonetwork that is light brown to dark brown in color with symmetrical arrangement and absence of gray color that usually typify lentigo maligna, although it can be found also in non-melanocytic lesions. Specific melanoma criteria include annular-granular structures, asymmetrically pigmented follicles, rhomboidal structures, and gray pseudonetwork (Stante et al. 2005).

5.3 Non-melanocytic Lesions (Criteria)

5.3.1 Blue-Gray Ovoidal Structures

Blue-gray ovoidal structures are round to oval and often irregular in shape. Color ranges from brownish-gray to blue-gray (Soyer et al. 2012; Braun et al. 2005). They correlate histopathologically to heavily pigmented, solid aggregations of basaloid cells in the papillary dermis of superficial or nodular basal cell carcinoma, especially when found in the absence of melanocytic lesion criteria. This feature can also be found in melanocytic lesions (Ferrara et al. 2002).

5.3.2 Arborizing Vessels

Arborizing vessels are thickened, in-focus, branched red vessels that are highly specific for basal cell carcinoma. Typically, the caliber of the vessels decreases regularly from the origin toward the branching, arborizing thinner vessels (Soyer et al. 2012; Zalaudek et al. 2010a, b).

5.3.3 Milia-Like Cysts

Milia-like cysts are white or yellowish round structures that histologically represent intraepidermal horn globules or horn pseudocysts. Multiple milia-like cysts are a common finding in seborrheic keratosis. They can be observed in dermal nevi and melanoma, but usually they are

fewer in number (Soyer et al. 2012; Braun et al. 2005).

5.3.4 Comedo-Like Openings

Comedo-like openings are irregularly shaped, sharply well-circumscribed structures that can be brownish-yellow or brown-black that correlate histopathologically to keratin plugs within dilated follicular openings. They are commonly found in seborrheic keratoses (Braun et al. 2005; Ferrara et al. 2002).

5.3.5 Red Lacunae

Red lacunae are well-demarcated, round to oval structures that can be red, red-blue, dark-red, white, or black. They correlate histopathologically to dilated vascular spaces located in the upper dermis. Lacunae are commonly found in hemangiomas and angiokeratomas (Soyer et al. 2012; Braun et al. 2005).

5.3.6 Central White Patch

The central white patch is a well-circumscribed, round to oval, white area usually in the center of a firm lesion. It is highly diagnostic of dermatofibroma although it can be found in a wide range of lesions (Ferrara et al. 2002; Zaballos et al. 2008).

5.4 Diagnostic Algorithms

Since the inception and popularization of dermoscopy in clinical practice, many authors have published various methods to perform organized differential diagnosis of pigmented skin lesions. The most commonly used algorithms will be discussed below.

5.4.1 Pattern Analysis

Pattern Analysis is based on a two-step process, first to recognize whether a lesion is melanocytic or non-melanocytic and second to evaluate the lesion for specific criteria. This method requires much experience and hence led to the development of other methods that require less training

and experience to diagnose skin lesions (Braun et al. 2005; Johr 2002).

5.4.2 ABCD Rule of Dermatoscopy

The ABCD rule of dermatoscopy was developed in an effort to simplify the process of lesion analysis. Four criteria are used for diagnosing melanoma, asymmetry (A), borders (B), colors (C), and different structural components (D). It is a semiquantitative, mathematical approach that awards points for the criteria identified in a lesion and a formula to determine a total dermatoscopy score (TDS) that is suggestive of diagnosis of benign, high-risk, or high diagnostic sensitivity for a melanoma (Johr 2002; Argenziano et al. 1998). To determine the asymmetry (A) score, the lesion is visually divided into two 90° right-angle axes and assigned a score ranging from 0 to 2. A lesion that is completely symmetrical in shape, color, and structure receives a score of 0. A lesion that is asymmetric in one axis is given a score of 1 and a lesion that is asymmetric in both axes is given a score of 2. The weight factor for asymmetry is 1.3 and subscores range from 0 to 2.6. To determine border (B) score, the lesion is visually divided into eight pie-shaped segments, and then the number of segments that contain an abrupt cutoff at the margins or the peripheral pigment pattern is noted, and each segment with an abrupt cutoff is given a score of 1. The weight factor for border score is 0.1 and subscores range from 0 to 0.8. Colors (C) evaluated include white, red, light brown, dark brown, black, and blue gray. It should be noted that white should only be counted if it is lighter than the surrounding skin and not confused with hypopigmentation. Each color is assigned one point, a weight factor of 0.5, and subscores range from 0.5 to 3.0. Different structural components (D) include pigment network, structureless areas, dots, globules, and streaks. Structureless or homogeneous areas should be greater than 10 % of the lesion, and branched streaks and dots are only counted when more than two are clearly seen. Each component is assigned one point, a weight factor of 0.5, and subscores range from 0.5 to 2.5. TDS is calculated by multiplying the total points in each category by their weight

factors: $(A \times 1.3) + (B \times 0.1) + (C \times 0.5) + (D \times 0.5) = \text{TDS}$. A TDS score <4.75 is suggestive of a benign lesion, 4.8–5.45 suggestive of suspicious for melanoma, and >5.45 highly suspicious for melanoma (Stolz et al. 1994).

5.4.3 Menzies Scoring Method

The Menzies method scores 11 different criteria as either present or absent which aims to reduce the intra and interobserver errors seen when criteria are graded numerically. The method has two categories: negative and positive features, with two and nine features, respectively, for each category. For melanoma diagnosis both of the negative features must not be found, and in addition at least one positive feature must be present. Negative features include point and axial symmetry of pigmentation and presence of a single color. Positive features include blue-white veil, multiple brown dots, peripheral black dots and globules, radial streaming and pseudopods, scar-like depigmentation (regression), multiple colors (five or six), multiple blue/gray dots, and broadened network. It should be noted that peripheral dots and globules must be black, and pseudopods/radial streaming should not be scored if they are regularly symmetrically arranged around the lesion periphery. Colors to be scored include black, tan, dark brown, red, gray, and blue. White is not counted as a color (Menzies et al. 1996, 2003; Johr 2002; Argenziano et al. 2011a).

5.4.4 7-Point Checklist

The 7-Point checklist is a newer method described by Argenziano and colleagues to analyze lesions that has fewer criteria than pattern analysis and is less complicated than the ABCD rule of dermatoscopy. It works on a point system that is divided into major and minor criteria found in a skin lesion. Major criteria receive two points each, and minor criteria receive one point each. Major criteria include atypical pigment network, blue-whitish veil, and an atypical vascular pattern. Minor criteria include irregular streaks, irregular pigmentation, irregular dots/globules, and regression structures. Irregular pigmentation is defined as black, brown, or gray featureless areas with

irregular shape and/or distribution. A total score of 3 or greater has a 95% sensitivity of being a melanoma, and excision is recommended. This system is limited to aiding melanoma diagnosis and does not include criteria that aid in differentiating pigmented skin lesions that are non-melanocytic, such as seborrheic keratosis or basal cell carcinoma (Johr 2002; Argenziano et al. 1998). Under the revised 7-Point algorithm proposed by Argenziano and colleagues in 2011, excision is recommended if the total score is greater than 1 (Argenziano et al. 2011a).

5.4.5 3-Point Checklist

The 3-Point checklist is a recently proposed method that improves the diagnostic accuracy when screening for melanoma in nonexperts and encourages clinicians in specialties other than dermatology to use dermatoscopy in general practice. The checklist is based on a simplified dermoscopic pattern analysis and consists of three criteria: asymmetry, atypical pigment network, and blue-white structures (Soyer et al. 2012). The definition of asymmetry is of color and structure in one or two perpendicular axes, and an atypical network is defined as pigment network with irregular holes and thick lines. The 3-Point checklist enables a clinician to have a sensitivity and specificity result comparable with the other algorithms that require much more training. In the original study the sensitivity of some of the nonexperts reached up to 96.3 %, and statistical analysis showed that the presence of any two of these criteria indicates a high likelihood of melanoma (Soyer et al. 2004; Zalaudek et al. 2006).

6 Applications

6.1 Skin Cancer

6.1.1 Melanoma

Melanoma-specific dermoscopic criteria include atypical network, irregular streaks, irregular dots/globules, irregular blotches, and blue-white structures. Specifically an atypical network with sharp cutoff at the lesion periphery, irregular dots

and globules that are unevenly distributed, irregular blotches that are well demarcated with irregular borders at the periphery of the lesion, and blue-white structures that either encompass the majority of the lesion or present with asymmetrical organization are all very suggestive of melanoma diagnosis (Soyer et al. 2012). Other dermoscopic criteria found in melanoma include crystalline structures (fine shiny white streaks visible under polarized light dermoscopy), atypical vascular structures, and negative pigment network (hypopigmented lines make up the grid and dark areas fill up the holes) (Haliosos et al. 2010; Balagula et al. 2012).

6.1.2 Lentigo Maligna

Lentigo maligna presents with specific dermoscopic features due to the presence of specific anatomy of the facial skin (Soyer et al. 2012). These criteria are not found in non-facial melanomas: annular-granular structures, asymmetrically pigmented follicles, rhomboidal structures, and gray pseudonetwork. Annular-granular structures are multiple brown or blue-gray dots surrounding the follicular adnexa with an annular-granular appearance. Asymmetrically pigmented follicles are gray circles/rings of pigmentation distributed asymmetrically around follicular adnexa. Sometimes, the gray circles may contain an inner gray dot or circle. Rhomboid structures are thickened areas of pigmentation surrounding the follicles with a rhomboidal appearance (a rhomboid is a parallelogram with unequal angles and sides). Gray pseudonetwork is gray pigmentation surrounding the follicular ostia formed by the confluence of annular-granular structures. Early lentigo maligna can be challenging and may reveal as the only clue to the presence of gray color predominantly surrounding the follicles. For this reason, any flat lesion arising on the face and presenting gray color should be carefully analyzed and either biopsied or monitored. It is imperative not to perform any treatment before obtaining a clear-cut diagnosis (Stante et al. 2005).

6.1.3 Basal Cell Carcinoma

Basal cell carcinoma dermoscopic features include arborizing vessels (telangiectasias), blue-gray blotches or ovoid nests, multiple blue-gray globules, leaf-like areas, spoke-wheel areas, and ulceration or multiple erosion (Soyer et al. 2012; Braun et al. 2005; Tiodorovic-Zivkovic et al. 2010; Sanchez-Martin et al. 2012).

6.1.4 Squamous Cell Carcinoma

Squamous cell carcinoma dermoscopic features include glomerular vessels, hairpin vessels, linear-irregular vessels, targetoid hair follicles, white structureless areas, a central mass of keratin, and ulceration (Soyer et al. 2012; Zalaudek et al. 2012; Rosendahl et al. 2012) (Fig. 1).

6.1.5 Merkel Cell Carcinoma

This rare aggressive cutaneous tumor usually presents as a nonspecific pink to red nodule, and due to its absence of characteristic clinical features, diagnosis is often delayed. Although there are no specific dermoscopic patterns for MCC, recent studies have shown that the majority of lesions present with a dermoscopic polymorphic vascular pattern composed of milky-red clods/areas in association with one or more additional vascular structures suggestive of malignancy such as arborizing, linear-irregular, dotted, and glomerular vessels (Dalle et al. 2012; Harting et al. 2012).

6.2 Melanocytic Lesions

6.2.1 Spitz/Reed Nevi

Spitz/Reed nevi present dermoscopically with a globular, starburst, or homogenous pattern before the lesion begins to involute. Lesions may present with central black homogeneous pigment network or blue-white structures (Argenziano et al. 1999a; Soyer et al. 2012). The globular pattern presents with numerous globules of various shape and size

Fig. 1 Malignant tumors.

(a) Melanoma; dermoscopic features: asymmetry, atypical network, irregular streaks, irregular dots/globules, irregular blotches, blue-white structures, sharply demarcated border. (b) Lentigo maligna; dermoscopic features: annular-granular structures, asymmetrically pigmented follicles, rhomboidal structures, gray pseudonetwork. (c) Basal cell carcinoma; dermoscopic features: clearly defined thick caliber arborizing vessels. (d) Squamous cell carcinoma; dermoscopic features: glomerular vessels, linear-irregular vessels, white structureless areas, a central mass of keratin

that are evenly distributed with color varying from light to dark brown, black, and blue. The starburst pattern presents with symmetrically arranged streaks and/or pseudopods at the lesion periphery. Differential diagnosis includes malignant melanoma, which in comparison may present with asymmetrical arrangement of pseudopods and/or streaks (Braun et al. 2005; Ferrara et al. 2002).

6.2.2 Clark Nevi

Clark nevi have an infinite variety of dermoscopic presentations and benefit from computer-aided digital dermoscopy, which provides rapid and exact digitized recording of skin lesions so that minor structural changes can be sensitively monitored and followed over time. In patients who present with many atypical nevi, the use of dermoscopy allows for the detection of the ugly duckling sign, a nevus or nevi that stand out from the rest of the patients' lesions, and helps guide the clinician to biopsy appropriate lesions for

histopathologic analysis (Soyer et al. 2012; Argenziano et al. 2011c). In patients with multiple nevi, the application of the comparative approach can result in a better management of the patient and less surgical excisions of benign lesions. The comparative approach is the evaluation of all nevi in a given patient and the comparison between them in order to grade the ugliest ones (Roesch et al. 2006).

6.2.3 Congenital Nevi

Congenital nevi are defined as lesions that originate in utero. They typically present with reticular pattern which are commonly found on the lower extremities and the globular pattern which occurs more frequently on the head, neck, and torso. The size of these lesions permits to distinguish them as small (<1.5 cm), medium (1.5–19.9 cm), and large (>20 cm). Small- and medium-sized congenital nevi are fairly homogeneous in appearance, whereas large congenital nevi are often

heterogeneous, having multiple uniform islands of color and an irregular topography (Haliasos et al. 2010; Changchien et al. 2007).

6.2.4 Ink Spot Lentigo

Ink spot lentigo has a characteristic dermoscopic pattern. It presents as a bizarre-looking pigment network that is usually black in color, sharply demarcated, and in the absence of other criteria (Soyer et al. 2012).

6.2.5 Dermal Nevi

Dermal nevi dermoscopic features include papillomatous comedo-like openings and comma-like vessels. Manual compressibility and easy movement from side to side are clinical and dermoscopic features in favor of benign nature (Soyer et al. 2012).

6.2.6 Blue Nevi

Blue nevi dermoscopic features include a global pattern characterized by homogeneous pigmentation that is blue, blue-gray, blue-brown, or blue-black in the absence of pigment network (Soyer et al. 2012). Whitish scar-like depigmentation, which correlates histopathologically to fibrosis, can also be found (Ferrara et al. 2002). Differential diagnosis include nodular melanoma, cutaneous melanoma metastasis, pigmented BCC, Spitz/Reed nevi, hemangioma, dermatofibroma, and dermal nevus (Di Cesare et al. 2012; Ferrara et al. 2007).

6.3 Non-melanocytic Lesions and Others

6.3.1 Seborrheic Keratosis

Seborrheic keratosis dermoscopic specific features include milia-like cysts, comedo-like openings, and brown pseudonetwork (Soyer et al. 2012; Braun et al. 2005).

6.3.2 Actinic Keratosis

Actinic keratosis nonspecific criteria/patterns include red or brown pseudonetwork on a

background of sun-damaged skin (Soyer et al. 2012; Zalaudek et al. 2012).

6.3.3 Keratoacanthoma

Keratoacanthoma nonspecific criteria/patterns include central keratotic plug, diffuse whitish coloration surrounding polymorphous vessels, and red to black streaks that represent hemorrhage (Soyer et al. 2012; Rosendahl et al. 2012).

6.3.4 Hemangioma

Hemangioma dermoscopic features include red lacunae that are in close proximity, without the presence of melanocytic lesion criteria (Ghibaud et al. 2009).

6.3.5 Angiokeratoma

Angiokeratoma common dermoscopic findings include dark or red lacunae, whitish veil, and peripheral erythema with a hemorrhagic crust (Kim et al. 2012; Zaballos et al. 2007).

6.3.6 Pyogenic Granuloma

Pyogenic granuloma dermoscopic features include reddish homogeneous area, white collarette, white rail lines, and vascular structures such as red lacunae and telangiectasias. Unfortunately dermoscopy does not substitute histologic examination in this common benign, vascular lesion due to its difficult differentiation from amelanotic melanoma (Zaballos et al. 2010).

6.3.7 Dermatofibroma

Dermatofibromas have a wide range of presentation, but the most common dermoscopic specific pattern is a central white patch surrounded by a light pigmentation or delicate pigment network (Soyer et al. 2012; Zaballos et al. 2008).

6.3.8 Lichen Planus-Like Keratosis (LPLK)

Dermoscopic features of LPLK include diffuse and localized granular pattern composed of multiple blue-gray dots (regression), areas of uniform tan pigmentation, absence of brown globules, and

Fig. 2 Benign lesions. (a) Benign nevus; dermoscopic features: symmetrical/typical reticular network, central black lamella. (b) Seborrheic keratosis; dermoscopic features: milia-like cysts, comedo-like openings, brown pseudonetwork, hairpin vessels. (c) Dermatofibroma; dermoscopic features: central white patch, dotted vessels. (d) Lichen planus-like keratosis; dermoscopic features: diffuse granular pattern composed of multiple blue-gray dots (regression), areas of uniform tan pigmentation, absence of brown globules

areas of pigmented lesions such as seborrheic keratosis or solar lentigo. LPLK differential diagnoses include erythematous type mimicking an actinic keratosis, the papulo-keratotic type simulating a seborrheic keratosis, and the plaque-like type with clinical features of Bowen's disease or pagetoid basal cell carcinoma. The prominent regression structures may make it indistinguishable from lentigo maligna although the distinction between the two is not always reliable on a clinical-dermoscopic basis (Bugatti and Filosa 2007; Panizzon and Skaria 1990; Zaballos et al. 2005, 2006; Crotty and Menzies 2004) (Fig. 2).

6.3.9 Kaposi Sarcoma

Kaposi sarcoma dermoscopic features include bluish-reddish coloration, "rainbow pattern," and scaly surface. The patient's history is an important factor when considering such vascular-appearing lesions (Bugatti and Filosa 2007; Hu et al. 2009).

6.3.10 Eccrine Poroma

Eccrine poroma dermoscopic features include polymorphous irregular vessels, creamy-red

areas, and multiple red lacunes. The polymorphic vascular pattern can be composed of irregular linear vessels, glomerular vessels, hairpin vessels, and newly described arborizing vessels combining with small circular endings with flowery appearance (Altamura et al. 2005; Aviles-Izquierdo et al. 2009; Aydingoz 2009).

6.3.11 Trichoscopy

Clinical diagnosis of hair and scalp disorders is not always straightforward, and traditionally a scalp biopsy is warranted in certain conditions that are deemed difficult to assess with the naked eye. Dermoscopy, particularly videodermoscopy, has been shown to improve the evaluation of these disorders and allows for the easy visualization of hair shafts of different types, hair follicles, cutaneous microvessels, and abnormalities of scalp color and structure (Ross et al. 2006a, b; Rudnicka et al. 2011; Mathew 2012).

6.3.12 Alopecia Areata

Alopecia areata trichoscopy features include yellow dots, black dots, micro-exclamation mark hairs, tapered hairs, upright regrowing hairs,

pigtail regrowing hairs, vellus hairs, and broken hairs. Yellow dots are predominant in long-lasting alopecia and are characterized by distention of the affected follicular infundibulum with keratinous material and sebum. Black dots and micro-exclamation mark hairs are markers of high disease activity (Ross et al. 2006b; Kowalska-Oledzka et al. 2012).

6.3.13 Cicatricial Alopecia

Cicatricial alopecia trichoscopy features include white and milky-red areas lacking follicular openings (Rakowska et al. 2012).

6.3.14 Androgenic Alopecia

Trichoscopy features include predominance of abnormalities in the frontal area, compared to the occipital area, which include increase proportion of thin and vellus hairs, hair shaft thickness heterogeneity, perifollicular discoloration (hyperpigmentation), and presence of a variable number of yellow dots (Rudnicka et al. 2011).

6.3.15 Tinea Capitis

Tinea capitis trichoscopy features include corkscrew hairs, comma hairs, and recently zigzag-shaped hairs with transverse structure gaps (Ross et al. 2006b).

6.3.16 Trichotillomania

Trichotillomania trichoscopy features include decreased hair density, short vellus hairs, broken hairs with different shaft lengths, coiled hairs, sparse yellow dots, and no exclamation mark hairs. Specifically in the differentiation of patchy alopecia, the absence of exclamation mark hairs suggests a diagnosis of trichotillomania (Ross et al. 2006b; Mathew 2012).

6.4 Inflammatory and Infectious Diseases

Dermoscopy is a useful tool in diagnosing inflammatory skin disorders and infectious diseases where unusual presentations precipitate difficult differentiation. Particularly the improved

visualization of vessels and color variegations and other structures that are difficult to recognize with the naked eye allow for improved clinical judgment. Dermoscopy can also be applied to entomology, termed entomodermoscopy, where such a modality can magnify structures not easily visible with the naked eye (Lallas et al. 2012a, 2013; Zalaudek and Argenziano 2006; Tschandl et al. 2009).

6.4.1 Discoid Lupus Erythematosus

Discoid lupus erythematosus represents the most common subtype of cutaneous lupus erythematosus, and the use of dermoscopy aids in the differential diagnosis of other scarring alopecia etiologies. The most commonly found dermoscopic criteria are perifollicular whitish halo, follicular keratotic plugs, and telangiectasias. In scalp lesions, follicular red dots are specific for active lupus erythematosus (Lallas et al. 2013; Tosti et al. 2009).

6.4.2 Lichen Planus

Lichen planus presents with the pathognomonic pattern of white-crossing lines (Wickham striae) surrounded by dotted or linear vessels (Lallas et al. 2012a; Zalaudek and Argenziano 2006; Todorovic-Zivkovic et al. 2012).

6.4.3 Reticulohistiocytosis

Reticulohistiocytosis dermoscopic features include homogeneous pattern with various shades of yellow (setting-sun pattern), brown reticular structures, and central white scar-like patches and streaks. The most commonly found pattern is the homogeneous sun-setting pattern with various shades of yellow in combination with brown reticular structures. Dermoscopic differential diagnosis includes dermatofibroma (Kacar et al. 2010).

6.4.4 Granuloma Faciale

Granuloma faciale is a rare benign form of chronic leukocytoclastic vasculitis that can have serious cosmetic implications due to difficult treatment. While there are no specific criteria for this disease, dermoscopic features include focused elongated

vessels (telangiectasias) associated with a translucent white-gray background intermingled with whitish streaks (Caldarola et al. 2011).

6.4.5 Psoriasis

Psoriasis, especially when it presents with isolated lesions, renders diagnostic challenge when differentiating other dermatoses, namely, seborrheic dermatitis. Dermoscopic patterns of psoriasis include red dots or globules arranged in a homogeneous, regular, or ringlike fashion, twisted red loops, glomerular vessels, and an association with diffuse white scales (Ross et al. 2006a, b; Lallas et al. 2012a; Zalaudek and Argenziano 2006; Vázquez-López et al. 2007; Kim et al. 2011).

6.4.6 Seborrheic Dermatitis

Seborrheic dermatitis dermoscopic features include arborizing vessels, atypical red vessels with the absence of red dots and globules, and featureless areas devoid of any particular vascular patterns (Ross et al. 2006b; Lallas et al. 2012a; Kim et al. 2011).

6.4.7 Pityriasis Rosea

Pityriasis rosea dermoscopic features include yellowish background, structureless center, dotted vessels, and peripheral scales (collarette scaling) (Lallas et al. 2012a; Chuh 2001).

6.4.8 Lupus Vulgaris

Lupus vulgaris dermoscopic features include orange to golden pigmentation with sharply circumscribed linear telangiectases and white, net-like lines (Tschandl et al. 2009; Brasiello et al. 2009).

6.4.9 Mycosis Fungoides

Mycosis fungoides dermoscopic features include short, linear vessels, orange-yellowish patchy areas, and a characteristic vascular pattern composed of a dotted and a short, curved linear vessel. Differential diagnosis includes chronic dermatitis, where dermoscopy shows the absence of orange-yellowish patchy areas and instead the presence of white or yellow surface scales (Lallas et al. 2012b).

6.4.10 Molluscum Contagiosum

Molluscum contagiosum may present as a single or several small, inflamed difficult to diagnose lesions. Dermoscopic features that may aid in its diagnosis are presence of orifices, vessel subtypes (crown, radial, and punctiform), and the newly described vascular flower pattern (Tschandl et al. 2009; Ianhez et al. 2011; Vázquez-López et al. 2004).

6.4.11 Tinea Nigra

Tinea nigra dermoscopic features include fine light brown in part clustered lines suggestive of a reticular pattern. Differential diagnosis includes acral melanoma (Ross et al. 2006a; Tschandl et al. 2009).

6.4.12 Tunga Penetrans

Tunga penetrans dermoscopic features include a white to light brown nodule with a black pore surrounded in a targetoid fashion by a brown ring. The central pore corresponds to the posterior part of the exoskeleton of the sand fly (Tschandl et al. 2009).

6.4.13 Trichomycosis Palmellina

Trichomycosis palmellina dermoscopic features include yellowish translucent granuloma-like crusts that are found around the hair shaft. Differential diagnoses include lice infestation and deodorant debris or scales on axillary or pubic hair (Tschandl et al. 2009).

6.4.14 Furuncular Myiasis

Furuncular myiasis, caused by *D. hominis*, is a disease inherent to South America that has a difficult clinical differential diagnosis of boils, epidermoid cysts, and abscesses (Tschandl et al. 2009). Dermoscopy can help to confirm the suspected diagnosis in such lesions by providing clearer visualization of the parasite. Dermoscopic features include visualization of the posterior segment of the larva with its breathing spiracles looking like birds feet, seen in the center of a creamy-white body surrounded by black dots shaped as a thorn crown, which represents small spines in a circular row (Abraham et al. 2011; Llamas-Velasco et al. 2010; Bakos and Bakos 2007).

6.4.15 Scabies

Scabies dermoscopic features include small, dark, triangular structures and a subtle linear segment that can be seen below the base of the triangle. In combination both structures resemble a jet with contrail. The triangular structure corresponds to the pigmented anterior section of the mite (Tschandl et al. 2009; Argenziano et al. 1997).

6.4.16 Ticks

Dermoscopy provides a convenient magnification and allows for confirmation of the diagnosis in cases of a doubtful situation due to the small size of ticks. It is also useful to find out whether the tick has been completely removed from the skin, specifically to assess whether the tick has lost its hypostomes (Tschandl et al. 2009; Oiso et al. 2010).

6.4.17 Nits and Pseudonits

Vital nits are seen dermoscopically as brown, ovoid structures with a convex end. Empty or hatched nits are translucent with a planar end. Pseudonits are visualized dermoscopically as white bizarrely shaped, amorphous structures that may represent peripilar keratin casts due to dandruff (Zalaudek and Argenziano 2012).

6.4.18 Viral Warts

Dermoscopic features of plantar warts include red or black dots on a white-yellow base detected in the dermis that correspond to capillary loops in the papillary dermis that supply the wart (Tschandl et al. 2009; Lee et al. 2009).

of skin tumors, defining the specific dermoscopic features that help to correctly identify them while reaching a high diagnostic accuracy. Dermoscopy has also found its application in inflammatory skin diseases and infectious diseases, demonstrating that all histologic substrates render a specific dermoscopic pattern. Future directions imply the combination of dermoscopy with devices that may offer a deeper evaluation of skin architecture, and in this scenario, confocal microscopy may represent the perfect link between dermoscopy and histopathology (Longo et al. 2012).

7 Conclusion

Dermoscopy, also called dermatoscopy, opened a new era for dermatologists and general practitioners actively working in skin oncology aiming to diagnose theoretically all melanomas and trying to avoid the surgical excisions of nevi looking as melanoma. Several publications, over 2,000 in the last 20 years, discovered the morphologic universe

KeywordsDigital photography • Aesthetic dermatology

1 Introduction

Digital photography offers interesting opportunities to dermatologists involved in aesthetic dermatology: low cost, flexibility, easiness and speediness of use, and possibility of computerized record keeping (Ali 2002; Becker 1999). A considerable number of applications have been developed to meet the needs of users and to automatize the most frequently used functions (image cropping or renaming, conversion into a different format, inclusion in a database, etc.), and most of these applications are free. The digital environment of photography has never been so performing and ergonomic.

However, a digital camera, regardless of its capacities, remains a camera with its own limits and constraints. Users should not ignore the basic rules of photography: exposure, aperture, shutter speed, and depth of field. These notions have always been and are still essential.

2 Fundamentals

In a digital camera (DC), as opposed to a classic camera (Daniel 2000), the film is replaced by a CCD (charge-coupled device) sensor composed of a multitude of photo sites (4–10 μm) sensitive to light (Bouillot 2005). These sites or photodetectors convert the photons that they receive into electrons by photoelectric effect, and these electrons will accumulate like in a basin. The number of electrons stored in each photo site is proportional to the intensity of light received. All detectors deliver an electric tension which can be converted and analyzed by the electronics and the software of the device. The CCD sensor is at the heart of the DC; its manufacturing quality and electronics determine the quality of the photograph which depends on the number of photo sites, therefore on the available points or pixels.

Current devices have more than 10 million pixels, and cameras with 16 million pixels are now commercially available (Canon Eos Mark II has a 24×36 mm CMOS sensor of 21 million pixels and achieves $5,616 \times 3,744$ pixel images). Photographs taken with such a resolution are of great definition, as beautiful on the panoramic monitor of a computer as on a large paper print (140 \times 120 cm minimum).

This CCD sensor can be fit into three main types of casing corresponding to three categories of DC: compact, bridge, and reflex. Compact cameras were originally entry-level digital cameras, but this is not the case any longer. As its name obviously reveals, it is made of a thin and light box (some models are waterproof and shock-proof) including a built-in motorized objective lens, and sometimes a $\times 4$ to $\times 7$ zoom lens. It is usually preset and automated so that the user has almost nothing to do to take a satisfactory photograph (Canon Powershot, Panasonic Lumix, Nikon Coolpix).

In a bridge camera with electronic viewfinder, an LCD (liquid crystal display) screen is fit behind the ocular like on a video camera (it is called digital back). The viewfinder is therefore not optical and is cheaper to manufacture than the actual reflex finder. A more powerful zoom lens ($\times 30$) is attached to the camera body which often includes a stabilized optical system. Like a compact camera, this type of DC can record a video or even a high-definition film (Fujifilm FinePix, Olympus SP100, Pentax X90). Finally, in a reflex camera, the image formed by the objective is sent back toward the viewfinder and its ocular system. The image seen in the finder and by the CCD sensor is therefore the same. The body of this type of camera is usually larger and more cumbersome, but all its objectives and flashes are interchangeable, and any framing or angle is therefore possible. Reflex cameras are beyond any doubt the preferred option to take photographs on a professional level (Canon Eos, Nikon, Sony Alpha). Their technological superiority over the other categories of DC in terms of sensitivity, color reproduction, and reactivity is unquestionable.

3 Settings and Basics of Photography

Basic principles are similar in digital photography and in film photography for the process before the CCD sensor (Bouillot 2003). The following optical and photographic notions are presented in the specific context of photography of the skin in medical practice.

3.1 Light and Exposure

To take a good photograph, one condition is crucial: the right amount of light is necessary, no more no less (Sainthillier et al. 2009, 2012). In this context, exposure is defined as the exposure to light of the sensitive surface that will record the image. It corresponds therefore to the amount of light transmitted to the CCD sensor or to the film. If there is too much light, the photograph is “burnt” or overexposed; details disappear and are replaced by white saturated surfaces. If there is not enough light, the photograph is too dark or underexposed; details disappear in black zones. In both cases and in spite of the possibilities given by photo editing software programs, missing information is definitively lost.

3.2 Shutter Speed

The shutter is an electronic system designed to control the time of exposure, i.e., the period during which the light penetrates the camera and reaches the sensor. It may be compared to an opaque curtain which makes the chamber where the CCD is located completely dark. When the photograph is taken, the shutter opens (lifts up) for a certain time to let in an amount of light through the aperture of the diaphragm. The shutter speed is composed of seconds and fractions of seconds. High shutter speeds (above $1/250 = 1/250$ th of second) are interesting for photographs of moving subjects. In static photography, the speed is usually set up at $1/60$. To avoid a blurry image, settings under $1/60$ are not recommended

(or the camera should be placed on a tripod to ensure stabilization).

3.3 Aperture of Diaphragm and Objective Lens

The lens of the device uses a diaphragm to dose the light entering the camera body. The aperture is between $f/1$ (wide aperture) and $f/32$ (small aperture). The letter f designates the quotient resulting from the division of the focal length by the aperture diameter of the diaphragm. For a given shutter speed, the amount of light penetrating the camera is multiplied by 2 when diaphragm settings are higher. A large aperture will let more light in, but it will also reduce the depth of field, i.e., the space between the foreground and the background where the photograph remains clear (Taheri et al. 2013). This can have a perturbing effect on the face, for example, because of its relief. If the focus is on the cheekbone, the nose and the forehead are blurry. A small aperture gives a large depth of field, but the flow of light reaching the CCD sensor is lower (Fig. 1).

The larger the aperture, the more luminous the viewfinder, and therefore, the more the lens can be used in difficult conditions, in poor light, or associated to higher shutter speeds. Manual and autofocus are also facilitated. The optical quality of a lens is globally based on its maximal aperture: 50 mm $f/1.8$

Fig. 1 In this extreme example ($F/4$, $1/60$, ISO 400), the effect of the wide aperture on the depth of field is visible. The lips are clear, but most of the image in the background is blurred (not retouched image)

is common (130 €), 50 mm f/1.2 is excellent (600 €), and 50 mm f/1 is superior (3,000 €).

Shutter speed and aperture are therefore closely associated. It is possible to maintain the same quality of global exposure by using various combinations of aperture and speed. This is called the law of reciprocity. For one photographed scene, there are several possible combinations to achieve the adequate exposure of the sensor. It is therefore possible to let the light in for a long time (e.g., 1/30) with a small aperture (f/11 for instance) or let the light in for a very short time (1/500) with a large aperture (f/2.8). In both cases, the CCD sensor will receive exactly the same amount of light; exposure is the same.

3.4 Focal Length and Zoom

The focal length expressed in millimeters designates the distance separating the photosensitive surface of the sensor from the optical center of the lens. The focal length of the lens allows to frame the photographed subject more or less accurately and is broadly defined according to three categories:

- Wide angles (28–35 mm), i.e., short lengths, tend to distort perspective with an angle of vision that is more important than the human eye angle of vision.
- Standard focal lengths (38–70 mm) are close to the angle of vision of the human eye and are the most widely used.
- Long focal lengths (80–200 mm) and teleobjectives with very long focal lengths (over 200 mm).

A zoom lens or lens with variable focal length is able to vary the focal length within specific limits and therefore to reframe the image without changing position and without altering resolution.

Some cameras have a function called “digital zoom.” It is in fact a software program; it increases the size of the digital image, not the actual image, through an interpolation method. This zoom lens is not relevant for photography in aesthetic dermatology and must be avoided.

3.5 Focus

In most cameras, it is an autofocus system triggered by gently pressing the push button. To get optimal focus, the contrast must be sufficient (it is difficult to operate the autofocus on a very homogeneous skin surface) or lighting must be adequate. In autofocus mode, detection points will not be found if the skin is not sufficiently exposed to light. In addition, the autofocus can be released and the focus can be activated manually in some circumstances.

3.6 Lighting and Flashlights

As indicated previously, light is the fundamental element in photography. In aesthetic dermatology, lighting must be sufficient to ensure adequate sharpness, without flattening the relief or erasing imperfections and without creating shadows on the face (Meneguini 2001). It also has to be constant in between camera shots to ensure that comparison before and after treatment is possible, for example.

A flash is a source of artificial light synchronized with the shutter and has a powerful but very short duration of lighting. Its power theoretically protects the DC from the influence of the changing character of ambient light. Its range is 0.5–3 m approximately. The built-in flash unit is usually not sufficient, and an additional flash unit can generally be mounted on an accessory shoe on top of the camera body. The additional flash unit is either more powerful (Canon Speedlite range) or not synchronized. Circular, annular, or twin flashes (Canon MT-24EX or METZ Mecablitz) are also very interesting. They ensure powerful, diffuse, and homogeneous lighting.

For entry-level models, it is also possible to adapt a flash diffuser (Delamax). It is a more or less rigid and transparent white case that is placed on top of the flash unit. Reflecting kits (Lumiquest Soft Screen) are also available at reasonable prices.

3.7 ISO Sensitivity

Photography requires light and a photosensitive surface. In traditional photography, this surface

is a film; in digital photography, it is an electronic sensor. The sensitivity of the support can be changed to adapt it to various lighting conditions.

The ISO speed (International Standards Organisation) replaces the old measuring systems (DIN, ASA) and identifies the sensitivity of a support. In normal conditions of daylight, the standard is set at 100 ISO. The higher the ISO speed (200, 400, 800, etc.), the more sensitive the support is to light, but the more the texture of the image is visible. A key point to remember is that the quality of the image is inversely proportional to the sensitivity of the sensor.

3.8 Polarization Filters

Some polarization filters are of interest to dermatologists because they break down the reflection of the light on the skin according to its diffuse or

specular component (brightness) (Bargo and Kollias 2010; Matsubara 2011). These filters are fixed on the flash units and on the lenses (HOYA circular filters). Depending on the orientation of the filter, parallel or cross polarization is obtained (Fig. 2).

- Parallel polarized light reveals and accentuates the skin irregularities and microrelief. Brightness and contrast are increased, whereas colorimetric data are lost. This type of lighting is used in the study of acne or to follow up scars or lesions that become more visible (Rizoca and Kligman 2001).
- In contrast, cross polarized light accentuates the color and saturation of the skin. Reflection and brightness of the skin are completely eliminated. This type of polarization is very useful in studies on vascular pathologies such as rosacea (Miyamoto et al. 2002) or on the effects of a whitening product.

Fig. 2 Photographs (details) in normal light (*top*), parallel polarized light (*centre*) and cross polarized light (*bottom*). In light, reflection is eliminated and vascularization is revealed.

In contrast, parallel polarization light accentuates reflection and brightness and gives the skin a metallic aspect

3.9 Reflection of UV Light

This type of lighting derives from Wood's work based on radiations found at the beginning and at the end of the visible spectrum (<450 nm) (Lucchina et al. 1996; Draelos et al. 2008). The flash unit produces UV-A without harming the volunteer. The resulting image provides visual evidence of the trace left by UV exposure. Several systems are commercially available (Canfield[®], Faraghan[®]). They operate with a DC set at maximum sensitivity (1600 ISO) in order to detect the very limited part of visible light emitted by the flash unit. This explains why these images are usually very dark (Fig. 3).

3.10 LCD Monitor

Color rendering by a DC depends mostly on the monitor used to visualize the photograph. LCD flat screens have now completely replaced previous cathode ray screens. The screens are now

very reactive with remanence under 5 ms, they are luminous, but they still present restricted angles of vision. Only panoramic screens are currently available (the ratio height/width, i.e., the format of the screen, is 16/9 or 16/10). A wide screen is recommended (24 or 26 in.), in 16/10, equipped with High-Definition Multimedia Interface (HDMI), allowing for an entirely digital audio/video interface (this implies to have also a graphic card with this interface). Asus, LG, and Iiyama provide very good quality monitors, and high-end screens can be found at Eizo (colorEdge) and NEC (SpectraView).

Calibration probes (Spyder3Pro of DataColor, i1Display LT of X-Rite) are used to ensure correct settings and adequate color rendering on a monitor. These probes of small size are fixed to the screen with suction pads and are directed by a software program that displays a series of known colors on the screen. The probe reads these colors and corrects the display deviations with a calibration profile or ICC (International Color Consortium) profile. This digital file

Fig. 3 Photographs in cross polarized light (*left*) and in UV light (*right*) taken with Visia[®] (Canfield) system. UV light reveals spots which are barely or not visible in normal light. UV photography is difficult to use because of its

sensitivity to environmental conditions. Images must be taken while lighting is neutralized (either in total darkness or in an integrated system like in this example). A piece of garment or a jewel may perturb the image contrast

describes how the screen reproduces colors; it is directly controlled by the operating system. The ICC profile can characterize a monitor, a scanner, or a printer.

Color rendering in video projection is more complex (Delmas 2005). Depending on the quality of the projector, the rendering of some colors (especially magenta) may be surprising. The same difficulties arise when images are printed. The quality of printer and paper has a considerable influence on color reproduction.

3.11 Integrated Devices or “Lighting Boxes”

In recent years, we have seen the arrival of integrated photographic systems to study the face, composed of the most recent camera inserted into a “box” with a lighting system, a support to maintain the chin and the forehead and a software program for image capture. The volunteer places his/her face inside the device (which is similar to an integration sphere) where it is lit in homogeneous and reproducible conditions. The aim of these systems (Visioface[®], Courage et Khazaka; Visia, Canfield[®]) is to obtain data for diagnostic purposes easily and speedily. They are of interest to dermatologists because they are comprehensive systems to take standardized photographs (Fig. 4).

Fig. 4 Example of integrated system “light box” (Visioface[®], C&K). This independent comprehensive system consists of a box fitted with a camera, white light LEOs, chin and forehead rests to position the face, and image capture software. Homogeneous illumination is given by mirrors (visible inside the box) which distribute the light evenly on the face

4 Use of Digital Photography in Clinical Practice

The DC is set in “automatic mode,” usually indicated on the mode control scroll wheel by a specific color. It calculates the aperture and shutter speed in relation to light exposure determined by a built-in exposure meter to find the ideal conditions. These constants are displayed in real time on the control monitor of the camera and in the viewfinder.

- If ambient light is adequate, the shutter speed will be between 1/60 and 1/125, the corresponding aperture of the diaphragm being f/5.6 and f/2.8, respectively. This is the

best compromise to take a photograph with satisfactory exposure. The settings are then adjusted automatically by the autofocus system, and the photograph is of good quality.

- If ambient light is low, the shutter speed is automatically set between 1/15 and 1/30 with identical apertures (f/5.6 and f/2.8). The risk of motion blur is in this case very high, and it is likely that the autofocus will not stabilize during settings.

What are the options?

- First solution: use manual settings and increase sensitivity (ISO) of the CCD sensor (e.g., set at ISO 200 instead of 100). Adjusting settings manually can also allow the user to take photographs with a shutter priority, by fixing the speed at 1/60 as a precaution to avoid motion blur. The camera will select the maximal adapted aperture to ensure correct exposure. The depth of field may then be seriously compromised.

- Second solution: add or increase the power of the flash unit (increase of power can be adjusted on high-end flash units). It is however essential to not overexpose the central part of the photograph. This option is rarely appropriate.
- Third solution: to mount the DC on a tripod (Manfrotto type). All DCs have an accessory shoe to fix or remove them very quickly. It is then possible to increase the shutter speed without risk and let the light in for a longer period of time.
- Fourth solution: to increase the lighting of the room, either with additional neon lights or studio flashlights (Multiblitz Profilux). This is an ideal choice for the intensive practice of photography in a clinical environment because it ensures identical lighting for each photographic shot, thus reproducibility.

5 Computer Management of Images

Before addressing this subject, it may be useful to review a few fundamentals of digital photography (Russ 2007; Gonzalez and Woods 2008). Basic rules of photography are of considerable importance in the treatments and corrections that will be carried out on the images at a later stage.

5.1 Coding and Color

A pixel is the smallest element constituting an image. It has a coded value which defines its color (chrominance) and its intensity (luminance). This code is quantified on a number of bits which is the smallest unit that can be processed by a computer: 8 bits = 1 octet. The amount of data on each pixel depends on the number of bits on which coding or quantification is performed.

For example, coding on 1 bit (0 or 1) defines only two possible colors for each pixel, without any tone, which corresponds to a black and white image. 8-bit coding is equivalent to 2^8 different intensities per pixel, i.e., 256 colors or levels of gray per pixel. 24-bit coding corresponds to present standards which attribute to each pixel three primary color components (red, green, blue, or

RGB coding), coded individually on 2^8 bits, giving a total of 2^{24} , equivalent to 16.7 million colors. In practice, the number of restituted colors depends on the quality of the screen and the graphic card. 32-bit coding has been available for a few years, but it requires computers at the highest end of the market.

5.2 White Balance

A new concept appears with the use of artificial lighting: color temperature. Each type of light includes a specific dominant color feature: rather orange for indoor lights (tungsten), bluish for daylight, whitish under overcast sky, or greenish under neon lights. Default automatic setting of color temperature for each photograph is done by the DC by trying to assess the lighting conditions; it is the auto white balance. If the adjustment is unsuitable, white, or neutral gray, look yellow or blue. It is possible to select the source of light in advance, so that it corrects the tone of the image. For these settings, a predetermined white balance adapted to the context of the shot is selected: incandescent light (halogen bulb), fluorescent tubes, sun (daylight), cloudy sky, and shadows. Reflex DCs can define a “personalized” white balance. For this adjustment, a white sheet (or a calibration gray card such as Kodak R27) is placed at the center of the scene. The camera is then set to adjust its balance from this photograph; these settings are saved in its internal memory.

5.3 Definition and Resolution

Definition and resolution are often confounded, but they refer to different features of an image.

Definition expresses the number of pixels or elementary points of an image in height (lines) and in width (columns). It is calculated by multiplying the number of lines and columns. An image of 3,000 lines and 4,000 columns has a definition of 12 million pixels.

Resolution defines the fineness of display or reproduction of the details of the image and

expresses the number of pixels that compose it by unit of length. Depending on the system of measurement used (either metric or customary), resolution is expressed in points per centimeter (ppc) and points per inch (ppp or dpi), respectively. One inch is equivalent to 2.54 cm; it is therefore easy to go from one system to the other. As a rule, the larger the number of pixels in a measurement unit, the higher the resolution. 300 ppp resolution provides a level of details much higher than 72 ppp resolution.

It is possible to adjust specifically the quality of image of a DC with internal settings (usually three levels of quality: fine, normal, and basic) that reduce the definition of the image gradually. This function was useful in the past when memory cards were very expensive and their capacity limited (high-definition images are very large and require a lot of space in cards). However, the latest flash cards (Compact Flash or SDHC Cards [Secure Digital High Capacity] of 16 or 32 Go) are affordable and can store several thousands high-definition photographs easily.

5.4 Main Image Formats

Among all the formats available in a DC, three are specifically designed for photography: JPEG, TIFF, and RAW. They are very different and require specific procedures.

JPEG (Joint Photographic Expert Group) format is the most widely used in DCs. Only reflex cameras and a few high-end compact cameras offer other saving formats. Its huge success lies mainly on its excellent compromise between storage size and image quality (the size of a noncompressed image is often divided by 10, or even more). JPEG has a lossy compression mode (i.e., with loss of data, which accounts for the efficacy of its compression algorithm) based on the perception properties of the eye and whose rate can be set by the user. The higher the rate or inversely the lower the quality of compression, the more important is the loss of data, hence the degradation of the captured image. Loss of data is mainly visible in variations of tones, on contours, but does not alter the rendering of the

variations of light. This degradation is cumulative (at each saving of the same JPEG file). Working on a JPEG file is therefore not recommended; it should be converted first into a format file of larger size, without altering data (TIFF files).

The **TIFF** (Tagged Image File Format) is an earlier graphic format which tends to disappear. It is able to store large size images (over 4 Go after compression) without impairing quality. It is independent from the operating system – which is an asset – and it can be found in PC, Mac, and Unix systems.

The **RAW** format is used in reflex cameras and high-end compact cameras (Canon PowerShot). Before creating the definitive file, the DC processes raw data issued from the sensor in order to correct some parameters such as the white balance. Then the data are converted into standard formats (TIFF or JPEG) and saved. In the RAW format, such preliminary treatments do not exist: the device creates a file with the raw data directly issued from the sensor. The captured photograph does not undergo any processing and has no compression-induced artifacts unlike with the JPEG format. In counterpart, this format has not really been standardized by the manufacturers (each new DC model induces a slight modification of the format and imposes an updating system), and it requires postproduction work with dedicated software (Adobe Lightroom, Photoshop CS6, or free software DC Raw). Finally, a RAW image has clearly a larger size than its copy in JPEG format.

As a reference, the size of a $3,504 \times 2,336$ image is approximately 2.23 Mo in JPEG (in fine mode), 23.4 Mo in TIFF, and 6.8 Mo in RAW.

EXIF (Exchangeable Image File Format) is a specification of file format incorporating metadata (data on data) for images in JPEG and TIFF formats. Metadata are tags embedded in the image file. They record the date and hour of the photographic shot, the settings (brand and model of DC, aperture, shutter, sensitivity, etc.), as well as GPS data if the camera has a geolocation system (Fig. 5). The latest image editing programs recognize these EXIF data and store them when the file is modified. It is directly accessible under Windows (XP, 7, or 8) in the menu “Properties of the image file” in the tab “Summary” and under Mac

Fig. 5 Example of EXIF data. The list includes the name of the manufacturer, the DC model, the date of creation, and the photographic settings (aperture, shutter, sensitivity). These data are helpful to adjust settings and find the best implementation in terms of equipment and environment to ensure optimal conditions of photography

OS X in the menu “Read data.” These data are very useful to find lost photographic settings or to fix them manually when they are deemed satisfactory. They can be used as criteria to find photographs taken with specific settings (e.g., all the images taken with $f/5.6$ aperture).

5.5 Software Programs

Many dedicated software programs are available and adapted to the photographers' requirements. The following selection (Table 1) presents the leading freewares or inexpensive tools available in both Windows and Mac environments.

5.6 How to Rename and Identify Images

The names of all the files saved in the memory card of the DC are not very explicit. The root

or prefix of the names is always invariant (DSC, IMG, IMAGE, etc., depending on the manufacturers). It is followed by a four-digit incremental order number and an extension (e.g., JPEG). It is therefore necessary to rename without delay the images according to the photographed area of the body, the subject's name, or pathology. This process can rarely be automated because of the variety of data that the user wants to highlight. It is possible to use FastStone Photo Resizer that has advanced functions to rename quickly and automatically a set of images. It can define all types of fields and rules to create prefixes or suffixes indexed on the number of selected files.

Once the images have been renamed satisfactorily, it is recommended to take time to add comments or key words, with the help of tools such as XnView or ThumbsPlus. The additional information is included in the image or the associated database.

Table 1 List of a few major software programs for the management of digital images and morphing (update in June 2013). Trial versions of all these programs are available

5.7 How to Visualize and Load Images

Intuitive and simultaneous visualization of several images is absolutely essential when their number is important. One must be able to quickly compare several photographs, select the best images, erase the blurry or missed shots, and remove doubles. To navigate easily among large numbers of images, recent software programs offer a visualization mode through tags similar to the miniatures used under Windows, i.e., shortcuts represented by small icons generated by and linked to original photographs. These icons can be manipulated, moved, or displayed in large numbers on contacts sheets. Most programs, such as IrfanView, ThumbsPlus, FastStone Image Viewer, Picasa (Windows), I photo, and Aperture (Mac OS X), also highlight with a color-coding system the files where images are stored. It is then easy to localize data quickly on the hard drive.

Another interesting ability of these programs is the possibility of a quick multicriteria research in a large database (ThumbsPlus manages databases of tens of thousands images). However, the efficacy of this type of research is based on the correct tagging of the images at the time of saving with a clear definition of key words. It is also possible to select images by similarity, by instructing the software program to find all the images resembling a reference image more or less exactly (a similarity threshold is defined).

Finally, these programs include simultaneous visualization of several images (FastStone Image Viewer is particularly efficient at this level). Before/after images can be synchronized and displayed side by side on the computer screen. All the moves inside an image (e.g., reframing or zooming) are instantly reproduced on the second image. The comparison of several images is therefore considerably facilitated (Fig. 6).

Fig. 6 Example of synchronization (with ThumbsPlus) between 3 photographs. All the operations (zooming, movements) on an image are reproduced on the other images, thus ensuring optimum comparison

5.8 How to Crop and Reframe Images

In view of their maximal definition, images from a DC cannot be used directly in good conditions. For example, the size of a slightly compressed 6 million pixel image in JPEG file format is 2.3 Mo.

The abovementioned systems are able to crop a series of images easily (for instance, all the images stored in a file) by batch processing (automated treatment) where the desired size or reduction percentage is indicated. Images can also be reframed by eliminating their edges systematically. Cropped or reframed images do not erase original images which remain available for future use.

Photographs used in PowerPoint presentations can be cropped in a definition not exceeding 800×600 pixels (even 640×480 pixels), quite sufficient for a computer monitor or a video projector. The presentation will be smooth even if it is used with a basic laptop.

In contrast, maximal definition is recommended for images used to illustrate articles since printing is usually carried out in high resolution. To obtain satisfactory printing results, the

resolution of the document must be approximately 600 points per inch (dpi). With a size of printed image of 10 cm in width, it corresponds therefore to a definition in column of the image of at least 2,500 pixels. Publishers also prefer to work with noncompressed images.

Other treatments can be automated by batch processing, such as global modification of contrast, increase of luminosity, conversion into levels of gray or another format (JPEG to TIFF, for instance), rotation, addition of a text or a logo inside the image, etc.

5.9 Photo Editing Software

Besides these very specific tools, more ambitious software programs can operate the complete centralized management of images. These creation and retouch programs have filters to correct and improve photographs.

For 20 years, Adobe Photoshop has been the imaging and retouch program par excellence and the most widely used by photographers. It is a complex program (in particular in the management of layers), powerful to work on, retouch, or

export images with a complete and accurate control on compression and the possibility to import and process RAW format files. An affordable version of this exceptional software is available to the general public (Photoshop Elements).

Freewares and comprehensive programs have also been available for a few years (GIMP and PhotoFiltre). They are continuously improved and perfected, and their users form a very active community on the Internet (online assistance, tips, advice, etc.).

6 Practice of Photography in Aesthetic Dermatology

In the field of aesthetic medicine, photography must satisfy two requirements: to be as close as possible to reality and to be comparative, i.e., to ensure that photographing is reproducible (Canfield 2002; Halpern et al. 2003; Galdino et al. 2001).

Alterations on the surface of the epidermis (erythrosis, rosacea, pigmented spots, atrophy) are sometimes not very spectacular. Photography must neither enhance them by accentuating them with cross lighting, nor diminish them with flashlight.

To assess the improvement induced by a treatment on the surface of the epidermis (such as chemical peel, laser rejuvenation), images must be comparative. It is therefore crucial that the technique ensures the reproducible character of the shots which must be performed in similar rigorous conditions.

How to ensure reproducibility?

- The subject/patient must have a neutral appearance.

The object of the photograph is the skin. All useless elements must be removed: necklace, earrings, scarf, etc. If the photograph is taken in a wider field, clothes must be covered with neutral material.

Anything that is likely to hide the lesions must be removed, especially makeup. Makeup should be removed at least 10 mn before the photograph is taken, or ideally no makeup should be applied on the day.

Even a basic skincare cream can cause alteration of the reflection of the light on the skin. Hair often hides or covers part of the forehead or sides of the face: it must be pulled back.

The face must show no expression: the subject must refrain from smiling which emphasizes expression wrinkles, in particular near the eyes.

The eyes must fix a point on a wall (either a clearly visible mark or a mirror). The subjects may also be asked to close their eyes quickly before the photograph is taken. Some authors recommend that the eyes be closed briefly to relax expression lines on the face (Tsukahara et al. 2009).

Photographs must be taken in controlled environmental conditions: they depend of course on the availability of each clinic. Ideally a room or part of a room with neutral walls and no visible object should be dedicated to photography.

To obtain comparative shots, all the photographs of a series (before/after) must be taken in the same conditions.

- The patient must be advised not to change his/her appearance between shots. After aesthetic treatment, one may be tempted to modify other features such as hair color, new haircut, etc. It is not always easy to convince the subject to refrain from changing until the comparative photograph has been taken. It is however a primary requirement because the objective judgment of improvement can be influenced by alterations.
- Constancy of angle of shot: the same protocol must be followed to take each photograph. The DC must always be placed at the same distance from the subject to have the same focus. Ideally it should be possible to move around the subject seated in a predetermined place in the room. The subject must always look in the same direction. The various angles of shot can be marked on the floor to ensure reproducibility.

- Height must be adjustable so that the axis of the objective lens is horizontal, using a tripod or an adjustable stool.
- Stable lighting conditions: an artificial source of light (flash unit or light projector) ensures that the operation takes place in the same conditions and facilitates reproducibility.
- Reproducibility of colors: color stability in reflex DCs is generally very good as long as the device is not changed during the protocol. Colors can be corrected after the photograph has been taken if a color chart has been placed in the scene (Mini Colorchecker color chart, X-Rite). The reference colors of the chart are then available to document and guide future corrections of colors (Grana et al. 2005; Vander Haeghen et al. 2001).

It is essential to do preliminary tests with the equipment and to determine the optimal settings. Once adequate settings are identified, it is important to respect them. EXIF data associated to the photographs will be loaded to document imaging. These data will help the operator to refine settings and to set up the best possible working conditions in terms of equipment and environment.

7 Digital Photography in Dermatology

Digital photography provides the opportunity to set up easily an iconographic database of the main techniques used by dermatologists in their practice. The before/after photographs will be easily accessible and available to the dermatologist. It is recommended to anonymize them by adding a black strip on the patient's eyes or by blurring them.

A dermatologist with intense aesthetic practice can have a database of samples (in PowerPoint format) to show technical gestures to the patients prior to treatment: wrinkle filling, chemical peel, resurfacing, etc., and the expected results. These images can be put on line very easily (with Picasa in particular), or a

dedicated website can be created. In this hypothesis, ethic regulations set by the medical authorities have to be respected.

Morphed images give the patient an idea of the results after treatment. Morphed images are produced with special effects used to create animated images that transform gradually and naturally an initial image into a final image. Professional software programs, such as Mirror Aesthetic Simulation, calculate a deformation of the image from the initial photograph, simulating the results after surgical treatment. This process is used mainly in plastic surgery. It is also interesting in aesthetic dermatology, for example, it can help illustrate changes in color to simulate postlaser erythema so that the patient is aware of the treatment side effects. Softwares such as Fantamorph or Popims Animator are easily accessible to dermatologists interested in this technique.

Although very attractive, these methods must not hide some negative effects. It is easy to make idealized simulations on the screen and to propose to the patients changes that will be difficult to achieve. The patients may be very disappointed.

Finally, it is essential to mention the existence of photographic scales (Bazin and Doublet 2007) which list in a book the criteria of cutaneous aging of female or male (Caucasian) faces. They are used to rate an area of the face with accuracy: glabella wrinkle, crow's foot wrinkles, wrinkles under the eyes, etc. The scales can also be used altogether to assess global aging of the face.

8 Conclusion

Digital photography does not simply imply a change of camera; it is a total change in the management of imaging, and it requires efficient mastering of information technology.

With this technique, working habits must be modified. One must keep in mind that digital photographs are saved and stored in a PC or laptop. They can be displayed on a monitor, projected, or printed with a color

printer or in a scientific article. However, in daily practice, digital imaging is used on the computer screen.

Computer science is not 100 % reliable, and it is essential to save data regularly. The widespread use of USB flash drives and external hard disks simplifies this process which was fastidious not so long ago. It is crucial that original photographs must be saved simultaneously on a high capacity hard drive and on CD-ROM or DVD.

The flexibility of the system, its reproducibility, and the possibility to classify and save images and to display several images on one screen to compare them make digital photography an ideal tool in aesthetic dermatology.

1 Under the Surface

Stratum corneum (SC) is the final product of the terminal differentiation of epidermal keratinocytes. It is elaborated on purpose and fulfills essential roles in terms of protection of the organism's living tissues. These functions encompass barrier functions against penetration of foreign molecules and pathogens, significant limitation of the transepidermal water loss, filtration of approximately 70 % of the deleterious UVB radiation, and mechanical resilience to other physical and chemical aggressions. Thanks to the continuous mitotic activity of the mother tissue, the epidermis, SC is continuously renewed. The cornified keratinocytes, corneocytes, are progressively shed from the skin surface, and their loss is adequately compensated through the keratinization of the most superficial living cells from the underlying *stratum granulosum*. This highly coordinated process ensures maintenance of the SC barrier and its adaptation to the environmental changes.

2 Formation of the SC: Process of Cornification

Formation of the SC is a very rapid and, thus, very interactive process. Transformation of the most superficial living keratinocytes in the *stratum granulosum* into the cornified cells takes only 1–1.5 days (Baker and Blair 1968). During this short period, the granular layer cell massively releases its secretory contents into the apical intercellular space and efficiently degrades all its cytoplasmic organelles, beginning with the nucleus and mitochondria. The process is initiated and regulated by changes in the extracellular calcium gradient (Menon et al. 1994; Elias et al. 2002) and is mediated by caspase 14 (Eckhart et al. 2000; Denecker et al. 2008). Structural and bioactive proteins, hydrolytic enzymes, enzyme inhibitors, and lipids synthesized in the granular layer are all delivered into the extracellular space via the complex vesiculo-tubular system originating in the *trans*-Golgi: the so-called lamellar granules (Serre et al. 1991; Rassner et al. 1999; Ishida-Yamamoto et al. 2005). Within the SC, all these elements self-organize at the molecular level and perform their respective roles in a manner no more dependent on the cellular activity but largely influenced by the physical and chemical factors, e.g., temperature, humidity/hydration, and pH (Bouwstra et al. 2003a; Haftek et al. 1998; Rawlings and Harding 2004). Upon the process of cornification, important changes occur within the cytosol. Degradation of organelles is paralleled by dispersion of the keratohyalin granules containing profilaggrin. Dephosphorylation of profilaggrin is the first step permitting its processing to filaggrin, the protein involved in aggregation of intermediate filaments of keratin and consolidation of the corneocyte interior into a relatively homogeneous composite structure (Harding and Scott 1983; Markova et al. 1993). Later in the process, the arginine residues of filaggrin shall be converted to citrulline, and this loss of charge shall lead to the protein dissociation from keratins and its further degradation to amino acids (Kamata et al. 2009; Méchin et al. 2010). These

hydrophilic final products of filaggrin processing largely influence water holding capacity of the SC and contribute to its acid pH. Histidine, one of the major components of filaggrin, is converted to urocanic acid, the latter being involved in protection against UV radiation (de Fine Olivarius et al. 1996; Mildner et al. 2010). At the keratinocyte periphery, various proteins become cross-linked by the cell membrane-bound transglutaminases, essentially TG1, TG3, and TG5, to form a cornified envelope (Kalinin et al. 2002; Candi et al. 2005). Several cytosolic proteins, including filaggrin and hornerin, are thus integrated into the highly insoluble peripheral structure principally composed of involucrin, loricrin, and small proline-rich proteins (Michel et al. 1988; Haftek et al. 1991; Steinert and Marekov 1999; Simon et al. 1996; Henry et al. 2011). Simultaneously, the plasma membrane phospholipids become replaced by the lamellar granule-derived sphingolipids (ceramides) (Elias et al. 2000). These latter molecules become also cross-linked by TG1 to the nascent cornified envelopes (Nemes et al. 1999). Thus, formed lipid envelopes constitute a matrix for alignment of the extracellular lipids and for formation of the intercorneocyte lipid bilayers (Wertz et al. 1989; Marekov and Steinert 1998). Together, the cornified cellular bricks and the self-organized lipid mortar form an efficient permeability barrier at the top of the skin (Elias 2006).

3 Structure of the SC

Cornified keratinocytes have the form of polygonal flat tiles. They are strikingly thinner than the underlying nucleated cells (1–2 μm thick) and about two times wider than the stratum spinosum keratinocytes (30–35 μm in diameter). This significant change in proportions comes with extensive cell overlapping and convolution of the lateral cell walls. In this setting, extracellular lipids structured in lamellae and filling intercorneocyte spaces are the principal factors limiting SC permeation either way:

outside in and inside out (Elias and Menon 1991). X-ray diffraction studies allow overall appreciation of the lipid lamellar phases present in the SC and indicate that SC lipids are organized in bilayers presenting two major periodicities (12–13 nm and 5–6 nm spacing between the polar head groups of lipid molecules within the bilayers). These studies reveal also the lateral packing pattern of molecules within the bilayer sheets (Bouwstra et al. 2003b). Long periodicity phase and orthorhombic lateral packing are predominant in normal SC, whereas a switch to the short periodicity phase and hexagonal lateral arrangement characterize functional states with increased SC permeability. Recently, ultrastructural studies of vitrified skin sections, in which the molecular arrangement has been preserved by ultra-rapid freezing of the tissue, have led to slightly different conclusions (Iwai et al. 2012; see also ► Chap. 33, “Cyanoacrylate Method”). Using this morphological approach, the authors propose that SC lipids are organized in homogeneous phases with 10–12 nm spacing of the repeating unit, corresponding to the length of a fully extended ceramide molecule. In the proposed model, one ceramide molecule would be associated with one fatty acid and one cholesterol molecule, consistent with our knowledge about the equimolar proportions between these major components of the SC lipid matrix (Bouwstra et al. 2003b). The spliced arrangement of ceramides would confer to the lipid bilayers more suppleness, compatible with the everyday physical requirements. However, the model does not integrate the variable length and nature of the hydrophobic carbon chains belonging to the different lipid species found in the SC. Also, it admits no space for water molecules within the SC extracellular spaces. Yet, water is necessary for functioning of the non-lipid components in the SC and notably those involved in the processing and rearrangement of the intercellular matrix. Lipid bilayers can be visualized with conventional electron microscopy using highly oxidizing reagents, such as osmium and ruthenium tetroxides. Although this classical approach induces notable artifacts related to the chemical fixation,

dehydration with solvents, and tissue contrasting methods, the structural modifications are reproducible and well defined. Using this technique, it is possible to observe hydrophilic “faults” in the semicrystalline structure of the intercorneocyte spaces (Hafték et al. 1998). Such hydrophilic lacunae increase in size and change emplacement upon SC hydration obtained with simple occlusion (Fig. 1). They also swell after SC treatment with agents disorganizing lamellar lipids and thus constitute the primary permeation pathways. Extensive exposure to water makes SC more voluminous, as corneocytes absorb and retain humidity. Water binding capacity varies with the SC depth and depends largely on the presence of the so-called natural moisturizing factor resulting from the processing of filaggrin to free amino acids. As a consequence, three zones showing different compactness and hydration may be distinguished (Bouwstra et al. 2003a; Richter et al. 2004). Cohesion within the SC is provided by corneodesmosomes, which are structurally modified desmosomes having incorporated corneodesmosin (Serre et al. 1991; Hafték et al. 2006). Lipids, initially proposed to participate in the SC cohesion, do not show adhesive properties and rather behave as a spacer (Chapman et al. 1991). In the lower portion of SC, called SC *compactum*, corneodesmosomes are distributed all around the cells. In this highly cohesive part, the intercorneocyte spaces are almost entirely filled with lamellar lipids, and, therefore, this is where the permeability barrier is mainly located. Subsequently, corneodesmosomes attaching the stacked consecutive corneocyte layers are progressively degraded by serine proteases, principally kallikreins 5 and 7 (Voegli and Rawlings 2012). This introduces horizontal dissociation in the upper portion of SC, therefrom named SC *disjunctum* (Fig. 2). Interestingly, lateral connections between the corneocytes do persist also at this level. As a result, the so-called “basket-weave” pattern of the SC is frequently observed in standard histological skin samples, after tissue delipidation during dehydration procedures. It can be further enhanced by the application of permeabilizing agents, which facilitate mobility

Fig. 1 Ultrastructure of intercorneocyte spaces in the SC *compactum* upon mild hydration. Normal human skin explants were examined with transmission electron microscopy using post-fixation with either osmium tetroxide (**a, c**) or with ruthenium tetroxide (**b, d**). Nonoccluded skin samples (**a, b**) showed rather narrow intercellular spaces containing focally hydrophilic (electron-dense) inclusions (*arrowheads*). Upon hydration, obtained by 6-h occlusion (**c, d**), the hydrophilic lacunae swelled, split the intercellular lipid lamellae, and were often

encountered next to corneodesmosomes (*arrows*). This illustrates how the SC hydration results in the focal increase of the extracellular hydrophilic compartment, likely containing protein components issued from the lamellar granule extrusion, and facilitates interaction between these elements and the corneodesmosome substrate proteins. Bars = 100 nm (Micrographs adapted from Haftek et al. 1998, with permission from Microscopy Research and Techniques, John Wiley and Sons)

Fig. 2 Ultrastructure of normal human SC at the interface between SC *compactum* and SC *disjunctum*. Corneodesmosomes (*small arrows*) that join SC *compactum* cells (C3–C5) are numerous and distributed both between the lateral cell-cell contacts and between the successive cell layers. The latter localization is the primary target of proteolytic enzymes resulting in virtual disappearance of the interlayer corneodesmosomes (*big arrows*) and creation of the SC *disjunctum* (C6–7). Bar = 200 nm

of the endogenous intercellular enzymes (Fig. 3). Better resistance of the lateral corneodesmosomes has long been unexplained, since these structures do not differ biochemically and mechanically from the junctions situated between the successive corneocyte layers. Recent visualization of the tight junction remnants cross-linked to the corneocyte envelopes and situated in the lateral portions of the cells solves the puzzle (Haftek et al. 2011). Indeed, lateral corneodesmosomes appear to be less accessible to the catabolic enzymes because of the presence of tight junction – like fusion spots between the cell envelopes at this localization.

4 Desquamation

Transition from the SC *compactum* to *disjunctum* indicates the beginning of the desquamation process. Proteolytic enzymes and their natural inhibitors secreted into the intercellular spaces interact

Fig. 3 Normal human SC dissociation induced by exposure to propylene glycol spares the lateral corneodesmosomes. The entire SC undergoes *disjunctum*-like transformation after 6-h topical application of the permeation agent, producing so-called basket-weave pattern (*inset*). Corneocytes maintain their lateral attachment, but lose corneodesmosomes providing interlayer contact

(*arrowheads*). Intact lateral corneodesmosomes (*arrows*) are sealed within the portions of fused cornified lipid envelopes. Such intercorneocyte fusions have been demonstrated to correspond to cross-linked tight junction – like structures issued from the underlying living epidermal layers. Bars = 500 nm

with their respective substrates in a manner depending on the structural constraints, i.e., mobility within the hydrophobic intercellular matrix, shape of the extracellular space, and presence of tight junction-derived fusion points between cell envelopes, and on the physicochemical operating conditions, i.e., pH, hydration, and temperature. It has been proposed that self-organization of the lipids in continuous multilayered sheets could contribute to the lateral displacement of intercellular hydrophilic lacunae containing hydrolytic enzymes toward the immobile corneodesmosome structures, the latter representing enzyme substrates (Hafték et al. 1998). Corneodesmosomes attaching successive cell layers are cleaved first. Corneocytes remain in layers attached at the cell periphery to the neighboring cells. This situation persists up to the SC surface, where individual cells chip off due to the mechanical stress brought by drying and abrasion (Hafték et al. 1997). In normal human skin, the desquamation rate is approximately one cell layer in 21 h (Hoath and Leahy 2002), so that

an adult loses about 2.5 million corneocytes every day.

5 Maintenance of the SC Homeostasis

Thickness of the SC varies between the anatomical sites from 5 to 20 corneocyte layers: an average of 16 layers (Grove and Kligman 1983). It takes in average 14 days to a corneocyte to evolve through the normal SC and to desquamate at its surface (Johannesson and Hammar 1978). Because changes in the shedding rate influence the SC barrier quality, they constitute signals to the living layers, and notably to the proliferative compartment, to adapt accordingly (Proksch et al. 1993). This interactivity is necessary to maintain the epidermal homeostasis, and thus adequate barrier function, in changing environmental conditions.

In physiological conditions, thickening of the SC may be observed during the winter period and

is related to a slowdown in corneodesmosome degradation (Simon et al. 2001). A similar mechanism could also be evoked in the case of age-related skin dryness. Compensatory thickening of the palmar or plantar SC is constantly observed upon recurrent mechanical stimulation leading to the occurrence of calluses.

Skin pathology abounds in the manifestations involving SC appearance and function. They may involve SC overproduction, retention, or premature shedding. Excessive retention of otherwise normally keratinized SC is called hyperkeratosis, e.g., accumulation of cholesterol sulfate – a powerful inhibitor of serine proteases in SC – occurs in recessive X-linked ichthyosis. In this case, deficit in steroid sulfatase leads to improper degradation of corneodesmosomes and SC retention (Zettersten et al. 1998; see Oji et al. 2010a for a recent consensus overview of inherited defects of keratinization). Parakeratosis, a situation where non-degraded nuclei stay in the SC, results from imperfect keratinization and is most often due to epidermal hyperproliferation and inflammation. A typical example of such condition is psoriasis, where skin inflammatory reaction induces the epidermal response with prominent parakeratotic scale production and proinflammatory cytokine secretion, thus entertaining the disease's vicious circle (Krengel et al. 1998). Among the ichthyoses (non-bullous), congenital ichthyosiform erythroderma is also characterized by the presence of parakeratotic SC. Mutations of the transglutaminase-1 gene have been demonstrated in one of its clinical subsets (Huber et al. 1995). Here, leaky corneocytes and imperfectly organized SC promote reactive inflammation, epidermal hyperproliferation, and compensatory overproduction of the SC, still invalid but thicker. A localized loss of the SC (Kanitakis et al. 2010) or its diffuse shedding (Komatsu et al. 2006) constitutes another family of the anomalies of keratinization.

Epidermal response to the impaired barrier function of any origin is, most often, a compensatory increase in the SC thickness. Several and various causes are related to the structural fragility and/or increased permeability of the SC components. Here are some examples:

In various hereditary conditions, problems of epidermal differentiation may result from a deficient expression of one of the cell-cell junction proteins that is insufficiently compensated by similar members of the same family. Palmo-plantar keratoderma in Vohwinkel syndrome is linked to a deficient intercellular communication due to a particular mutation in the gene coding for connexin 26 (Maestrini et al. 1999), whereas erythrokeratoderma variabilis is caused by mutations in the genes of connexins 31 or 30.3 (Richard et al. 2003). The clinical manifestation of this ailment is thickening of the epidermis (acanthosis) with hyperkeratosis.

In the Ichthyosis, Hypotrychosis and Sclerosing Cholangitis (IHSC) syndrome, claudin-1 – deficient epidermis develops leaky tight junctions (Hadj-Rabia et al. 2004). In this case, ichthyosis appears to be due to the compensatory overexpression of tight junction -like structures in the SC (Haftek et al. 2013).

Mutations in genes coding for epidermal differentiation – associated keratins (K10, K1, K2e) lead to the mechanical fragility of the upper layers of keratinocytes in keratinopathic ichthyoses (epidermolytic types). Collapse of the keratinocyte cytoskeletons may provoke formation of superficial blisters; however, the typical tissue response is hyperkeratosis (Oji et al. 2010a; Osawa et al. 2011). In the Netherton's syndrome, it is the loss of intercorneocyte cohesion that underlies the appearance of festooned inflammatory and desquamating skin lesions. Premature corneodesmosome breakdown observed in this disease is caused by the absence of serine protease inhibitor LEKTI-1 encoded by Spink 5 gene (Chavanas et al. 2000). Clinical manifestations of peeling skin disease, provoked by the absence of corneodesmosin, concern exclusively the interface between the *stratum granulosum* and SC (Oji et al. 2010b). Cell-cell junctions lacking corneodesmosin are still present in the patients' SC and are protected by overexpressed tight junction – derived structures (Haftek et al. 2012). The resulting SC is quite resistant and functional. However, it can be easily peeled off as a whole sheet because the underlying desmosomes at the top of the living layers are fragile: not yet

consolidated by cross-linking to the cornified envelopes and not reinforced by the deficient corneodesmosin.

Permeability of the SC is largely dependent on its lipid content. Insufficient delivery of the intercellular lipids occurs in the skin of harlequin ichthyosis patients with a mutated ABCA12 lipid transporter gene (Akiyama et al. 2005). Retention of the lamellar granules results also in abnormally low levels of the extracellular proteolytic enzymes and, thus, decreased desquamation. Extensive hyperkeratosis occurs already *in utero* and, if the baby survives, evolves towards ichthyotic erythroderma (Haftek et al. 1996).

Imperfect lamellar lipid composition and, thus, deficient SC barrier function are encountered in patients with various dyslipidemias of dietary or metabolic origin (Elias et al. 2011). These clinical situations are also associated with abnormal keratinization.

Permeable cornified envelopes constitute another important factor influencing SC barrier function. Apart the previously mentioned case of transglutaminase 1 deficiency leading to non-bullous congenital ichthyotic erythroderma, mutations of genes coding various envelope components may result in a similar or related phenotype. Well-known examples include filaggrin mutations causing ichthyosis vulgaris and underlying some forms of atopic dermatitis (McLean and Irvine 2012) and Vohwinkel syndromic ichthyosis due to mutations in the lorcrin gene (Schmuth et al. 2004).

6 Conclusion

SC formation is controlled by the underlying viable epidermal layers. Once secreted into the SC intercellular spaces, various components self-organize and interact in a highly ordered manner, in order to preserve the unique and functional architecture. Environmental conditions and pathological situations influence the structure and function of SC, resulting in compensatory responses. They lead, in vast majority of the cases, to the buildup of the SC barrier.

1 Introduction

The basic function of skin is to constitute a waterproof barrier between the body and the environment. In human, like in other land-living higher vertebrates, this barrier is essentially composed of uniquely organized lipids situated in the skin's horny layer.

The lack of knowledge about the molecular organization of the horny layer's lipid material has limited our understanding of the skin both in healthy and disease states. However, a recent breakthrough has come from the use of very high magnification cryo-electron microscopy of vitreous skin section (CEMOVIS) combined with electron microscopy (EM) simulation. This has allowed for molecular structure determination of the lipid material directly in situ and in its *near native state* (Iwai et al. 2012). The lipid material is organized in an arrangement not previously described in a biological system – stacked bilayers of fully extended ceramides with cholesterol molecules associated with the ceramide sphingoid moiety (Iwai et al. 2012).

Fig. 1 Historical time-line of skin barrier research (Adapted from Norlén (2013), with permission)

Below follows a brief account of current knowledge about the molecular organization of the horny layer's lipid material.

2 Brief History of Skin Barrier Research

Ever since it became clear that the skin's barrier function essentially is located to the epidermis (Homolle 1853; Duriau 1856), the molecular structure and function of the skin barrier have intrigued researchers (Fig. 1).

By sandpapering the skin surface, Winsor and Burch (1944) showed in the 1940s that the skin's barrier actually resides in the epidermal horny layer. In the 1950s–1960s, Berenson and Burch (Burch and Berenson 1951) and Onken and Moyer (1963) showed that horny layer impermeability essentially was a function of its lipid content. Brody (1966) then managed to locate the horny layer lipids to the extracellular space.

The first electron microscopy visualizations of the lipid material's stacked lamellar morphology came with Breathnach et al. (1973) and Elias and Friend (1975) in the early 1970s.

In the 1980s, the lipid material's basic composition was determined. A heterogeneous mixture of saturated, long-chain ceramides, free fatty acids, and cholesterol in a roughly 1:1:1 molar ratio (Wertz and Downing 1983; Wertz et al. 1987, 2003). Another important step was the introduction of ruthenium tetroxide staining, which revealed the lipid material's characteristic broad:narrow:broad electron lucent band staining pattern (Madison et al. 1987).

Soon afterwards, using small-angle X-ray diffraction on isolated horny layer, White et al. (1988), Garson et al. (1991), and Bouwstra et al. (1991) reported the presence of one shorter (ca 4.5 nm) and one longer (ca 6.5 nm) diffraction peak related to lipids. Also, McIntosh (2003) observed an asymmetric distribution of cholesterol molecules within model systems composed of extracted horny layer lipids.

In the early 1990s, the importance of the lipid material's phase state for its barrier properties

began to be stressed (Forslind 1994). In 2001, Norlén proposed that the lipid material exists as a single and coherent gel phase (Norlén 2001), which was later supported by the experimental work of Iwai et al. (2012).

In 2012, Iwai et al. showed that the horny layer's lipid material is organized as stacked bilayers of fully extended ceramides with cholesterol molecules associated with the ceramide sphingoid moiety (Figs. 2 and 3; Iwai et al. 2012).

3 Skin Lipid Composition and Phase State

The most characteristic features of the lipid composition (Wertz et al. 2003) are (i) extensive compositional heterogeneity with broad, but invariable, chain length distributions (20–32C; peaking at 24C) in the ceramide fatty acid and free fatty acid fractions, (ii) almost complete dominance of saturated very long hydrocarbon chains (C20:0–C32:0), and (iii) large relative amounts of cholesterol (about 30 mol%).

These are the same as the factors that typically stabilize lipid gel phases. It was therefore proposed that the horny layer's lipid material exists as a single and coherent gel phase (Norlén 2001). The viscous gel-like behavior of the lipid material was recently demonstrated experimentally by its remarkable malleability in situ (Fig. 4; Iwai et al. 2012).

4 Molecular Structure Determination Directly In Situ

Cryo-electron microscopy of vitreous tissue section (CEMOVIS) yields high-resolution images of the horny layer's lipid material in situ and in its *near native state*. When combined with molecular modeling and electron microscopy (EM) simulation, CEMOVIS has proved to be remarkably effective in identifying the molecular organization of the horny layer lipids (Iwai et al. 2012).

Fig. 2 Molecular arrangement of the skin barrier. The horny layer's lipid material is organized as stacked bilayers of fully extended ceramides with cholesterol molecules associated with the ceramide sphingoid moiety (Iwai et al. 2012). *Green spheres* represent hydrogen and carbon atoms in ceramides, cholesterol, and free fatty acids. *Red spheres* represent oxygen atoms (Adapted from Norlén (2013), with permission)

Fig. 3 Schematic drawing of skin. *Left part:* schematic cellular-scale drawing of epidermis. *Midpart:* molecular-scale drawing of the lamellar lipid material occupying the space between the cells of the horny layer. *Right part:* atomic model of the lipid material's repeating unit,

composed of two mirrored subunits, each composed of one fully extended ceramide (CER) molecule, one cholesterol (CHOL) molecule, and one free fatty acid (FFA) molecule (Adapted from Norlén (2012), with permission)

The CEMOVIS-based structure determination procedure involves four stages (Norlén et al. 2013): cryo-electron microscopy of vitreous skin section (CEMOVIS) to yield high-resolution (~ 1 nm) images of the lipid material (Fig. 5), construction of candidate molecular models for the lipid material (Fig. 6), simulation of electron micrographs resulting from the proposed molecular models (Fig. 6), and confrontation of the simulated micrographs with those observed experimentally to identify a molecular

organization that is consistent with the observed CEMOVIS data (Fig. 7).

For a detailed description of the experimental procedure, see Norlén et al. (2013).

5 Skin Lipid Structure

The lipid organization that emerged from the high-resolution CEMOVIS data analysis of the horny layer's lipid material is a bilayer

Fig. 4 The horny layer's lipid material is, despite its crystalline-like character, malleable. The horny layer's extracellular lipid material is folded locally. The folding decreases on hydration and increases on dehydration. Low magnification CEMOVIS micrographs of the horny layer after hydration in vivo (a), at normal in vivo conditions (b),

and after hydration in vivo followed by dehydration ex vivo (c). The lower panel illustrates the folded pattern of the extracellular space. Image side lengths: 5 μm (Adapted from Iwai et al. (2012) (online supplementary material), with permission)

structure of fully extended (splayed chain) ceramides with the sphingoid moieties interfacing. Both cholesterol and the free fatty acid are distributed selectively: cholesterol at the ceramide sphingoid end and the free fatty acid at the ceramide fatty acid end (Iwai et al. 2012; Figs. 2 and 3).

6 Skin Lipid Function

A stacked, fully extended (splayed chain) ceramide bilayer arrangement (Figs. 2 and 3) with high cholesterol content (~ 30 mol%) and a highly heterogeneous but characteristic, lipid composition of saturated, long-chain ceramides and free fatty acids may represent an ideal

barrier material for skin. This is because it may be largely impermeable to water as well as to both hydrophilic and lipophilic substances, because of its condensed chain packing and its alternating lipophilic (alkyl chain) and hydrophilic (headgroup) regions. Likewise, it may be resistant to both hydration and dehydration because of its lack of exchangeable water between lipid leaflets. It may also be resistant towards other kinds of environmental stress, such as temperature and pressure changes, because of its heterogeneous lipid composition and high cholesterol content, which stabilize gel-like chain packing and thereby prevent both lateral domain formation and induction of "pores" or nonlamellar morphologies. Further, this bilayer arrangement

Fig. 5 The CEMOVIS intensity pattern of the horny layer's extracellular lipid material consists of folded stacked layers. (a) Medium magnification CEMOVIS micrograph of the interface between two cells in the midpart of the horny layer. Note that in CEMOVIS the tissue is unstained and that the pixel intensity is directly related to the local electron density of the sample. The stacked lamellar pattern represents the extracellular lipid material. Dark ~10 nm dots represent keratin intermediate filaments filling out the intracellular space. (b) High-magnification CEMOVIS micrograph of the extracellular space in the midpart of the horny layer. The averaged intensity profile of the lipid material was obtained by

fuzzy distance-based image analysis. The red stars in (b) represent the manually chosen start and end points for fuzzy distance based path growing. (c) The red line represents the traced out path. Stacked lines mark extracted intensity profiles. (d) Enlarged area of the central part of (b). (e) Reversed averaged pixel intensity profile obtained from the extracted area in (c). Peaks in (e) correspond to dark bands and valleys to lucent bands in (d). Black arrows in (b) denote electron lucent narrow bands at the center of the 6.5 nm bands. Section thickness ~50 nm (a–d). Scale bar (a): 100 nm. Pixel size in (a–d): 6.02 Å (Adapted from Iwai et al. (2012), with permission)

may account for horny layer cell cohesion without advocating specialized intercellular adhesion structures such as desmosomes. The absence of desmosomes in the horny layer (above the fourth to fifth layers) may hence allow for sliding of horny layer cells to accommodate skin bending. Finally, as the interaction between the individual layers of the lipid material involves only hydrocarbons, the layers may be relatively free to slide with respect to one another, making the lipid material pliable. The fully extended ceramide bilayer arrangement, with high cholesterol content and heterogeneous saturated long-chain lipid composition, may thus meet the barrier needs of skin by being simultaneously impermeable and robust (Iwai et al. 2012).

7 Future Perspective

The elucidation of the basic molecular organization of the skin lipids is a first step towards building a complete molecular model for the stratum corneum that also includes the corneocytes. Outstanding questions in this respect are the nature of the molecular-level structure of the corneocyte keratin filament network and the interfacial corneocyte cell envelope. The potential application and further development of the combined approach of cryo-electron microscopy coupled with simulation is presently explored to elucidate the molecular organization of these remaining stratum corneum key components (Norlén et al. 2013; Figs. 8, 9, and 10).

Fig. 6 Electron microscopy simulation of the horny layer's extracellular lipid material. (a) High-magnification CEMOVIS micrograph of the extracellular space in the midpart of the horny layer. (b) Corresponding averaged intensity profile obtained by fuzzy distance-based path growing. (c) Schematic 2D illustration of ceramides (tetracosanylphytosphingosine (C24:0)) in fully extended conformation with cholesterol associated with the ceramide sphingoid part and free fatty acids (lignoceric acid (C24:0)) associated with the ceramide

fatty acid part. (d) Atomic 3D model of the repeating unit composed of two mirrored subunits, each composed of one fully extended ceramide molecule, one cholesterol molecule, and one free fatty acid molecule. (e) Calculated electron scattering potential of one model subunit. (f) Calculated electron scattering potential 3D maps of the top-most layer out of 20 superimposed layers used to generate the simulated electron micrograph (g). Defocus (a, g): $-2.5 \mu\text{m}$. Pixel size in (a, g): 3.31 \AA (Adapted from Iwai et al. (2012), with permission)

Fig. 7 Electron microscopy simulation of alternating fully extended ceramides with selective localization of cholesterol to the ceramide sphingoid part accurately accounts for the observed CEMOVIS intensity patterns as well as for the interference pattern changes observed in sequential CEMOVIS micrograph defocus-series obtained at very high magnification (≤ 1.88 Å pixel size). (a–c) High-magnification CEMOVIS micrographs (first exposure images) of the extracellular space in the midpart of the horny layer obtained at -0.5 μm (a), -2 μm (b), and -5 μm (c) defocus. At very low defocuses (-0.5 μm), (a) CEMOVIS intensity patterns can only be observed at very high magnification (≤ 1.88 Å pixel size). At very high defocuses (-5 μm), (c) image resolution is low but still allows for resolution of the ~ 11 nm repeating unit. The slightly larger lamellar repeat distance in (b) (~ 12 nm) compared to (a) and (c) (~ 11 nm) may be due to more pronounced compression of the vitreous skin section during cryo-sectioning along the lamellar plane in (b) compared to (a) and (c). (d–f) represents corresponding atomic 3D model (cf. Fig. 3 right part; Fig. 6d) electron microscopy simulation images recorded at -0.5 μm (d), -2 μm (e) and -5 μm (f) defocus. (g–i) Sequential CEMOVIS micrograph defocus-series obtained at very high

magnification (1.88 Å pixel size). Note the fine changes in interference patterns caused by gradually increasing the microscope's defocus during repeated image acquisition at a fixed position. Due to electron beam damage after repeated electron exposure, the image contrast is lower in micrographs (h–i) compared to micrograph (g), which was acquired first. In micrograph (i) some shrinkage can be observed. This is probably due to mass loss during repeated electron exposure. Also, the curvature of the lamellar pattern is slightly increased in micrographs (h–i) compared to micrograph (g), which likewise may be caused by nonhomogeneous mass loss during repeated electron exposure. (j–l) represents corresponding atomic 3D model (cf. Fig. 3 right part; Fig. 6d) electron microscopy simulation images recorded at -1 μm (j), -2 μm (k), and -3 μm (l) defocus. It is shown that the atomic 3D model in Fig. 5 accurately accounts not only for the major features of the CEMOVIS micrographs (a–f) but also for the interference intensity pattern changes observed upon varying the microscope's defocus during image acquisition at very high magnification (g–l). Pixel size in (c, f): 3.31 Å, in (b, e): 6.02 Å, and in (a, d and g–l): 1.88 Å (Adapted from Iwai et al. (2012), with permission)

Fig. 8 Electron microscopy simulation results from seven fully extended ceramide bilayer models with varying cholesterol distribution. (a–c) CEMOVIS micrographs of the horny layer’s extracellular lipid material acquired at $-5\ \mu\text{m}$ (a), $-2\ \mu\text{m}$ (b), and $-0.5\ \mu\text{m}$ (c) defocus. (D3–J3) Corresponding simulated electron micrographs obtained from seven fully extended ceramide models. (D1–J1) Repeating units for each simulated model. (D2–J2) Calculated electron scattering potential 3D maps of the topmost layer out of 20 superimposed layers used to generate each individual simulated micrograph (D3–J3). In model (d), cholesterol is selectively localized to the ceramide sphingoid part. In model (e), cholesterol has been removed to evaluate whether the simulation method could discriminate the presence (d) or absence (e) of cholesterol. In

model (f), cholesterol is selectively localized to the ceramide fatty acid part. In models (g–j), cholesterol is homogeneously distributed between the ceramide sphingoid and fatty acid parts. Contrary to models (g, j), models (h, i) express axial headgroup displacement of cholesterol and free fatty acids. Models (h, i) differ in that model (h) expresses a pairwise lateral distribution of ceramides while model (i) expresses a homogeneous lateral distribution of ceramides. Note that except for the position of the lipid headgroups, the localization of cholesterol within the fully extended ceramide structure largely determines the electron scattering properties of the models (Adapted from Iwai et al. (2012) (online supplementary material), with permission)

Fig. 9 Electron microscopy simulation results from seven fully extended ceramide stacked monolayer models with varying cholesterol distribution. (a–c) CEMOVIS micrographs of the horny layer’s extracellular lipid material acquired at $-5\ \mu\text{m}$ (a), $-2\ \mu\text{m}$ (b), and $-0.5\ \mu\text{m}$ (c) defocus. (D3–J6) Corresponding simulated electron micrographs obtained from seven stacked fully extended ceramide models. (D1–J1) Two repeating units for each simulated model. (D2–J2) Calculated electron scattering potential 3D maps of the topmost layer out of 20 superimposed layers used to generate each individual simulated micrograph (D3–J5). In model (d), cholesterol is selectively localized to the ceramide sphingoid part. In model (e), cholesterol has been removed to evaluate whether the simulation method could discriminate the presence (d) or absence

(e) of cholesterol. In model (f), cholesterol is selectively localized to the ceramide fatty acid part. In models (g–j), cholesterol is distributed homogeneously between the ceramide sphingoid and fatty acid parts. Contrary to models (g, j), models (h, i) express axial headgroup displacement of cholesterol and free fatty acids. Models (h, i) differ in that model (h) expresses a pairwise lateral distribution of ceramides, while model (i) expresses a homogeneous lateral distribution of ceramides. Note that except for the position of the lipid headgroups, the localization of cholesterol within the fully extended ceramide structure largely determines the electron scattering properties of the models (Adapted from Iwai et al. (2012) (online supplementary material), with permission)

Fig. 10 Electron microscopy simulation results from two-folded ceramide bilayer models with and without the presence of cholesterol. (a–c) CEMOVIS micrographs of the horny layer’s extracellular lipid material acquired at $-5\ \mu\text{m}$ (a), $-2\ \mu\text{m}$ (b), and $-0.5\ \mu\text{m}$ (c) defocus. (D3–E5) Corresponding simulated electron micrographs obtained from two-folded ceramide models. (D1–E1) Repeating units for each simulated model. (D2–E2) Calculated electron scattering potential 3D maps of the topmost layer out of 20 superimposed layers used to

generate each individual simulated micrograph (D3–E5). In model (d), cholesterol is present. In model (e), cholesterol has been removed to ascertain if the simulation method could distinguish the presence (d) or absence (e) of cholesterol. Note that the presence of cholesterol within the folded ceramide structure largely determines the electron scattering properties of the models (Adapted from Iwai et al. (2012) (online supplementary material), with permission)

8 Summary

The skin barrier is essentially constituted by a uniquely organized lipid material situated between the cells of the horny layer of skin. This lipid material is organized as stacked bilayers of fully extended ceramides.

The physical state of the skin’s lipid material is gel like.

The skin’s lipid material is responsible for both the skin barrier’s low permeability and its robustness towards environmental stress.

1 Introduction

The epidermis is the continuous stratified squamous epithelium covering the skin. Both the physiologic cohesion and exfoliation are balanced functions of the stratum corneum (SC) integrity (Mohammed et al. 2011). Corneocyte desquamation is a complex multistep process that is globally related to the long-term keratinocyte renewal, but disconnected from the epidermal maturation (Piérard et al. 2000; Chu and Kollias 2011; Ishida-Yamamoto et al. 2011; Lin et al. 2012). By a matter of fact, the imperceptibly corneocyte casting off from the skin surface can be properly

appreciated only after considering the whole physiology of keratinocytes. In addition, it is essential to consider the molecular structures involved in the regular corneocyte adhesion and cohesion in order to perceive the intercellular binding defects present in the rough/dry skin condition, xerosis, and ichthyoses. Indeed, the SC is not simply an assembly of dead cells, but it represents a dynamic and metabolically interactive tissue.

Cell surface glycoproteins, specialized intercellular junctions such as (corneo)-desmosomes, focal adherens contacts, tight junctions, gap junctions, and keratinosomes play major roles in keratinocyte communications and adhesion (Haftek et al. 2011; Igawa et al. 2011). Desmosomes represent specific cell membrane contacts between adjacent keratinocytes forming well-circumscribed symmetrical intercellular junctions exhibiting specific ultrastructural features. They correspond to electron-dense plaques apposed along the cell membrane. They are composed of three parallel bands. The inner fibrillar band is the area where intracellular keratin filaments loop. Traversing filaments extend between intermediate filaments and globular structures located in the cell membrane. The intercellular space encased between the desmosomal plaques is about 30 nm thick and is centered by a dense line.

Plaque components were identified as desmoplakin I in simple epithelia, desmoplakin II in squamous epithelia, desmoplakin III or plakoglobin, desmoplakin IV in stratified epithelia, and desmocollin which is a calmodulin-binding protein and D1 antigen. Desmoplakins are related to the cadherin family. Desmoglein and desmocollins I and II are transmembrane glycoproteins present in the intercellular area inside desmosomes.

The number of desmosomes globally increases with the maturation of the stratum spinosum. During the upward migration of keratinocytes, desmosomes are subject to endocytosis and are degraded inside the cells. Formation of new desmosomes probably occurs where cells are pushed in close contact to each other. During epidermal cornification in humans, desmosomal structures become asymmetrical. At the level of the first layer of

corneocytes, plasma membrane thickening occurs in areas outside desmosomes. In upper layers, the characteristic trilaminar structure of desmosomes is altered into an electron-dense plug referred to as corneodesmosome. Strength of corneocyte attachment correlates with the number and distribution of corneodesmosomes. These structures are evenly distributed in the deep SC compactum and only present to corneocyte edges in the uppermost SC disjunctum. Interneocyte adhesion has a tongue-and-groove appearance with corneodesmosomes riveting corneocyte peripheries into a lipped groove on adjoining cells.

2 Disorders of Cornification and of Interneocyte Cohesion

As described above, the molecular structure of the normal SC is complex. Therefore, a broad scope of defects commonly underlies a variety of scaling disorders. Changes in the SC cohesion and renewal are then commonly uneven, and clumps of corneocytes are released from the skin surface instead of the normal single cell shedding. This phenomenon is defined as scaliness.

The epidermal turnover time (ETT) of the epidermis is the amount of time for the self-renewal of the whole keratinocyte population. It applies for the transit time of cells in the whole epidermis or in the SC alone. ETT represents the time needed for a given cell to pass from the basal layer to the outer surface of the skin. It represents about 52–75 days in the normal epidermis. ETT is typically reduced in most hyperproliferative conditions. The SC turnover time is about 2 weeks. It is evaluated by the dansyl chloride (DC) (Takahashi et al. 1987; Piérard 1992) or dihydroxyacetone (DHA) (Piérard and Piérard-Franchimont 1993; Uhoda et al. 2004) tests. In regular proliferative conditions, a xerotic SC is produced at a normal rate, but fails to desquamate due to persistent corneocyte cohesion. The relationship between disorders of cornification and hyperproliferative disorders encompasses two distinct conditions. In the first group, scaling commonly results from the flooding

of the SC with immature or incompletely mature cells (parakeratotic cells). In the second group, any altered barrier function drives epidermal hyperproliferation and in some instances tissue hyperplasia. The most common conditions where abnormal desquamation occurs are known to the layman as dandruff (12) and the so-called dry skin (Piérard 1989).

A key aspect of the orthokeratotic xerosis resides in a relative lack of the intracellular natural moisturizing factor (NMF) which maintains the corneocyte hydration as they move toward the skin surface. The osmotically active NMF results from the degradation of filaggrin. It represents the primary moisturization process of the SC. It fails due to interindividual variations, old age, and various other factors. Another unrelated reason for orthokeratotic xerosis is a defect in the breakdown of corneodesmosomes. Such process is normally due to enzymatic action released by keratinosomes (Egelrud and Lundstrom 1991). Changes in epidermal lipids, especially in ceramides and cholesterol sulfate, are commonly linked to changes in protease activity or access to corneodesmosomes. Failure to degrade corneodesmosomes correctly is a fundamental factor in many or most skin conditions where flaking occurs.

3 Treatments Affecting Desquamation

Retinoids are important regulators of terminal differentiation of the epidermis (Piérard-Franchimont et al. 1998; Kim et al. 2011). They are used as potent drugs to treat a series of hyperkeratotic disorders. The so-called keratolytics such as the α - and β -hydroxy acids are in fact desquamating agents probably acting on corneodesmosomal proteins, but leaving keratin molecules intact (Piérard-Franchimont et al. 1998; Lévêque et al. 1995). Both the emollients and moisturizers modify in an indirect way the corneocyte-to-corneocyte adhesion. Both cause a buildup of water in the SC. They lead to greater flexibility and extensibility of the SC.

4 Methods for Determining the Desquamation Rate

Various methods for evaluating the cohesion and exfoliation of the SC have been designed over the past decades (Roberts and Marks 1980; Piérard 1996; Piérard et al. 1992). They are associated with possible specific drawbacks in the sampling procedure and/or in the quantification process.

4.1 Quasi-Passive Collection Methods

Dandruff is probably the only skin condition allowing the collection of desquamating products in a really passive way (Piérard et al. 2006). A specific adhesive-coated disk (ACD) (D-Squame, CuDerm Corp., Dallas, TX, USA, or Corneodisc, C+K Electronic, Cologne, Germany) is applied under moderate pressure and for a few seconds on the target area of the scalp. On removal, dandruff remains stuck to the ACD. After deposition onto a dedicated background, the material is ready for the assessment. A crude method compares the aspect of the samples using a visual grading reference card. Such data are only provided on an ordinal scale. Another procedure relies on recording the specular light reflectance of the samples using adequate Charge coupled advice (CCD) cameras such as the Visiopor[®] PP34 (C+K Electronic). Image analysis provides quantitative data (Piérard-Franchimont et al. 2011). Still another procedure uses a staining step of the squames by a toluidine blue-basic fuchsin stain followed by the global assessment of the color. The chroma C value is used in reflectance colorimetry (Piérard et al. 2006, 2015).

In other circumstances, when the spontaneous desquamation is not accessible by direct sampling, visualization of corneocytes remaining in the SC after a defined period of time is possible. The procedure begins by staining the SC with the fluorescent DC or the self-tanning DHA dye. Two ways of assessment are possible. The first assessment means consists of *in vivo* fluoro- or photometric measurements performed at regular

intervals. A kinetics of the dye fading can be performed (Takahashi et al. 1987; Uhoda et al. 2004). The procedure is affected by external factors altering desquamation, such as the mechanical effects of clothing, toiletries (Paye et al. 1994), and social contacts. The second assessment means consists of collecting the superficial part of the SC after a defined period of time (about 10 days). The harvesting methods are ACD and the cyanoacrylate skin surface stripping (CSSS). The material is examined under a fluorescence or white light microscope (Piérard 1992; Piérard and Piérard-Franchimont 1993; Piérard et al. 2014). Image analysis allows the quantification and localization of the stained and unstained corneocytes.

Still another cumbersome approach is the older chamber technique collecting all shedding corneocytes and squames from a defined skin area for a given time (Corcuff et al. 1987). A nonionic surfactant added in the chamber somewhat interferes with the natural spontaneous process of desquamation.

4.2 Mechanically Forced Collection Methods

The procedure of forced desquamation results from the application of some forces overcoming the intercorneocyte binding forces. This is achieved by rubbing or scratching the SC or following application of some adhesive-coated material. Early methods used various mechanical scrubbing devices. The access to such approaches was limited to a few laboratories. Tape strippings were not frequently used because the binding strength of the adhesive to the SC was heterogeneous between tapes.

Currently, the most common method for assessing scaliness and desquamation relies on controlled squamometry involving the commercially available ACD (Piérard et al. 1992; Paye et al. 1999; Shimizu and Maibach 1999; Piérard-Franchimont et al. 2000). The application pressure must be controlled by a dynamometer. It

usually ranges between 10 and 25 kPa. The set time of ACD application must be defined. It is commonly limited to 5, 10, or 30 s, but possibly extended to 60 s when some effects of the transepidermal water loss are scrutinized. The assessments are similar to the abovementioned procedures in dandruff assessments. A high-resolution fluorescent visualization of corneocytes is provided by the combination of complimentary dyes (Guz et al. 2009).

Corneocyte quantification is possible using densitometry and spectroscopy methods (Schwarz et al. 2012). A gravimetric approach is also possible by carefully weighing the ACD before and immediately after sampling. This procedure requires much expertise to avoid any desiccation effect.

CSSS can be used for descriptive reports about the topography of hyperkeratosis in order to show the uneven pattern of scaliness over the skin surface (Piérard-Franchimont and Piérard 1985). Such evaluation is possibly combined to the recording of the skin capacitance mapping/imaging (SCMI) (Bazin et al. 2010).

1 Introduction

Tape stripping is a technique which is widely used for investigating skin absorption of topically applied products. Adhesive tapes are repeatedly applied to the same skin area treated with a cosmetic or pharmaceutical product to remove thin layers of stratum corneum (SC). The amount, of, for example, a pharmacologically active ingredient (API), can be determined directly by

spectroscopic methods (e.g., by performing Attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) on the tapes or on the stripped skin surface) or after extracting the tape strips with a suitable solvent which dissolves the API.

Tape stripping is particularly useful for evaluating topical bioavailability of locally acting drugs for which systemic levels (in the blood or urine) are either not measurable or, except for estimating systemic side effects, have little meaning for their actual pharmacological efficacy. The data that is obtained is either reported as cumulative amount of API absorbed into the SC after a certain time (by summing up the amount of API extracted from all tapes, Fig. 1a) or as API concentration versus SC depth profiles (Fig. 1b). In order to determine API concentration at a certain SC depth, the amount of SC on each tape strip must be known. This amount is necessary to first of all determine the relative position within the SC and to calculate the volume of SC removed by the tape and thus determine the API concentration in this SC volume.

By performing tape stripping after different incubation times, the dermatopharmacokinetics (DPK) can be evaluated. This includes the maximum concentration (c_{max}), the time of maximum concentration (t_{max}), and the area under the SC

concentration versus time curve (Fig. 1b). The tape stripping method has great potential as an alternative method for testing bioequivalence (BE) of topically applied generics in comparison to a reference product. Unfortunately, an FDA draft guideline recommending tape stripping for this purpose was withdrawn in 2002, after issues arose due to poorly defined experimental standardization. Currently, tape stripping is only recommended by the FDA for BE testing of drug classes which target the SC, such as antifungals (Narkar 2010). Furthermore for corticosteroids the in vivo skin blanching or vasoconstriction assay is recommended by the FDA for demonstrating BE, while any other topical generics have to be evaluated clinically.

In an effort to reestablish acceptance of tape stripping as a method for BE testing which is not limited to certain drug classes, standardization of the procedure is imperative. In this regard, methods to quantify the amount of SC removed by each tape strip have become the focus of research. Especially in the older literature, it is commonly assumed that one tape strip uniformly removes a single layer of corneocytes. Assuming a total SC thickness of, for example, 20 μm in humans, with each layer having a thickness of ca. 1 μm , this leads to the conclusion that a total number of 20 tapes will remove

Fig. 1 Example: skin absorption of an API with MW 300 Da, XlogP3, finite dose 15 mg/15 μl in aqueous medium applied to an area of 1.767 cm^2 full thickness human skin in a Franz diffusion cell with acceptor volume of 3.5 ml; the data were simulated with DSkin Software Version 1.2.2, Scientific Consilience, Saarbrücken,

Germany. (a) Cumulative amount of API penetrated into the SC after a certain time; (b) API concentration versus SC depth profiles (black solid line 15 min, black dotted line 30 min, black short-dashed line 1 h, black dash-dotted line 6 h, black long-dashed line 24 h)

the SC down to the viable epidermis. Meanwhile it is widely accepted that these assumptions may be misleading. First of all the SC thickness clearly differs between individuals and body regions and may also be influenced by the applied formulation. The most important parameter influencing tape stripping is intercorneocyte cohesion. Corneocyte cohesion decreases from the inside to the outside of the SC and is minimal in the stratum disjunctum which is ready to being desquamated. Consequently, usually the first two tapes remove considerably larger portions of SC than later tapes, while the last tapes usually remove very little amount of SC. Corneocyte cohesion further depends on skin hydration and is less in dry skin. Also, the stickiness of different adhesive tapes varies and will influence the amount of SC removed. In the event, for example, the number of tapes required to reach a certain depth within the SC or the total number of tapes to remove the SC quantitatively may differ between persons, test groups, and body sites. Thus it is necessary to employ a method to accurately determine the amount of SC on each tape strip. NIR densitometry is aptly suited for this purpose.

2 Near-Infrared (NIR) Densitometry for Standardizing Tape Stripping

NIR densitometry relies on measuring pseudo-absorption in the infrared range generated by a partially transparent obstacle obstructing the light path. For this purpose a circular infrared beam (wavelength 850 nm, 13 mm diameter) is directed onto a photodiode. A sample holder which takes up the tape strips is inserted into the beam path, and the intensity reduction in comparison to a blank reference tape (i.e., a tape strip which had not been in contact with the skin surface) is measured. Assuming homogeneous removal of the SC and thus homogeneous coverage density of the SC across the tape area, the corrected NIR pseudo-absorption $((\text{abs. } 850 \text{ nm}) - (\text{abs. } 850 \text{ nm blank}))$ in % can be related to the average amount of SC removed per area (wt_{SC}/A):

$$wt_{SC}/A = ((\text{abs. } 850 \text{ nm}) - (\text{abs. } 850 \text{ nm blank}))/a \quad (1)$$

In Eq. 1 a is a constant obtained from linear regression analysis of the corrected NIR pseudo-absorption versus the amount of SC per area measured, for example, by protein quantification (Voegeli et al. 2007; Klang et al. 2011; Franzen et al. 2012). The constant may depend on the species and body region which is used, as well as on the adhesive tape brand. It has to be determined for the specific requirements of the experiment. SC from human or animal skin can be obtained for this purpose by trypsinization followed by freeze drying or desiccation (Kligman and Christophers 1963; Hansen et al. 2008). A calibration curve of accurately weighed amounts of dry SC is prepared, the protein is extracted by combined treatment with alkaline solution and shear stress, and the solution is neutralized and buffered if necessary. Tissue debris is removed by centrifugation, and the protein content in the so-prepared standards is determined by a custom protein quantification kit with adequate sensitivity. For further instructions see also the following references: Hahn et al. (2010) and Franzen et al. (2012). It should be kept in mind that if a protein assay is used as a reference method to compare against the NIR densitometry, this assay needs to be calibrated with SC protein from the same species that is later used in the experiments. This is necessary as the reaction efficiency of many assays strongly depends on the protein used (Klang et al. 2011). For example, our experience shows that 1 g of bovine serum albumin (BSA) corresponds to 4.27 g of human SC but only 1.84 g of SC from pig ears when analyzed under identical conditions (micro-BCA assay, see also Franzen et al. (2012)).

NIR densitometry has considerable advantages over other established methods which quantify the amount of SC removed by tape stripping, such as through quantifying the amount of protein on each tape, through gravimetric or other optical methods (Dreher et al. 1998, 2005; Weigmann et al. 1999; Jacobi et al. 2005). Voegeli et al. could demonstrate that NIR densitometry is robust with respect

to factors such as gender, age, body site, pH, and skin hydration (Voegeli et al. 2007). Most importantly, the result is available without delay, and tape and API are not destroyed by the measurement so that they are available for further analysis.

Thus the amount of SC and the amount of API can be determined on exactly the same tape strip.

To obtain the SC thickness l_{SC} on each tape, both sides of Eq. 1 are divided by protein density ρ_{SC} . A reasonable estimate would be $\rho_{SC} = 1 \text{ g/cm}^3$ (Hansen et al. 2009):

$$l_{SC} [\mu\text{m}] = \frac{wt_{SC}/A}{\rho_{SC}} = \frac{((\text{abs. } 850 \text{ nm}) - (\text{abs. } 850 \text{ nm blank}))/a'}{\rho_{SC}} \quad (2)$$

For tape stripping of pig ear skin in vitro, Franzen et al. determined a value of $a' = 23.9 \mu\text{m}^{-1}$. They found no significant differences between D-Squame tape and tesafilm kristall-klar which can both be used with this constant (Franzen et al. 2012). In the literature only this value for pig ear skin in vitro is available. No values for human skin in vitro or in vivo have been published although several publications report correlations between NIR densitometry and protein quantification data; however in all cases, other proteins than SC protein were used for the calibration so that a' cannot easily be calculated.

Figure 2 and Table 1 show NIR pseudo-absorption data obtained for tape stripping of fresh and frozen human skin in vitro (Fig. 2a) and human skin in vivo (Fig. 2b) correlated with the respective SC weight per area data

determined by a micro-protein assay. A linear regression analysis was performed, and the results are presented in Table 1. Tape stripping in vitro was performed on excised abdominal skin from three female Caucasian donors undergoing abdominal reduction surgery which was either used “fresh” on the day of surgery or after storing “frozen” at $-26 \text{ }^\circ\text{C}$ for not longer than 3 months, taking care that the skin underwent no repeated freeze-thaw cycles. Tape stripping in vivo was performed on the inner forearm of two volunteers who had signed informed consent forms. Ethical agreement by the ethical committee of “Arztekammer des Saarlandes” was available. The tape stripping, NIR densitometry, and protein quantification procedures that were used have already been described by Franzen et al. (2012). Tape stripping was

Fig. 2 (a) In vitro, human skin, *filled circle/solid line* = frozen skin, linear regression analysis: $n = 344$, slope = 0.159, $r^2 = 0.340$. *Open circle/dotted line* = fresh skin, linear regression analysis: $n = 52$, slope = 0.152,

$r^2 = 0.619$. Overall fit, $n = 396$, linear regression analysis: $n = 52$, slope = 0.158, $r^2 = 0.387$. (b) In vivo, human skin; linear regression analysis: $n = 110$, slope = 0.145, $r^2 = 0.612$

Table 1 Conversion factor a' for different species, applicable to D-Squame tape and tesafilm kristall-klar

	a' (μm^{-1})

Human skin in vitro	15.8
Human skin in vivo	14.5

continued until the lower limit of quantification of the NIR densitometry was reached which indicates the complete removal of the SC (Hahn et al. 2010; Franzen et al. 2012).

The data in Fig. 2/Table 1 indicate that the constant a' obviously depends on species. It is higher for pig ear skin than human skin. Between a' for human skin in vitro and in vivo, there is only a small difference; differences between frozen and fresh skin in vitro are marginal. A higher value of a' indicates a steeper slope of the graph in Fig. 2, i.e., a lower SC mass per area generates a higher NIR pseudo-absorption. This difference is at least partially due to the different reaction efficiencies of human and porcine SC extract in the protein assay, as already mentioned. To check the accuracy of the obtained results for a' for both species, in a following section a' will be used to calculate the total SC thickness, and the results will be compared to a reference value determined by histological analysis.

3 Influence of Storage Time

For human skin the data in Fig. 2 shows that for the in vitro data storage over some limited time in the freezer at -26°C considerably increases variability (compare $r^2 = 0.340$ and 0.619 for frozen and fresh skin in vitro, although a' is not influenced). The general recommendation based on this data is that NIR densitometry is suitable for analyzing the SC amount on tape strips obtained in vivo in human volunteers and in vitro only on fresh, non-frozen skin. This is different from excised pig ears in vitro where Franzen et al. reported that storage over 3 months (at 4°C for up to 24 h and at -21°C for up to 3 months) did not significantly influence the results (Franzen et al. 2012).

4 In Situ Determination of Total Stratum Corneum Thickness

It has now been established that NIR densitometry accurately determines the thickness of SC removed by each tape (Hahn et al. 2010), as well as the number of tapes required to remove the SC quantitatively (for in vitro human SC and stripping with tesafilm kristall-klar, the efficiency was 97 %; for excised pig ear skin with the same tape, the efficiency was 83 %; with D-Squame tape, it was 92 %) (Voegeli et al. 2007; Hahn et al. 2010; Klang et al. 2011; Franzen et al. 2012). Consequently, by continuing tape stripping down to the viable epidermis and by calculating the cumulative amount of SC removed, the result should equal the total SC thickness l_{SC-tot} :

$$l_{sc-tot} = \sum_{n=1}^{\infty} l_{SC-n} \quad (3)$$

Franzen et al. have demonstrated for tape stripping on excised pig ears that the total SC thickness can indeed be accurately determined based on Eq. 3 (Franzen et al. 2012). For eight different pig ears, they found no significant differences between the average thickness determined by NIR densitometry and the common histological method based on skin biopsies (Franzen et al. 2012). The data is reproduced in Table 2 and augmented by a value for fresh human skin in vitro. There were no significant differences between the NIR- and histology-based values for fresh human skin. It was interesting to observe that although the total SC thickness was very similar between human abdominal and pig ear skin, it took ca. 50 or even more tape strips to quantitatively remove the porcine SC, while ca. 20 tapes sufficed for human SC (tesafilm kristall-klar or D-Squame in both cases). This demonstrates once again the greater cohesion of porcine SC which had already been mentioned by, e.g., Klang et al. (2011).

Compared to histology NIR densitometry is quicker and averages the SC thickness over a

Fig. 3 Cross section (6 μm thickness) through frozen pig ear skin obtained using a cryomicrotome (MEV Cryostat, SLEE, Mainz, Germany) and stained using Mayer’s hematoxylin and eosin. The optical microscope images were taken using a Zeiss Axio Scope A1 light microscope

(Carl Zeiss Microscopy GmbH, Oberkochen, Germany) equipped with a digital camera (AxioCam ERc 5 s). Images were edited and labeled using the software ZEN lite 2011 (Carl Zeiss Microscopy GmbH, Oberkochen, Germany)

Table 2 SC thickness calculated according to Eq. 3 from NIR densitometry and histology

		NIR densitometry [μm]	Histology [μm]
Pig ear skin in vitro ^a	#1	14.9 ± 3.9	9.5 ± 2.2
	#2	10.9 ± 0.7	14.5 ± 5.2
	#3	9.0 ± 0.9	14.3 ± 4.7
	#4	8.6 ± 1.6	11.1 ± 3.3
	#5	9.9 ± 2.6	13.4 ± 4.8
	#6	13.1 ± 2.0	12.8 ± 3.7
	#7	12.7 ± 3.6	14.7 ± 6.7
	#8	12.6 ± 1.2	11.4 ± 2.4
Fresh human skin in vitro		10.0 ± 1.4	10.5 ± 2.9

^aData was reproduced from Franzen et al. (2012) (mean ± sd)

larger area (1.327 cm²). In contrast the histological method requires an enormous amount of repeat measurements based on light microscopy images of cryosections from different skin biopsies to get a reasonable average of the total SC thickness, as the thickness varies visibly over a stretch of SC (Fig. 3).

In summary, NIR densitometry is a nondestructive, quick, and reliable method which can be a valuable alternative for determining the

amount of SC on tape strips and the total SC thickness in situ.

1 Introduction: The Tape Stripping Method

The tape stripping method, where SC proteins are removed from the skin surface by means of standardized adhesive tapes, is a well-established method to obtain skin penetration data. The common experimental setup involves in vivo tape stripping on human forearm skin after application of a penetrant of interest. The parameters of application, such as the amount of formulation per cm², the location of the treated area, and the application time, have to be defined precisely. In this fashion, the skin penetration potential of penetrants such as drugs from newly developed vehicles can be evaluated.

The nature of the adhesive tapes employed for such experiments has to be defined as well. In order to ensure constant adhesive power of the tapes and better comparability between experiments, it is recommended to use a constant tape brand, e.g., Tesa[®], D-Squame[®], or Corneofix[®], in all studies. The experimenter should be aware of

his role in ensuring constant application time and pressure as well as a rapid tape removal.

Having removed the adhesive tapes from the skin, the latter must be analyzed for two aspects. Firstly, the amount of penetrated drug has to be determined for each individual tape. In order to obtain an accurate penetration profile of an applied drug, it is not sufficient to merely correlate the recovered drug amounts to the tape number. So, secondly, the exact amount of SC thickness, i.e., the mass of corneocytes removed with each tape, has to be determined and correlated to the amount of drug recovered from the respective tape. By analyzing both drug content and amount of corneocyte aggregates on each tape, the accurate penetration depth of applied drugs can be determined (Weigmann et al. 1999).

For the quantification of SC proteins *in vivo*, different analytical methods have been proposed, such as differential weighing (Bommannan et al. 1996; Kalia et al. 1996, 2000; Weigmann et al. 2003; Martin et al. 1996; Herkenne et al. 2006), microscopic techniques (Lindemann et al. 2003), and protein assays (Dreher et al. 1998, 2005). These techniques are comparatively time-consuming and may exhibit drawbacks in terms of accuracy, e.g., the gravimetric analysis is affected by residual moisture on the tapes. Recently, a new imaging method based on the analysis of pixel grayscale values and distribution has been introduced for quantification of SC proteins (Russell and Guy 2012). This technique is more accurate than differential weighing and has an acceptable signal-to-noise ratio.

A different approach is optical spectroscopy in the visible range, where the pseudo-absorption of the SC proteins serves to indirectly quantify the mass of corneocytes on the tapes (Weigmann et al. 1999, 2003). The pseudo-absorption is composed of reflection, scattering, and diffraction of the light by corneocytes and is not disturbed by the presence of other skin components (Weigmann et al. 1999, 2003, 2005, 2009; Lademann et al. 2009). The only drawback of this well-established method is the need for manual preparation of the sample tapes in order to analyze them with a specifically modified UV/Vis spectrophotometer with a larger measurement area.

Following these strategies developed by Lademann and co-workers, the use of IR-D represents a rapid and convenient approach to determine the optical pseudo-absorption of the proteins (Voegeli et al. 2007). In the past years, this technique has been found to be both practical and accurate for quantification of human corneocytes during tape stripping experiments on the human skin *in vivo* (Voegeli et al. 2007) and *in vitro* (Hahn et al. 2010). A particular advantage of IR-D is its nondestructive nature: after analysis of the tapes, the latter can be further analyzed, e.g., for their drug content. Recently, the technique of IR-D has been validated against gravimetric analysis for SC quantification of the human skin *in vivo* (Mohammed et al. 2012). Likewise, recent studies validating IR-D against the well-established method of UV/Vis spectroscopy were conducted by our group for both the human skin *in vivo* and porcine skin *in vitro* (Schwarz et al. 2012).

In summary, the discussed techniques for SC quantification have been mostly employed for the human skin *in vivo* or sometimes *in vitro*. Since the use of the human skin is not always an option due to legislative and organizational issues, efforts have been made to establish an *in vitro* substitute model for tape stripping experiments using the porcine ear (Schwarz et al. 2012; Klang et al. 2011, 2012). Porcine ear skin is generally accepted as a suitable *in vitro* substitute for the human skin (Herkenne et al. 2006) and particularly so regarding *in vitro* tape stripping (Sekkatt et al. 2002; Jacobi et al. 2007). Porcine ears can be obtained from local farmers or slaughterhouses after clarifying that removal of the ears prior to sanitation processes such as high steam cleaning is essential.

2 Particularities of the Porcine Skin in Tape Stripping Experiments

Porcine ear skin requires preparation before starting tape stripping experiments. Firstly, it must be clarified whether fresh, refrigerated, or defrosted ears will be employed. Although differences have been shown to be small or negligible

for both the human skin in vitro (Hahn et al. 2010) and porcine skin in vitro (Klang et al. 2011; Franzen et al. 2012), it is recommended to choose one of the above options to obtain maximum reproducibility and comparability between results. In case of porcine ear skin, higher amounts of SC remained after tape stripping up to the IR-densitometric detection limit after 3 months of storage when compared to fresh porcine ear skin, i.e., the cohesion between the lower layers of corneocytes appeared to be increased. As a result, the calculated SC thickness might be systematically underestimated. Since the remaining SC, however, is frequently located within wrinkles, no errors in the calculated SC thickness will occur in such cases (Franzen et al. 2012).

For both fresh and defrosted ears, the subsequent preparation steps include cleaning of the ears, freeing them from hair, and confirming the intactness of the skin barrier function, e.g., by measuring the transepidermal water loss (Klang et al. 2011; Sekkat et al. 2002).

General aspects to keep in mind for in vitro tape stripping include exact marking of the stripping area, constant intensity and duration of pressure application, constant velocity of tape removal (Weigmann et al. 2003; Breternitz et al. 2007), and reduction of the influence of wrinkles by stretching and fixing of the ears and applying pressure with a rolling movement (Lademann et al. 2009; Breternitz et al. 2007; Dickel et al. 2010). Further aspects to be considered are the role of skin-cleaning procedures (Schwarz et al. 2012) and the possible interaction between the tapes and the applied formulations (Klang et al. 2012; Nagelreiter et al. 2013). For in vitro tape stripping, higher pressure may be required to obtain reproducible amounts of SC proteins (Hahn et al. 2010; Klang et al. 2011; Wagner et al. 2000).

When conducting the tape stripping process, porcine skin shows a different corneocyte distribution on the adhesive tapes than the human skin (Fig. 1). This is due to structural differences: the porcine skin cells throughout the epidermis are organized in polygonal clusters or columns that are separated by “canyons” (Carrer et al. 2008). These structures cause a distinct pattern of large

corneocyte aggregates and intercluster regions that can be observed particularly on the first adhesive tapes removed from the skin surface. No such patterns are observed during tape stripping on the human skin.

The intercluster regions of porcine skin, which start as wrinkles on the skin surface, will exhibit lower corneocyte density on the tapes throughout the tape stripping process. Since the first few tapes generally exhibit the highest protein density due to the lower cohesion between corneocytes within the upper layers, comparatively inhomogeneous protein coverage of the tapes is obtained. As the tape stripping process proceeds, more homogeneous protein coverage is observed.

The type of tape plays a role in this context as well. Higher adhesive power will lead to a more irregular pattern of protein removal due to overall higher corneocyte content of the tapes. Consequently, D-Squame[®] tapes showed a more irregular protein removal due to their higher adhesive power than Comeofix[®] tapes, which was reflected in a lower coefficient of determination R^2 in our studies ($R^2 = 0.812$ for Comeofix[®], $R^2 = 0.732$ for D-Squame[®] (Klang et al. 2011)). In independent studies using porcine ear skin, only slightly different values were obtained when comparing D-Squame[®] ($R^2 = 0.761$) and tesafilm[®] kristall-klar ($R^2 = 0.704$) (Franzen et al. 2012). In case of the human skin in vitro, better correlations were generally found using D-Squame[®] when compared to tesafilm[®] kristall-klar (Hahn et al. 2010).

Due to the canyon-like structures and the resulting inhomogeneous protein coverage of the tapes, it is all the more important to follow an exact working protocol including a highly reproducible way of pressure application and tape removal. Keeping these aspects in mind, accurate data can nevertheless be obtained with tape stripping on porcine skin and subsequent analysis of the pseudo-absorption, e.g., by UV/VIS spectroscopy (Weigmann et al. 2009). Despite the potential role of the “canyons” as shunt pathways through the epidermis, nearly identical penetration behavior was found for different sunscreens after tape stripping of the human skin in vivo and porcine skin in vitro (Weigmann et al. 2009). In general, a slightly higher permeability for porcine

Fig. 1 Adhesive films removed from the skin surface of the human skin (**a**) and porcine ear skin (**b**) in the course of a tape stripping experiment. The shown adhesive tapes represent the respective first tapes to be removed from the skin surface, hence the large amount of adherent corneocytes (Figure 1a reprinted from Klang et al. (2011), Copyright © 2011, Karger Publishers)

skin has been reported (Singh et al. 2002; Godin and Touitou 2007), which may however also be related to the larger dimension of porcine hair follicles (Weigmann et al. 2009). Despite certain challenges regarding tape stripping on porcine skin, representative results can be obtained when keeping to an accurate working protocol. For

in vitro experiments, porcine ear skin might be even more suitable than excised human skin since the porcine ear remains intact and the skin is still stretched out on the cartilage when the experiment is started; thus, contraction of elastic fibers and the resulting decrease of follicular penetration are avoided (Patzelt et al. 2008).

3 IR-Densitometry for the Quantification of Porcine Stratum Corneum Proteins

The IR-densitometer SquameScan™ 850A (Heiland electronic GmbH, Germany) was shown to be an efficient tool for quantification of SC proteins not only for the human skin in vivo (Voegeli et al. 2007) and in vitro (Hahn et al. 2010) but also for excised porcine ear skin (Klang et al. 2011; Franzen et al. 2012).

The device is used to determine the decrease in light intensity of a circular infrared laser beam at a wavelength of 850 nm (Fig. 2). This so-called pseudo-absorption value is then corrected against the pseudo-absorption measured for a blank adhesive tape within the same sample holder. The resulting pseudo-absorption value in % has then to be converted into the corresponding amount of protein per tape in $\mu\text{g}/\text{cm}^2$. This amount of SC proteins can furthermore be converted into the SC thickness removed with each tape.

To achieve these goals, validation of the IR densitometer for the quantification of porcine SC proteins was performed as follows: having conducted a set of tape stripping experiments, the amount of SC proteins on the tapes was subsequently determined by both IR-densitometry and the Micro BCA™ protein assay. The latter is a colorimetric assay based on the formation of a chelate complex that can be quantified by UV/Vis spectroscopy at $\lambda = 550 \text{ nm}$. Methodological details can be found in the literature (Voegeli et al. 2007; Franzen et al. 2012). In order to calculate the SC mass removed with each tape, an estimated calibration curve based on the use of bovine serum albumin for calibration of the

Fig. 2 The IR-densitometer SquameScan™ 850A (Heiland electronic GmbH, Germany) for analysis of SC proteins on adhesive tapes. The sample holders provide

space for a blank adhesive tape for correction against the background, followed by the sample tapes

protein assay was proposed (Klang et al. 2011). Taking into account the higher reaction efficiency of bovine serum albumin when compared to extracted porcine SC (Franzen et al. 2012), a more accurate calibration is obtained. The subsequent linear regression analysis between protein mass per tape and pseudo-absorption was performed for different standardized tape brands. Figure 3 shows the overall linear regression taking into account all tapes irrespective of obviously inhomogeneous protein coverage and tape brand. The resulting coefficient of determination R^2 of 0.729 is only slightly lower than that obtained when evaluating the samples of the two tape brands separately (Corneofix® with $R^2 = 0.812$ and D-Squame® with $R^2 = 0.732$ (Klang et al. 2011)) and is in good agreement with data from other working groups (D-Squame® with $R^2 = 0.761$, tesafilm® kristall-klar with $R^2 = 0.704$ (Franzen et al. 2012)).

In order to facilitate protein quantification by IR-D, a more restrictive evaluation was applied (Weigmann et al. 2003; Klang et al. 2011). Individual calibration curves for each experiment were calculated and extrapolated to the total SC depth, as represented by additional zero values. Taking into account all individual curves, a mean factor of proportionality $k = 0.224$ was obtained.

The mass of SC proteins (m) on a normalized tape area of 1 cm^2 can be calculated using this value after IR-densitometric analysis of the respective pseudo-absorption at 850 nm (A_{corr} , after correction against a blank tape) by using the equation

$$m = \frac{A_{corr}}{0.224} \quad (\text{in } \mu\text{g}/\text{cm}^2). \quad (1)$$

The obtained corneocyte mass on each tape can then be transformed into the corresponding SC thickness assuming a mean protein density (ρ_{sc}) of $1 \text{ g}/\text{cm}^3$ within the tissue (Sekkat et al. 2002). In accordance with the proposition of Franzen et al. (2012), this can be expressed as

$$t_{sc} = \frac{A_{corr}}{0.224 \cdot \rho_{sc}} = \frac{A_{corr}}{22.4} \quad (\text{in } \mu\text{m}). \quad (2)$$

The accuracy of the proposed calculations and the resulting factor of proportionality k can be visualized by correlating the SC thickness determined by the two methods, i.e., the protein assay and IR-D, against the respective tape number (Klang et al. 2011). For Corneofix® tapes, the calculated SC thickness is highly comparable for the two methods (Fig. 4). In case of D-Squame®

Fig. 3 Linear regression analysis of SC protein samples after sequential tape stripping on porcine ear skin ($n = 480$, all samples included irrespective of tape brand). For two types of adhesive film, Corneofix[®] and DSquame[®], 12 experiments were, respectively, conducted during each

of which 20 adhesive films were removed ($n = 240$ for each type of adhesive tape). The protein content of each tape was determined by IR-D at 850 nm and with the Micro BCA[™] protein assay; the resulting data were plotted against each other

Fig. 4 Calculated SC depth reached after removal of 20 sequential Corneofix[®] adhesive tapes. The SC depth as determined after analysis of the tapes with the Micro BCA[™] protein assay, taking into account a correction factor for bovine serum albumin versus SC protein

(Franzen et al. 2012), is indicated by *black squares*. The corresponding values obtained after indirect protein quantification by IR-D at 850 nm using the proposed conversion factor of 0.224 are indicated by *white circles*. Values are means \pm SD of $n = 12$ experiments

tapes, which possess higher adhesive power, a slight discrepancy between the values indicates that inhomogeneous protein coverage occurs more frequently.

The total SC thickness of the employed porcine skin in vitro can likewise be determined using IR-D. To this end, quantitative tape stripping experiments are performed until the detection limit of the IR densitometer is reached (Klang et al. 2011; Franzen et al. 2012). By summarizing the calculated amounts of SC on each tape, the entire thickness of removed SC can be calculated. Histological studies showed that the SC thickness as obtained by IR-D is highly comparable to that observed under the microscope (Franzen et al. 2012). The calculations of Franzen and colleagues and the above-presented equations deliver highly comparable results in terms of protein content per tape and corresponding SC thickness. Slightly different values in numerical outcome are obtained, but do not reach statistical significance ($p > 0.05$ for representative data sets); the method of IR-D has thus been validated in independent studies of different laboratories.

As opposed to the human skin, porcine corneocytes are removed in large clusters, which may lead to a more frequent occurrence of the stack effect and thus skewed IR-densitometric values of SC mass (Weigmann et al. 2003). Likewise, the relative amount of SC remaining after tape stripping was found to be higher for porcine skin in vitro than for the human skin in vitro (Franzen et al. 2012). Since the majority of the remaining corneocytes was however located within wrinkles, it can generally be assumed that the calculated SC thickness is sufficiently accurate.

In summary, IR-D is thus a convenient and nondestructive method for quantification of porcine SC proteins in tape stripping experiments using porcine ear skin. Despite the particularities of porcine SC when compared to its human counterpart, reproducible results can be obtained if a strict working protocol is maintained throughout all experiments.

1 Introduction

The epidermis consists of the physical, biochemical, and immunological barriers. The stratum corneum (SC) with its outermost layers serves as the principal physical barrier primarily against percutaneous penetration of various substances (Berrutti et al. 2000; Proksch et al. 2008; Zhang and Monteiro-Riviere 2008).

In 1939, Wolf (1939) introduced the tape-stripping method, whereby successive layers of the SC are removed by repeated strippings with adhesive cellophane tape, thus enabling to study morphologic details of human SC cells. In 1953, Spier and Natzel (1953) were the first to use this technique prior to patch testing, thus thinning the SC of the test area by mechanical reduction of corneocyte layers. Since then, the so-called strip patch test (SPT) is used as a modification of conventional patch testing (PT) to increase the bio-availability of test substances in the deeper epidermal cell layers, with the aim of lowering the minimum triggering level for positive test reactions in sensitized patients (Dickel et al. 2009b; Fernandes et al. 2007; Frosch et al. 1988; Oldhoff et al. 2004; Spier and Sixt 1955).

We proposed a first standardized protocol for performing uniformly the SPT (Dickel et al. 2004) and subsequently proved a significant increase of

test sensitivity of SPT versus PT (Dickel et al. 2009a). It is still an open question, however, whether the considerable interindividual variation of tape strips for the SPT as derived from our protocol (Dickel et al. 2008) results in an interindividual similarity, i.e., reproducibility, of SC reduction. The latter would make SPT reactions comparable and further qualify the SPT procedure for practical use. Here, we report a clinical study which is aimed to investigate the variability and inter-rater agreement of our standardized SC reduction by the use of in vivo confocal laser scanning microscopy (CLSM).

2 Materials and Methods

This prospective, investigator-blinded clinical study was approved by the ethics committee of the Medical Faculty of Ruhr University Bochum (registration no. 2881, date of vote 2009-03-03). Procedures were explained in detail to all subjects, who signed informed consent forms prior to participation. The study was performed in September 2009 at the Department of Dermatology and Allergology, Ruhr University Bochum, Germany. Subjects received a small allowance for their voluntary study participation.

2.1 Study Population

For inclusion, subjects had to be at least 18 years old and had to have clinically normal skin on the back. Exclusion criteria were pregnancy and lactation.

2.2 Tape Stripping

Tape stripping was performed according to our formerly proposed protocol for performing the SPT (Dickel et al. 2004). Tape strips were carried out with a 3M™ Blendederm™ surgical tape (3M™ Medica, 3M Deutschland GmbH, Neuss, Germany; metric 25 mm × 4.5 m; CE no. 0493–BSI 0086–class I; batch no. 201407, exp. date 2014-07-01); any body hair was

Fig. 1 Randomly chosen assembly of test areas on the back of one subject for rater 1 (a) and rater 2 (b) with no tape strips (B, B'), tape strips down to the stratum lucidum

(G, G'), and calculated tape strips (tape strips down to the stratum lucidum $\times 11/26$) for the SPT (A, A')

removed before with a 3M™ clipper. In derogation from the original protocol, patch test substances were not applied.

All subjects were tested on one randomly chosen side of the back by rater 1 (A.G.; Fig. 1a). Three test areas were randomly marked with A, B, and G receiving the following treatments: B = no tape strips (baseline value of SC thickness measurement), G = strips down to the stratum lucidum (SL: reference value for calculating tape strips for the SPT), and A = calculated tape strips for the SPT (formula: tape strips down to the SL $\times 11/26$ (Dickel et al. 2004); target value of SC thickness measurement). Randomization of test side and test areas was conducted according to a randomization list in the total of 75 subjects (supervised by O.K.). A subgroup of 18 subjects was additionally tested on the contralateral side of the back by rater 2 (H.D.) in a blinded manner (Fig. 1b). The three test areas receiving the same treatments were mirrored.

2.3 In Vivo Confocal Laser Scanning Microscopy

Confocal images of all test areas were obtained noninvasively using a VivaScope® 1500 (Lucid® Inc., Rochester, NY, USA) with VivaScan® Version 7 software. The technique applied with a laser

wavelength of 830 nm gave confocal images with a lateral resolution of 0.5 μm and the ability to section SC to papillary dermis (penetration depth of imaging) in 0.94 μm vertical layers. For each test area, a stack consisting of such 140 vertical layers was captured. Quantitative image analysis was then performed with the public domain, Java-based image processing program ImageJ (National Institutes of Health, USA). For SC thickness measurements, vertical sections were reconstructed from the native stacks (Fig. 2a). The appearance of the densely packed keratin bundles in the SC reflecting the white rooflight produced by the CLSM was used to calculate SC thickness (Lucid® Inc. 2005). This reflection makes the SC appear more bright, while the other cell layers of the epidermis and papillary dermis appear darker. Per vertical section the mean out of five measured points put at random was defined as the SC thickness of the corresponding test area (performed by T.G.; Fig. 2a, b).

By using CLSM, we avoided biopsies from each of the test areas on the one hand and artifacts in SC thickness measurements in vitro by histological preparation on the other hand.

2.4 Blinding

Rater 2 was blinded with respect to (i) the number of tape strips performed in the test areas A and G and (ii) the skin reactions in these test areas treated

Fig. 2 Reconstructed vertical section (low-pass filter: Gaussian blur with $\sigma = 3$) of an in vivo confocal image stack of a test area (a). The white rooflights represent the stratum corneum (SC). Plotted in the image are the five measured points (blue) for calculating the mean of SC

thickness. An exemplary intensity curve of the third measuring point is displayed (b); SC thickness is the distance between maximum and minimum of the first derivative of the function to the curve

accordingly by rater 1; the latter is depicted in Fig. 1b. The physician performing SC thickness measurements was blinded with respect to the kind of treatment of the respective test area.

2.5 Statistical Analysis

For sample size calculation, we assumed the values of SC reduction (relative to baseline before tape stripping) being normally distributed with a mean μ of 50 % (Frosch et al. 1988; Spier and Sixt 1955) and a standard deviation σ of 5 %. According to the 2σ -rule, this would mean that roughly 95 % of all relative SC reduction values would lie between 40 % and 60 %. We defined a length of 20 % points for this 4σ -interval as indicating clinical similarity of SC reduction across subjects, i.e., good reproducibility of our proposed protocol for performing the SPT (Dickel et al. 2004). As σ is the central parameter for this 4σ -interval, we planned this study based on a 95 % confidence interval (CI) for σ . By using a small simulation program (SAS code is available from O.K. on request), we found that 60 subjects would be enough to ensure

that the length of this CI would not be larger than two units σ with an 80 % probability.

For descriptive purposes we report categorical variables as absolute (relative) frequencies and continuous variable as median (min-max, Q1, Q3). For the variable of central interest of the SC reduction (in %), we additionally give a histogram and report its standard deviation s together with the corresponding 4s-interval. All statistics are given with the respective 95 % CIs. As a sensitivity analysis, we also calculated the 4s-interval from a nonparametric bootstrap experiment (Haukoos and Lewis 2005) not using the assumption of normally distributed SC reduction values. We additionally checked (by Pearson correlation and differences in means) if subjects' age, sex, and Fitzpatrick skin phototype change the observed SC reduction of rater 1.

To assess inter-rater agreement, we drew a Bland-Altman plot (Bland and Altman 1986). This is defined as a scatterplot plotting, for all subjects, rater difference against the mean value of raters. Good agreement is indicated by (1) a random scatter of points in the plot and (2) most of the points

lying within the limits of agreement (mean rater difference ± 2 standard deviations (SD) of rater differences). Statistical analyses were conducted with SAS[®] (SAS Institute, Cary, NC, USA), version 9.2.

3 Results

Demographic and clinical characteristics of the 75 subjects tape stripped by rater 1 are summarized in Table 1. The complete distribution of relative SC reduction values is given in Fig. 3. As can be seen from the fitted normal density curve ($\mu = 31.3\%$ and $\sigma = 4.4\%$), the values can safely be assumed as normally distributed. The estimated standard deviation s of 4.4% (95% CI, 3.8%; 5.2%) results in a $4s$ -interval from 22.5% to 40.0% with a length of 17.5% (95% CI, 15.1%; 20.9%). We therefore conclude that 95% of all SC reduction values lie within an interval of length 17.5% (95% CI, 15.1%; 20.9%). As can be seen, the upper bound of the confidence is slightly larger than our prespecified critical value of clinical similarity of SC reduction of 20%. The $4s$ -interval from the bootstrap experiment had a length of 19.3% (95% CI, 14.0%; 20.5%).

SC reduction by rater 1 was statistically significant but not clinically relevant changed by Fitzpatrick skin phototype ($P = 0.04$, F-test) because the subject with Fitzpatrick skin phototype V showed an outlying SC reduction value of 19.4% (data not shown). However, no difference was seen for age (Pearson correlation -0.16 (95% CI, $-0.38; 0.07$), $P = 0.16$) or sex (difference in means 0.5% (95% CI, $-1.6\%; 2.5\%$), $P = 0.66$, t -test).

Clinical characteristics of the subgroup of 18 subjects tape stripped independently by rater 1 and 2 are summarized in Table 2. In Fig. 4 we give the Bland-Altman plot to assess agreement in the subgroup of subjects that were rated by the two independent raters. We observe good agreement between the two raters, indicated by a decent random scatter of points and only a single value lying outside the limits of agreement.

Table 1 Demographic and clinical subject characteristics ($N = 75$; rater 1)

Characteristic	Value
Age (years), median (min-max, Q1, Q3)	25 (18–59, 23, 29)
Sex, n (%)	
Female	42 (56.0)
Male	33 (44.0)
Fitzpatrick skin phototype, n (%)	
I	4 (5.3)
II	26 (34.7)
III	35 (46.7)
IV	9 (12.0)
V	1 (1.3)
VI	0 (0.0)
Tape strips down to the SL, median (min-max, Q1, Q3)	38 (14–75, 30, 46)
Tape strips for the SPT,* median (min-max, Q1, Q3)	16 (6–32, 13, 19)
SC thickness (μm), median (min-max, Q1, Q3)	
Before tape stripping	13.0 (10.0–19.0, 11.6, 14.3)
After tape stripping	8.8 (6.9–12.8, 8.1, 9.6)
SC reduction (%), median (min-max, Q1, Q3)	31.6 (19.3–39.8, 28.6, 34.6)

Q1 25th percentile, Q3 75th percentile, SL stratum lucidum, SPT strip patch test; * = tape strips down to the SL $\times 11/26$, SC stratum corneum

4 Discussion

In the present study, our proposed SPT protocol (Dickel et al. 2004) proved to be reproducible with respect to different patients or users. In daily clinical routine, we can therefore expect to receive a uniform SC reduction of approximately 30% by this SPT protocol without any accessory equipment except for the 3M[™] Blenderm[™] surgical tape. Our in vivo SC thickness measurements on the upper back in the range from 10.0 to 19.0 μm with a median SC thickness of 13.0 μm (Table 1) coincide well with the literature reporting a range from 10.0 to 20.0 μm (Breternitz et al. 2007; Piroet et al. 1997; Scheuplein and Blank 1971) and a mean SC thickness of 11.0 μm and 9.4 μm , respectively (Holbrook and Odland 1974; Sandby-Møller et al. 2003).

Our results demonstrate further that the number of tape strippings performed for the SPT needs

Fig. 3 Histogram for the stratum corneum (SC) reduction (in %) in the total of subjects ($N = 75$) by rater 1. Given is also fitted normal density curve with parameters $\mu = 31.3$ and $\sigma = 4.4$

Table 2 Clinical subject characteristics of subgroup ($n = 18$; rater 1 and 2)

Characteristic	Value
Tape strips down to the SL, median (min-max, Q1, Q3)	
Rater 1	28 (15–49, 26, 31)
Rater 2	29 (22–45, 27, 37)
Tape strips for the SPT,* median (min-max, Q1, Q3)	
Rater 1	12 (6–21, 11, 13)
Rater 2	12 (9–19, 11, 16)
SC thickness (μm), median (min-max, Q1, Q3)	
Before tape stripping	
Rater 1	13.2 (10.7–19.0, 12.0, 14.3)
Rater 2	12.3 (10.7–16.9, 11.8, 12.8)
After tape stripping	
Rater 1	9.0 (7.5–11.5, 8.4, 9.6)
Rater 2	8.6 (7.9–10.3, 8.1, 9.0)
SC reduction (%), median (min-max, Q1, Q3)	
Rater 1	31.5 (24.6–39.8, 29.7, 34.6)
Rater 2	31.0 (26.2–38.9, 27.3, 32.8)

Q1 25th percentile, Q3 75th percentile, SL stratum lucidum, SPT strip patch test; * = tape strips down to the SL \times 11/26, SC stratum corneum

to be individualized (Table 1 and 2) (Dickel et al. 2008; Dickel et al. 2009a) and that a fixed, patient-independent number of tape strips for the SPT (cf. Lachapelle and Maibach 2009) is not appropriate. While a certain number of tape strip-pings may be sufficient to enhance absorption and permeability in one individual, it may be insufficient in another mainly due to interindividual differences in the SC structure (Berrutti et al. 2000; Jacobi et al. 2003; Weigmann et al. 2005). Thus, the variability in the amount

of corneocyte layers removed between individual patients seems to be satisfactorily considered by our SPT protocol.

Although tape stripping increases considerably the absorption and penetration of applied substances to the skin (Choi et al. 2003), the reported effect is substantially dependent on the extent of SC removal (Kezic and Nielsen 2009). In pigskin it could be demonstrated that the outermost four or five corneocyte layers contain 40 % of the lipid and constitute most of the barrier function limiting cutaneous water loss and absorption or penetration of substances (Berrutti et al. 2000). Transferred to the human skin by assuming approximately 16 corneocyte layers of equal thickness on the back of Caucasian skin (Holbrook and Odland 1974; Rawlings 2006), reducing the SC by 30 % would hypothetically result in removing the same number of outermost corneocyte layers. However, our observed SC reduction value of 31 % by the SPT protocol (Fig. 3) contrasts with previous reports. To date, a fixed, patient-independent number of tape strips for the SPT – between 9 and 15 depending on source – was claimed to reduce the SC at about 50 % (Frosch et al. 1988; Müller 1980; Spier and Sixt 1955), but systematic investigations on this are not published yet. By drawing an analogy to biopharmaceutical data, Jacobi et al. (2005) described an equation of nonlinear correlation for estimating the relative amount of SC removed by sequential tape strips. For mathematical deduction, they studied the amount of SC removed by each tape strip in 11 subjects on the flexor

Fig. 4 Bland-Altman plot for measuring agreement between rater 1 and 2 in the subgroup of subjects ($n = 18$). Given is also a cubic polynomial fit for the data (black line) and lines indicating the mean difference of

stratum corneum (SC) reductions (mean = 1.21 %) together with the limits of agreement (mean difference of SC reduction ± 2 SD (SD = 4.18 %), gray lines). SD standard deviation

forearms by pseudoabsorption using a UV/Vis spectrometer. According to their equation, a SC reduction of 31 % and 50 %, respectively, would be achieved by 8 and 14 tape strips. However, a direct transferability to our results is somewhat hampered most likely because of a differently chosen skin site and type of adhesive tape (Weigmann et al. 2005).

We understand that our SPT protocol (Dickel et al. 2004) may serve as a clinically useful guide for a uniform SPT procedure, not aiming at a general guideline for the tape-stripping procedure (Breternitz et al. 2007; Lindemann et al. 2003; Löffler et al. 2004). When SPT is employed according to our protocol, three crucial factors remain for improved standardization: (1) the exact pressure applied to the tape strip prior to stripping (default: “gently pressed downward by fingertips” Dickel et al. 2004), (2) the exact contact time of the tape strip to the skin (default: “2 seconds” Dickel et al. 2004), and (3) the exact tape strip removal rate (default: “one quick movement” Dickel et al. 2004; Breternitz et al. 2007; Choi et al. 2003; Lademann et al. 2009; Löffler et al. 2004). Achieving these factors, one might expect that the SC reduction values would lie closer together, i.e., within a smaller range than the found 22.5 % to 40.0 % in this study. However, we have to consider that the more technical demands are specified, the less

frequently the SPT may be used in daily clinical routine (Lachapelle and Maibach 2009).

While it is the main objective of the SPT to reduce the SC penetration-limiting layer by defined and reproducible tape stripping prior to patch testing, there seems to be additional effects with at least partially overlapping pathophysiology which may explain the presence of contact dermatitis in patients with negative PT (Dickel et al. 2008). It is well known that in allergic contact dermatitis inflammation is a basic prerequisite for the adaptive immune system to respond (Bianchi and Manfredi 2009; Grabbe and Schwarz 1998; Martin and Jakob 2008). On the one side, repeated tape stripping itself is capable of evoking a mild and transient inflammation of the skin, thus leading to an immediate release of pro-inflammatory cytokines and chemokines and subsequently the accumulation of antigen-specific cells at the site of inflammation (Fluhr et al. 2008; Holzmann et al. 2004; Nickoloff and Naidu 1994; Onoue et al. 2009). The SPT might be therefore additionally understood as a combined diagnostic tool applying test substances with an irritant which gives the “danger signal” (Friedmann 2007) and hence maximizes the chance of the immune system to respond, i.e., augments allergic responses to the test substances. On the other side, enhanced penetration of a test substance into the living epidermis may increase the degree of skin

trauma by the test substance itself and thus increase the production of localized immunological trauma signals initiating an allergic response to the test substance (Basketter et al. 2008). However, parts of these defined multistage processes need to be further scrutinized.

In the present study, our proposed SPT protocol (Dickel et al. 2004) showed a good reproducibility with a SC reduction of 31 % and a good inter-rater agreement yielding a clinically adequate standardization. Uniformly performing the SPT is thus realizable in clinical practice with minimal effort and appears safe for clinical use because it is inexpensive and minimally invasive.

1 Introduction

The determination of *stratum corneum* (SC) water content has now become a widespread if not systematic practice in the assessment of cosmetics efficacy. It is also of importance in dermatology, allergology, and occupational medicine. The results are of special interest due to the multiple effects of hydration, in particular:

- On the suppleness of the *stratum corneum* and, hence, of all the skin
- On the decrease in the barrier function of the *stratum corneum* and, hence, on the modification of the physiology of cutaneous absorption
- On the activation of enzymatic processes in the intercorneocytic spaces and, hence, on the process of desquamation
- On the acceleration of bacterial proliferation in the *stratum disjunctum* and, hence, on the modification of the ecosystem of the skin surface

Numerous methods are available, and a considerable number of studies have been undertaken to find a simple, practical, and, above all, direct method. The difficulty resides precisely in the latter point. This chapter is a presentation of the methods currently available, in order to assist in selecting a technique, but also a presentation of some methods still confined to research laboratories, with the aim of showing the impressive range of possibilities and inciting development of devices that we would like to see appear on the market. This chapter exclusively addresses the determination of the water content of the *stratum corneum*.

1.1 Physicochemical Aspects of *Stratum Corneum* Water Content

The influence of the water content of the *stratum corneum* (SC) on its mechanical properties has long been known. In 1952, Blank (1952) described the changes in plasticity and flexibility of the SC related to its ability to retain exogenous water. In addition, the barrier property of the SC against transdermal water loss and the influence of water content on the cutaneous permeation of exogenous molecules are of primary importance in physiology and pharmacology.

1.1.1 State of the Water in the *Stratum Corneum*

In the SC, water exists in two thermodynamically very different states, mainly evidenced by thermal methods (differential scanning calorimetry (DSC), thermogravimetry):

- Free water, which can be frozen very close to 0 °C, in which numerous ionized and nonionized molecules are dissolved (metal salts, amino acids, urea)
- Bound water, which cannot be frozen at 0 °C but at much lower temperatures, in interaction with the proteins and lipids of the SC, and which accounts for 20–30 % of the total volume of water contained in the water-saturated layer (e.g., Walkley (1972), Inoue et al. (1986))

Bound water has mainly been studied by thermal methods (DSC, thermogravimetry) and by various vibration-based techniques (IR spectroscopy, NMR) (Hansen and Yellin 1972; Barry 1987). These two authors have shown that very strongly bound water (up to 7 % by weight) exists. The remainder is moderately strongly bound. The binding energies (15 and 18 kcal/mol, respectively) determined by Lévêque et al. (1987a) are of the same order as those of the hydrogen bonds between proteins and water known as “structural” bonds. Water-lipid interactions have been pointed out: modifications in structure occur in the

organization of the lipids of the SC when the water content increases. Water is mainly confined to the polar regions, for which it has a great affinity (ion dipole interactions). The insertion of water between these regions induces a decrease in the attractive forces of aliphatic chains and hence greater lipid fluidity (Barry 1987; Golden et al. 1986). The same mechanism is reported to underlie the increase in the cutaneous penetration (Behl and Barret 1981) of numerous drugs and vehicles (organic molecules).

1.1.2 Water Content Gradient

The water content of the SC is not uniformly distributed through its thickness: the more superficial layers are in equilibrium with the ambient water content, while the deeper layers exchange their free water with the epidermis and are close to saturation. It is not easy to demonstrate the gradient in vivo, but Warner et al. (1988) have confirmed it in skin biopsy specimens using electronic diffraction. In their results, water concentrations falls off regularly from 70 % at *stratum granulosum* level to 25 % superficially, which means that the water is entirely present in bound form even for moderately high water content values.

In vivo, Salter et al. (1992) attempted to study skin moisturization through nuclear magnetic resonance (NMR). Querleux et al. (1994) with the same technique confirmed the existence of a water

gradient in the SC of the plantar area and observed the modifications induced by a hydrating cream or a detergent (see ► Chap. 44, “In Vivo Magnetic Resonance Imaging of the Skin”). Recent developments in confocal Raman spectroscopy (Caspers et al. 2001) have asserted the existence of this gradient and have enabled its quantification through a direct measure of the water content of the SC layers. More details are presented in Sect. 6.4.

1.1.3 Water Uptake by the *Stratum Corneum*

An isothermal SC water absorption curve is given in Fig. 1. This curve was plotted by pooling the results obtained by Blank (1952) with those of Lévêque et al. (1992). When the water content units are standardized, the results match perfectly. It is clearly shown that water content varies little between 30 % and 60 % relative humidity (RH), then increases considerably. The value extrapolated to 100 % RH is, according to Blank et al. (1984), of the order of 0.8 g/cm³ (weight of water expressed relative to the total volume), i.e., a weight of water that is about threefold superior to that of the SC. Under those conditions, the thickness of the SC is also three times greater than that of the dry SC (Blank et al. 1984). In practice, the mass of water rarely exceeds that of the dry weight, equivalent to about 99 % relative humidity.

Fig. 1 Plot of the water absorption by the *Stratum Corneum* as a function of the relative humidity of the ambient air. C_v is expressed as the weight of water per volume of hydrated SC, while α is the ratio of the weight of

water to the weight of dry SC. The C_v value extrapolated to saturation is about 0.8 g/cm³, i.e., $\alpha = 3$ g/g (Blank et al. 1984)

1.1.4 Dermatological and Cosmetic Aspects

For a physicist or a chemist in charge of developing tests and methods to evaluate skin moisturization, this concept is mainly expressed in terms of the variation in the water content of the SC (most frequently measured by the variations in physical properties). For the dermatologist or cosmetics expert, cutaneous hydration is frequently a psychosensory phenomenon: a well moisturized skin is soft, smooth and, in other words, “in good condition.” In contrast, a “dry skin” has special characteristics (desquamation, white and scaly plaques, irritation). It has been stated that this type of skin frequently lacks water (de Rigal et al. 1993) but that opinion remains controversial. Apart from the special unattractive appearance, dry skin has characteristics which, in an extreme form, may induce dermatological problems. The SC of a dry skin is twofold less flexible or deformable (Fig. 2) than that of a normal skin (Lévêque et al. 1987b). Repeatedly stressed during movements, the SC will tend to

“fracture” constituting an open portal for infectious phenomena. On the legs, this is one of the characteristics of “scaly” skin, in which the margins of hard and smooth plaques are frequently surrounded by a red border, reflecting inflammation (de Rigal et al. 1993). A study of the variation in corneocyte size depending on the degree of dryness had previously pointed out the inflammatory characteristic of dry skin (Lévêque et al. 1987b).

The common concept of “dry skin” cannot, however, be considered equivalent to dehydration since it covers several states of miscellaneous etiologies the pathogenesis of which is not always clear. Such states may be induced by various agents (sun, surfactants), be of natural origin (aging), or result from climatic conditions (winter xerosis). It is, however, difficult to characterize these skin types in a rational manner (Piérard 1997). Each of the states, deriving from different mechanisms, has specific histological or biochemical characteristics (e.g., composition of the SC), although the clinical presentations may be the same. Some such states are indeed accompanied by dehydration of the SC.

Since Irvin Blank’s work (Blank 1952) in the 1950s, it is now fully accepted that water plays a preponderant role in the physical properties of the SC. More recently, in the case of dry skin due to retention, corneosomes (the main agents responsible for the cohesion of corneocytes) are disturbed, as are the structures of the intercorneocyte lipid bilayers. In contrast to what is observed in moisturized skin, the corneosomes undergo less enzymatic degradation and thus remain present in high numbers in the more superficial layers of the SC (Piérard 1997). Since these results, several teams have demonstrated that hydration is an important factor in the mechanism of SC desquamation and that a proper water content promotes enzymatic function and regulates desquamation in isolated cells. The role of moisturizing agents (glycerol, urea, lactic acid, etc.) has been demonstrated and their beneficial influence clearly shown (Koyama et al. 1996; Rawling et al. 1992, 1995).

Fig. 2 Relationship between extensibility and clinical dry skin score (After Lévêque et al. (1987b))

1.2 Presentation of the Methods Developed to Determine the Water Content of the SC

The early physical methods were based on the consequences of the presence of water in tissues. It is well known that a wet tissue is more supple (more deformable) and conducts electricity and heat better. Indirect methodologies were thus initially developed (measurement of electrical or thermal conductivity and mechanical measurements). However, the main disadvantage of those methods stays in the complexity of the relationship between the variation in water content and the changes in the measured physical property. In most cases, other factors are obviously involved in this relationship, in particular all the problems related to the contact between electrodes and skin and the influence of relief and mechanical properties on electrical and thermal properties (increased suppleness of the SC induces improved contact). Direct methods such as thermal analysis of the SC by DSC are not concerned by such questions and offer monitoring of the energy transitions of water molecules in the SC. Unfortunately, these techniques cannot be applied in vivo in humans.

This presentation will begin with thermal techniques, followed by techniques based on

mechanical properties of the skin. Electrical measurements will take a major place, since they form the most popular group of techniques to evaluate skin hydration. Very clever methods combining optics and heat, so-called photothermal and photoacoustics will then be presented.

Techniques targeting directly the water molecule, and suitable for use in vivo, are still in development:

They concern essentially spectroscopy (near and middle infrared, Raman scattering) and will be exposed at the end of the chapter.

2 Thermal Techniques

2.1 Measurement of the Thermal Conductivity of the SC

2.1.1 Principle

The general law which governs the transport of energy or matter under the action of a potential F (thermal, mechanical, electrical, or chemical) states that the flux Φ of the quantity transported (heat, quantity of movement, electrical charge, number of molecules) is proportional and opposite to the gradient of the potential which creates the movement ∇F :

$$\Phi = -k \cdot \nabla F \text{ (bold characters represent three-dimensional vectors)} \quad (1)$$

In the case of heat transport, Φ is the directional flow of heat (W/m^2) and ∇F is replaced by the temperature gradient ∇T present in the medium. The constant k is then the thermal conductivity, expressed in W/m° .

A complex medium like the skin may be considered as a set of parallel thermal conductors. Hence, its average thermal conductivity is equal

to the sum of the products of the elementary conductivities by the relative volume of each component, divided by the total volume. For the SC, two components are distinguished: free water ($k = 0.6 \text{ W}/\text{m}^\circ$) and the bound water-protein-lipid set ($k = 0.18 \text{ W}/\text{m}^\circ$). The overall thermal conductivity may then be approximated by Poppendieck et al. (1966):

$$k(\text{W}/\text{m}^\circ) = \text{Fraction of free water per unit volume} \times 0.6 \\ + \text{Fraction of the set (protein + lipids + bound water) per unit volume} \times 0.18$$

Note that the fraction of free water per unit volume is identical to the free water content, expressed in g/cm^3 . The latter can thus be calculated from the determination of thermal conductivity, k , if the second fraction per unit volume is known.

Thermal conductivity determinations on human skin have become a well-established practice since Lefevre (1901) conducted the first experiment in 1901. The first transducers for cutaneous use became available much more recently (Challoner 1975; Hensel and Brandt 1977). They functioned by dissipating a constant heating power and measuring the resulting heating effect. This “isocaloric” mode has several disadvantages, in particular the nonlinearity of the response which is, moreover, very slow. Since then, the principle of transducers operating in isothermal mode has been definitively adopted. The transducer maintains the tissue at a constant heat relative to the baseline temperature. The power dissipated by the transducer to maintain that heating effect is proportional to the thermal conductivity of the tissue. A continuous feedback loop permanently regulates heating with great precision. Thanks to this control loop, a rapid response time can be reached (time constant of about 0.1 s). (Note that the time constant is the time required for the phenomenon to fall to 37 % of its initial value).

2.1.2 Continuous-Heating Method: Hematron[®]

The continuous-heating method provides permanent monitoring of the variations in the thermal conductivity of the skin, but the corresponding probes must use two temperature transducers in

order to measure the temperature difference between the heated and unheated medium at all times. Moreover, the determination of the water content of the SC requires using a special probe generating very superficial “microthermal” flux lines that do not reach the vascularized layer of the skin. The measurement probe shown in Fig. 3 is rectangular, and the two cavities are open so as to prevent occlusion of the skin and to ensure enhanced thermal insulation between the measurement and reference transducers. The flux lines are on the surface of the skin, particularly since their density falls off with the square of the depth considered.

2.1.3 Pulse-Heating Method

The probe is much simplified since it is merely a thermistor, which both generates the heat and determines temperature (Dittmar et al. 1988). The measurement is based on a two-phase cycle:

1. Passive phase of duration 24 s, during which the temperature of the skin at rest is determined
2. Active phase of duration 6 s, during which the temperature of the probe is stabilized at $+6\text{ }^\circ\text{C}$ above the previous value by a proportional, integral, and derivative regulator (PID)

The heating power necessary to maintain the temperature difference depends on the water content of the superficial layers (SC and living epidermis) but also on microcirculation in the dermis because of the propagation of the heat field in the skin. The power falls off very quickly with time, reaching a value that is almost constant (asymptotic P_{SS}) after 2 s. In a homogeneous material, the power obeys a law of the type:

Fig. 3 Example of a thermal probe used to determine the superficial thermal conductivity of the skin: the Hematron of A. Dittmar (1988) has been marketed by the DERMSCAN company (France). Dimensions of the heating element: 1 mm \times 15 mm

Fig. 4 The power dissipated by the probe on the skin of the cheek. Zone 1 corresponds to the *stratum corneum*: $P_{ss1} = 5.8 \text{ mW}$, i.e., $k = 0.25 \text{ W/m}^\circ$ (After Arnaud et al. (1994))

$$P = \beta/\sqrt{t} + P_{SS} \tag{2}$$

the plot of which is shown in Fig. 4, in which the time scale is in $1/\sqrt{t}$. The asymptotic power, P_{SS} , depends on the thermal conductivity of the medium and the thermal characteristics of the probe. Given P and t , P_{SS} may be determined by Eq. 2, by extrapolating to infinite time. In addition, calibration with various homogeneous materials (gels containing variable amounts of glycol, petrolatum, polystyrene foam) has confirmed the linear relationship below (Eq. 3), between $1/P_{SS}$ and $1/k$, as indicated by the theory:

$$1/P_{SS} \text{ (mW}^{-1}\text{)} = 0.11 + 0.014 \times 1/k \text{ (m}^\circ\text{.W}^{-1}\text{)} \tag{3}$$

Given that relationship, the determination of k only requires determination of P_{SS} by extrapolation from the linear regression conducted on the experimental plot.

Figure 4 is an example obtained on the skin. It will be observed that the heating power does not obey the function (1) over the entire time interval. Power has to be adjusted by two functions of type (1), equivalent to two different β and P_{SS} . The value of P_{SS} for zone 1 of the graph enables calculation of the thermal conductivity of the superficial layer while that of zone 2 is related to the deeper layers and microcirculation. Figure 5 shows a typical result obtained with the device described above, used to determine the hydration of the skin on the forearm before and after application of an occlusion patch for 4 h. The increase

in thermal conductivity reflects a marked variation in hydration (40–72 % of water volume relative to total volume). During the study, the authors showed that the occlusive patch did not markedly modify the cutaneous microcirculation (P_{SS2} of Fig. 4).

2.2 Determination of Thermal Effusivity

The water content of the SC may also be determined using the thermal effusivity, e , whose square is equal to the product of the thermal conductivity, k , the thermal capacity per unit volume, c , and the density, ρ , ($e^2 = k \cdot \rho \cdot c$). (The thermal capacity per unit volume of a body is the quantity of heat necessary to raise the temperature of a unit volume of the body from 24.5 to 25.5 °C. Thermal capacity is expressed in $\text{cal.m}^{-3}.\text{C}^{-1}$ or in $\text{J.m}^{-3}.\text{C}^{-1}$.) Thermal effusivity characterizes the aptitude of a medium to exchange heat with another medium. In the case of the water content of the SC, free water acts, in the same direction, on k and c , and hence the effusivity is particularly sensitive to water content.

In 1958, Hendler (Hendler et al. 1958) conducted in Hardy team initial determinations of skin effusivity using the method of photothermal radiometry described further in this chapter (§ 5.1). Balageas (1986) worked on the skin and modeled the heat transfers between the various layers. He demonstrated the feasibility of determining hydration by that method, with or without contact, which is of particular interest. A

Fig. 6 Principle of differential scanning calorimetry
T thermocouples, *G* voltage amplifier, *E* isolated chamber

review of the various methods used by that team was published in 1990 (Balageas 1991).

2.3 Differential Scanning Calorimetry (DSC)

Differential scanning calorimetry (DSC) remains the reference method for characterizing the type of water contained in the SC since it enables direct measurement of the energies of interaction and phase changes of the various constituents of the SC. The method is therefore highly appropriate for the determination of the free and bound water contents of SC samples. Combined with physico-chemical methods (cutaneous permeation) and structural methods (electron microscopy), DSC has also elucidated the influence of hydration on the molecular organization of the SC and explained the water retention and chemical barrier mechanisms cited above.

As indicated in Fig. 6, an SC sample (10 mg) is placed in one of the holders of the measurement chamber, while the reference holder contains a weight of distilled water with a thermal capacity as close as possible to that of the reference. The temperature of the measurement holder is then slowly and linearly increased (e.g., 1 °C/min) and the temperature difference, ΔT between the two chambers, is permanently measured by the thermocouples *T*. For as long as no energy absorption occurs in the SC, the quantity of heat required to heat the two chambers is identical (at least theoretically, because in practice a slight disequilibrium may occur) and hence ΔT is nil. However, if heat absorption occurs, this will no longer be the case. After calibrating the instrument, the electrical output signal of the apparatus (proportional to ΔT) can be directly related to the heat energy absorbed. The temperature at which heat absorption occurs and the intensity of that absorption are highly influenced by the water content of the

Fig. 7 Thermogram of human SC with 25 % (w/w) water content (After Goodman and Barry (1989))

SC. Determination of the transition temperatures and heat energy absorbed is thus a means of measuring the water content of the SC sample. In modern systems, ΔT is permanently nil since energy is supplied in an amount equal to that absorbed at all times. A DSC thermogram (Fig. 7) thus shows the instantly supplied power (negative) or, in the present case, the absorbed power (positive) related to the transition phenomenon observed. The area under each of the peaks is equivalent to the enthalpy of the corresponding transition. (Note that the variation in enthalpy, at constant pressure and in absence of work exchanges, as in the present case, is equivalent to the variation in the internal energy of the system.)

2.3.1 Application to Skin

Figure 7 shows an example of a thermogram obtained on human SC containing 25 % (w/w) of water. Each peak reflects a transition phenomenon directly related to the conformation of the SC:

- Peak 1: This peak is not systematically observed, even on healthy SC. If a sample is rendered lipid-free using an organic solvent, the peak disappears. The peak is therefore considered due to the melting of sebaceous lipids located at the surface of the skin (Golden et al. 1986).
- Peak 2: This peak reflects the melting of intracellular lipids (Golden et al. 1986). It is considered to reflect melting of the hydrophobic chains inserted into the lipid bilayers, similar to membranes (Barry 1987; Goodman and Barry 1989).

Table 1 Variations in the transition temperatures of each of the peaks for several SC water contents (After Goodman and Barry (1989))

Water content	Transition temperature (°C)			
	Peak 1	Peak 2	Peak 3	Peak 4
Dry	42 ± 1	77 ± 1	91 ± 22	not measured
10–20 %	41 ± 3	73 ± 1	86 ± 2	113 ± 5
30–40 %	39 ± 3	72 ± 1	85 ± 2	99 ± 3
50–60 %	37 ± 2	71 ± 1	83 ± 1	98 ± 5
>60 %	38 ± 2	70 ± 1	83 ± 2	95 ± 2

- Peak 3: This peak is very sensitive to hydration. Its transition temperature decreases, as does the area, when the water content of the SC increases (Golden et al. 1986, 1987). This peak is not easy to interpret, and one hypothesis is that it is associated with the changes induced by heat (thermal transition) in the lipid-protein complex between the intercellular lipids and corneocyte membrane (Golden et al. 1986, 1987; Khan and Kellaway 1989).
- Peak 4: This peak is considered, by many authors, to be due to thermal denaturation of intracellular keratin (α -keratin transformed into β -keratin). The denaturation is irreversible and observed even with lipid-free SC (Barry 1987; Golden et al. 1986; Knutson et al. 1985; Christensen et al. 1977).

The Table 1, after Goodman and Barry (1989), displays the variations in the transition

temperatures of each of the peaks for several SC water contents.

The decrease in the temperatures of the peak apices (transition temperatures) when hydration increases is accompanied by a decrease in the corresponding areas under the curve (enthalpies). Hydration introduces a change in the structure of the SC, which is located in the polar regions of the lipids (peaks 1, 2, and 3) and the intracellular keratin molecules (peak 4) (Barry 1987; Golden et al. 1986; Goodman and Barry 1989; van Duzec 1975). The greater fluidity of intercellular lipids is also considered to facilitate the transcutaneous absorption of polar or nonpolar drugs (Behl and Barret 1981). The position and enthalpy of peak 3 may be an indicator of the SC water content.

However, *use of DSC around the freezing temperature of free water* is a preferable technique, since it directly determines the weight of the free water contained in the sample. The sample is taken out after equilibration at ambient humidity (in general by stripping), then frozen as rapidly as possibly to keep the water in the sample. Figure 8 shows the thermograms obtained at about 0 °C for SC samples with different water contents: at 18 % no transition occurs, but at 33 % a small peak becomes visible. The peak continues to grow with higher water contents. The latent heat of melting of ice at atmospheric pressure is 80 cal/g (332 J/g) at 0 °C. Determining the transition enthalpy at about 0 °C enables direct calculation of the free water content of the sample. A further 30 % of bound water (not freezable) must be added to yield the total hydration of the SC. For

water contents of less than 30 %, the method cannot be used directly, since Walkey (1972) has shown that the water of the SC was then mainly in bound form (in fact, the relationship between total water and bound water is linear, with an almost constant shift of 5 % by weight).

Differential scanning calorimetry thus enables the state of the water in the SC to be studied in thermodynamic terms. While not feasible in vivo, the method is readily used on ex vivo SC, i.e., immediately after stripping. Moreover, the method has the considerable advantage of avoiding complex and uncertain calibration (as is required, for example, with optical or electrical methods). Numerous systems are available commercially (Perkin-Elmer, etc.) for other industrial uses but may be directly used on SC samples.

3 Methods Based on Mechanical Properties

The mechanical properties of the skin reflect the behavior of its constituents, their organization, and their respective modifications. In consequence, mechanical methods of measurement enable rapid and simple determination of the variations in SC water content. The methods currently used are noninvasive and allow successive determinations on a given site in order to monitor the kinetics of a treatment and its carry-over effects.

The methods developed in the last 20 years may be divided into two main categories:

Fig. 8 Thermograms of skin with different water contents showing only freezable water. Bound water is not visible since it does not undergo a phase change at about 0 °C (After Walkey (1972))

- Those using deformation perpendicular to the plane of the skin (indentation, suction, levarometry, ballistometry)
- Those applying deformation in the plane of the skin (uniaxial extensibility, torsion, vibration, gas bearing electrodynamicometer)

The latter methods are advantageous in that they measure the properties of the most superficial tissues, independent of the deep (adipose) tissues, providing the geometric dimensions of the assay and the imposed deformations are small (Vlashloom 1967; Christensen et al. 1977).

In recent years, methods based on the propagation of sound waves in tissues have emerged. Determination of the attenuation coefficients of the ultrasound waves leads to the intrinsic mechanical characteristics of the material under test by means of calculation and modeling (Bamber and Tristam 1990). These methods have encountered some success with respect to bulky organs like the liver but, for the time being, are not widespread and not routinely used on the skin.

3.1 Deformation in the Plane of the Skin

3.1.1 Torsion Method: Twistometer® or Dermal Torque Meter®

The first studies with this type of apparatus were conducted by Vlasbloom (1967). The system developed at that time had no ring to limit the geometry of the measurement zone. Following numerous improvements, a system was later marketed under the proprietary name of “Dermal Torque Meter” by the Diastron company (Andover, Surrey, UK). The stress is applied in the plane of the skin using a disk stuck onto it (double-sided adhesive). An angular displacement transducer measures the resultant deformation (it is in fact a method based on the measure of creep or deformation under a constant applied torque). A concentric guard ring (stuck also onto the skin) restricts the zone subject to the stress. The geometry and a few simplifying approximations enable calculation and generation of Young’s modulus for the tissue under study (Agache et al. 1980).

Fig. 9 Diagram of the Twistometer (After Lévêque and de Rigal (1985)) *M* torque motor, *C* angular displacement transducer, *G* guard ring, *W* gap width

Figure 9 shows the apparatus, and Fig. 10 displays the profile of the skin response curve.

The response diagrams are modeled by an equation of the following type:

$$U(t) = U_e + U_v(1 - \text{Exp}(-t/c)) + A \cdot t^m \quad (4)$$

On the response, the profile of which is the same no matter the method, several parameters may be determined:

- U_e : immediate extensibility
- U_r : immediate recovery
- U_v : viscous deformation amplitude
- U_r/U_e : elasticity

On the basis of these parameters, the coefficients of Burger’s rheological model, combining a Maxwell and a Kelvin-Voigt model in series as shown on Fig. 11 (the simplest for modeling the skin (Pichon et al. 1990)), can be calculated:

$$K_0 = C/U_e \quad K_1 = C/U_v \\ \eta_0 = C/A \quad \eta_1 = \tau.K_1 = \tau.C/U_v$$

Fig. 10 General profile of the response curves of skin to stress and the main extensibility parameters determined from these curves (After L ev eque and de Rigal (1985))

Fig. 11 Skin mechanical model for torsion measurements

where C is the value of the torque applied, K_0 and K_1 are the stiffness parameters and η_0 and η_1 are the viscosity parameters.

The value of m in Eq. 4 varies, depending on the author. Pichon et al. (1990) studied the recorded deformation using the finite element method (De Rigal 1996) and confirmed a value of $m = 1/3$. In the same publication, the hydration phenomenon is shown to be measured mainly by the variations in parameter U_e (or K_0) and, to a lesser extent, K_1 and η_1 . The latter parameter, η_0 , is more clearly related to deeper structures (superficial dermis) (De Rigal 1996), as was to be clearly shown subsequently. Some authors use a value of m equal to 1 (Salter et al. 1992). Other rheological, and non-rheological, models have also been put forward (Salter 1993).

In 1985, L ev eque and de Rigal (1985) showed that the contribution of the SC to the

measurement was of the order of 60–80 % for a gap width of 1 mm (Fig. 12a). The contribution decreased when this width increased (20 % for a width of 5 mm). The “immediate” moisturizing efficacy of a cosmetic formulation is shown in Fig. 12b. Figure 13 shows an example of the long-term effect of treatment. References Aubert et al. (1985a) and Randall Wicket et al. (1997) cite probative examples of the possibilities of the method with regard to evidencing short- and long-term moisturizing effects. It is clear that the apparatus measures deformations and that the parameters thus determined depend on any variations in the thickness of the *stratum corneum*. In the event of repeated determinations over several weeks or, more definitely, in the event of exposure to the sun, those variations must be taken into account in the interpretation. Moreover, caution is required in using

Fig. 12 (a) Influence of the geometry of the skin area under stress on the contribution of the *stratum corneum* to the determination (After L ev eque and de Rigal (1985)). **w** gap width. (b) Variation in the moisturizing efficacy of an emulsion following a single application (After Aubert et al. (1985a))

Fig. 13 Comparison of the moisturizing efficacy of three emulsions (same vehicle), treatment for 3 weeks and carry-over for 1 week, on the legs of 15 people per group. It will be observed that only the emulsion containing glycerol had a carry-over effect (After Lev eque and de Rigal (1985))

dimensionless quantities: the ratio between two deformations obviously eliminates the dependency on thickness, which is true for some of them (e.g., U_e / U_f), while others remain time-dependent, such as U_f / U_e and U_v / U_e (through the exponential term).

3.1.2 Uniaxial Extension

Several authors have addressed this uniaxial extension method (Wijn 1980; Gunner et al. 1979). Two pads are stuck to the surface of the skin at a distance that varies as a function of the skin area subject to the stress. Either a force is generated by an electromagnet and the induced displacement measured as a function of time (the principle is identical to that of the Twistometer) or the displacement is imposed by a motor and the force recorded (relaxation phenomenon). These methods, while potentially interesting, have been little used in the study of hydration phenomena. In addition, they have the disadvantage of being sensitive to the orientation of the axis of the stress relative to the natural tension lines of the skin (Langer's lines) and that the area submitted to stress is not well defined.

3.1.3 Gas Bearing Electrodynamicometer®

A little used but potentially very promising method has been developed by Christensen et al. (1977) and Hargens (1981), and used in cosmetic applications by Mass et al. (1983) and Cooper et al. (1985). The apparatus consists in the gas bearing electrodynamicometer. It measures the displacement (3–4 mm) of a sensor stuck to the skin using a small disk and 2-sided adhesive. The sensor is alternately actuated by a sinusoidal electromagnetic field (1–2 Hz) generating a force

of less than 10^{-3} N (Fig. 14). An oscilloscope displays the skin response (force-displacement plot) which is in the form of a hysteresis loop, characteristic of viscoelastic materials. The loop figure is used to calculate the following parameters:

- The slope of the main axis of the loop (or DSR, dynamic spring rate), comparable to Young's modulus
- The ratio between loop opening and displacement, or loss angle (for a purely elastic material, that angle is equal to 0)

The authors (Christensen et al. 1977, Hargens 1981) showed that the more the skin is hydrated, the more the angle of loss increases and the more the hysteresis loop is inclined on the displacement axis (same force but greater displacement) (Fig. 15). The effect of various formulations containing moisturizing active substances has been clearly shown (Schade 1912). According to the designers, this method has the major advantage of making it possible to record immediately after formulation application and thus studying the immediate moisturizing effects (in the very first few minutes).

3.1.4 Determination by Acoustic Wave Propagation

The principle is described in detail in reference (Potts et al. 1980). Broadly speaking, a vibrating

Fig. 14 Diagram of the gas bearing electrodynamicometer (After Christensen et al. 1977). LVDT linear variable differential transformer

Fig. 15 Profile of the traction elongation curves obtained with the GBE, for water (*figure on left*) and an emulsion (*figure on right*). Note the differences in kinetics and efficacy (After Christensen et al. (1977))

source is placed on the zone under study and two vibration transducers in the axis of propagation determine the propagation velocity of the wave and the amplitude of the vibrations. The propagation velocity and damping coefficient are studied over a frequency band from 8 to 1016 Hz. The same authors (Potts and Buras 1985) showed that those parameters have a minimum for a frequency, F_{min} , whose values are 400 and 700 Hz for hydrated and dry skin, respectively. It should be noted that the F_{min} value increases with age, reflecting the dryness of the skin in the elderly.

This method does not seem to have undergone marked development in cosmetic or dermatological applications. It should be taken again into consideration for a new development with modern technologies.

3.2 Stress Perpendicular to the Plane of the Skin

Several methods stressing the skin perpendicular to its plane have been developed. The first studies were carried out by Grahame (1970). The best known and most widely used instrument is the

Cutometer[®] which belongs to the suction group. Other methods include indentation, levarometry, and ballistometry.

3.2.1 Suction: Dermaflex[®], Cutometer[®]

The Cutometer is by far the most widely used of this type of apparatus and is the only apparatus enabling determination of the mechanical properties of the SC using a probe of diameter 2 mm. The record profile is the same as that recorded using the Twistometer, and the parameters measured are identified using the same symbols.

3.2.2 Indentation or Levarometry

Since Schade's work (Schade 1912), several authors (review in Aframian and Dikstein (1995a)) have developed levarometric methods (traction perpendicular to the plane of the skin). The authors having attempted to determine hydration by indentation are equally numerous (Aframian and Dikstein 1995b). However, no moisturizing effect has been demonstrated even with very low pressures (Dikstein and Hartzshtark 1983) because the SC is very rigid and transmits stress to tissues with much lower stiffness.

3.2.3 Ballistometry

The principle of this system was developed by Tosti and is described in detail in reference (Tosti et al. 1977). The initial developments date back to the 1930s when an apparatus intended for ophthalmology, to determine ocular pressure, was used. That apparatus has no application in the determination of moisturizing effects.

3.3 Comparison of Method Sensitivities

Among the numerous mechanical methods, and apart from the problems related to the interpretation of the results, it is important to determine which method is the most pertinent or the most sensitive in order to quantify the moisturizing properties of cosmetic formulations. Several authors have studied the correlations, relative to moisturizing efficacy, of the various methods. Wickett's study (Wickett et al. 1996) showed that the parameters determined by the Twistometer or Dermal Torque Meter are more sensitive to hydration than those measured with the Cutometer. The sensitivity to variations in water content of the parameters determined with the Cutometer was compared to that of the determinations using the Dermal Phase Impedance Meter (NOVA) (Murray and Wickett 1996). This study showed that several parameters may vary under the influence of the water content of the SC, but no general rule could be given. Several reasons can be suggested:

- The absence of correlation between parameters assumed to measure the same effects may be due to different depths of investigation.
- The differences in sensitivity of the Cutometer parameters to water content may be due to effects of treatment with different formulations, since Aubert et al. (1985b) did show that some formulations respond more from a mechanical point of view, while others respond more from a dielectric point of view.

Various comparative studies have pointed out the difficulty to interpret the results of mechanical determinations in terms of water content and showed that the protocol and/or formulation (vehicle) of the moisturizing active substances can markedly affect the validity of the determinations.

4 Methods Based on Electrical Measurements

4.1 Definitions

As is the case for heat energy transport, electrical energy transport obeys the Eq. 1 but here the function, F , is the electric potential and ∇F the electric field. The flux, Φ , is the flux of the electrical charges. The constant k becomes the electrical conductivity, σ .

The relationship of Eq. 1, in its electrical form, leads, in an homogeneous conductor, to Ohm's classic law:

$$\mathbf{I} = \mathbf{G} \cdot \mathbf{V} \quad (5)$$

where \mathbf{I} is the current, \mathbf{V} the potential difference, \mathbf{G} the conductance of the conductor through which the current is running and R its resistance. $R = 1/G$. G or R are the magnitudes measured in practice with our instruments. They enable the electrical conductivity, σ , to be determined. The latter is strongly dependent on the water content of the skin.

For an homogeneous conductor, $\mathbf{G} = \mathbf{a} \cdot \sigma$ where \mathbf{a} is a purely geometric factor of the medium measured. The conductance (or its reciprocal, the resistance) thus depends on the electrical conductivity but also the geometry of the conductor. This is the main problem encountered in interpreting the determinations on skin since it is difficult to accurately determine the geometry of the "conductor" in the skin. Moreover, since the skin is far to be homogeneous, σ will also depend on the path of the field lines in the "conductor."

Conductivity determinations on skin are rarely carried out using DC current since phenomena of

charge accumulation at the electrodes (polarization) and migration of ions and molecules (electrophoresis) occur. Moreover, the determination of potential differences using direct current is subject to interference from galvanic effects. It is therefore necessary to use alternating potentials and currents to obtain usable cutaneous conductivity determinations.

Let us see what happens to Eq. 5 (Ohm's law) if a sinusoidal alternating potential difference of frequency f and pulsation $\omega = 2\pi f$ is applied to a slab of conducting material such as skin.

$$V = V_0 \sin(\omega.t)$$

The corresponding current flowing through the slab will generally not be in phase with the potential difference and will thus be expressed as follows:

$$I = I_0 \sin(\omega.t + \phi)$$

ϕ is known as the phase shift or, more improperly, the "phase" of the potential relative to the current.

To take into account the phase shift, we must use the concept of admittance Y (and its reciprocal named impedance Z), Eq. 5 becoming:

$$I(\omega) = Y(\omega).V(\omega)$$

The admittance Y depends on frequency and consists in a conductive term G (in phase with the potential) and a capacitive term C (90° phase shift), frequently known, respectively, as real and imaginary terms, with reference to the complex notation used to handle admittances and impedances. Measuring Y at a given frequency requires the determination of the ratio I_0/V_0 called its modulus $|Y|$ and that of its phase ϕ . From these two values, G and C can be computed using an electrical model.

Let's take a simple example of a circuit consisting of a conductance G and capacitance C in parallel (this circuit is the simplest to be proposed to reflect the electrical behavior of the skin (Schwan 1957), although very imperfect). The Y modulus is given by:

$$|Y| = \sqrt{G^2 + (C.\omega)^2} \quad (6)$$

and the phase shift ϕ between V and I is such that: $\tan \phi = C.\omega / G = R.C.\omega$. To simplify the explanation of the conductive and capacitive terms, it should be remembered that the first is proportional to σ ($G = a.\sigma$, a being a geometric factor), hence to the number and mobility of the free charges in the medium, while the second depends on its polarizability measured by its dielectric constant ϵ ($C = a.\epsilon$). (Note that a perfect dielectric is an insulator of electrical DC current). A dielectric is characterized by its relative dielectric constant, ϵ . In vacuum, $\epsilon = 1$. For air, $\epsilon = 1$. For distilled water, $\epsilon = 80$.) In consequence, we frequently separate the current circulating in a complex medium such as the skin into conduction current (term in phase with the potential difference) and out-of-phase current (term in quadrature).

4.2 Dielectric Properties of the Skin

Schwan (1957) was the first to show that living tissues and, in particular, the skin have, like all materials, domains of dielectric relaxation. In other words, the dielectric constant and hence the material's property to polarize decrease for given frequencies of the applied alternating current. Three relaxation domains have been identified:

- Relaxation α at low frequencies (0.1–1000 Hz) mainly related to the *stratum corneum* since they almost entirely disappear following stripping
- Relaxation β between 100 kHz and 500 MHz related to the polarizability (permanent and induced) of macromolecules and the water associated with them ("structural" water)
- Relaxation γ at hyperfrequencies (3–30 GHz) reflecting vibration of water molecules that are free, to some extent, in the tissue

These relaxation mechanisms are far from being fully elucidated despite numerous modeling

attempts: in addition to the structural complexity of the layers of the skin, our knowledge of the local electric field and the elementary currents induced by that field is imperfect. If we restrict ourselves to the problem of the water content of the SC, there are at least two possible effects of water content on its electrical properties:

- An increase in conductivity, σ , due to the ions dissolved in extra- and intracellular water
- An increase in the dielectric constant, ϵ , due either to a change in the structure of the lipid and protein layers (plasticizing effects (Barry 1987)) or an increase in the free water content

The methods used to measure the water content of the SC thus attempt to exploit those three effects, depending on the frequency used and the quantity measured (G , C or complex admittance Y). An excellent review of the various electrical methods applied to the determination of cutaneous hydration was published in 1983 by Lévêque and de Rigo (1983). Since that date, a rather high number of instruments have been launched on the market, each manufacturer claiming to offer the best. To get a more precise idea on these devices from an experimental point of view, many authors have published comparison studies. As a good introduction, we suggest the work of Fluhr et al. (1999) in which five instruments based on electric measurements (among the most popular) are tested and compared.

4.3 Low-Frequency Instruments

The frequency range of the relaxation α , mainly being due to the SC, may seem the most appropriate for determination of water content. However, electrode polarization phenomena are very important: the electrode-skin contact may be considered (as a first approximation) as a capacitor in series with the impedance to be determined. The influence will be all the stronger, the lower the frequency. As an indication, with an electrode capacitance of $1 \mu\text{F}/\text{cm}^2$ (usual value), an electrode of area 1 cm^2 will have a complex impedance of modulus $|Z| = 1600\Omega$ at 100 Hz. This

impedance will be in series with the skin and will modify both the determination of the modulus and the phase of the signal.

Several solutions have been suggested to overcome that difficulty:

- A conducting gel containing a mixture of polyethylene glycol and saline, in adequate proportions to define a given relative humidity (RH). Clar et al. (1975) were thus able to demonstrate, on the forearm, the efficacy of several moisturizing creams using a measurement electrode of diameter 1.7 cm filled with the gel. The reference electrode was a large-area silver/silver chloride electrode placed on the same arm. Their results show that the conductance G and capacitance C both increase when the water content of the skin increases. This is logical since both the conductivity (because of dissolved ions) and the dielectric constant (due to the high dielectric constant of free water) increase.
- By way of an example, the conductance and capacitance of the skin of the forearm nearly double when the ambient relative humidity (RH) increases from 66 to 86 %, and this remains valid over the frequency range from 10 Hz to 10 kHz (relaxation α). Figure 16 shows the relaxation for the two relative humidity levels defined above.
- Electrodes which undergo little polarization (e.g., a combined Ag/AgCl electrode) and have a small area ($<1 \text{ cm}^2$) are used. Once again, the density of the current flowing through the skin must remain low ($<1 \mu\text{A}/\text{cm}^2$) to minimize the electrolytic effects at the electrodes and the electrophoretic effect in the skin. Kalia et al. (1996) have studied the relaxation of arm skin by measuring the modulus and the phase of the impedance of a small surface of the skin, from 1 to 1000 Hz, before and after several stripping procedures.
- A four electrode assembly can be used. In this case, two electrodes of relatively large area supply the current to the medium, while two thin electrodes measure the potential difference at the terminals, under a very high impedance, on part of the medium in which the electric field is uniform. The polarization of the voltage

Fig. 16 Variations in conductance G and capacitance C at low frequency for two relative humidity levels *solid line* RH = 66 %, *dotted line* RH = 86 %

Fig. 17 Example of low-frequency capacitance determination (100 Hz) using the method by Serban et al. (1983). C_U and C_T are the capacitances measured on the skin pre- and post-occlusion using a film of liquid paraffin (Water diffusion index, $WDI = C_T/C_U - 1$)

electrodes has then no importance with respect to the determination. This principle has long been used for determinations on solutions (Ferris 1963; Bernengo and Hanss 1976) but is more difficult to use on the skin in vivo. Campbell et al. (1977) have succeeded in obtaining results which appeared promising.

- Several investigators decided to work with electrodes applied dry to the skin, a solution which presents the obvious advantage of enabling fast determination in equilibrium with the ambient relative humidity. In that case, the impedance of the contact at the electrode-skin interface is very sensitive to the pressure exerted on the electrode, and it is necessary to exert a slight, controlled overpressure to obtain reproducible results. As an illustration, Dikstein and Bercovici (1985) worked

with gold-coated electrodes specially designed to apply constant pressure and obtained good results on water content by determining capacitance at 16 Hz.

Serban et al. (1983) used an innovative electrode (Serban et al. 1981) consisting of a grid closing a chamber in which a slight negative pressure was maintained in order to ensure that the electrode was applied to the skin with constant pressure (this electrode is marketed by Bor-Tru Inc., W. Redding, CT, USA). The reference electrode was an aluminum foil placed under the tongue. The capacitance of the skin under the electrode was measured, using an impedance meter, at 100 Hz. The values ranged from 0.5 to 25 nF, depending on the area and degree of hydration. Figure 17 shows the sensitivity of the

method, at occlusion, on two skin types subjectively rated dry and normal. The plot clearly shows that a stable capacitance value is obtained after 10 min of occlusion. This value is taken as the reference for maximum water content in order to calculate a “water diffusion index” (WDI) as follows:

$$\text{WDI} = (C_{10} - C_0)/C_0$$

The index was well correlated with the subjective evaluation of skin dryness and with ambient relative humidity, after sufficiently long equilibration.

4.4 High-Frequency Instruments

Over the β relaxation frequency range, the electrode polarization interferes much less with the measurements than at low frequencies. Similarly, the ionic conductivity of any interfacial fluid or the variation in electrolyte concentration in the SC tends to be negligible at high frequencies. The investigator must nonetheless be conscious that the measurements are also related to the deep layers of the skin (the water content of which is fixed and high). Almost all commercially available instruments for determining cutaneous hydration operate at high frequency and are based on the following principle (Fig. 18):

A sinusoidal current generator $I(\omega)$ is connected to the measurement electrodes (generally concentric) either directly or through a matching coaxial cable. The external electrode acts as a guard ring to prevent dispersion of the flux lines (compulsory at high frequencies). A

selective AC voltmeter tuned on the frequency of the generator or an instrument fulfilling that function such as a synchronous detector is used for measuring the amplitude and phase of the potential difference across the electrode terminals.

Although both admittance terms may be determined, only conductance G is generally used. Barel et al. (1991) have rigorously compared the respective advantages of conductance and capacitance determination in the evaluation of the water content of the SC. Tagami (1995), on the basis of *in vivo* and *in vitro* studies, reached the conclusion that, except for certain particularly thick areas of the SC, conductance provided a better feature of the water content of the SC than capacitance and yielded more reproducible results. It is nonetheless true that the calibration of a conductance determination in terms of the water content of the SC is highly delicate and will depend on the electrode-skin contact, the thickness of the SC, and the electrical properties of the deeper tissues.

4.4.1 Main Achievements

Lévêque and de Rigal (1983) have designed a portable instrument based on the principle described above and known as the *Dermodiag*[®]. The instrument uses a 10 MHz generator and determines the conductance between two concentric electrodes of external diameter 10 mm and interelectrode gap of about 1–4 mm. A constant pressure on the skin is ensured by a spring system. The instrument is routinely used in L’Oréal research laboratories to evaluate the action of moisturizing products and, more generally, the water content of the SC but is not commercially available.

Fig. 18 Schematics of a concentric two electrodes high frequency device

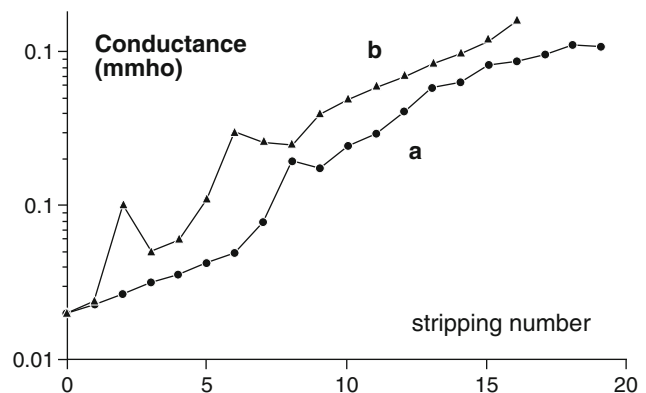

Based on the same principle but fitted with a set of six variable diameter rings and a multifrequency generator, the SCIM[®] developed by S. Ollmar (Copenhagen, Denmark) (Erntestam and Ollmar 1993) is marketed by its designer. The apparatus uses a set of gaps to evaluate the impact of deeper tissues on the impedance determination of superficial layers and better elucidate the trajectory of the flux lines. A computer program uses five determinations at different gaps and different frequencies (between 1 kHz and 1 MHz) to calculate the water content of the epidermis and superficial dermis. In its current state, the instrument is not suitable for determining the water content of the SC since the range of impedances for which it has been designed is not compatible with the impedances of the dry SC (even in equilibrium with normal ambient relative humidity). The determinations are made by moisturizing the skin as much as possible using a compress soaked in normal saline, before positioning the apparatus, procedure which particularly addresses the changes in deep water contents observed in the course of irritant or inflammatory processes. The principle could nonetheless be advantageously applied to the determination of superficial water content.

Since 1980, Tagami et al. (1980) have been using a device developed by Masuda et al. (1980) to determine the amplitude and phase of the admittance of the skin at 3.5 MHz. Measurement electrode coupling is ensured by a matching circuit followed by a coaxial cable, thus providing great flexibility in use. The electrodes are

concentric and have diameters from 1 to 4 mm. However, a 2-mm central electrode may also be used to enhance sensitivity. When the electrodes are applied to the skin, an initial fast rise in conductance and capacitance values is observed, followed by a slow drift due to the transepidermal water loss. Contact is thus maintained for a minimum time of 3 s to carry out the determination.

The apparatus, marketed under the proprietary name Skicon-200[®] by IBS Ltd. (Japan), has been thoroughly tested by Moseley et al. (1985) and calibration conducted on models consisting in SC placed on water-saturated filter paper (Tagami 1995). The authors admit that, since the determination is conducted on a small area, marked geographic variability is observed even between neighboring sites, due, for instance, to the density of the sweat glands and variations in SC thickness. As was the case with the previously considered instruments, a pressure control system is provided. A set of results is given indicatively in Fig. 19. The figure shows the time course of cutaneous conductance, as a function of the number of stripping procedures, on a healthy adult forearm. Numerous other results concerning the relationship between water content and transepidermal water loss in healthy and pathological skin are also available (Tagami 1988, 1995; Tagami and Yoshikuni 1985; Horii et al. 1989). A new concentric ring probe has been recently launched under the reference 200EX[®] announced to present a much smaller depth of measurement.

(a) 34-year-old woman,
(b) 58-year-old man

An apparatus based on a very similar principle to that used in the previous device, and measuring high-frequency conductance changes, is manufactured by Nova Technologies, Gloucester (UK): the Nova DPM 9003[®].

Martinsen et al. (1993) have presented a 3-electrode measurement system. The skin is included in the negative feedback loop of an operational amplifier. Since this circuit achieves a virtual ground, a unipolar determination is carried out, irrespective of electrode impedances, at least in theory. The current crossing the measurement electrode is determined by a current-tension converter, and since the alternating potential is imposed by a voltage generator, the admittance thus determined is exactly related to the volume of skin under the electrode. A frequency of 100 kHz was selected as a good compromise between electrode polarization and high capacitance leakages that occur at high frequency. The authors show that significant variations in admittance are measured with progressive moisturization of the skin but also report electrode-related reproducibility problems. While the 3-electrode system is based on an elegant principle, it is not certain that it contributes any marked improvement compared to existing high-frequency instruments.

The Corneometer[®] CM 825 from Courage and Khazaka (Cologne, Germany) has been described in detail by Barel and Clarys (1995) and has also been tested by Moseley et al. (1985) and Blichman and Serup (1988). The capacitance variations of the electrode-skin assembly ($C_0 + C_{\text{skin}}$) are measured by the displacement of the resonance frequency of the oscillating circuit connected to the oscillator. If the conductance G in parallel with the capacitance C is low, the oscillation frequency of an oscillating circuit containing an inductance L and a capacitance C in parallel is given by:

$$f_0 = 1 / (2\pi \cdot \sqrt{L \cdot C}) \text{ where } C = C_0 + C_{\text{skin}} \quad (7)$$

The early models of this type operated between 75 kHz empty and 40 kHz when moisturization is at a maximum, equivalent to a 3.5-fold variation

in capacitance C . Since the dielectric constant of the SC ranges from 8 (dry SC) to 80 (pure water), the capacitance of the skin should also vary in the same ratio, if the determination only addresses the SC and not the deeper tissues. New models are supposed to operate at higher frequencies around 1 MHz.

The electrodes are innovative. They are comb shaped interdigitated on a grid, as shown in the Fig. 21 below, and gold coated. The electrodes are not in ohmic contact with the skin, since they are coated with a thin layer of vitrified insulating material (thickness 20 μ) with a low dielectric constant. The dimensions of the network are as follows: line width 50 μ , between-line space 75 μ , and size of the active part 7 \times 7 mm. Former probes versions were analogic, while a digital version is now proposed, announced to be more stable (in frequency and amplitude). The comb shape has been kept unchanged.

An example of results obtained with this instrument on the forearm skin at several RH is given on Fig. 20. The correlation between readings and ambient humidity is quite satisfactory.

Since knowledge of the penetration depth of the electric field is essential for the interpretation of the results obtained by this method, layers of polyester film were inserted between the electrodes and the skin (Barel and Clarys 1995). This approach showed that the measurement depth was up to 100 μ m, but the contribution of the total capacitance of a layer at that depth did not exceed one tenth of what it would have been at the surface. On the basis of these results, it is clear that the influence of the epidermis on the determination can be neglected. We may also suspect that the low water content values obtained in “dry skin” phenomenon and in other states of abnormal rugosity of the skin are only due to the persistence of imperfect contact with the skin surface. According to computations based on recent publications dealing with open comb capacitance modeling (Starzyk 2008), the presence of a layer of air of a few μ m thickness under the sensor should not, theoretically, influence the measurements. These publications, together with well-known methods such as finite elements approach, might be used to better investigate the electric

Fig. 20 Relationship between the corneometer reading and ambient relative humidity determined on the forearm at 22 C. Values obtained on 15 subjects aged 18–30 years. Correlation coefficient $r = 0.98$ (After Barel and Clarys (1995))

Fig. 21 Comb interdigitated electrodes for surface dielectric measurements

field strength inside the skin, considered as a multilayer dielectrics.

To conclude this chapter, let us have a look on Clarys et al. publication (Clarys et al. 2012). Recently, the authors have extensively compared two modern instruments: the Corneometer CM825[®] (C & K), which measures a capacitance, and the Skicon-200EX[®] (IDS), measuring a conductance. Due to their different principle, the devices calibration is very different: the value recorded on a filter patch saturated with a physiological solution is set to 120 arbitrary units (Corneometer), while a standard precision resistor is proposed for the Skicon. In vitro penetration depth evaluations led to values about 45 μm for the Corneometer and 20 μm for the Skicon.

In vivo hydration measurements were carried out on healthy male and female volunteers ($n = 20$) varying from 20 to 71 years of age. Several skin sites were examined to get hydration values from very dry to well hydrated. Correlations between the instruments were all highly significant (all $P < 0.001$). The mean intraperson

variability, calculated over the total range of hydration measurements, is improved in the new version of both instruments, with a coefficient of variation (CV) figure around 7 % for the Corneometer and 10 % for the Skicon. The authors conclude that both devices are reliable and able to measure skin hydration, though presenting specificities: capacitance measurements being more sensitive on dry skins and conductance better suited for high hydration levels.

4.5 Hyperfrequency Measurements

Water is a polar liquid, in other words, composed of molecules bearing a permanent electric charge and, in consequence, oriented under the action of an external electric field. The relaxation frequency of this phenomenon is centered on 18 GHz at 20 °C and thus can be observed at hyperfrequencies. The water molecules bound to proteins relax at lower frequencies of the order of the GHz or even lower (according to the nature of

bound water, as already mentioned at the beginning of this chapter). Schwan (1957) was the first to carry out dielectric measurements on skin at hyperfrequencies with coaxial lines supplied by a klystron (A klystron is a very high-frequency generator (>1 GHz)). The γ relaxation described by this author being obviously related to water, it seemed obvious to try and exploit that phenomenon to determine the water content of the SC, particularly since hyperfrequencies propagate essentially at the surface of conductors (“skin” effect).

The development, in the 1970s, of coaxial cable testing, lead to the production of hyperfrequency equipment operating with pulses in the time domain (measure over time of the response to a pulse, time domain reflectometry, TDR). This technique opened the way for a new type of studies on living tissues, which were then directly placed at the end of the coaxial measurement line.

Moreover, as the theoretical studies progressed, the method proved to ensure concomitant monitoring of the relaxation of bound water and free water. The complexity of the required hyperfrequency instrumentation and the difficult interpretation of the results have not allowed a widespread use of these determinations on skin, despite the considerable potential. Following a doctoral dissertation on the subject (Djeldjellani 1989), investigations on skin water content were conducted by the L’Oréal research laboratories (Diakate et al. 1994). The major difficulty in the technique is associated with the applicator which ensures the transition between the coaxial line carrying the electromagnetic field and the skin. A “ground plane” antenna was developed (Djeldjellani 1989), but we consider that the future of the technique resides in the use of “strip lines” which can be placed in direct contact with the skin.

Using conventional instrumentation employing 1-GHz sinusoidal waves, Jacques (1979) determined the water content of the SC using an innovative interdigitated applicator which ensures extremely superficial flux lines (penetration depth: $3 \mu\text{m}$). A linear relationship between the conduction current due to the free

charges of the dielectric medium and the water content of the most superficial part of the SC was thus established. Hyperfrequency techniques, although very promising, have not yet been extensively used in dermatological and cosmetic metrology.

5 Photothermal and Photoacoustic Techniques

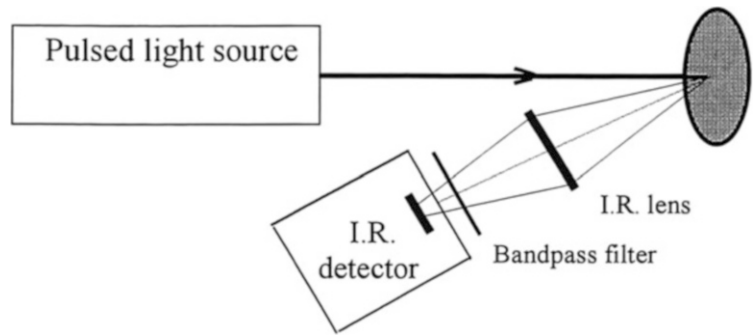

These techniques are based on the conversion of light energy into heat energy in the skin. This heat energy can then be directly detected by IR radiometry or be converted into pressure variations in an adiabatic chamber. The incident energy may be modulated periodically at a frequency, f (frequency mode or CW), or delivered in pulses (temporal or pulse mode). The collected signal will depend on the optical properties (absorption, diffusion) and thermal properties (diffusivity, effusivity) of the skin.

5.1 Pulse Radiometry

The principle is simple: a powerful pulse source (flashlight or laser) is targeted on a small surface area and the transient increase in temperature that occurs during beam absorption is monitored by infrared radiometry. The wavelength of the source depends on the application. This wavelength must match one absorption band of the tissue to ensure that optimal heat transfer takes place (Fig. 22).

Balageas et al. (1986) in their studies used a ruby laser emitting in the red range, a pulse duration of $350 \mu\text{s}$, and an energy of 0.2 J/cm^2 . They blackened the skin with carbon black to ensure the required heat transfer (of the order of $20 \text{ }^\circ\text{C}$). Detection was conducted using an HgCdTe element cooled with liquid nitrogen and sensitive over the range $7 - 12 \mu\text{m}$. The temperature was monitored from 2 ms to 100 s after the light pulse. In a thermally uniform medium, the temperature variation, ΔT , due to the energy Q impinging on a unit area of the medium falls off as a function of time in accordance with the following relationship:

Fig. 22 Principle of pulsed photothermal measurements with infra-red detection

$$\Delta T = Q / (e \cdot \sqrt{\pi} \cdot \sqrt{t}) \quad (8)$$

$e(t)$ is the medium effusivity (cf. Sect. 2.2)

If the medium is not homogeneous (as is the case with the SC), $e(t)$ may be calculated at any time during the return to thermal equilibrium. For short times (<0.1 s), the measured effusivity is that of the SC (of the order of $1000 \text{ J/m}^2/\text{s}^{1/2}/\text{K}$). Since the square of the effusivity is proportional to the product of the thermal conductivity and the thermal capacity (cf. Sect. 2.1.5), the effusivity is very sensitive to the quantity of free water and, moreover, a contact-free measurement of water content is perfectly feasible. The authors observed that effusivity is not constant over time from 2 ms to 100 ms (as might have been expected with a homogeneous layer model (Stolwijk and Hardy 1965)) but regularly increased. The authors deduced that there is a variation in the thermal properties of the SC from the surface to its deep boundary. This variation may be explained by the gradient in water content. The free water concentration gradient in the SC may therefore be explored.

A related photothermal approach known as optothermal transient emission radiometry (OTTER) has been developed by Imhof et al. (1990). The authors used a cryogenic detector identical to that used above but their source was a Yag-Neodyme laser, 1.06μ , delivering very short pulses (15 ns) with a repetition frequency of 20 Hz and fit with a harmonic generator so that the working wavelength be divided by 2, 3, or 4. The area illuminated by an optical fiber has a diameter of 6 mm, while the infrared beam is collected by an ellipsoidal mirror with a high numerical

aperture focused on the detector. The signals received by the detector at each laser pulse are accumulated in a digital memory in order to enhance the signal/noise ratio. Filters are used to restrict the optical pass band of the detector so as to characterize (at least by a few points) the emission spectrum of the skin. In the study presented in Imhof et al. (1990), a wavelength of 355 nm was used and the temperature profiles were determined over a very short time, less than 10 ms. Under those conditions, only the SC is concerned by the thermal signal, as expected. Contact-free SC water content studies were conducted by the same team (Bindra et al. 1994) using this method. Currently, the method is among the most promising, although the instrumentation required is complex and expensive.

Using this technique, the Imhof team (Guo et al. 2001) has published results concerning the water content of SC samples, in terms of free and bound water (interacting with keratin). These samples were of the same kind as for Lévêque et al. study (Lévêque et al. 1987a), i.e., normal, delipidized, and delipidized + water rinsed SC. A tunable laser source allowed to investigate water absorption around the 2.94μ band, while the light emission is recorded at 13μ . The authors observed that the absorption band of bound water at low humidity was neatly shifted towards high wavelengths, and was also narrower, compared to the bulk water band. The position of the peak envelope was shifted of about 30 nm downwards when the relative humidity rises from 3 % to 100 %. This shift showed a plateau between 10 % and 40 % RH on delipidized samples, while the decay was regular on normal SC. These results are in accordance

with previous data (Lévêque et al. 1987a) and show the powerful potentialities of OTTER techniques.

Recently, the same authors' team compared its OTTER technique with four popular instruments devoted to skin hydration measurements: Corneometer (C & K), NOVA DPM (DermLab), Moisture Checker (Scalar), and Fingerprint sensor (Fujitsu FBS200) (Xiao et al. 2010). Except for the last one, they all rely on some kind of impedance (capacitance or conductance) determination. OTTER showed a repeatability at least as good as the others, and a good correlation was found between the whole set of measurements, regarding several hydration conditions, from dry to wet skin.

5.2 Photoacoustic Spectrometry

The absorption of a light beam by the skin results in a localized temperature increase. The photoacoustic effect consists in transforming those temperature variations into gas pressure variations and the latter into an acoustic signal. The studies on skin were essentially carried out with an amplitude-modulated light beam at low frequency. We shall therefore restrict ourselves to this approach, which is more appropriate to the thickness of the SC, although techniques using pulsed rather than modulated light exposures have been developed (Patel and Tam 1981).

The theory of the photoacoustic effect is rather complex (e.g., Rosencwaig and Gersho 1976). Two aspects have to be looked for: From an optical point of view, the diffusion and absorption properties of the skin (absorption spectrum, optical penetration depth μ_0) are essential. Obviously, when working with the SC, UV radiation is preferable because it is particularly absorbed by that layer. Moreover, the technique is frequently used since Rosencwaig and Pines early works (1977) to study sunscreens. On the other hand, the production of thermal waves is bound to the thermal diffusion length μ_T , inside the skin layers, which is an important factor to determine the depth at which the signal detected at the surface is generated. It is given by the relationship:

$$\mu_T = \sqrt{\alpha/(\pi \cdot f)} \quad (9)$$

in which α is the thermal diffusivity and f the frequency of light beam modulation. For example, if the thermal diffusivity of the tissue is taken to be equal to that of pure water, μ_T is equal to 6.8 μm at 1000 Hz while $\mu_T = 215 \mu\text{m}$ at 1 Hz. It is thus clear that rather high frequencies are to be used for the SC and very low frequencies for studies of intracutaneous penetration (Bernengo et al. 1998).

The main limitation in the method in "in vivo" determinations is that the surface of the skin to be studied must be placed in a closed chamber to ensure adiabatic conversion of heat waves to sound waves and detection of the latter using a microphone. The measurements require a relatively long integration time due to the weakness of the electrical signal from the microphone. Hence, an increase in water content due to occlusion is inevitable.

The measuring cell has to be carefully designed to enable strong illumination of the skin and to feed the weak acoustic signal to the detection microphone. Several open models have been designed for in vivo work. Figure 23 shows three different cells that have been successfully used. Though synchronous detection is used, the signal at low frequency is greatly disturbed in vivo by body sounds (heart beat, muscles, blood circulation). For that reason, differential cells have been developed (Poulet and Chambron 1982; Guy and Bemengo 1986) with an at least tenfold improvement in the signal/noise ratio compared to the simple chamber cell.

Since the first UV spectra of the skin in vitro published by Pines and Cunningham (1981), numerous researchers have conducted studies of SC water content in vitro and in vivo (Campbell et al. 1979; Poulet and Chambron 1983; Giese and Kolmel 1983; Poulet 1985). Simon et al. in 1981 (Simon et al. 1981), working with the absorption band of water at 1.9 μm , determined the water content profile of the SC in vivo. While the free water contents obtained in this study were not accurate, since the bilayer model used at this time was not suitable (as showed later by Poulet (1985)), the concept nonetheless remains seductive. More recently, Takamoto et al. (1994)

Fig. 23 Three types of cell used for photoacoustic measurements on skin. (a) direct illumination through the cell by Simon et al. (1981) (b) resonant cell by Takamoto et al.

(1994) (c) low-frequency differential cell by Guy and Bernengo (1986) S: output of the electrical signal from the microphone, M

developed a very small volume (40 μL) resonance cell matched on 2.2 kHz. After optimizing the device, they obtained a fivefold gain in sensitivity compared to a conventional open cell. This gain led them to markedly lower the integration time, therefore reducing the passive hydration by occlusion and the dose of UV radiation received by the skin. Working with hairless mice, the authors were able to measure the variations in the photoacoustic signal induced by percutaneous absorption of an ointment (1 % IDM in PEG). Their results relate to the very superficial layers of the SC, since they were generated using a doubled argon laser at a wavelength of 257 nm, absorbed in the first few microns of the SC. The authors argue that the use of their device on man is problem-free since the energy received by the skin is low, less than 40 mJ for the study described above.

Lastly, it should be noted that some signal processing techniques used by photoacoustic scientists working on plastic and ceramic materials have been borrowed by researchers in the skin field: Baesso et al. (1994a) conducted phase measurements on the photoacoustic signal with a modulation frequency from 18 Hz to 62 Hz. The authors confirmed the SC diffusivity values obtained through photothermal determinations. The same authors studied the penetration of products into the skin using Fourier transform photoacoustic spectroscopy (Baesso et al. 1994b), thus adopting a pulsed technique that is

in widespread use for powders and sintered materials (Patel et al. 1981).

Rompe et al. (2005) in 2005 have studied SC properties through photoacoustic technique, using a powerful xenon lamp and a monochromator in the range 240–400 nm. Frequency modulation was 17 and 70 Hz. They claimed a thermal diffusion length of 15 μm at the latter frequency and displayed a set of PA spectra of SC, showing clearly the influence of hydration on the spectral shape.

6 Optical Techniques in the Near and Middle Infrared

These optical methods target directly the water molecule, insofar as they quantify the amplitude variations of the reflected light inside and outside the absorbance peaks of that molecule. While calibration can be easily carried out in vitro, the transposition in vivo is not easy, and it is therefore frequently not possible to directly quantify water content. For the methods using the near IR (as for nearly all others), the calibration relationships determined in vitro (usually on multilayer phantoms) do not obviously apply in vivo since the light penetration conditions cannot be exactly compared and present a much higher variability (skin localization, SC thickness, molecular absorbers such as melanin, etc.). The influence of the surface state of the skin (diffusion, variation

in refractive index, etc.) may be very strong and lead to tricky interpretations of the results in terms of variation in water content.

6.1 Attenuated Total Reflection (ATR) Infrared Spectroscopy

Used both in the intermediate IR field (by chemists) and in the near-IR (NIR) range, ATR methods rely on the phenomena of multiple attenuated reflection to enhance determination sensitivity (Gloor et al. 1981a). The principle is shown on Fig. 24:

The optically perfect surface of a zinc or germanium selenide crystal (transparent in the IR) is applied to the skin. The incident beam is propagated by multiple reflections within the crystal. Following each reflection by the surface of the crystal in contact with the skin, a part of the energy is absorbed by the skin because of the evanescent wave phenomenon, related to the electromagnetic nature of light. When the beam leaves the crystal, the skin's absorption spectrum is recorded by an appropriate IR detector (thermal or semiconductors). Because of the submicronic penetration of evanescent waves, this method has the major advantage of only analyzing the first micron of SC thickness or even less. Schneider and Hansen (1997) have confirmed that the choice of crystal and angle of incidence enable analysis of the skin at depths ranging from 0.3 to 0.9 μ , i.e., of the order of the thickness of 1–2 layers of corneocytes. In consequence, the measures are strongly dependent on variations in ambient air humidity and therefore require rigorous equilibrium of the patients in laboratory ambient air. In addition, such measurements are also strongly dependent on the thickness of the sebum film (or residual cosmetic cream) on the skin surface. Some results supposedly related to SC had in fact to be partly or even totally attributed by such film effects.

Fig. 24 The attenuated total reflexion (ATR) applicator

In the homogeneous medium external to the prism, of refractive index n_2 (here the SC), the wave theory of light shows that the intensity of the evanescent wave decays exponentially from the surface of the prism (index n_1). The depth of penetration z (defined as the value for which the light intensity is divided by $e = 2.7$) is proportional to the wavelength, λ , and inversely proportional to a term including the sine of the angle of incidence. It depends on the refractive index n_2 of the SC and, hence, on its water content.

As an example, the values of z in a totally hydrated SC of index 1.33 are given below, for the four angles available on the Skin Analyzer (which description follows):

Angle	40°	45°	52°	60°
Depth z	0.3 λ	0.18 λ	0.14 λ	0.11 λ

It should be carefully noted that the parameter z does not define an abrupt penetration limit and that a noteworthy quantity of energy is absorbed at deeper levels. Those levels nonetheless remain much smaller than the thickness of the SC.

Several methods of quantifying water content on the basis of the ATR spectral data have been applied. They mainly refer to the middle IR absorption bands, though near IR can also be successfully used.

Middle IR techniques:

- The ratio between the absorbances of the amide I and II bands (6.06 and 6.45 μ m, i.e., 1649 and 1540 cm^{-1}). This is a measurement of the water content (Gloor et al. 1980, 1981a), since the 6.06 μ m band interferes with the 6.1 μ m water band, the 6.45 μ m band being independent.
- Measurement of the area of the water absorbance peak at 4.76 μ m (2100 cm^{-1}) (Potts et al. 1985; Potts 1985) on the basis of calibration conducted in vitro, without using an internal standard.

- Measurement of the absorbance at 8.94 μm (1118 cm^{-1}) and 9.65 μm (1036 cm^{-1}) (Comaish 1968).

Near IR experiment:

- The ratio between the absorbances at two wavelengths, 1.95 and 1.8 μm . The peak at 1.95 is specific of water (Koelmel and Mercer 1980), which does not absorb at the reference wavelength of 1.8 μm (Comaish 1968).

In order to enhance the resolution and quality of the results, the spectral determinations were analyzed using a Fourier transform IR spectrometer (Klimisch and Chandrag 1986). An ATR adapter is commercially available under the proprietary name Skin Analyzer from Perkin-Elmer, France. Three total reflection prisms providing different angles of incidence (between 40° and 60°) and hence different penetration depths are supplied. Zinc selenide is the most widely used prism material. The surface of the prism in contact with the skin is horizontal, and outside of the apparatus, so that the forearm can be layed on it. Zn-Se crystals mounted at the end of an optical fiber are now commercially available and allow measurements everywhere on the body, even on lips.

Unfortunately, the spectral acquisition duration, which is relatively long, induces a marked occlusion, which affects the measurements. Moreover, application of a cosmetic formulation, enhancing the quality of skin contact with the sensor, is liable to induce an artefactual increase in water content. The opposite effect occurs following serial treatment with surfactants. The influence of posttreatment modifications of the skin refractive index has not been evaluated, particularly in the presence of oil residues. It is true that the influence of the latter two sources of artifacts may be reduced by data processing methods (use of a ratio or an absorbance difference between two wavelengths, one being taken as the reference). Several authors have studied the influence of cosmetic formulations using this technique (Gloor et al. 1981b; Wirchrowski et al. 1985).

6.2 Near Infrared Spectroscopy (0.7–2.3 μ)

We are dealing in this chapter with direct reflection near infrared spectroscopy, as opposed to multiple reflexion ATR spectroscopy. This technique is employed in the analysis of the composition of materials and in the food industry for many years (Norris and Hart 1965). The method has been applied on skin to determine SC water content (Walling and Dabney 1989; Martin 1993) and cutaneous lipid content. It has a certain number of advantages compared to middle IR spectrophotometry:

- Greater sensitivity to water molecules, the absorbance peaks being well defined and rather isolated.
- Providing the signal is specifically processed, it is possible to extract information on bound and free water from the spectra.
- The analysis of surface diffusion enables characterization of the squamous conditions of the skin (in principle).
- The measurement time is sufficiently short for occlusion phenomena not to occur and for the water content to remain undisturbed.

In contrast, the technique has a marked disadvantage on ATR, related to variations in wave penetration into the skin. The volume under analyze varies with the wavelength in a complex manner, as is the photon path inside the skin multiple layers. Multiple scattering and nonradiative energy loss (absorption) occur simultaneously, and numerous models have been studied to work out quantitatively the light penetration in tissues (see for example (Kenji Iino et al. 2003)). As a rule, while scattering decreases when λ increases (whatever scattering model is considered), the mean absorption increases (without even considering lipid or water peaks). Skin transparency shows a maximum around 1.2 μm , at which the subcutaneous lipid peak is clearly visible, while it disappears at higher wavelengths.

In order to optimize exploitation of all the information contained in near IR spectra, many methods

of calculation have been developed. The simplest method consists in determining the ratio of reflected intensities or the difference between absorbances at two wavelengths selected as a function of the problem under study. In principle, the absorbance at the characteristic wavelength of the constituent is weighted by the absorbance at a wavelength at which the constituent does not absorb. An example is given for water in reference (de Rigal et al. 1993). With regard to the correction of the effects related to surface scattering, the multiple scattering correction (MSC) method makes it possible to recalculate an ideal spectrum (Isaksson and Mass 1988; Osborne and Fearn 1986; Geladi and MacDougall 1985). Other methods based on multivariate analysis or multiple regression are applied to spectral study, in which first or second derivatives calculus delivers enhanced information (Maes and Martens 1988). Methods based on partial least square (PLS) regression seem to be increasingly used. Those methods limit the information loss induced by a necessarily limited selection of wavelengths, when modeling the phenomenon under study (Wold et al. 1998). The various data processing methods were applied and compared in a single moisturizing efficacy study (Martin 1992).

Several basic research studies on the characterization of dry skin and the efficacy of moisturizing formulations have been published. They attempt to answer one frequently raised question,

particularly by Kligman: “Is dry skin dry?” (de Rigal et al. 1993; Walling and Dabney 1989). A convincing study was carried out by de Rigal et al. (1993) using the Infra-Analyzer 500 from the Bran & Lubbe Company. The analyzer was modified in order to take “in vivo” determinations on all body areas. Its modification is shown in Fig. 25. The modified device, while maintaining basic performances and an integration sphere, made acquisition and processing of data in real time possible, which was not yet the case elsewhere (Wirchowski et al. 1985). Working with isolated SC maintained under increasing controlled humidity conditions, the absorbance at 1.94 μm , expressed relative to that of a reference at 1.1 μm , was shown to be linearly correlated with water content. These results confirm those in reference (Walling and Dabney 1989), expressed as the absorbance at 1.94 μm , relative to a reference at 1.85 μm , although the data were acquired and processed by two different equipments.

Typical spectra recorded on the skin *in vitro* are shown in Fig. 26. The absorbance of the dermis alone is greater than that of the whole skin. This is due both to the increase in the analyzed volume (related to the greater penetration of the IR radiation), the absence of the less hydrated layer, and a reduced surface scattering. However, all the spectra show the peaks characteristic of water at 1.94 and 1.45 μm .

Fig. 25 Schematic representation of the modifications made to the Infra-Analyzer 500 (After de Rigal et al. (1993))

Fig. 26 Near-infrared absorbance spectra of the whole skin, epidermis, and dermis (After de Rigal et al. (1993))

Fig. 27 Near-IR spectra of the skin at various dry skin scores. Intermediate scores are not shown. Each spectrum is a mean of the individual spectra for the same score (After de Rigal et al. (1993))

The study of skin hydration was carried out on the legs of a population of 159 women, following a clinical analysis of the skin condition using the following criteria: parchment-like, rugosity, presence of squamae, presence of scales (“snake skin”), and irritation (subclinical inflammation). Each of the criteria was scored 1 to 5 and the scores summed. The spectra obtained on Fig. 27 are related to the mean score, and the correlation with the set of clinical data is given on Fig. 28a. It

is clear that the absorbance decreases when the dry skin condition becomes increasingly severe. This work also showed that the conductance method employed in parallel was not correlated with IR for high scores, since it appeared to saturate (Fig. 28b). This fact confirms and illustrates what has been frequently emphasized in this chapter: the artefactual influence of contact impedance when using dielectric methods (cf. Lévêque and de Rigal 1983).

Fig. 28 (a) Linear correlation between near-IR absorbance (determined at 1936 nm) and overall clinical score for dry skin (After de Rigal et al. (1993)). (b) Relation

between overall dry skin score and conductance. The correlation coefficients are for the entire data set (de Rigal et al. 1993)

In the same study, the efficacy of the five daily cosmetic treatments over a duration of 4 weeks has been sought for. The comparison between the clinical dry skin score and conductance and IR measurements illustrates their complementarity and evidences the difficulties of interpretation encountered with contact methods. The near-infrared analysis indubitably yields the classification that is the closest to reality in physical terms of water

content, while the impedance determination was disturbed by the presence of squamae or scales.

Near-infrared spectroscopy affords also the possibility, after calibration, of predicting dry skin score, as shown by Walling and Dabney (1989). The conclusion of those two studies is that near-infrared spectroscopy is undoubtedly the reference method for skin moisturization measurements.

More recently, similar studies have been carried out with modern equipments (Kilpatrick-Liverman et al. 2006): A NIR5000 spectrometer (Cary/Agilent) equipped with a fiber optics probe (“Smartprobe”) attachment delivered IR spectra, while conductivity measurements were completed using the Skicon 200 (IBS), which measures conductance at a frequency of 3.5 MHz. Clinical scores were performed either. Comparable NIR, Skicon, and visual dryness results were obtained for most of the experiments. However, the NIR was more effective to detect skin water content variations as a function of external humidity changes. As a matter of fact, the authors observed a direct correlation between the NIR readings and the relative humidity percentage (RH) unlike what was observed for the Skicon measurements. This last point confirms what was already noticed (Lévêque and de Rigal 1983; Rawling et al. 1992).

6.2.1 Near-Infrared Spectroscopic Imaging

Instruments have been designed to image the skin at NIR wavelengths. Apart from the well-known capillary observation, imaging devices working at 1450 nm or 1950 nm have appeared on the market and are now used to get images of water into the SC. Several groups are specialized on this subject. See for instance Wichrowski et al. (1995), Attas et al. (2001), and Zhang et al. (2005). Though skin hydration seems to be efficiently measured through that technique, it seems more adapted to precise molecular imaging of hemoglobin, lipids, and proteins in deeper skin layers.

6.3 Near-Infrared Ratiometry at Two Wavelengths

The analysis of near-infrared spectra of skin shows clearly the presence of two water absorption bands around 1450 and 1950 nm. Devices measuring simultaneously the reflectance at one wavelength outside and one inside absorption bands have been build and offered on the market. They have become recently light and affordable, due to the apparition of IR emitting diodes and detectors at the convenient wavelengths. Though

very simple on the principle, care has to be taken to interpret the results on skin, since the two wavelengths penetration is very different if one is absorbed and the other is not. The same remark applies for the optical path of an outgoing ray. To get accurate measurements, a complex modelisation has to be carried out to take into account this optical path difference.

Random Monte Carlo-based calculations are widely used for this purpose (Kenji Iino et al. 2003), but practical application to skin relies on the knowledge of parameters which are all but well determined.

It appears liable in the first approach to bypass this question as long as variations on the same skin area are recorded, the technique being reliable and easy to perform. Nevertheless should beam penetration always be kept on mind.

Small devices have been widely marketed for the packaging and food industries, and chinese manufacturers have designed pen-sized skin moisturization measuring instruments (Konmision SC069 and other models). After a long validation period, a ratiometric NIR device working at 1950 and 1450 nm should be soon on the market (Non Invasive Technologies, Paris). These two wavelengths were selected because the penetration depths have been found (through computation and in vitro measurements) about identical, hence discarding the abovementioned drawback.

6.4 Confocal Raman Microspectroscopy

Raman spectroscopy is a vibrational spectroscopy, similar to IR spectroscopy but based on inelastic light scattering rather than absorption of light. It is out of this chapter’s scope to expose the theory of Raman effect, which can be found in many textbooks. Let us recall that, in contrary to Rayleigh scattering, the scattered beam contains a small fraction at wavelengths longer than that of the incident light. This withdrawn energy has been gained by molecules to excite vibrations and depends on the structure, the interactions, and the chemical environment of these molecules.

As for IR spectra, Raman spectra are labeled in wave numbers (usually cm^{-1}), i.e., the reciprocal of the corresponding IR absorption wavelength. This scale is generalized because it is linear in energy: higher the wavenumber, higher is the vibrational energy involved in the wavelength shift.

Confocal Raman microspectroscopy brings the potential of Raman analysis to the field of confocal microscopy, its main feature being the aptitude to record Raman spectra of very thin optical slices. Casper and coworkers have pioneered the adaptation of the technique to skin observation (Caspers et al. 2001). Several instruments (more or less dedicated to dermo-cosmetology) are now on the market: **River Diagnostics** (3510 model), **B & W tek** (i-Raman model), and **Horiba** (LabRam-inv model).

Major applications of the technique in Dermatology are found in the characterization of intrinsic or extrinsic skin molecules under normal or pathological situations. For instance, Chrit et al. (2005) designed a very efficient and practical microprobe for “in vivo” chemical analysis. Recently, Zhao et al. (2010) compared melanin and protein spectra of normal skin and benign and malign diseases in the range $600\text{--}1700\text{ cm}^{-1}$, pointing out the potentialities of Raman microscopy for skin disease diagnostic.

As long as SC hydration is concerned, the water band around 3400 cm^{-1} (O-H stretching) is generally compared to a protein peak around 2920 cm^{-1} (C-H³ stretching). The excitation wavelength is in near IR, at 671, 730, or 850 nm, in order to minimize spurious fluorescence emission. At these wavelengths, the resolution in depth is about $5\text{ }\mu\text{m}$. Since averaging is compulsory to make signal getting out of noise, exposure times might be rather long (1 min or more for Casper study (Caspers et al. 2001)), but the quality of modern equipments have shortened the measurement duration down to seconds.

The first water profiles published by Casper et al. on several locations of the arm (volar forearm, thenar) (Caspers et al. 2001) have been reproduced on Fig. 29, together with the Raman spectra from which they were computed. Ordinates have been directly labeled in %water

weight/100 g of wet tissue, after conversion from the ratio of the two peak areas ($I_{3350\text{--}3550}/I_{2910\text{--}2965}$).

These striking results have been later confirmed by other works, such as Chrit et al. (2005), already mentioned, working on a HORIBA microspectroscopic instrument, and Nakagawa et al. (2010) on a River Diagnostics model 3510. This latter publication shows SC water profiles obtained in a very short time (1–5 s), with a depth resolution of $2\text{ }\mu\text{m}$, which emphasize the quality of the results obtained through the Raman microscopy technique.

Though optical coherence spectroscopy (Knuttel and Boehlau-Godau 2000) and nuclear magnetic resonance (Querleux et al. 1994) did show promising potentialities to give images of water inside SC, confocal Raman scattering appears as one of the best techniques to measure in depth the water content with a rather good resolution ($2\text{ }\mu\text{m}$). Since the acquisition times have been drastically lowered, its major drawback has to be found in the complexity and cost of the equipment. The assignment of bands might not be obvious, mainly on noisy spectra, but dedicated softwares and peak libraries are helpful in such conditions. These last years, manufacturers made efforts to deliver on the market portable and light Raman instruments (palm-hand devices), fiber coupled to an applicator (B & W tek). Such devices are macroscopic, and can only deliver an average SC water content, but offer plenty of capabilities to follow chemical events inside the skin.

7 Conclusion

To bring a conclusion to this long chapter, we hope to have shown the importance of the technical resources committed by public and private laboratories in an attempt to quantify the water content of the *Stratum Corneum*. The importance of those resources is justified by the considerable importance of this determination in dermatology and cosmetics.

Table 2 shows a summary of the main characteristics of the methods presented in this chapter,

Fig. 29 Confocal Raman microspectroscopy of forearm skin at several depths and corresponding water content profile. Excitation in the near IR. The depth resolution is around 5 μm (From Casper et al. (2001))

in order to facilitate a selection by potential users. Many of them make use of equipment that is difficult to use for nonphysicists and which is, in addition, very expensive, making marketing them as integrated systems a poor profitability proposition, both for the manufacturer and the user. *The thermal and optical methods* warrant detailed discussion since they have given us precise determinations and thus *act as references for the calibration of devices which are more simple* with regard to their principles (but not with regard

to result interpretation). The latter devices (mainly mechanical and electrical), which are essentially those marketed, supply reproducible and exploitable indications, if the user remains permanently aware of the variability of the physical and physicochemical parameters of the skin, as a function of site, age, environment and even, for moisturization, the subject's emotional status. The user must also bear in mind the physical properties of the various products and emulsions applied to the skin before or during moisturization

Table 2 Main characteristics of the in vivo SC water content measurement techniques

Principle	Instruments available	Contact with the skin	Potential interference with	Recommended use	Critical use
Electrical impedance methods	Skicon 200 XM ^a Comeometer CM825 ^b Nova DPM9103 ^c Moisturemeter SC4 ^d Dermalab ^e	In vivo Yes	Surface variations (weak). Plasticity variations. Influence of ions on conductance	Short-term moisturizing efficacy. Comparative studies on contralateral zones.	Inter-individual comparisons
Thermal conductance methods	Hématron	In vivo Yes	Relief variations (weak). Plasticity variations	Short-term moisturizing efficacy. Comparative studies on contralateral zones.	
Mechanical methods	Cutometer Dermal Torque Meter Gas Bearing Electrodynamometer	In vivo Yes	Variations in <i>stratum corneum</i> thickness	Short-term moisturizing efficacy. Comparative studies on contralateral zones. Long-term moisturizing efficacy with associated thickness determinations.	Inter-individual comparisons with or without thickness determinations.
Calorimetric methods	DSC (many commercial instruments)	In vitro	Complex involvement of water molecules in the skin structures	Understanding of moisturization mechanisms and Lipid/water structural relationships	
Photothermal methods	OTTER	In vivo No contact	Presence of molecules absorbing light in the water bands	All types of study (nearly independent of surface state)	
	Photoacoustic (visible or IR)	No (not at the measurement site)	Presence of molecules absorbing light at the working wavelength. Variations in excitation. signal penetration (refractive index, surface state).	Short- and long-term moisturizing efficacy. Intra-individual comparative studies. Actinic effects on water content	Very colored or scattering formulations (locate the absorption window)

Spectroscopic methods: Near IR ATR IR FT IR	Many IR spectrographs are adaptable: Infra-Analyzer, Agilent “Smartprobe”	In vivo, might be avoided at the measurement site	Variations in surface back scattering. Modification in analysed volume (depth of penetration)	Short- and long-term moisturizing efficacy. Intra-individual comparative studies. Inter-individual comparisons.	Studies in the (residual) presence of formulations
Microspectroscopy RAMAN (confocal or conventional)	River Diagnostics 3510 ^f Horiba LabRam inv ^g B&W tek i-Raman ^h	In vivo	Body movements occlusion for long exposures	In depth visualization of water in SC Short-term effects on molecular content are visible	Formulations may interfere (lipids)

tests and particularly since they can themselves modify the signal detected by the sensor in addition to the required effect on the skin.

Finally, we would like to emphasize that only close cooperation between physicists, physico-chemists, and biologists of the skin (including, of course, cosmetics specialists and dermatologists) was able to increase our basic knowledge and understanding of such a complex material as living skin and to allow the development of the very sophisticated methods described in this chapter.

1 Introduction

The surface of normal healthy skin is covered by an extremely thin and soft, but highly efficient, barrier membrane, i.e., the stratum corneum (SC), so that any substance from the environment with a molecular weight greater than 500 Da can hardly penetrate through it. Thus, even a small molecule such as water cannot easily penetrate it from the underlying wet, viable epidermis to the surrounding dry environment. Therefore, we can evaluate the barrier function of the SC *in vivo* instrumentally by measuring the amount of water evaporating from the skin surface as transepidermal water loss (TEWL) in a cool and dry environmental condition where no sweating takes place. In such a way, we can demonstrate that, clinically, even the merely pruritic dry skin surface found in atopic dermatitis (AD), i.e., atopic xerosis, shows slight but significantly higher TEWL than the normal skin of healthy individuals (Watanabe et al. 1991).

Moreover, the SC of a healthy skin surface maintains soft and smooth properties by binding water efficiently. In contrast, the SC produced in pathologic skin cannot effectively bind water, producing a dry, scaly skin surface due to the decrease in the SC hydration state, as noted in atopic xerosis or ichthyosis vulgaris. In such patients, even large protein molecules such as environmental allergens can penetrate into viable cutaneous tissue through finely cracked areas of the SC and induce hypersensitivity reactions. We can evaluate this hydration state of the superficial part of the SC that is under direct environmental influence by conducting instrumental measurements of the high-frequency conductance or capacitance of the skin *in vivo* (Tagami et al. 1980).

The SC is produced by the epidermis whose keratinocytes slowly differentiate into flat corneocytes, which overlap and tightly bind to each other with their corneodesmosomes to construct an extremely thin and flexible, but efficient, membranous barrier covering the normal skin.

Although it is only 15 μm thick at most portions of our body surface, the SC of healthy skin enables us to live even in a very dry atmosphere. To construct an SC equipped with such an efficient barrier function, the narrow spaces between each overlapped, flattened corneocyte are tightly packed with unique intercellular lipids that are produced and excreted by the most differentiated keratinocytes present in the uppermost portion of the epidermis, the stratum granulosum. These lipids, which are uniquely composed of ceramides, cholesterol, and fatty acids, not only provide the SC an efficient barrier function but also exert a water-holding capacity to maintain the soft and flexible properties of the SC with the so-called natural moisturizing factor (NMF), which is mainly composed of amino acids derived from filaggrin after intracellular enzymatic proteolysis within the corneocytes, in addition to sweat-derived lactate and urea and sebum secreted from sebaceous glands of the adult face and scalp skin. Thus, the thin membranous SC covering healthy skin remains soft and smooth to the touch, in contrast to the rough and dry pathologic SC that is produced under diseased conditions. Because the latter is unable to bind water efficiently, firm, but fragile, dry SC is produced, which is clinically observable as a scaly, finely fissured skin surface even under normal ambient environmental conditions.

The hydration state of the SC is determined in a dynamic equilibrium between the water supply to the SC from the underlying wet epidermis and its loss from the skin surface, which is dependent on the ability of the SC to absorb water and to retain it. The water is supplied to the SC not only from the underlying living skin tissues but also from the outside, such as the atmospheric moisture, sweat, bath, shower, and topically applied hydrating agents.

As mentioned above, the water-binding capacity of the SC depends mainly on the presence of highly hygroscopic molecules, NMF, as well as polar lipids such as the ceramides present in the intercellular spaces (Yamamura and Tezuka 1989)

and even structural proteins. A small amount of water supplied from the outer layers of the SC also contributes to the maintenance of its flexibility as well as to facilitating the enzymatic reactions that drive the maturation of the SC (Rawlings et al. 1994; Rawlings and Harding 2004). The dynamic hydration tests of the SC described below give us much more information about the physiological or pathological properties of the SC than the simple, routinely conducted instrumental evaluations.

In this chapter, we describe three representative *in vivo* functional tests of the SC, i.e., SC dynamic hydration tests, the sorption-desorption test (SDT), moisture accumulation test (MAT), and plastic occlusion stress test (POST), to obtain detailed information noninvasively about the functional properties of the SC.

2 Stratum Corneum Hydration

2.1 Endogenous Hydration

The SC is the extremely thin and soft biological barrier membrane that protects the body from desiccation as well as from the invasion of various external, injurious agents. The deepest layer of the SC contacts with the wet living epidermal tissue, whereas the outermost layer of the SC is directly exposed to the dry environment. Thus, the SC constitutes a thin, but vital, membranous structure covering the whole body surface as a water permeation barrier, together with the tight junction of the granular layer of the epidermis. Moreover, there exists a decreasing water gradient from the deeper SC layers (70 %) toward the outermost SC ones (30 %) (Warner et al. 1988; Caspers et al. 2001; Egawa and Tagami 2008) in this extremely thin membranous structure. A steep water gradient is present from the superficial to a mid part of the SC, followed by a rather gradual gradient ranging from the mid to the deep part of the SC, as clearly demonstrable by *in vivo* Raman spectroscopy (Egawa and Kajikawa 2009).

The water within the SC exists as bound water and free water. The former is either tightly bound primary water or weakly bound secondary water. The secondary bound water, whose amount depends on the amounts of NMFs and extracellular polar lipids (Yamamura and Tezuka 1989), is decreased in the pathologic SC such as found in various dermatitic skin lesions or in clinically non-inflamed dry skin such as ichthyosis and senile xerosis, whereas the primary water does not show any great change even in pathologic, scaly skin (Takenouchi et al. 1986). The water present in the intercellular spaces is attracted toward the skin surface, due to the lower humidity of the atmosphere compared to that of the living skin tissue, where it is continuously evaporated from the skin surface as TEWL. Thus, the so-called TEWL consists of the water diffusing through the SC from the viable epidermis (true TEWL) and that lost from the physiological dehydration of corneocytes. Water from these two sources permeates the intercellular spaces of the SC that are also the routes for percutaneous absorption of various small molecular substances from the environment (Agache and Black 2004).

When the water evaporation is inhibited for a long period of time by covering the skin with an occlusive film, excessive water accumulates in the SC. If more than 50 % w/w hydration occurs, the corneocytes are observed to swell with the water behaving like bulk liquid water, i.e., free water. In the case of a hydration level of >300 % w/w, even extracellular pools of water become observable, making the SC fragile, and clinically noted as maceration.

2.2 Exogenous Hydration

When water contacts the skin surface, it so quickly permeates through the intercellular spaces of the SC and later crosses the cell membranes to swell the corneocytes, depending on the length of contact time (Tagami et al. 1980). Even with a short external water application, the

water content in the superficial part of the SC is increased rapidly, while that observed in the mid and lower part of the SC occurs more slowly (Egawa and Kajikawa 2009). This quick water uptake into the SC is thought to be the result of three physical phenomena, i.e., the first one is simple adhesion via surface tension forces, the second is diffusion (Fick's law) due to the lower water content of the cells and hydrophilic domains of the intercellular spaces, whereas the third one is absorbed possibly by an osmotic process via the semipermeable corneocyte cell wall due to the presence of intracellular NMF (van't Hoff's law). In this way, the water penetrates into the corneocytes, eventually causing their swelling. The resultant cell distension and intensity of the osmotic pressure may alter the property of the cell membranes, which accounts for the partial loss of small molecular NMF that takes place after prolonged water immersion. According to van't Hoff's law, the osmotic pressure, p , can be shown as $p = RTC$, where R is the perfect gas constant, T the absolute temperature, and C the concentration of hygroscopic substances, i.e., their number per unit volume is independent of their size or nature. Osmotic pressure increases considerably in the suprabasal portion of the SC where filaggrin disintegrates enzymatically into numerous molecules of NMF, releasing its strongly bound water. At the superficial SC layers, this pressure is much less since the NMF concentration is decreased (Agache and Black 2004).

When the applied exogenous water is removed, a drying process takes place rapidly at first and then more slowly afterward. This desorption is called skin surface water loss (SSWL), which is, however, different from TEWL (true TEWL). Both SSWL and TEWL can be measured by evaporimetry.

2.3 Instruments to Measure the Hydration State of the SC

As mentioned above, the hydration state of the SC, especially the hydration state of the skin surface, can be evaluated noninvasively by

measuring the components of high-frequency impedance, i.e., conductance or capacitance, by simply applying the electrodes to the skin surface (Tagami et al. 1980). These instruments can also be employed in SC dynamic hydration tests. The skin surface hygrometers Skicon 200 EX (IBS Ltd., Hamamatsu, Japan) and Nova DPM 9003 (NOVA Technology Corporation, USA) are available for measurement of the high-frequency conductance. By contrast, Corneometer CM 825 (Courage and Khazaka, Köln, Germany) measures the high-frequency capacitance of the skin. Usually, the recordings of conductance or capacitance with these devices are made within 3 s to avoid the accumulation of evaporating water from the skin surface beneath the electrodes.

Since these instruments measure the skin hydration based on their own unique parameters, it is difficult to compare data inter-instrumentally. They also cannot provide the depth profile of water in the SC. However, as shown by Hashimoto-Kumasaka et al. (1993), the conductance measurement is more suitable for the evaluation of the hydration change taking place in the superficial portion of the SC, while the capacitance measurements assess the hydration state including much deeper portions of the SC. Namely, the former is more sensitive for assessing the hydration changes caused by the application of moisturizers or to conduct a water sorption-desorption test, whereas the latter is suited for evaluating even dry pathologic SC, such as a scaly skin surface (Fig. 1). Thus, in a simulation model of in vivo SC, the high-frequency conductance device shows a much closer correlation with the hydration state of the surface SC ($r = 0.99$) than the capacitance device ($r = 0.79$), suggesting that the former can more accurately assess the hydration dynamics of the superficial portion of the normal healthy SC, particularly that due to the accumulation of easily releasable secondary bound water (Hashimoto-Kumasaka et al. 1991). These characteristics can also be shown more clearly by comparing the obtained values after serial tape stripping of the SC (Hashimoto-Kumasaka et al. 1993) (Fig. 2).

Fig. 1 In vivo water sorption-desorption test measured with the high-frequency conductance with Skicon 200 and the capacitance with Corneometer CM420, CM820 (From reference Hashimoto-Kumasaka et al. 1993). Skicon more clearly shows the increase in

the SC hydration state compared with Corneometer after water application when comparing between the normal skin, the skin of suction blister, and scaly skin of a psoriasis patient

Fig. 2 Influence of serial tape stripping of SC on the electrical parameters in vivo

3 Stratum Corneum Dynamic Hydration Tests

3.1 Sorption-Desorption Test

The sorption-desorption test (SDT), a synonym of water sorption-desorption test, was originally proposed by Tagami et al. (1982) as a simple and practical method to assess the functional

properties of the skin surface, i.e., the uppermost portion of the SC, in vivo in a short period of time. The test procedure consists of electromeasurements before and after the application of a droplet of water on the skin surface for 10 s to obtain data on the hygroscopic property of the skin surface and later serial measurements at intervals of 30 s for 2 min to evaluate the water-holding capacity of the skin surface (Tagami et al. 1982). The time course of water desorption

assessed by high-frequency conductance approximates the exponential curve, $W = W_{\max} \cdot e^{-\lambda t}$, since the measured values can be plotted in a straight line on a semilogarithmic graph. λ indicates desorption rate constant (Tagami and Yoshikuni 1985).

3.2 Test Procedure Originally Described by Tagami et al.

The original authors utilized a high-frequency electric current of 3.5 MHz with a skin surface hygrometer that measures high-frequency conductance, Skicon, to follow the changes in the hydration state of the SC. First, a test area at least 1 cm in diameter is marked on the skin surface and the conductance value is measured with Skicon to obtain a prehydration level. Then, a drop of distilled water is placed over the test area for 10 s. Immediately after blotting the site with a pad of gauze or tissue paper, the measurement is made and repeated at intervals of 30 s for 2 min. Instead of distilled water, saline or PBS can also be used since the results are not greatly affected by the presence of electrolytes but only by the exogenous supply of water in vivo. They showed that the longer the water application time, the higher the hygroscopicity and water-holding capacity. Thus, they utilized 10 s for the water application time for the practical reason finishing this whole procedure in 2 min.

3.3 Normal Skin Water Kinetics

Under usual ambient conditions, normal skin surface shows a high rise in conductance just after the application of water, which is followed by a rapid falloff within 30 s, and thereafter by a gradual return to the prehydration levels within 2 min. By performing SDT before and after serial tape stripping, it is clearly demonstrable that a deeper portion of the SC is more hygroscopic than the superficial part (Tagami et al. 1982) (Fig. 3). Interestingly, the SDT with an in vivo

Fig. 3 Water sorption-desorption test on normal skin surface and that repeated 3 min after adhesive tape stripping of the SC 10 times (From reference Tagami et al. 1982)

simulation model by using a sheet of SC showed that the lowermost surface of the SC, which consists of only newly formed immature SC, exhibits much less water-holding capacity than the upper surface, because of the lower concentrations of NMF in the freshly produced corneocytes than those covering the skin surface (Hashimoto-Kumasaka et al. 1991). The finding that the largest amount of free amino acids is in the midportion indicates that the midportion has the greatest water-holding capacity (Hashimoto-Kumasaka et al. 1991). Therefore, by introducing a procedure of partial stripping of the SC before SDT, we can evaluate the functional properties at various levels of the midportion of the SC.

3.4 Modified Procedure of SDT and Definition of Functional Parameters

Modified procedures using other instruments and/or with longer water application time have been reported after the initial proposal of SDT by Tagami et al. (1982). Instead of skin hygrometer, Skicon, other measuring instruments such as

Corneometer (Agache et al. 2001; Pellacani and Seidenari 2001) or Nova DPM (Treffel and Gabard 1995) have been used to assess the hydration state of the SC.

The water application time of 10 s can also be elongated, which, however, requires a much longer follow-up time. Agache et al. (2001) reported such a modified methodology in which water was applied for 60 s then removed with soft paper towel. Thereafter, skin capacitance and TEWL were measured together there by employing Corneometer CM 820 and Evaporimeter EP1, respectively, after every 90 s up to 630 s. The areas under the TEWL-versus-time curve provide the absolute amounts of residual absorbed water. They were similarly bi-exponential, i.e., an initial rapid then a subsequent slower curve in the decrease kinetics measured with both instruments. The Corneometer values were found to change monoexponentially, reflecting the influence of the water content that is present even in the deeper portion of the SC.

The WHC, which is defined as the area under the curve (AUC) plotted by capacitance measurements, can be calculated by assuming that the prehydration value is equal to 0. The difference between the capacitance value measured immediately after water removal and that of the prehydration state can be defined as the water-sorption capacity (hygroscopicity) (Pellacani and Seidenari 2001).

3.5 SDT on Various Skin Conditions

3.5.1 Scaly Skin

The SDT can be performed on pathologically scaly skin due to various inflammatory dermatoses such as psoriasis, eczematous dermatitis, tinea corporis, and pityriasis alba, all of which demonstrated lower hygroscopicity and WHC values than those measured on the adjacent normal skin areas (Fig. 4) (Tagami et al. 1982; Urano-Suehisa and Tagami 1985). It is also possible to increase the sensitivity of the probe by using an MCC probe (Measurement Technologies Cincinnati, USA), whose skin-

attaching portion is studded with 8 needle-like electrodes instead of an ordinary flat surface for the measurement of dry skin (Sasai et al. 1996). The sensitivity of the probe from the manufacturer (IBS Ltd., Hamamatsu, Japan) can also be increased with Skicon 200 EX as compared with Skicon 200.

3.5.2 Hypertrophic Scars and Keloids

Unique functional changes are found in the clinically smooth skin surfaces of hypertrophic scars and keloids. They show elevated values in both TEWL and high-frequency conductance compared to those obtained at the skin surface of mature atrophic scars (Suetake et al. 1996). These unique functional changes are much more clearly demonstrable with SDT, which shows both elevated hygroscopicity and WHC in fresh scar lesions, distinct from what is ordinarily observed in chronically inflamed lesions. These functional characteristics of hypertrophic scars have been noted to gradually return to those of normal skin levels when the scar characteristics later change into those of mature, flat, atrophic scars.

3.5.3 Functional Changes After Repeated Applications of Topical Steroids or Calcineurin Inhibitor

The SDT can detect even slight functional SC abnormalities of the skin, even when the static functional parameters do not show much change. It is known that repeated topical applications of high-potency glucocorticoid such as clobetasol propionate for a few weeks on normal skin produce not only a decreased barrier function that is demonstrable as enhanced TEWL but also a decreased hydration state of the SC (Kolbe et al. 2001). Topical ointment containing 0.12 % betamethasone-17-valerate, which is a less potent steroid than clobetasol propionate, did not induce these functional changes in TEWL or the hydration state in the normal skin surface even after twice-daily applications for 3 weeks. In this case, however, a decrease in both hygroscopicity and in WHC on the skin treated with this potent steroid ointment was clearly revealed by the SDT. In contrast, no such changes were observed on the

Fig. 4 Water sorption-desorption test carried out on eczematous lesions. As compared to diffusely scaly lesions (a), thin scaly ones (b) show more hygroscopicity, but water-holding capacity is still low (From reference Tagami et al. 1982)

skin after such repeated applications with either petrolatum or a calcineurin inhibitor, tacrolimus ointment for 3 weeks (Kikuchi and Tagami 2002).

3.5.4 The Skin Changes After Topical Application of Skin Moisturizers

Topical application of skin moisturizers obviously affects the hydration state of the SC, especially on its outer surface, immediately after their application. Such induced differences in the dynamic hydration state can be observed at certain periods of time after starting the application of various kinds of emollients by conducting the SDT. After 15 min acclimatization in an environmental chamber whose room temperature and relative humidity are maintained at 21 ± 1 °C and 50 ± 3 %, respectively, baseline measurements of the hydration state of the SC at the test area on the lower leg were performed with Skicon 200 EX (IBS Ltd., Hamamatsu, Japan). Then petrolatum,

Hirudoid[®] Soft Ointment (W/O), and Hirudoid[®] Lotion (O/W) were applied on each test area. Both Hirudoid[®] Soft Ointment and Hirudoid[®] Lotion are popularly prescribed moisturizers in Japan that contain a heparinoid substance and glycerol as the main humectants. Two hours after the application of these moisturizers, the SDT was conducted with a slight modification of the original method described by Tagami et al. (1982). Namely, instead of applying a droplet of distilled water on the skin surface, cotton soaked with distilled water was applied on the skin surface for 10 s to avoid spilling of the water from the test area. The obtained hygroscopicity was highest on the area treated with Hirudoid[®] Lotion (O/W), followed by treated with Hirudoid[®] Soft Ointment (W/O), whereas it was lowest after the application of petrolatum. Judging from the most gradual logarithmic decay curve of water desorption, the WHC after the application of Hirudoid[®] Soft Ointment

Fig. 5 The SDT on the skin after the application of various topical lubricants. Hygroscopicity was the highest after the application of Hirudoid® Lotion (O/W) (a), whereas the

water-holding capacity (WHC) was better after the application of Hirudoid® Soft Ointment (W/O) (b)

(W/O) was found to be superior, although Hirudoid® Lotion was better than the other moisturizers considering the largest AUC due to its immediate effect (Fig. 5a, b). In contrast, it was difficult to find any increase in high-frequency conductance just after the application of oily lubricants such as petrolatum because they exert an occlusive effect at first that lowers the obtained hydration values just after the application.

3.5.5 Differences Among Different Anatomical Locations

Using the SDT, differences in the hydration functions of the SC were compared between the skin of the flexor forearm, flexor lower leg, and hyperkeratotic heel skin with fissures, after 15 min acclimatization in an environmental chamber whose room temperature and relative humidity were maintained at 21 ± 1 °C and 50 ± 3 %, respectively. The value of TEWL was highest on the heel, followed by the forearm, then the leg (29.5 , 3.4 , and 1.5 $\text{gm}^{-2}\text{h}^{-1}$, respectively). Baseline high-frequency conductance values on the heel, the forearm, and the leg were 7 , 21 , and

45 μS , respectively. Hygroscopicity was lowest on the heel and its WHC was also lowest, thus reflecting the uniquely firm skin surface characteristics of the plantar skin (Fig. 6a, b).

3.6 Moisture Accumulation Test (MAT)

As described above, the electrical parameters commonly used for evaluation of the hydration state of the SC, i.e., high-frequency conductance and capacitance, are usually obtained several seconds after application of the electrode to the skin surface in order to avoid the influence of accumulating water between the electrode and the skin surface that is induced by prolonging the electrode application time. In contrast, the MAT is devised to measure the pattern of this increase in the water content taking place in the upper portion of the SC due to the occlusive application of the electrodes.

Van Neste (1990) described the procedure of the MAT as follows. The Corneometer probe is applied continuously to the skin surface with

Fig. 6 The SDT on the skin of volar forearm, flexor lower leg, and hyperkeratotic heel associated with fissures. The hygroscopicity (a) as well as the WHC (b) on the heel was lowest among the test areas

moderate pressure. The obtained values of capacitance are then recorded every 3 s for up to 45 s. It initially increases rapidly, then more slowly afterward. Thus, the water accumulation velocity (WAV) is observed as a biphasic slope of increase in capacitance, consisting of an initial steep one that is followed by a gradual decrease afterward. This probably reflects the rapid hydrating process of the intercellular spaces of the corneocytes induced by the interruption of TEWL (initial phase), subsequently followed by the cellular hydration of the SC. The latter may arise from osmotic hydration, simple diffusion, or both. Thus, it is useful to assess these two parameters separately (Agache and Black 2004).

This MAT can also be performed using conductance-measuring instruments, i.e., Skicon or Nova DPM. Instead of those measurements at every 3 s up to 45 s as reported by van Neste, the hydration value can be read every 30 s for up to 3 (Treffel and Gabard 1995) or 5 min (Pellacani and Seidenari 2001), as modified by other researchers according to their respective purposes. The WAV during the first 30 s is calculated from the obtained readings (the reading made at 30 s – baseline value)/30, and the water accumulation (WA) is represented by the area under the curve (AUC) between the values of the baseline and those at the end of the measurements.

3.7 MAT Conducted Under Various Skin Conditions

The MAT and the abovementioned SDT clearly show differences in the dynamic parameters of the SC hydration function after the application of moisturizers or after irritation with sodium lauryl sulfate (SLS). The WAV was shown to be higher after the application of cream W/O than after that of cream O/W (Treffel and Gabard 1995).

3.7.1 Differences Among Anatomical Locations

We conducted the MAT on the skin of the flexor lower leg with or without partial tape stripping and on the hyperkeratotic heel by measuring the high-frequency conductance with Skicon 200 EX every 30 s up to 3 min in an environmental chamber whose room temperature and relative humidity were maintained at 21 ± 1 °C and 50 ± 3 %, respectively. The obtained values of TEWL on the flexor leg, heel, and 15 times' tape-stripped leg skin were 2.1, 18.9, and 16.8 $\text{gm}^{-2}\text{h}^{-1}$, respectively. The WA and the WAV were remarkably high on the skin after partial tape stripping as compared to those of the untreated heel or the leg skin (Fig. 7a). Moreover, the WA and the WAV were higher on the leg than on the heel (Fig. 7b), clearly indicating the poor water-holding capacity of the plantar SC despite the

Fig. 7 The moisture accumulation test (MAT) on the skin of the flexor lower leg, with or without serial tape stripping, and a hyperkeratotic heel showing fissures. The water accumulation velocity (WAV) and the water accumulation

(WA) were much higher on the skin after partial tape stripping of the SC (a). The WAV and WA were higher on the flexor leg than on the heel (b)

fact that its TEWL level was higher than that of the leg. This probably reflects the unique functional properties of the plantar SC, which is extremely thick as compared to the SC of other body locations (Ya-Xian et al. 1999). It is necessary to be firm enough to support the body weight without causing any damage to the underlying living skin tissues. In addition, it is also necessary for the plantar SC to maintain a certain level of flexibility, which can be attained with an adequate hydration state, in order to avoid painful cracking in such extremely thick SC. Therefore, the water barrier function of the plantar SC does not need to be so efficient as compared to that of the SC of other body locations, because of its rather massive water supply from the underlying wet epidermal tissue, helping the thick planter to maintain a certain level of flexibility.

3.7.2 After the Application of Skin Moisturizers

We also assessed the hydration state of the SC with the MAT after the application of various moisturizers. The same moisturizers employed in the SDT section were applied on the test areas of the lower legs. Two hours after the application of the moisturizers, the MAT was conducted together with measurement of the high-frequency

conductance by Skicon 200 EX in the same environment as described above. The WA on the skin after the application of Hirudoid[®] Lotion (O/W) was the highest, but those after the application of Hirudoid[®] Soft Ointment or that of petrolatum were not higher than that of the non-treated control, indicating that the medium consisting of lotion has greater water-binding ability than W/O cream or petrolatum (Fig. 8).

3.8 Plastic Occlusion Stress Test (POST)

The POST involves measurement of the skin surface water loss (SSWL) by evaporimetry on a previously occluded skin site for an abnormally long period of time. It was first proposed by Berardesca and Maibach in 1988 (Berardesca and Maibach 1988, 1990). After abnormally long occlusion of the skin surface with an impermeable plastic film, the SC becomes overhydrated due to the permeation of water from the viable skin tissue. As described previously, with more than 50 % w/w hydration, the corneocytes become swollen where the accumulated water behaves like bulk liquid water. At hydration levels of >300 % w/w, extracellular pools of water become

Fig. 8 The MAT conducted on the skin after the application of various moisturizers. The WA on the skin after Hirudoid[®] Lotion application was the highest among these topical agents

observable morphologically. Thus, SSWL is highest immediately after removal of the occlusion due to the excessive water evaporation from the SC. Then, the SSWL decreases together with water vaporization from the SC.

The practical procedure of the POST is as follows: first, an initial SSWL value (so-called TEWL) is measured on the test site with evaporimetry using Evaporimeter EP1 (SeroMed AB, Stockholm, Sweden), Tewameter (Courage and Khazaka, Köln, Germany), or DermaLab (Cortex Technologies, Denmark). Then, the test site is occluded with a water-impermeable film for 24 h. Immediately after removal of the film, the visible excess water on the skin surface is quickly wiped off with tissue paper and the SSWL is monitored every minute (or every 5 min) for 25–30 min (Berardesca and Maibach 1990).

The obtained SSWL decay curve appears to be bi-exponential, which can be easily quantified through logarithmic transformation. The second slope that appears after 10 min is subtracted from the overall log curve, allowing the initial decay curve to be obtained (0–9 min). The parameters

obtained are the slope and the y-intercept of the SSWL/time log regression lines. The slopes (SSWL decrease rate constant) are expressed as a percentage of the SSWL decrease per unit time. The intercept of the initial slope is the log of the initial SSWL (it should not be mistaken for the total desorbed water). This parameter is of less value than the SSWL rate constant (Agache and Black 2004).

The POST may also be performed using impedance meters, but in this case the measurement would be that of SC hydration and not that of SSWL.

3.9 POST Conducted in Various Skin Conditions

The POST was utilized to demonstrate non-visible skin damage such as that produced by a 3-day open application of 7 % sodium lauryl sulfate (SLS). SSWL decay curves are reported to show significant differences between control and SLS-treated skin (Berardesca and Maibach 1990). By performing the POST on the skin where different types of skin damage were elicited by tape stripping, lipid extraction, or skin surface biopsy, different parameters could be obtained as compared to non-treated control skin (Rosado et al. 2005). Furthermore, there was also a significant difference in the parameters obtained from the wrist and the volar forearm (Rosado et al. 2005), indicating the unique functional characteristics of the SC covering an area frequently placed under flexion and extension.

4 Discussion

The three representative *in vivo* tests, the SDT, MAT, and POST, described above demonstrate the dynamic hydration changes, induced either exogenously or endogenously in the SC, using different artificial hydration procedures. These hydration changes are followed by instrumental measurements. The SDT employs only exogenous water applied on the skin surface, whereas the MAT and the POST utilize water endogenously

accumulated by preventing water evaporation from the skin surface. When such excessive water accumulation is induced in the SC experimentally, it first quickly permeates into the intercellular spaces and thereafter even into the corneocytes where the water exists as secondary bound water and, much later, even as free water in the SC. Thus, the dynamic hydration of the SC depends on the ability of water-binding substances such as NMF as well as the function of the intercellular lipids. Namely, these tests can evaluate the ability of the SC to absorb water quickly and to hold it as long as possible. These dynamic changes in the hydration state of the SC are monitored by measuring the components of high-frequency impedance, i.e., conductance or capacitance, by simply applying an electrode to the skin surface of the test area. High-frequency conductance measured with the skin surface hygrometer, Skicon, most closely reflects the changes in the amount of water in the uppermost portion of the SC. Thus, this instrument appears to be the most practical and useful for conducting the SC dynamic hydration tests for evaluating the hydrating properties of the skin surface. The POST is rather time-consuming and complicated as compared to the SDT or the MAT, because the overhydration induced by the long-time occlusion may produce even structural damage in the SC such as maceration.

From a practical point of view, the SDT and MAT appear to be superior to the POST because of the ease of use even at outpatient clinics or at the bedside. Additionally, they can be finished within 5 min, whereas the latter requires a more than 24 h occlusion procedure before conducting the instrumental measurements.

5 Conclusion

The SDT and MAT conducted using high-frequency conductance may be the most practical and useful tests for assessing the dynamic hydration in the SC. By conducting these tests, we can demonstrate even slight changes in the SC moisturizing function, as observed in various skin conditions, as well as those changes occurring in the

skin surface induced by the application of various skin care products and topical pharmacological agents. Despite various modifications proposed for conducting these tests as well as for evaluating the obtained functional parameters, further investigations are needed to standardize these practical tests to characterize further the local differences in the body surface, which will provide us better information for producing new skin care products appropriate to each body site.

1 Introduction

Stratum corneum (SC) is the outmost skin layer, which is about 15–20 layers and about 20 μm in thickness. Stratum corneum is dry outside and wet inside; there must be a water concentration gradient. The water exists in stratum corneum also in different status, i.e., free water and bound water. The water content in stratum corneum plays a key role in skin's barrier function as well as skin's cosmetic properties. However, to measure the water content within stratum corneum, especially the water distribution and/or status of water, is very difficult. Optothermal transient emission radiometry (OTTER) (Imhof et al. 1984, 1994, 1995) is an infrared remote sensing technology that can be used for such measurements. OTTER is a form of photothermal radiometry (PTR) or optothermal radiometry (OTR), which can be used for different purposes depending on the laser sources used and detection wavelengths selected. By using Nd:YAG laser (532 nm) or tunable OPO laser (400–590 nm) with broadband detection wavelength (5–13 μm), OTTER can be used for measuring skin pigments, e.g., melanin and hemoglobin, and epidermal thickness (Bindra et al. 1994a; Xiao et al. 1999, 2001a; Xiao and

P. Xiao (✉)
School of Engineering, London South Bank University,
London, UK
e-mail: xiaop@lsbu.ac.uk

Imhof 1999a). By using Er:YAG laser (2.94 μm) with 13.1 μm detection wavelength, OTTER can be used for measuring stratum corneum hydration, i.e., water concentration (Bindra et al. 1994b), stratum corneum surface hydration and hydration gradient (Xiao and Imhof 1996, 1998), stratum corneum thickness (Xiao and Imhof 1997; Xiao et al. 2007), water diffusion within stratum corneum (Xiao and Imhof 1999b), and stratum corneum hydration depth profiles, as well as topically applied solvent concentration depth profiles (Xiao et al. 2001b, 2012a). OTTER can also be used for skin damage assessment (Bindra et al. 1996) and nail water content measurements (Xiao et al. 2009, 2011). By using a tunable OPO laser near 3 μm wavelength, OTTER can be used for studying stratum corneum water binding energy (Guo et al. 1999). Combined with transepidermal water loss (TEWL) measurements, OTTER can also be used for studying stratum corneum water diffusion coefficient, the status of water, and stratum corneum water-holding capability (Xiao et al. 2007, 2012b). By using Er:YAG laser (2.94 μm) with 9.5 μm detection wavelength, OTTER can also be used for topically applied solvent penetration measurements through the skin or nail (Xiao et al. 2001a, 2009, 2011).

2 Experimental Apparatus and Procedures

2.1 Apparatus

The water distribution within stratum corneum measurements was performed on traditional OTTER apparatus (see Fig. 1), which uses a pulsed laser (Q-switched Er:YAG, 2.94 μm wavelength, 100 ns pulse duration, 5 Hz repetition rate, 3–4 mJ/pulse, ~ 1 mm diameter laser spot size) as heat source to heat up the sample and a fast infrared detector (mercury cadmium telluride, or MCT) to pick up the consequent blackbody radiation increase from the sample surface.

By analyzing the shape of the signal, we can get information on the optical properties, thermal

properties, and layered structure of the sample. Depending on the detection wavelength, the OTTER signals can either reflect the water concentration information in the skin (13.1 μm wavelength) or solvent concentration information within the skin (9.5 μm wavelength). With the detection depth less than 20 μm , OTTER is the only technology that can confine measurements within the stratum corneum.

2.2 Samples and Experimental Procedures

All the optothermal measurements were performed in an air condition-controlled standard laboratory environment (21 ± 1 $^{\circ}\text{C}$ and 40 ± 5 % relative humidity). For the *in vivo* measurements, skin sites of healthy volunteers were chosen. The volunteers were acclimatized for 20 min, and each skin site was wiped clean with EtOH/water (95 % solution, prior to measurements.

3 Results and Discussions

3.1 In Vitro Skin Immersive Hydration

Skin immersive hydration was performed on a piece of skin sample from the sole of a volunteer's foot. It was fully hydrated by soaking in water overnight. Figure 2 shows the drying curves of the sample in the laboratory ambient environment (Xiao and Imhof 1999b). We can divide the drying process into three periods, A to B, B to C, and C to D. In the first period, the skin surface hydration, i.e., surface water content, is decreasing rapidly while the hydration gradient remains close to zero. The low hydration gradient indicates that the skin sample is and remains uniformly hydrated, and only surface water, i.e. free water, is lost during this period. In the second period, the skin sample begins to lose near-surface water, i.e., bound water, causing the surface hydration to decrease rapidly. This also causes the hydration gradient to increase rapidly, as a diffusion gradient is established close to the

Fig. 1 Schematic diagram of optothermal transient emission radiometry (OTTER)

Fig. 2 Surface hydration (solid squares) and hydration gradient (open squares) measured on excised SC during a drying experiment

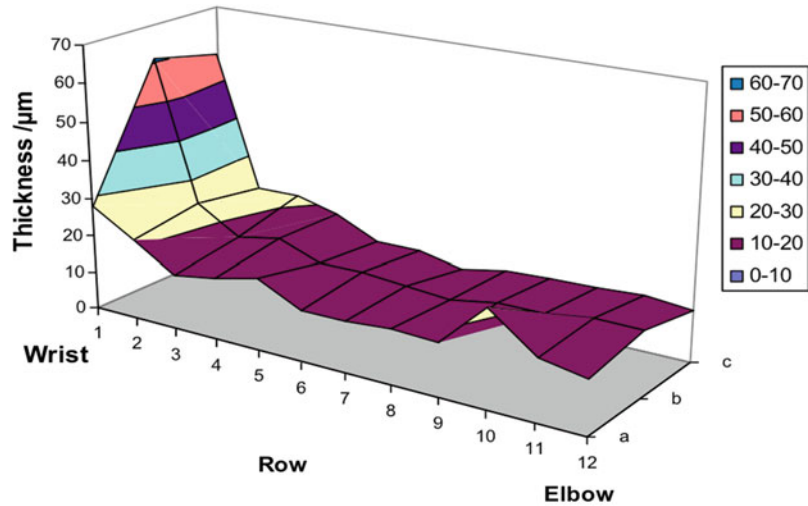

surface. This gradient peaks sharply during this period, as the diffusion region spreads inward from the surface. In the last period, steady

conditions of water loss from the surface and diffusion of water within the whole of the sample are established. Surface hydration and hydration gradients are decreasing slowly during this period, as the sample approaches equilibrium with the moisture in the surrounding air.

3.2 In Vivo Volar Forearm Stratum Corneum Thickness Map

By combining the stratum corneum surface hydration and hydration gradient information, it is possible to calculate an estimated stratum corneum thickness. Figure 3 shows the stratum corneum thickness map of the volar forearm of a healthy male volunteer aged 20–30 (Xiao and Imhof 1997). The results show that stratum corneum is relatively thin and uniform for most part of the volar forearm; it thickens rapidly near the wrist. Such information could be very useful for transdermal drug delivery studies.

Fig. 3 Map of in vivo stratum corneum thickness of the left forearm

3.3 In Vivo Different Skin Site Measurements

Figure 4 shows the measurement results of different skin sites of four healthy volunteers, both male and female, aged 20–40. Figure 4a shows the stratum corneum surface hydration and hydration gradient results.

The results show that the stratum corneum surface hydration is high on the face, and low on the palm and finger, while, the hydration gradient is high on the arm and low on the palm and finger. Figure 4b shows the stratum corneum thickness results, which shows that it is thicker on the palm and finger and thinner on the arm. By combining the stratum corneum surface hydration and hydration gradient results (Fig. 4a) and TEWL results (Fig. 4c), we can also calculate the stratum corneum water diffusion coefficients of the different skin sites using Fick's first law (see Fig. 4d). The arm has lowest water diffusion coefficient and the palm has highest water diffusion coefficient. Water diffusion coefficient is also very useful for understanding the skin properties as well as in transdermal drug delivery studies.

3.4 In Vivo Stratum Corneum Hydration Depth Profiles

By analyzing the OTTER signal using segmented-least squares fitting, it is also possible to perform depth profiling of stratum corneum hydration, or topically applied solvent (Xiao et al. 2001b). Figure 5a shows the results of depth profiles at different skin sites, plus the nail and hair.

The results show that the face and forearm have the highest water hydration and hydration gradient, while the nail and hair have much lower hydration and hydration gradient. The curved structure of hair water hydration depth profile is likely to reflect the layered structure of the hair which holds different amounts of water. Figure 5b shows the stratum corneum hydration depth profiles on a volar forearm skin site during tape stripping using Scotch 3M tape. Each tape removes about 1 μm thickness of the stratum corneum. As tape strip number increases, the stratum corneum hydration depth profile also increases.

By scanning the skin surface, it is also possible to create a 3D hydration depth profile map. Figure 6 shows a 3D stratum corneum hydration depth profiles of a skin area from the wrist to the palm of a healthy male volunteer aged 20–30 (Pascut

Fig. 4 (a) Stratum corneum surface hydration (*top* series) and hydration gradient (*bottom* series) at different skin sites; (b) Stratum corneum thickness at different skin sites; (c) TEWL at different skin sites; (d) Stratum corneum water diffusion coefficients at different skin sites

Fig. 5 (a) The stratum corneum hydration depth profiles of different skin sites (from *top* to *bottom*): the face, forearm, hand, finger, nail, and hair; (b) The stratum corneum hydration depth profiles during tape stripping

Fig. 6 3-D water hydration profile within SC on an area from the wrist to palm (X represents wrist-palm direction). The *color-coded* legend represents the normalized optical absorption coefficients

et al. 2003). The results show that from the wrist toward the palm, stratum corneum is getting dryer and thicker.

4 Conclusions

The results show that OTTER is a promising technology that can be used for stratum corneum hydration measurements, stratum

corneum surface hydration and hydration gradient measurements, stratum corneum thickness measurements, stratum corneum hydration depth profiling, and topically applied solvent penetration depth profiling. By combining with TEWL measurements, it is also possible to measure stratum corneum water diffusion coefficient and stratum corneum water-holding capabilities.

1 Introduction

The human stratum corneum (SC) is composed of keratin-enriched corneocytes embedded in a lipid-enriched intercellular matrix homing specific proteases and glycosidases. The SC represents a water-tight barrier controlling the internal aqueous balance of the body. It normally consists of about 20 tightly stacked layers of corneocytes that are renewed on a regular basis. This process is regulated by the progressive inconspicuous shedding of single corneocytes at the skin surface. Regional variations exist in the SC structure, and the palmoplantar epidermis strongly differs from all other body surfaces.

2 Sampling Procedure

Cyanoacrylate skin surface stripping (CSSS), formerly named skin surface biopsy, was designed when high-bond clear glues became available (Marks and Dawber 1971; Agache et al. 1972). Using a polyethylene slide as the sampling support was a further decisive step in the development of this technique (Lachapelle et al. 1977). At the dawn of the 1980s, CSSS entered the diagnostic world of dermatopathology (Piérard-Franchimont and Piérard 1985, 1987). The material is currently available as the 3S-Biokit (Courage +Khazaka Electronic, Cologne, Germany) (Piérard et al. 2014).

CSSS relies on collecting a thin layer from the outermost part of the healthy or diseased SC. Its thickness is uniform when collected from normal skin. This material is examined under the microscope looking for the presence of serum, parakeratosis, bacteria, fungi, parasites, neoplastic cells, and any other unusual structures. To perform a CSSS, a drop of cyanoacrylate is deposited off-center onto the polyester slide so as to leave an area free of glue for further handling in the laboratory and sampling identification. The part of the slide coated with cyanoacrylate is applied firmly to the skin and held in place for about 15–30 s. Harvesting the upper portion of the SC is obtained following a gentle traction exerted in parallel to the skin surface while the polyester slide is gently lifted up.

CSSS is conveniently collected from any glabrous area of the body, with two provisos. First, sampling from a hairy area is typically painful because of the hair tearing off, and the sampling quality is inadequate owing to the partial contact of the glue with the SC. It is therefore useful to shave these skin areas before harvesting a CSSS. Second, intracorneal cohesion on the palms and soles is such that it is difficult to collect a uniform continuous sheet of corneocytes. However, on these sites,

sampling is commonly easier in conditions when the SC texture is compromised.

3 Microrelief Network of the Normal Stratum Corneum

Clinical examination of the normal skin surface commonly reveals the ordered network of microdepressions corresponding to first- and second-order lines (Piérard-Franchimont and Piérard 1987). Each pattern of line orientation is typical for each specific part of the body, but varies in appearance from one location to another. A correlation exists between the pattern of primary lines of the skin and grooves in the lattice-work papillary relief at the dermoepidermal interface (Piérard et al. 1974). The skin of youngsters is characterized by the patterned intersections between the primary and secondary lines creating regular polyhedric plateaus. With aging, such a network alters its shape, aligning itself preferentially along major skin tension lines (Piérard-Franchimont and Piérard 1987; Makki et al. 1979). This process ends with the innate microrelief network disappearing among another configuration of wrinkles (Piérard-Franchimont and Piérard 1987). It is therefore possible to assess the texture of the superficial dermis indirectly on CSSS (Piérard-Franchimont and Piérard 1987). As a result, the skin microtopography, the dermal aging, as well as corticosteroid-induced atrophy, sclerosis, striae distensae, and many other changes in the connective tissue are conveniently assessed noninvasively on CSSS (Piérard-Franchimont and Piérard 1987). Such a microtopographic assessment is possibly highlighted using computerized image analysis (Arrese et al. 2004; Corcuff et al. 1989).

CSSS also collects some cornified material present in the pilosebaceous follicles at their openings (acrotichium) at the skin surface. It is therefore possible to assess both the follicular density per surface area and the presence of any follicular

hyperkeratosis (Keriosis), comedones, trichostasis spinulosa, sebum, and some intrafollicular bacteria and mites (Mills and Kligman 1983; Piérard 1987; Groh et al. 1992; Pagnoni et al. 1994; Piérard et al. 1995; Uhoda et al. 2003a; Gerber et al. 2011).

4 CSSS Structural Changes of the Stratum Corneum

Noninfectious erythematous-squamous disorders conveniently assessed by CSSS include xeroses, as well as various spongiotic and parakeratotic dermatoses. Xeroses correspond to various forms of orthokeratotic and parakeratotic hyperkeratosis. This condition encompasses the presentation commonly referred to as “dry skin.” This is similar to ichthyoses although at a different level of severity (Piérard-Franchimont and Piérard 1984, 1985, 1987; Franchimont 1980; Piérard 1996). Spongiotic conditions encompass superficial inflammatory reactions resulting in spongiosis and microvesiculation. Allergic contact dermatitis, atopic dermatitis, and pityriasis rosea belong to this group. Parakeratotic dermatoses commonly correspond to eczematids (ids) and stable psoriasis. Seborrheic dermatitis comes within this category when *Pityrosporum* yeasts are rare.

Contrasting with the uniformity of a normal SC in young people, xerosis is usually variable over the SC. A motley collection of corneocytes is responsible for a skin surface harshness. Parakeratotic corneocytes commonly keep tight intercellular connection. They form clumps and flakes.

Some structural changes alter the shape of individual corneocytes. Some environmental variations (temperature, moisture, dew point, etc.) influence the cohesion of the upmost SC. The effect of some chemicals (acids, bases, surfactants, penetration enhancers, etc.) significantly alters the protein composition of the corneocyte membrane or the nature of the intercellular lipids.

Many of the above-mentioned changes are discernible on CSSS using morphological or molecular techniques.

5 CSSS in Clinical Pharmacology Related to Epithelial Renewal

Some pharmacological agents and cosmetics attempt at improving the epidermal renewal rate. In fact, the keratinocyte proliferation is retarded in certain xeroses and during most aging types. Thus, it is wise to assess noninvasively the SC renewal in order to support any relevant therapeutic efficacy (Piérard 1996). One of these procedures involves application of dansyl chloride (DC) as a fluorescent dye to the skin (Takahashi et al. 1986; Piérard 1992). The progressive desquamation of the SC is responsible for a fluorescence decrease in proportion to the increased epidermal renewal by the test product. Harvesting a CSSS on the tenth day of this test reveals the area of renewed SC under a fluorescence microscope (Piérard 1992). The extent of persisting DC fluorescent areas is conveniently quantified by photodensitometry and morphometric analyses. The relationship between the DC fluorescence fading and the keratinocyte renewal depends on the experimental design. For instance, surfactants remove DC from the SC (Paye et al. 1994).

Due to the induction of contact dermatitis induced by DC, dihydroxyacetone (DHA) was introduced as a substitute (Piérard and Piérard-Franchimont 1993; Uhoda et al. 2004).

The various aspects of the acrotrichium help in making objective evaluations of comedogenesis induction and, conversely, some comedolytic effect of dedicated cosmetic products (Piérard et al. 1995; Mills and Kligman 1982a, b). The same samples, observed under fluorescence microscopy, possibly reveal the accumulation of certain anti-acne drugs, such as fluorescent tetracyclines, or again the presence of intrafollicular

fluorescent porphyrins focally secreted by bacteria of the genus *Propionibacterium acnes*.

6 Corneofluorescence and Corneoxenometry

CSSS is the substrate used for the corneofluorescence (CSM) bioassay predicting the irritant potential of cleansing products, such as surfactants present in personal care and household detergents (Piérard et al. 1994; Goffin et al. 1997; Henry et al. 1997; Uhoda et al. 2003b; Xhaufflaire-Uhoda et al. 2006). Corneoxenometry (CXM) is a variant bioassay suitable for various other xenobiotics (Goffin et al. 2000; Xhaufflaire-Uhoda et al. 2008a, b). The samples are sprinkled with a dilute solution of the test product (soap, shampoo, washing-up liquid, etc.). After a 2-h contact time, samples are stained with a toluidine blue-basic fuchsin solution. The intensity of the color is proportional to the degradation of the corneocyte wall (proteins and lipids) induced by the surfactant.

Stratum corneum collection • Cyanoacrylate method • Stratum corneum lipids • Ceramides

Different methods have been used for the collection of stratum corneum for lipid analysis, all with different advantages and disadvantages (Table 1). We used the cyanoacrylate method, because of its simplicity and ability to produce low intraindividual differences (Jungersted et al. 2010).

The area of interest (the forearm) is wiped with acetone to eliminate contamination from surface lipids. A rinsed glass slide with a droplet of LiquiBand® (MedLogic, Plymouth, UK) cyanoacrylate glue is placed in one end, and held unto the skin for 1 min, and then slowly removed (Fig. 1). Hereby, a sample of the SC is attached to the glass slide, and the sample is then kept frozen until further analysis with high-performance thin-layer chromatography (HPTLC).

1 Critical Approach/Limitations

One concern could be that if the acetone used would change the lipid profile, however in a study on mouse skin, it has been shown that the SC lipids are not affected by the wiping with acetone (Rissmann et al. 2009).

The cyanoacrylate method does not give information on how deep into the stratum corneum the

Table 1 SC collection methods

Method	Procedure	Advantages	Disadvantages
Biopsy	Punch or skin biopsies obtained from excess of skin from patients undergoing cosmetic surgery	Large amounts of SC	Risk of contamination from other lipids of epidermis when separating SC from rest of biopsy
Tape stripping	Tape stripping followed by analysis of SC attached to tape	Easily performed; no contamination from other layers of SC	Amount of SC obtained is limited; contamination from tape material
Cyanoacrylate stripping	Drop of cyanoacrylate resin on glass slide, pressed onto skin and then removed	Easily performed; no contamination from other layers of SC	Amount of SC obtained is limited
Organic solvents	Extraction chamber with organic solvents placed directly on skin, solvent stirred and then collected using pipette	Extracted lipids ready for further analysis	Method is inconvenient; measures have to be taken to avoid inhaling organic solvent; impossible to estimate from how deep in SC lipids are obtained
Azerbaijani scrub	Scrubbing of skin with moist crepe mitten	Simply performed; produces large amounts of SC	Must include large areas of skin to obtain enough SC, therefore method cannot be applied on localized anatomical sites; risk of contamination from surface lipids
Mechanically removed by scraping	Scraping of skin with scalpel	Large amounts of SC	Time-consuming

Reprint from Jungersted et al. (2010) (see article for references)

Fig. 1 Photo of the cyanoacrylate method

sample is obtained. The importance of this was investigated in a study where the cyanoacrylate method was compared to a method, where most of the SC was scraped off using a scalpel, and comparable results were achieved (Jungersted et al. 2010). The same is evident for the ceramide distribution at different depths of SC (Jungersted et al. 2010; Weerheim and Ponc 2001; Nörlén

et al. 1999). One should also note that compared to other methods used, it is fast and easy to handle, which is an important aspect when used in vivo on humans in an experimental setting (Jungersted et al. 2010).

Since all the samples from AD patients were taken from non-lesional skin, one could argue on the relevance of examining lesional skin as well.

However, before interpreting data of SC lipids from lesional skin, one would need to address confounding aspects, such as the difference in precise location of the lesion, as well as the unknown effect of superinfection and the degree and age of the lesion, which are why non-lesional skin was chosen.

Stratum mechanics friction

1 Key Messages

- The stratum corneum layer has a net contribution to the skin's mechanical properties.
- The different constituents of SC (i.e., lipids, NMF, etc.) have a key role in maintaining these mechanical properties.
- In particular lipids seem to prevent the plastification of SC in presence of water. The absence of lipids and NMF rigidify the SC structure.
- SC flexibility would mainly be related to corneocyte connections and the macromolecular mobility and plasticization of intercellular spaces.
- Moisturizers can work efficiently by par example creating mechanically resistant surface films on the surfaces.
- The SC contributes to the friction properties of skin, in particular at low pressures.
- Lipids contribute to maintain the intrinsic friction of SC. Its absence diminishes the friction coefficient.
- The presence of water and humidity increases the friction of SC by its plastifying effect.
- Moisturizer's action on friction is dependent on the absence or presence of thin films at the surface of SC either decreasing or increasing it, respectively.

2 Importance of the Stratum Corneum and Skin Physical Properties

The stratum corneum (SC) participates in the functional properties of the skin (Elias 2005). It protects our body from harsh environmental factors and mechanical insults. In the meantime, its ability to distort and its softness are responsible for the comfort of the skin. Most of the cosmetic treatments try to improve or repair the intrinsic properties of skin with SC as a prime target which eventually reflects in enhanced mechanical and tribological behavior.

3 The Structure of SC

The stratum corneum could be considered as a composite material mainly made of corneocytes embedded in intercellular cement containing lipids, water-soluble materials, and proteoglycans. Corneocytes are linked by glycoprotein junctions called corneodesmosomes. They form the elemental bricks of the brick/mortar pattern proposed to describe stratum corneum structure. Corneocytes are produced from living epidermal cells, the keratinocytes which undergo considerable structural and biochemical and mechanical changes eventually leading to fully keratinized, hard corneocytes (Elias 2005; Agache and Varchon 2004). Cell membrane and structure dramatically change along the process to ultimately take the well-known penta- or hexagonal flat shape ca. 200 nm thick and 40 μm wide.

4 Mechanical Properties

The influence of SC layer on the overall mechanical properties of the skin is recognized (Agache and Varchon 2004; Batisse et al. 2002). The stratum corneum can be isolated from skin and its robustness allows it to be tested using common mechanical traction tests. So, stress relaxation tests can be performed on human SC (Park and Baddiel 1972a, b; Wildnauer et al. 1970; Koutroupi and Barbenel 1990; Druot et al. 1985; Rochefort

et al. 1986). A typical stress-strain (load-elongation) curve for human SC conditioned in water at 25 °C for one hour reveals three distinct regions separated by inflections at approximately 25 % and 125 % elongation. Using pure shear specimen geometry, SC showed nonlinear load-elongation behavior and stress relaxation, although the extensibility and rate of stress relaxation was considerably lower than that shown by other soft connective tissues (Koutroupi and Barbenel 1990). Rheological models have also been used to explain the results of tensile tests at constant strain rate (Druot et al. 1985). Finally, several mechanical instruments are used to measure the elastic modulus E and the effect of water or cosmetic ingredients as a function of application time (Lévêque et al. 1987; Takahashi et al. 1984, 1985; Rasseneur et al. 1982).

Ultrastructural changes in the SC were examined by Rawlings et al. (1995) using electron microscopy. The lipid layers progressively become disorganized soon after 5 % extension unlike desmosomes that resist until just before fracture of the tissue. Lévêque et al. (2002) combined transmission electron microscopy and X-ray diffraction. At 60 % extension, and although the detachment of lipid layers from one of the adjacent corneocytes was observed, X-ray analysis data showed that intercellular lipid organization kept unaltered.

Other experiments have explored the mechanical properties in the direction normal to the skin surface by fracture techniques. They allowed, for example, the fracture surface energy between two layers of SC (delamination energy) to be assessed. It has been estimated to be 3.6 kJ/m^2 which is comparable to that of tougher synthetic polymers (Koutroupi and Barbenel 1990). Delamination energy seems to be governed by cohesive properties of the intercellular boundaries of SC (Wu et al. 2002, 2006a, b) as it decreases when temperature and hydration level increase. On the other hand, it increases when lipids are extracted due to the interaction between remaining components that are less affected by hydration. Finally it is believed that delamination energy is not strongly correlated with expected corneosome cohesive contribution (Chapman et al. 1991; Wu et al. 2006b).

The SC stiffness in the direction normal to the skin surface is much lower than that reported in-plane. The mechanisms involved in this heterogeneity may be related to additional SC microstructure (Wu et al. 2006b). Keratin intermediate filaments (IF) are linked to corneodesmosomes that build a bridge through the intercellular space to connect adjacent cells. The structural orientation and possible alignment of these keratin fibers, still controversial, might have a strong impact on mechanical anisotropy. Corneodesmosomes may facilitate the transmission of tensile forces between cells leading to greater stiffness and higher fracture energy observed in the in-plane orientation (Wu et al. 2002).

Another approach, reported (Richter et al. 2001) is based on the physical isolation of the individual components. Corneocyte is likely to be the most studied component. Although several studies have looked into the ultrastructure of corneocytes using optical and electron microscopes, few give insights into mechanical properties. Much work done in this field used “indirect” observations based on morphological changes of isolated corneocytes as a function of RH, for example. Richter et al. (2001) investigated and quantified the swelling of corneocytes in water using atomic force microscopy (AFM). They mainly observed change in thickness with no significant lateral alteration. A more direct approach was resorted to by Lévêque et al. (1988). The authors recorded the force needed to elongate isolated corneocytes immersed in water using a micro-handling technique. The calculated Young’s elastic modulus was $E \sim 4.5 \times 10^8$ Pa although it was considered by the authors to be underestimated due to technical difficulties. Other teams like Yuan and Verma (2006) used atomic force microscope (AFM) together with a Triboscope nanoindenter and a nano-DMA (Hysitron, Minneapolis, MN, USA) to measure viscoelastic moduli (E' and E'') at the microscale. Measurements were made on isolated dry and wet stratum corneum at varying depths. Elastic moduli values obtained with a pure elastic model were of the order of 100 and 10 MPa for dry and wet SC, respectively. Tan δ

increased from approximately 0.1–0.25. An apparent modulus variation with indentation depth was noticed. The origin of this behavior is not understood.

In our laboratories, we have focused on measuring mechanical properties of the stratum corneum at a submicron length scale in order to investigate the effect of SC components, humidity, and cosmetic treatments.

Here we report nanoindentation tests (Pavan et al. 2005; Potter et al. 2007) at controlled temperature and humidity that were performed with an MTS Nanoindenter XP using the continuous stiffness measurement method to assess SC viscoelastoplastic properties. The method consisted in superimposing a small shifting oscillation at a given frequency ($a = 5$ nm) during the indentation test. The frequency of added harmonic vibration was 32 Hz. The device was placed within a climatic chamber. Reduced Young’s modulus and loss factor as a function of penetration depth were continuously recorded by simultaneous measurement of normal load and contact stiffness.

4.1 Influence of Humidity

The flexibility of the stratum corneum depends on its water content (Wildnauer et al. 1970; Druot et al. 1985; Lévêque et al. 1987; Takahashi et al. 1984). The effect of relative humidity on elastic modulus over the range 30–100 % is reflected, for example, by E value changing from 2 GPa at 30 %RH to 3 MPa at 100 % RH (Park and Baddiel 1972a).

Lévêque et al. studied water-keratin interactions in human SC (Lévêque et al. 1987). They recorded elastic modulus of human SC as well as water content and water interaction energy at various rates of relative humidity (RH). The important changes in the elastic modulus at RH lower than 60 % would be related to the condensation of a single layer of water molecules on active hydrophilic sites with a high interaction energy suggesting that the binding state of water molecules with keratin is an important factor in skin mechanics.

Fig. 1 Change in loss factor as a function of SC treatments at two humidity rates

In our experiments SC was used at 25 %, 50 %, and 70 % RH rates and then immersed in distilled water. The results are reported in Fig. 1.

Reduced Young's modulus was found to decrease and loss factor increased with increasing HR rate. Our hypothesis is that loss factor ($\tan \delta$) is closely related to macromolecular mobility and viscosity of lipid intercellular spaces.

A gradient of mechanical properties according to indentation plastic depth was noticed.

4.2 Influence of Lipids

Lipids are key SC structural elements which can be easily extracted. Intercellular lipids appear to play an important role in protecting the hydrosoluble substances (Park and Baddiel 1972a, b; L ev eque et al. 1987). It has however been fully recognized now that corneodesmosome complexes are key components in tissue cohesion and desquamation process (a role usually assigned to lipids).

The precise relationship between lipids and stratum corneum elasticity remains controversial. According to Middleton (1968), lipid removal has no consistent effect on SC extensibility, while Park and Baddiel (1972a, b) stated it did not

influence SC elastic properties. In contrast, Leveque et al. (1987) suggested that lipids slightly contributed to plasticization of the stratum corneum.

Our results (Fig. 1) bring out:

- The role of intercellular lipids: At 70 % RH, loss factor is slightly higher with lipid-extracted SC than with untreated stratum corneum. In the former, water would easily reach hydrophilic intercellular spaces and plastification would be more significant. Viscosity of intercellular macromolecules (corneodesmosomes or other proteoglycans) is increased.
- The role of NMF: At 70 % RH, if in addition to lipids, NMF and other soluble intra- and extracellular proteins are extracted, the SC becomes stiffer and less dissipative. Water diffusion toward intracellular keratin sites is most likely restricted.
- The role of corneodesmosomes: At 15 and 70 % RH, the elastic modulus of the "corneocyte" film is much higher than that of natural stratum corneum. Loss factor is much smaller. "Corneocyte" film is stiffer. Macromolecular mobility of the junctions between constitutive elements (corneocytes) is very difficult.

Fig. 2 Different elements of stratum corneum structure

These results demonstrate the importance of intercellular spaces in mechanical behavior of the stratum corneum. SC flexibility would mainly be related to corneocyte connections and the macromolecular mobility and plasticization of these junctions (Fig. 2).

4.3 Effect of Moisturizers

The effect of a cosmetic agent has been traditionally studied through the influence on stress-strain curve of a traction experiment. For example, the softening effect of emollients on stratum corneum is clearly seen and bigger than that of water alone (Rocheffort et al. 1986). Water is unable to durably soften the stratum corneum whereas emollients are able to act *in vitro*, where the large pool of water in the deeper tissue layers is missing.

Takahashi et al. (1984, 1985) assessed the change in skin-softening effect of moisturizers and hydroxy acids with time following topical application thereby distinguishing the influence of typical formula components.

In our experiments we studied the effects of glycerol and a polymer (Aristoflex LNC). Loss factor values at 1 μm depth are reported in Fig. 3. After applying the moisturizing polymer, SC elastic modulus is reduced and loss factor is increased. This well-known plasticizing effect is induced by an increase in water retention within the stratum corneum.

The surface mechanical properties can also be measured. The mechanical values are reported at 100 nm depth (Fig. 8). The surface modulus was decreased after applying glycerol or urea solution. Amphiphilic polymer Aristoflex LNC increased the surface modulus as a result of surface polymer film formation.

With the nanoindentation technique, it is possible to measure both mass and surface mechanical properties of the stratum corneum. It allows us to investigate the effect of humidity or moisturizers and to identify the role of the various SC components.

The proposed hypothesis is that softness and flexibility of the stratum corneum are mainly related to corneocyte connections and to the viscosity and macromolecular mobility of intercellular space components. The strong effect of urea treatment on loss factor value supports this hypothesis. Further studies using specific treatments and different RH rates have to be conducted to substantiate this hypothesis.

The results contribute also to distinguishing the way different types of moisturizer work: hydrating effect of glycerol, plasticizing effect of urea associated with a strong interaction with protein components, and a new moisturizing mechanism by surface structuration with an amphiphilic polymer.

5 Friction Properties

To better understand the skin surface behavior and particularly the contribution of stratum corneum to general physical behavior of the skin, research based on tribological methods was developed. Needless to say, tribological data alone cannot explain the sensorial properties of the skin, but they can emphasize relevant physical parameters which allow skin condition and behavior to be more clearly described and understood. Together with other physical methods, tribology can help build a table of physical parameters useful to explore and decipher skin biophysics. As shown in the previous section, local experimental approaches involving instruments like tribometers and indenters are helpful to analyze skin, *in vitro*

Fig. 3 Loss factor $\tan\delta$ ($1\ \mu\text{m}$ depth) at 50 % HR of SC treated with aqueous solution of glycerol 3 %, aqueous solution of urea 3 %, and aqueous solution of polymer Aristoflex LNC 1 % (Clariant), respectively

and/or in vivo, to optimize critical parameters, and to advance reliable explanations.

While morphological deformation of the whole skin has been discussed in many papers as being at the origin of the observed friction in vivo (Johnson et al. 1993; Adams et al. 1999, 2007; Derler and Gerhardt 2012), it is worth noticing that few studies have been devoted to tribological properties of the stratum corneum itself (Johnson et al. 1993; Adams et al. 2007; Pailler-Mattei et al. 2007b).

To check whether skin physical properties change in relation to external conditions, scientists have performed in vivo experiments varying normal force (F_n), tangential force (F_t), and other physical parameters and analyzing friction coefficient (μ). Comaish and Bottom (1971) already noticed the problems associated with measure reproducibility when the load was not controlled. Much work has been done to describe the tribological properties of the skin (Gitis and Sivamani 2004; Johnson et al. 1993; Adams et al. 1999, 2007; Pailler-Mattei et al. 2007b; Comaish and Bottoms 1971; Sivamani and Maibach 2006; Sivamani et al. 2003a, b).

Friction force is known to follow Amontón's law in many systems. This basic law states that friction is simply linearly proportional to the applied load:

$$F = \mu L \quad (1)$$

From classical tribology (Bowden and Tabor 1954), friction force is known to have two contributing factors: an adhesion related term F_{adh} and another one related to deformation F_{def} . The adhesion term is linked to the surface energy (i.e., electrostatic, van der Waals, capillary forces) and to the contact area (Adams et al. 2007):

$$F = F_s + F_d \quad (2)$$

In general the deformation part can be ignored in non-dissipative contact as it may happen in elastic surfaces or low loads. The interfacial component is then mostly controlled by adhesion phenomena and is defined as:

$$F_s = \tau A \quad (3)$$

where A is the area of contact and τ the interfacial shear strength.

A general observation is the complexity of measurements and data interpretation. The differences originate from the complexity of the substrate, the explored zone, the geometry of the probe used, and the variety of experimental conditions (applied force, temperature, etc.).

In general we observe that friction coefficient depends on:

- Hygrometry (increase with it)
- Anatomical site
- Use of emollients and creams
- Applied load

In relation to the load, it is clear that Amonton's law ($F = \mu F_n$) is not always followed by skin friction. Derler et al. (2007) found that friction coefficient μ measured at the finger surface as a function of load ($F_n \sim 0.2\text{--}15\text{ N}$) was constant ca. (0.3–0.4) for dried skin. For hydrated skin, the friction coefficient was higher (~ 0.6) and decreased with load presumably due to adhesion. F_n decreases, just as Young's modulus. Consequently, the Amonton's law was not applicable to such surfaces (flexible).

Skin viscoelasticity can be in part responsible for the deviations from Amonton's law (Comaish and Bottoms 1971). El-Shimi et al. (1977) found that friction coefficient decreased with load ($F_n \sim 0.25\text{--}1.8\text{ N}$), while it became constant ($\mu = 0.5$) at higher forces ($>7\text{ N}$) also attributing this decrease to the viscoelastic properties of the skin, entailing the nonlinear deformation. Wolfram et al. (1983) suggested that at small forces (0.1–0.9 N), μ increased with F_n due to adhesion and softening of skin. Dowson et al. (1997) also suggested that adhesion influenced friction coefficient by increasing the surface of contact, adhesion increases, and μ value as well. It is likely that adhesion and surface deformation due to the applied force together influence friction coefficient value (μ) and the Amonton's law illegibility for such specific case is related to skin viscoelasticity.

Skin has a complex multilayer structure. Most of in vivo studies try to understand the sensorial perception in conditions where skin deformation is important. But when the charge is minimized, the influence of the deeper layers of skin is also minimized and the deformation term F_d decreases as the dissipative or viscoelastic contribution decreases (Bowden and Tabor 1954). In these conditions the SC characteristics and effect are maximized and may control the delicate texture observed at the surface of the skin. It is worth

mentioning that most of in vivo studies are done with applied loads from 0.5 to 15 N.

Consequently, to understand the intrinsic properties of the stratum corneum (SC), several questions might be asked, such as:

- Does the physico-chemistry of SC play a key role in skin health and appearance?
- Does SC contribute to the general physical behavior of the skin tissue?
- How the tribological parameters are influenced by a cosmetic product?
- Do the interactions between water/moisturizer and SC influence consumer perception?

As we have previously mentioned, few studies have focused on the tribology of the stratum corneum ex vivo, isolated from the other layers. The advantage of isolating SC is the considerable potential for finding correlations with the dermatological efficacy of a treatment or product on this outermost layer of skin, before clinical studies.

It is worth mentioning here the work by Pailler-Mattei et al. (2007b) who used tape stripping to analyze the effect of SC ex vivo. By stripping successive layers of forearm skin in vivo, the authors did not observe much effect on friction behavior but an increase in adhesion. They concluded that there is not much effect on the bulk skin properties. In parallel, using an XP Nanoindenter (MTS) and a spherical diamond indenter of $\sim 7\text{ }\mu\text{m}$ radius, they made some first measurements on isolated stratum corneum at low loads (0.1–1.0 mN) and at $\sim 1\text{ }\mu\text{m/s}$ speed. After a transition zone (first 100 μm move), they measured a surprisingly high friction coefficient (~ 20), then decreasing to ~ 2 after sliding for 500 μm . These values are much higher than what is known for skin in vivo.

It is most likely that a steady state was not achieved in these experiments. In addition using a nanoindenter on SC makes the approach less direct than with a tribometer.

To assess specific answers with a view to explain the physical behavior of SC and the influence of SC surface topology, several aspects will be described: a short description of tribological

Fig. 4 Nanotribometer

parameters that enhance sensorial behavior, the effect of hydration, the role of intracellular lipids in SC physical integrity, and the effect of cosmetic ingredients on SC tribological properties. These effects are illustrated with some examples of experiment carried out in our laboratories.

5.1 Friction Properties of SC In Vitro

We used a nanotribometer from ©CSM Instruments (Neuchâtel, Switzerland). A brief description of the device is shown in Fig. 4.

- **Module:** can change the tribometer from the straight mode to the circular mode.
- **Post:** it is a 12 mm diameter metallic disk on which we glue the substrate. In straight mode, its goes back and forth with an amplitude L .
- **Substrate:** fixed to the post to measure its friction factor. Here the substrate is *stratum corneum*, the upper layer of the skin from samples from abdominal plastic surgery.
- **Bead:** 1 mm in diameter, can be in steel, glass, and polymer. We chose stainless steel.
- **Cantilever:** it acts as a finite spring modulus and maintains the bead at one end.
- **Mirrors:** they are perpendicular to each other and linked to the cantilever. Their angle varies when the cantilever moves.

- **Optical fibers:** they send a light signal on the mirrors and detect variations of the reflected light signal, thanks to the mirrors' deflection when the cantilever moves.

Here are the characteristics of the cantilever used (Table 1):

We have focused on small normal loads F_n (2–20 mN) where few data is reported in the literature. It is important to note that for the consumer perception, the in vivo pressure can be between 5 and 10 kPa. For the 1 mm radius sphere of our tribometer, we have estimated it to be in the same range (6.4 kPa at 10 mN load).

We used isolated human stratum corneum whose thickness was 10–15 μm . Special care was taken on using clean samples. The stratum corneum was stuck with double glue line adhesive tape on 2 cm radius disks on the post. Finally, the experiments were performed at ambient temperature (25–30 $^{\circ}\text{C}$) and controlled fixed humidity. Fig. 5 shows an example of the friction coefficient μ raw traces during each subsequent back and forth sliding cycle. Negative values represent an opposite sliding direction. It is worth noticing the friction behavior reproducibility after up to the 5 cycles used in these experiments.

Friction coefficient on the nude stratum corneum was measured on two or three positions, in order to have baseline value. Figure 5 shows an

Max cycles numbers	Up to 100

*Experimentally Measured

example of the friction coefficient μ raw traces during each subsequent back and forth sliding cycle. Negative values represent an opposite sliding direction. It is worth noticing the friction behavior reproducibility after up to the 5 cycles used in these experiments.

Several other materials were measured for comparison. It is of interest to notice that, in the same type of experiment, the SC friction coefficient is in the same range (0.2–0.4) as that measured for elastomeric silicone surfaces (See Fig. 6). As expected, Teflon showed a lower value.

Friction coefficient of human SC (see Fig. 7) did not change much according to load thus approaching an Amonton's behavior (friction force proportional to load) although we found a

tendency to decrease at higher loads (~50 mN). As mentioned previously we have maintained in our trials 10 mN load as being close to in vivo applications.

In addition other experiments (not shown) have been done including a rubberlike layer below the stratum corneum. No alteration was observed in the results which confirm that the experimental conditions are appropriate for testing the stratum corneum without any concern about possible effect of the substrate underneath.

These results are of interest when compared with data reported in the literature for skin. In general, as discussed previously, the friction coefficient tends to decrease with load in in vivo experiment on skin (Wolfram 1983; Koudine et al. 2000). On the other hand, El-Shimi et al. (1977) observed an increase in the range of 0.2–1.8 N. In contrast, in our experiments, it seems that the stratum corneum deformations have not been big enough for this effect to be observed. It is most likely that the use of low loads and the mechanical properties of the stratum corneum itself make it more stable in terms of friction coefficient.

Another observation is that the traces observed at low loads are much richer in their shape, a phenomenon like stick-slip is enhanced, and the variability of friction coefficient during sliding is not stochastic. The traces are more sensible to the topography and micro relief of the stratum corneum. It is in these low load conditions where skin texture is most influencing sensorial touch, as suggested by some authors (Gitis and Sivamani 2004).

5.2 Influence of Humidity

Several experiments have been carried out at different humidity levels (25 %, 50 %, and 80 %).

In general we can observe an increase in friction coefficient with humidity level. The difference is more notable at 80 % where we observe a higher influence of load. If we add a water layer on the stratum corneum (by applying a drop, ~100 % relative humidity), there is a clear increase in friction coefficient (Fig. 8).

Fig. 5 Aspect of friction traces obtained on human stratum corneum during different back and forth sliding cycles (the red sinusoidal curve represents the movement of the slider). Notice the reproducibility of traces after each cycle

Fig. 6 Comparison of measured friction coefficients one way (μ_a) and return (μ_b) for stratum corneum and other reference materials. Conditions of measurement: $F_n = 2 \text{ mN}$, $v = 0,2 \text{ cm/s}$, $L = 400 \text{ nm}$

It is most likely that in these conditions, the changes in mechanical properties (reduced modulus and increasing dissipation) seen in the previous section play an important role through altering the properties of the stratum corneum and through

an increased influence of deformation on friction. In addition, the presence of a water layer further increases adhesion due to capillary forces. Both effects could be at the origin of the observed increase.

Fig. 7 Values of friction coefficient for human stratum corneum (*filled symbols*) and Teflon (*empty circles*) surfaces

Fig. 8 Values of friction coefficient as a function of ambient humidity for two independent sources of stratum corneum samples (1 and 2 in the Figure)

5.3 Influence of Lipids

As discussed in the section on mechanical properties, the lipids form a barrier whose effect is clearly seen when they are removed. Water is lost faster and the stratum becomes less hydrated.

Our first experiments (Fig. 9) show that friction coefficient is indeed smaller when lipids are extracted from the stratum corneum. To our knowledge these measurements have been performed for the first time. We believe that the absence of lipids and the dryness of the stratum in such conditions diminish the influence of the deformation term on friction properties therefore decreasing friction coefficient.

5.4 Influence of Moisturizers

We deposited a cosmetic formulation containing a polymer of interest and glycerol (always the same amount of formulation). We measured it at different time points over 2 h post drying (2, 5, 10, 15, 20, 30, 60, and 120 min). Between two measurements, the bead was cleaned, to remove the formulation deposit.

5.4.1 Tested Formulas

Glycerol (7 %), or a polymer (Artistoflex LNC), was added to simplex formulation (*placebo*) belonging to moisturizer technology and containing Arlacel[®] (mannide monooleate) and Myrij[®] fatty alcohol, which is a neutral

Fig. 9 Friction coefficient observed for stratum corneum before (*squares*) and after (*circles*) lipid extraction. Measurement conditions HR = 45 %, F_n = 2, 5, 10, 20 mN

Fig. 10 Diagram showing the structure of copolymer Aristoflex LNC (Clariant)

formulation from a sensory point of view. We compared the properties of both formulas versus simplex formulation on isolated human stratum corneum, prepared from skin samples from abdominal plastic surgery.

In cosmetics, glycerol is often used as a moisturizing agent, solvent, and lubricant. Aristoflex LNC is a brush polymer with a PolyAMPS (2-acryloylamido-2-methylpropane-sulphonic acid) backbone, where polyethylene glycol (PEG) and polyethylene (PE) have been grafted (Fig. 10).

The friction measurements were performed according to the following conditions:

- Normal force: F_n = 20 mN
- Friction speed: V_x = 400 μm/s

- Measurement length: L = 670 μm
- Number of cycles: 1

Each formula was studied many times over a 2 h drying. Measurements were done before formula application (*t* = 0) and at different time points up to 120 min after application.

The results were compared with those from untreated stratum corneum. Figure 11 shows friction coefficient modulations after normalization with the stratum corneum friction coefficient:

$$\Delta\mu_d(\%) = 100 \frac{\mu_d(\text{formula}) - \mu_d(\text{SC})}{\mu_d(\text{SC})}$$

Observations

- The placebo lowers μ_d .
- Aristoflex LNC increases μ_d .
- Glycerol lowers μ_d more than placebo.

We can thus rank the different formulas as follows:

$$\mu_d(\text{glycerol}) < \mu_d(\text{placebo}) < \mu_d(\text{SC}) < \mu_d(\text{Aristoflex})$$

Once again we observe a completely different pattern with film-forming polymers.

Fig. 11 Relative friction coefficient modulation during formula drying

Glycerol slightly decreases the friction coefficient of placebo formula that penetrates well into the stratum corneum. The decrease in friction coefficient can be related to the effect of glycerol still present at the surface with placebo formulation.

The polymer, which acts more as an occlusive moisturizer, hardens during the first 2–3 h following application but then softens slightly as seen in the mechanical tests. The higher friction is most likely related to the increase in effective viscosity of the film. Further penetration of the polymer film in the upper layers of SC makes film thinner, reducing its contribution in terms of viscous drag to the coefficient of friction.

stratum corneum components (i.e., lipids), we can have more insight about their physical role. Finally some examples are given on the effect of glycerol and a common polymer on moisturizing formulations, emphasizing the important role of the absence or presence of thin coating films at the skin surface.

Further studies are needed to explore the properties of this outermost layer of the skin, especially to understand the effect of topography on skin friction particularly in those conditions where the deformations are minimized in vivo and where surface texture prevails. The effect of surface properties is not negligible and has been explored in other areas like packaging or textiles (Shao et al. 2010). Such experiments bring about the importance not only of roughness but also of spatial ordering of the surface pattern in the sensory perception.

6 Conclusion

We have reviewed recent knowledge on the mechanical and tribological properties of the outermost surface of the skin, the stratum corneum. While SC contribution in skin is considered to be important, few studies have allowed its role in vivo to be quantified.

New tests are now available that can help us to explore these properties in vitro. In particular we have shown the complex mechanical and frictional behavior of the stratum corneum can now be studied using nanoindentation technique and nano-tribometers. By selectively removing certain

Sebum • Stratum corneum • Skin barrier function • Drug transport • Human in vivo • Lipid morphology

The differentiation process of sebocyte, the most active lipid-producing cell in the human beings, results in formation of sebum. As the sebum leaves from the sebocytes, it contains triglycerides, squalene, wax esters, and small amount of cholesterol esters. The bacterial enzymes along the follicular canal partially hydrolyzed the triglycerides of the sebum during the passage through follicular canal, so that the sebum content reaching the skin surface contained about 15–40 % free fatty acids, with the unsaturated fatty acid being more irritating than the saturated fatty acid. The sebum mixed with the deranged lamellar lipids from the keratinizing epithelium and formed the skin surface lipid film (SSLF) as it arrived at the skin surface. SSLF is a mixture of large amount of sebum combined with small portion of epidermal lipids. Occasionally, detached corneocytes are also present as demonstrated from the ultrastructural observations made by ruthenium tetroxide staining (Fig. 1). Our observation also demonstrated presence of sebum between the layers of desquamating corneocytes from the outermost several layers of the stratum corneum (SC) (Sheu et al. 1999). Previous infrared spectroscopic study demonstrated greater quantities and more disordered lipids in the outer layer of SC, an observation that is consistent with our morphological observation. These observations suggest a

Deranged lipid lamellae (*arrows*) within the SSLF are observed

possible interaction of SSLF with the corneocytes in the outermost layers of the SC (Bommanna et al. 1990).

1 Effects of Sebum on Epidermal Barrier Function and Stratum Corneum Lipid Morphology

The effects of sebum on skin barrier function have not been thoroughly investigated. Several *in vitro* studies suggested that sebum has negative effects on the skin permeability barrier. Functional study by electron diffraction demonstrated that human SC lipids were arranged in an orthorhombic packing pattern (crystalline phase). Upon mixing with sebaceous lipids, the presence of the hexagonal lattice (gel phase) increased (Pilgram et al. 2001). Therefore, the interaction between lipids from sebocytes with human SC lipids increased the fluidity of SC lipids, and it might also increase the SC permeability. Squire et al. demonstrated that sebum increases the permeability of the skin. They suggested that the damage to corny layer by the unsaturated fatty acid such as C16:1 Δ 6 may be involved in the process (Squier et al. 1994).

The orderly structure of SC lipids is disrupted resulting in the change of drug permeability through the corneum layer when unsaturated fatty acid interacts with the corneum layer (Aungst et al. 1986). As shown in Fig. 2, sebum supplement on the human forearm *in vivo* produced a significant shift ($3.8 \pm 0.8 \text{ cm}^{-1}$, $p < 0.001$) of CH₂ asymmetric stretching frequency in the attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectra of the SC in comparison to the untreated site. Additionally, sebum removal from the forehead *in vivo* decreased the frequency of the CH₂ asymmetric stretching ($1.2 \pm 0.6 \text{ cm}^{-1}$, $p = 0.001$). As demonstrated in Fig. 2b, the results of the CH₂ symmetric stretching frequency shift paralleled that of CH₂ asymmetric stretching frequencies ($p < 0.001$) (Tsai et al. 2012). These frequencies have been demonstrated to correlate with the SC water permeability. More specifically, a shift to higher frequency in this region reflected an increased number of gauche conformers of the CH₂ groups along the alkyl chain, and these events resulted in more disorderly arrangement of SC lipid and increased membrane fluidity (Potts and Francoeur 1990). Taken together,

Fig. 2 Frequencies of CH₂ asymmetric and symmetric stretching bands in the ATR-FTIR spectra on the forearm and forehead by sebum treatments ($n = 8$). Sebum supplement increased, while sebum removal decreased the frequency of the CH₂ asymmetric and symmetric stretching strength

these results indicated that sebum per se has a detrimental effect on the structural and functional properties of skin barrier (Guo et al. 2015).

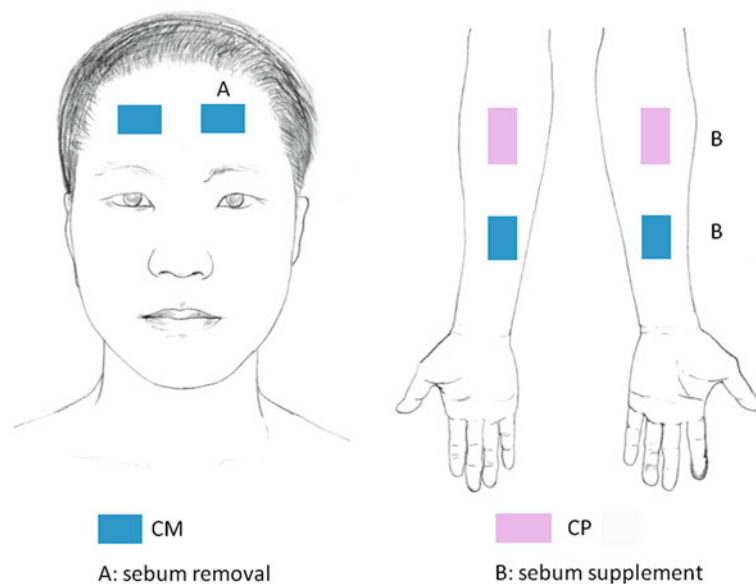

2 In Vivo Drug Permeation Protocol and Data Analysis

As shown in Fig. 3, by applying an aqueous gel containing 15 % bentonite clay and 0.2 % carboxymethyl cellulose to one side of each subject's forehead for 10 min and then washed with water, the sebum removal from the subject was achieved (Downing et al. 1982). On the other hand, sebum supplementation was achieved by treating the subject's forearm with 1 $\mu\text{l}/\text{cm}^2$ sebum (0.56 ± 0.04 mg/ μl total lipids) for 1 h, and the unabsorbed sebum on the skin surface was removed using Kimwipes[®] at the end of the application period. After sebum removal or sebum

supplementation as described above, saturated aqueous solutions of CP (4-cyanophenol) and CM (cimetidine) were applied to the skin of the forearm for 15 min and 5 h, respectively. For forehead, CM was applied for 0.5 h, using a patch. The skin surface was gently cleaned and dried with gauze pad after the indicated treatment period. Subsequently, repetitive adhesive-tape stripping for up to 10–15 times over 2–3 min was performed to quickly and progressively remove SC. The amount of CP and CM contained in the tape strips were determined with either ATR-FTIR spectroscopy or high-performance liquid chromatography. A balance with sensitivity of 10 μg was used to determine the mass of SC on each tape strip. Drug concentration ($C(x)$) was then expressed as a function of depth into the SC (Tsai et al. 2003).

The human SC thickness (L) during the in vivo studies was estimated by the two-point analysis in

Fig. 3 Drug application scheme. *CM* cimetidine, *CP* 4-cyanophenol

accordance with the equation described by Pirot et al. (1998):

$$L = x \cdot \text{TEWL}_x / (\text{TEWL}_x - \text{TEWL}_0) \quad (1)$$

where x represents the cumulative SC thickness removed by all the tape stripping, TEWL_0 (TEWL: transepidermal water loss) represents the average initial TEWL measured, and TEWL_x represents the average value of TEWL measured when $x \mu\text{m}$ of SC have been removed.

With the SC thickness estimated from the equations described above, the data were then fitted into the following equation according to the Fick's second law of diffusion:

$$C(x) = KC_{veh} \left\{ 1 - \frac{x}{L} \right\} - \sum_{n=1}^{\infty} \frac{2}{n\pi} KC_{veh} * \sin\left(\frac{n\pi x}{L}\right) \exp\left(\frac{-Dn^2 \pi^2 t}{L^2}\right) \quad (2)$$

under the following boundary and initial conditions: (1) $C = C_0 = KC_{veh}$, at $x = 0$, $t \geq 0$; (2) $C = 0$, at $x = L$, $t \geq 0$; (3) $C = 0$, at $0 < x < L$, $t = 0$, where C_0 is the drug concentration at the skin surface (i.e., $x = 0$), D is the drug's diffusivity, and K is the SC/water partition coefficient of the drug, to yield values of K and D . The

drug permeability ($P = KD/L$) into the SC was then deduced (Pirot et al. 1997).

3 Effects of Sebum on Drug Transport Across Human SC

The concentration profiles of CM in the SC on the subject No. 7's forehead were demonstrated in Fig. 4a. Figure 4b demonstrated the CM profile for the untreated and sebum-treated forearm from subject No. 8 after 5-h exposures to CM solution. The CP profiles for the forearm of subject No. 7 after 15-min exposure to CP solution are shown in Fig. 4c. The SC transport parameters K , D , and P of CM and CP for the nine subjects on the forehead with and without sebum removal, and on the forearm with and without sebum supplementation, are summarized in Table 1. Sebum content of the forehead reduced from 159.7 ± 36.7 to $6.5 \pm 5.2 \mu\text{g}/\text{cm}^2$ after the sebum removal process. Sebum content of the forearm increased from 1.0 ± 1.2 to $140.9 \pm 33.4 \mu\text{g}/\text{cm}^2$ after human sebum supplementation derived from washing the subjects' hair with alcohol.

These results demonstrated that in high sebum-containing areas including forehead, the SC permeability of CM (P_{CM}), a hydrophilic molecule,

Fig. 4 Representative drug concentration profiles as a function of normalized depth (x/L) into the SC. The data points were experimentally determined. The *lines* through

the results represent the best fits of Eq. 2. (a) CM on forehead of subject No. 7; (b) CM on forearm of subject No. 8; (c) CP on forearm of subject No. 7

may be four times higher than that for the forearm (39.2 ± 13.6 versus $10.3 \pm 5.5 \times 10^{-5}$ cm/h). In addition, the SC diffusivity of CM (D_{CM}) of the forehead may be eightfold of that in the forearm (61.7 ± 15.5 vs. $7.3 \pm 3.4 \times 10^{-9}$ cm²/h). On the other hand, the drug partition into the SC (K_{CM}) of the forehead was only 43 % of the forearm (7.6 ± 1.4 vs. 17.6 ± 5.1). The differences in K_{CM} , D_{CM} , and P_{CM} between forehead and forearms were statistically significant ($p < 0.001$). The variations in SC permeability of CM between the forehead and forearm may be contributed by differences in thermodynamic and kinetic components. In support of our finding, similar results were previously shown for the regional variation of P_{CM} of other skin sites (Tsai et al. 2003). In murine skin model, chronic application of sebum induced structural changes in the SC (Guo

et al. 2015), which could account for the eightfold differences in D_{CM} between the two untreated sites. Taken together, these results suggest that in clinical situations such as seborrheic dermatitis, a condition that involves excess sebum secretion and barrier disruption, the permeability barrier to hydrophilic molecules might be further aggravated.

As a result of sebum removal from the forehead, the partition K_{CM} increased 1.39-fold (9.8 ± 1.8 vs. 7.6 ± 1.4), and D_{CM} decreased 0.61-fold in comparison to the untreated site (37.9 ± 14.3 vs. $61.7 \pm 15.5 \times 10^{-9}$ cm²/h). Subsequently, P_{CM} was decreased to 0.78-fold of control (30.8 ± 13.4 vs. $39.2 \pm 13.6 \times 10^{-5}$ cm/h). In the group which receive sebum supplementation to the forearm, D_{CM} increased 3.52-fold (23.7 ± 8.3 vs. $7.3 \pm 3.4 \times 10^{-9}$ cm²/h) while the K_{CM} remained unchanged, such that P_{CM} at the

$D_{\text{CP}} (\times 10^7 \text{ cm}^2/\text{h})$					5.8	± 2.2	8.5	± 2.6
$P_{\text{CP}} (\times 10^3 \text{ cm}/\text{h})$					11.3	± 4.9	11.0	± 4.0

forearm supplemented with sebum was 3.25-fold of that of the control (34.2 ± 11.3 vs. $10.3 \pm 5.5 \times 10^{-5}$ cm/h). The permeability of CP (P_{CP}) was almost constant regardless of sebum supplementation to the forearm, which was the result of a 0.67-fold decrease in K_{CP} (15.4 ± 3.2 vs. 23.0 ± 2.9) and a 1.46-fold increase in D_{CP} (8.5 ± 2.6 vs. $5.8 \pm 2.2 \times 10^{-7}$ cm²/h). All the transport parameters between the untreated and treated subject at the same site were significantly different ($p < 0.05$) for the same drug except for the $K_{\text{SC}/\text{W}}$ of CM and P_{CP} on the forearm. These results demonstrated that the magnitude of decrease in D_{CM} for the forehead by sebum removal (0.78-fold) to be less than the magnitude of increase for the forearm by sebum supplementation (3.52-fold). It is also likely that the presence of sebum in the forehead or forearm increased the diffusion of lipophilic and hydrophilic molecules, while the effect on partition is dependent on sites and drugs selected. These results were in accordance with previous report from Valiveti et al. (2008) and Valiveti and Lu (2007) using artificial sebum. More specifically, they suggested that there is no correlation between $\log K_{\text{sebum}}$ versus $\log K_{\text{SC}}$ for compounds with different chemical structures, and maximal flux observed through sebum was found to be higher than their corresponding skin fluxes for a homologous series of 4-hydroxybenzoic acid esters.

Finally, the observed CH_2 stretching frequency shift resulting from sebum treatment as

demonstrated in Fig. 2 also reflected the alterations of SC permeability on CM. Therefore, the increased SC permeability of hydrophilic drug and altered barrier function of SC was achieved by sebum supplementation through disordering the structures of the intercellular lipid molecules.

4 Conclusions

For the first time in vivo, the effect of sebum on drug transport across human SC was demonstrated. For hydrophilic molecules, such as CM, the SC permeability on the forehead may be as much as four times the permeability on the forearm. Sebum supplement on the forearm, while has little effect on CP, increased the SC permeability of CM more than threefold. The SC permeability of the CM has a small but significant alteration (-22%) after removal of sebum from the forehead. Although the sebum supplementation in both the forehead and forearm increased the diffusion of both lipophilic and hydrophilic molecules, the effect of sebum supplementation on partition is site and drug dependent. The alteration of SC permeability by sebum supplementation to hydrophilic drug may be attributable to the barrier function changes of SC induced by disordering structures of the intercellular lipid molecules. It is likely that removing the sebum from the face will reduce the absorption of hydrophilic compounds

contained in the formulations that were topically applied.

This chapter describes the epidermis, formerly called the Malpighi's layer. As the skin's outer layer, the epidermis provides the barrier function protecting mammals from environmental influences such as physical, chemical, or thermal stress and also against dehydration. The epidermis is a multilayered epithelium consisting of the interfollicular epidermis and associated hair follicles, sebaceous glands, and eccrine sweat glands. Although keratinocytes are the main epidermal cell type (95 % of the total cells), other cells are found in mammalian epidermis, such as melanocytes and Merkel and Langerhans cells. Merkel cells are neuroendocrine cells responsible for the touch sensory function of the skin. Melanocytes are specialized pigment cells producing melanin granules, which are transferred to keratinocytes for their protection against UV-induced DNA damage. Langerhans cells are epidermal dendritic cells involved in the adaptive immune

response, playing a critical role in the barrier function of the skin. The epidermis itself is divided into five layers which are, from the inner to the outer most, the stratum germinativum (basal), stratum spinosum (spinosus), stratum granulosum (granular), stratum lucidum (only found in thickened areas of the epidermis), and the stratum corneum (cornified). The epidermis consists in approximately ten layers of keratinocytes piled up from the basal layer to the cornified layer. In contrast with the stratum corneum that features a horizontal plane, the basal layer juxtaposes the dermis with the dermal-epidermal junction in a corrugated outline manner, alternating in-depth epidermal cones and dermal expansions named “papillae” (Fig. 1). The thickness of the viable epidermis lies from 75 to 150 μm according to anatomical site to reach 0.8 mm on the palms of the hands and 1.4 mm on the soles of the feet. Its metabolism seems close to $0.4 \text{ ml min}^{-1}/100 \text{ g}$ tissue (Krueger et al. 1994) (resting muscle, <0.2 ; muscle on exercise, 13–15; brain, 3–4 (Holtz 1996)).

Its fundamental and first known function is to generate the stratum corneum, the dead but vital barrier that separates our body from the environment. It is accomplished through its perpetual renewal from the division of basal cells and keratinization of uppermost layers: the total turnover takes about 15 days, the same as that of the stratum corneum. Other fundamental functions are extracellular matrix component production; hormone secretion; cytokine production ruling angiogenesis and vasomotricity in the papillary dermis; homing and maturation of cells responsible for the immune barrier (Aubin 2004) protection against ultraviolet light and homing of melanocytes (► Chap. 101, “Skin Photoprotection Function”); participation to the skin neurosensorial function and homing of Merkel cells (see dedicated chapters); participation in the skin mechanical protective function, thanks to its cellular abundant keratin filaments (see the dedicated chapter); and finally the capacity of self-repair (see the ► Chap. 47, “Skin Wound Healing Assessment”).

1 Epidermal Proliferation and Differentiation

The epidermis is continuously renewed by the proliferation of stem cells and the differentiation of their progeny, which undergo terminal differentiation as they leave the basal layer and move upward toward the surface, where they die and slough off. As for most epithelial tissues, proliferation and differentiation occur in two juxtaposed compartments, represented by the basal layer and the numerous suprabasal layers. The keratinocyte population can be divided into at least three functional types, keratinocyte stem cells, transit amplifying cells, and postmitotic differentiating cells. Stem cells, responsible for tissue renewal, have a high mitotic potential but are rarely dividing. They give birth to transit amplifying cells, which after a finite number of division, are committed to differentiate. By this way, a high output of differentiated cells can be issued from a small number of infrequently solicited stem cells. The **growth fraction**

of human epidermis has been estimated to 10 % of stem cells and 50 % of transit amplifying cells versus 40 % of differentiated cells (Heenen and Galand 1997). On the basis of their morphological and functional characteristics, the proliferating cells have also been described as clonogenic keratinocytes: holoclones, meroclones, and paraclones (Barrandon and Green 1987). Located in the basal layer and in the bulge of hair follicles, stem cells can be characterized by their size (Barrandon and Green 1985), their high adhesive properties (Kaur and Li 2000), their high level of $\beta 1$ integrin (Zhu et al. 1999), their expression of keratin K19 (Michel et al. 1996), and their high content in cytoplasmic β -catenin (Zhu and Watt 1999). Their spatial distribution in the basal layer is not randomly disposed, showing clusters of stem cells from which migrate transit amplifying cells (Jensen et al. 1999). Generation of differentiated progeny from stem cell is regulated by internal mechanisms such as transcription factors and by external controls in the cellular microenvironment such as secreted mediators, cellular interactions, integrins, or other elements (Watt and Hogan 2000). In this system, $\beta 1$ integrin is particularly involved and induce, depending on the signaling pathway involved, either cellular adhesion or differentiation (Levy et al. 2000). Decrease of adhesion related to modifications of integrins (Kaur and Li 2000) and reduction in mitogen-activated protein (MAP) kinase activation (Zhu et al. 1999) induce this cellular exit from the stem cell compartment. After a finite number of divisions, the transit amplifying cells undergo an irreversible multistage process of differentiation. Keratinocytes committed to the differentiation program downregulate integrins to become less adhesive, move to the suprabasal compartment, and continue their upward movement until they are terminally differentiated and shed off. This produces several layers of keratinocytes, at different stages of differentiation that can be identified by the expression of keratins. Basal keratinocytes express keratins K5, K14, and K15, whereas differentiating keratinocytes express keratins K1 and K10. Integrins $\beta 1$ and hemidesmosomal components (integrin $\alpha 6\beta 4$ and BP180) decrease by

transcriptional decrease of mRNA and by a post-translational mechanism of ineffective subunits. Some intracellular organelles disappear (mitochondria, nucleus, etc.) when other elements (keratohyalin granules, filaggrin, etc.) appear, leading to the future horny layer cells. During this cellular differentiation, modifications of receptors' expression are observed, either decreasing (receptors for TGF $\beta 1$, PDGF A, etc.) or increasing (receptors for acid FGF, basic FGF, PDGF β r, IL-1ra, etc.). Modulation of transmembrane ion transport is also noted with upregulation of sodium channels (Brouard et al. 1999; Deliconstantinos et al. 1995; Eming et al. 1998; Fenjves et al. 1989; Heenen and Galand 1997; Holick 1988; Insogna et al. 1988; Jensen et al. 1999; Kaplan et al. 1988; Katz and Taichman 1994, 1999; Kaur and Li 2000; Krueger et al. 1994; Kupper 1990; Levy et al. 2000; Malaviya et al. 1996; Martinez et al. 1997; Maruyama et al. 1995; Mazereeuw Hautier et al. 2000; Michel et al. 1996; Nathan and Sporn 1991; Oda et al. 1999).

2 Epidermal Secretions

Beside a function of protective barrier, epidermis has also a secretory activity (Boyce 1994), estimated in vitro to a rate of 0,67 μg protein/h/ 10^6 cells (Katz and Taichman 1994).

2.1 Cytokine Secretion

Non-lesional epidermis is in a low steady state of secretion and keratinocytes seem quiescent. After endogenous or exogenous (physical, chemical, biological, or immunological) stimulation, the keratinocyte is "activated" and secretes various peptides. These peptides are represented by cytokines (IL-1 α , IL-1 β , IL-6), tumor necrosis factor (TNF α), growth factors (GM-CSF, G-CSF, M-CSF, TGF α , acid and basic FGF, KGF, PDGF A, PDGF B, NGF), chemokines (IL-8, IFN γ -IL10, huGRO of G-X-C family, or MCAF of G-C family), or suppressor factors/anticytokines (TGF β , K

LIF, Contra IL-1) (Stoof et al. 1994). Cytokines are small protein hormones primarily secreted by immune cells and are important mediators of host defense, post-injury repair, cell growth, and maturation. This secretion shows particular characteristics (Kupper 1990), such as the release of secondary cytokines after stimulation by primary cytokines. The activated keratinocyte is modulated through the action of specific receptors present on the cell membrane (IL-1 receptors, IFN γ receptors, etc.) and induced by stimulation. Species of activated keratinocytes and secretion types would differ depending on the nature of the signal. All these pleiotropic or specific peptides act by autocrine or paracrine mechanisms (Schröder 1995). Their action must be evaluated, considering numerous mechanisms of amplifying or inhibitory regulation (Nathan and Sporn 1991) such as action of anticytokines, direct antagonism between several cytokines (Reinartz et al. 1996), or specific action of the cytokine on the same keratinocyte (Maruyama et al. 1995). Structural proteins (heparin, decorin, etc.) or cellular environment such as interaction with fibroblastic cells (Boxman et al. 1996) or with a structure like the skin immune system (Bos and Kapsenberg 1993) modulates the effect of these factors (Figs. 2, 3, and 4).

Other proteins secreted by the epidermis are regularly identified. Katz and Taichman (Katz and Taichman 1999) listed a catalogue of twenty proteins released by keratinocytes in culture, suggesting new physiological functions to be identified. These proteins may induce various cellular responses. Among these, the phospholipase A2 was suggested to play a role in the maintenance of tissue integrity (Mazereeuw Hautier et al. 2000) and regeneration (Rys-Sikora et al. 2000). The multifunctional peptide adrenomedullin is involved in epithelial homeostasis or even in epidermal protection (Martinez et al. 1997). Many proteins, such as proteases (Katz and Taichman 1999) or antileukoproteinas (Wiedow et al. 1998), have been shown to be involved in matrix remodeling. Keratinocytes produce the basement membrane laminin 332 and modulate fibroblast behavior through the secretion of β 1G-H3 (Katz and Taichman 1999).

2.2 Endocrine Secretion

In normal conditions, epidermis can also be a source of circulating compounds that have effects at distant sites in the body. The role of epidermis

Fig. 2 Stratum basale protrusions into the dermis. Thick keratin filaments bundles separate into small bundles which attach to hemidesmosomes at cell periphery (Small arrow head). in vitamin D synthesis has been early shown (Holick 1988). Keratinocytes also release chemicals like triiodothyronine (Kaplan et al. 1988) or parathyroid hormone-related proteins (Insogna et al. 1988; Jensen et al. 1999; Kaplan et al. 1988; Katz and Taichman 1994, 1999; Kaur and Li 2000; Krueger et al. 1994; Kupper 1990; Levy et al. 2000; Malaviya et al. 1996; Martinez et al. 1997; Maruyama et al. 1995; Mazereeuw Hautier et al. 2000; Michel et al. 1996; Nathan and Sporn 1991; Oda et al. 1999; Reinartz et al. 1996; Rys-Sikora et al. 2000; Schauer et al. 1994; Shimizu et al. 1997; Schröder 1995; Stoof et al. 1994; Watt and Hogan 2000; Wiedow et al. 1998; Wysolmerski and Stewart 1998), endothelin, and the C3 complement component. Neuropeptides such as substance P (Bae et al. 1999) and neurohormones such as proopiomelanocortin and derived peptides α MSH and ACTH (Schauer et al. 1994) are produced by epidermal cells. The generation of nitric oxide (Deliconstantinos et al. 1995; Eming et al. 1998; Fenjves et al. 1989; Heenen and Galand 1997; Holick 1988; Insogna et al. 1988; Jensen et al. 1999; Kaplan et al. 1988; Katz and Taichman 1994, 1999; Kaur and Li 2000; Krueger et al. 1994;

Kupper 1990; Levy et al. 2000; Malaviya et al. 1996; Martinez et al. 1997; Maruyama et al. 1995; Mazereeuw Hautier et al. 2000; Michel et al. 1996; Nathan and Sporn 1991; Oda et al. 1999; Reinartz et al. 1996; Rys-Sikora et al. 2000; Schauer et al. 1994; Shimizu et al. 1997) or histamine (Malaviya et al. 1996) has been also confirmed, showing the role of stimulated epidermis in inflammatory reactions. The systemic distribution of naturally produced protein has been found even after epidermal transplantation, as proved for apolipoprotein E (Fenjves et al. 1989). These results may permit the use of keratinocytes for gene therapy (Eming et al. 1998; Fenjves et al. 1989; Heenen and Galand 1997; Holick 1988; Insogna et al. 1988; Jensen et al. 1999; Kaplan et al. 1988; Katz and Taichman 1994; Katz and Taichman 1999; Kaur and Li 2000; Krueger et al. 1994).

Keratinocytes can synthesize acetylcholine and its receptors and thereby generate an autocrine system, which has been shown to regulate cell motility. Besides, the epidermis has the ability to generate catecholamine mediators including epinephrine. These catecholamines can activate adrenergic receptors present on keratinocytes to modulate their migratory behavior.

As in the whole epidermis, desmosomes bind cells at their tonofilaments bundles. Phosphate buffered glutaraldehyde and osmium after fixation. Uranyl acetate and lead citrate staining. $\times 30,000$

2.3 Other Roles

A fine balance between cell proliferation and differentiation maintains the barrier function of the epidermis. In quiescent tissue, homeostasis is regulated by both autocrine and paracrine secretions. After stimulation, these secretions are amplified, and the epidermis acts as a transducer, transforming exogenous stimulations into specific immune or inflammatory responses.

Human keratinocytes play an important role in the innate immune response and produce several antibacterial peptides that are important for both homeostatic and wound healing purposes. Human keratinocytes are known to produce four

such peptides: human beta defensin 1 (hBD-1), hBD-2, hBD-3, and hCAP-18 (as well as its biologic active proteolytic product LL-37) (Harder et al. 1997; Nizet et al. 2001). hCAP-18 is a member of the cathelicidin family of antimicrobials. Both hCAP-18 and LL-37 are expressed and released in response to an inflammatory stimulus (Ong et al. 2002). The cathelicidin hCAP-18 is normally processed and stored in the lamellar bodies of the keratinocytes and may be released as a result of injury or exposure to microbial components. After secretion, hCAP-18 is processed into LL-37 and various other peptides, which are important in killing the skin pathogens *S. aureus* and *C. albicans*. They might have a

major role in epithelium protection during wound healing (Dorschner et al. 2001) and psoriasis (Ong et al. 2002). In atopic dermatitis, the heavy carriage of *S. aureus* and the increased sensitivity to herpes and *M. contagiosum* infection may be related to a lower expression of both peptides, due to the production of IL-4 and IL-13 cytokines by Th2-T4 lymphocytes (Ong et al. 2002). Epidermis is also active by an intensive release of other peptides during wound healing. Beta-defensin-2 and LL-37 are upregulated in the epidermis of wounded human skin within 24 h of wounding, reaching highest levels at 48 h post-wounding and returning to basal levels when the wound is re-epithelialized.

Glossary

ACTH Adrenocorticotrophic hormone
Autocrine Peptides (cytokine, extracellular matrix components, epidermal proteins etc.) are released but bind immediately to receptors and act on the cell that produced them.
Contra IL-1 Contra interleukin 1
Endocrine Peptides, synthesized by the keratinocytes, enter the circulation and induce specific biologic responses in distant target tissues.
Exocrine Release of secretion toward the external part of the body. Glandular epithelia (sebaceous and sweat) of the skin are specialized for this function.
FGF Fibroblast growth factor. Either acid FGF or basic FGF
GCSF Granulocyte colony-stimulating factor
GMCSF Granulocyte-/macrophage-stimulating factor
Homeostasis Maintenance of the organism's physiological parameters at their normal value
huGRO Human growth factor
IL Interleukin: IL-1 α , interleukin 1 α ; IL-1 β , interleukin 1 β ; IL-1ra, interleukin 1 receptor antagonist; IL-6, interleukin 6
IFN γ -IP10 Interferon gamma-induced protein
Juxtacrine Peptides are released and will act on cells in contact with the producing cell.

KGF Keratinocyte growth factor
K LIF Keratinocyte-derived lymphocyte inhibitory factor
MCAF Monocyte chemotactic and activating factor
MCSF Macrophage colony-stimulating factor
MSH Melanocyte-stimulating hormone
NGF Nerve growth factor
Paracrine Peptides are released by a cell and will act on cells immediately surrounding the producing cell.
PDGF Platelet-derived growth factor
TGF α Transforming growth factor alpha
TGF β 1 Transforming growth factor beta 1
TNF α Tumor necrosis factor alpha

The epidermis is characterized by its capacity to maintain homeostasis through a balanced equilibrium between proliferation and differentiation. It may also respond by a rapid and temporary amplification of cell turnover when a sudden tissue renewal is needed in wounds. Study and control of mechanisms involved in this response are of great interest.

They may be studied *in vitro* with carefully chosen experimental models (Dover 1994; Prignano et al. 1999) since the culture conditions often modify the homeostasis observed *in vivo*. Primary keratinocytes provide ideal experimental systems (Dotto 1999), and epidermal growth on dermal equivalents (Sanquer et al. 1990) and reepithelialization of partial thickness wounds (Jansson et al. 1996) have been studied for periods of 7–15 days. The expression of proliferation- and differentiation-specific markers enables to discriminate between epidermal growth and maturation.

1 Epidermal Proliferation

Proliferating keratinocytes display specific morphological characteristics, at both nuclear and cytoplasmic levels.

1.1 Nuclear Proliferation Markers

Proliferation-specific markers are numerous and the most frequently used will be listed below. Static data such as relative length of cell cycle phases, or dynamic measurements such as cell cycle kinetics, can be obtained with these markers (Figs. 1, 2, 3, 4, and 5).

1.1.1 Static Methods

Methods with Prior Incubation

While nucleotides like adenine and guanine are incorporated into both DNA and RNA, thymidine is incorporated only in DNA. Incubation of a tissue or a biopsy with radiolabeled thymidine diluted in culture medium highlights the cellular fraction engaged in DNA synthesis during the incubation period. The development of anti 5-bromo-2-deoxyuridine (BrdU) antibody has provided an excellent thymidine analogue for a similar use. If both tritiated thymidine and BrdU are specifically incorporated during the cellular S-phase, the use of BrdU is easier to perform. However, experimental conditions influence the cellular responses to this labeling. The use of occlusive

dressings enhances *in vivo* cutaneous penetration of BrdU. Labeling may be increased when endogenous synthesis of thymidine monophosphate is previously blocked (Wolff and Gnas 1989). Variable marker's distribution to the central cells of the biopsy, a possible toxicity induced by a prolonged incubation (Dover 1994), and different rates of incorporation into DNA (Hume and Saffhill 1986) must be also considered during the experimentation (Tables 1, 2, 3, 4, and 5).

Methods Without Prior Incubation

Unlike the precedent methods, these markers can be analyzed directly without pretreatment of samples. The proliferating cell nuclear antigen (PCNA) is a 36 kDa protein, cofactor of the DNA polymerase- δ necessary to the DNA replication (Celis et al. 1987). Expressed at low level in quiescent cells, PCNA is most abundant in late G1-phase and during the S-phase (Stewart and Dell'Orco 1992). The proportion of PCNA-positive cells exceeds that of tritiated thymidine-positive (Galand and Degraef 1989) or BrdU-positive cells (Jones et al. 1993) because some cells in the G0-phase are also weakly labeled. In a quiescent epidermis, the expression of PCNA is limited to rare cells in the basal layer (Furukawa et al. 1992), while *in vitro*, its expression is modulated by the culture conditions (Miyagawa et al. 1989). Its expression is enhanced by EGF (Jaskulski et al. 1988) and inhibited by rapamycin (Javier et al. 1997).

Ki67 is a nuclear protein expressed in cycling cells (G1-, S-, G2-, and M-phase) and absent in

Fig. 3 In vitro epidermal differentiation. Expression of keratohyalin granules in the upper epidermis and profilaggrin in desquamating cells. Antiprofilaggrin antibody revealed by immunofluorescence. Magnification $\times 200$

quiescent cells in G₀-phase (Knaggs et al. 1994). Even if the nuclear labeling is restricted to proliferating cells of the basal layer, the index obtained with Ki67 is similar to that given by PCNA and exceeds the value obtained with BrdU. To allow antigen retrieval, labeling of paraffin-embedded tissue slices by immunohistochemistry requires a pretreatment prior to incubation with the antibody (Szekeres and de Giacomoni 1994); however, direct immunostaining is also possible on frozen tissue sections.

Histone genes are tightly coupled to the replicative stages of the cell cycle. The messenger RNAs (mRNAs) encoding these proteins are synthesized during the replication of DNA and are rapidly destabilized at the end of the S-phase of the cycle. Histone mRNAs may be detected by a classical in situ hybridization method. Unlike PCNA or Ki67, labeling with histone mRNAs is strictly similar to the value obtained with BrdU (Smith et al. 1995).

1.1.2 Dynamic Methods

Sequential labeling with two proliferation markers specific for the S-phase (tritiated

thymidine and BrdU or BrdU and IodoUdR) enables to discriminate the different populations entering this phase. The measure of the different cellular fractions provides dynamic parameters such as the S-phase duration and total cell cycle times (Hyatt and Beebe 1992; Yanik et al. 1992). By this double-label technique, the determination of the cell cycle times may be correlated with the localization of a cytokine (Miller et al. 1992) or the measurement of the DNA content (Lin and Allison 1993; Van Erp et al. 1996).

1.2 Cytoplasmic Proliferation Markers

The transition from basal cell to corneocyte is a complex process that requires the simultaneous activation and inactivation of a wide variety of proteins and genes. In order for differentiation to produce a normal epidermal surface, these genes must be expressed at the correct time and location. The members of the keratin family are expressed

Fig. 4 In vitro epidermal differentiation. Expression of keratohyalin granules in superficial layers. Transmission electronic microscopy. Magnification $\times 6000$

Fig. 5 In vivo epidermal differentiation. Detection of suprabasal cytokeratins by immunofluorescence (antiKL1 antibody). The subepidermal orange line highlights the dermo-epidermal junction. The basal epidermal layer is located in the non-labeled zone between this orange line and the fluorescent of KL1 cytokeratins. Magnification $\times 100$

in a tightly regulated manner. The cytokeratins are a family of over 30 proteins that are assembled to form the intermediate filaments in epithelial cells. Based on sequence homology and expression pattern, the keratins can be divided into acidic and neutral-basic families. Keratins are expressed in pairs to assure the presence of a neutral-basic and acidic partner to permit filament assembly. Some data suggests that, reciprocally, some of these keratins influence cell proliferation and differentiation (Paramio et al. 1999). In quiescent epidermis, basal proliferative keratinocytes express cytokeratins K5 and K14. During hyperproliferative cellular responses in culture or during wound healing, keratinocytes express keratins K6, K16, and K17. Labeling of keratins alone or coupled with the measure of DNA content may be used to characterize epidermal proliferation (Mommers et al. 2000).

2 Cellular Differentiation

Biochemical and morphological modifications are observed during epidermal differentiation, leading to the appearance of specific cellular organelles, used as differentiation markers. The most frequently used are the keratins, the histidine-rich proteins (filaggrin/keratohyalin granules), the transglutaminases, and the cornified envelope precursors such as involucrin, loricrin, and small proline-rich proteins (Lee et al. 1999; Seishima et al. 1999). Numerous antibodies have been developed against these proteins during the recent years, enabling us to evaluate the degree of epidermal maturation.

When they differentiate, keratinocytes switch off keratins K5 and K14 and start K1 and K10 expression (Moll et al. 1982) in suprabasal layers.

PCNA proliferating cell nuclear antigen

^aI = fraction of positive cells reported to 500 or more cells counted at 400 magnification, with three separate counts for each determination

Keratins K2, K11, and K9 are also present in cornified epidermis.

Histidine-rich proteins aggregate with keratin filaments in cornified layers and represent an important source of amino acids necessary to the stratum corneum hydric balance. Profilaggrin, the precursor of filaggrin, is expressed in some populations of keratohyalin granules of suprabasal layers and is converted to filaggrin, which packages the keratin filaments into fibrils.

Profilaggrin, filaggrin, and keratohyalin granules are indistinctly revealed by the same immunological labeling. Keratohyalin granules and filaggrin represent excellent markers of terminal differentiation, since their expression is noted from the granular layer (Bernerd and Asselineau 1997; Gerritsen et al. 1997) and is absent in nonkeratinized epidermis. Their expression in vitro is considered as a proof of a differentiated culture (Jansson et al. 1996).

Involucrin and loricrin are envelope precursor proteins that are expressed in the epidermal suprabasal layers. These proteins are cross-linked to form the cornified envelope by the enzyme transglutaminase which catalyzes the formation of inter-protein ϵ -(γ -glutamyl)lysine bonds. These transglutaminases are membrane-associated proteins, expressed in upper spinous and granular layers of the epidermis (Kim et al. 1995). Involucrin, rich in glutamine content, is the major cornified envelope precursor protein. Increasing calcium concentration stimulates the promoter activity of the gene encoding for involucrin (Ng et al. 2000; Tu et al. 1999). The expression of involucrin begins in high spinous and granular layers of the epidermis, distant from the proliferative layers. During wound healing, this expression may be found in all the suprabasal layers (Jansson et al. 1996; Mansbridge and Knapp 1987). In cellular culture or in psoriasis, involucrin is also expressed by S-phase keratinocytes (Dover and Watt 1987). Due to its expression in nonkeratinized corneal epithelium,

involucrin is considered as an intermediate differentiation marker. Small proline-rich (SPR) proteins are synthesized sequentially after involucrin during differentiation (Ishida et al. 1997). Other cornified envelope precursors may be used, cornifin expressed in spinous or granular layers and loricrin in corneocytes (Bernerd and Asselineau 1997).

Epidermal homeostasis is maintained through a fine balance between cellular proliferation and differentiation. In normal epidermis, many factors (Schoop et al. 1999; Tu et al. 1999) control this cellular transition occurring in specific compartments. These signals include the activation of an extracellular Ca^{2+} receptor mechanism, the increase in cell-cell adhesions, and the detachment from the substratum. During wound healing, under the action of exogenous factors, this control may be less strictly determined, inducing defects in the balance between proliferation and differentiation. Specific markers allow to study each event, of which dysfunction may induce a pathological status.

Table 5 Main epidermal proliferation and differentiation markers. Specific localization and meanings

Marker	Localization	Signification	Technical conditions
BrdU	Basal layer First suprabasal layer Nuclear labeling	Proliferative cell S-Phase	C, Pa, Pn ^a
Histone mRNAs	Basal layer First suprabasal layer Cytoplasmic labeling	Proliferative cell S-Phase	Pa ^a
PCNA	Basal layer Nuclear labeling	Proliferative cell S- and G1-phase	Pa, Pn, IB, Cy ^a
Ki67	Basal layer First three suprabasal layers	Cycling cell G1-, S-, G2-, M-phase	C, Pa, IB, Ag, Cy ^a
Cytokeratins K6, K16, K17.	Cytoplasmic labeling	Cellular proliferation (fast "turnover")	C ^a
Cytokeratins K5, K14	Basal layer Cytoplasmic labeling	Non-differentiated cells	C, Pa, Ag ^a
Cytokeratin K19	Basal layers	Stem cell	C, Pa, Ag ^a
Cytokeratins K1, K10, K2, K11	Suprabasal layers Cytoplasmic labeling	Epidermal differentiation	C ^a
Involucrin	Upper spinous layers Granular layer Cytoplasmic labeling	Intermediate differentiation	C, Pa ^a
Comifin	Spinous layer Granular layer	Epidermal differentiation	C
Transglutaminases	Granular layers Membrane labeling	Epidermal differentiation	C, IB ^a
Profilaggrin (KHG)	Granular layer and upper Cytoplasmic labeling	Terminal differentiation	C, Pa ^a
Loricrin	Horny layer	Terminal differentiation	C

^aCommercially available to this day. Possible use of these antibodies in C, cryosections; P, paraffin; Cy, cytometry; IB, immunoblot; Ag, treatment prior to label (heating, digestion, unmasking solution, etc.); NP, nuclear permeabilization

Annex

There are many suppliers of antibodies, and the number of available antibodies (immunohistology, cytometry, etc.) regularly increases. Some suppliers seek worldwide for a specific product if wanted by the customer.

Ask for the technical bulletin of each product. This indicates the recommended method (histology, electrophoresis, cytometry, etc.) and conditions of use (fixation, congelation, treatment, etc.). Dilutions are just indicative and must be evaluated for each tissue and protocol.

Immunohistological studies are performed according to standard methodologies, with or without amplification or treatment. Many kits are actually available.

Some addresses of suppliers or distributors are given below. This list is far from being complete.

SSM	Superficial spreading melanomas

1 Introduction

Reflectance confocal microscopy (RCM) is a new noninvasive tool that enables the analysis of skin morphology at nearly histologic resolution (Rajadhyaksha et al. 1995, 1999; Gonzalez et al. 2001). Among the plethora of noninvasive tools applied in the clinical field for skin cancer diagnosis, RCM has emerged as a unique method for its capability to visualize the skin tissue with a resolution that is comparable to conventional histopathology. It allows a horizontal scanning of the imaged tissue with the great advantage of exploring a larger field of view compared to vertical sectioning obtained with conventional histopathology. Additionally, the horizontal plane offers a perfect overlap with clinical and dermoscopic image, and this is crucial to obtain a correct

diagnosis rendered by putting together all lesion's aspects. In this chapter we aim to report the main confocal applications in clinical practice.

1.1 Instruments

Currently, there are basically two types of confocal microscopes commercially available, which are fundamentally distinct in their approach: one is a full-scale microscope constituted by a large scanning head and the other is a handheld device.

The former confocal microscope (VivaScope[®] 1500, Lucid Inc., Rochester NY, USA) contains a probe (the head of the microscope) that is attached to the skin by using a disposable plastic window that is in turn taped to a metal ring. A confocal microscope consists of a point source of light, condenser, objective lenses, and a point detector (Rajadhyaksha et al. 1995, 1999). The pinhole collects light emanating only from the in-focus plane. The mechanism of bright contrast in reflectance confocal microscopy is backscattering. In gray-scale confocal images, structures that appear bright (white) have components with high refractive index compared with their surroundings and are similar in size to the wavelength of light. Backscattering is primarily governed by the structures' refractive index compared to surrounding medium. Highly reflective skin components include melanin, collagen, and keratin. The confocal scanning produces high-resolution black and white horizontal images (0.5×0.5 mm) with a lateral resolution of $1.0 \mu\text{m}$ and axial resolution of $3\text{--}5 \mu\text{m}$. A sequence of full-resolution individual images at a given depth is acquired and "stitched" together to create a mosaic ranging in size from 2×2 to 8×8 mm. A vertical VivaStack[®] can be imaged. It consists of single high-resolution images acquired from the top skin surface up to $200 \mu\text{m}$, corresponding to the papillary dermis, to obtain a sort of "optic biopsy."

The handheld RCM has been recently introduced on the market (VivaScope[®] 3000). This version is a smaller, flexible device that is quite useful in difficult to access areas (skin folds, ears). Unlike the 1500 version, it has a manual control for laser power on the probe, imaging depth, and

capture, but it does not allow scanning of a large field of view needed, for example, to analyze the architecture of tumors. However, it is a promising tool that found its application in surgical pre-mapping or when multiple site imaging is requested.

2 Confocal Criteria for Melanocytic Lesions

2.1 Melanocytic Tumors

The major issue in skin oncology is to detect all tumors while reducing the number of unnecessary biopsies of benign lesions. To accomplish this goal, several instruments are being applied in clinical practice although the current gold standard relies on the combination of clinical inspection and dermoscopy. Dermoscopy is a noninvasive and cost-effective technique that has proven to be an essential tool in skin oncology (Argenziano et al. 2006, 2012) and general dermatology (Zalaudek et al. 2006) since it allows to check all lesions in a given patients in few minutes. RCM is currently considered a second-level examination in clinical practice with specific application in challenging cases or in special instances. In addition to dermoscopy, RCM is capable of delivering single-cell resolution in a few minutes at the patient's bedside (Pellacani et al. 2005a, 2007; Guitera et al. 2010).

2.2 Melanocytic Tumors

2.2.1 Nevi

Different patterns of melanocytic proliferation can be easily and reliably detected upon RCM (Pellacani et al. 2009a). Junctional nevi show a predominance of single-cell proliferation at DEJ that results in the presence of single small bright polygonal cells outlining the dermal papillae, generating the so-called ringed pattern on RCM (Pellacani et al. 2005b; Fig. 1). Some junctional nevi also display few nests located at the tip of the cristae, and this aspect shows up as a "meshwork" pattern on RCM that is made by the junctional

Fig. 1 Junctional nevi: they can show a ringed pattern showing bright rings surrounding hyporefractive dermal papillae or a meshwork pattern due to the presence of enlarging junctional nests (arrows)

enlargement between the papillae (Fig. 2). In these lesions, the presence of cytologic atypia is uncommon. Intra-dermal nevi reveal the presence of the so-called “clod” pattern where several nests fulfill completely the dermal compartment. Nests into the dermis can show up as compact dense or as “dense& sparse” nests (Pellacani et al. 2005c, d) where the aggregates are large and made by large roundish cells outlined by epidermal strands (Fig. 3).

Moreover, a combination of meshwork pattern + ringed or clod + meshwork + ringed can be found (Fig. 4). Usually the presence of clod pattern is apparent in the center of the lesion corresponding to the clinical palpable area and to the presence of variable sized dermal nests.

RCM is particularly useful in discriminating these lesions from melanoma since dermoscopy can be not enough specific, thus leading to the overlooking of these nevi.

This nevus type with combination of more than one RCM pattern is comprised also of the so-called atypical or dysplastic nevi. These nevi represent a puzzling picture that is shared by both RCM and histopathology. Upon RCM, it is possible to detect some morphologic aspects (Pellacani et al. 2012) such as bridging of the nests or the presence of atypical cells, but it is not always feasible to draw a line between a severe dysplastic nevus and an incipient melanoma. This challenge

relies on the clinician’s ability to “read” the confocal image or on his or her belief in the existence of a precursor lesion. The same scenario is present also in dermatopathology and accounts for the low interobserver agreement found when analyzing these kinds of pigmented lesions (Shoo et al. 2010; Weyers 2012).

Spitz/Reed nevi are a family of lesions that vary in terms of clinical-dermoscopic aspect, histologic features, and biologic attitudes. Confocal microscopy allows the analysis of the superficial dermis, and, thus, the exploration of the deeper part is not possible, hampering the evaluation of some relevant aspects such as maturation (Pellacani et al. 2004, 2009b).

Although the confocal features of Spitz nevi are partially characteristic, they remain in most cases, indistinguishable from melanoma. A good correlation was found for some histopathologic aspects and RCM features (Fig. 4), some of which are considered characteristic of Spitz nevi, such as sharp lateral demarcation and the presence of spindled cells. Other correlates that are not very specific include pagetoid infiltration, junctional and dermal nests, parakeratosis, trans-epidermal melanin elimination, and inflammatory infiltrate rich in melanophages. The frequent presence of features suggestive of malignancy in Spitz nevi, such as pagetoid and atypical cells, non-edged papillae, and dishomogeneous nests, and the

Fig. 2 Intradermal nevi are characterized by the presence of an overall clod pattern constituted by dense and sparse nests

Fig. 3 Nevus showing a complex pattern with clod pattern in the center of the lesion (*blue square*) and ringed ones at the periphery (*purple square*)

impossibility to explore the deeper parts of a given lesion hamper a reliable diagnosis with RCM.

Blue nevi appear as a consequence of dermal proliferation of melanocytes. Since the RCM allows the visualization only of the upper dermis, these nevi do not represent the best candidate for confocal imaging. However, a few case reports describe the presence of spindled/dendritic melanocytes as a confocal clue that may be useful for the diagnosis of blue nevi (Puig et al. 2012).

2.2.2 Melanoma

Currently, melanoma (MM) is thought to be not a single entity but a family of diseases that includes distinct subtypes typified by peculiar morphologic and biologic aspects (Langley et al. 2001; Zalaudek et al. 2008; Segura et al. 2008; Longo et al. 2011). RCM diagnosis is based on major and minor criteria that have been extensively identified and tested for diagnostic accuracy (Pellacani et al. 2005a; Segura et al. 2009). To sum up, the most relevant criteria include the presence of

Fig. 4 A typical Spitz/Reed nevus showing a sharp lateral demarcation with large peripheral nests (arrows)

pagetoid spread, cytologic atypia at the DEJ, nonspecific architecture (non-edged papillae) (Fig. 5), melanocytes infiltrating dermal papillae, and atypical nesting including several nest type in particular sheetlike structures and cerebriform nests (Fig. 6). Pagetoid spread is one of the most striking criteria (Pellacani et al. 2005e; Longo et al. 2007), and it refers to the presence of melanocytes, round or dendritic shaped, arranged as single cells or small nests, within the epidermis. The presence of cytologic atypia is defined by the occurrence of atypical melanocytes at the DEJ. When evaluating the architecture, MMs typically show the absence of either a “regular” ringed clods or meshwork pattern as usually seen in nevi. Instead, they display an obvious interruption of the architecture with the onset of the so-called non-edged papillae (Pellacani et al. 2005b) when the contour of the papillae is not readily detectable, and it is often associated to the presence of atypical cells. In MMs, the junctional and dermal nesting is usually typified by the presence of atypical melanocytes and different degree of discohesion within the nests (dense& sparse nests and sheetlike structures).

2.2.3 Melanoma Subtypes

In superficial spreading melanomas (SSM), pagetoid spread is a hallmark, and it is characterized by the presence of variably shaped bright melanocytes with focal or widespread distribution. Pagetoid spread is also commonly observed

in lentigo maligna type (Tannous et al. 2002; Guitera et al. 2010), especially around the hair follicles. Conversely, pagetoid cells are quite rare in “pure” nodular melanoma, whereas ulceration is a common finding at the epidermal level (Segura et al. 2008).

RCM highlights different shapes of melanocytes scattered throughout the epidermis at various levels in melanoma. Pagetoid cells usually have a round shape with bright granular cytoplasm and hyporefractive nucleus but can display a dendritic shape with a barely visible body and variably long branching terminal structures. A clear-cut distinction between dendritic-shaped melanocytes and Langerhans cells has not yet been established (Hashemi et al. 2012).

In MMs, especially in superficial spreading and lentigo maligna, the DEJ is characterized by ringed and/or meshwork architecture with large and bright pleomorphic (“atypical”) cells in early MMs (Pellacani et al. 2005a). The cells can show the tendency to form nests that can still be compact or can be loosely arranged, depending on tumor progression. In early lesions it is a common finding to observe alteration or abrupt interruption of the normal DEJ architecture due to flattening of rete ridges resulting in irregularly shaped and not well-defined papillae (non-edged papillae) (Pellacani et al. 2005b) or disappearance of dermal papillae substituted by strands of atypical cells. In advanced stage of SSM, the massive tumor proliferation occupies the entire junction

Fig. 5 Confocal criteria for melanoma diagnosis: large pagetoid cells with branching structures (*arrows*) and cytologic atypia typified by the presence of atypical melanocytes (*arrows*) outlining non-edged papillae

Fig. 6 Confocal criteria for melanoma diagnosis: atypical melanocytes infiltrating non-edged dermal papilla (*arrows*) and atypical nesting with loosely aggregates of large and bizarre-shaped melanocytes (*arrows*)

and can push up into the epidermal layers as loose aggregates of bright, large, and pleomorphic melanocytes. In nodular melanomas, RCM shows the presence of so-called “cerebriform” nests (Pellacani et al. 2005c, d) that consist of small and hyporefractive cells forming a large tumor mass separated by dark thin fissures and bright collagen septae.

Lesions with regression represent an important indication for RCM. When we deal with lesions that are exclusively characterized by bluish to grayish granules, the differential diagnosis includes lichenoid keratosis or a regressive

melanoma. RCM is a powerful tool since it permits to discriminate between the former, showing only a florid inflammatory infiltrate, and the latter constituted by atypical melanocytes.

3 Malignant Non-melanoma Skin Tumors

Non-melanocytic tumors include basal cell carcinoma (BCC), actinic keratosis (AK), and squamous cell carcinoma (SCC), just to include the most common tumors.

Fig. 7 Basal cell carcinoma showing solid and well-outlined basaloid islands (*asterisks*) and peripheral palisading (*arrows*)

3.1 Basal Cell Carcinoma

The main confocal features of BCC list the presence of tightly packed aggregates with peripheral palisading and lobulated shape (González and Tannous 2002; Ulrich et al. 2011; Nori et al. 2004; Agero et al. 2006), epidermal polarization, and the presence of blood vessels (Fig. 7). Basaloid aggregates are outlined by dark spaces that correspond to mucin and often are surrounded by a prominent vascularity. Histopathologically, the aggregates correspond to the basaloid islands. Interestingly, RCM highlights very well the presence of dendritic melanocytes entrapped within the basaloid islands observable in heavily pigmented BCC. RCM is particularly useful in pink flat BCCs not showing all dermoscopic criteria and in heavily pigmented BCCs that simulate MM.

3.2 Actinic Keratosis and Squamous Cell Carcinoma

AK and SCC display the presence of variable KC atypia. At the stratum corneum, superficial disruption with single detached keratinocytes seen as bright, polygonal cells of high reflectance can be observed (Aghassi et al. 2000; Ulrich et al. 2007).

Furthermore, nucleated, highly reflective cells with dark center and sharp demarcation appear within the stratum corneum corresponding to parakeratosis. Atypical honeycomb pattern and architectural disarray of variable degree are seen at the level of the stratum granulosum and stratum spinosum corresponding to different degrees of keratinocyte dysplasia on histopathological exam. In SCC an atypical honeycomb or disarranged pattern of the spinous-granular layer is found along with round nucleated cells corresponding to pleomorphic keratinocytes (Fig. 8). Round blood vessels traversing through the dermal papillae perpendicular to the skin surface and scale crust appearing as brightly reflective amorphous islands on the surface of the skin are common findings in SCC (Rishpon et al. 2009). In cases with marked hyperkeratosis or abundant scale covering the entire lesion, in-depth imaging is limited by the keratin scattering, limiting exploration of the DEJ, which is fundamental for complete diagnosis.

4 Inflammatory Skin Diseases

Inflammatory skin diseases include spongiotic dermatitis, psoriasisiform diseases, diseases with interface involvement, and pigmentary

Fig. 8 Squamous cell carcinoma reveals the presence of atypical honeycombed pattern with variably shaped keratinocytes and S-shaped vessels (*arrow*)

non-tumoral skin disorders (i.e., vitiligo, melasma).

The main feature of spongiotic dermatitis on RCM is the presence of inter- or intracellular spongiosis. This corresponds to an increased intercellular brightness due to inter- or intracellular fluid accumulation that leads to the appearance of a regular honeycombed morphology (González et al. 1999; Astner et al. 2005). When spongiosis is more pronounced, it is possible to detect vesicle formation that appears as well-demarcated, dark hollow spaces between granular and spinous layer KCs. Commonly, exocytosis is associated with spongiosis, whereby the inflammatory cells are seen on RCM as bright, round highly refractive structures of about 8–10 μm , interspersed between keratinocytes. Inflammatory cells may also be observed to various extents in a perifollicular, perivascular, or interstitial dermal distribution.

Psoriasisiform disease is distinguished by the presence of an increased number of non-rimmed papillae at the dermo-epidermal junction, resulting in a junctional profile similar to that of normal skin but with papillae surrounded by faint rings of basal KCs, instead of the typical bright rings (Gonzalez et al. 1999). Interestingly, S-shaped blood vessels

are seen within the papillae, and they resemble the pattern observed in SCC in situ.

The hallmark in interface dermatitis is the inflammatory involvement of the dermo-epidermal junction. The inflammatory cells tend to obscure the junction profile and the dermal papillae with a more diffuse involvement in lichen planus and a focal distribution in lupus erythematosus (Moscarella et al. 2012). In the latter, the presence of inflammatory infiltrate can be seen in proximity of the adnexa that usually appear dilated (larger than 80–100 μm) and filled by highly refractive material in the lumen (hyperkeratotic infundibula).

Among the acquired pigmented disorders, RCM has been used to study vitiligo. Vitiligo lesional skin shows disappearance of the normal brightness at the dermo-epidermal junction where the edged papillae appear as a remnant of the pre-existing papillary ring (Ardigo et al. 2007).

5 Infectious Diseases

RCM has been applied in some infectious diseases although studies based on large cases are still lacking. Superficial mycosis can be easily

detected by RCM since it has a high-level resolution for the upper epidermis. Dermatophyte hyphae appear as bright linear branching structures within the epidermis with an excellent correlation with the ones seen upon light microscopy (Markus et al. 2001). With the same high resolution, it is possible to detect the presence of *Demodex folliculorum* within the hair follicles (Longo et al. 2012a). *Demodex* usually show up as multiple roundish well-outlined structures corresponding to the head-down mites living in the hair follicles. *Sarcoptes scabiei* is readily observed using RCM, including its feces and eggs within the burrow (Longo et al. 2005).

6 Monitoring of Nonsurgical Therapies

Due to its noninvasiveness and high resolution, RCM is a suitable candidate for treatment monitoring. Its role has been investigated for monitoring treatment efficacy of imiquimod in AK (Ulrich et al. 2010). RCM was able to visualize the inflammatory response induced by imiquimod and photodynamic therapy (Longo et al. 2012b) in clinically visible as well as in subclinical lesions within the cancerization field. Another study evaluated the efficacy of cryotherapy for superficial BCC (Ahlgrimm-Siess et al. 2009), showing early cell necrosis at the basal layer and within the superficial dermis 5 h after application of liquid nitrogen indicating effective cryotherapy. In this regard, RCM may allow the immediate evaluation of treatment efficacy after cryotherapy and may indicate if a second cryotherapy session is needed. RCM has also been employed in lentigo maligna treated with imiquimod (Nadiminti et al. 2010). RCM has also found application for the efficacy assessment of laser therapy for solar lentigines, vascular lesions, skin rejuvenation (Longo et al. 2013), and acne scars demonstrating the skin changes occurring after treatment and in long-term follow-up. The possibility to closely monitor the morphologic changes over time and gain new insight into the mechanism of action of laser devices could be useful in understanding side effects.

7 Conclusions

The introduction of RCM in clinical practice opened for the first time the possibility to obtain a histologic view of the skin in a noninvasive way with the main advantage of being painless, not scarring, and repeatable over time. The possibility to monitor lesions over time implies the opportunity to gain new insight into nevus development, melanoma biology, and therapy monitoring. However, the correct interpretation of RCM images requires an adequate training and of the main histopathologic aspects of each particular lesion.

1 Introduction

Reflectance confocal microscopy is established as a valuable tool for in vivo non-invasive diagnosis of skin tumors and other skin conditions. The same technique can be used also for microscopic imaging of freshly excised tissue. After application of fluorescent dyes and by using lasers with different wavelengths for excitation, a staining of nuclei is possible in the fluorescence mode. The grayscale images in the reflectance and the fluorescence mode can be combined and converted digitally into pseudo-color images looking like an H&E (hematoxylin/eosin) staining. Ex vivo confocal microscopy is a promising tool for rapid pathology of fresh tissue, especially for Mohs micrographic surgery of basal cell carcinoma.

2 Technique

The ex vivo confocal microscopy device VivaScope 2500 (Mavig, Germany) is a multiwave system. Three lasers with different

wavelengths at 488 nm, 658 nm, and 830 nm are installed. The laser at 830 nm is used for reflectance imaging. The first two lasers at 488 nm and 658 nm are combined with filters for elimination of the reflection, allowing only the fluorescence at longer wavelength to pass through. The fresh tissue is placed on a glass slide above the lens system and fixed by another plate to ensure a flat surface. The surface is scanned by imaging single square spots of $750 \mu\text{m} \times 750 \mu\text{m}$, composed to maps of up to $12 \text{mm} \times 12 \text{mm}$ by lateral scanning, which takes some minutes.

3 Fluorescent Dyes

The first step of fresh tissue preparation is the application of 10 % acetic acid for 60 s to increase the contrast (“acetowhitening”). After rinsing with buffer solution, fluorescent dyes can be applied.

At 488 nm, acridine orange and sodium fluorescein are dyes, which are excited by illumination, leading to fluorescence at longer wavelength.

At 658 nm, methylene blue, toluidine blue, patent blue, and nile blue can be used for fluorescent staining.

The concentrations of the dyes are crucial to achieve optimal results. If the concentration is too low, the fluorescence signal is weak. If it is too high, quenching may occur, resulting in dark images. The effect of photo bleaching should also be considered, especially when using methylene blue. To avoid bleaching, the measurement time and scanning should be fast. Some dyes like nile blue are susceptible to changes of the pH value which might lead to a shift of the excitation and emission wavelength.

Our recommendations regarding the concentrations of the different dyes are:

- Acridine orange 0.6 mM, 1.2 mg/ml
- Sodium fluorescein 0.2–0.4 %
- Patent blue V 0.25 mg/ml (<6.25 mg/ml)
- Methylene blue 2 mg/ml
- Nile blue 0.2 mg/ml in 70 % ethanol

In our experience, the fluorescence dyes acridine orange and nile blue provide the best and most stable results.

4 Digital Staining

In the reflectance mode, collagen fibers and cytoplasm are the main sources of contrast, whereas in the fluorescence mode, the collagen is nearly invisible and the nuclei are stained strongly. By combining both images and by digital transformation of the grayscale into pseudo-colors, the images mimic the conventional H&E (hematoxylin/eosin) staining of histology (Bini et al. 2011). This may further facilitate the detection of small strands of epithelium within connective tissue and increase the sensitivity and specificity of ex vivo confocal microscopy.

5 Results

Confocal microscopy is meanwhile well established for the noninvasive in vivo imaging in dermatology, but just as long it has been successfully applied to image freshly excised tissue

Fig. 1 Ex vivo confocal microscopy of normal skin in the reflectance mode. The epidermis (*E*), the dermis (*D*), glands and hair follicles (*F*), and subcutaneous fat (*S*) are displayed

Fig. 2 Ex vivo confocal image of a basal cell carcinoma in the reflectance mode (*left*) compared to corresponding histology of the same tumor (*right*). The appearance of the small tumor nests is similar

Fig. 3 Sweat gland with surrounding connective tissue in the reflectance mode (*left*) and fluorescence mode (*right*) after staining with patent blue. The dye stains the nuclei,

whereas the connective tissue is left unstained (*right*), but shows a bright signal in the reflectance mode (*left*)

ex vivo. The first studies were performed using the reflectance mode. The normal skin architecture and basal cell carcinomas are clearly visible (Figs. 1 and 2). Typical histologic features were described, corresponding to conventional histology (Gareau et al. 2009b). Also squamous cell carcinomas were imaged and showed characteristic features like densely packed atypical nuclei (Horn et al. 2007). However, the contrast of

reflectance confocal microscopy especially for detection of small residues of fibrotic basal cell carcinomas with dense, bright stroma was limited (Chung et al. 2004). Confocal and light microscopy findings were consistent in 84.6 % (Kaeb et al. 2009). The sensitivity to detect basal cell carcinomas in tissue margins was limited to 73.7 % resp. 80 % depending on the technique (Ziefle et al. 2010).

Fig. 4 Basal cell carcinoma in the reflectance mode (a), in the fluorescence mode after staining with acridine orange (b) and after combination of both images and digital staining (c). The latter image simulates the H&E staining

of conventional histology. The tumor is easily detectable. Digital staining software by Dan Gareau and Milind Rajadhyaksha, Memorial Sloan-Kettering Cancer Center, New York

The development of multiwave systems for fluorescence confocal microscopy enhanced the diagnostic capability for examination of freshly excised tissue (Bennassar et al. 2013a). The first step was to develop and evaluate staining protocols of fluorescent dyes. Several different dyes were investigated. Acridine orange was the most commonly used fluorescent dye, which gave stable and reproducible results (Gareau et al. 2008). Fluorescence confocal microscopy is demonstrated to be advantageous to the reflectance mode because epithelium shows more contrast to the stroma after fluorescence staining of the nuclei (Fig. 3). Therefore, it is easier to detect small tumors within a fibrotic connective tissue. This led to a high sensitivity of 96.6 % and specificity of 89.2 % in basal cell carcinomas (Gareau et al. 2009a; Karen et al. 2009).

Fluorescence confocal microscopy is not only used for diagnosing skin tumors but also for rapid surgical pathology because the staining and imaging take only a few minutes compared to fresh frozen tissue microscopy (Gareau et al. 2008). Case reports demonstrated its feasibility for bedside pathology (Bennassar et al. 2012; Longo et al. 2013). Especially for histologic examination of tumor margins, the so-called Mohs micrographic surgery, ex vivo fluorescence confocal microscopy has demonstrated its value. The sensitivity for detection of basal cell carcinoma residues in the borders is 88 % and the specificity 99 % (Bennassar et al. 2013b). Digital staining may further facilitate the interpretation of the confocal images (Fig. 4) (Bini et al. 2011; Gareau et al. 2012). First studies in general pathology demonstrated that the technique could also be used for

microscopy of other tissues than the skin like the breast, colon, and thyroid gland (Ragazzi et al. 2013).

The VivaScope 2500 is further improved. In the latest upgrade, the optical lens system is optimized for better image matching, and the measuring field is enlarged up to 20 mm × 20 mm.

6 Conclusion

Fluorescence confocal microscopy is a fast and reliable method for diagnosis of skin tumors and other pathologies in freshly excised tissue. It may represent an alternative to frozen sections for rapid surgical pathology and is of special interest for Mohs micrographic surgery to investigate tumor margins of basal cell carcinomas.

1 Introduction

Oxygen is an essential fuel and also a poison for living organisms. On the one hand, it can violently oxidize vital macromolecules (e.g., proteins and nucleic acids), and on the other hand, some of these macromolecules are specially designed to capture, transport, and use oxygen in many cascades of chemical reactions. These paradoxical properties have led, through adaptive evolution, organisms to develop strategies to precisely control and adapt the absorption of oxygen from the environment. Mammals mainly use their lungs through breathing and have developed their interfacial surface to meet their body's requirements in oxygen. The second interfacial surface of body in direct contact with environmental oxygen is human skin. Very naturally, an intimate relation emerged between the skin and oxygen homeostasis. And although the skin cannot anymore be considered as a "breathing organ" in humans, it has deep implications in oxygen supply management.

Nowadays, medical attention has been driven toward body supply in oxygen due to its wide impact on various physiopathological processes such as wound healing, skin aging, and immune reactions. Beyond hyperbaric oxygen therapy, innovative formulation technologies are being developed to enable oxygen delivery in a handy and efficient manner.

2 General Aspects on Oxygen and Skin

2.1 Physicochemistry of Oxygen

Atomic oxygen is a highly electronegative chemical element (symbol "O"; atomic number, 8) that forms compounds with most elements in often highly exothermic reactions. It is the most

abundant element on earth surface. Furthermore, it represents 62 % (m/m) of the human body. Under normal conditions of temperature and pressure, atomic oxygen binds to form a diatomic colorless, odorless gas called oxygen (O₂). Oxygen is a small molecule with a molecular weight of 31.999 g/mol that exhibits a pressure and reverse-temperature-dependent solubility in water (i.e., 8.3 mg/L at 25 °C under atmospheric pressure).

2.2 Oxygen Physiology

Oxygen acts toward the human body at the same time (i) as a major metabolic substrate for cellular chemistry and (ii) as a signal in multiple metabolic pathways with a remnant effect after return to normal oxygen levels (Ladizinsky and Roe 2010).

Many essential physiological reactions require the presence of oxygen. Most importantly, oxygen is the terminal electron acceptor in mitochondrial respiration and it also plays a central role in many other metabolic processes. For instance, oxygen is required (i) for the production of nitric oxide by NO synthases, (ii) for the hydroxylation of the collagen, and (iii) for cholesterol synthesis.

Furthermore, oxygen levels are monitored at different points within the human body (e.g., the carotid, liver, and kidney) to induce homeostatic response to hypoxia (i.e., differential vasoconstriction/dilatation, erythropoietin, and red blood cell production). In case of acute environmental hypoxia, concomitant pulmonary vasoconstriction and systemic vasodilatation occur to ensure correct oxygenation of vital organs. Surprisingly, unlike the rest of systemic vasculature, skin vasculature undergoes vasoconstriction in response to acute environmental hypoxia. If hypoxia is prolonged, a hypoxia-inducible transcription factor (HIF)-mediated response progressively restores the cutaneous blood flow in the skin, leading to liver and kidney hypoxia and subsequent erythropoietin synthesis to enhance blood's oxygen-carrying capacity. Thus, the skin is the central actor of a bimodal response to acute/chronic environmental hypoxia in mammals (Boutin et al. 2008; Semenza 2008).

Eventually, oxygen supply is intimately intricate in skin aging processes as a cause (i.e., production of reactive oxygen species or ROS) and a potential treatment for a variety of skin discomforts; therefore, the development of oxygen therapies is a major interest of cosmetic companies with important economic and sanitary outcomes (Asadamongkol and Zhang 2014).

2.3 Oxygen Supply

Oxygen supply to human body's organs and tissues is mainly ensured by pulmonary absorption. In the lungs, gaseous oxygen needs to become dissolved in a fluid state to cross alveolar membrane. Once dissolved, oxygen diffuses within the body from areas of high concentration to areas of low concentration. Hemoglobin within red blood cells acts as a reservoir ensuring that plasmatic dissolved oxygen level is sufficiently maintained to ensure delivery to organs and tissues via capillary perfusion (Ladizinsky and Roe 2010).

Although transcutaneous absorption of oxygen is now known to occur in human, the ratio of the absorption surface between the skin and lungs (1–2 m² and 70 m², respectively) limits its impact as a source of systemic oxygenation. Overall, apart in premature infants, atmospheric oxygen transported through the human skin contributes in a negligible way (i.e., 2 %) to body oxygenation (Roe et al. 2010). As dermal vasculature does not cross its basal membrane, the epidermis can be considered as a physiologically hypoxic tissue where anaerobic glycolysis is likely to be important to sustain its high metabolic activity due to constant renewal (Boutin et al. 2008; Straseski et al. 2009). Moreover, due to its highly organized structure, skin barrier function further limits the extent of transcutaneous absorption of oxygen. However, considering local skin oxygen supply, transcutaneous absorption is (i) a physiologically relevant oxygen source down to the superficial dermis and (ii) the major source of oxygen for the outermost layers of unperfused epidermis (Ladizinsky and Roe 2010).

In human, skin's partial pressure in oxygen levels (pO₂) is highly correlated to the

physiopathological state of the skin (Reading et al. 2013). For instance, wound repair outcome may be estimated regarding local oxygen tension. Non-hypoxic wounds (i.e., pO₂ >30 mmHg) will heal rapidly with no complications such as infection oppositely to hypoxic wounds (i.e., pO₂ between 13 and 30 mmHg). When pO₂ drops under 13 mmHg, basal metabolic activity cannot be sustained which leads to gangrenization (Roe et al. 2010).

2.4 Oxygen Skin Permeability

Due to its small molecular size, permeation of oxygen through the skin is likely to occur massively through porous structures such as skin appendages (e.g., eccrine glands). Permeation of oxygen through nonporous regions of the skin could also follow the transcellular pathway via transmembrane proteins such as aquaporins that exhibit gas transport capacities (Roe et al. 2010; Wang and Tajkhorshid 2007). Data is scarce on oxygen skin permeability but suggests it relies mostly on passive physicochemical-mediated transport and not active cellular mechanisms (Roe et al. 2010). Oxygen delivery from a saturated aqueous vehicle was assessed *ex vivo* using porcine skin. Exogenous (i.e., via the *stratum corneum*) and endogenous (i.e., via the dermis) administrations were simulated and revealed a higher permeation for endogenous delivery and a better skin penetration supposedly due to reservoir effect of *stratum corneum* lipid matrix with exogenous administration. However, some studies suggest tape stripping of the epidermis leads to enhanced oxygen penetration into the skin from an aqueous oxygen penetration into the skin from an aqueous formulation (Ladizinsky and Roe 2010; Atrux-Tallau et al. 2009). Therefore, it is not clear if skin stratified structure and more specifically the *stratum corneum* can be considered as a major barrier to transcutaneous penetration of oxygen. Overall, oxygen absorption in the epidermis from the environment can be described using a Fickian model where a pO₂ gradient governs oxygen penetration. This theoretically enables local therapeutic approaches based on topical application of oxygen-loaded formulations (Reading et al. 2013).

3 Compounding Strategies for Oxygen

3.1 Gaseous Formulations of Oxygen

Oxygen therapy in the context of wound healing should be able to deliver sufficient oxygen to reach pO_2 found in healthy well-perfused tissues (i.e., >30 mmHg). Hyperbaric oxygen therapy is known to have significant impact on wound healing processes as long as blood perfusion is effective in the targeted tissue. Concerning the skin, hyperbaric oxygen therapy raises subcutaneous oxygen tension for several hours after return to normobaric conditions (Ladizinsky and Roe 2010). However, gaseous formulations of oxygen require that gaseous oxygen overcomes the gas/liquid phase boundary before it becomes bioavailable (Roe et al. 2010). Furthermore, high-pressure gaseous oxygen administration is limited as it will mechanically cause microvascular occlusion at administration site (Reading et al. 2013).

3.2 Liquid Formulations of Oxygen

3.2.1 Aqueous Formulations

As oxygen is bioavailable if dissolved in a fluid state, liquid formulations of oxygen might provide better biopharmaceutical capacity to deliver oxygen to the skin. Dissolved oxygen applied topically shows (i) faster rate and (ii) deeper depth of penetration in human skin than gaseous oxygen formulations applied topically (Roe et al. 2010).

Water shows higher penetration capacities through the skin than molecular oxygen and is capable of retaining up to 50 mg of oxygen per liter using simple enriching techniques. Therefore, water may be an interesting and inexpensive vehicle for a liquid formulation of oxygen. Furthermore, an aqueous-based formulation is likely to be supplemented with a large variety of compounds meant to support wound healing process in addition to oxygen (Reading et al. 2013).

Recent reports have shown the absorption of oxygen through the plantar surface of the foot and palmar surface of the hand, when immersed in

water that contains high levels of dissolved oxygen. Moreover, age and patient's condition (e.g., diabetes) influence oxygen absorption and/or retention (Reading et al. 2013).

3.2.2 Fluorocarbons

Fluorocarbons are inert synthetic linear or cyclic hydrocarbons ranging from C8 to C10, wherein all or part of the hydrogen atoms have been replaced by fluorine or bromine. They exhibit low molecular weights (i.e., 450–500 Da) and are immiscible with both hydrophobic and aqueous solutions. They are used in industry as a refrigerant and propellant in aerosol canisters but also show a high capacity to dissolve and release oxygen and carbon dioxide. With their oxygen-carrying capacity being 50 times greater than that of water, fluorocarbons feature a better liquid vehicle than water for oxygen transport through the skin (Isaacs et al. 2011). Although nearly twice as dense, most have a similar kinematic viscosity as water.

The solubilization and release of oxygen by fluorocarbon are a physical entirely passive process, unlike the bonding and release of oxygen from hemoglobin in the blood. The amount of dissolved gas is (i) proportional to the partial pressure of the gas in the liquid which is in equilibrium, (ii) inversely proportional to the molecular weight of the fluorocarbons, and (iii) directly related to the number of fluorine atoms present. Physicochemical properties of selected fluorocarbons are given in Table 1 (Kaisers et al. 2003).

Linear fluorocarbons are better oxygen carriers. They are biologically and chemically inert and non-metabolized, and, being volatile, they are excreted through the lungs within a week. However, they accumulate in the reticuloendothelial system where their long-term effects are not yet established (Krafft 2001).

A major drawback consists in their immiscibility to water. Therefore, they must be administered either (i) as an emulsion, to be carried in the vasculature, or (ii) as a dispersion of fine particles of 0.1–0.2 mm in suspension in isotonic saline electrolyte. To obtain stable emulsions at ambient temperature, emulsifiers are necessary. Emulsifiers commonly used, such as egg yolk

phospholipids, provide stable emulsions and can be sterilized without degradation. The ability to transport oxygen of these emulsions is dependent on the concentration of fluorocarbon. The emulsions that contain 45–60 % of fluorocarbon (w/v) seem optimal to transport oxygen, but their high viscosity limits the concentrations used.

3.3 Colloidal Formulations

3.3.1 Micro- and Nanosponges

Nanosponge and microsponge delivery systems were originally developed for topical delivery of drugs. This controlled release technology for

topical agents consist of nano- or microporous beads loaded with active agent obtained by cross-linking of cyclodextrin. The average diameter of a nanosponge is below one micrometer, whereas for microsponges it ranges from 10 to 25 μm. These vehicles are designed to deliver efficiently a pharmaceutical active ingredient at minimum dose and to enhance stability. Nanosponge formulations might be potential gas delivery systems showing the ability to store and to release oxygen slowly over time. Furthermore, nanosponges exhibit high loading capacity for other gases (e.g., carbon dioxide and methylcyclopropene) (Cavalli et al. 2010; Patel and Oswal 2012).

3.3.2 Micro- and Nanobubbles

Microbubbles and nanobubbles are spherical gas-filled low-density structures with a mean diameter of 1–8 μm and $>1 \mu\text{m}$, respectively. They comprise a spherical cavity containing gas (e.g., oxygen) and gas-loading agents such as fluorocarbons. They are stabilized by a lipidic or polymeric coating. When introduced in an oxygen-deprived environment, oxygen-containing fluorocarbon microbubble will deflate, liberating their oxygen content. Subsequently, if the environment is reoxygenated, microbubbles will reload oxygen and recover a spherical shape. This property has important medical applications, for instance, in the development of synthetic blood substitutes. Furthermore, micro- and nanobubbles respond to ultrasonic stimulation by liberating their gaseous content, enabling to develop ultrasonic-driven targeting therapeutic strategies (Unger et al. 2004). For instance, gene transfection in reconstructed human skin was achieved by ultrasonic-enhanced microbubble delivery (Yang et al. 2005), and micro-/nanobubbles are presented as ultrasound-targeting oxygen delivery systems as adjuvant to antibiotics in anaerobic infections. Furthermore, many medical conditions, such as diabetes, burns, bedsores, and wounds, are possible fields of application of oxygen-filled micro-/nanobubbles besides other oxygenation approaches (Cavalli et al. 2009).

4 Clinical Applications

4.1 Interest of Oxygen Therapies

Numerous diseases are caused by tissular ischemia or hypoxia. Under some conditions, the HIF-mediated homeostatic response is not sufficient, and the use of hyperbaric oxygen therapy is required. Hyperbaric oxygen therapy has been shown to enhance bone, muscle, and skin healing, particularly in conditions of ischemia and low oxygen tension. In the skin, it is proved that hyperbaric oxygen has positive treatment effect on promoting wound healing of, e.g., chronic ulcers and diabetic foot (Thackham et al. 2008; Eskes et al. 2010). Moreover, hyperbaric oxygen

increases levels of growth factors, such as vascular endothelial growth factor, and stimulates vasculogenic stem cell mobilization from the bone marrow in response to oxidative stress.

The goal of an oxygen therapy for wound care is to transfer sufficient oxygen to interstitial tissues to maintain a concentration above 30 mmHg found in healthy, well-perfused tissues. Oxygen concentration is paramount to the proliferation and differentiation of a variety of cell types. Various mechanisms have been proposed to explain positive effects of oxygen therapies on injured tissues. Indeed, high levels of oxygen stimulate the proliferation of fibroblasts and endothelial cells, differentiation and migration of keratinocytes, and angiogenesis and decrease edema in the periwound skin, through a vasoconstrictive effect. The functioning of several enzymes needed for the correct synthesis of collagen requires oxygen as a cofactor (Zgonis et al. 2005). Furthermore, hyperoxia facilitates the elimination of anaerobic bacteria by leukocytes through activation of the oxygen-dependent peroxidase system and promotes the production of ROS that attack bacterial structures (Fife et al. 2002).

4.2 Drawback of Oxygen Therapies

The use of oxygen therapy in hypoxic conditions is promising; however, abusive use poses risks, notably oxidative stress. This is especially true in the context of widespread oxygen therapies for cosmetic and esthetic means.

One potential danger is that ROS produced from oxygen are highly reactive and therefore exhibit potent toxicity, which often occurs under hyperbaric conditions. When oxygen exposure overpowers the tolerance of tissues, further exposure may eventually result in toxicity or oxidative injury. Oxygen toxicity occurs after extended periods of hyperbaric oxygen exposure and/or at high pressure.

It has also been reported that hyperbaric oxygen therapy increases the production of ROS within the tissue (Matsunami et al. 2009), thereby mobilizing cellular antioxidant responses (Godman et al. 2010). ROS can oxidize proteins and lipids and

Table 2 Contrasting hyperbaric oxygen therapy with topical oxygen delivery modalities for wound care

Systemic hyperbaric oxygenation	Topical delivery of oxygen
Systematically oxygenated blood at 2–3 atm	Topically oxygenated wound tissue at 1 atm
Requires specialized facilities and personnel	Portable device
Relatively expensive	Inexpensive
Relies on vascular system to deliver oxygen in wounds	Delivers oxygen to superficial wounded tissues severed from circulation
Poor vascularity of wound tissue limits oxygen diffusion	Oxygenation is independent of vascular bed
Risk of multiorgan oxygen toxicity	Limited and localized risk of toxicity

react with DNA to cause single-strand breaks and base modifications. This process imparts a number of molecular changes to skin tissue and an overwhelming of cellular protective responses, ultimately leading to increased levels of cell death (Pustisek and Situm 2012).

4.3 Topical Oxygen Delivery Strategies

As we have seen, different formulations exist that enable oxygen loading and dermal application in chronic wounds and to address the lack of oxygen due to low perfusion in certain skin diseases. As oxygen was found to better penetrate skin layers from exogenous supply than from endogenous supply, local topical delivery of oxygen appears a rational approach to enhance pO_2 in the skin (Atrux-Tallau et al. 2009).

Gas formulations are readily developed and available such as hyperbaric oxygen therapy; however, they remain inconvenient in terms of administration (Table 2). Liquid formulations in aqueous media or enhanced loading capacity media such as fluorocarbons appear handier, but drawbacks in compounding and delivery control have led to develop more complex formulations with targeting and controlled release characteristics. Colloidal formulations able to entrap oxygen show promising aptitudes and best meet these criteria. Other strategies such as incorporation of a vasodilating agent (e.g., nicotinate esters) may be interestingly combined to oxygen delivery systems to improve skin oxygen content by exogenous and endogenous supply (Krzic et al. 2001).

5 Conclusion

The perceived health and physiologic functioning of the skin depend on adequate oxygen availability, both oxygen present in the body and oxygen contributed by the external environment. The capacity of the skin to absorb oxygen from air has often been overlooked but can account for up to 2 % of the total oxygen consumed by the body and is especially important to the epidermis.

Formulations have been developed to overcome skin hypoxia. Complex colloidal formulations are not yet used at their full potential in the skin care area, however in rapid progress. Nevertheless, vigilance is required about frequent and or abusive use as high amounts of oxygen can cause oxidative stress resulting in the exact opposite of therapeutically expected effect.

Dermis • Elaunin fibers • Glycosaminoglycans (GAGs) • Lymphocytes • Microfibril-associated glycoproteins (MAGP) • Papillary/adventitial dermis • Reticular dermis • Skin appendages

The dermis (also called the cutis) is by far the thickest skin layer and amounts to about 7 % of the body weight. Its connective tissue is special because of its structure and because it holds many independent small organs, the hairs, and the sweat glands, together called skin appendages. Like other connective tissues, the dermis appears at first as a mesh of interconnected collagen fibers, elastic fibers and an interstitial ground substance rich in proteins and glycosaminoglycans (GAGs) (Fig. 1). Most of the collagen is formed by the assembly at regular intervals of strong fibrils (thickness: 20–100 nm) (Breathnagh 1971) (Fig. 2) separated by proteoglycans, arranged in interconnected bundles forming a network without detectable free extremities. The elastic fibers have a fibrillar skeleton composed of fibrillin (type 1 and 2) (thickness: 1.0–1.3 nm) and other fibrillar proteins (fibulin, microfibril-associated fibrillar protein, MAFP), at the center of which an amorphous substance, elastin, is deposited. They are interwoven with collagen fibers (Fig. 3). The fibrillar collagens and the elastic fibers are embedded in a viscous gel (so-called ground substance) made of nonfibrillar collagens,

proteoglycans (association of proteins and glycosaminoglycans), and microfibril-associated glycoproteins (MAGP) (Pope 1998). All these components of the dermis are synthesized by the fibrocytes (also called fibroblasts, although they are mature cells) that are abundant in young tissue but rare in older ones. Finally, a substantial amount of water is retained because of the high hygroscopic power of the MAGP. Microscope or ultrasound examination reveals two types of dermal connective tissue depending on the structure and location: the papillary/subpapillary and adventitial dermis, 20–100 μm wide, and the reticular dermis (or chorion) 10–20 times thicker.

1 Subpapillary and Adventitial Dermis

1.1 Structure

The subpapillary (subepidermal) or adventitial (around the pilosebaceous or sudoral appendages) dermis holds a thin fibrillar network mainly composed of type I and III collagen, type VII collagen, thin elastic fibers (type 2 fibrillin) and fibrillin 2 without elastin (oxytalan fibers) (Pope 1998). In the deeper part of the subepidermal dermis, collagen and elastic fibers are horizontally oriented, whereas in the upper part they are mostly vertical and connect the horizontal network to the dermoepidermal junction. This type of dermis looks clear under optical microscope because the ground substance (MAFP, MAGP) and the water it retains constitute the major part of its volume. Cohesion to epidermis is ensured by a basal membrane (a mesh of collagen IV, fibronectin, other fibrillar proteins, and globular collagens) connected to the epidermal keratinocytes by hemidesmosomes and to the collagen network by anchoring fibers (collagen VII) and a ramification of oxytalan fibers (see ► Chap. 36, “Epidermal Physiology,” Fig. 2).

1.2 Function

The papillary/adventitial dermis functions are numerous:

1. It ensures the nutrition of the overlying layers of epithelium and their hormonal and paracrine exchanges thanks to the numerous vessels (arterioles, venules, blood and lymphatic capillaries) that it contains. As such, its thickness varies in relation to the activity of the overlying epithelium layers, and it must be regenerated before the healing of a wound begins. However, in this case, the papillary dermis reconstituted from inflammatory granulation tissue is generally more fibrous than normal, with few elastic fibers, and the dermoepidermal junction is devoid of papillary relief.
2. It partly controls percutaneous absorption thanks to its blood and lymphatic vessels. The lower the

elastin and fibrillin. Some collagen fibrils seem to stick to fibrocytes, others to elastic fibers (*arrows*). Bar = 1 μ m (Courtesy of Prof. Laurent, Department of Dermatology, University of Besançon, France)

blood or lymph flow, the slower the decrease in the permeant concentration in the epidermis intercellular spaces; this process may explain the lower percutaneous absorption in the aged, in spite of the reduced thickness of the epidermis.

3. It has an architectural function: the collagen, fibrillin, and elastic fiber framework contributes to the protection of vessels and cells against mechanical aggressions (the reticular dermis fulfills this function more efficiently). The elastic fiber network ensures full recovery of shape after deformation. Elaunin fibers (elastic fibers with very little elastin) may be responsible for the maintenance of the dermoepidermal papillary relief; they disappear during actinic aging. Both synthesis and degradation of collagen, elastin, and fundamental substance by fibrocytes are possible, but what triggers the production of proteolytic enzymes is mainly inflammatory cells. It contains most of the nerve endings responsible for the tactile function of the hair (see ► [Chaps. 76, “Scalp Sebaceous Function Assessment,”](#) and ► [99, “Skin Tensile Strength in Scleroderma”](#)).
4. In addition, adventitial/subepidermal dermis contains inflammation inducers, among them type C and A δ nerve fibers providing proinflammatory neuropeptides, and (for the most part perivascularly located) mast cells, which are a source of potentially highly inflammatory

substances. Accordingly, this type of dermis is mainly responsible for the strong reactivity of the skin. Around sweat gland secretory coils, abundant cholinergic nerves provide the acetylcholine responsible for sweat secretion when excited.

5. The papillary dermis contributes, together with the epidermis, to the immunological function of the skin by ensuring the transit of the immunocompetent cells (Langerhans cells, lymphocytes) toward the lymph nodes, directly or through its lymphatic vessels. Dendrocytes (Riley 1974), lymphocytes, and histiocytes also play a part in the SALT (skin-associated lymphoid tissue), which is of paramount importance in delayed hypersensitivity phenomena. Mast cells are also a major step in immediate hypersensitivity reactions.
6. An important quota of macrophages and histiocytes aid the dermis to remove the barely soluble waste of cellular or metabolic origin (e.g., extravasated red blood cells).

2 Reticular Dermis

The reticular dermis is very different, over 500 μ m thick and subdivided sometimes into mid-dermis and deeper dermis. Under the optical microscope,

only a thick mesh of collagen bundles orientated in all directions in a plane parallel to the surface is detected. Vessel sections are rare. In most anatomical areas, they are only transfer arterioles and venules. In the palms and soles, numerous arteriole-venular shunts can also be found, which are involved in the thermal regulation of the extremities. The mid-dermis contains the pilosebaceous appendages (downy or vellus hairs) and the deep dermis contains the coiled part of the sweat glands and their excretory ducts. Apart from these epithelial structures (surrounded by adventitial dermis), there are few cells, almost only fibrocytes. The collagen bundles of the reticular dermis are formed by type 1 collagen (Fig. 2) coated with MAGP and MAFP, which maintain the fibers separated from one another (Scott 1992) and contribute to the water binding onto their surface, thus making the tissue swell. Scanning electron microscopy shows that these bundles appear curved and stretched in the direction of the highest tension of the skin as a result of thick elastic fibers (Piérard and Lapière 1987) (Fig. 4). They are made of type 1 fibrillin and elastin. The deep dermis is a little more dense than the mid-dermis but has a similar structure.

The reticular dermis function is mainly mechanical. It forms a solid structure, although distensible (up to about 25 %) as well as compressible, and protects the adnexal epithelia against mechanical aggressions. Because of its elasticity, it is responsible for the maintenance of the tissue shape and architecture. A partial failure of this function is found in hypertrophic scars, keloids, and stretch marks (*striae gravidarum*, *striae distensae*). Finally, the permanent tension of the reticular dermis, due to the traction exerted by elastic fibers, generates the folding of nonelastic overlying structures (viable epidermis

Fig. 4 Reticular dermis (scanning electron microscope). The spontaneous skin tension has been preserved and the ground substance discarded. Elastic fibers form a tense network attached to a curved collagen bundle. $\times 100,000$ (Courtesy of Prof. Piérard, Department of Dermatopathology, University of Liège, Belgium)

and stratum corneum). This is the origin of the skin surface relief, which appears first at the deeper level of subpapillary dermis.

Sonography • 22–100 MHz • Stratum corneum • Viable epidermis • Dermis • Subcutis • Inflammatory skin diseases • Skin tumors

1 Introduction

Clinical examination of skin pathology by inspection and palpation delivers crucial hints to determine the correct dermatological diagnosis. When examining tumorous or inflammatory diseases – apart from the involved skin area – the registration of in-depth expansion of the process is a further important clinical parameter. Sonography is an interesting tool to collect this missing information.

It has already conquered many specialities in medicine. Until 1975 ultrasound transducers with a center frequency and bandwidth of maximal 7.5 MHz were available. Attempts to evaluate inflammatory and tumorous processes in the skin using 1,5–5 MHz transducers delivered very unsatisfactory results (Rukinava and Mohar 1979). The pioneers Alexander and Miller (1979) were the first scientists measuring skin thickness using 15 MHz pulsed ultrasound.

Subsequently in the 1980s and 1990s specific 15 – 20 MHz ultrasound imaging systems were developed.

Fig. 1 Medline publications on noninvasive skin imaging methods. *MRI* magnetic resonance imaging, *OCT* optical coherence tomography, *CLSM* confocal laser scanning microscopy

Sonography is the oldest method to look at skin layers *beneath* the skin surface and was widely introduced to clinical dermatology in the 1990s. As the above chart (Fig. 1) displays, scientific research focused on epiluminescence microscopy ten years ago. The latter delivers additional information allowing one to differentiate between malignant and benign pigmented skin tumors, wherefore it was highly targeted by researchers during this period of time. Recent research deals with “subsurface” methods – e.g., confocal laser scanning microscopy and multiphoton microscopy – as they enable the evaluation of skin diseases and tumors at a cellular level, thus reducing skin biopsies. Many of these new exciting methods are presented elsewhere in this book.

During the past 25 years, 25 MHz sonography of the skin has become an accepted noninvasive imaging method in dermatology. Clinical applications are the preoperative determination of the extension of skin tumors (Hoffmann et al. 1992b; Fornage et al. 1993; Gropper et al. 1993; Harland et al. 1993; El Gammal et al. 1993; Gupta et al. 1996a; Desai et al. 2007), the monitoring of inflammatory lesions (Di Nardo et al. 1992; Stiller et al. 1994; Vaillant et al. 1994; Hoffmann et al. 1995; Gupta et al. 1996b) and sclerotic processes (Cole et al. 1981; Serup 1984; Myers et al. 1986; Akesson et al. 1986; Hoffmann et al. 1992a; Lévy et al. 1993; Ihn et al. 1995), and the objective judgment of skin tests, such as patch test reactions (Serup and Staberg 1987; Seidenari and di Nardo 1992; Seidenari 1995) and tuberculin test reaction (Beck et al. 1986), to name just a few.

Sonograms of the normal skin show, at their upper border, a thin, very echorich line, the

so-called *skin entry echo*. Beneath, a broad, echorich band with scattered reflexes is seen, which corresponds to the dermis (Fig. 2). The subcutaneous fatty tissue is echolucent and traversed by obliquely oriented echorich connective tissue septae. As the epidermis is echopoor it cannot be visualized, and certainly structures within the epidermis cannot be differentiated (El Gammal et al. 1993; Fornage et al. 1993) due to the lack of resolution of transducers with center frequencies below 20 MHz.

To investigate the epidermis, the resolution must be improved. The axial resolution is mainly influenced by the bandwidth (Fig. 3). The lateral resolution is proportional to the center frequency and indirectly proportional to the focal length (El Gammal et al. 1993, 1995, 1999, 2007). By raising the center frequency and in consequence the bandwidth of the ultrasound transducer, the resolution increases.

At the same time signal penetration depth into the skin is reduced (Fig. 4); a burden one has to accept in order to receive more detailed sonograms.

The 100 MHz transducer technology was modified in such a way that skin structures up to 2 mm depth can be visualized (Paßmann et al. 1989; Ermert et al. 1997; El Gammal et al. 1999) at a very high resolution (Fig. 2 inset).

Considering that dermatology includes *all structures* from the skin surface to the muscle fascia, lower frequencies are necessary to study deep skin structures.

Today 10–18 MHz sonography is used to evaluate the peripheral lymph nodes of patients with skin tumors (Beyer et al. 1982; Brockmann et al. 1985; Blum and Dill-Müller 1998, 1999; Dill-Müller and Maschke 2007).

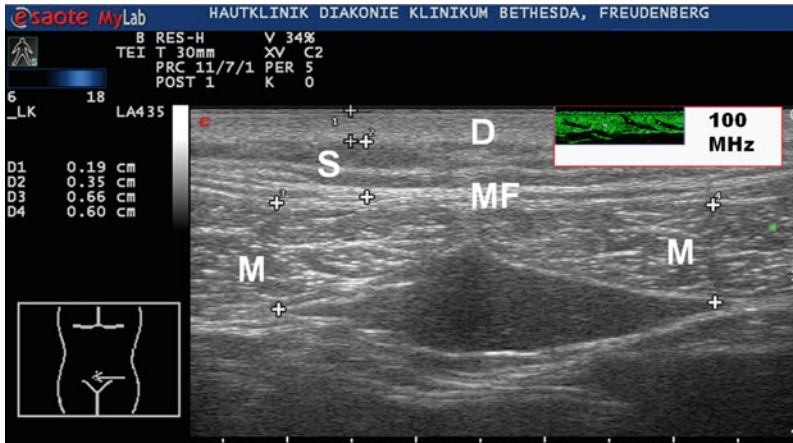

Fig. 2 Comparison of 15 MHz and 100 MHz sonography (*inset*). At 15 MHz the dermis is an ill-defined line at the upper part of sonogram due to insufficient resolution; at 100 MHz structures within the dermis are visualized (e.g.,

obliquely oriented hair follicles). *D* dermis, *S* subcutis, *MF* muscle fascia, *M* musculus rectus abdominis. The distance between two neighboring lines (*right border of 15 MHz picture*) is 5 mm

Fig. 3 Physical parameters influencing the axial and lateral resolution. The axial resolution is mainly influenced by the bandwidth of the transducer, the lateral resolution by the geometry of the transducer in the focus zone. The near and far field of the transducer bear multiple artifacts

Since 1995 “Sonography of the skin and subcutis (including the peripheral lymph nodes)” is part of the educational curriculum for dermatologists in Germany, a testimony that this method has become a routine diagnostic tool in dermatology.

2 Methods and Patients

To study the subcutis, an Esaote MyLaB60 ultrasound unit equipped with a 9–18 MHz linear array applicator was used. Ultrasound gel was used as coupling medium.

Examination of the dermis, epidermis, and stratum corneum was done with an experimental ultrasound imaging unit which can be operated with different transducers ranging from 20 to 250 MHz. Technical details have been published elsewhere (Ermert et al. 1997; Paßmann et al. 1989; El Gammal et al. 1995, 1999; Vogt et al. 2001; for transducer details see El Gammal et al. 2007).

A highly focused 100 MHz ceramic transducer (with a short depth in the focus zone of only 400 µm) with an excellent lateral resolution (Fig. 5b) was utilized. In order to obtain sharp sonograms not only from a stripe of 400 µm, but

Fig. 4 Center frequency and in-depth penetration of the ultrasound beam. The curves have been plotted down to 0.01 (1–40 dB) of the initial energy I_0 (100 %, 1.00). When the center frequency is raised (and thereby the axial resolution is improved), the in-depth penetration of the ultrasound beam decreases significantly

Fig. 5 (a) Usually long-focused transducer is used in mechanical scanners. The focal zone is defined by the focal width Fw and focal depth Fd . (b) To improve lateral resolution (Fw), we used a short-focused transducer. The

focal depth Fd is reduced to 400 μm . $Fw = 30 \mu\text{m}$. (c) B/D-Scan. The final sonogram is composed of several 400 μm wide image stripes, which are recorded one after the other, each in the focus zone of the transducer

from a wider part of the skin, we developed a mechanical focusing procedure, called Brightness/Depth-Scan (B/D-Scan; Fig. 5c). The principle of this method is to compose the sonogram of several 400 μm wide image stripes, which

are recorded one after the other, each in the focus zone of the transducer (Ermert et al. 1997; Paßmann et al. 1989). After the uppermost stripe is recorded by lateral movement of the transducer over the selected area, the transducer is moved

vertically 400 μm toward the skin surface before the next image stripe is recorded. To eliminate movement artifacts between adjacent stripes, the overlapping parts (near field and far field) are used for adjustment by the computer program, which puts together the final image.

Before we put the image stripes together, every single stripe was processed in two steps. First, the internal echoes of the 100 MHz transducer were eliminated. The oscillation curves of all neighboring A-scans of the image were averaged, and the mean oscillation curve was then subtracted from every single A-scan. Secondly, the A-scans were demodulated. The envelope curve was determined by two complex fast Fourier transformations for every A-scan. This procedure provides optimal results, but does not allow to promptly view the recorded data. For this purpose a fast method of demodulation consisting of a digital rectification of the high-frequency A-scan combined with a non-recursive digital filter of the order of ten was additionally implemented. This linear-phase filter has a passband cutoff frequency of 150 MHz.

2.1 Patients and Volunteers

All volunteers and patients gave informed consent for all examinations.

Healthy Palmar Skin: ten right-handed volunteers with healthy skin (five men and five women, age 29–76, mean 56.4) were investigated. The index fingertip of the left hand was occluded for 30 min with an emulsion using a Finn chamber.

Healthy Glabrous Skin: Sonograms were taken from volunteers with healthy skin (age 20–32, mean 24.1) on the abdomen about 3 cm lateral the umbilicus ($n = 8$), the upper back over the scapula ($n = 11$), the dorsal forearm ($n = 9$), and the calf ($n = 14$). Sonograms of the volar wrist at the transition from palmar to glabrous skin were recorded ($n > 4$).

Psoriasis Vulgaris and Lichen Planus: 35 untreated, infiltrated, and slightly scaly psoriatic lesions on the extremities of 18 patients with chronic plaque-type psoriasis vulgaris and ten

lichen planus papules of six patients were investigated. Sonograms were taken in the center and the margin of the lesions and in the surrounding normal skin.

Skin Tumors: Sonograms were taken from skin tumors (basal cell carcinoma, malignant melanoma, seborrheic keratosis, nevocellular nevi) and normal adjacent or contralateral skin. Then the tumors were excised for histology (see below). Only skin tumors with a poor subluminal infiltrate in histology were included in our study: a total of 27 superficial basal cell carcinomas, 13 malignant melanomas, 16 nevocellular nevi, and 11 seborrheic keratoses were evaluated using statistical methods.

2.2 Image Processing and Statistical Evaluation

Image analysis was performed using the program AnalySIS[®] (Soft Imaging Software GmbH, Münster, Germany). Structures of interest within the sonographic image (e.g., entry echo or echopoor band) were manually delimited by a polygon, using a position cursor. The mean diameter in y-axis (average length of all A-scans in the polygon) and the mean gray level of the polygon area (value between 0 (black) and 255 (white)) were calculated.

In every sonogram all structures of interest (thickness of the skin entry echo, echodensity of the skin entry echo, echodensity of the echopoor tumor area, echodensity of the subluminal region) were measured in the skin tumor region and in the adjacent or contralateral normal skin. Values were calculated as an index (% of the normal skin).

Finally, the *U*-test (Mann-Whitney-Wilcoxon) for unpaired observations was used to compare the parameters mentioned above. *P*-values of < 0.05 were considered significant.

2.3 Correlation with Histology

From 79 patients (psoriasis plaques: $n = 11$, lichen planus papules: $n = 6$, basal cell carcinoma: $n = 27$, malignant melanoma: $n = 13$, nevocellular

nevi: $n = 16$, seborrheic keratoses: $n = 6$) a biopsy was taken after sonography. In order to obtain exactly correlating sonographic and histological images, a 10 mm long line was painted on the skin in the plane of the B-scan. After local anesthesia of the area, the skin was cut along this line down to the subcutis. Then a spindle-shaped excision was performed with this cut in the center. The two halves of the tissue spindle were separated and their central cutting planes placed on cardboard, to prevent distortion of the tissue during formalin fixation.

In all histological sections, the thickness of the epidermis (from the stratum granulosum to the lowest points of the rete pegs) and the thickness of the inflammatory infiltrate (from the uppermost parts of the dermal papillae downward) were measured. Furthermore it was checked whether there is a significant correlation between the thickness measurements in sonographic images and the corresponding histologic sections by using linear regression analysis.

3 Results

3.1 Normal Glabrous Skin

Sonograms of normal skin show at their upper border a thin, very echogenic line, the so-called *skin entry echo*. The skin entry echo emerges due to an impedance jump at the intersection between the water (water is used as the coupling medium) and the waterpoor stratum corneum. The thin stratum corneum of glabrous skin obviously cannot be differentiated in 100 MHz sonograms. There is a tiny echopoor band (EPB) between the entry echo and the dermal reflexes. Below, a broad, echogenic band with scattered reflexes is seen, which corresponds to the dermis (Fig. 6). The subcutaneous fatty tissue is echolucent with obliquely oriented echogenic connective tissue septae.

The reticular dermis is visible as an echogenic zone with densely scattered, confluent echo reflexes. It is sharply demarcated from the very echopoor subcutaneous fat. Within the dermis,

hair follicle complexes are visible as homogeneous echopoor structures (Fig. 6). To find out which structures of the hair follicle complex can be visualized sonographically, “noninvasive” three-dimensional reconstructions were performed. The principles of three-dimensional reconstruction have extensively been discussed elsewhere (El Gammal et al. 1992, 1993). In Fig. 7a the sonograms of the left column are oriented perpendicular to the sonograms of the right column. The upper left sonogram shows a sharply delineated trifoliate echopoor structure at the dermis-subcutis interface. The middle left sonogram shows the hair follicle canal. The lower left sonogram exhibits an ill-defined structure in the dermis corresponding to the lobular structure of the sebaceous gland. The three-dimensional reconstruction (Fig. 7b) exhibits that the hair canal has an angle of 30° to the skin surface. The lobular structure of the sebaceous gland can be visualized. Using three-dimensional reconstructions, anagen follicles can be differentiated from telogen follicles (El Gammal et al. 1992).

3.2 Normal Palmar Skin

In 100 MHz sonograms of palmar skin, an echogenic entry echo is seen at the upper border (Fig. 8). Where the dermatoglyphics are crossly cut (which is mostly the case), the entry echo is wavy; in parts with longitudinally cut dermatoglyphics, it appears as a straight line. Below the entry echo, there is an echopoor band, which will be referred to as EPB 1 (echopoor band 1) in the following. Next comes an echogenic line, which runs parallel to the entry echo but is less intense (Figs. 8, 9, and 10). El Gammal et al. (1999) were able to show that the EPB 1 truly represents the stratum corneum by removing (tape stripping) and swelling (occlusion with petrolatum) of the horny layer.

Below the EPB 1, a second echopoor band is seen, which will be referred to as EPB 2 (echopoor band 2). Neither removal nor swelling of the horny layer changes its thickness significantly

Fig. 6 Hair follicles are represented as echopoor structures in the echorich dermis. **(a)** Thigh; * longitudinal section of hair follicles; *Inset*: correlating histology. **(b)** Thigh; * cross sections of hair follicles. *E* Skin entry echo, *D* dermis, *S* subcutaneous fatty tissue, *CT* connective tissue septae in the subcutis, *H* hair (cross sectioned). Distance between two graduation marks = 100 μ m

(El Gammal et al. 1999). The EPB 2 is separated from the EPB 1 by an echorich line. This line represents the interface between the waterpoor stratum corneum and the moist, living part of the epidermis. The lower border of the EPB 2 is defined by the scattered reflexes of the dermis (Figs. 8 and 9). This border is too straight to correspond to the undulating dermo-epidermal junction; it rather represents the interface between the papillary and reticular dermis.

In the EPB 1, twisted, echorich, about 100 μ m wide structures are seen, which cross the EPB 1 vertically. The distance between the two of

them is 800–950 μ m or a multiple. Each of them ends in a small dip on top of a dermatoglyphic crest (Fig. 9). These structures represent eccrine sweat gland ducts. In the EPB 2 they are rarely visible; in the echorich dermis, they cannot be detected either.

Figure 10 shows the transition from palmar to glabrous skin on the wrist: The upper and lower border of the EPB 1 (skin entry echo and echorich line below) merge into one echorich line in glabrous skin, so that the EPB 1 disappears. The thin stratum corneum of glabrous skin cannot be differentiated in 100 MHz sonograms. The EPB

2 remains as the only echopoor band between the entry echo and the dermal reflexes. While the thickness of the entry echo is similar to the one in palmar skin, the echopoor band (EPB) of glabrous skin is markedly thinner than on the palms.

On the lower extremities, it is thicker than on the trunk (El Gammal et al. 1999).

Concurrent with the sudden appearance of EPB 1, when moving from glabrous to ridged skin (palmar and plantar), the echogenicity of the

Fig. 7 Serial sections (a) and three-dimensional reconstruction of the hair follicle complex on the calf of a 23-year-old woman at 50 MHz. Voxel cube of 3,2 mm (thickness) \times 6 \times 6 mm. Sections were taken at 50 μ m intervals. (a) The sonograms of the left column are perpendicular to the sonograms of the right. *Left upper* sonogram: sharply delimited trifoliate echopoor structure at the dermis-subcutis interface. *Left middle* sonogram: hair follicle canal. *Left lower* sonogram: ill-defined lobular structure of the sebaceous gland. *Right* sonograms: longitudinal

section of the hair follicle. Note that the hair is slightly bent. (b) Three-dimensional reconstruction. The hair is oriented 30° to the skin surface. The hair can be seen in the middle of the hair canal (line reconstruction) and is invisible where it is more obliquely oriented (echo reflexes do not return to the transducer). The hair becomes visible again when it is oriented parallel to the skin surface. *Red* = lobular structure of the sebaceous gland. Distance between two graduation marks = 100 μ m (with permission from El Gammal et al. 1992)

dermis is reduced compared to the glabrous skin. This can be explained by the strong absorption of the ultrasound energy in the upper layers of the stratum corneum.

3.3 Inflammatory Skin Diseases

Psoriasis vulgaris: Compared to normal skin, lesions of psoriasis vulgaris exhibit distinct alterations of the upper dermis.

At the border of a psoriatic lesion, the echopoor band (EPB) of normal skin widens into a broad echopoor band. The thickness of this band correlates very well with the thickness of the acanthotic epidermis plus the dermis with the inflammatory infiltrate in the corresponding histology ($r = 0,94$). No significant correlation was observed between the thickness of the echopoor band and the epidermis respectively the infiltrated dermis

alone (El Gammal et al. 1999). The lower, quite straight border of EPB 2 is defined by the scattered reflexes of the dermis.

Furthermore, compared to normal skin distinct alterations of the entry echo are observed in psoriasis lesions. In untreated scaly plaques, several parallel, echorich lines are seen directly below the entry echo. They melt with the entry echo into an echorich band, which is significantly thicker than the entry echo in normal skin ($111 \pm 16 \mu\text{m}$, $n = 35$, $p < 0,001$) and has a much more irregular surface.

The following observations show that the described band with varying echodensities represents the hyperkeratotic horny layer: After the application of petrolatum under occlusion for 60 min on a hyperkeratotic psoriatic plaque, the thickness of the echopoor band (EPB) increases, and its echodensity markedly decreases. Repeated tape stripping of the scaly surface results in a gradual decrease of the thickness of the echorich

Fig. 8 Palmar side of the left index finger of a 30-year-old woman (distal phalanx) before (c) and after (d) 30 min occlusion of an emulsion. *W* water (coupling medium), *E* entry echo, *EPB 1* echopoor band 1, *EPB 2* echopoor band 2, *D* dermis. Distance between two graduation marks = 100 μm . *Insets*: photos of the finger before and after occlusion

band. When the scales are removed entirely, only a single echorich line remains.

In conclusion, the horny layer is echorich in untreated scaly psoriatic plaques; after treatment with petrolatum, its echodensity decreases. Furthermore the acanthotic epidermis and the dermis with the inflammatory infiltrate are represented as one single echopoor band (El Gammal et al. 1999, 2007).

Lichen planus: In lichen planus papules, the echopoor band (EPB) of normal glabrous skin focally widens into a spindle-shaped echopoor area. The maximal thickness of this band correlates well with the maximal thickness of the acanthotic epidermis and the dermal inflammatory

infiltrate in the corresponding histology ($r = 0,86$). Thick lichen planus papules (Fig. 11) often exhibit an echopoor line (EPB 1) beneath the skin entry echo (El Gammal et al. 1999).

3.4 Skin Tumors

To study whether the improved resolution at 100 MHz has an impact on visualization of skin tumor details, thin basal cell carcinoma were evaluated using image analysis. The correlation of sonograms and histology reveals that the tumor parenchyma and stroma seen histologically as separate structures (inset, Fig. 12) are summed

up to a uniform spindle-shaped echopoor area in the upper dermis in sonograms (Fig. 12). Tumor parenchyma and stroma are represented as one single echopoor area.

We further studied thin skin tumors (basal cell carcinoma, malignant melanoma, seborrheic keratosis, nevocellular nevi) using sonography and histology. Sonograms were evaluated by comparing the skin tumor region with the adjacent or contralateral normal skin (% change of the normal skin). Most parameters were not significant (Table 1). In seborrheic keratosis, the thickness of the skin entry echo was significantly increased. Furthermore in seborrheic keratosis, the mean

echo intensity of the subtumoral region correlated with the thickness of the skin entry echo ($r = 0.92$).

In all tumors, the echodensity of the echopoor tumor region (Table 2a) did not vary in a statistically significant way, save seborrheic keratosis versus nevocellular nevus ($p = 0.05$). The echodensity of the subtumoral area was significantly ($p < 0.01$) different for all tumors (Table 2b), save for malignant melanoma versus nevocellular nevus ($p < 0.05$).

It can be concluded that differentiation between skin tumors is not possible by studying the echodensity of the echopoor tumor region. On the other hand, the echodensity of the subtumoral

Fig. 11 Lichen planus papule on the thigh of a 65-year-old woman. In the middle of papule, an echopoor line (*) is seen between the skin entry echo and the echorich line beneath. Corresponding histology (*inset*) exhibits that this region has a significant hyperkeratosis. The histology

exhibits furthermore that the EPB 2 corresponds to the str. Malpighii and the inflammatory infiltrate in the upper dermis. EPB 2 echopoor band 2, D dermis. Distance between two graduation marks = 100 µm

Fig. 12 Basal cell carcinoma on the back of a 78-year-old woman. Corresponding histology (*inset*) reveals that tumor parenchyma and stroma (together 912 µm thick) are summed up to a spindle-shaped echopoor area (maximal thickness 770 µm) in the upper dermis of the sonogram. Distance between two graduation marks = 100 µm

Table 2 Evaluation of skin tumors, focusing on (a) the tumoral echopoor area and (b) the subtumoral region. (a) In all tumors, the echodensity of the echopoor tumor region does not vary in a statistically significant way, save SebK versus NCN ($p = 0.05$). (b) The subtumoral area is significantly ($p < 0.01$) different for all tumors, save for MM versus NCN ($p < 0.05$). *SebK* seborrheic keratosis, *MM* malignant melanoma, *Bas* basal cell carcinoma, *NCN* nevocellular nevus

(normal) dermis gives an *indirect hint* about the absorption characteristics of the tumor region: these findings suggest that the absorption of echo reflexes is significantly different for all examined pigmented skin tumors, save malignant melanoma versus nevocellular nevus.

4 Discussion

Dermatology deals with all skin structures from the skin surface to the muscle fascia. Therefore imaging tools to look beneath the skin are required. Sonography is a particularly interesting method, because it is noninvasive and harmless (no radiation) and can be repeated if necessary.

7.5–15 MHz sonography has become a common tool to study the subcutis and subcutaneous pathologies. Typical examples are connective tissue diseases, cellulite, blood vessel diseases, soft tissue tumors, and lymph node pathology (Blum and Dill-Müller 1998, 1999; Dill-Müller and Maschke 2007; El Gammal et al. 2007).

20 MHz sonography is used to study the dermis. Different pathological processes (virtually all skin tumors, inflammatory infiltrates, edema, scar tissue, elastosis) as well as skin appendages and large blood vessels are represented as echopoor areas (Altmeyer et al. 1992; El Gammal et al. 1993; Fornage et al. 1993) within the echorich dermis.

Our 100 MHz experimental sonography unit allows a far more detailed visualization of the upper skin layers as compared to 20 MHz sonography. Especially with regard to the *in vivo* assessment of the horny layer, 100 MHz sonography is a valuable tool. Whereas in normal glabrous skin the stratum corneum is too thin (Kligman 1964, about 12–15 μm ; Idson 1978, mean thickness of 15 μm for dry stratum corneum and 48 μm after hydration) to be separated from the entry echo, in the palmar skin and hyperkeratotic states, it is represented as a distinct band and its thickness can be easily determined. The results suggest that the echodensity of the horny layer depends on its water content: psoriatic scales,

appearing silvery because of the included air, are, for example, much more echogenic than the moist stratum corneum of the palms. The significant impedance gap between the stratum corneum and the Malpighian layer – visible as an echogenic line – can be explained by the different hydration states of these layers (El Gammal et al. 1999).

Today most authors agree that the skin entry echo is an artifact caused by the change in impedance between the coupling water and the horny layer (Querleux et al. 1988; Gniadecka et al. 1994; Hoffmann et al. 1994; Seidenari 1995). This hypothesis is confirmed by the presented results: the thickness and echodensity of the entry echo remain constant, no matter whether the horny layer is stripped, occluded with topical agents, or entirely removed (El Gammal et al. 1999). In most 20 MHz studies, the echo signal was strongly amplified to reach a high signal depth penetration. This however leads to a significant blurring of the entry echo. This effect as well as the low lateral resolution of only 200 μm entails that the entry echo is represented as a 100–250 μm thick, relatively homogeneous band at 20 MHz (Hoffmann et al. 1994). During image acquisition of the 100 MHz sonograms, the B/D-scan technology, which allows to select a specific amplification for each of the four to eight horizontal stripes, that compose the sonographic image was applied. An overamplification of the entry echo is thus avoided. Its thickness is about 80 μm and due to the excellent lateral resolution of 27 μm , it reflects even fine irregularities of the skin surface like the dermatoglyphics or the rough surface of psoriatic lesions.

In 20 MHz sonograms of normal glabrous skin, the dermal reflexes are directly adjacent to the entry echo; the viable epidermis, which is about 80 μm thick, cannot be visualized. At 100 MHz, the resolution is sufficient to show a thin echopoor band above the dermal reflexes in normal skin. Its thickness and its straight lower border suggest that it represents the viable epidermis together with the papillary dermis. At the transition from normal skin to a psoriatic plaque, this band widens into a 400–500 μm thick echolucent band. An echolucent band of comparable thickness has

also been observed in 20 MHz sonograms of psoriatic lesions (Di Nardo et al. 1992; Fornage et al. 1993; Hoffmann et al. 1995; Seidenari 1995; Stiller et al. 1994; Vaillant et al. 1994). Conflicting theories have been proposed regarding its nature. While some authors equate it with the sum of acanthosis and the upper dermis with the inflammatory infiltrate (Fornage et al. 1993; Murakami and Miki 1989; Hoffmann et al. 1995), others interpret it as a correlate of the papillary dermis (Di Nardo et al. 1992; Stiller et al. 1994; Vaillant et al. 1994). Our results favor the first hypothesis: comparison with the corresponding histology revealed an excellent correlation between the thickness of this band and the histometric thickness of the Malpighian layer plus the inflammatory infiltrate. Moreover, in 100 MHz sonograms, this echopoor band always shows fairly straight borders. If it represented the viable epidermis only, we would expect an undulating lower border; if it was the correlate of the papillary dermis, the upper border would be wavy, especially in psoriatic lesions where there are prominent rete pegs. The lateral resolution of the 100 MHz transducer is high enough to depict structures of this dimension, as the cross sections of the dermatoglyphics in the palmar skin demonstrate. We can conclude that both the viable epidermis and the infiltrated dermis are echopoor and cannot be differentiated from each other.

These reflections illustrate that it is not only a question of resolution, whether a structure is visualized sonographically. As the study shows, the resolution of 100 MHz sonography allows to detect structures as small as a sweat gland duct in the horny layer. On the other hand, the viable epidermis cannot be distinguished from the papillary dermis, and, as one has learnt by studying skin tumors, the stroma of basal cell carcinoma cannot be distinguished from the tumor cell nests (Fig. 12), and inflammatory infiltrate cannot be distinguished from the papillary dermis (Fig. 11).

How can this be explained? According to Fields and Dunn (1973), echoes are only reflected from the border between two tissues, when they have a different acoustic impedance at the applied frequency. Obviously, there is no difference in

impedance between the viable epidermis, fine fibrillary connective tissue of the papillary dermis, compact tumor masses and dense lymphocytic infiltrate at 100 MHz but only between these structures and the reticular dermis. These acoustic tissue properties basically remain similar at 20 MHz and higher frequencies.

An entirely exact correlation of histometry and sonometry cannot be expected as various artifacts influence the measurements in both methods:

- Histological processing leads to tissue shrinkage and fat dissolution. The originally compact stratum corneum is transformed into the characteristic basket-weave structure which does not correspond to in vivo anatomy.
- Sonographic examination requires water as the coupling medium which itself may lead to swelling of the horny layer. To be able to calculate distances, the tissue-specific ultrasound speed has to be known. In dermatological sonography, distance calculations from the echo signal time-lapse are usually based on the sound speed of the dermis (1580 m/s) (Alexander and Miller 1979; Beck et al. 1986). In the nail plate however, Finlay et al. (1987) found a sound speed of 2,140 m/s comparing 20 MHz sonography and thickness measurements by a micrometer screw. Jemec and Serup (1989) divided the nail into two compartments with different speeds, an upper dry one (3,103 m/s) and a lower humid inner one (2,125 m/s). A similar situation must be postulated for the stratum corneum which consists of keratin and has a low content of water thereby having similar properties to the upper nail compartment.

Inflammatory Processes. Inflammatory dermatoses such as psoriasis vulgaris, lichen planus, and acute or chronic dermatitis show a characteristic echolucent band beneath the skin entry echo. It represents the acanthosis of the epidermis and the dermal infiltrate. In other words, the sonography does not discriminate between the acanthotic epithelium and subepidermal inflammatory infiltrate (Table 3). Despite this problem, high-resolution sonography has proven to be an excellent non-

Table 3 Echopoor and echorich structures in high-resolution sonography

Echopoor	Echorich

^aArtifact due to the impedance jump between neighboring structures

invasive method to study and follow-up progression and regression of cutaneous inflammation during the treatment of inflammatory skin diseases.

Skin Tumors. Skin tumors can be well delineated, as long as they are confined to the echorich dermis. Nearly all skin tumors (of epithelial, melanocytic, angiomatous, or connective tissue origin) are echopoor. Exceptions are strong reflecting keratin inclusions, e.g., seborrheic keratosis and calcifications (calcinosis cutis).

Concerning skin tumor characterization, 50–100 MHz sonography was of little advantage in comparison to 20 MHz sonography: inflammatory infiltrate, tumor parenchyma, and stroma – they all were echopoor and looked alike (Table 3). As expected, the sonographic vertical thickness (the echopoor region comprises tumor and inflammatory infiltrate) of malignant melanoma was overestimated using 20 MHz (and to a lesser extent using 100 MHz) in comparison to histology (Gamblicher et al. 2007).

Differentiation between skin tumors was not possible when focusing on the echopoor tumor region (see Results). On the other hand, the echodensity of the subtumoral (normal) dermis gave an *indirect hint* about the absorption characteristics of the tumor region. This interesting finding has been confirmed by Harland et al. (2000).

Alterations of the dermal connective tissue. Both, the fibrosing of the dermis, e.g., in scars or in scleroderma, and the augmentation of elastotic material with simultaneous rarefaction of collagen in actinic elastosis lead to reduced echodensity sonographically; the dermis is represented darker. Since the tissue depth penetration at 20 MHz is up to 7 mm, thickened connective tissue structures in the dermis and the sclerosing process in the fatty tissue can be visualized in scleroderma. In different studies, it has been shown that progression and regression of scleroderma plaques can be quantitatively evaluated using sonography (Cole et al. 1981; Serup 1984; Akesson et al. 1986; Myers et al. 1986; Levy et al. 1993). Hoffmann et al. (1992b) found in 63 patients with morphea (circumscribed scleroderma) a mean increase of the thickness of the dermis of over 60 % in comparison to the contralateral healthy body side. In the inguinal region, where the healthy dermis is particularly thin, the dermal thickness increased significantly during the sclerosing phase (Hoffmann et al. 1992b).

1 Introduction

In daily dermatologic practice, skin tumors are a common cause of consultation. They are brought to the physician's attention by the patient, family members, friends, care takers, or other physicians. The appropriate therapeutic decision will have to be taken in each case: some tumors will be left untreated, some will be removed for cosmetic reasons, and others to relieve symptoms, and finally and most importantly, tumors will need to be treated for oncological reasons.

P. Pasquali (✉)
Dermatology Department, Pius Hospital de Valls, Valls,
Spain
e-mail: pasqualipaola@gmail.com

For those tumors in which an intervention decision has been taken, one will need to obtain as much information as possible. The more one knows about the tumor, the better the choice of a therapeutic method. The best treatment is the one done right from the beginning, avoiding recurrences and additional interventions.

A complete clinical and dermoscopic evaluation by a dermatologist can raise the sensitivity for diagnosis of malignant tumors as high as 98 % (Ahnlide and Bjellerup 2013); however, the clinical/dermoscopic diagnosis will benefit from the use of noninvasive imaging techniques (NIIT) which add, complement, change, or confirm the original diagnosis.

High-frequency ultrasound (HFUS/HRUS, high-resolution ultrasound, high-resolution echography) is one of such techniques (Wortsman 2012; Wortsman and Wortsman 2010). It allows

for a noninvasive evaluation of hidden parts of the tumor for further assessment and measurement (Pasquali et al. 2014; Hoffmann et al. 1989; Desai et al. 2007).

Some tumor characteristics that can be visualized by HFUS evaluation are the following:

- **Volume/Shape.** The knowledge of the volume of tumors can provide information on the nature of the tumor; for instance, most nodular basal cell carcinomas are roughly elliptical; invasive tumors show irregular shapes with indentations at the bottom; superficial basal cells are flat and elongated (Fig. 1). This knowledge helps in choosing the proper site for biopsy or helps in deciding the best tumor removal method.
- **Depth.** The knowledge of the depth of tumors helps decide the correct surgical technique. For

Fig. 1 Four tumors with different biological behavior and recognizable by HFUS. (a) Nodular BCC, tend to be elliptical; (b) superficial BCC, usually shallow lesions that can present themselves as isolated tumor islands, “pearl collar” array, or a thin and large tumor; (c) morpheiform BCC,

tend to show their expansive and invasive nature in the form of indentations visible at the bottom or sides; they tend to have irregular shapes; and (d) keratoacanthoma, round, elliptical, and very large tumors with a protruding (external) part

example, superficial BCC lesions can be diagnosed by clinical/dermoscopic (Argenziano et al. 2013) examination. Treatment options include cryosurgery, topical immunomodulators like imiquimod, photodynamic therapy (PDT), and curettage/electrocoagulation, among others. There is no need for costly or invasive techniques like Mohs micrographic surgery. The HFUS image of a superficial BCC shows a hypoechoic elliptical area(s) of less than 1 mm in depth. They can be an elongated and shallow, single small oval, or multiple pebble-like lesions (Fig. 2) connected by a shallow hypoechoic stream that reminds of a collar necklace. Individually, each island of tumor is less than a millimeter in depth. Lengthwise, they can be small (1–2 mm) but can also be quite big, requiring a segmental HFUS evaluation in order to cover the whole area. In general, the length/depth ratio is 6 to 1 (Pasquali et al. 2012a). HFUS allows determining if BCC is only superficial or if the apparently looking “superficial BCC” is in reality an admixture tumor, as it is the case of roughly one-third of all BCC (Sexton et al. 1990; Crowson 2006) (Fig. 3). The latter

is a common cause for treatment failure and recurrence that occur years later (Fig. 4). HFUS should be used to evaluate the entire tumor to note its depth in every point. The information obtained with the help of the HFUS technique is superior to a skin biopsy alone done “blindly” on the tumor (Kamyab-Hesari et al. 2012). Tumor visualization will be limited to certain dimension; for instance, with a 22 MHz TPM[®] equipment, depth determination is limited to 8 mm.

- **Length.** Some tumors have iceberg shape: they look small at the surface while the length underneath the surface is larger. This could be the cause of positive margins after surgery. Tumor visualization will be limited to certain dimension; for instance, with a 22 MHz TPM[®] equipment, length determination is limited to 13 mm.

A further use of HFUS is in an ex vivo setting (Petrella et al. 2010, 2012). Tumors are scanned once excised (surgery, shaving, or saucerization) in order to confirm total excision before sending the specimen to the pathologist. It is a noninvasive image that provides reassurance to the surgeon of having removed the tumor completely or

Fig. 2 The typical “pearl collar” image of a superficial BCC

Fig. 3 An admixture tumor showing one part nodular BCC (*red arrow*) and one part superficial BCC (*white arrow*)

Fig. 4 Patient with a recurrence of a BCC that had been treated 15 years before with E&C (electrocoagulation with curettage). The tumoral mass underneath the skin mimicked an infected cyst

the need to extend the surgical margins. This “pre-path” surgical margin analysis does not substitute the need for histological evaluation nor pretend to correspond to Mohs surgery margin evaluation. It does however reassure the surgeon in requiring a minimum extra effort that translates in a better management of tumors.

Cases in the present chapter come from a public hospital practice and therefore are mostly skin malignancies.

2 High-Frequency Ultrasound Versus Pathology Versus Dermoscopy: From Bidimensional to Tridimensional Imaging

For tumors with visible margins, clinical and dermoscopic evaluations give bidimensional information (length and width) of the lesion. Dermoscopy will further confirm or even allow making a diagnosis, better define tumor boundaries, and determine in many cases

histopathologic subtype (Lallas et al. 2014). With this information (bidimensional, coplanar), the area of the tumor (on the surface) can be obtained.

HFUS gives length, width, and depth (tridimensional information) as well as area and density. With a 22 MHz ultrasound equipment from TPM[®], one can reach up to 8 mm in depth with a

bandwidth that goes up to 28 MHz, enabling to see the epidermis and dermis with a resolution of over 72 μm. The maximum length/width is 12.8 mm lineal.

A correlation between ultrasound (HFUS), histologic, and dermoscopic (DMS) measurements has been determined by several authors

Fig. 5 Correlation of HFUS versus histology length (mm). The average length obtained from HFUS is greater than the histologic length

(Jovanovic and Pesic 2013; Crisan et al. 2013; Hinz et al. 2012; Nassiri-Kashani et al. 2013). In our personal series of BCCs, tumors' length was obtained from dermoscopy (superficial length), HFUS, and histology. We confirmed other author's observations that showed a correlation between HFUS length in relation to the one obtained on histopathologic specimen. We found a strong correlation between the HFUS and histologic lengths (Fig. 5). In addition, in 58/60 of cases, the average length obtained from the HFUS was greater than the histologic length (mean = 60.1 %, $r^2 = 0.66$).

As far as depth, measurement obtained by HFUS/HRUS in 49/61 cases was larger than the one obtained by histology, showing an average increase of 27 % and a moderately strong correlation ($r^2 = 0.65$). For larger tumors the percentage increase of HFUS/HRUS versus histology was smaller, but with a weak correlation ($r^2 = 0.29$).

A series of 24 BCCs dermoscopic, HFUS, and histologic lengths were compared, finding a clear relationship between them. Dermoscopic length was closer to HFUS and always larger than histology (Fig. 6). These results show that HFUS dimensions are closer to in situ tumor dimension.

3 Ex Vivo High-Frequency Ultrasound

Ex vivo HFUS is a simple and fast procedure where an ultrasound exam is performed on a surgical skin specimen removed by excision, shaving, or saucerization. The specimen is placed on gauze and covered with ultrasound gel. This evaluation helps visualize the whole tumor to confirm its complete removal. The HFUS probe should be placed over the specimen, maintaining the same position as in the presurgical HFUS. A previous mark in the skin along the longitudinal axis of tumor will help identify the correct position, especially for larger tumors.

In our series (Pasquali et al. 2012b) Pasquali et al. (In Press) of 62 patients, 74 tumors were measured both presurgically and ex vivo by HFUS before sending specimens for histologic examination (Fig. 7). In this group of tumors, only 12 were benign (1 foreign body, 2 dermatofibromas, 1 hamartoma, 5 intradermic nevi, 2 cysts, and 1 keloid) and the rest were malignant (58 BCC, 2 SCC, 1 atypical fibroxanthoma, and 1 hypertrophic actinic keratosis).

Fig. 6 Correlation between the dermoscopic, HFUS, and histologic length. The dermoscopic length was closer to the HFUS and always larger than the histologic length

Fig. 7 Presurgical HFUS (*top image*) and ex vivo HFUS (*bottom image*) of a nodular BCC on the shoulder

As far as the anatomical location, 47 cases (63.5 %) were in the head/neck, 14 (18.9 %) were located in the posterior thorax, 4 in the chest/abdomen (5.4 %), 3 in upper extremities (4.1 %), and 6 in lower extremities (8.1 %).

A positive correlation was found between the ex vivo versus presurgical HFUS measurements both in length and depth. This correlation was moderately strong ($r^2 = 0.681$) for length while strong ($r^2 = 0.876$) for depth.

Although with some volatility, both length measurements by HFUS (presurgical and ex vivo) are not very far apart from each other (5 % average difference), but when compared to histology, they are always larger (36.1 % average difference between histology and ex vivo HFUS). The relationship between the length measurements can be seen in Fig. 8.

As far as the depth, the average difference between histology and ex vivo is 21.7 %. The

Fig. 8 Comparison of lengths obtained from presurgical (red line) and ex vivo (blue line) HFUS and histology (green line). Histologic length is smaller than both HFUS readings

Fig. 9 Comparison of depths obtained from presurgical (red line) and ex vivo (blue line) HFUS and histology (green line)

relationship between the depth measurements can be seen in (Fig. 9).

The purpose of doing an ex vivo measurement is to visualize the total volume of tumor/margin. In addition to tumor’s surface area information,

HFUS evaluation can add value by providing the area of a longitudinal section. This can be obtained from HFUS by delimiting manually the tumor area (Figs. 10 and 11). The comparison of the areas obtained by presurgical and ex vivo

Fig. 10 Presurgical HFUS (*top image*) (area, 10.02 mm^2) and ex vivo HFUS (*bottom image*) (area, 10.20 mm^2) of a nodular BCC on the face

HFUS could give a better indication on the wholeness of removal. In the case of histology, an approximation can be done by using the area of an ellipse (area = $\pi * l * d$; l is length/2 and d is depth/2) and selecting those tumors of such shape such as nodular BCCs.

The correlation between both presurgical versus ex vivo HFUS areas and presurgical versus histology was strong ($r^2 = 0.794$ and $r^2 = 0.766$). The comparison between areas is shown in Fig. 12. On average, histology area is 32.9 % smaller than presurgical HFUS and 34.4 %

Fig. 11 Presurgical HFUS (*top image*) (area, 6.22 mm²) and ex vivo HFUS (*bottom image*) (area, 7.23 mm²) of an intradermal nevus on the face

smaller than ex vivo HFUS area. Ex vivo HFUS is 5 % larger than presurgery.

In 10/74 cases, the histology reported positive margins (3 benign lesions, 7 malignant lesions). Five out of seven malignant tumors were larger than 12 mm or deeper than 5 mm, leaving only 2/74 (2.7 %) tumors with positive histologic margins nonidentifiable by HFUS.

4 Conclusion

HFUS is a noninvasive technique that is affordable, versatile, and simple to utilize and learn. It is not time consuming in comparison to other NIIT and is readily accepted by patients. New generations of equipment are getting smaller to the point

Fig. 12 Comparison of the areas obtained from presurgical (red line) and ex vivo (blue line) HFUS and histology (green line). Histologic tumor areas tend to be smaller than both presurgical and ex vivo HFUS

of fitting in the palm of a hand, can be transported from one operating room to another, and costwise are less expensive than most NIIT. In spite of this, HFUS is still not as popular as other NIITs.

The information obtained from a HFUS of a tumor is extremely useful for therapeutic planning or as a follow-up method for nonsurgical treatment. Many errors that occur when managing skin tumors could be reduced if surgeons had more information on them. Undertreating tumors has oncological, cosmetic, and economic consequences; in overtreatment cosmetic and economic consequences can be an issue.

HFUS/HRUS on skin tumors helps evaluate size, shape, and volume. It is a technique that is simple to learn, versatile with low cost, and available. However, it does not give information at cellular level like confocal microscopy does.

As far as volume, HFUS measurements give a discrete overestimation of tumor's size probably due to the presence of inflammatory infiltrates in the area immediately surrounding the tumor. On the other end, there is always an underestimation on histology which is probably due to the retraction of the tissue/loss of skin tightness/dehydration due to fixation of preparation.

The ex vivo HFUS overestimation is probably due to infiltration of local anesthesia and fluids

from the surgical manipulation. Another consideration is specimen's orientation which can further introduce variations in measurements between HFUS and histology.

Comparison of HFUS/HRUS to histology dimensions gives valuable information to the surgeon. Histology reports do not reveal real tumor size and/or margins by underestimation. For a benign nevus excision, this is surely unimportant; however, in malignant tumors where margin excision has to follow specific guidelines, underestimation of tumor and free margins could appear as an incomplete excision and result in legal problems. Dermoscopy and HFUS give more accurate information on tumor dimension.

Ex vivo tumor measurements give surgeons reassurance of complete excision. Small tumors can just be saucerized or shaved, avoiding unnecessary surgery. Large admixture tumors can be removed surgically only on the deep parts, leaving the shallow areas for other less invasive forms of therapy.

HFUS/HRUS can be used to evaluate presurgical margins (Marmur et al. 2010). Ex vivo HFUS/HRUS could also be used to evaluate tumoral margins as well as to keep a record on the amount of the normal skin removed.

Additional clinical studies aimed to establish morphological differences between BCC subtypes and ex vivo margin correlation versus recurrences and broaden the spectrum to other malignant tumors are warranted.

1 Introduction

As skin is an external human body wrap, it is usually examined by the clinical senses of sight and touch. Its composition and structure were first analyzed using optical microscopy and then electron microscopy from biopsy samples. Noninvasive imaging techniques of the skin have been first developed to improve the diagnostic accuracy of skin tumors (Smith and Macneil 2011).

The thickness of the skin and its heterogeneity require a submillimetric spatial resolution. Actual noninvasive imaging techniques are high-resolution ultrasound (US), confocal microscopy, optical coherence tomography, and magnetic resonance imaging (MRI). High-frequency ultrasound (20–100 MHz) is easy to use, is cheap, and provides an excellent axial and lateral

resolution (Lassau et al. 2007; Querleux et al. 1988; Fornage et al. 1993). Its correlation coefficient with histology for thickness analysis of tumors is superior or equal to 0.95 (Fornage et al. 1993; Harland et al. 1993). But its field of view, focused on the epidermis and dermis, is smaller than MRI. Confocal microscopy and optical coherence tomography appear complementary rather rivals to MRI because their field of examination concern in particular the superficial layers of the skin: confocal microscopy solely allows the study of the epidermis (Corcuff et al. 1993; Rajadhyaksha et al. 1995; Masters et al. 1997), and coherence tomography does not allow in-depth exploration beyond the papillary dermis (Mordon 2002; Welzel 2004).

MRI of the skin is a recent imaging technique: Bittoun et al. (1990) and Richard et al. (1991, 1993) were the first to carry out MRI of the skin in the early 1990s. Although it is expensive, it offers many advantages. Because of its wider field of view than US, its spatial resolution under 100 μm , and its excellent contrast, MRI allows high-quality imaging of every skin layers.

In addition to morphological analysis, it is also able to study some physical and biochemical properties of the skin. The objectives of this article are to remind technical aspect of MRI of the skin, to describe the normal features of the skin, to discuss challenges in diagnosis of skin disorders, and to present the principal applications of MRI for the in vivo characterization of its biochemical properties.

2 Technical Constraints

The order of magnitude of the thickness of the hypodermis is centimeter. That of the dermis is millimeter, and that of the epidermis and stratum corneum is 100 μm . Hence, compared to other applications of MRI, spatial resolution must reach 100 μm in order to analyze skin layers. The quality of any examination is the result of a compromise between acquisition time, signal-to-noise ratio, and spatial resolution. In daily practice, the length of each sequence is limited to 6 min in order to avoid motion artifacts. The design of small receive-only surface coils (Denis et al. 2008; Hyde et al. 1987; Kwon Song et al. 1997) has enabled to increase spatial resolution thanks to small field of views (2–6 cm) (Fig. 1). Higher magnetic fields (Bittoun et al. 1990; Aubry et al. 2009; Barral et al. 2010) increase signal-to-noise ratio, thus improving contrast and spatial resolution. However, even if the power of magnetic field may be correlated with some technical artifacts, it has been shown that, although visible, they do not hinder the interpretation of the images (Aubry et al. 2009). In vivo using high-field MRI and small dedicated coils, Aubry et al. (2009) demonstrated the good quality of normal skin images with resolution of 87 μm on spin-echo T1-weighted images corresponding to a field of view that is less than 3 cm. Basic sequences are T1 weighted ($T1_w$) and T2 weighted ($T2_w$). Contrast-enhanced T1_w images may also be realized to study tumors (Pennasilico et al. 2002).

Fig. 1 Dedicated receive-only MRI coil. Its small diameter enables skin imaging with small field of view, aiming at increasing spatial resolution of images

3 Morphological Analysis of Normal Skin

The skin is composed of four main layers. Their MRI appearance is, from the surface to the deepest layer, as follows (Bittoun et al. 1990, 2006; Denis et al. 2008; Aubry et al. 2009) (Fig. 2):

- **The stratum corneum**

The outermost protective layer, the stratum corneum is mainly composed of dead keratinocytes. It is visualized only at the heel (Denis et al. 2008) and the fingertips (Mirrashed and Sharp 2004a; Stefanowska 2010) as a high-signal band separated from the living epidermis by a low-signal band.

- **The epidermis**

This layer is composed of keratinized stratified squamous epithelium. It appears as a thin superficial layer of high signal on T1_w and T2_w images.

- **The dermis**

Fibrous tissue rich in collagen, the dermis is subdivided into papillary and reticular dermis. It contains cutaneous appendages including the hair follicles, sweat glands, and pilosebaceous follicles. The dermis has a low signal, visible deep within the epidermis. Pilosebaceous follicles appear as fine oblique lines running parallel, seen as high-signal intensity structures. These lines come from the hypodermis, passing through the dermis and the epidermis.

In the face, on 3D fast imaging employing steady-state acquisition (FIESTA) images and

on T1_w images, the dermis can be subdivided into a superficial layer with higher-signal intensity and a deeper layer of lower signal (9) (Fig. 3). Richard (Richard et al. 1993) highlighted an increase in protonic density in the superficial dermis which is more significant among elderly people and could explain this MRI appearance. This may also correspond to the subepidermic hypoechoic band described on US images (Sandby-Moller and Wulf 2004), but its exact meaning remains to be found.

- **The hypodermis**

The hypodermis is mainly composed of fat. It is sometimes considered part of the skin and sometimes as subcutaneous tissue (Bittoun et al. 2006; James 2006; Kim et al. 2008). This deepest layer of the skin is easily identified on MRI because of its considerably high signal on T1_w and T2_w images with fatty expansions in the deeper part of the dermis. The interlobular septum and its vessels determine the lobules and are characteristically low-signal intensity structures within the hypodermis.

Variations of normal MRI appearance of the skin depending on studied localization have to be known in order not to be misdiagnosed as abnormal: normal visualization of thick stratum corneum of the heel (Denis et al. 2008) and normal visualization of two sublayers within the dermis of the face (Aubry et al. 2009) (Fig. 3). Variations of the thickness of the dermis and epidermis depending on localization are also known (Fig. 4).

Fig. 2 T1_w image of normal skin of the calf. The epidermis (*white arrow*) is a thin superficial line of high signal. The underlying dermis has a low signal, crossed by thin lines corresponding to pilosebaceous follicles (*white arrowhead*). The hypodermis has a high signal due to its high amount of fat. Within the hypodermis, *thin* low-signal lines correspond to interlobar septa (*black arrow*)

Fig. 3 At the face, on this T1_w image, a superficial band of high-signal (*white arrows*) contrasts with a low-signal band at the deep aspect of the dermis (*white arrowhead*)

Fig. 4 The dermis of the back (*left, white arrowhead*) is thicker than that of the foot (*right*). On the other hand, at the sole, the epidermis (*white arrow*) appears to be thicker. We can also notice the extremely dense connective tissue within the hypodermis of the soles (*black arrow*)

4 MRI of Skin Disorders

Among all noninvasive skin imaging methods, ultrasound was the first to demonstrate an excellent correlation between image-derived skin thickness and histological measurements (Edwards et al. 1989); in fact the usefulness of US was demonstrated in the preoperative prediction of melanocytic tumor thickness and its effectiveness in differentiating between tumors ≤ 1 mm and those >1 mm (Hayashi et al. 2009; Vilana et al. 2009).

The remarkable anatomic detail and contrast obtained on MRI images has been used to generate in vivo 3D representations of skin pathologies such as nevi, acne, psoriasis, scleroderma, etc.

(Sans et al.), although such images are not required for the diagnosis of these pathologies. In most clinical applications, the aim of MRI is to differentiate the different kinds of skin tumor and to estimate their extent before surgery in the case where surgical resection should be minimized in the example of facial tumor. It is also a help to diagnosis, localization, and delineation of some tumors that may be difficult to detect because of their topography, such as subungual glomus tumors. It also allows determining the degree of invasion of malignant tumors within deeper soft tissues and to measure their size and thickness. A review published in 2008 (Kim et al. 2008) aimed at listing the MRI features of most common aspects of several benign and malignant skin tumors.

4.1 Dermatofibrosarcoma Protuberans

This uncommon spindle cell tumor that typically develops in the dermis as an outward protruding mass is considered to be an intermediate-grade lesion. These lesions are typically within the dermis but can extend freely over the hypodermis and deeper, so leading sometimes to confusions with higher-grade sarcomas. Its most frequent localization is the trunk, accounting for almost half of all cases. Dermatofibrosarcoma protuberans has an excellent prognosis after complete resection but has a marked tendency to recur locally if inadequate surgical resection margins are obtained, which underlines the interest of MRI to delineate it.

On MR imaging the tumor appears as a well-defined lesion with a low signal on T1_w images and a high signal on T2_w images and usually is enhanced more strongly than other skin tumors on contrast-enhanced T1_w images (Fig. 5). Occasionally hemorrhages occur in this tumor which results in a heterogeneous appearance on MR images (Torreggiani et al. 2002; Kransdorf and Meis-Kindblom 1994).

4.2 Glomus Tumor

Glomus tumor is a rare benign tumor that develops from neuromyoarterial glomus body which consists of an afferent arteriole, a tortuous arteriovenous, a system of collecting veins, and a

neurovascular reticulum that regulates the flow of blood through the anastomosis. Glomus bodies are present in the stratum reticularis of the dermis throughout the body, but they are highly concentrated in the digits, palms, and soles of the feet. They may be difficult to detect when subungueal hence the interest of MRI (Bittoun et al. 2006; Goettmann et al. 1994; Drape et al. 1996).

MR imaging features that are considered diagnostic for glomus tumors include intermediate- or low-signal intensity on T1_w images, marked high signal on T2_w images, and strong enhancement after IV gadolinium infusion. Typical MR angiographic findings include areas of strong enhancement in the arterial phase and tumor blush, which increases in size in the delayed phase (Baek et al. 2010) (Fig. 6).

4.3 Malignant Melanoma

Most melanomas apparently arise de novo, but some develop in association with a preexisting nevus. Melanoma and pigmented tumors were first explored because the melanin pigments are paramagnetic and induce a shortening of T1 and T2 relaxation times (Zemtsov et al. 1989). Therefore, the expected signal for melanotic melanoma is high signal on T1_w images and low signal on T2_w images (Hawnaur et al. 1996; Marghoob et al. 2003). MRI may be used to measure the thickness and depth extension of melanomas and their volume and vascularization (Marghoob et al. 2003; Psaty and Halpern 2009). In a small

Fig. 5 MRI of a dermatofibrosarcoma. It has a slightly higher signal than the normal dermis on T1_w image (left). On fat-saturated contrast-enhanced T1_w image (right), this epidermal and dermal lesion (between white arrows) presents a strong enhancement and invades the hypodermis (white arrowhead) to a depth of 6 mm

Fig. 6 This glomus tumor of the fourth finger appears as high-signal ovoid image of 3 mm diameter on proton density fat-saturated coronal image (*left, white arrow*). It

is strongly enhanced on angiographic contrast-enhanced sequence (*right, white arrowhead*)

sample containing two melanomas, Ono et al. (Ono and Kaneko 1995) found a good correlation between the morphology and in-depth invasion of skin tumors in MRI with histological data.

4.4 Keratinocytic Skin Tumors

Keratinocytic skin tumors are derived from epidermal and keratinocytes of appendages, mainly including basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). They account for approximately 90 % of all skin malignancies, and their incidence has increased rapidly in the past few years (Miller 2000). In vitro, using 7 Tesla MRI, (Aubry et al. 2012) have shown a good correlation between MRI and histologic measurements of nonmelanoma skin cancer (Fig. 7), but these results remain difficult to transpose to clinical routine because of time of acquisition and cost problems. Basal cell carcinoma, the most frequent, is a slow-growing tumor, mostly local, which rarely metastasize. Gufler et al. (2007) on seven cases of basal cell carcinoma of the face in 1.5 T MRI confirmed the usefulness of MRI to determine the extent of

these tumors compared to adjacent soft tissues and the level in depth of tumor infiltration and to exclude a possible bone involvement.

Keratinocytic skin tumors have nonspecific signal intensity patterns, with high-signal intensity on T2_w images, with relatively homogeneous enhancement after IV gadolinium chelates infusion. SCC may also be heterogeneous and include unenhanced region on the contrast-enhanced T1_w images (Kim et al. 2008).

4.5 Benign Fibrous Histiocytoma

This is a very frequent tumor, located preferentially in the dermis where it is called histiocytoma cutis or dermatofibroma. These tumors arise most frequently between the second and the fourth decade and are mainly located at the extremities (Gonzalez and Duarte 1982).

On MR imaging the tumor appears as low to intermediate signal on T1w images and low- to high-signal intensity on fluid-sensitive MR sequences (Fig. 8). Occasionally hemorrhages occur in this tumor which results in a heterogeneous appearance on MR images (Kransdorf 2006).

Fig. 7 Postoperative photograph of an ulcerated squamous cell carcinoma of the scalp (*left*). In vitro 7 Tesla $T2_W$ image through short axis of the tumor reveals that it invades the whole thickness of the sample: surgical

margins were confirmed by pathologist to be positive. Contrast between the tumor and the skin is good enough to measure it accurately

5 Parametric Analysis of Biochemical Parameters of the Skin

5.1 T1 and T2 Relaxation Time and Proton Density

Compared to other imaging modalities, MRI has the particularity to capture a signal depending on the intrinsic parameters of the tissue: it provides information on the characteristics of water in the skin, through measurements of the relaxation times T_1 , T_2 , and proton density which reflect mobile water and lipid levels in the different skin layers (Richard et al. 1991; Querleux 2001). At the calf, T_2 relaxation times have been estimated to 22.3 ± 7 ms for the epidermis, 13 ± 2.4 ms for the dermis, and 35.4 ± 3.6 ms for the hypodermis (Richard et al. 1991). Richard et al. (1993) demonstrated that the level of mobile water is twice as high in the epidermis than in the dermis, whatever the age of the subject. This quantitative measurement of the level of mobile water has also been used to calculate the hydration in the field of cosmetology. Recent changes in European

directives require manufacturers to prove the effectiveness of cosmetics leading to researches in this field of skin hydration. Querleux et al. (1994) studied the hydration of the stratum corneum at the heel. Aubry et al. (Calzolari 2013) recently tried to estimate the T_2 relaxation time and proton density of the dermis before and after applying moisturizer using the T_2 -mapping sequence (Fig. 9). Researchers also tried to distinguish benign versus malignant-pigmented skin cancer by measuring the relaxation times and T_2 signal of lesions (Takahashi and Kohda 1992) (Fig. 8).

5.2 Magnetization Transfer

This property can be used in MRI to quantify mobile water of the different skin layers (Bittoun et al. 2006; Mirrashed and Sharp 2004a). A study published in 2004 showed a percentage of magnetization transfer activity in the dermis lower than the epidermis. Authors also observed a higher percentage of magnetization transfer activity in the papillary dermis compared to the reticular dermis (Mirrashed and Sharp 2004b).

Fig. 8 T1_w image of a histiocytoma. It has a slightly higher signal than the normal dermis (a). It invades the hypodermis to a depth of 7.8 mm. On T2 mapping

(b), its T2 relaxation time is longer than the normal dermis (54–59 ms vs. 44 ms)

Fig. 9 T2-mapping image of a normal dermis of the calf. The T2 relaxation time of the dermis may be calculated with this sequence. This parameter may be useful for quantitative evaluation of cosmetics or for characterization of skin lesions

5.3 Water Diffusion Coefficient

Diffusion-weighted images give information on the microscopic movements of water in the skin. It is widely used in neuroradiology to detect early signs of ischemic stroke. Several studies have been conducted reporting a possible use of this sequence to quantify the mobility of free water in the skin with possible applications in the future to study the mechanisms of skin barrier function of the living epidermis healthy and pathological (Bittoun et al. 2006; Kinsey et al. 1997; McDonald et al. 2005; Lee et al. 1998).

5.4 Spectroscopy

MR spectroscopy of the skin is recent and remains a research activity. Studies conducted have focused on normal skin and hydration profile and feasibility of this technique (Querleux 2004; Weis et al. 2001). Several methods aim to obtain separate images and information of different molecules (water, lipids). The majority of researches have been done with phosphorous spectroscopy (Chen et al. 1992; Zemtsov et al. 1994; Collier et al. 1994) and very few with proton spectroscopy (Kim et al. 1989).

6 Conclusion

MRI is a noninvasive, non-radiating imaging modality that is also reproducible and non-operator dependent. Its good spatial resolution and contrast allow imaging of the different skin layers. Even if in clinical daily practice its spatial resolution is not sufficient for optimal analysis of the epidermis and very thin lesions, this imaging technique is distinguished from others by its holistic approach of the skin. Numerous studies have validated its feasibility and its interest to study the normal and pathological skin. MRI seems able to play a useful role in the diagnosis and surgical assessment of particular cases of tumors. In addition, biochemical parameters evaluated by MRI are also promising to evaluate skin physiology, skin hydration, and effects of cosmetic products.

1 Introduction

The most common use of optical absorption spectroscopy is the quantification of substances in chemical systems. This application requires a homogeneous distribution of the absorbing substances, which results in a linear correlation between the spectroscopic data and the amount of the absorber under discussion (Beer-Lambert law). The measured overall signal is reduced if there are areas of different concentration or areas that are not covered with absorbing substances inside the examined area. For this reason, spectroscopy is suitable for determining the degree of inhomogeneity in the distribution of absorbers.

The surface of the human skin is characterized by specific structures, which differ individually. As furrows, wrinkles, hair follicles, sweat glands, dermal lesions, and the corneocytes (Schaefer and Redelmeier 1996; Fritsch 2004) form a typical surface character (Helfrich et al. 2008; Krutmann et al. 2008), topically applied formulations are distributed inhomogeneously. This

refers to cosmetic products generally and is of special interest considering in terms of sunscreens.

The protection efficacy of sunscreens is primarily determined by specific filter substances, which are included in these products. A given filter concentration results in a defined lowering of the radiation intensity by the absorbing species. This effect is reduced if the homogenous distribution is disturbed by the typical surface relief that reduces the protection efficacy of sunscreens (Jain et al. 2010; Rohr et al. 2010; Schroeder et al. 2010). A characterization of these changes can be achieved to determine a spectroscopically measured factor of inhomogeneity by comparing the absorbance measured for the applied sunscreen with the value of the identical amount of absorbers spread homogeneously. This value is well suited to quantify the filter distribution of topically applied substances on the surface of the human skin and to investigate the influence of different parameters (Weigmann et al. 2012a).

2 Materials and Methods

2.1 Volunteers

The study was conducted with 18 healthy volunteers (skin phototypes II and III (Fitzpatrick et al. 1993)), which were aged between 20 and 35 years. The volunteers had provided their written informed consent in agreement with the ethical approval obtained from the Ethics Committee of the Charité – Universitätsmedizin Berlin.

2.2 Applied Formulations

The investigation was realized using five different sunscreen formulations, COLIPA low standard product P1 (SPF 4), CTFA high standard product P2 (SPF 12), high standard product P3 (SPF 15.5) (COLIPA 1994), and commercial products, NIVEA Sun Sonnenmilch, SPF 8 and NIVEA

Sun Feuchtigkeits-Sonnenmilch, SPF 26, which were applied onto the flexor forearm (2.0 mg/cm^2) (COLIPA 1994).

2.3 Tape Stripping

Tape stripping was performed 30 min after application using the standard protocol (Lademann et al. 2009; Weigmann et al. 1999). The adhesive film (*tesa* film No. 5529; Beiersdorf, Hamburg, Germany) was pressed onto the skin with a stamp for 5 s (pressure: 15 kp/cm^2) and then removed in one rapid movement.

2.4 UV/Visible Spectroscopic Measurements

The spectra were recorded in a range from 240 to 500 nm, using the UV/visible spectrometer (Lambda 5, PerkinElmer, Frankfurt/Main, Germany) with an integrating sphere. The extinction in the maximum of the UVB absorption bands was used as reference quantity.

2.4.1 Tape Strips

The original spectra measured with an empty tape as a reference were corrected by the spectra obtained from an untreated skin site using the software UV WinLab Version 2.70.01 (PerkinElmer), in order to eliminate the influence of the individual horny layer particles. Foregoing investigations (data not shown) indicated that the first tape strips reflect the degree of inhomogeneity most effectively.

2.4.2 Solutions

The absorbance values, characterizing the homogenous distribution of the absorbers, were determined after solving a definite part of the immediately measured tape strips in an adequate amount of ethanol (UVASOL; Merck, Darmstadt, Germany) and a subsequent separation from the horny layer particles by centrifugation (centrifuge MR 1812; Jouan GmbH, Unterhaching, Germany).

2.5 In Vivo Laser Scanning Microscopy

Laser scanning microscopy (VivaScope 1500 Multilaser, MAVIG GmbH München) with sodium fluorescein as marker substance was used to compare the distribution of topically applied substances on the human skin and on the tape strips immediately after stripping.

3 Results and Discussion

3.1 Illustration of the Distribution of Topically Applied Absorbers

The results obtained regarding the local distribution of topically applied substances using laser scanning microscopy are shown in Fig. 1.

The in vivo distribution of the fluorescent dye fluorescein on the skin (image a) is compared with the distribution found on tape strips immediately after their removal (image b). In both cases, the dye is concentrated around the corneocytes in the inter-lipid phase of the skin, illustrating one type of an inhomogeneous distribution pattern. The agreement found for the distribution in both

samples verifies that the situation on the skin surface is correctly transferred to the tape strips. Therefore, the spectroscopic data determined after tape stripping should be suitable to quantify the degree of the inhomogeneity of topically applied substances on the skin.

3.2 Definition of a Factor of Inhomogeneity

The homogeneity of the distribution of topically applied formulations on the skin is not only influenced by the individual surface profile but additionally by the composition of the specific sunscreen.

3.2.1 Variation of the Volunteer-Specific Absorbance Values

The homogeneous absorbance in solution (A_{hom}) is compared with the absorbance found for the tape strips, reflecting the in vivo efficacy of the absorber in the investigated skin area (A_{inhom}). The results obtained for one model formulation (COLIPA P1) for six volunteers are shown in Fig. 2.

The actual absorbance measured in solution (A_{hom}) was determined by the concrete amount of

Fig. 1 Distribution of a fluorescent substance (sodium fluorescein) added to a topically applied sunscreen on the human skin. (a) Measured in vivo. (b) Measured in vitro on a tape strip that was removed from a corresponding skin site

Fig. 2 Comparison of the absorbance measured for the model sunscreen COLIPA P1 (first tape strips of six volunteers). A_{inhom} absorbance on tape strips immediately after removal. A_{hom} absorbance in solution obtained after extraction of the tape strips

absorbing substances present in the investigated skin area. In three experiments, the corresponding value was nearly constant ($A_{\text{hom}} = 1.7$), according to identical amounts. Moreover, two data points were clearly different, verifying the well-known situation that the distribution inside the skin area under investigation is nonuniform.

The broad variation of the absorbance ($A_{\text{inhom}} = 0.4\text{--}0.62$) measured for the corresponding tape strips reflected the individual differences in the individual skin profiles of the three volunteers with nearly constant $A_{\text{hom}} = 1.7$. Both results illustrated the information provided by the spectroscopic data. Similar results were obtained for the other sunscreens under investigation.

3.2.2 Determination of the Factor of Inhomogeneity

The difference of the discussed spectroscopic values, i.e., the absorbance measured for the absolute amount of absorber, A_{hom} , and the profile-correlated spectroscopic data obtained from the tape strips, A_{inhom} , reflects the skin-specific distribution of the absorbers. Calculating the quotient between both values enables the definition of a factor of inhomogeneity:

$$F_{\text{inhom}} = A_{\text{hom}}/A_{\text{inhom}}.$$

In order to test the applicability of the obtained factors, the parameter influences must be considered.

3.3 Parameters Influencing the Factor of Inhomogeneity

3.3.1 Influence of Different Volunteers and Formulations

Discussing the parameter dependence of the proposed measured value, the range of variation found for the different volunteers and formulations must be considered. In Table 1, the obtained results are summarized.

The formulation-correlated mean values of the factors of inhomogeneity were the basis for obtaining information regarding the sunscreen-related changes in the distribution and the influences of the different volunteers.

The sunscreen-correlated values varied from $F_{\text{inhom}} = 3.9$ to 11.9. The mean value of all sunscreens amounted to $F_{\text{inhom}} = 8.3$, which corresponded to a standard deviation of 40 % for these data. This value described to what extent the investigated sunscreens change the inhomogeneity of the distribution. The reference to the mean values eliminated the influences of the different skin profiles of the volunteers.

The variation found for the individual volunteers is provided by the factors of inhomogeneity, which are summarized in the upper part of column 2–6. Considering the mean value of these standard deviations in percent amounted to 1.9, which corresponded to an overall value of 23 %.

The comparison of the two percentage values, 40 % and 23 %, indicated that the factors of

Table 1 Variation of the factor of inhomogeneity found for different volunteers and different formulations

Volunteer	Factor of inhomogeneity				
	individual values for the different volunteers				
	COLIPA P1 SPF 4	COLIPA P2 SPF 12	COLIPA P3 SPF 15.5	Sunscreen SPF 8	Sunscreen SPF 26
1	2.7	8.8	8.0	4.4	13.8
2	5.5	14.5	8.7	7.6	14.6
3	4.3	8.9	7.5	7.9	7.9
4	4.6	10.7	9.3	6.0	9.4
5	3.4	16.2	10.4	5.2	9.3
6	2.8	12.2	9.3	4.8	10.0
F_{inhom} mean value \pm standard deviation (in percent)	3.9 ± 1.0 (26 %)	11.9 ± 3.0 (25 %)	9.0 ± 1.5 (15 %)	6.0 ± 1.5 (25 %)	10.8 ± 2.7 (25 %)

Overall mean value for the five formulations (3.9–11.9): $F_{\text{inhom}} = 8.3$, corresponding to a standard deviation of 40 %
Mean value of the standard deviations of the six volunteers (1.0–3.0) = 1.9 corresponding to a standard deviation of 23 %

inhomogeneity were influenced more strongly by the investigated formulations than by the individual skin structures of the volunteers.

3.3.2 Influence of Skin Pretreatment

An essential aspect for studying the distribution of absorbers on the skin surface was the correlation to the efficacy of sunscreens. From earlier investigations it is known that the inhomogeneous distribution reduced the protection by a factor of 10 (Lademann et al. 2004). On the contrary, a higher homogeneity enhances the protection. In a previously published study (Weigmann et al. 2012b), the influence of a pretreatment of the skin with a body lotion on the distribution of a sunscreen with SPF 8 was investigated. In the considered system, the factor of inhomogeneity evidently reflected the upgrade achieved by the pretreatment. The value $A_{\text{inhom}} = 11.5$ had dropped to $A_{\text{inhom}} = 6.5$ after pretreatment. Conformity was obtained, taking into account the enhancement of another spectroscopic value that characterizes the increased absorption of the incident sun radiation, the sum absorbance. This value increases after body lotion application.

Nevertheless, another study showed that a pretreatment led to a faster removal of the applied sunscreens from the skin during contact with water (Klusckke et al. 2014).

3.3.3 Comparison of the Factor of Inhomogeneity with the Optically Determined Volume of Furrows Characterizing the Skin Profile

The importance of the proposed factor of inhomogeneity was evaluated by comparing the results obtained by spectroscopy with data measured by another optical method (Gebauer et al. 2012). Using this technique, the skin profile was characterized directly by a specific optical three-dimensional measuring system that determines the characteristics of surfaces, taking into account the volume between the highest and the lowest points of the skin relief.

When these data were compared to the spectroscopic values, taking into account the three sunscreens, linear correlations were obtained at a statistical significance of $p \leq 0.01$ and a correlation coefficient of 0.98, 0.67, and 0.66, respectively. The reduced coefficients reflect different changes that were due to an individual modification of the skin surface following topical application of the sunscreen.

This compilation shows that the factor of inhomogeneity is not only well suited to recognize and to optimize the distribution of topically applied substances but also reflects correctly differences in the surface profile of the human skin.

4 Conclusion

The typical structure of the human skin influences the distribution of topically applied sunscreens characteristically. The resulting inhomogeneity determines the spectroscopic absorbance measured for tape strips after removal, A_{inhom} . The calculation of a quotient, taking into account the corresponding absorbance values obtained after extraction of the removed tape strips (A_{hom}), resulted in a factor of inhomogeneity: $F_{inhom} = A_{hom}/A_{inhom}$. Comparing the variation of the results obtained for different volunteers and sunscreens, it was found that the influence of the different formulations was higher than the volunteer-correlated data. The relevance of the factor of inhomogeneity was verified by results which were obtained by considering the influence a pretreatment of the skin before sunscreen application and by the good correlation found to the volume of furrows and wrinkles obtained by an independent method.

1 Background

Optical coherence tomography (OCT) is a non-invasive optical imaging technology routinely used in ophthalmology for retinal imaging. OCT has gained a prominent position in ophthalmological routine imaging since the 1990s (Huang et al. 1991; Swanson et al. 1993). The technology also has the potential to provide high-resolution images of other tissues such as the skin where it not only allows bedside in vivo diagnosis but also the noninvasive monitoring of lesional evolution or treatment. The OCT images are primarily displayed in a vertical view similar to ultrasound imaging. Compared to ultrasound, OCT images have a higher resolution albeit a lower penetration depth. Horizontal OCT

imaging akin to *in vivo* confocal microscopy is also possible. During the last 10–15 years, the OCT technique has been improved for skin imaging, reflecting both development in data processing and in optics.

2 Method and Basic Principles

OCT is an interferometric imaging technique that enables noninvasive, real-time, high-resolution, cross-sectional imaging *in vivo*. It works by detecting reflected and backscattered light from the tissue.

The images can either be two- or three-dimensional with a lateral resolution of $<7.5 \mu\text{m}$ and axial resolution of $<5 \mu\text{m}$. The images can roughly be compared to histological morphology at a low resolution, but imaging of individual cells is not possible. The one-dimensional depth scan is called an A-scan, and many adjacent A-scans can be combined to thereby create a 2D or 3D image that provides more information about the specific sample.

When analyzing OCT images qualitatively, several types of reflectivity and scattering are relevant. Areas appearing white appear so due to reflection, whereas areas appearing black are sites of absorbing tissue. In normal skin, fluid and air are hyporeflexive/absorbing media and therefore appear dark or even completely black. Areas with dense keratin or collagen are hyperreflective areas appearing bright.

High-definition OCT (HD-OCT) is a novel technique based on the principle of conventional OCT. During the past 2 years, several conducted studies have reported HD-OCT to have an improved resolution and with the possibility of imaging single cells which however comes with a diminished penetration depth. HD-OCT has been compared to reflectance confocal microscopy (RCM) (Boone et al. 2012a) in normal skin reporting that RCM offers the best lateral resolution, whereas HD-OCT provides the best penetration depth suggesting that HD-OCT fills the imaging gap between RCM and conventional OCT.

3 How to Use the OCT

OCT imaging is generally straightforward. All the commercial OCT systems come with a handheld probe. Most of the probes are in the size range of a standard cordless phone. This sometimes makes OCT imaging inside the ear and around the medial canthus difficult. The recording of an image ranging 6 mm takes a few seconds. Hundreds of images can be saved during a single OCT scan.

4 Applications in Dermatology

OCT imaging in dermatology has significantly advanced during the last decade (Gambichler et al. 2005; Olsen et al. 2015). Several clinical studies have found advantageous use of OCT in diagnosis of inflammatory skin conditions, wound healing, non-melanoma skin tumors, and blistering diseases, among others.

Skin biopsies are currently the gold standard for diagnosing a large number of dermatological diseases especially the non-melanoma skin cancers. Since biopsies are easily acquired, precise, and low cost, they constitute a tough competition to the introduction of any new imaging technologies in dermatology. However, in relation to non-melanoma skin cancer, there are several factors speaking in favor of noninvasive diagnosing.

First and foremost, noninvasive techniques, such as OCT, provide a nontraumatic and non-scarring aid to diagnosis which can be performed bedside and be repeated over time to monitor potential recurrence of an already diagnosed disease. Secondly, with the increase in noninvasive treatments, the need for rapid diagnosis and noninvasive monitoring is increased as well. Lastly, immunosuppressed patients have a higher incidence of non-melanoma skin cancer (Kempf et al. 2013; Jemec and Holm 2003), and OCT imaging could potentially save these patients from excessive biopsies and excisions of tumor-suspicious lesions.

OCT images of healthy skin present skin fluid and air as hyporeflexive/absorbing areas, and

Fig. 1 Healthy skin. Healthy skin of the lower leg of a 28-year-old female. The penetration depth depends on the specific tissue, and in this OCT image of the skin, a penetration depth of 1.84 mm has been obtained. The *thin white*

hyperreflective line (thick blue arrow) is not part of the skin but represents the entrance signal due to the shift from one medium (air) to another (skin). *Thin red arrows*: intact dermoepidermal junction. *Asterisks*: vessels

they appear dark/completely black, while hyperreflective areas appear bright. The penetration depth depends on the specific tissue. The abrupt change in refractive index from air to skin can result in a large entrance signal (Fig. 1) which can be reduced by using contact or coupling media on the part of the probe that is in contact with the skin. The media reduce the refractive index at the surface of the stratum corneum. In this way, glycerol absorbed into the skin seems to increase penetration depth by decreasing scattering and thus improving the OCT image (Serup et al. 2006). It has been suggested that speckle reduction by the appliance of the so-called spatial diversity compounding scheme (Mogensen et al. 2010) also has an improving effect on the imaging quality leading to better defined delineations of, e.g., skin tumors.

4.1 Basal Cell Carcinomas

Basal cell carcinomas (BCCs) have successfully been diagnosed with OCT in several clinical studies (Mogensen et al. 2009a). The clinical characteristics of BCC lesions in OCT images are alteration of the dermoepidermal junction (DEJ) and dark ovoid basaloid cell islands, and sometimes a dark, hyporeflexive peripheral boundary (halo) can be identified. Secondary features include absence of normal hair follicles and glands and altered dermal capillaries directed

toward the basaloid cell islands (Fig. 2; Hussain et al. 2015).

Studies have shown that certain histological features influence the quality of OCT images of BCC (Mogensen et al. 2011). The presence of inflammatory infiltrate significantly impairs the quality of images, while elastosis is associated with improved quality. Meanwhile, neither ulceration nor hyperkeratosis seemed to impair the quality of OCT images of BCC significantly which is of great importance as most BCC lesions have a hyperkeratotic surface.

The increasing incidence of BCC, making it the most common form of cancer in many countries (Madan et al. 2010), has given rise to extensive research to etiology, pathogenesis, and treatment. Skin biopsies and curettage or excision are currently the gold standard for diagnosis and treatment of non-melanoma skin cancer (NMSC). Taken into account that biopsies and excisions are invasive, are scarring, and have the potential of leading to infection, the noninvasive treatment options have been well received in dermatology. Imiquimod is a cream which can be used to treat superficial BCC. A recent study (Banzhaf et al. 2014) has shown that OCT can be used in the whole process of treating a superficial BCC – from the primary diagnosis to monitoring treatment effect and follow-up of potential residual tumor tissue. Photodynamic therapy with methyl aminolevulinate (MAL-PDT) is another noninvasive type of treatment. In a study (Themstrup et al. 2014) where OCT was performed

Fig. 2 (a) Basal cell carcinoma. OCT image of a 77-year-old man with a basal cell carcinoma lesion above the eyebrow. The OCT image shows disruption of the dermoepidermal junction (*thick blue arrow*) and an elevated darker area right at the skin surface corresponding to a small ulceration/crust (*thin blue arrow*). In the dermis, there are two rounded structures surrounded by a dark rim

(*asterisk*). These structures correspond to basal cell tumor islands. The vertical hyporeflective streak stretching from the surface is a hair casting a shadow (*red arrow*). (b) Healthy skin adjacent to basal cell carcinoma lesion with the epidermis (*blue bars*), intact dermoepidermal junction and an underlying homogenous dermis

before MAL-PDT treatment and at a 3-month follow-up on 18 cases (14 BCC lesions and 4 actinic keratosis), the results showed that immediately after the MAL-PDT, it was not possible to monitor the treatment due to blurring and crust formation. At the follow-up, recurrence was suspected clinically in 5/18 cases and with OCT in 7/18 cases suggesting that OCT is able to identify 29 % more recurrences than clinical examinations alone which was subsequently confirmed by histology. This study implies that OCT is most suitable in the diagnosis and follow-up of treatment. A study on OCT monitoring of BCC treated with ingenol mebutate is being conducted at the moment.

Surgeons performing Mohs surgery (Wang et al. 2013; Alawi et al. 2013; Chan and Rohrer 2012) can use OCT to reduce the excised area without compromising the integrity of tumor-free borders. This reduces the number of invasive procedures needed. One study (Alawi et al. 2013)

showed that in 84 % of cases, the OCT-defined lateral margins correctly indicated complete removal of the tumor. Furthermore, the surgical margins outlined by the surgeon never fell below the OCT-defined margin suggesting that OCT may be helpful.

OCT imaging of cutaneous lymphomas is also an area of development. A case report (Christian Ring et al. 2012) visualizing cutaneous T-cell lymphoma has illustrated a thickened and hyperreflective stratum corneum and several elongated hyporeflective structures (interpreted as lymphomatous infiltrates) in the dermis. There was a good immediate correlation between histology and OCT imaging of the sample. Similar findings in the dermis have been described in ocular lymphoma and may therefore be of importance in cutaneous lymphomas as well.

A pilot study regarding basal cell carcinoma (BCC) lesions (Boone et al. 2012b) visualized by

HD-OCT implied that HD-OCT facilitated *in vivo* diagnosis of BCC and even allowed the distinction between different BCC subtypes which is something that has not been possible with conventional OCT.

4.2 Actinic Keratosis

The OCT morphology of actinic keratosis (AK) is somewhat similar to that of a superficial squamous cell carcinoma (SCC). The AK lesions have the potential to regress spontaneously. However, a substantial proportion of AK lesions can progress to SCC. Unlike BCC lesions, SCC carries a risk of metastasizing (Schmitt and Bordeaux 2013).

It is a possibility to treat AK lesions noninvasively with, e.g., MAL-PDT, imiquimod, or cryosurgery. Cryotherapy is a commonly used lesionally directed therapy in which the tissue is frozen, and the tissue destruction occurs due to cellular damage incurred during the freeze-thaw cycles. Liquid nitrogen ($-196\text{ }^{\circ}\text{C}$) is the most commonly used coolant, but solid carbon dioxide ($-78.5\text{ }^{\circ}\text{C}$) and liquid CO_2 ($-56.6\text{ }^{\circ}\text{C}$) have also been used. When AKs are treated by cryotherapy, tissue destruction is frequently preceded by clinical blistering. When the skin starts healing, the lesion tissue will peel off and thereby allow the appearance of new skin.

Due to the noninvasive treatment, it is quite relevant to have a noninvasive and non-scarring way of monitoring the treatment. Several conducted studies (Mogensen and Jemec 2007; Mogensen et al. 2009b, c) have implied that OCT can be beneficially used in AK diagnosis, treatment, and monitoring. The OCT characteristics of an AK include atypical thickening of the epidermis, especially the stratum corneum. Lymphocytic infiltrate from inflammation can at times be seen in the underlying area of the AK.

A recent study (Themstrup et al. 2012) indicates that OCT has the potential of monitoring cryotherapy in AK lesions. It was demonstrated that OCT can visualize and delineate the AK lesion with high accuracy. When cryotherapy is

applied, an opaque iceball is imaged followed by vesicle formation shortly after the treatment. It was not possible to detect the freezing depth during the cryotherapy.

It has been reported that the *in vivo* diagnosis and grading of different actinic keratoses were possible using HD-OCT (Maier et al. 2013).

4.3 Inflammatory Skin Diseases

Another use for OCT is the visualization of common inflammatory diseases such as psoriasis and contact dermatitis. In the majority of cases, the diagnosis can be made by the naked eye, but in cases of doubt, skin biopsies and histology are performed for confirmation.

Psoriasis is a disease affecting a high number of patients. OCT can monitor the severity of the disease and monitor specific treatments by measuring structural changes such as epidermal thickness and optical density of the dermis (Gambichler et al. 2005; Morsy et al. 2010). In a recent study, the thickness of skin with psoriatic plaques was compared to healthy skin with a difference of 30–40 μm .

Furthermore, a study looked at psoriasis arthritis and nail abnormalities with OCT (Aydin et al. 2011, 2013). Eighteen patients with nail abnormalities were scanned with OCT and ultrasound, and the study implies that among the 180 nails, 67.8 % had clinical findings, whereas 33.9 % were abnormal with ultrasound and 44.4 % with OCT. OCT was reported to detect subtle abnormalities in 12 clinically normal nails and in 41 nails with normal ultrasound findings. The study found that a positive OCT had a sensitivity of 44.4 % and specificity of 95.8 % suggesting that OCT has a potential for detecting nail abnormalities. Regarding nail abnormalities, a study (Grover and Khurana 2012) focusing on onychomycosis reported OCT's ability to screen several areas within a nail plate and hence detect persisting fungal elements during local or systemic therapy.

Contact dermatitis (Morsy et al. 2010) is another common inflammatory skin disease. The OCT scanning visualized a higher and enlarged

entrance signal corresponding with the changes in stratum corneum with hyperkeratosis and parakeratosis.

A recent study applying Ackerman's algorithmic method of pattern recognition (Boone et al. 2013) indicated that HD-OCT is a promising method for noninvasive diagnosis, evaluation, and management of common inflammatory skin diseases by the visualization of individual cells in the epidermis and dermis and morphology of the DEJ, papillary dermis, and reticular dermis.

A case study (Banzhaf and Jemec 2012) showing OCT imaging of granulomatous lesions of the skin reported the visualization of a new shape, resembling a wing. Further studies on granulomatous skin diseases are required.

4.4 Fibrotic Diseases

Scleroderma and other fibrotic diseases, e.g., morphea (localized scleroderma), lichen sclerosus

et atrophicus (LSA), keloids, and scars, are all characterized by fibrosis of the skin. Preliminary data suggest that OCT imaging of fibrotic diseases are characterized by a disarray of layering with a rather effaced DEJ. The dermis itself has been visualized as very homogenous and hyperreflective due to extensive fibrosis. The dermis may also display an intricate hyporeflective pattern. A characterization of the unique morphological differences may aid the understanding of lesional evolution and assessment of possible treatments. This is particularly important for scleroderma.

Systemic scleroderma is characterized by deposition of collagen, fibrointimal proliferation of small vessels, and vasospastic episodes. Over time, it may lead to tissue ischemia and extensive fibrosis of the skin and other organs. Due to the lack of curative treatment, the treatment goal is the prevention of disease progression by the use of, e.g., anti-fibrosing agents, topical emollients, and PUVA. With the rise of novel anti-fibrosing

Fig. 3 (a) Bullous pemphigoid. OCT image of an 81-year-old woman with a bulla on the right thigh. The *blue bar* marks the intact dermoepidermal junction distinguishing the epidermis from the dermis. Notice the split in the skin (*blue arrow*) and the subepidermal location

of the bulla. The actual bulla (*blue asterisk*) is hyporeflective due to the liquid content. The hyperreflective strokes inside the bulla may be the visualization of polymorphous inflammatory infiltrate. **(b)** OCT image showing healthy skin adjacent to the bulla

agents, the noninvasive monitoring of dermal collagen morphology becomes relevant in treatment trials (Abignano et al. 2013; Ring et al. 2015).

4.5 Bullous Diseases

Skin conditions involving bullae have been the subject of very few OCT studies and are still an area of interest with ongoing research. Fluid is an absorbing media and therefore appears dark (hyporeflective) or completely black (reflective).

It has been demonstrated that it is possible to differentiate between certain forms of bullous diseases. Overall bullae appear as dark, ovoid to round well-demarcated structures. It is possible to differentiate between intraepidermal and subepidermal bullae and thereby between blistering diseases such as bullous pemphigoid, burns, and pemphigus (Mogensen et al. 2008). However, the

difference between bullous pemphigoid and pemphigus was too subtle to differentiate between the two diseases in the published series. Burn blisters were significantly different. These challenges may be met by future enhancement of the resolution of the OCT images (Fig. 3).

Porphyria cutanea tarda (PCT) blisters usually appear on sun-exposed areas of the body blisters especially on the dorsum of the hands. The bullae contain porphyrin-rich serous fluid and can be painful. Figure 4 depicts the difference between PCT on a hand and adjacent normal skin.

4.6 Wound Healing

Well-known complications subsequent to surgery and laser treatment, such as infection or prolonged wound healing, are challenging tasks in dermatology.

Fig. 4 (a) Porphyria cutanea tarda. Dorsum manus dexter of a 67-year-old female patient with porphyria cutanea tarda (PCT). The dermoepidermal junction is intact (*blue bars*), and the remains of a bulla (*thin blue arrow*) can be seen reaching down through the epidermis

and into the dermis. The rounded structure (*blue arrow*) is the remainder of a bulla. The *blue bars* mark the dermoepidermal junction showing how the bulla extends into the dermis explaining why PCT heals with scarring. (b) Healthy skin adjacent to porphyria cutanea tarda

Fig. 5 (a) **Actinic keratosis.** OCT image of actinic keratosis lesion located on the back 20 min after 10 s of cryosurgery. *Asterisks:* a reflective bullae located along the dermoepidermal junction. *Upper blue arrow:* epidermis. *Lower blue arrow:* dermis. (b) **Residual basal cell carcinoma lesion.** OCT image showing residual basal cell

carcinoma lesion at 3-month follow-up after photodynamic therapy. The lesion was located on the temple. *Blue vertical line:* disruption of normal layering. *Asterisk:* hyporeflective, necrotic center. *Thick blue arrow:* tumor stroma. *Thin blue arrows:* artifacts from hairs casting shadows

An animal study (Wang et al. 2008) tracking and monitoring morphological transformation during wound healing and tissue regeneration, after a collagen implant, indicated the possibility to detect reepithelialization, granulation tissue formation, and inflammatory response. Furthermore, it was reported that when longitudinal OCT was coupled with ultrahigh-resolution Doppler, it was possible to enhance the image fidelity and track neovascularization which is a common feature associated with tissue regeneration and cell/tissue differentiation. Another study (Kuck et al. 2014) concluded that there are comparable results between histological findings and OCT reporting that OCT allowed the detection of partial loss of the epidermis, vasoconstriction, vasodilatation, and epithelialization.

It has also been reported (Sattler et al. 2013) that confocal laser scanning microscopy (CLSM) and OCT can be used to quantify the kinetics of the dynamic wound healing process. Even though the wound healing seemed to be clinically complete after day 7 and 14 following fractional laser therapy, the majority of treated areas imaged by CLSM and OCT detected subepidermal defect even after 21 days (Fig. 5).

Banzhaf et al. (2016) recently investigated the closure of in vivo ablative fractional laser (AFXL)-channels using OCT and RCM. AFXL disrupts the skin barrier by creating microscopic vertical channels, inducing a wound healing response to moderate skin appearance. Depending on the applied energy level, the AFXL-channels appeared to remain open during

the first 24 hours, which may raise perspectives for optimal timing of laser-assisted drug delivery.

5 Conclusion

OCT imaging in dermatology is a diverse imaging tool easy and fast to apply at the bedside – and the images are relatively easy to interpret because of their similarity to more conventional imaging such as ultrasound and to histology. In general, the OCT imaging technique can supplement ultrasound imaging of the skin by performing high-resolution imaging of the epidermis and upper dermis. Because OCT imaging is easy to use and provides high-resolution skin images, the obstacle for clinical use is not the equipment itself – but rather the need for proper diagnostic research trials. It is imperative that OCT images of skin diseases, be it skin cancer, actinic keratosis, wounds, or blistering diseases, are correlated to different degrees or severities of the disease and non-diseased skin but also that inter- and intraobserver agreement is assessed in trials. At the current stage of OCT research in dermatology, most trials are still case reports and preliminary trials – but the future looks promising in many ways.

6 Future Development

Considering the fact that OCT in dermatology is still a novel technique, there are a number of dermatological diseases that still have not been investigated or investigated sufficiently using OCT. For NMSC and other diseases that have already been the subject of some studies, the future development involves validation of the diagnostic method including optimized definitions, sensitivity, specificity, inter- and intraobserver variation, and the development of diagnostic algorithms for the assessment of OCT images.

The measurement of surface area, volume, and color of a chronic wound is an important step in its follow-up over time. Numerous techniques are available, ranging from the simple use of tracings to more sophisticated methods requiring the use of cameras, videos, and computers. When they exist, the techniques usually employed in outpatient care units to record the wound state over various time points are often inaccurate. Furthermore, studies of wound healing are often complicated by the few objective measurement methods that can be used in a noninvasive and ethical way in humans (Ahroni et al. 1992). However, quantitative methods that assess the wound healing rate are essential for checking the response to treatments, either drug-containing dressings or systemic therapies.

Briefly, wound measurements are of value for three main reasons:

- To monitor the time course of the wound (this is a part of patient assessment)
- To assess the efficacy of topical and/or systemic therapies
- To attempt to forecast the time required for healing

The degree of precision required is related to the purpose of the measurement as well as the technique to be used.

Wound assessment encounters three main difficulties:

- The definition of the wound perimeter. This is an entirely subjective estimate that depends on the observer, who decides what forms part of a

wound or not. The most frequent source of error comes from the difficult delineation of the epidermis edge, owing to its thinness and translucency.

- The variable aspect of large, deep wounds, which depends on the position of the patient. Such wounds are capable of marked changes in appearance that render measurements unreliable if the patient is not placed in exactly the same position each time the wound is measured.
- The convex shape of human limbs. Measurements frequently do not take into account possible errors due to this factor.

Despite such problems, several measurement techniques can be employed to assess the surface or volume of wounds. Table 1 lists the principal ones.

1 Wound Parameters: Perimeter and Surface Area

The parameters most frequently used to measure a wound are the length of the principal axes (length and width of the wound), the projected surface area, and the perimeter. Different mathematical calculations can establish a relationship between the surface area of a wound, its perimeter, length, and width.

1.1 Direct Measurement of Wound Dimensions with a Ruler

Historically, the first parameters used were the outer dimensions of the wound: length (along the longest axis, L) and width (smaller axis perpendicular to the first, W). These parameters are measured directly on the wound using a graduated instrument. The same instrument must always be used if the aim is to compare dimensions, and strict conditions of asepsis must prevail to prevent the transmission of micro-organisms between patients. Although imprecise, this technique is the first objective approach to a wound (Fig. 1).

Table 1 Wound measurement techniques

In contact with the wound	Tracing: dimensions, surface area and contours
	Measurement of depth
	Volume: liquid or molding
Not in contact with the wound	Photography
	Video film
	Stereophotogrammetry
	Analysis of structured light

Fig. 1 Direct measurement of the length and width of a wound. Length 6.7 cm, width 4.8 cm. Calculation of surface area: $A = 6.7 \text{ cm} \times 4.8 \text{ cm} = 32.16 \text{ cm}^2$. Corrected surface area: $A' = 32.16 \times \pi/4 = 25.26 \text{ cm}^2$. By

counting the number of $1 \times 1 \text{ mm}$ squares, $A = 25 \text{ m}^2$. By using computerized digital image analysis, $A = 26.28 \text{ cm}^2$

It calculates the surface area (A), which of course is subject to some error, but these can be partly circumvented through the application of formulae for corrected surface area (Vowden 1995; Mayrovitz 1997). Thus, according to Mayrovitz (1997), $A = 0.73 \times L \times W$ for a rectangular wound. The area of an elliptic wound may be calculated as follows: $A = 0.763 \times L \times W$ (Schubert 1997) or $A = 0.785 \times L \times W$ (Kundin 1989). This technique is principally applicable when wounds are rather shallow and regularly shaped. Good training in such measurements improves their sensitivity.

1.2 Transparent Tracings

1.2.1 Delineation of Perimeter on Transparent Material

The most commonly employed technique is that which uses an acetate film to obtain a tracing of the wound perimeter, drawn using a fine marker pen. The paper may be a plain transparent film or may be already calibrated in millimeters. As a general rule, it is better to use a double sheet of transparent material; the tracing is drawn on the upper sheet and the lower sheet, which is in direct contact with the wound and may be soiled by exudate, can be

discarded. Flexigrid OpSite (Smith and Nephew) is an adhesive, polyurethane film, which comprises a protective, cross-ruled film that can serve as a tracing to follow-up the treatment of superficial wounds. The principal limitation to this technique is the difficulty encountered by the observer in determining the perimeter of the wound with enough precision (Bohannon and Pfaller 1983). An overly thick line is also a source of error.

This is a rapid method (less than 1 min is required to complete the tracing of a wound), which is inexpensive and requires minimal training.

1.2.2 Use of Scale Paper

The next stage consists in analyzing the tracing. As above, the two main diameters, the perimeter, and the surface area can be measured. It is simplest to measure the surface area by placing the tracing on a sheet of graph paper and counting the number of 1-mm squares within the area (Gowland Hopkins and Jamieson 1983; Majeske 1992). This is a tiresome and lengthy method (10 min for a 70-cm² wound). When the wound outline does not perfectly meet the cross-ruling, the area can be deduced using the formula: $(N + N_C/2) \times \text{surface of a square}$, where N is the number of squares fully contained and N_C the number of those that cross the outline. A more rapid method consists in cutting out the tracing or its copy on a card with a regular thickness, then weighing it on a high-precision scale (Bohannon and Pfaller 1983). Additional errors are possible when the drawing is reproduced and the card or film cut out.

The use of a scanner that copies the shape of the tracing and enters the data into a computer, or the use of a flat or camera scanner, obviates such drawbacks. A program then provides a rapid and accurate analysis of the tracings, calculating the area and the area of islands of newly formed epidermis that might have been recognized within the wound and traced (Coleridge Smith and Scurr 1989). This technique is the most widely employed in clinical studies aimed at validating products for wound treatment.

1.3 Computer-Assisted Planimetric Measurement

Computer-assisted planimetry is a wound measurement method often used in clinical studies. The perimeter of the wound is delineated by the clinician using a pen linked to a computer. There is a close correlation between the surface area of a wound measured by planimetry and the following parameters: length, width, perimeter, and the product of length by width (Kantor and Margolis 1998a, b). However, this correlation diminishes in the case of very large wounds. In addition, these parameters would be predictive of healing after 24 weeks. They may be taken either directly on the wound or indirectly from a tracing made on a transparent substrate (tracing paper, plastic film, or mylar) (Liskay et al. 1993), or from a standardized photograph.

All such measurements can calculate the healing rate, and more particularly the epithelialization. The latter appeared to be constant in certain studies (Redden et al. 1998), reaching about 1–2 mm per week. Furthermore, this rate would be independent of the size of the wound.

1.4 Photography

It is possible to measure a wound's parameters from a standardized photograph. The method has been compared with the conventional tracing method in certain studies, and the results obtained did not differ significantly (Griffin et al. 1993). This procedure by-passes an important disadvantage in the above-mentioned methods: direct contact with the wound, which may be painful and a source of contamination. However, note that, as an indirect procedure, it has a certain number of drawbacks. In order to know the scale of the image, a graduated ruler must be placed alongside the wound. It is often difficult to compensate for the concave or convex nature of the wound. The photograph must be taken exactly perpendicular to the wound. A deviation of only 20° from the perpendicular axis will cause a reduction in the

wound surface area of about 10 % (Palmer et al. 1989). Indeed, photography must take place under clearly defined placement and lighting conditions, and these conditions must be reproducible (Teot et al. 1996).

Different options are available when analyzing a photograph: computer-assisted image analysis is highly preferable to the old-fashioned projection of the photo onto a paper and the secondary tracing of wound contours. Interestingly, the information obtained from photographs can assess wound parameters other than dimensional ones: aspect of the wound bed, changes in color, as well as presence of necrosis, fibrin, granulation tissue, epithelialization. Standardization of the technique is essential: choice of focal distance, adjustment of speed and diaphragm, lighting, distance from the wound, and angle of shot. One group of authors (Minns and Whittle 1992) used a Polaroid camera with accessories, which allowed them to take photos at a constant angle and distance from the wound; photos could thus be compared. New Polaroid systems are particularly well-suited to the measurement of wounds. The Health Cam System allows the alignment of two lights, so that photographs are taken in a reproducible and comparable manner. Gridfilm allows for the superimposition of a grid over the wound for direct measurement. In most cases, a graduated scale is placed alongside the wound for easy measurement of its dimensions, whatever the magnification of the photo. In the semimanual recording technique, the contour of the wound is followed by a digital pen. The signal thus emitted, whose motion has

previously been calibrated, is processed by micro-computer. Another technique consists in superimposing the contour traced by the operator using a mouse over the digital image of the wound, and visualizing it directly on the computer screen (image patterning process) (Mignot 1996).

In practice, a direct data recording from a photograph is difficult to obtain, except in the case of a wound with a simple, geometric shape and a well-defined perimeter. The use of calibrated photographs may be of value when studies are made in a single center, because the reproducibility required with respect to the conditions of photography at different stages of a treatment can be satisfactory. The current need for multicentre studies to assess wounds limits this method of evaluation, and tracings should be preferred. Techniques involving photographs appear to benefit from a certain degree of reliability and reproducibility, only if strict rules are respected (Etris et al. 1994; Griffin et al. 1993).

1.5 Video Image Analysis

Video image analysis employs a video camera to film a wound (Solomon et al. 1995). The recording of the image is then analyzed by computer using special software that corrects the figures obtained for wound dimensions to compensate for the concave or convex nature of the wound. The technique is more accurate than the analysis of photographs, and is simple, rapid, and inexpensive.

A comparison of measurements using rulers, tracings, or photographs is shown in Table 2.

Table 2 Comparison of three techniques to measure the surface area of a wound (From (Plassman 1995), with permission)

	Ruler (length, width)	Tracing of wound	Photograph
Ease of use	Easy	Easy	Moderately easy
Time required for recording	1 min	A few minutes	A few minutes
Cost	Very low	Low	Moderate
Use	Common	Common	Common
Type of record	Numbers	Tracing and numbers	Image and numbers
Contact with wound	Yes	Yes	No
Learning	Little	Moderate	Moderate
Percentage error ^a	20–25 %	8–10 %	10–12 %

^aThe lowest percentage corresponds to large wounds and the highest percentage to small wounds

2 Wound Volume

2.1 Graduated Ruler

The depth of a wound is not accessible to the measurement systems we have described above, because most wounds are three-dimensional, and therefore special techniques are necessary. The simplest consists in using a sterile blunt-tipped rod to assess the maximum depth of the wound (Covington et al. 1989; Thomas and Wysocki 1990). The technique involving the use of a cotton tip is easier in practice. However, such measurements are often inaccurate, and determination of the deepest point of the wound is subjective.

In 1989, Kundin (1989, 1985) developed a mathematical formula to assess the volume (V) of a wound through its surface area (A), using the two largest diameters (length, L , and width, W) and the depth (D): $V = A \times D \times 0.327$, where $A = L \times W \times 0.785$. Thomas (Thomas and Wysocki 1990) showed that these measurements were comparable to those obtained with tracings and photographs in the case of small wounds, and were consistently underestimated in the event of large or irregular wounds (particularly those with a sinuous shape). Variation in the measurement of the same wound, with the patient in the same position, nevertheless demonstrated standard deviations of 40 % regarding wound volume when using these methods (Plassmann et al. 1994).

2.2 Wound Molds Using Silicone Rubber

Since silicon rubber can harden and be stored, this high-precision and simple method uses profilometric analysis followed by computerized volume assessment (Zahouani et al. 1992; Humbert et al. 1998). The first stage consists in making a negative imprint of the wound using silicone rubber of a type frequently used in dentistry for its safety. Two products are commonly used: Silflo and Xantopren. The mixture obtained by mixing the silicone rubber with its catalyst has a viscous consistency and is applied into the wound using a spatula. It will shape all the

wound contours to a very fine extent, penetrating into the smallest crevices. After 2–3 min to polymerize, and thus harden, it is easy to remove as a single piece corresponding to the negative shape of the wound. It is possible to store and archive this mould, as it would be unaffected by time. It is then scanned by a laser beam, which recognizes the location of each point using a positional detector. The vertical position of the laser spot (about 30 μm in diameter) can be deduced using double triangulation (Stil, Marseille, France and Digital Surf, Besançon, France) or after refocalization of the beam (Optilas, Evry, France). Parallel linear scanings of the mold surface create a certain number of profiles, the sum of which calculates wound volume. When assessing the volume of a leg ulcer, it is recommended that laser scanning be done along the axis of the leg, so as to cancel out the usual concave shape of the wound in this site. In some cases, this method also provides a precise definition of wound contours by automatic detection, which is achieved by comparing the altitude at each point with that of adjacent healthy skin.

The time course of a wound, or its healing, is a dynamic process. Monitoring thus requires repeated measurements over time. This method makes such measurements possible, particularly because of the safety of the silicone rubber used and the painless and nontraumatic nature of its application.

2.3 Weighing Alginate Molds

The use of an alginate mould makes it possible to measure wound volume by weighing or water displacement (Stotts et al. 1996). However, this method has certain limitations, particularly because of possible alterations in the alginate mold depending on its water content, conditions of storage, and on wound volume.

2.4 Stereophotogrammetry

Stereophotogrammetry (Bulstrode et al. 1986) measures the contours, surface area, and volume of a wound. It is based on determining the depth of

the wound viewing it from two different angles. The first models of this device were difficult to manipulate (Erikson et al. 1979), but new, simpler models are now available (Bulstrode et al. 1986). This method provides an accuracy of roughly 3.5 % for measurement of the surface area and 5 % for volume. This method, developed by Bulstrode in 1986 (Bulstrode et al. 1986), is not widely used. The time necessary for each evaluation is a further limitation to its everyday use.

2.5 Direct Measurement of Volume Using Physiological Saline and Polyurethane Film

Berg et al. (1990) reiterated the value of this simple method, which consists in placing a transparent adhesive film over a wound, and then injecting physiological saline below the film. The quantity of saline corresponds to the wound volume.

In practice, the wound is covered with a sterile polyurethane film and then filled with physiological saline solution, which is injected using a needle piercing the film. Evaluation of this method has shown that accuracy of more than 20 % is rarely possible (Plassmann et al. 1994), principally because some amount of liquid is absorbed by the wound, and losses by leakage occur around the adhesive through detachment of the film from the wound perimeter. Furthermore, it is sometimes impossible to place the patient in a satisfactory position to fill the wound with a liquid. Tissue detachment also constitutes a limitation to this technique, as does the potential risk of infection, discomfort for the patient, and the risk of trauma to the wound, which is inherent in any technique involving direct contact.

2.6 Analysis of Structured Light

Analyzing structured light measures the surface area and volume of a wound without direct physical contact. Parallel lines of colored light are projected onto the wound surface area. A video camera connected to a computer records any distortion to the light beams. The dimensions of the

wound are then calculated by triangulation. The accuracy of this method is similar to the previous one, but its implementation is simpler (Plassman and Jones 1992).

2.7 Ultrasound

Ultrasound takes advantage of the difference in path length of an ultrasound wave reflecting at the bottom of the wound as compared with the adjacent normal skin. Healing may be assessed using this technique (Pugliese et al. 1992), as was demonstrated in a clinical study of wounds caused by punch biopsies in volunteer subjects. In this study, the depth and internal diameter of the wound were assessed by ultrasound at intervals while its outer surface area was measured by planimetry after first taking a tracing. This technique appears to be of value only if the wound is small in size, because it is necessary for the wound edges to lie within the field of the ultrasound beam, as they serve as a reference to measure wound depth. Application of the probe must not flatten these edges; appropriate precautions must be taken to avoid this. Several ultrasound scans should be taken (usually three), from which mean values of the parameters are determined. Ultrasound may also be useful to monitor wound dimensions following cryosurgery, or to better assess the quality of perilesional tissue (Rippon et al. 1998; Wertheim et al. 1999).

2.8 In Vivo Measurement Using Interferometry and Fringe Projection

A new technology based on the interferometry principle has been developed in the Besançon Laboratory of Engineering (France) (P. Humbert, unpublished data) in order to quantify the volume of ulcers in vivo. The three-dimensional reconstruction of wound profiles is based on the Fourier transform method of fringe pattern analysis (Fig. 1).

The system is composed of CCD camera and a projection module. The resolution of the system depends on the fringe width and on the angle

Table 3 Comparison of five methods to measure wound volume (From Plassmann et al. (1994), with permission)

	Ruler and cotton tip	Mold	Saline	Stereophotogrammetry	Structured light
Ease of use	Easy	Moderately easy	Moderately easy	Difficult	Difficult
Time required for recording	1 min	A few minutes	A few minutes	20–30 min	4–5 min
Cost	Very low	Low	Low	Very high	High
Use	Common	Common	Common	Research	Prototype
Type of record	Numbers	Mold and numbers	numbers	3D reconstitution	Image and numbers
Contact with wound	Yes	Yes	Yes	No	No
Training	A few hours	Less than 1 h	1 h	A few hours	A few hours
Percentage error ^a	10–40 %	5–15 %	8–25 %	0–3 %	3–5 %

^aThe lowest percentage corresponds to large wounds and the highest percentage to small wounds

between the optical axis of the camera and the optical axis of the projector. The deformation of the fringes over the reference plane is proportional to the height separating the object and the reference plane. Thus, an appropriate algorithm reconstructs the 3D profile from the projected fringes on the object, in this case the wound.

This system has a z-resolution of 10 μm for a $5 \times 5\text{-cm}^2$ area. The search for the perimeter and the volume of the wound is based on the previously described method by Zahouani et al. (1992).

A comparison between the above-mentioned measurement techniques is shown in Table 3.

3 Colorimetry or the Red-Yellow-Black Concept

The technology for colorimetry was developed by Hellgren and Vincent (1993; Vincent et al. 1994) and consists in taking account of the color characteristics of an ulcer, which are a function of its clinical stage. Necrotic lesions are black, a fibrinous surface looks yellow, and granulation tissue is red. This clinical description has been accepted worldwide as an indication of the stage and prognosis of an ulceration (Stotts 1990; Thomas 1990). Thus computerized colorimetry analysis (CWA, computerized wound analysis) was developed to ensure more objective measurements (Engström et al. 1990). A photograph of the wound is taken, together with a grey scale placed

alongside the lesion to control the quality of the photograph. Photographic data are transmitted to a computer. The image is digitalized and reconstituted in the form of colored pixels. The color of each pixel is expressed in red, blue, and green values of intensity (each from 0 to 255). This method has been the subject of validation studies. In practice, the clinician takes the photographs using a camera recommended by the CWA Institute in Sweden, the promoter of the technique. Images are then sent to this center, where they are processed blind. The results are returned within 6 weeks. A detailed guide is provided regarding the best way to take the photo, as the reliability of the results depends upon its quality.

4 Conclusion

The clinical follow-up of wound healing requires data on the geometry of the lesion. This quantification is necessary to ensure an objective

assessment. The techniques most widely employed in clinical studies involve the tracing of wound contours using transparent film. Only rigorous training in this technique can lend credence to the results obtained. More sophisticated techniques that increase the accuracy of wound volume measurements are currently available, but are at present only employed in the research setting.

Like any other organ, the skin has a vascular system. Because of its dimensions (1 mm thickness), this system belongs to microcirculation only. Like all epithelia epidermis, pilosebaceous follicles, sweat glands, and their excretory ducts do not contain vessels and need a close nutritive network. Furthermore, this network must be able to develop angiogenesis, even in adults, in order to repair wounds. But the role of skin microcirculation goes beyond organ nutrition alone. Its involvement is essential in the thermal regulation of the organism and plays an important role in hemodynamics since it represents at least 9 % of the blood mass, with important variations up to 50 % (Martineaud and Seroussi 1977).

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

1 Microvasculature

The nutritive vessels consist of subepithelial dense capillary networks where exchanges with the extravascular elements take place (Fig. 1). There are three kinds of networks. The subepidermal network is the easiest to study. It

Fig. 1 A diagram of the skin microvasculature. 1 Sub-epidermal plexus, 2 perisudoral plexus, 3 perisebaceous plexus, 4 ascending arteriole, 5 perifollicular plexus; 6 cutaneous artery and subcutaneous plexus, a epidermal ridges horizontally cut (Modified from Stüttgen and Forssman (1981))

Fig. 2 Subepidermal plexus in the supramalleolar area, injected with Indian ink and viewed from above the skin. Arrows papillary loops. M A mesh of the subepidermal network (Laboratoire de Biophysique cutanée, Besançon, France and Revier (1981), with permission)

consists of the papillary loops (visible in capillaroscopy) and the horizontal plexus of the superficial dermis in which the loops emerge (Fig. 2). The second type consists of the perifollicular networks which nourish the pilosebaceous follicles: each has a well-developed papillary loop and a vascular netting around the external epithelial sheath, i.e., the outside part of the hair. There are as many networks as hairs, and their development follows the hair growth, which explains why a scalp wound causes substantial bleeding. The perisudoral networks form the third type of network. They are dense and placed around each sweat gland and the excretory duct until its emergence into the epidermis; there are between 10 and 700 eccrine glands per square centimeter of skin, depending on the area. The development of the perifollicular and perisudoral networks is at its maximum in the medium and deep dermis.

In addition, the dermis vascularization seems sparse, sometimes almost absent, showing transfer, not exchange, vessels. The supply of the sub-epidermal loops is ensured by progressive arterioles divided like the arms of a candelabrum in the upper part of the medium dermis (Spalteholz 1927) (Fig. 3). The deep dermis directly irrigates the progressive arterioles and the periadnexal networks; it receives its vessels from a large peri-fascia hypodermic plexus, which

Fig. 3 (a, b) Candelabrum-like arborescence of a terminal arteriole. Three-dimensional reconstruction from histological slides. (b) The same arborescence as seen from above (after 70° rotation). Note the peripheral collection of blood. Arterioles are in *black*, venules in *gray* (From Braverman et al. (1990), with permission)

is supplied by the arteries intended for the integument (Casey 1990).

The subepithelial networks have an embryological origin in situ from mesenchymatous buds differentiating under the influence of epithelial stimuli (Ryan 1973). Inversely, the subcutaneous and deep dermal vessels are branches of the embryonic metamerical vessels (Ryan 1973). In addition to these embryological differences, the subepidermal circulation (observed in capillaroscopy) is relatively autonomous compared to the deep circulation (observed with laser Doppler) (Fagrell et al. 1986). Is this fact sufficient to suggest there are two different systems? From an anatomical point of view, the answer is negative.

The cutaneous vessels are very anastomosed between themselves at all levels, from the hypodermis to the epidermis. The occurrence of a

cutaneous infarction following a localized arteriole obliteration is therefore impossible. Some anastomoses such as the Masson glomus have a nerve command; they are especially numerous at the extremities where their role in the thermal exchanges with the environment is essential.

2 Metabolic and Thermoregulatory Needs

Two peculiar features characterize cutaneous vessels. First, their low differentiation in arterioles or venules, reflecting a reversible functional specialization in relation to the metabolic needs of the adjacent epithelium: the latter control both the morphology and the development level of the subepithelial capillary networks. For example, the microcirculation evolves in parallel with the

cycle of hair growth or the proliferation stage of the psoriatic epidermis (Braverman and Sibley 1982). Second, the deepest vessels are surrounded by smooth muscle fibers and the more superficial ones by pericytes (Higgins and Eady 1981). These cells give a better contractility and mechanical resistance to the cutaneous vessels than to the visceral capillary vessels. These two properties may be related to the sudden compression of the skin when it has to support the weight of the body changing position. In such cases, the blood is expelled in all directions, even against the flow, and still isolated blood pockets may form and persist as long as the position remains unchanged (In some circumstances, it may be useful to determine the pressure exerted by the body on a skin area (e.g., on the soles when standing, on the coccyx or scapulae when lying down, etc.). The firm RS Scan International (Belgium-RSscan INTERNATIONAL, Lammerdries 27, B-2250 Olen) provides tools for such measurements over solid surfaces: 60 × 50-cm measuring plates, with possible pressure averaging or mapping.)

The skin must be self-sufficient during these long perfusion breaks and, when there is no compression, the blood flow has to be higher than apparently needed by the metabolism. This factor is usually overlooked and adds to the requirements of the skin thermoregulation function: to eliminate excess calories, the superficial networks must behave like a radiator. The skin blood flow (Martineaud and Seroussi 1977) is approximately 0.5 l/min (heart, 5.5), reaching 0.9 l min⁻¹ during moderate exercise (heart, 9.7) and up to 7 l min⁻¹ during strenuous exercise in hot conditions. Inversely, the minimum blood flow is about 0.02 l min⁻¹. The range of flows is therefore wide, by a factor of 1 to 350. Since one of the major functions of the skin is to eliminate heat, its temperature is generally under 37 °C, even under clothes (Agache 2004).

As a consequence, in comfortable thermal conditions, i.e., the skin is not compressed, the blood flow exceeds actual needs and the blood composition is very close to arterial blood. This means that arterial blood gas can be measured by sampling cutaneous blood from the ear lobe.

3 Variations with Body Site and Age

The study of blood flow in resting conditions shows considerable differences between body areas (Tur et al. 1983), variations in both density and architecture of the vascular network. The head and extremities are particularly notable for their high vascular density. Age is another variation factor (Ryan 1993). In newborn babies, microcirculation is rich and homogenous, then vascular regression appears, especially on the surface (hence a less fresh complexion) followed by progressive specialization ending in a less good complexion and telangiectasias in older people. However, the global flow decreases little. Vasoconstriction induced by smoking has the same effect and contributes to premature vascular aging.

4 Resistive Vessels

The cutaneous blood flow, as in the rest of the body, is operated by two physical quantities: perfusion pressure and resistance to this perfusion. An Ohm law equivalent describes the relationship between the three quantities: flow is perfusion pressure/peripheral resistance. Perfusion pressure depends on the heart ejection and the condition of the proximal arteries. It is impaired in heart deficiency and arterial obstruction. On the other hand, peripheral resistance is controlled by the arterioles. These are numerous in the skin and have a strong tone. Consequently, they play an essential role in regulating blood pressure and protecting the capillary bed against endovascular pressure. In forehead arterioles, especially in dorsal recumbency, the systolic pressure varies with age (from 40 to 80 torr), in parallel with the systolic blood pressure, whereas the diastolic pressure remains constant: 15–20 torr whatever the age (Agache et al. 1993). Because of the tone of their wall, the cutaneous venules also take part in this resistive power but in a minor way.

5 Vasoconstriction

The permanent vasoconstriction of arterioles and venules comes from vasoconstrictor tone, which has a mixed origin: orthosympathetic (local release of noradrenaline) and myogenic (autonomous but permanent and powerful local response of the vascular wall to distension by blood pressure) (Holtz 1996). The orthosympathetic system is also responsible for the venoarteriolar reflex: arteriolar constriction in response to a distension of the venous walls. Its most noticeable effect is the considerable reduction in blood flow in the lower limbs, which prevents blood pressure from falling when one goes from a lying to a standing position.

The main vasoconstriction stimuli of central origin (Martineaud and Seroussi 1977) are inhalation, attempting to exhale with the glottis closed (Valsalva's maneuver), mental arithmetic, concentration, and psychological stresses. The main circulating substances having a vasoconstriction effect in the skin are corticoids (by inhibition of the NO vasodilator), adrenaline (action on the arteriole and venule α receptors, as it seems that there are no β receptors in the cutaneous vessels), and noradrenaline. Cold is a powerful cutaneous vasoconstrictor; most of the blood stored in the veins and venules (capacitive system) is shifted to the viscera, and the blood reaching the hypodermal plexus is shunted through the opening of the arteriovenous shunts. The skin becomes colder (outside cold and reduction in indoor heating). However, when the skin temperature decreases below 12 °C, vasoconstriction and vasodilatation take place alternately, probably to avoid the excessive cooling of the tissues (phenomenon called hunting).

Vasoconstriction can also be induced by the endothelial secretion of thromboxane A₂, prostaglandin H₂, angiotensin II, and endothelin, toward the parietal smooth muscle. Endothelin-1 is perhaps the most powerful vasoconstrictor peptide via its ETA receptor on vascular smooth muscle cell, while via its ETB receptor on endothelial cells it mediates vasodilatation.

6 Capacitive Vessels

The venules, because of their distensibility and volume and because they outnumber the arterioles, make up the capacitive vasculature. This accounts for the sudden reduction in blood flow velocity in these vessels, which favors transparietal exchanges. The venules of the subepithelial plexus, because of their good parietal permeability, are exchange vessels and are identified with what is usually called cutaneous capillaries. If the reduction in the blood flow velocity at their level is intensified by an added vasodilatation, as in inflammation, for example, stasis develops with possible leukocyte adherence, activation and diapedesis, and immune complex deposits. Cutaneous vasculitis is, in fact, venulitis. For the entire integument, the storage capacity of the skin is estimated at 600 ml, or 12 % of the blood volume (Martineaud and Seroussi 1977). Vascular congestion and increased permeability associated with erythrodermia lead to a reduction in plasmatic volume (Worm and Nielsen 1981). Strenuous exercise in very hot conditions (for example, running a marathon) can overdilate the capacitive skin vasculature, which can induce heart deficiency (Martineaud and Seroussi 1977). The same observation was made concerning generalized telangiectasias (Agache et al. 1973).

7 Vasodilatation

In cold or temperate climates, the skin temperature remains permanently below the central temperature: 95 °F (35 °C) on the face, 89.6 °F (32 °C) at the extremities. Vasodilatation takes place in case of heating of internal origin (muscular effort, digestion) or external origin (sun exposure), even without visible erythema. Beyond 107.6 °F (43 °C) vasoconstrictor orthosympathetic reflexes are annihilated. There is, therefore, a risk of orthostatic hypotension in someone suddenly standing up after sunbathing. Generalized cutaneous vasodilatation occurs during

Fig. 4 Vasomotion as observed with laser Doppler

pregnancy and postpartum, as well as in the luteal phase of the menstrual cycle. It is also observed in the evening and the early hours of the night (Martineaud and Seroussi 1977). Emotional or reflex (spicy food) vasodilatation is well known. Finally, any cutaneous ischemia (sustained local pressure, limb tourniquet) is followed by an apparently compensatory phase of reactive hyperemia.

The mechanism of vasodilatation is double: inhibition of the vasoconstrictor tone and local relaxation of the vessels under the influence of the reduced blood flow (pendent foot erythrosis in arterial insufficiency), local reflexes (NO-ergic), endothelial secretions (e.g., NO via activation of NO synthase by endothelial endothelin-1 ETB receptor (Tsukahara et al. 1994) and local vasodilators such as histamine, eicosanoids, PAF, kinins, etc.) (Worm and Nielsen 1981) and even secretions from the adjacent epithelium: when irritated the epidermis secretes NO (Palacio et al. 1997).

8 The Skin Blood Flow

Because of the numerous and continuous vasoconstrictive and vasodilative stimuli, the skin blood flow is permanently changing. Furthermore, some arterioles seem to function only sporadically: no explanation has been found for this phenomenon (Braverman et al. 1990). In addition, the vessels show local and autonomous variations in their diameter. The laser Doppler shows a rhythmic contraction of the skin vessels called vasomotion, superimposed on the heart-beat ($60\text{--}80\text{ min}^{-1}$) and the inspiratory vasoconstriction ($18\text{--}24\text{ min}^{-1}$). These variations in diameter have a low frequency: neurogenous β waves ($6\text{--}10\text{ min}^{-1}$) (they are eliminated by

anesthetics), and myogenous α waves ($1\text{--}2\text{ min}^{-1}$) (they are generated by the smooth muscle coat of the vessel) (Kastrup et al. 1989) (Fig. 4). They are spontaneous, autonomous, and often not synchronous with those of the adjacent areas. Vasomotion facilitates the blood flow (Wilkin 1989) and is triggered or amplified after periods of relative ischemia and in arterial insufficiency of the lower limbs (Bollinger et al. 1991).

9 Conclusion

The skin microcirculation is an anastomotic system of vessels which are barely differentiated and have rather resistant walls; only near the epithelium is their structure well defined. This network has four major functions:

- (a) A role in peripheral resistance,
- (b) Nutrition of the epidermis and its annexes, and in particular resistance of the skin in long periods of compressive ischemia,
- (c) Considerable vasomotion reactivity necessary for thermoregulation, and
- (d) A major part in inflammation and skin reactivity.

Functions (b) and (c) reveal that at resting periods the blood flow is much higher than necessary for nutritional purposes. Finally, the skin microcirculation regulates transcutaneous absorption, ensures the nutrition of the interstitial dermal structures and neurosensorial elements, restorative angiogenesis, as well as classic endothelial functions, especially coagulation, fibrinolysis, and possibly fixation and elimination of the immune complexes.

1 Indications

Peripheral arterial occlusive disease, vascular diseases of the extremities, arterial hypertension, lipodermatosclerosis and leg ulcers, stasis dermatitis, measurement of local vasoconstriction or vasodilatation.

2 Principle

Photoplethysmography (PPG) is an early technique (Hertzman 1937) based on the relative transparency of the human skin for red or near-infrared light (700–1000 nm), and on the diffusing effect of red blood cells (RBCs) which reduces these wavelengths retrodiffusion (Weinman 1967). The variation in the quantity of RBCs within the skin induces an inverse variations of the retrodiffused light detected on the surface

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

(about 1 % of incident light). Therefore, PPG (from the Greek words $\pi\lambda\epsilon\theta\iota\sigma\mu\omicron\xi$ “increase” and $\Gamma\rho\alpha\phi\eta$ “writing”) provides a measurement of any type (active or passive) blood volume *variation* at the tested site.

In practice, the source of light is placed against the skin (obviously the output will be better with red light rather than white light) and the retrodiffused light is detected by a photoelectric cell located in the same place. Two types of signals can be used: either the retrodiffused light systolic-diastolic variation, or through systolic-diastolic variation damping, the variation of the retrodiffused light baseline. In the first case, one deals with sphygmic or arterial PPG, in the second case with volumic or venous PPG. As a matter of fact the first type records the behaviour of the resistive vessels, whereas the second one is mainly influenced by the capacitive vessels. Historically the sphygmic PPG was the first method available but it was replaced in clinical practice by laser-doppler in the Seventies. However it provides irreplaceable data, but today, since the sphygmic PPG is rarely used, the term PPG usually applies to the volumic PPG.

As the amount of incident light remains constant, that of the retrodiffused light depends only on the variation of the quantity of RBCs within the illuminated volume, i.e., the skin vascular volume. The larger is this volume, and the lower is the retrodiffused light. The cutis deeper vessels and those of the subcutaneous plexus (small cutaneous arteries and veins) will mostly be responsible since they are larger than the superficial vessels. The PPG signal can be obtained only in arbitrary units (volts) because neither the volume of diffusion of the incident light, nor its absorption rate by tissues are known. PPG may be used on any part of the body, including the mouth and vagina.

3 Sphygmic (or systolic) PPG

In the devices, the signal is acquired at a frequency of about 20 Hz and always inverted in order to vary parallel to vascular volume. Therefore it is a pulse wave.

3.1 Morphology and Normal Values

The shape of the PPG pulse wave (Fig. 1) is similar to that of arteries, however it often shows in its descending part a shouldering and even an actual dicrotic wave occasionally. In the case of very elastic arterioles several rebound waves of decreasing amplitude may be observed (polycrotism). Quantification of the various parts of the curve has been carried out: total area of the sphygmic wave, ascending slope, descending slope, maximal amplitude, total duration of the wave, number and areas of the dicrotic waves. Comparative measurements require the stability of the device physical sensitivity with time (it has to be calibrated at regular intervals, gain should always be recorded, etc.) and of the similar physiological and environmental conditions (room temperature, subject acclimatisation, position, etc.). Unfortunately owing to the large variety of devices, no absolute value (in volts) can be proposed. Standardisation should be done.

In recumbent subjects at rest, on most areas of the body normal values are low and barely fluctuate (Fig. 2) (Tur et al. 1983). Head and neck on the one hand, and limb extremities on the other hand, are salient exceptions because the signal (systolic-diastolic variation) is both considerably higher and subject to great variation. This demonstrate

Fig. 1 Pulse waves obtained using sphygmic PPG (Laboratory of Skin Biophysics, Besançon)

Fig. 2 Sphygmic PPG pulse waves amplitude distribution (in 10 naked recumbent subjects; room at 20–22 °C) (Tur et al. 1983). Mean and standard deviation (arbitrary units). Sites numbers: 1 supra-scapular, 2 infra-scapular, 3 infra-costal posterior, 4 upper buttock, 5 lower buttock, 6 thorax lateral, 7 infra-costal laterale, 8 hip, 9 below trochanter, 10 arm posterior, 11 forearm posterior, 12 palm, 13 forefinger pad, 14 upper thigh posterior, 15 lower thigh posterior, 16 popliteal area, 17 calf, 18 heel, 19 sole, 20 great toe pad, 21 upper thigh lateral, 22 lower thigh lateral, 23 popliteal

lateral, 24 calf lateral, 25 sub-claviar, 26 infra-mammary, 27 para-umbilical, 28 iliac fossa, 30 arm anterior, 31 forearm anterior, 32 dorsal hand, 33 dorsal forefinger, 34 upper thigh anterior, 35 lower thigh anterior 36 knee anterior, 37 upper leg anterior, 38 lower leg anterior, 39 dorsum foot, 40 medial upper thigh, 41 medial lower thigh, 42 medial knee, 43 medial calf, 44 middle forehead, 45 upper forehead lateral, 46 forehead lateral, 47 zygomatic area, 48 lower cheek, 49 ear lobe, 50 ear back, 51 mastoid area, 52 neck lateral

huge differences in the skin vasculature volume volume as well as in the vasomotor capacity: a phenomenon that the rather low room temperature in Fig. 2 experiment has helped revealing, given that the subjects were naked at 23 ± 2 °C, which is well below the thermal neutrality temperature (30 °C); indeed one could be surprised by the very low values found for the soles and the toe pads, since it is well known that in these sites blood flow is considerably increased in warm conditions (Agache 2004). The PPG signal amplitude is greater in men than women and increases with age. After 60, this amplitude is on average more than double the amplitude found between the age of 20 and 57 (Lévêque et al. 1993), and parallels

the elevation of blood pressure and the decrease of the microvasculature compliance. The PPG also reveals the vasomotion waves which, with a frequency of 6–8 per minute, shift up and down the baseline without modifying the pulse wave morphology.

3.2 Morphogenesis of the Microvasculature Pulse Wave

The shape of the PPG pulse wave depicts the systolic-diastolic variation of the vascular volume which itself depends on the transmural pressure. The latter results from two factors: the

perfusion pressure and the compliance (elasticity) of the vessel wall. The perfusion pressure depends on the arterial pressure upstream and on the resistance downstream. The latter is ruled by the vasoconstrictive tone of the skin vessels and the filling of the veins downstream. A reduced compliance makes the changes of vascular volume more sudden (steeper ascending and descending slopes) and precludes rebounds. Lifting the limb up, which reduces the perfusion pressure and therefore the transmural pressure, increases the amplitude, and inversely lowering the limb or standing up reduce the amplitude because the transmural pressure is increased due to the addition of the hydrostatic pressure. The same effect is observed in venous stasis and venous thrombosis.

3.3 Use in Disease

In the lower limbs an arterial occlusion upstream causes a reduction of the maximal amplitude, decreased slopes and makes the descending phase rigid. Should there be any doubt in the diagnosis, the latter would be confirmed by observing the reactive hyperaemia following 3 min proximal occlusion. While the norm is 3.4 ± 0.8 s to reach half the amplitude before occlusion, it would take over 10 s in case of peripheral occlusive arterial disease (Fronek et al. 1977). The venous hemodynamic troubles also reduce amplitude, weaken the slopes and mostly generate an important dicrotic wave (typical in acrocyanosis). If there was any ambiguity, the venous origin of troubles would be confirmed by their alleviation when the limb is lifted up (Rettori 1998).

3.4 Other Uses of the Sphygmie PPG

3.4.1 Measurement of the Distal Systolic Arterial Pressure

This can be achieved in a limb only. A tourniquet is placed proximal to the PPG sensor and the compression elevated so as to completely suppress the pulse waves; then the compression is

gradually released. The systolic pressure is attained when pulse appears again.

3.4.2 Systolic Pressure, Diastolic Pressure and Compliance of the Skin Microvasculature

This important measurement can be achieved via vertical compression of the applied sensor (Agache et al. 1993). At first an increase of the wave amplitude is observed, then its decrease and finally its suppression when the compression equals the systolic pressure. At peak amplitude, the compression equals the diastolic pressure. This technical device thus provides the absolute value of the so-called "peripheral resistances" at the tested area. It is currently the only non invasive method allowing to obtain these parameters. Its rationale is the same as in the measurement of the blood pressure by the oscillometric method (Geddes 1970; Raines et al. 1973). Furthermore, the ratio peak amplitude/initial amplitude is a compliance index of the microvasculature. In a study carried out on 16 children, 18 adults and 25 subjects over 60, the systolic pressure was found 25 ± 4 , 65 ± 8 and 150 ± 10 torr (1 torr = 1 mm Hg (in Torricelli's honour)), respectively; these values are 42 %, 42 % and 54 % respectively of the arm blood pressure in the same subjects. The diastolic pressures were 15, 18 and 16 torr, respectively, thus about the same in the three age groups. These figures match those in the nail capillaries as found using catheters (Mahler et al. 1979; Shore et al. 1993). The average compliance index decreased regularly with age, respectively at 6.0, 3.5 and 1.8 (Agache et al. 1993). PPG parameters characterise the deep vessels, as alluded to earlier. However the skin whitening pressure, which matches the sub-epidermal plexus vessels transmural pressure, remained stable, 30 torr, in the three age groups (Agache et al. 1993).

4 Volume (Diastolic) PPG

This type of PPG, also called light reflection rheography has met with considerable success when its utility was shown in venous stasis syndromes of the lower limbs. It records the baseline

Fig. 3 Volumic PPG record in lower limb. lors d'un test de reflux veineux sous-cutané dans le membre inférieur. (a) normal (skin filling time: 25 s). (b) great saphene incompetence (skin filling time: 9 s), return to normal following great saphena compression above knee. (c) leg perforating

veins incompetence (skin filling time: 7 s), no change following great saphena compression above knee; note the low calf pump efficacy (Laboratory of Skin Biophysics, Besançon)

signal through its systolic-diastolic variation damping. The sensor is that of pulse PPG but recording use direct current. The *difference* in the baseline level following its raise or decrease is a way to assess the skin blood volume *variation* (in volts) at the tested site. As for the pulse PPG it is mandatory to have external or internal calibration in order to be able to compare different subjects and confirm that the detector sensitivity has not shifted. The temperature of the test room should be between 20 °C and 25 °C, otherwise important vasomotor changes might occur. The subject, in resting position, must have been acclimated to the room temperature for 15 min at least.

To check the blood flow in a lower limb in case of lipodermatosclerosis with or without leg ulcer, the subject keep standing immobile (or if this is not possible, seated with his foot resting on a support). The probe is attached with double sided adhesive tape. When a stable value is obtained, the subject is asked to lift his heels regularly keeping the forefoot on the

ground (for example every second for 10 s); the help of a metronome is useful. Another manoeuvre consists in doing ten maximal fore-foot lifting while keeping the heel on the ground (Belcaro et al. 1995). A decrease of the skin blood volume is observed during the first contractions (Fig. 3). While the foot is kept on the ground the recording is continued for the following 60 s. As soon as the movements stop, the skin starts to refill: the time required to reach the initial level (or so that 90 % of the emptying is corrected) is measured. It is important that the patient keeps immobile and relaxed until the end of the examination (without speaking, breathing normally).

The normal refilling time is usually 35 ± 12 s (Belcaro et al. 1995). When found shorter by more than two standard deviations (i.e., less than 11 s) it indicates deep intra-cutaneous or sub-cutaneous abnormal venous reflux. The emptying rate is another parameter which is related to the skin

blood content under a known hydrostatic pressure and consequently depends on the vertical distance between the PPG probe and the right auricle. The blood volume after the test is not always the same as the initial volume.

Note that the techniques of air or strain gauge plethysmography, when applied on the lower limb, measure the venous calf muscle pump efficacy, but not the possible venular refluxes, whereas the latter may be associated with a disturbed or apparently normal calf pump. The resolution of the imaging-doppler is too low to detect less than 1 mm diameter venules. The volumic PPG is therefore currently the only technique allowing to pinpoint venular backflow into the dermis or subcutis. Its suppression or reduction following application of a venous proximal tourniquet, suggests the responsibility of the saphenous system. If the tourniquet has no effect the backflow is either of local or of deep origin.

In other areas, the volumic PPG provides a measurement of the skin blood volume variation with changes of the perfusion pressure, or the venous pressure or the hydrostatic pressure. For a given pressure variation, the measurement of the skin blood volume variation allows to assess the tone (elasticity) of the capacity vessels. In cold environment the vasoconstriction is transcribed as a lowered baseline, with opposite results when the temperature rises. The volumic PPG also shows the vasomotion waves.

5 Precautions

- To ensure the good reproducibility, it is essential that the detector (which consists of a source of light and a photoelectric cell) is positioned parallel to the skin surface and with a constant and stable pressure. The latter must be as light as possible or it will alter the signal. It is even possible to avoid contact with the skin. It is convenient to use a ring of double sided adhesive paper, which should be preferred to the traditional pliers used on the fingertips.
- If the skin is wet or oily, the light penetration and outflow can be facilitated because the

stratum corneum is more transparent; this induces an increase of the signal.

- The room temperature must be set between 20 °C and 25 °C for a subject dressed normally, otherwise important vasomotor changes will occur. The subject should be in resting position and acclimated to the temperature for 15 min.
- At present the voltage given by each type of device is different, since no external standard is available. Users should therefore have their own norm for each body site, age and skin temperature.

6 Commercialised Devices

- Medasonics (USA)
- Hemodynamics AV 1000 (Laumann Medizintechnik GmbH, Germany) is developed especially for the supramalleolar volumic PPG and has a metronome, a temperature detector and a standard test for the foot movements.

Previous chapters witness the numerous methods available to measure skin blood flow. Each of them characterizes specific parameters. Consequently, it is necessary to compare these methods and replace them in the anatomical and physiological context. Thereupon can be examined their potential contribution in various situations: healthy skin or pathological conditions, skin pharmacology, skin metrology, etc. This chapter first examines at which depth the signal comes from, therefore the type of blood flow investigated, either deep or superficial. Secondly it will tentatively help select the most appropriate methods to investigate principally either the resistive or capacitive domain of the skin vascular network.

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

1 Selection from Anatomical Considerations

1.1 Measurement of Subepidermal Blood Flow

Two methods are specific and exclusive to the most superficial part of the subepidermal plexus and the papillary loops: transcutaneous oxygen

pressure (tcPO₂) and capillaroscopy. Their meaning and parameters are very different.

- The tcPO₂ at 37 °C is theoretically able to measure the blood flow in the papillary loops in absolute units, and therefore is potentially a very useful method. However, the signal is so low and variable that the measurement is often not reliable; thus additional studies are required before using it for this purpose.

Usually the tcPO₂ is measured on the skin heated to 44 °C, a temperature which suppresses the vasoconstrictive tone. Its value is thus related to the capacity of the outermost part of the subepidermal vascular network to vasodilate (for example, tcPO₂ is reduced in lipodermatosclerosis and venous leg ulcers, and in lower limb arteriosclerosis). It also appears that the skin blood flow could be measured in specific units from the rate of the tcPO₂ reappearance after proximal occlusion release, but clinical confirmation is still lacking. On the other hand, the tcPO₂ falling rate during proximal occlusion is a way to measure oxygen consumption by the epidermis, and thus its metabolism. Although few studies have been carried out, this technique seems promising in skin disease.

Capillaroscopy has become feasible at any site of the skin. The extent of the superficial part of the subepidermal plexus and papillary loops can be quantified by image analysis. It is also possible to measure (in specific units) the dimensions of the vessels and the speed of the red blood cells. Both figures, once combined, can give access to blood flow in specific units, an uncommon and invaluable parameter. Few studies are available, but a priori the method could be used in diseased as well as in healthy skin, or to assess small variations of inflammatory origin.

1.2 The Subepidermal Plexus as a Whole

Several methods appear to be ideal for measuring the subepidermal plexus because of their operating mode: green laser Doppler, reflectometry, and

colorimetry on the one hand, based on the absorption of a wavelength by hemoglobin, and thermal and epicutaneous xenon clearances on the other hand.

- Green laser Doppler uses a wavelength (543 nm) specifically absorbed by oxyhemoglobin. Its penetration depth probably goes beyond the most superficial parts of the subepidermal plexus, which provides a thorough investigation. However, it does not penetrate beyond that point, as indicated by its very weak signal. It is therefore an interesting means of measuring the average flux (amount of moving red blood cells multiplied by their average speed), probably in the entire plexus. Since it is given in arbitrary units, this value cannot be compared with the absolute values provided by the previous methods.
- Reflectometry detects the absorption of green light by hemoglobin and its signal is made up exclusively of the 546- and 568-nm wavelength retrodiffusion following absorption. The mid-dermis (cutis) acts as a partial reflecting screen. This method therefore provides the measurement of the amount of blood almost exclusively present in the superficial dermis, i.e., the subepidermal plexus, unfortunately in arbitrary units. Easy-to-use devices are on the market. The same technique can be improved by the use of a spectrophotometer, which scans the skin surface at 5-nm intervals and selects the wavelengths specific to oxyhemoglobin and reduced hemoglobin, in order to measure the variations in the skin content in arteriolar (active vasodilatation) and venous (stasis, passive vasodilatation) blood separately.
- Colorimetry measures the retrodiffusion of a red-green-blue light tristimulus. The device transforms the intensity of the retrodiffused RGB spectrum into skin color expressed by the parameters $L^*a^*b^*$. In principle, blue is immediately and totally absorbed by hemoglobin. So is green, although to a lesser degree, as it goes down to the mid-dermis; its reflectance should therefore involve the entire superficial

dermal plexus. Red reaches the hypodermis; it is not absorbed but diffused by the red blood cells; therefore the amount of retrodiffused red decreases in relation to the deeper blood volume. Colorimetry could therefore explore all the skin vessels, whatever their depth, and assess the retrodiffused spectrum resulting from the whole skin blood. This spectrum is unknown and only its coordinates L^*a^*b are available. However, since the absorption of blue and green are predominant, it is probable that the signal is mainly influenced by the blood in the superficial dermis. Spectrocolorimeters operate according to the same principle, but they scan the skin surface over the entire visible spectrum. They are in principle more accurate.

- Clearance methods are obviously based on the washing out of a marker (xenon-133 or heat) that has diffused in the skin from the surface: hence a concentration gradient decreasing with penetration. The elimination process implies first the penetration of the vascular walls, which depends on their cumulated surface and the difference in concentration on each side of the wall. From skin biopsy autoradiography, it is known that the xenon gas capture by the vessels occurs entirely in the superficial dermis, therefore in the subepidermal plexus. The advantage of this method relies on the flow rate absolute value given in milliliters per minute per 100 g tissue, equivalent to milliliters per minute per square meter, assuming that the density and average thickness of the superficial dermis are 1 and 0.1 mm. Unfortunately, this method is cumbersome and available only in nuclear medicine units.

In contrast, thermal clearance implementation is easy and results are displayed immediately. It is based on the same principle. The heat wash-out depends on the cumulated surface of the vascular walls and the temperature difference between the interstitial ground substance and blood. On the one hand, it is more important in the relatively cool superficial blood than in the deeper blood, and on the other hand, according to the author, the thermal gradient decreases steeply and concerns

almost exclusively the first 100 μm , i.e., the superficial dermis. Thus, the signal reflects mainly the blood flow variation in the subepidermal plexus, expressed in skin thermal conductivity units. However, it appears that further investigations could lead to flow rate units since the thermal conductivity is given in absolute units. This promising method is no longer available, but a new device is said to be under development.

1.3 Measurement of the Whole Skin Blood Flow

The whole skin blood flow is given by methods using red or near-infrared light, since its penetration reaches the hypodermis. The vascular volume and the flow rate at this level are considerably higher than in the superficial dermis; consequently, these methods measure mainly the blood flow in the deep dermis and the superficial hypodermis (excluding adipose tissue).

- Laser Doppler devices indicate the number of moving red blood cells, their average speed, and the product of both measurements, giving the flow rate, all in arbitrary units. New technologies present two considerable advantages since they avoid contact between the transmitter and the skin and allow skin scanning. Therefore, blood flow is not altered by the measurement, and blood flow mapping is made possible. As a consequence, the measurement of vasomotor reactions in healthy or diseased skin is more accurate than with telethermography and can be done whatever the condition of the skin surface (wet, ulcerated, etc.), provided, obviously, that there is no ointment acting as a screen. In many experiments, the laser Doppler imager supersedes traditional laser Doppler because it also makes it possible to observe and record the flow on a fairly large area over a long period of time. However, one must be aware that flow changes restricted to the subepidermal plexus may go unnoticed with this method: a typical example is vasoconstriction from topical corticosteroids.

– Photoplethysmography (PPG) measures the blood volume variation within the constant skin illuminated volume. Each red blood cell diffuses light and reduces retrodiffusion proportionally. This method provides either the diastolic blood volume in the deeper part of the skin or its systolic increase. Its advantages are simplicity and low cost, and above all its capacity to separately analyze the resistive and capacitive sectors of skin microcirculation.

2 Selecting a Method Based on the Vessel Type to be Studied

2.1 Nutritive Capillaries

These vessels are located near the epidermis and appendage epithelia. Only the former are specifically accessible, using $t\text{cPO}_2$ and capillaroscopy. It seems that the papillary loops are not the only nutritive vessels of the epidermis: the more superficial venules also take part in this process, as well as in anatomical sites without papillary design. This underlines the advantage of newer capillaroscopy techniques, which make it possible to visualize the superficial part of the subepidermal plexus. The green laser Doppler is a technique that can also be considered as a means to measure the nutritive sector, although it also applies to vessels located deeper in this plexus. The nutritive capillaries of the pilosebaceous follicles and the sweat glands participate in the vascularization of the mid- and deep dermis and the global measurement of their volume or flow rate is a part of the PPG or laser Doppler signal.

2.2 Arterioles

The arteriolar, or upstream portion of the skin vascular system is specifically analyzed by thermal methods. Except for the extremities, the skin's spontaneous warm temperature indicates the arrival of a flow coming from the core, therefore from some skin arterioles being open. The

available methods are punctual or liquid crystal thermometry, which gives an approximate mapping, and telethermography. The latter bears two salient advantages: it is a non-contact technique, allows sustained measurements, and provides skin temperature mapping. Active arteriolar vasodilatation (as in inflammation) and arteriolar spasm (as in hypersensitivity to cold or arterial hypertension) will therefore theoretically be investigated thoroughly by these methods. Skin surface thermometry is not sufficiently reliable, as it is influenced by external temperature. This is not the case for thermography, which measures IR light emission. Unfortunately, telethermography devices are very expensive.

The laser Doppler imager is currently challenging thermography in this field of investigation. In mid- or deep dermis or hypodermis, the flow is controlled by arterioles, which are not dilated during stasis or passive vasodilatation (also characterized by a stable or reduced flow). The topographical resolution (0.5 mm, sometimes 0.2 mm) is higher than that of thermography (5 mm). A 0.2-mm resolution even detects continuously perfused areas, each probably corresponding to a single arteriole. But on thin-skinned sites, venous blood is also recorded. Finally, the laser Doppler imager, as opposed to thermography, is not sensitive to wetness and is able to measure the flow on a de-epidermized area.

Systolic PPG is the oldest method to have been used in the study of skin microcirculation. The signal is a sphygmoc wave, the morphology of which varies according to local hemodynamic conditions. It indicates the systolic-diastolic blood volume variation with time in the deep dermis. Arterioles are mainly concerned since they are the most pulsatile vessels. The PPG pulse wave morphological parameters have been used qualitatively to try and identify circulatory alterations downstream (e.g., stasis or increase in resistance) or upstream (e.g., arterial stricture or occlusion). This method was abandoned when laser Doppler was developed. However, the data provided by the systolic PPG are quite different and remain irreplaceable. A quantitative analysis

Table 1 The summary of the available methods for measuring the skin microcirculation and their characteristics.

	High pressure sector (arterioles, small arteries)	Subepidermal nutritive vessels (capillaries, venules)	Low-pressure sector (venules, small veins)
Anatomical level	Small total volume	Very small total volume	Large total volume
Subepidermal		TcPO ₂ Capillaroscopy Green laser Doppler	Reflectometry Colorimetry Thermal clearance Xenon-133 clearance
Dermis and upper subcutis	Systolic PPG Red laser Doppler Thermometry Telethermography		Diastolic PPG

of morphological parameters would also be very useful: further physical and physiological studies are required.

2.3 Venules

The diastolic PPG signal expresses the sum of the arteriolar and venular volumes of the deep dermis and near hypodermis. As such, it can be a measure (in arbitrary units) of the skin passive blood supply during variations in the hydrostatic pressure or during a venular backflow from the subcutaneous veins in lower-limb venous insufficiency. It is obviously a useful method, which is irreplaceable in such diseases.

Clearance methods give greater importance to the capacitive sector of the subepidermal plexus because their walls are more permeable than those of the arterioles and the number of venules and the cumulated surface of their walls are much larger. The blood flow rate measured by xenon-133 clearance is probably closer to the venular than the arteriolar flow rate. The same holds true for the flow rate measured by thermal clearance.

3 Fingers and Toes

The examination of the extremities, in particular the fingertips and toes, is particular because of the large number of intradermal arteriovenous anastomoses, the interference of intense vasomotricity in relation to thermoregulation, and the thickness of the stratum corneum on the palmar aspects. As a result, the above-mentioned methods measuring the subepidermal nutritive blood flow cannot be used, and measurements with other methods are subject to error. Another old method, strain gauge plethysmography, can be used. Its principle is the measurement of the stretching of a strain gauge placed around a finger, resulting from the passage of the pulse or the position of the limb. The gauge is usually a thin rubber tube filled with mercury, the electric resistance of which, measured by a Wheatstone bridge, increases from its elongation and narrowing. The signal is similar to that of the PPG: a pulse wave or a horizontal straight line representing the limb or finger diastolic perimeter. If the gauge is calibrated, the measured difference in perimeter (i.e., in

volume) is given in absolute units: milliliters per minute for 100 ml soft tissue. The latter consists of the dermis with its numerous microvessels (arterioles, venules, capillaries, arteriovenous anastomoses), the hypodermis including fat, but also the laterodigital small arteries, the flow rate of which is impossible to evaluate separately.

4 Conclusion

The choice of one or several methods to measure skin microcirculation must therefore be determined according to specific needs, for example

in phlebology: $tcPO_2$, PPG, and epicutaneous xenon-133 clearance are informative. Using several techniques for a single purpose is often rewarding because the meaning of experimental data is more easily understood. If a single device is to be used to measure an erythema or a pigmentation, colorimetry or reflectometry are particularly recommended. The choice of the device should also be made in relation with the request of a quantitative or semiquantitative type of measurement. Finally, whenever possible, measurements in absolute and specific units are always preferable. The table below summarizes the characteristics of available methods.

1 Structure and Function

The lymphatic system is an open-ended network that returns lymph back to blood circulation. Microcirculation is the site where exchanges between blood or lymphatic vessels and tissues occur. Interstitial fluid that does not return to the blood by venules is collected by lymphatic capillaries and constitutes the lymph, a protein-rich exudate containing cells and macromolecules (Cueni and Detmar 2006; Parsi et al. 2011). Therefore, the lymph system plays an important role in homeostasis by this reabsorption of extracellular fluid (Van der Auwera et al. 2006). Lymphatic capillaries appear in the papillary dermis and drain into precollector vessels that link them to collector vessels. Lymph returns to the blood by large lymphatic trunks. Lymph vessels go through lymph nodes and constitute the way for immune circulating cells. The lymphatic system also plays an immune role that is particularly important in the skin as Langerhans cells pass by these vessels to reach lymph nodes (Bruyère and Noël 2010; Parsi et al. 2011). The lymphatic system originates

from embryonic veins, and the development of lymphatic system begins when the cardiovascular system is already functioning (Cueni and Detmar 2006).

Lymphatic capillaries are blind-ended vessels that arise in the interstitial spaces of the dermal papillae. They are much larger than blood capillaries and stay away from epidermis, while blood capillary loops are close to the epidermis. These microvessels are lined by a single, nonfenestrated layer of endothelial cells that overlap but lack a basement membrane and pericytes (Parsi et al. 2011). These cells are linked to the extracellular dermal matrix by anchoring filaments. When interstitial pressure increases, LECs are pulled allowing capillary lumen to widen and excess fluid to be taken up.

Lymphatic vessels are particularly numerous in the dermis but are absent in the epidermis (Cueni and Detmar 2006). Lymphatic vessel density shows some anatomic variability that may contribute to the metastatic potential of primary cutaneous tumors (Duffy et al. 2010). However, body repartition of lymphatic vessels appears symmetric on both sides of a middle vertical line (Reynolds et al. 2010).

2 Identification of Initial Lymphatic Vessels

In spite of their high number, lymphatic vessels are difficult to distinguish in routine histological sections (Wu et al. 2012). BECs and LECs share many structural and molecular characteristics and are difficult to differentiate by histological morphology alone (Cueni and Detmar 2008; Oliver and Detmar 2002; Van der Auwera et al. 2006).

Little attention was paid to the lymphatic system until this century and most of the knowledge result from research performed during these last 10 years (Lee et al. 2010). Assessment of skin lymphatic microcirculation is of great importance in lymphedema, psoriasis, and systemic sclerosis pathogenesis as well as in tumor metastasis and wound healing. Some methods such as microlymphangiography via intradermal injections of

fluorescein or dye allow to study the functional aspect of this microcirculation but do not really quantify it (Wu et al. 2012).

Immunohistochemical labeling is still the most common method to identify LECs. Lymphatic vascular endothelial hyaluronan receptor-1 (Lyve-1), Prox-1, podoplanin, VEGF-receptor-3 (VEGFR-3), and desmoplakin are the most frequent specific lymphatic markers studied (Bruyère and Noël 2010). Lyve-1 is highly expressed in lymphatic capillaries and at a lesser degree in larger vessels. Prox-1 is considered to be the most specific marker (Cueni and Detmar 2006), but its nuclear immunohistochemistry localization is not suitable for microscopic quantification. Therefore, for this purpose, it should be preferably used in double staining with others markers. Podoplanin is recognized by the D2-40 antibody. Several non-endothelial cells (basal keratinocytes by example) and some malignant tumors can also be labeled by this antibody. Despite the fact that VEGFR-3 is expressed by LECs in adult tissues, it can also be expressed by BECs in fenestrated capillaries and in pathological conditions (tumoral angiogenesis) (Cueni and Detmar 2006; Van der Auwera et al. 2006). Desmoplakin, a cytoplasmic protein, enters in the composition of junctions between LCE and extracellular matrix (Cueni and Detmar 2006). To obtain a reliable differentiation between BECs and LECs, several markers should be associated.

Currently, immunohistochemistry allows the assessment of important parameters such as structural characteristics, density, diameter, perimeter, surface area, and absolute c-vascular volume by using imaging quantification (Lokmic and Mitchell 2011; Wu et al. 2012). Confocal microscopy of whole-mount preparations and computer graphic three-dimensional reconstruction provide three-dimensional images and permit the quantification of lymphatic capillaries by imaging software (Cui 2006; Wu et al. 2012). However, these techniques are expensive, complex, and subject to artifacts. Further studies are necessary to determine the best method for studying lymphatic microcirculation (Wu et al. 2012).

1 Introduction

Laser Doppler flowmetry has been employed for many years to assess cutaneous microvascular function in health and disease. It is often used in conjunction with transdermal iontophoresis of acetylcholine, as this provides information about the integrity both of the microvascular endothelium and the cutaneous sensory nerve supply. The reproducibility of this approach is reviewed below, and alternatives are discussed. In addition, some clinical applications are described.

2 Laser Doppler Flowmetry

This involves projection of a laser beam (typically 780 nm) into the skin and measurement of intensity and Doppler shifts in frequency in the near-infrared range of the backscattered light. The intensity of the reflected light is proportional to the concentration of red blood cells illuminated by the laser beam, and the shift in frequency is proportional to the

University, Perth, WA, Australia
e-mail: p.drummond@murdoch.edu.au

velocity of red blood cells moving through the illuminated tissue. When combined, these two values provide a measure of perfusion that varies in a linear fashion with microvascular blood flow (Ahn et al. 1987). The depth of measured flow (in the order of 1–1.5 mm) depends on the wavelength of the laser source (penetration is greater with longer wavelengths) (Berardesca et al. 2002). Thus, in the skin, the laser Doppler signal represents net flow through cutaneous arterioles, venous plexuses, and arteriovenous anastomoses.

Although laser Doppler flowmetry can be used to measure relative changes in skin blood flow, the signal cannot be calibrated in absolute units because of the complex nature of light scattering and site-to-site differences in the density and structure of the cutaneous microvasculature (Berardesca et al. 2002). Preferably, then, microvascular reactivity (e.g., to a drug or thermal challenge) should be expressed in perfusion units, normalized to measures taken at the same site under standard conditions (e.g., at rest or in response to a standard provocation).

Flow is sometimes expressed in relation to near-maximal flow at the site of interest. Heating the skin to 42 °C induces an axon reflex that peaks within a few minutes (Minson et al. 2001). Blood flow drops briefly then continues to rise gradually over the next 30–40 min, due to nonneural influences on the local microvasculature that involve nitric oxide (Kellogg et al. 2008). This approach evokes near-maximal increases in flow but can be cumbersome and time-consuming and controls only for the upper limit of nonneural influences on flow. Flow may also be expressed in response to vasodilatation evoked by administration of the nitric oxide donor sodium nitroprusside. However, the reproducibility of this response is extremely poor when assessed by laser Doppler flowmetry (Roustit and Cracowski 2012) and does not control for other influences on blood flow (e.g., the capacity of the sensory and autonomic nerve supply, vascular smooth muscle and endothelium, infiltrating immune cells and resident mast cells, fibroblasts and keratinocytes to release vasoactive substances). Another option is to express flow in relation to the peak of the axon reflex induced by 5–6 min of local heating (Brocx

and Drummond 2009). This controls for spatial microvascular variations and sensory neural influences on blood flow, but may not account for nonneural influences on flow.

Perhaps the most commonly used approach is to express flow as a proportion of levels recorded during the baseline period before stimulus onset. Although this controls for site-to-site variation in cutaneous vascular and neural architecture, the response depends critically on the conditions under which baseline measures are obtained. Thus, it is important to standardize ambient temperature, time of day, prior levels of muscular activity, prior ingestion of substances that might influence flow (e.g., caffeine, nicotine, and alcohol), and, as much as possible, the participant's psychological state.

Flow is sometimes normalized in relation to mean blood pressure (i.e., so that flow is expressed in units of cutaneous vascular conductance), to control for effects of pressure on perfusion. However, the assumption that systemic pressure reflects perfusion pressure in the local microvasculature might not always hold true (e.g., when vasoactive drugs are administered locally or when the site of interest is heated or cooled).

3 Iontophoresis

Transdermal iontophoresis involves the use of an electric current to transfer charged or polarized molecules through the skin barrier. This typically involves passing a weak direct current through a drug solution contained in a capsule attached to the skin, to assist penetration of the drug through the stratum corneum. In this way, positively charged ions are repelled from the anode, and negatively charged ions are repelled from the cathode. Charged molecules enter primarily through hair follicles and sweat ducts and then diffuse through the extracellular space to the cutaneous microvasculature where they are dispersed through the circulating blood supply (Tesselaar and Sjoberg 2011). The dose delivered by this method is proportional to the current strength (measured in amperes) and duration (seconds)

and can be expressed as the iontophoretic charge (in Coulombs). However, the physiologically active component of the dose cannot be measured accurately because some of the electric current is carried by nondrug ions (e.g., in the solution vehicle or which originate in the skin). Furthermore, the relationship between dose and response is complex because some of the infused drug may bind nonselectively to cells in the stratum corneum or deeper within the skin or is cleared rapidly through the microvascular bed (particularly vasodilator drugs).

In addition, the electric current employed in iontophoresis can induce nonspecific vasodilator responses that alter local blood flow (Grossmann et al. 1995). This nonspecific response is stronger at the cathode than the anode and may involve several mechanisms. During iontophoresis, the electrolysis of water into hydrogen and oxygen results in an accumulation of hydrogen ions under the anode (Sato et al. 1993). Together with direct effects of the electric current on the resting potential of neural membranes, local changes in pH in the skin may depolarize sensory nerve fibers and trigger the antidromic release of vasoactive neuropeptides such as substance P and calcitonin gene-related peptide (CGRP) from the dermal network of nerve terminals (a process known as axon reflex vasodilatation). Thus, skin blood flow may increase within the receptive field of stimulated nerves up to several cm from the stimulated site. This component of the response can be blocked by prior treatment with capsaicin cream to desensitize C-nociceptive fibers and with local anesthetic agents such as EMLA cream that prevent depolarization (Durand et al. 2002). In addition to these mechanisms, local heating and other changes evoked by the movement of charged molecules through the skin may induce the production of prostaglandins which, in turn, trigger vasodilatation. For instance, the cyclooxygenase inhibitor indomethacin blocks anodal current-induced vasodilatation (Tartas et al. 2005). Curiously, pretreatment with celecoxib (which inhibits the formation of an inducible isoform of cyclooxygenase produced during inflammation) has no effect on anodal current-induced vasodilatation (Tartas et al. 2005), suggesting that the response

is driven by the constitutive rather than the inducible cyclooxygenase isoform.

4 Measuring Microvascular Responses During Iontophoresis

Changes in blood flow during iontophoresis are often measured via a Laser Doppler flow probe inserted in the roof of the drug chamber directly over the site of drug infusion. This provides continuous measurement of blood flow from a single spot 2–3 mm in diameter at the site where the drug enters the skin. Unfortunately, microvascular responses vary considerably from one spot to another due to anatomical variation in the microvasculature (Braverman et al. 1990). For example, in a study in our laboratory, the reproducibility of the microvascular response to transdermal iontophoresis of acetylcholine was greater when the iontophoresis was repeated at the same site after a 50 min interval than when the iontophoresis was carried out at sites 10 cm apart on the volar forearm (Brocx and Drummond 2009). Responses were greater at proximal than distal sites in the forearm, possibly due to differences in thickness of the stratum corneum or in sweat gland or microvascular density. Thus, it is important to standardize the test site when making comparisons within individuals or between groups of patients and controls.

One solution to this problem is to measure changes in flow over a large surface area. Laser Doppler imaging achieves this by moving a laser beam across the region of interest to create a map of local blood flow. Although this minimizes the effect of structural variations on blood flow, it is difficult to capture rapid changes in flow because of the time required to scan the region of interest. An alternative is to use laser speckle contrast imaging, which employs a camera to generate a perfusion map of illuminated tissue based on the motion of particles in the region of interest. As perfusion maps can be generated quickly, rapid responses can be tracked with this approach (Mahe et al. 2012). In contrast to laser Doppler techniques, which detect flow to a depth of around

1 mm with a 780 nm laser beam, flow is detected to a depth of approximately 0.3 mm with laser speckle contrast imaging (corresponding to nutritional rather than arterial flow) (Mahe et al. 2012). The reproducibility of measures of blood flow is greater with laser Doppler imaging and laser speckle contrast imaging than with spot measures of laser Doppler flow (Mahe et al. 2012; Roustit and Cracowski 2012).

5 Reproducibility of the Cutaneous Vascular Response to Acetylcholine

Acetylcholine induces endothelium-dependent vasodilatation via stimulation of muscarinic receptors on the vascular endothelial surface (Cracowski et al. 2006). This releases nitric oxide, which induces vascular smooth muscle relaxation and, hence, vasodilatation. In addition, a flare surrounding the site of acetylcholine iontophoresis is mediated by an axon reflex that involves production of prostanoids (Berghoff et al. 2002).

The reproducibility of cutaneous microvascular responses to acetylcholine iontophoresis has not been firmly established due, in part, to the variety of doses, data expression methods, and protocols that have been employed (Agarwal et al. 2010; Klonizakis et al. 2011; Puissant et al. 2013; Tibirica et al. 2011). However, we recently used this technique to examine the reproducibility of vascular responses to stepped increases in acetylcholine delivered transdermally by iontophoresis (Brocx and Drummond 2009). One probe was positioned inside the iontophoresis chamber (to measure the direct endothelium-dependent component of the response), and another probe was positioned 5–8 mm outside the iontophoresis chamber (to measure the axon reflex) (Brocx and Drummond 2009). At the site of acetylcholine iontophoresis, laser Doppler flux data were expressed as a proportion of baseline and a proportion of the response to heating for 5–6 min. The reproducibility of each form of data expression was investigated within and across different forearm sites.

The direct response to acetylcholine was most reproducible when expressed in proportion to levels recorded after 5–6 min of local heating to 42 °C (the percentage of shared variance was 55 % when the iontophoresis was repeated at the same site on the volar forearm, and mean increases in flow were similar on both occasions) (Fig. 1). The association was also strong when expressed in proportion to levels recorded at baseline – the percentage of shared variance was 74 % when the acetylcholine iontophoresis was repeated at the same site. However, when data were expressed in this way, responses were consistently smaller during the second than first iontophoresis, in part because of a residual elevation of the baseline from the first iontophoresis (cumulative increases in flow across all doses were 68 times greater than baseline during the first iontophoresis compared with only 30 times greater than baseline during the second iontophoresis) (Fig. 2). Similarly, for axon reflex vasodilatation, 38 % of variance was shared between responses at times 1 and 2 when the iontophoresis was repeated at the same site on the volar forearm; however, responses were greater on the first than second occasion (cumulative increases in flow were 22 vs. 14 times greater than baseline, respectively) (Fig. 2). This illustrates the importance of minimizing nonspecific influences on basal flow if this form of data expression is used. We also attempted to identify the optimal current strength and duration for the iontophoresis of acetylcholine. The “dose-response” curve peaked at the site of iontophoresis but the axon reflex failed to plateau (Fig. 2), suggesting that a higher dose might be required to fully capture this response.

Additional variables that might influence the reproducibility of the vasodilator response to acetylcholine have been investigated recently. For example, microvascular responses in the legs to iontophoretic administration of acetylcholine were found to be lower in the standing than supine positions, presumably due to postural vasoconstrictor reflexes (Klonizakis et al. 2011). Nevertheless, responses were reproducible over a 2-week interval when measured with a laser

Fig. 1 Changes in blood flow (\pm standard error) during the transdermal iontophoresis of acetylcholine in the volar forearm 5 cm below the elbow, expressed as a proportion of the peak in blood flow when the forearm was heated to 42–43 °C for 5–6 min. For each dose of acetylcholine, an anodal current was supplied for 60 s in a drug chamber (internal diameter, 10 mm), and blood flow was monitored

for a further 2 min at the site of drug administration. The entire procedure was repeated at the same site after an interval of 50 min. When expressed as a proportion of the peak in blood flow during forearm heating, peak and overall increases in blood flow were similar during both series of iontophoreses (Based on data presented by Brocx and Drummond (2009))

Fig. 2 Changes in blood flow (\pm standard error) during the transdermal iontophoresis of acetylcholine at the direct site (expressing endothelium-dependent vasodilatation) and 5–8 mm away (a site of axon reflex vasodilatation). Changes in blood flow (flux) are presented in arbitrary perfusion units (PU) and as a proportion of levels recorded

for 2 min before the current was applied (baseline). When expressed as a proportion of baseline, increases in flow were greater during the first than second series of iontophoreses, due to residual basal vasodilatation after the first series (Based on data presented by Brocx and Drummond (2009))

Doppler imager and expressed in arbitrary perfusion units. In addition, the reproducibility of the peak response to acetylcholine iontophoresis was similar during single and incremental doses,

despite concerns that axon reflex vasodilatation might mask endothelium-dependent vasodilatation to acetylcholine with incremental doses (Puissant et al. 2013).

6 Intradermal Delivery of Acetylcholine by Microdialysis

As an alternative to transdermal iontophoresis, drugs can be delivered intradermally through microdialysis fibers. This involves the insertion of porous catheters 0.5–1 mm under the skin surface for distances of several cm so that drugs can be delivered directly to the dermis, bypassing the skin barrier. An additional advantage of this technique is that biomarkers that diffuse from the extracellular fluid into the microdialysis fibers can be measured in the dialyzate, thereby providing an estimate of their local concentration.

One difficulty with microdialysis is that insertion of the fibers into the skin provokes an inflammatory reaction that might alter responses to the drug being delivered and/or the concentration of biomarkers of interest (Stenken et al. 2010). However, this inflammatory reaction appears to produce effects that differ from those provoked by axon reflexes during iontophoresis. For example, we found that iontophoresis of α_1 -adrenoceptor agonists such as methoxamine and phenylephrine provoked an axon reflex when delivered transdermally by iontophoresis (Drummond 2009, 2011). The axon reflex could be blocked by prior application of local anesthetic agent (EMLA cream) to the skin surface and by α_1 -adrenoceptor blockade and was inhibited by topical application of ibuprofen gel. In contrast, direct intradermal delivery of phenylephrine through microdialysis fibers did not provoke an axon reflex (Zahn et al. 2004). One interpretation of these findings is that phenylephrine amplifies an axon reflex initiated by the iontophoretic current, perhaps by stimulating α_1 -adrenoceptors on keratinocytes or cutaneous nociceptors (Dawson et al. 2011).

When delivered through microdialysis fibers, acetylcholine triggers a flare in the surrounding skin that is mediated by antidromic release of neuropeptides such as CGRP from sensory nerve fibers (Schlereth et al. 2013). In addition, acetylcholine delivered intradermally through microdialysis fibers induces endothelium-dependent vasodilatation via nitric oxide and

prostaglandins release (Medow et al. 2008). Thus, although intradermal delivery of acetylcholine by microdialysis may avoid some of the nonspecific effects evoked by current-assisted transdermal delivery, responses seem to be broadly similar in both modes of delivery.

7 Clinical Findings

Efficient regulation of local blood flow is crucial for optimal tissue functioning. Hence, many diseases are associated with vascular endothelial dysfunction and disruption of neurogenic inflammatory responses (Steinhoff et al. 2003; Widlansky et al. 2003). The integrity of these responses can be investigated clinically using acetylcholine to provoke endothelium-dependent and neurogenic vasodilatation.

Serum glucose has a strong inhibitory effect on endothelium-dependent vasodilatation via oxidative stress and low-grade inflammation and contributes to endothelial dysfunction in diabetes (Sena et al. 2013). This ultimately results in atherosclerosis, coronary artery disease, and widespread tissue destruction and organ failure (e.g., in diabetic neuropathy and retinopathy) (Gilbert 2013). In contrast, insulin augments endothelium-dependent vasodilatation in the skin (de Jongh et al. 2004). Thus, transdermal iontophoresis of acetylcholine is useful for detecting the extent of microvascular disturbances in patients with cardiovascular disease. For example, in patients with diabetic retinopathy, vasodilator responses to acetylcholine iontophoresis were smaller than in diabetic patients without retinopathy (Nguyen et al. 2011; Sasongko et al. 2012). The compromised vasodilator response was associated with low serum levels of high-density lipoprotein (HDL) cholesterol and apolipoprotein A1, a major component of HDL cholesterol (Sasongko et al. 2012). Similarly, the microvascular reaction to transdermal iontophoresis of acetylcholine was lower in patients with peripheral diabetic neuropathy than in diabetic patients without neuropathy (Tomesova et al. 2013). The microvascular disturbances associated with diabetic neuropathy

increase the likelihood of impaired wound healing, ulceration, and subsequent amputation of affected limbs (Chao and Cheing 2009).

Microvascular reactivity to transdermal acetylcholine is also impaired in obese individuals (Al-Tahami et al. 2011; de Jongh et al. 2004; Jonk et al. 2011). For example, acetylcholine-mediated vasodilatation was found to be smaller in obese insulin-resistant but nondiabetic individuals after ingesting a liquid mixed meal than in lean individuals (Jonk et al. 2011). However, deficits may depend on developmental factors or disease chronicity, as endothelium-dependent vasodilatation evoked by transdermal iontophoresis of acetylcholine was similar to responses in normotensive controls in lean, overweight, and obese hypertensive adolescents (Monostori et al. 2010).

Microvascular disturbances in patients with cardiovascular disease may be reversed by certain dietary substances and exercise. For example, the flavonoids in cocoa and dark chocolate appear to increase endothelium-dependent vasodilatation and counteract insulin resistance by increasing nitric oxide bioavailability (Grassi et al. 2013). Similar effects are associated with dietary supplementation with tuna fish oil (Khan et al. 2003). In addition, vitamin C may counteract the inhibitory influence of reactive oxygen species on endothelium-dependent vasodilatation (Rousseau et al. 2010). Acetylcholine-evoked vasodilatation is greater in active than sedentary individuals (Demiot et al. 2007) and increases after exercise training (Hodges et al. 2010). This may be particularly important for maintaining increased skin blood flow during exercise in older people, as microvascular disturbances increase with aging (Simmons et al. 2011).

Increases in skin blood flow can be detected up to 1 cm away from the site of acetylcholine iontophoresis; as these increases can be blocked by prior treatment of the skin with a topical anesthetic agent, they appear to result from axon reflexes mediated by C-fiber nociceptors (Caselli et al. 2003). This response was impaired in patients with peripheral diabetic neuropathy (Caselli et al. 2003, 2006), and deficits were associated with deficits in other indices of sensory and

autonomic nerve function. As neurogenic vasodilatation to acetylcholine is attenuated in patients with mild symptoms of diabetic neuropathy (Caselli et al. 2006), loss of the neurogenic vasodilator response may represent an early marker of nerve dysfunction in patients with subclinical neuropathy.

Conversely, neurogenic vasodilatation to acetylcholine may be augmented in patients with inflammatory dermatological disorders such as rosacea. This condition generally affects the cheeks, nose, chin, or forehead and is characterized by flushing and acne-like facial papules or pustules (Elewski et al. 2011). We recently investigated endothelium-dependent and neurogenic vasodilator responses to transdermal iontophoresis of acetylcholine in patients with mild or severe rosacea and compared these responses to those in age- and sex-matched controls (Drummond and Su 2012). The intensity of stinging sensations provoked by the iontophoresis was greater in patients than controls. In addition, neurogenic vasodilatation was greater in patients with severe than mild symptoms, suggesting that axon reflexes augment flushing. If so, agents that decrease neurovascular reactivity (e.g., capsaicin cream) may alleviate symptoms in patients with severe rosacea.

8 Conclusions

Using laser Doppler flowmetry to monitor changes in blood flow during transdermal iontophoresis of acetylcholine has provided insights into microvascular function both in health and disease. Unfortunately, however, progress has been impeded by methodological difficulties – particularly concerning errors introduced by nonspecific responses to iontophoresis and the relatively poor reproducibility of spot measures of flow. In addition, the technique has suffered from a lack of standardization both in the form of delivery and the expression of data. Nevertheless, recent advances have partly overcome these problems. In particular, the reproducibility of responses is greater with laser Doppler imaging and laser speckle contrast imaging than with laser

Doppler flowmetry (Roustit and Cracowski 2012), as spatial variability in the microvascular architecture is minimized by averaging across a large region of interest. In addition, large chamber sizes (Ferrell et al. 2002) and low-density currents help to minimize the nonspecific component of response in iontophoresis (Droog et al. 2004). As these techniques are safe and noninvasive, they hold great promise as a window for assessing microvascular responses that reflect important elements of cardiovascular health.

Keywords

Skin microcirculation • Capillaroscopy • Nailfold capillaroscopy

1 Introduction

Capillaroscopy is based on optical microscopy *in vivo* and designed to visualize superficial microvessels, i.e., arterioles (<300 μm), capillaries, and venules (Rhodin 1981). Although used in the study of the connective tissue, the retina, and the lingual and labial mucosae (Davis and Landau 1966; Merlen 1980), the main application fields of capillaroscopy are the skin and the nails. Skin capillaroscopy can be associated with sophisticated methods to analyze the blood flow speed, the capillary pressure, and the concentration of a fluorescent tracer, thus allowing accurate physiological and pharmacological investigations in humans (Table 1). However the straightforward morphological analysis of the superficial dermal capillary network provides a precise and non-traumatic assessment of various diseases involving microvessels; it is therefore nowadays the most widely used technique to study microcirculation in human clinics.

Laser Speckle contrast imaging
Tissue viability imaging
Hyperspectral imaging

Its principle is easy. After skin transparency has been enhanced, an optical magnifying system allows to visualize directly through the epidermis, the skin subepidermal microvasculature.

2 The Skin Subepidermal Microvasculature

The skin microvasculature comprises two horizontal plexuses, one located 1–1.5 mm below the skin surface and the other at the dermal-subcutaneous junction that mostly comprises collecting veins. Only the first one can be looked at using capillaroscopy. Arterioles rise from the deeper layers and divide into many capillary loops at the subepidermal level (Rhodin 1981; Braverman 2000). Then, the loops converge into collecting venules of the subepidermal plexus. The vascular network of the skin varies considerably from one area to another (Bongard and Bounameaux 1993; Miniati et al. 2001) (see ► Chap. 48, “Skin Blood Flow: Histophysiology”).

Different functions are devolved to microcirculation in general and to the skin microcirculation particularly (Table 2). Tissue nutrition is its main function, besides metabolic exchanges, homeostasis of the interstitial fluid, blood pressure regulation, and thermoregulation. Thus, it may be considered that the skin microcirculation is composed of two functionally vascular beds: the thermoregulatory one which contributes 85 % of the total blood flow in the skin and the nutritive one contributing up to 15 % of the total blood flow, and that is mainly represented by the capillaries (see ► Chap. 48, “Skin Blood Flow: Histophysiology”). Both functional domains at their subepidermal level can be investigated by capillaroscopy.

Metabolic exchanges and nutrition
Homeostasis of the interstitial fluid
Regulation of blood pressure
Thermoregulation

3 Biomicroscopes and Binocular Magnifying Glasses

The optical devices used are mainly stereomicroscopes (Carpentier 1999) or binocular magnifying glasses with the following requirements (Maricq 1981):

- Lighting is incident (epi-illumination), as powerful as possible for improved visualization, lateral because low-angled incidence increases contrast, and in cold light to avoid vasodilatation artifacts.
- The magnification varies from $\times 15$ to $\times 100$, but the features of diagnostic interest, especially the capillary network distribution, are easier to analyze using a low magnification; its panoramic vision also allows comprehensive and faster examination.
- The field depth is important, because it controls the sharpness of the capillary images since they are never exactly on a same plane.
- Several-centimeter frontal distance (objective-object) enables to examine uncooperative subjects or subjects with palmar retractions (for nail capillaroscopy) or with protruding lesions.
- The skin is prepared with the application of a drop of immersion oil. Sometimes, when its thickness remains a problem, the horny layer may be slightly stripped using adhesive tape.

- Microscope images can be collected by a camera or video camera.

4 Capillaroscopy (Humbert et al. 2006)

Among the different techniques available (Carpentier 1999; Allen et al. 2014) to study skin microcirculation, human skin capillaroscopy, a specialized form of intravital microscopy, is a method that allows direct visualization of the capillary network in vivo. Its principle is easy. After skin transparency has been enhanced by a drop of oil, an optical magnifying system allows visualization of its vascular network directly through the skin.

The optical devices used to examine the cutaneous capillaries in vivo are most of the time the light microscope and stereomicroscope (Carpentier 1999) but also the videocapillaroscope.

4.1 Contact Videomicroscopy

Videocapillaroscopy (Fig. 1) tends to replace the more conventional capillaroscopy. Contact videomicroscopy devices, appeared initially in the industry for nondestructive control processes, are now commercially available for skin

Fig. 1 Contact videocapillaroscopy with monitoring on TV. Videomicroscope Optican high-definition system (FORT ZI de la Gaudrée, 91415 Dourdan, France). Videotape recorder: SVO 9500 MDP Sony (Shinagawa, Ko Tokyo sp, Japan). Monitor: Sony PVM 1440 QM Japan. The $\times 200$ magnification displays a 1.73 mm^2 area (Laboratory of Engineering and Cutaneous Biology, Besançon)

examination. They require epi-illumination of the skin surface (Jairo and Monari 2000) and image transmission to a video camera via the optics of a microscope. Their main characteristics are:

- The sensor is located at one end of a flexible cord which easily allows investigation of any skin site.
- The sensor is in contact with the skin, optical fibers conveying illuminating light.
- Lighting is provided by the handheld probe; it can therefore be accurately positioned in order to avoid specular reflection.
- The oil can be replaced by a thin layer of ultrasound gel.
- Images are displayed on a screen.
- Image computerization can be done during the examination; therefore the data quality can be controlled at once – the cost is currently equivalent to that of traditional microscopes.

The video imaging systems (Scopeman[®], Microvision[®], Microwatcher Model VS-10[®] (**commercially available equipment:** CapiFlow[®], CapiFlow AB, Kista, Sweden; OP-120, Optilia Instruments AB, Sollentuna, Sweden; CapXview HD, Xport technologies, Craponne, France ; VideoCap, DS Medica, Milan, Italie ; CapiScope, KK Technology, Honiton, England; Scopeman Microtech, Mendota, UK; Microwatcher Model VS10, Mitsubishi Kasei Corp, Tokyo, Japan))

consist of a video signal control unit and a mini CCD camera. Flexible optical fibers convey an intense illuminating light to the dome cap of the camera head. A manually adjusted focusing system coupled with the camera head allows to obtain a sharp image of the capillary network. Magnification ranges from $\times 100$ to $\times 1000$. A magnification higher than $\times 600$ enables visualizing blood cells into the capillary. Venous congestion increases the number of capillaries detected. The video signal is then transformed into RGB images or recorded on videotape. Every picture can then be saved in a standardized image file format.

4.2 Periungual Capillaroscopy

Nailfold capillaroscopy (Figs. 2 and 3) is usually performed in order to search for capillary deformations, characterizing a pathological situation. In this area, capillaries lie in a horizontal plane, so that a large part of their loops can be observed. They have a special feature: loops are parallel and oriented toward the extremity of the finger. They look like hairpin bends with a diameter of 6–15 μm , and they flow in a more or less straight line. They are lined up in several rows. Capillaroscopy does not provide observation of the walls of the capillary, but of the erythrocytes column. Therefore only the capillaries which are functional during the study are visible. Some particular aspects of the capillary loops allow to

Fig. 2 Capillaroscopy equipment for the nailfold area analysis. Nikon SMZ system (Laboratory of Engineering and Cutaneous Biology, Besançon)

Fig. 3 Nailfold capillaroscopy: normal subject

detect some systemic conditions such as progressive systemic sclerosis and lupus erythematosus. Raynaud's phenomenon is the typical condition where capillaroscopy is of paramount importance because the capillary loop feature is often specific or predictive for a systemic disease. Thus, morphological abnormalities must systematically be looked for on all accessible fingers.

- Red blood cell extravasations produce brown deposits which move toward the epidermal edge in successive waves; these microhemorrhages show capillary malfunction which may be connected with microangiopathy or intense vasomotor storms or traumas.
- Meandering or little ramified capillaries (minor dystrophies) have no precise pathological significance, whereas the existence of many richly ramifying loops (like ferns or bushes) indicates capillary neogenesis suggesting vasculitis or connective tissue disease without pointing to more accurate diagnosis.
- An interesting feature is the existence of giant capillaries (over 50 μm diameter, five times the normal size), associated with heterogeneous decrease in capillary density and disorganization of the loop distribution. Such image is the hallmark of the so-called connective tissue diseases, evoking especially systemic sclerosis (Table 3), dermatomyositis, and conditions evolving into a scleroderma (Sharp and

Table 3 Sensitivity and specificity of periungual capillaroscopy in the diagnosis of systemic scleroderma (From Carpentier and Maricq 1990)

	Sensitivity (%)	Specificity (%)
Maricq	84	98
Vayssairat	95	92
Carpentier	97	89
Houtman	–	92
Joyal	83	97
Jouany	97	83
Blockmans	85	93

- CREST syndromes) (Table 4). This feature, which occurs early in the course of the diseases, can be used in decision making (Carpentier and Maricq 1990; Maricq et al. 1980, 1982) (Fig. 4) and justifies periungual capillaroscopy in all cases of Raynaud's phenomenon (Maricq et al. 1982; Blockmans et al. 1996; Priollet et al. 1987).
- Moderate dilatations without rarefaction may hint to a moderate acrocyanosis which further on may typically show an important stasis in the venous limb inducing its sausage-like dilatation (monitoring may be needed while warming).
 - Less frequent morphological variants may be of prognosis value. In systemic sclerosis with bad prognosis, capillaroscopy may show capillary destruction, rarefaction, and disorganization, but sometimes reactive

Table 4 Prognostic value of the periungual capillaroscopy in an apparently isolated Raynaud's phenomenon (From Carpentier and Maricq 1990)

	Number of patients	Follow-up (years)	Incidence percentage of scleroderma	
			Normal capillaroscopy	Scleroderma pattern
Maricq (1983)	51	2.8	4.0	57
Priollet (1987)	73	4.7	1.9	65
Fitzgerald (1988)	58	2.7	4.8	60
Weiner (1991)	77	4.0	7.9	76

Fig. 4 Nailfold capillaroscopy: dilated capillaries with heterogeneous distribution

neogenesis with ramifications prevails over dilatation. Numerous megacapillaries are often found in limited and less progressive forms (Maricq et al. 1983; Lamboba et al. 2010).

4.3 "Any Site" Capillaroscopy

The availability of videomicroscopes together with advances in our knowledge about the importance of microcirculation in the pathogenesis of trophic complications of arterial and venous insufficiencies explains the present development of capillaroscopy on the skin.

4.3.1 Qualitative Capillaroscopy

Different architectural frameworks are found in the various skin body areas (Table 5). They might be related to the different epidermal thickness and microvasculature arrangements (Miniati et al. 2001). Parallel arrangement is observed in

areas where the skin is thinner. On the opposite, perpendicular arrangement is observed on thicker skin areas.

Normal architectural framework shows two main patterns, a parallel and a perpendicular arrangement of capillary loops with respect to the skin surface. Capillaries with a parallel arrangement constitute the vascular network with meshes. These meshes can be regular or not. In most of skin body areas, loops are perpendicular to the skin surface, so that only the top can be seen. It looks like a point or a comma (Fig. 5). Capillary diameters vary from 15 to 20 μm in regions with parallel arrangement. The density ranges from 14 to 30 capillary loops per mm^2 in skin regions where loops are arranged perpendicular to the skin surface (Miniati et al. 2001). Both diameter and density variations are important in assessing the severity of arterial and venous diseases. Capillaroscopy possible clinical application seems therefore to increase considerably (Prasad et al. 1995).

Table 5 Different architectural frameworks of skin capillary network (Miniati et al. 2001)

Parallel arrangement and regular meshes network	Parallel arrangement with irregular meshes network	Perpendicular arrangement and regular dot line	Perpendicular arrangement and irregular dot line	Special pattern with parallel arrangement
Forehead	Trunk (anterior and posterior aspects)	Fingertip	Palm of hands	Fingernail fold
Cheekbone region		Eminencia tenar	Back of the hand and the foot	Labial mucosa
Cheek	Breast	Eminencia hipotenar		
Chin	Arms (external surface)	Tip of toes	Nipple	
Internal surface of arms	Legs (internal and external surfaces)			

Fig. 5 Capillary network observed by videocapillaroscopy (volar forearm). *Dark red dots* are the tops of papillary loops. Below them, out of focus, the superficial

part of the subepidermal vascular plexus is seen, where loops are inserted (magnification $\times 100$)

5 Capillaroscopy and Systemic Diseases

Capillary network analysis in the volar aspect of the forearm, or in the fingers, could be of interest in **arterial hypertension**. It has been suggested that capillary rarefaction may be associated with the genesis of primary hypertension as it has been described in various tissues from patients with essential hypertension. A 15–20 % reduction in capillary density was found in nailfold capillaroscopy, and intravital fluorescein angiography found a 20 % reduction in capillary density

in the forearm skin of hypertensive subjects compared with normotensive subjects (Prasad et al. 1995). Several other conditions such as peripheral arterial occlusion disease, lower limb venous insufficiency, diabetes mellitus, and psoriasis (Table 6) are serious candidates for subepidermal microcirculatory evaluation. Videocapillaroscopy is mainly performed on the instep in venous insufficiency and on the dorsum foot (first inter-metatarsal space and toes) in arterial insufficiency. **Venous insufficiency** is characterized by a decrease in capillary density, widening of dermal papillae the size of which becomes heterogeneous, and the contours marked by

dermite ocre hemosiderin deposits. The decrease in the capillary density is partially compensated for by their increased length, inducing an increased number of meanders, which can even take the shape of a glomerular cluster in the most severe forms (lipodermatosclerosis, white atrophy). As soon as the first trophic troubles occur, the venules are not visible any longer (Fig. 6) (Fagrell 1995a; Franzeck et al. 1984; Stucker et al. 1995).

In **arterial insufficiency**, Fagrell has described three classes of increasing severity and validated

their discriminating value for the local trophic prognosis (Fagrell et al. 1984; Bollinger and Fagrell 1990):

- (A) Capillary dilatation
- (B) Edema impairing capillary visualization
- (C) Absence of visible capillary (pre-necrosis stage)

Qualitative capillaroscopy is mainly used for the morphological information it provides, and it is superior to indirect techniques (laser Doppler, transcutaneous PO₂) because it is free from interpretation artifacts, a considerable advantage in a field as complex as microcirculation. However the absence of quantification and the subjective and operator-dependent character of capillaroscopy show its limitations, but they are about to be overcome with image analysis techniques which currently allow the development of quantitative capillaroscopy.

Table 6 Pathological or cosmetic usefulness of videocapillaroscopy

Peripheral arterial obliterative disorders (Fagrell 1995b)	Specific morphological changes
Venous insufficiency (Fagrell 1995b)	Rarefaction and dilatation of the capillary loops
Diabetes mellitus (Chang et al. 1997)	Tortuous and dilated capillaries
Hypertension (Serne et al. 2001)	Capillary rarefaction
Psoriasis (Bull et al. 1992)	Grossly dilated and tortuous capillaries Many more perfused capillaries
Aging (Priollet et al. 1987; Kelly et al. 1995)	Reduced dermal papillary loops
Effects of topical cosmetics or chemical agents	

6 Capillaroscopy and Smoke

Smoking induces morphological changes of capillary loops which become more tortuous but also leads to a decrease in capillary loop number in the face (Petitjean et al. 2006a). It has to be related to a decrease of the radiance in smokers (Petitjean et al. 2006b).

Fig. 6 Lower limb venous insufficiency: dilated loops and heterogeneous distribution

7 Age-Related Changes of the Cutaneous Microcirculation

A significant decrease in cutaneous capillary loop density is observed with age. The microvasculature is regularly formed in young skin, with many orderly arranged capillary loops (dots) and some horizontal vessels (lines) (Li et al. 2004). It becomes thicker, twisted, and irregular in older skins, with horizontal vessels that appear tortuous, elongated, disorganized, and dilated (Zhu V. Assessment of cutaneous microvasculature in aging and photoaging: a videocapillaroscopic study on Caucasian women. Personal data). Thus, the parallel vasculature can be more easily observed with aging. The result accords with that of biopsy specimens observed by light or electric microscope. As the epidermis becomes thinner, the transparency of the skin increases, facilitating the observation of the papillary vascular plexus. And as the vasculature expands and thickens, some of the microvasculature usually difficult to observe and the deeper vasculature can also be examined.

The capillary loops in the dermal papillae decrease but the subpapillary plexus increase with age (Li et al. 2006a). A marked site and age effect on the skin microcirculation has been demonstrated (Li et al. 2006b). The density of capillary loops in old people decrease by 40–70 % compared with young, whereas the vascular length increases by 35–150 %. Besides the capillary density in the back of the hand is four times higher than in the crow's feet. The vascular length in the crow's feet is three times longer than in the back of the hand.

8 Pharmacological Inhibition of the Dermal Microcirculation

A pharmacological agent such as Neo-Synephrine is able to induce dermal capillary density reduction after topical application (Degouy et al. 2002; Sainthillier et al. 2002). In this case, videocapillaroscopy is a reliable tool to quantify in vivo the capillary loop density in the dermis before and after the application of the

solution. This pharmacological model could be useful to evaluate the effects of different cosmetic or drug agents able to inhibit the dermal adrenergic response in dermis.

9 Morphometry and Capillary Densitometry In Vivo

9.1 Imaging and Pattern Analysis

Automated morphometry in nailfold capillaroscopy is now available, based on the association of numerical image analysis with videomicroscopy (Michoud et al. 1994). The technique is quickly progressing in its processing capacities while its cost is reducing. The systems currently developed for skin microcirculation allow the automatic quantification of diameters, lengths, areas, and capillary densities; it is therefore possible to obtain very discriminating parameters for the diagnosis of connective tissue diseases while comparative follow-up is facilitated (Michoud et al. 1994).

9.2 Geometrical Capillary Network Analysis (Humbert et al. 2006)

In any body site quantitative capillaroscopy is made possible due to the development of computerized systems. Capillary position, size distribution and density, intercapillary distance, and volume fraction can be extracted from the images (Hern and Mortimer 1999; Sainthillier et al. 2003) (Figs. 7 and 8). An automated counting of capillaries is also available. Zhong et al. described a method to describe the capillary network by using image processing and Delaunay triangulation (Fig. 9) (Zhong et al. 2000). Since recent years have witnessed a strong resurgence of interest in the field on neural networks, we can imagine neural architectures for treating capillary distribution in the skin. Accordingly the efficiency of using auto-associative memory to detect and store quantitative capillary features is under investigation in some laboratories, while capillary networks are tentatively built up using capillary coordinates computed by the neural system (Sainthillier et al. 2005).

Fig. 7 Example of Delaunay triangulation applied to an image with noise (scalp, $1.52 \times 1.14 \text{ mm}^2$, objective $\times 200$). The red dots mark the detected capillaries, the black dots the capillaries located on the convex envelop. An artefact without capillaries is visible at the centre, it loosens the structure of the network in this area

Fig. 8 Example of Voronoi diagram (scalp, $1.524 \times 1.14 \text{ mm}^2$, objective $\times 200$). Each polygonal cell is defined by a set of dots that are closer to the centre of the cell than any other dot in the diagram. The green arrows indicate the polygons eliminated from the calculation of surface (after normalisation of the distribution of the surfaces)

10 Capillary Hemodynamics

As far as clinical research is concerned, some capillaroscopy techniques have dealt with a quantitative approach of capillary hemodynamics.

10.1 Capillary Pressure Measurement

The direct measurement of the capillary pressure is possible with a micropipette controlled

by a micro-manipulating device; the examined finger is carefully attached in order to avoid any movement. The measured pressure is that of the counterpressure that has to be exerted to avoid the return of the capillary red blood cells toward the micropipette. Instantaneous pressure can therefore be recorded on a simple water column, but a device has been developed which allows the recording of the pressure variations according to the weather using a servo control system based on the electrical resistance

Fig. 9 The Voronoi diagram is a partition of the space into polyhedrons. Each polyhedron, called the Voronoi cell, is defined as the set of points which are closer to the center of the cell than to any other point in the diagram. The set of all Voronoi cells and their faces forms a cell complex. The

verticals of this complex are called the Voronoi verticals, and the peripheral unbounded edges are the Voronoi rays. In this two-dimensional image each capillary barycenter is considered as the center of a polygon (Laboratory of Engineering and Cutaneous Biology, Besançon)

variations of the micropipette associated with blood inflow. This “servo-nulling system” (IPM[®]) enabled Mahler to show persistent synchronous oscillations of the arterial pulses at capillary level (Bollinger and Fagrell 1990). These techniques have been applied by Tooke’s team also; they studied the influence of the skin temperature and position on the capillary pressure (Bollinger and Fagrell 1990). They have also shown the existence of a dysregulation of the skin capillary pressure in diabetic patients (Tooke 1995). The use of these techniques is rare because they require a sophisticated equipment, a great skill, a lot of experience, and the subjects’ full cooperation.

10.2 Red Blood Cell Speed Assessment

Videocapillaroscopy (such as IPM[®]) has shown the heterogeneity of the capillary content (red blood cell aggregates, leukocytes, and plasmatic gaps and their moves along the blood flow). The optical density variations with time can be recorded in different points of the capillary loop, and by image cross correlation it

has been possible to calculate the time necessary for the red blood cells to go from one point to the other and deduce their average speed.

CapiFlow[®] is a software permitting a direct and noninvasive assessment of blood cell velocity in single capillaries. The microscope is coupled with a television set up and a higher magnification (250–1000 \times) is needed than for videocapillaroscopy. So, one can easily observe blood cell aggregates in the lumen of the capillary loops. These aggregates are separated by plasma gaps. Obtaining a good, sharp, and contrasted picture is needed, and a relatively long straight portion (>40 μm) of the capillary loop has to be observed. The method requires very good optical quality images obtained with high magnification and without interfering movements and seemingly can only be used on periungual areas. It has allowed Fagrell’s group to study vasomotion and post-ischemic reactive hyperemia at capillary level, in healthy subjects and in various diseases: arteritis, diabetes, and myeloproliferative syndromes (Bollinger and Fagrell 1990; Fagrell 1985; Hahn et al. 1998).

The technique called “flying spot” is simpler and consists in generating a virtual image moving

parallel to a capillary and controlling its speed while recording a capillary flow sequence. The red blood cell speed is then that of the virtual object; it is therefore an operator-dependent technique; however it can be used with average quality images (Boss et al. 1987).

11 Capillaroscopy and Fluorescent Tracers

Common capillaroscopy methods use the natural contrast produced by hemoglobin. As seen earlier, they do not visualize the capillary wall, but only the red blood cells that cast the vessel. Thus, only functional capillaries can be detected. But the column of red blood cells is most of the time separated from the vessel wall by a non-negligible plasma layer, even in periungual capillaries. Some capillaries may even be filled with plasma only, as in cases of hyperviscosity syndromes or vasoconstrictive episodes. The use of fluorescent products with plasmatic diffusion has permitted to visualize and measure the actual vessel diameter (Lamah et al. 1996). Furthermore the transcapillary diffusion of fluorescent tracers could also be quantified by videodensitometry. These techniques have mainly been developed, in humans, by Bollinger's group in Zurich. They used fluorescent tracers, mainly Na-fluorescein,

which require a fluorescence microscope, that is to say with a system of mercury vapor illumination and a system of appropriate excitation and absorption filters (Bollinger and Fagrell 1990; Bollinger et al. 1982).

The more usual method uses intravenous injection of 0.02 ml/kg 20 % sodium fluoresceinate, a compound widely used in ophthalmology. The compound diffuses more or less quickly through the skin capillary wall. The technique has been used to quantify the transcapillary exchanges of small molecules. Plasma-perfused capillaries are delineated allowing the calculation of several perfusion indices (Carpentier and Maricq 1990). More invasive, because of the necessity to perform an intravenous injection, this technique improves greatly the detection of pathological abnormalities of the nutritional network. Diffusion was found increased in diabetes and systemic sclerosis (Fig. 10) (Bollinger and Fagrell 1990; Bollinger et al. 1982, 1986). Troubles resulting from endothelial damage have also been evidenced in lower limb chronic ischemia of arterial origin and in vasculitis.

The dextran FITC of molecular weight 150,000, injected intradermally, is resorbed by the lymphatic system and can therefore visualize its more superficial elements. The visualization of the small lymphatic canals has given information about their hydrodynamics (pressure, speed) with the

Fig. 10 Fluorescence capillaroscopy in a patient with systemic sclerosis. Large perivascular halo

abovementioned techniques used in blood capillaries (Bollinger et al. 1989; Franzeck et al. 1993; Mellor and Mortimer 2004).

The use of indocyanine green, which binds to albumin, explores the permeability to macromolecules. It has allowed to measure the capillary dimensions with accuracy and showed the existence of microaneurysms undetected by classic capillaroscopy. This technique requires infrared videomicroscopy. All these techniques remain in the field of research, as the innocuousness of compound injection has not been proved yet.

12 Conclusion

The determination of morphological or dynamic changes in the cutaneous microcirculation is one of the main objectives of the noninvasive biometry techniques. As far as subepidermal microvasculature is concerned, capillaroscopy is both the oldest and the simplest one, while also the soundest as it is based on a visual and direct observation. Recent progress has made it available for any skin site, which is of major importance in dermatology and cosmetology. Thus, every capillary modification due to topical cosmetic products or chemical agents can be observed from now. In pathology, numerous are the conditions that can be examined with this new system. Hence, it is now being used routinely in most hospitals and companies. Furthermore capillaroscopy is becoming a quantitative tool, which will enhance its potential and foster its use both in research and clinical practice. Accordingly it is in the verge to serve as an irreplaceable way of studying the physiology and pathophysiology of the skin capillary circulation in health and disease.

1 Assessing Cutaneous Sensory Function

Noninvasive assessment of cutaneous sensory can be divided into three main categories:

- Quantitative assessment of ongoing clinical sensory abnormalities (e.g., itch, pain)
- Quantitative assessment of experimentally evoked cutaneous sensory responses for diagnosis and monitoring in the clinic
- Quantitative assessment of experimentally evoked cutaneous sensation for basic studies in healthy volunteers under normal conditions and conditions with experimentally induced cutaneous hyperexcitability (e.g., allokinesis, allodynia)

Quantitative sensory testing (QST) involves a large variety of stimulus modalities (thermal, mechanical, chemical, electrical) and assessment methods (psychophysics, electrophysiology, imaging, microdialysis). QST can provide an understanding of the mechanisms involved in sensory transduction, transmission, and perception under normal and pathophysiological conditions and hopefully provide mechanism-based diagnosis, prevention, and management of skin-related

disorders. Different QST protocols have been suggested for profiling patients (particularly in the area of pain), and the QST battery developed by the German Research Network on Neuropathic Pain is the one applied in most studies (Geber et al. 2011; Magerl et al. 2010; Maier et al. 2010). Briefly, the protocol assesses the function of small (thermal thresholds) and large (tactile and vibration thresholds) nerve fiber pathways and increased/decreased pain sensitivity (hyperalgesia, allodynia, hyperpathia, windup-like pain). The battery consists predominantly of cutaneous stimulus modalities but not including, e.g., itch and associated aspects such as allokinesis. The challenges for the future are to develop QST platforms adequate for children or elderly possible demented patients.

In QST studies, the focus and mind-set is often toward hyperexcitable responses, but it is important to focus both on “gain-of-sensory-function” and on “loss-of-sensory-function” as, e.g., hyperalgesia, analgesia, allodynia, and allokinesis.

Individual QST technologies for assessing sensory function can furthermore be used for drug profiling and for development of new therapies for, e.g., itch or pain.

A number of fundamental sensory mechanisms observed in animals have important implications, for which QST techniques should be developed and how they can be applied in human basic, clinical, and drug screening studies.

A variety of the sensory stimulation procedures may cause additional responses in association with the sensory responses. One such additional response is provocation of vasomotor reactions.

2 Assessing Provoked Vasomotor Reactions

Under physiological conditions, skin blood flow plays an essential role in thermoregulation. Proper and timely responses to heating and cooling due to, e.g., environmental changes control and maintain the body homeostasis. Cutaneous vasodilation and vasoconstriction are the two key components of this thermoregulatory system. In

humans, cutaneous circulation is under control of several systems including endothelial, adrenergic, and sensory systems. Several factors have been identified that alter function of these systems and malfunctioning result in different skin circulation disorders.

Application of direct local controlled heat on the skin promotes a transient vasodilation through an axon reflex that reaches to a plateau status. This phase is thought to be nitric oxide dependent and is followed by the die-away phenomenon, which is a slow reversal and has been shown to rely on intact sympathetic vasoconstrictor nerves. Barcroft and Edholm (1943) were first to test the effects of warming and cooling using a wide range of temperatures in human forearm skin. They found that blood flow reached its highest level at 42 °C, which was the maximum applied heat. They also reported a pattern following local heating that is mainly characterized by an early transient peak in skin blood flow, followed by a prolonged plateau phase and a return to blood flow levels of baseline over time. Their investigations provided a basis for later studies looking into possible involved mechanisms, e.g., how direct skin warming causes vasodilation. It has been known that direct warming of the skin causes a vasodilation that depends on several parameters, for instance, the degree of applied heat and that how fast the heat is being delivered (Hodges et al. 2009; Minson et al. 2001). Rapid application of local heat to 42 °C increases the skin blood flow to its maximum in the applied area (Minson et al. 2001; Johnson et al. 1986). This unique characteristic is perhaps due to the fact that at this temperature, cutaneous vascular smooth muscle is fully relaxed, and local warming to 42 °C is often used in experiment comparing blood flow measurement at different sites or different subjects (Kellogg et al. 1993). Several systems have an influence on the response pattern: the NO system, adrenergic nerves, and sensory nerves. Mechanisms underlying changes due to local warming have been reviewed elsewhere (Johnson and Kellogg 2010; Charkoudian 2010).

Based on the fact that local heat enhances blood flow in regional microcirculation and to some extent blood vessel permeability, this technique can be

used to facilitate drug transfer to the systemic circulation. Controlled heat application is a simple and noninvasive method that may improve transcutaneous drug delivery most likely through the enhancement of skin penetration of a topically applied medication or increasing of drug absorption.

Below, we highlight cutaneous vasomotor reactions in response to direct local controlled heat based on our findings through series of experiments in healthy humans. Although glabrous skin in the forearm has been the most commonly used site, various body regions have been tested in line with any potential sex-related difference that can alter response to direct local heating.

2.1 Paradigms of Direct Local Controlled Heat Application

Skin vasomotor responses in several different body regions of healthy men and women were

recorded after application of direct local controlled heat (Gazerani and Arendt-Nielsen 2011). Different paradigms were applied (38, 41, and 43 °C, each for 15, 30, and 60 s) in forehead, forearm, dorsal hand, dorsal foot, and abdomen. Skin blood flow and skin temperature are measured by sophisticated techniques of laser Doppler imaging (MoorLDI), speckle contrast imaging (MoorFLPI), and thermography. Figures 1 and 2 show representative images taken by MoorFLPI and FLIR thermal camera following the application of transient direct local controlled heat (43°/60 s). One should consider that a linear association between surface temperature and blood flow has not always been shown (Vuksanovic et al. 2008). This study aimed at finding a standard basis to produce a stable and significant potentiating of skin perfusion that might be applicable for drug delivery purposes. Findings indicated that a transient direct local controlled heat application at 43 °C for 60 s can significantly elevate skin blood

Fig. 1 Speckle contrast images taken by FLPI (Moor Instruments, Devon, UK). Recordings made from forearms at baseline, 1 min, 5 min, 10 min, and 15 min (left to right in the row) following the application of transient direct

local controlled heat (43°/60 s). *Red* color represents high flow rates and *blue* color represents low flow rates. *ROI* region of interest 3 × 3 cm

Fig. 2 Thermographic images taken by FLIR (ThermoVision A40M, Sweden). Recordings made from forearms at baseline, 1 min, 5 min, 10 min, and 15 min (left to right in the row) following the application of transient

direct local controlled heat (43°/60 s). *Red* color represents higher temperatures and *blue* color represents lower temperatures. *ROI* region of interest 3 × 3 cm

flow and skin temperature with a peak at 5 min and maintenance above baseline for up to 15 min after termination of heat application (60 s). Interestingly, the various body regions did not show any difference, and the phenomenon of enhanced vasomotor responses was sex independent, pain-free, and well tolerated. In addition, the effect is retainable by repeated application of the same paradigm at 10 min intervals (Gazerani and Arendt-Nielsen 2011).

Enhancement of drug absorption from transdermal or subcutaneous delivery systems has been shown during a heat exposure (Shomaker et al. 2000; Klemsdal et al. 1992). This technique leads to elevated absorption rate and the total amount of the absorbed drug (plasma concentration) (Barry 2001). Enhanced drug absorption, through increased tissue perfusion, depends on several factors including the ability of a drug to diffuse across the membrane of the vessels, permeability of blood vessels within that region, and to some extent surface area available for drug diffusion (Song 1984). The anatomy of the vessel plexus in the skin and also the duration of vasodilatory response are important factors (Braverman 2000). Local controlled heat most likely enhances drug delivery by influencing the upper horizontal plexus which is located in the papillary dermis just below the epidermis. However, prolonged application of heat might also affect the lower horizontal plexus located in the deep dermis at the border of the underlying subcutaneous tissue. Results from the chosen paradigm in our study were not site or sex dependent, which reflect the general application of such technique to enhance vasomotor responses in human skin.

2.2 Application of the Selected Paradigm of Local Controlled Heat for Drug Delivery

Following setting up of the parameters, in two subsequent studies, we have tried to utilize the local controlled heat-evoked vasomotor response to investigate whether this technique can enhance the absorption of nicotine from a patch (Petersen

et al. 2011) or insulin following subcutaneous injection (Jakobsen et al. 2011).

The nicotine patch study was based on previous reports on elevated drug uptake in subjects wearing a nicotine patch in a sauna (Vanakoski and Seppala 1998). Similar cases have been reported on elevated absorption of nitroglycerine from patches during exposure to high ambient temperature (Barkve et al. 1986).

2.2.1 Nicotine

For nicotine, we investigated whether the application of controlled local heat would result in elevated transdermal delivery from the nicotine patch mounted on the upper arm of healthy nonsmoking male Caucasian subjects. In addition to monitoring the vasomotor responses to heat by LDI and thermography, the residue of the nicotine patches was determined by high-performance liquid chromatography (HPLC) to have a measure of nicotine uptake from the patch. This study revealed a positive correlation between nicotine absorption and vasomotor response (Petersen et al. 2011). However, individual variation in responses was a limiting factor. Theoretically, following application of controlled local heat, drug uptake would increase from patches, and it may give a possibility for drug absorption at higher level or quickly when it is needed. It is valuable to note that drug concentration following heat application should still remain within the therapeutic range to avoid any safety issue and toxicity. To achieve this, different drugs should be tested in order to validate controlled local heat application as a method in cutaneous drug delivery.

2.2.2 Insulin

For insulin, we aimed to investigate whether local controlled heat application can enhance the absorption of drug from a reservoir in the subcutaneous tissue and elevate the insulin level or reduce the blood glucose (Jakobsen et al. 2011). The study was designed in a pharmacokinetic-type study to follow up changes over time with repeated blood sampling. This strategy allowed us to study the rate and amount of absorption of subcutaneously injected insulin (short-acting insulin: Actrapid[®], 100 IU/ml). Controlled heat

application at the site of insulin injection significantly enhanced tissue perfusion. However, no correlation was found between insulin absorption and tissue perfusion. This finding suggests that tissue perfusion is not the rate-limiting factor in the absorption of high-concentration short-acting insulin from a subcutaneous depot. This is most likely due to the fact that dissociation of insulin hexamers into dimers and monomers is a major rate-limiting factor in this case. Therefore, insulin analogues can be better choices as these types are only present on absorbable forms, whereby dissociation should not constitute a limiting factor.

Insulin absorption rate from an injection site has been shown that it is related to ambient temperature (Vanakoski and Seppala 1998; Guerci and Sauvanet 2005; Koivisto et al. 1981). Warm environment has been associated for up to fivefold higher insulin absorption most likely due to elevated skin temperature and blood flow (Koivisto et al. 1981). The effect of sauna on insulin absorption from a subcutaneous injection site has also been investigated (Koivisto 1980; Cuppers et al. 1980).

3 Application of the Local Controlled Heat in Sensitized Skin

In a recent study (Nielsen et al. 2013), the magnitude, temporal and spatial pattern, and sex differences of the vasomotor responses to local controlled heat (43 °C for 60 s) before and after topical capsaicin (cream, 1 %) were assessed. This study aimed at finding the effect of controlled local heat on a pre-sensitized skin. Regions of interests were defined and monitored thoroughly by thermography and speckle contrast imager. The latter novel technique is highly sensitive with higher temporal resolution that can take blood flow images of large areas in different skin regions at the same time. Priming of skin sensitivity by topical capsaicin in this study significantly enhanced skin vasomotor responses for up to 30 min. The response was with a greater magnitude in females but longer and well spread in males. This prolonged and spatially expanded

vasomotor response to the standardized local heat application was limited due to ceiling effect of the vascular network responses to capsaicin-induced neurogenic inflammation, which highlights the point that using controlled heat technique for drug delivery purposes might not yield the same results under normal intact skin in comparison with primed sensitized skin.

4 Conclusion

In summary, application of heat (43 °C) for a short duration of time (60 s) can enhance the local vasomotor responses with no associated short- or long-term side effect. Under normal condition, it lasts for 15 min, while the response is twice longer in a sensitized skin. The applied paradigm (43 °C for 60 s) was independent of body region or sex under normal condition; however, in a sensitized skin, females respond with a greater magnitude and males with longer lasting and more spread. Testing the method for two different drugs administered by two different routes showed that both routes of administration and drug itself are important factors to find a correlation (nicotine) or not to find a correlation (insulin).

1 Introduction

The term “microcirculation” refers to the blood vessels with a diameter smaller to 150 μm , which encompasses arterioles, capillaries, and venules. Recently, a physiology-based definition was proposed, according to which microcirculation refers to all vessels responding to an increase of internal pressure by a myogenic reduction in lumen diameter. This definition also includes small arteries (Levy et al. 2001). Microcirculation vessels provide a large surface area which is needed for blood-tissue exchange (Verdant and De Backer 2005), while avoiding large fluctuations in capillary hydrostatic pressure and determining the overall peripheral resistance (Levy et al. 2001).

1.1 Skin Microcirculation

The cutaneous vessels are present in the dermis and, according to their dimension, belong to the microcirculation. They are responsible for three main functions – skin tissue nutrition, thermoregulation heat exchange, and blood flow redistribution during stress (Roddie 1983). The skin vasculature has a peculiar organization, consisting of two horizontal arterial plexuses in the dermis –

an upper (superficial) horizontal plexus in the papillary dermis, involved in the skin nutrition, and a lower (deep) horizontal plexus at the dermal-subcutaneous border, involved in thermoregulation (Braverman 1997). A special feature of human skin microcirculation is arteriovenous anastomoses (AVAs), which are direct connections between arterioles and venules at the deep plexus. These are mainly found in the apical regions of the skin and are particularly numerous in the nail beds, digital tips and palmar surfaces, and soles and are practically absent in these areas dorsum (Braverman 1997).

Skin blood flow is regulated by both neural and local mechanisms. Neural mechanisms consist of sympathetic vasoconstrictor fibers that supply all skin areas, both glabrous and non-glabrous, and sympathetic vasodilator fibers that supply only the latter (Lenasi 2011). These neural-mediated mechanisms are modulated by diurnal rhythms (Aoki et al. 2003), physical exercise (Johnson et al. 1996), and menstrual cycle (Charkoudian and Johnson 2000).

The local mechanisms that control skin blood flow include factors released by the vascular endothelium and by local nerve endings. The endothelium responds to physical and chemical stimuli via production of a wide range of vasoconstrictor and vasodilator substances, which regulate vascular tone, cellular adhesion, thromboresistance, smooth muscle cell proliferation, and vessel wall inflammation (Deanfield et al. 2007; Minson 2010).

The skin is a favorable site for microvascular investigation because it is readily accessible and it allows the application of stimuli with noninvasive or minimally invasive procedures (Minson 2010). Furthermore, it has been suggested that the cutaneous microcirculation can serve as potentially representative of vasculature for the study of physiological regulation and systemic dysfunction mechanisms (Holowatz et al. 2008). Since microvascular dysfunction is a systemic process that occurs in a similar way in multiple tissue beds throughout the body (Sax et al. 1987), the skin can likely be used as a surrogate marker of systemic microvascular function in various diseases (Holowatz et al. 2008). It has been

used as a research model for hypercholesterolemia (Khan et al. 1999), hypertension (Rizzoni et al. 2003), renal disease (Stewart et al. 2004), type II diabetes (Sokolnicki et al. 2006), peripheral vascular disease (Rossi and Carpi 2004), atherosclerotic coronary artery disease (Shamim-Uzzaman et al. 2002), heart failure (Cui et al. 2005), and primary aging (Thompson-torgerson et al. 2007).

Laser Doppler flowmetry (LDF) is definitely one of the most popular assessment techniques, although its use is not very common in the clinical setting. LDF is based upon measurement of the Doppler frequency shift in monochromatic laser light which is backscattered from cutaneous tissue. The frequency shift is associated with velocity of moving particles within the tissue, primarily red blood cells (Sacks et al. 1988). Moreover, it can be continuously measured when coupled to provocation tests which can change the resting flow conditions, allowing to assess the mechanisms involved (Holowatz et al. 2008; Rossi and Carpi 2004; Thompson-torgerson et al. 2007; Cracowski et al. 2006). The most commonly employed tests include postural changes (Abu-Own et al. 1994; Husmann et al. 2008; Silva et al. 2013a), limb occlusion (Silva et al. 2013a; Berry et al. 2000; Morales et al. 2005), drug application (Morris and Shore 1996), heating the skin (Minson et al. 1985; Schubert 2000), and oxygen breathing (Silva et al. 2013b; Crawford et al. 1985; Harward et al. 1985).

LDF provides a sensitive, continuous, noninvasive, and real-time assessment of blood flow, uninfluenced by the underlying skeletal muscle blood flow (Saumet et al. 1988). The considerably complex nature of the signal variability (Srinivasa and Sujatha 2011), however, can make LDF difficult to understand, justifying the use of several strategies to look further to its components, as follows:

1.2 Wavelet Transform

The oscillatory components of LDF signal have been investigated with linear methods, such as the

Fourier transform (Rossi et al. 2006) and the wavelet analysis (Bernjak et al. 2008).

A wavelet is defined as a small wave or oscillation that decays quickly. Morlet considered wavelets as a family of functions constructed from translations and dilations of a single function called the “mother wavelet” $\Psi(t)$ defined as (Sifuzzaman et al. 2009)

$$\Psi_{a,b}(t) = \frac{1}{\sqrt{|a|}} \Psi\left(\frac{t-b}{a}\right), a, b \in R, a \neq 0 \quad (1)$$

The parameter a is the scaling parameter or scale, and it measures the degree of compression. The parameter b is the translation parameter which determines the time location of the wavelet. If $|a| < 1$, then the wavelet in the above equation is the compressed version (smaller support in time domain) of the mother wavelet and corresponds mainly to higher frequencies. On the other hand, when $|a| > 1$, then $\Psi_{a,b}(t)$ has a larger time-width than $\Psi(t)$ and corresponds to lower frequencies. Thus, wavelets have time-widths adapted to their frequencies (Sifuzzaman et al. 2009).

These spectral analyses have shown several components, or oscillators, that regulate local blood flow and which are well-defined in their own frequency interval:

- Heart (0.6–2 Hz)
- Respiration (0.15–0.6 Hz)
- Myogenic activity at vessel wall (0.052–0.15 Hz)
- Sympathetic activity (0.021–0.052 Hz)
- NO-dependent metabolic activity (0.095–0.021 Hz) (Landsverk et al. 2007)

However, there is a complex interaction between these components, making the isolation of individual signals a difficult task.

1.3 Detrended Fluctuation Analysis

The detrended fluctuation analysis (DFA), a method developed by Peng et al. (1994), provides a quantitative parameter, the scaling exponent α that represents the correlation properties of

nonstationary, noisy time series. The following procedure is used to calculate the scaling exponent α (Peng et al. 1995):

First, given a time series $x_i, i = 1, \dots, N$, is obtained:

$$y(k) = \sum_{i=1}^k [x_i - \bar{x}], \quad (2)$$

where

$$\bar{x} = \frac{1}{N} \sum_{i=1}^N x_i \quad (3)$$

Then, the cumulative summed series $y(k)$ is divided into nonoverlapping boxes of equal length, n . In each box, we fit $y(k)$, using a least-square line fit, which represent the local trend in that box. The y-coordinate of the fit line in each box is denoted by $y_n(k)$. The cumulatively summed signal, $y(k)$, is detrended by subtracting the local trend, $y_n(k)$, in each box of length n . For a given box size n , the root-mean-square (rms) fluctuation for this cumulatively summed and detrended signal is calculated:

$$F(n) = \sqrt{\frac{1}{N} \sum_{k=1}^N [y(k) - y_n(k)]^2} \quad (4)$$

Repeating this calculation over all box sizes, we obtain a relationship between $F(n)$ and the box size n . For fractal, self-similar, signals, $F(n)$ behaves as a power-law function of n , and the data can be described by

$$F(n) \stackrel{d}{=} Cn^\alpha \quad (5)$$

where C is a constant of proportionality and the \equiv symbol represents that the statistical properties of both sides of the previous equation are identical only in distribution. The scaling exponent α represents the correlation properties of the signal and $e [F(n)]$ to $\log n, \log[F(n)] = \log C + \alpha \log n$.

The classification of a fractal signal by DFA is possible based on the value of α (Eke et al. 2002): for the $0 < \alpha \leq 1$ corresponds to the fractional Gaussian noise (fGn). A value of $\alpha = 0.5$ indicates that the signal is completely uncorrelated

(white noise). When $\alpha < 0.5$ the signal indicates short-range correlation. Long-range correlations are present when $0.5 < \alpha \leq 1$. In the case of $\alpha > 1$, the time series is analogous to another class of fractal time signal, fractional Brownian motion (fBm). The value of $\alpha = 1.5$ corresponds to long-range correlations that are not necessarily related to stochastic processes and may be reflecting deterministic correlations.

The advantage of DFA over conventional methods is that it permits the detection of long-range correlations embedded in a seemingly nonstationary time series, while avoiding the spurious detection of apparent long-range correlations that are an artifact of nonstationarity (Peng et al. 1995). The DFA scaling exponents have been used to distinguish signals obtained from physiologic and pathophysiological conditions and have shown some utility as a diagnostic tool (Esen and Esen 2006).

1.4 Multiscale Entropy Analysis

Costa et al. (2002, 2012) proposed the multiscale entropy (MSE) concept, which allows the analyst to approach short and noisy physiological time series; MSE consists of obtaining the entropy values, which are a measure of uncertainty, through several scales. For this purpose, given a time series x_i , $i = 1, \dots, N$, a consecutive coarse-grained time series $y^{(\tau)}$ is constructed:

$$y_j^{(\tau)} = \frac{1}{\tau} \sum_{i=(j-1)\tau+1}^{j\tau} x_i \quad (6)$$

where τ represents the scale factor and $1 \leq j \leq N/\tau$. The sample entropy (SampEn) of each coarse-grained is then computed. $SampEn(m, r, N)$ is the negative natural logarithm of the conditional probability that a dataset of length N , having repeated itself with a tolerance r for m points, will also repeat itself for $m + 1$ points, without allowing self-matches:

$$SampEn(m, r, N) = -\ln \frac{A^m(r)}{B^m(r)} \quad (7)$$

where $A^m(r)$ is the probability that two sequences will match for $m + 1$ points and $B^m(r)$ is the probability that two sequences will match for m points. The more regular and predictable a time series, the lower the value of SampEn. The more random a time series, the higher the value of SampEn.

This chapter aims to discuss how the LDF signal obtained from a healthy group of volunteers performing a classic tourniquet-cuff occlusion in the lower limb can be obtained and characterized, having in mind its potential application as a powerful quantitative indicator of in vivo vascular function.

2 Materials and Methods

2.1 Subjects

A group of 30 subjects (15 males and 15 females), aged between 18 and 26 (22.3 ± 3.1) years old, was studied after informed written consent. The subjects had no known cardiovascular or metabolic disease, were nonsmokers, and were not taking any kind of medication, with the exception of four women who were taking oral contraceptives. Restrictions included caffeine and alcohol consumption as well as any topical products application 24 h before the test.

The experimental protocols conformed to standards set in the latest revision of the Declaration of Helsinki (*World Medical Association Declaration of Helsinki: ethical principles for medical research involving human subjects* 2013) and was approved by the Institutional Ethics Committee.

2.2 Instrument

Microcirculatory blood flow, expressed in arbitrary units (AU), was assessed by LDF (PeriFlux PF 5010 system, Perimed, Sweden), whose probe was applied on the plantar aspect of the second toe. A total of 23 min of LDF signal was recorded for each subject, with a sampling rate of 32 Hz.

2.3 Experimental Design

All measurements were performed with controlled room conditions (temperature: 21–23 °C; humidity: 40–60 %, with minimal air movement over the subject). Volunteers were lightly clothed and acclimatized for 30 min prior to any procedure, sitting upright with their feet exposed. The ankle-brachial index (ABI) was determined in all patients to exclude peripheral arterial disease. ABI is obtained by dividing the systolic blood pressure (SBP) measured at ankle level by the systolic blood pressure measured at arm level (Anderson et al. 2013). The suprasystolic occlusion maneuver, a perfusion-reducing protocol, was performed at the ankle level. With the subject seated in the upright position, a pneumatic cuff (PF 5051 Pressure Accessory Kit) was applied approximately 1 cm above the ankle for 10 min (phase I). Then, the cuff was manually inflated to 200 mmHg for 3 min (phase II). After this period the cuff was quickly deflated, allowing recovery (phase III). The experimental setting is illustrated in Fig. 1.

Fig. 1 Illustrative scheme of the experimental procedure

2.4 Data Analysis

The LDF signal was partitioned using a Morlet wavelet transform and subsequently selected based on the limits of the determined cone of influence. The subsequent analyses were performed on the LDF data excluding the segments inside the cone of influence. The amplitude ratio of each frequency component was determined by dividing the area under the curve of each component sine wave by the area under the curve of all components' sine waves.

The DFA α coefficient and MSE complexity index (CI), which corresponds to the area under the MSE curve, were determined for each segment of the LDF signal and for each component of the wavelet transform using MATLAB toolboxes. The DFA algorithm was implemented in which the LDF signal was divided into 100 boxes of 5,000 samples each. The MSE algorithm was implemented with $\tau = 36$, $m = 2$, and $r = 0.15 \times SD$, where SD is the standard deviation of the original time series.

Three periods, one of each phase of the protocol, were selected for statistical analysis: resting phase was considered between 6:30 and 9:30 min, the provocation phase was considered between 10:00 and 13:00 min, and the recovery phase was considered between 18:00 and 21:00 min. All statistical analyses were made with *IBM Corp. Released 2012. IBM SPSS Statistics for Windows, Version 21.0. Armonk, NY: IBM Corp.* The LDF signal component amplitude ratios, α exponents, and complexity indexes were compared for each phase of the protocol by the Wilcoxon matched-pairs signed-rank test. Gender contributions were compared with the Mann-Whitney U test for independent samples. A 95 % confidence interval was adopted.

3 Results and Discussion

Sample characteristics are displayed in Table 1. ABI values were normal in the two aged-matched groups, thus excluding peripheral arterial disease from our sample. The resting blood flow showed a wide variability, which could be attributed to the fact that all variables that influence it could not be controlled. These variables may include normal levels of physical activity, food intake before the procedure, phases of menstrual cycle (for women), and/or the different timings for measurements in different days (Tables 2 and 3).

The LDF signal for a representative volunteer is depicted in Fig. 2. The suprasystolic occlusion provokes a significant reduction in blood flow to the foot, due to the mechanical compression. As expected, when the occlusion was terminated, a reactive hyperemia was observed – a physiological response elicited in order to restore the tissue’s viability and enable its recovery. After this period, the resting perfusion value is reestablished, suggesting recovery. Males were found to have a higher blood flow in the resting and recovery phases, and to suffer a lower perfusion reduction during occlusion, although none of these differences were found to be statistically significant.

3.1 Wavelet Transform Analysis

The wavelet transform has a finite resolution, resulting in broadened frequency peaks. The same was observed for the LDF signal. We observed that the lower frequency components displayed broader waves and higher frequency components displayed narrower waves, as displayed in Fig. 3. The LDF signal was found

to be mainly of sympathetic and endothelial origin, owing to the large amplitude of these components’ amplitude ratios. During limb occlusion there was a significant decrease in the cardiac, respiration, myogenic, and sympathetic amplitude ratios. However, the metabolic amplitude ratio increased significantly, suggesting that during occlusion there is an endothelium-dependent NO production increase. This supports known data (Dakak et al. 1998), since an important contributing stimulus for the development of the said hyperemia is the relaxation of vascular smooth muscle due to NO production. During the recovery period, all components’ amplitudes returned to baseline, further suggesting a full recovery of the resting conditions.

3.2 DFA Analysis

The unpartitioned LDF signal showed $\alpha \sim 1.0$ during the resting phase, suggesting a $1/f$ noise-like behavior. The α exponent increased, although nonsignificantly, during the provocation phase. In addition, no significant differences were found between the resting and recovery phases. Figure 4 displays the DFA analysis of the LDF signal, suggesting different scaling regions for each segment. No gender differences were found in the α exponent for any of the phases of the procedure, suggesting a similar behavior of the LDF signal in males and females.

Regarding the partitioned LDF signal, all wavelet components showed $\alpha > 0.5$, translating positive self-correlated signals. However, different α exponents were observed for different components, as shown in Fig. 5. In the resting period, heart and respiration activity components showed $\alpha \sim 1.0$, suggesting that these phenomena have a $1/f$ noise-like behavior. However, myogenic ($\alpha \sim 1.42$), sympathetic ($\alpha \sim 1.55$), and metabolic ($\alpha \sim 1.50$) activity components could reflect physiological processes with characteristics closer to Brownian noise ($\alpha = 1.5$). The α exponents of the heart, respiration, myogenic, and sympathetic components significantly increased during occlusion and decreased for the metabolic activity component. During the recovery period, all activity

components, α exponents, and complexity indexes return to baseline, suggesting a full perfusion recovery under the present experimental conditions. Our results are consistent with previously

published studies (Ferreira et al. 2011), demonstrating that DFA is a sensitive method for assessing microvascular dynamics with corresponding changes in the scaling regions.

Fig. 4 Detrended fluctuation analysis of the LDF time series (one representative subject) shown in Fig. 2: resting (red), provocation (green), and recovery (blue)

Fig. 5 Plot showing detrended fluctuation analysis (DFA) α exponents versus wavelet amplitude ratios (abscissa axis in log10 scale). The different frequency components are indicated by colors (heart, blue; respiration, green; myogenic, pink; sympathetic, yellow; and metabolic, red), and

the different segments are indicated by symbols (baseline, filled circles; provocation, open squares; recovery, filled diamonds). Dashed lines for $\alpha=1$ (1/f noise) and $\alpha=1.5$ (Brownian noise) are shown for reference

3.3 MSE Analysis

The entropy of the unfractionated LDF signal in the resting phase decreased significantly during

occlusion, likely due to its decrease in variability. The entropy value returned to baseline during recovery. No gender differences were determined for any of the phases of the procedure.

Fig. 6 Sample entropy versus scale factor of the different LDF signal segments (*red*, baseline; *green*, provocation; *blue*, recovery). Vertical bars represent the standard deviation

A plot of the scale factor versus CI for the different phases of the protocol is shown in Fig. 6. Our results have shown that MSE profiles for the three phases of the protocol were nonmonotonic, as previously observed (Guerreschi et al. 2012). In the resting and recovery phases, CI values increased to reach a maximum on $\tau = 8$ and $\tau = 9$. After reaching this maximum, CI values decreased until reaching $\tau = 12$, where they increased upon reaching $\tau = 15$ and $\tau = 16$ in the resting and recovery phases, respectively. From these time scales, the CI values decreased again until reaching a minimum on $\tau = 26$ and $\tau = 24$ for the resting and recovery phases, respectively. For the provocation phase, the MSE profile was also nonmonotonic, although less variable. CI values increased to a maximum for $\tau = 9$ and then decreased. For all phases, the processes occurring around the time scales corresponding to these maximum values had the highest irregularity, after which the processes become more regular and predictable.

Figure 7 shows a plot of alpha exponent of three LDF signal segments versus CI. It shows that the dispersion clouds related to resting and recovery are practically superimposed, further

suggesting recovery of the LDF signal. The dispersion cloud related to the occlusion period, although partially detached from the other two, cannot be clearly isolated.

As observed in Fig. 8, the heart component exhibited the highest entropy value, suggesting a more random-like signal. Myogenic, sympathetic, and endothelial components were present with lower entropy values, suggesting a more regular and predictable signal. The entropy of the frequency components was significantly reduced during occlusion and returned to baseline during recovery.

4 Conclusions

The combined use of wavelet transform, DFA, and MSE appears to have interesting potential to become a complementary analysis tool for laser Doppler flowmetry. A deeper look into the oscillatory components of this complex measurement results, not only in a better view over the phenomena regulating skin microcirculation, but also contributes to expand the practical usefulness of LDF in clinical, diagnostic, or research settings.

Epicutaneous xenon-133 clearance • Skin blood flow

Developed in the late 1960s (Sejrsen 1969), epicutaneous xenon-133 clearance was a considerable step forward: for the first time, an absolute measurement of the skin blood flow was possible. As such, it is still unchallenged and valid today. Although noninvasive, it requires complex and expensive equipment that can be used only in nuclear medicine units. For that reason, it has been supplanted by less reliable methods that are more accessible.

1 Principle

The principle of epicutaneous xenon-133 clearance is simple. A chemically inert although radioactive gas, xenon-133, is applied on the skin only for the time necessary for a small amount to penetrate. Then its gradual disappearance from the injection site is measured, since it is washed out depending on the blood flow. Once in the dermis, the xenon is extracted from the tissues by the blood capillaries, then evacuated by the collecting venules. However, the gas tissue/blood partition coefficients (ratio of the solubilities in both) are 0.7 and 10 for the dermis and adipose tissue, respectively. Such high liposolubility makes the whole process complicated. When going through

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title Measuring the Skin. The content has not been changed.

the hypodermis dissolved in the venous blood, a fraction of the gas leaves the veins toward the adipose tissue, but it is extracted from the adipose tissue after a short time by the xenon-deprived venous blood originating from the completely purified dermis. Furthermore, another fraction of the gas is dissolved in the stratum corneum, a structure rich in lipids, thus introducing a third source of elimination directly into the air at the skin surface. Monitoring the decreasing amount of xenon-133 vs time at the injection site is made possible with the γ rays (Xenon-133 also emits X-rays and β -rays (electrons)). It is 50 available at CIS-BIO International, 91400 Saclay, 51 France) it sends out. The detector is a simple γ probe with a meter, set on 80-keV radiation; a gamma camera is not necessary. Xenon-133's physical half-life is 5.27 days; therefore its disintegration is next to zero following an examination lasting 1.5 h maximum.

2 Technique

Sweating must be avoided because stratum corneum hyperhydration and the presence of sweat in the sweat ducts and on the skin surface could facilitate a retrograde flow of xenon toward the surface. On dry skin free of any ointment, carefully degreased with ether and shaved if necessary, a plastic gas-proof chamber is attached to the skin with double-sided adhesive tape (No chamber is on the market and consequently it must be custom made, for example from the cast of a mylar sheet.). The air of the chamber is removed with a syringe and replaced by xenon-133 (specific activity, 10 mCi/cm³) injected with another syringe. It is left in place for 3 min, then all the xenon is aspirated. The perfect adherence of the chamber to the skin must be checked during both aspirations. The chamber is then carefully removed (avoid a shock that might induce vasodilatation) and radioactivity is measured immediately at short intervals at first (for example every 10 s), then less often (for example every minute). Because of the relatively slow elimination, the test must last at least 1 h. These operations are performed under an extractor, and both operator

and patient wear a lead protective apron, following the usual safety procedures against ionizing rays. The risk of radiodermatitis is insignificant. The chamber holds 1 cm³ of xenon-133 gas, hence 10 mCi (370 mBq), and the recuperated volume is identical. The amount absorbed cannot be measured accurately, but from the number of counts found per minute (2,000–5,000); it is approximately 160 kBq, an insignificant amount because it represents roughly 10⁻⁴ times the dose of radiation generally used for diagnosis in thyroid gland diseases. Furthermore, in these diseases, the radioactive product (iodine-131) remains concentrated in a limited volume of tissue, whereas xenon is eliminated quickly by the respiratory system.

After test completion, the radioactivity vs time curve is smoothed and then mathematically processed using a two-compartment model that takes into account the anatomical xenon path and its two tissue/blood partition coefficients (Sejrsen 1969, 1995; Cardot et al. 1977). Its breakdown into two exponential curves (Fig. 1) provides the dermis and hypodermis wash-out time constants. These constants, multiplied by the respective partition coefficients, give the blood flows for 100 ml tissue, according to the

Fig. 1 Epicutaneous ¹³³-xenon clearance. Schematic treatment of the signal vs time curve. Ordinate: counts/min natural logarithm. *a* Slope of the initial exponential curve (from the first 3 or 4 counts) describing the washing-out from the stratum corneum toward outside. *b* Slope of the final exponential curve (during the second half-hour) describing the washing-out from fat tissue toward venous blood. *c* Slope of the middle exponential curve (during the first half-hour) describing the washing-out from the dermis toward venous blood

formula: flow rate = $0.693\lambda/t_{1/2}$ where λ is the partition coefficient and $t_{1/2}$ the time necessary for the xenon wash-out to reach 50 %. The calculation of the fraction of xenon that penetrates the subcutaneous tissue (slow exponential) is noticeably influenced by diffusion time; therefore the total length of the latter should be at least 30 min and if possible 1 h (Cardot et al. 1977).

A third exponential, which decreases very rapidly, sometimes interferes with the beginning of the curves. It corresponds to xenon's direct passage to the outside, probably picked up by the stratum corneum, which can be calculated by the slope of the first three or four points on the curve. The value obtained can be verified by applying a tourniquet that cuts off the blood flow proximally; a very slow decreasing curve is then observed, representing about 1 % of the wash-out (Sejrsen 1969; Greeson et al. 1973). Some authors ignore these first three or four points of the curve (Nyfors and Rothenborg 1970; Greeson et al. 1973; Kristensen and Wadskov 1977). Their elimination is better achieved by using the so-called peeling method (Baud et al. 1981), which also cancels out the artifacts due to subject movement during data recording.

3 Skin Blood Flow Values

Normal values (milliliters per minute for 100 g tissue) in recumbency, are displayed in Table 1. In psoriasis plaques (Bazin et al. 1981), the

cutaneous and subcutaneous blood flows were 2.0 and 2.1 times as high as those of healthy skin, respectively. When healed following PUVA therapy, the same plaque values both drop to 1.3 times the values of healthy skin.

In systemic scleroderma (LeRoy et al. 1971), the blood flow in fingers collapses: 18 % of the normal flow usually found in this body site.

4 Comments

The pulse frequency is too high to be visible on the wash-out curve. But the additional low-frequency oscillations (6–8/min) corresponding to vasomotion may be visible if recording is done less than every 5 s.

An interesting comparative study (Cardot et al. 1979) of blood flow in the rabbit ear (rich in venoarterial shunts) and back (absence of shunts) shows that the ear subcutaneous flow is 25 % higher than skin blood flow at 18 °C, and only 7 % higher at 25 °C ($p < 0.01$). In the back, the opposite is observed: +26 % at 25 °C and –3 % at 18 °C. It is reasonable to think that the method could provide a means to assess venoarterial shunts, which in this example would represent about one-fourth of the global skin blood flow.

Flow measurement is based on the xenon diffusion from the tissues toward the vessels, which depends on the exchange area, i.e., the cumulated areas of the capillary walls. Therefore, the

Table 1 Normal skin blood flow (ml/100 g tissue). Epicutaneous 133-xenon technique

Site	Dermis	Hypodermis	Total	Author
First finger web	3.0 ± 1.0	5.7 ± 1.2		Sejrsen (1971)
Dorsum middle finger	6.4 ± 10.6			LeRoy (Cardot et al. 1979)
1 st phalanx at 18 °C				
Idem after warming	28.0 ± 6.3			LeRoy (Cardot et al. 1979)
Forearm	5.1 ± 1.7			Sejrsen (1969)
Forearm	6.2 ± 0.8			Greeson et al. (1973)
Abdomen	4.5			Sejrsen (1969)
Beardless cheek	9.0			Sejrsen (1969)
Bearded cheek	15.2 ± 3.0			Sejrsen (1969)
Dorsum hand	6.9 ± 1.3		8.9 ± 0.9	Kristensen and Wadskov (1977)
Above lateral malleolus	6.2 ± 1.1	3.8 ± 1.6		Cardot et al. (1977)
Leg, lateral aspect	5.7 ± 1.2			Sejrsen (1969)

difference in blood flow measured using this method should be lower than the systolic-diastolic volume variations measured by photoplethysmography (PPG). Using PPG, the plaque/healthy skin ratios in psoriasis were 3.7 ± 1.6 ($n = 29$) and 1.2 ± 1.3 ($n = 18$) before and after treatment, respectively (Bazin et al. 1981). Using the xenon method, in the same patients, the ratios were 2.0 ± 1.5 ($n = 18$) and 1.3 ± 1.5 ($n = 10$) before and after treatment, respectively. In the same plaque, after healing by PUVA therapy ($n = 10$), the two methods reached the same proportion, 1.3 ± 1.4 and 1.3 ± 1.5 times that of the healthy skin.

Usefulness: Blood CO₂ monitoring in anesthesiology and intensive care medicine, evaluation of skin respiration, and skin blood flow measurement (incidentally).

1 Physiology

There is a small but continuous carbon dioxide (CO₂) release from the skin surface (Abermethy 1793). The gas originates both from the vascular subepidermal plexus and from an epidermal metabolic production. The transfer is a passive process of diffusion obeying Fick's first law. Accordingly, at a given temperature, the tcPCO₂ value depends on CO₂ concentration in the blood perfusing the skin, subepidermal skin blood flow, CO₂ epidermal production, CO₂ concentration in the ambient air, and CO₂ diffusion resistance across superficial skin tissues, especially the stratum corneum. The CO₂ partial pressure in the atmosphere is very low (less than 0.4 torr). On the other hand, the CO₂ diffusional resistance across superficial skin tissues is weak (1/28.5 times that of oxygen) and may be considered as constant in normal skin. Consequently, the main

factors of tcPCO_2 variation are the CO_2 concentration in the blood perfusing the skin, the subepidermal skin blood flow, and the CO_2 epidermal metabolic production. All these factors are temperature dependent.

In normal conditions, the cutaneous blood PCO_2 is close or identical to arterial PCO_2 because of the low skin metabolism and the great excess of blood as compared to the needs for skin nutrition. This is the reason why blood gases in the past were measured by puncturing the ear lobe. The usual value is 40 torr. In case of impaired pulmonary function and defective oxygen uptake, hypercapnia occurs, which leads to an increased tcPCO_2 . Conversely in acidosis, for example in uremia, there is a reduction in the blood CO_2 and a concomitant drop in tcPCO_2 .

Carbon dioxide emission increases with the skin temperature above a 34°C threshold (Shaw et al. 1929). Variation was found identical to that of transepidermal water loss (Thiele and Van Kempen 1972), probably through increased skin blood flow and diffusion coefficient across stratum corneum. Sweating, either spontaneous or pharmacologically induced (Thiele and Van Kempen 1972), also augments tcPCO_2 , most probably through the increased blood flow associated with sweat gland activation. Occlusion of the skin surface increases tcPCO_2 (King et al. 1978), possibly by increasing stratum corneum permeability through its hydration, as simply applying water on the skin surface also raises the CO_2 emission (Frame et al. 1972). Direct exposure of the head and neck to sunlight induced an increased CO_2 loss at the volar forearm, although the skin temperature remained constant (Thiele and Van Kempen 1972); one can assume that subclinical sweating may have occurred. On the other hand, venous stasis with greatly increased CO_2 content in the blood did not increase transepidermal CO_2 loss (Ernstene and Volk 1932; Rothman 1957). During occlusion, forearm tcPCO_2 increases, possibly through anaerobic metabolic generation of lactic acid and titration of skin HCO_3^- (Severinghaus et al. 1978). Upon occlusion release, tcPCO_2 shows a quasi-exponential return to control

values, with a time constant depending on the skin blood flow.

2 Measurement

Several methods have been used for the measurement of cutaneous CO_2 release, including spectrophotometry by infrared analysis (CO_2 absorbs light at a $4.3\text{-}\mu\text{m}$ wavelength) (Thiele and Van Kempen 1972) and mass spectrometry (Christensen et al. 1991). They have been replaced by a polarographic method, which uses a contact electrode (Severinghaus' electrode) whose output is called the transcutaneous CO_2 pressure (tcPCO_2), although a fraction of the gas originates from the epidermis. As the CO_2 diffusion resistance is low and the electrode consumes no CO_2 , the tcPCO_2 casual level and variation can be easily monitored when the skin is at 33°C , the usual forearm temperature. Detailed measurement procedures can be found in Winberley et al. (1990) and Nickelsen (1995).

Current devices permit the simultaneous measurements of tcPCO_2 and tcPO_2 , and the latter demands the skin to be heated to 44°C . Consequently, tcPCO_2 is usually measured at $43\text{--}44^\circ\text{C}$. A reasonable correction for temperature of about 4 % per degree Celsius has been proposed (Thiele and Van Kempen 1972) and supported by the data obtained by Christensen et al. (1991). Accordingly, the tcPCO_2 at 33°C should be approximately 0.56 tcPCO_2 at 44°C . On the other hand, the CO_2 arterial partial pressure (PaCO_2) can be deduced from tcPCO_2 using the following formula: at 43°C tcPCO_2 (torr) = 1.245 PaCO_2 (torr) - 0.8 ($p = 0.98$) (Goldman et al. 1982). Subsequent correction for temperature should be made as stated above.

3 Normal Figures

3.1 tcPCO_2

In ten healthy males aged 24–36, regional variations were found (Takiwaki et al. 1991).

Forehead	67.2 ± 2.4 torr
Cheek	69.2 ± 2.8
Volar forearm	62.6 ± 3.3
Abdomen	63.7 ± 2.4
Back	63.9 ± 3.1
Leg, anterior aspect	61.1 ± 4.1
Leg, posterior aspect	62.8 ± 2.9
Palm	60.5 ± 3.1
Earlobe	315.7 ± 42.0 (42.1 ± 5.6 kPa) (<i>n</i> = 7) (Christensen et al. 1991)

The surprisingly high earlobe figure may originate from higher blood flow and/or lower resistance of a thinner stratum corneum, or a different method (mass spectrometry). The figures on the face are significantly higher ($p < 0.01$) than on the volar forearm. The difference may stem from either inconspicuous sweating or higher metabolism on the face.

3.2 Transcutaneous CO₂ loss (nl cm⁻² min⁻¹)

Site	tcPCO ₂ (nl cm ⁻² min ⁻¹)	Reference
Hand	46	(Frame et al. 1972)
Forearm	18	(Frame et al. 1972)
Forearm ^a	77.3 ± 47.2 (<i>n</i> = 7)	(Thiele and Van Kempen 1972)
Forearm	23.1 ± 6.8 (<i>n</i> = 30)	(Wilson and Maibach 1982)
Upper back	28.1 ± 5.4 (<i>n</i> = 21 neonates)	(Wilson and Maibach 1982)

^aAs calculated for 32 °C (the usual skin temperature)

Earlier studies found figures roughly ten times higher (as quoted in Frame et al. (1972)), which may be due to different methodologies.

4 TcPCO₂ and Skin Diseases

In various skin lesions, whether sclerotic, inflammatory, acanthotic, or hyperkeratotic, in leg ulcers and in skin neoplasms, tcPCO₂ remained stable (Takiwaki et al. 1991). It was substantially elevated over preneurotic tissues such as bullous

lesions (pemphigoid) and ischemic lesions (necrotizing fasciitis, arterial insufficiency) “An extraordinarily high tcPCO₂ with low tcPO₂ may be regarded as a marker of preneurotic epidermis and/or dermis caused by the severe disturbance of blood-gas exchange in the skin” (Takiwaki et al. 1991). Very high values probably indicate anaerobic tissue metabolism secondary to skin ischemia. Following skin damage by application of diluted NaOH solutions, the tcCO₂ loss increased in parallel with the transcutaneous water loss (Malten and Thiele 1973).

Conclusions can be drawn from Takiwaki’s opinion (Takiwaki et al. 1991): “Unlike tcPO₂, tcPCO₂ is less influenced by cutaneous factors,” and Bourgain and Grenouillet (1985) “The reasons why tcPCO₂ is less sensitive to circulatory variation (than tcPO₂) remain poorly understood.” Accordingly, tcPCO₂ measurement may be useful, especially when done in association with tcPO₂ measurement, for investigating either lung or skin respiration.

Keywords

Anesthesiology • Child resuscitation • Dermatology • Heart surgery • Reactive hyperemia test • tcPO₂ with kinetic tests • tcPO₂ dynamic tests • Transcutaneous oxygen index • Transcutaneous oxygen pressure

In normal circulatory conditions, a fraction of the oxygen dissolved in plasma crosses the capillary wall and reaches the tissues, thus providing for their metabolic needs. This occurs in the skin subepithelial plexuses, in particular the subepidermal plexus. When the oxygen supply exceeds metabolic needs, the gas reaches the skin surface where it can be detected by a polarographic electrode and its partial pressure measured (It can also be detected by a mass spectrometer, but this technique is not as widely used.). The transcutaneous oxygen pressure (tcPO₂) depends on the O₂ plasmatic saturation level and local factors such as epidermal metabolic activity, the oxygen diffusion rate through superficial layers, oxyhemoglobin (HbO₂) supply, blood flow, and HbO₂ dissociation. When pulmonary function is normal, with no sign of anemia or proximal arterial insufficiency, only local factors are involved. Among them, blood flow is essential because it regulates the local oxygen supply. When the skin temperature is below 37 °C, the tcPO₂ is often low, barely measurable, and furthermore the diameter of the skin vessels varies continuously. For this reason, the tcPO₂ is usually measured after bringing the skin temperature up to 44 °C, which induces maximal vasodilation and skin blood flow while the skin temperature remains constant. As a consequence, the tcPO₂ is strongly increased and becomes easy to measure.

1 Consequences of Heating the Skin to 44 °C

There are a number of consequences when the skin is heated to 44 °C (Lübbers 1981).

- The O₂ diffusion through the stratum corneum is facilitated because of the increased fluidity of the intercellular lipid.
- The O₂ epidermal consumption is increased for some (Severinghaus 1979), reduced for others (Christensen et al. 1991).
- The HbO₂ dissociation curve is shifted to the right, which facilitates the release of oxygen from the red blood cells.
- Vasoconstriction due to the sympathetic tone is suppressed, inducing major arteriolar and capillary vasodilation: hence the skin blood is arterialized, with a PO₂ similar to the arterial PaO₂.
- The venoarteriolar reflex is suppressed; consequently, a venous distension (for example, by increased hydrostatic pressure) will no longer generate arterial and arteriolar vasoconstriction, but only passive vasodilation.

This shows that such a strong heating induces a nonphysiological state, which must not be overlooked for tcPO₂ interpretation.

2 Basal 44 °C tcPO₂, with Patient Supine

2.1 Regional Variations

The tcPO₂ measured on the chest (second intercostal space on the mid-clavicular line) is considered as the nearest to the PaO₂. In young adults, it is nearly 80 torr (1 torr = 1 mmHg (in honor of Torricelli)). On the thigh, it is 6 % lower, on the foot or the leg, 10 % lower (Hauser and Shoemaker 1983). There is no significant difference between the foot and the leg in healthy subjects (Hauser and Shoemaker 1983; Agache et al. 1992). The table below (Takiwaki 1994), although it provides slightly low figures, is of interest since it shows surprising regional variations that have yet to be explained.

Anatomical site	tcPO ₂ (torr)	References (probands)
Ear lobe	49.2 ± 8.3	(Christensen et al. 1991) (7 young adults)
Forehead	26.6 ± 21.0	(Takiwaki 1994) (10 men aged 20–36 years)
Cheek	29.6 ± 9.8	(Takiwaki 1994)
Volar forearm	69.6 ± 5.3	(Takiwaki 1994)
Abdomen	63.8 ± 6.4	(Takiwaki 1994)
Back	60.6 ± 12.2	(Takiwaki 1994)
Over the shin	66.6 ± 6.1	(Takiwaki 1994)
Calf	67.3 ± 6.8	(Takiwaki 1994)
Palm	26.4 ± 6.6	(Takiwaki 1994)

When the stratum corneum is removed, the tcPO₂ on the palms rises to forearm values; however, on the forehead it remains low (Takiwaki 1994), perhaps due to higher epidermal metabolism. In children (10 subjects aged 3–9 years), the figures on the face (71.6 ± 7.9 torr) were similar to those of the forearm (76.3 ± 5.5 torr). This might indicate a change in facial vascular subepidermal network anatomy from childhood to adulthood (Takiwaki 1994).

2.2 Physiological Variations

The ratio tcPO₂/PaO₂ (transcutaneous index, TCI) is close to 1 in premature babies, exceeds 0.9 in children, and is approximately 0.8 in adults. In premature babies, the diffusion of oxygen is inversely proportional to the birth weight (Versmold et al. 1979).

In a single individual, the variability from 1 day to the next is nearly 10 % (Coleman et al. 1986). In a study on 75 healthy subjects, tcPO₂ was found higher in women by about 10 torr than in men (Agache et al. 1992), with a steady decrease with age: the regression lines were as follows (Agache et al. 1992):

- Women: tcPO₂ (torr) = 92.6 torr – 0.37 age (years)

- Men: tcPO₂ (torr) = 83.6 torr – 0.31 age (years).

The difference between sexes was highly significant for absolute values but regression slopes were identical. Reasons for lower values in men are not known, but can perhaps be explained by the thicker stratum corneum or higher epidermal metabolism.

2.3 Guidelines for tcPO₂ Interpretation

The basal tcPO₂ value at 44 °C, patient supine, depends on numerous factors that differ with pathology. Their identification is essential for a precise interpretation. The influence of each factor, the others being supposedly normal, is as follows:

- Respiratory factors: in premature and newborn babies, the tcPO₂ at 44 °C equals the oxygen partial pressure (PaO₂) of the arterial blood; hence the first use of this technique was in monitoring premature babies and in child anesthesia. In adults, tcPO₂ ≈ 0.8 PaO₂ (Dautzenberg et al. 1981). Any abnormality in pulmonary ventilation or gas exchange alters the tcPO₂ (e.g., in diffuse scleroderma).
- General hemodynamic and hematological factors: shock (when the cardiac index is below 2.2 dm³ min⁻¹ m⁻², the tcPO₂ decreases and does not reflect PaO₂ accurately (Bourgain and Grenouillet 1985)), HbO₂ saturation (smoking increases HbCO and reduces HbO₂, therefore the tcPO₂ as well), and hematocrit (its increase raises the tcPO₂).
- Local hemodynamic and hematological factors: volume of the capillaries per cubic centimeter of skin (in healthy subjects the tcPO₂ increases parallel to the density of papillary loops (Huch et al. 1983; Ryan 1992)), perfusion pressure (tcPO₂ decreases proportionally

with lowering of perfusion pressure (Eickhoff et al. 1980), but it does not increase in subjects with high blood pressure; hence the routine use of this technique in arterial insufficiency), and venous pressure (the tcPO₂ increases in parallel (Eickhoff et al. 1980)).

- Local tissue factor: O₂ diffusion through viable skin tissues, epidermal metabolism (the application of eugenol, which slows down the epidermal metabolism, increases tcPO₂ (Patel et al. 1989)), and O₂ diffusion within the stratum corneum. In case of very low tcPO₂, it is possible to obtain a measurable tcPO₂ by stripping the stratum corneum with 15 successive applications of adhesive tape, thus partially removing an obstacle to diffusion.

When the results indicate reduced tcPO₂, it is essential to be aware of technical errors such as erroneous calibration, alteration of the electrode membrane, lack of electrolyte, equilibration time too short, etc.

3 Basal tcPO₂ at 37 °C, Patient Supine

The basal tcPO₂ at 37 °C reflects the superficial blood flow in casual (physiological) conditions. At 37 °C, the superficial skin flow is irregular and much lower than at 44 °C. As a consequence, the basal tcPO₂ shows low and changing values (in the earlobe, 18.2 ± 16 torr (Christensen et al. 1991)). Furthermore, since physiological conditions are respected, the venoarteriolar reflex is maintained, thus the passage from lying position to standing or sitting position generally brings the tcPO₂ down to zero.

In psoriasis, its value is increased parallel to that of the laser Doppler because the vasodilatation is both superficial and deep sited (Duteil et al. 1993). In lipodermatosclerosis, the tcPO₂ at 37 °C is increased, indicating a high superficial flow rate (Dodd et al. 1985), while at 44 °C it drops, showing a drastic reduction of the vasodilatation reserve of superficial vessels.

Therefore, the 37 °C tcPO₂ is useful because it reflects exclusively the casual subepidermal blood flow, as opposed to the 44 °C tcPO₂, which reflects the subepidermal flow under maximal vasodilatation (i.e., the vasodilatation reserve), and the laser Doppler, which measures the flow in the deeper skin layers. As normal values are very low, stripping the stratum corneum may be of some interest in this case.

4 44 °C tcPO₂: Dynamic Tests

4.1 Reactive Hyperemia

The reactive hyperemia test can be done on limbs using a proximal (arterial) tourniquet for 3 min, or on another site by strong compression for the same length of time. The peak/basal ratio value is measured, together with the peak surface and the time necessary to reach this peak. It is a measure of the capacity of the local blood flow to increase from either a rise in perfusion pressure (from the reactive vasodilatation upstream) or an augmentation of the in situ vascular volume (number and diameter of the superficial capillaries), or both.

4.2 Switching the Subject from Lying to Sitting or Standing Position

Both the capillary volume and the intracapillary pressure change with the effect of the hydrostatic pressure (the perfusion pressure does not change): an increase in pressure in body sites below the heart, a decrease in pressure in sites located above the heart level.

4.3 Exercising

The tcPO₂ increases from the vasodilatation of the arteries upstream. The tests generally used are standardized “exercises” (walking on a treadmill, standing about, or tiptoeing in rhythm with a metronome). For information on these tests, see (Agache et al. 1993).

4.4 Oxygen Inhalation

The $tcPO_2$ increases in oxygen inhalation (5–10 dm³/min) and may exceed the PaO_2 physiological values. In patients with arterial insufficiency, the extent of the increase is of value for prognosis (Bongard et al. 1992).

4.5 Partial Venous Occlusion

Partial venous occlusion (generally a 50-torr pressure through a tourniquet) is equivalent to a passage from a lying to a standing position.

5 $tcPO_2$ with Kinetic Tests

5.1 $tcPO_2$ Reduction Rate from Occlusion During O₂ Inhalation

This maneuver makes it possible to calculate the tissue consumption of O₂ using the formula: consumption = $\alpha(\Delta tcPO_2/\Delta t)$ (Severinghaus et al. 1978), where $\Delta tcPO_2$ is the difference before and after occlusion, Δt the reduction time, and α the solubility of O₂ ($\alpha = 28.8 \cdot 10^{-6}$ ml g⁻¹ torr⁻¹ at 44 °C, and $31.3 \cdot 10^{-6}$ ml g⁻¹ torr⁻¹ at 37 °C). The $tcPO_2$ reduction rate in healthy subjects' forearms is approximately 130 torr min⁻¹ at 44 °C and 90 torr min⁻¹ at 37 °C. This consumption is about $3.7 \cdot 10^{-3}$ ml g⁻¹ min⁻¹ at 44 °C and $2.7 \cdot 10^{-3}$ ml g⁻¹ min⁻¹ at 37 °C (Severinghaus et al. 1978). It is related to the epidermal metabolism.

5.2 $tcPO_2$ Recovery Rate After Suppression of the Occlusion

The $tcPO_2$ recovery rate after removing the occlusion (O₂ recovery index, ORI) reflects the superficial capillary blood flow, which depends on the available capillary volume and the perfusion pressure (Severinghaus et al. 1978). The same holds true for the basal $tcPO_2$ recovery time (O₂ reappearance time, ORT).

5.3 The $tcPO_2$ Recovery Rate

The use of Eugenol as a contact medium in the measurement of transcutaneous oxygen ($tcPO_2$) partially inhibits the metabolism in the underlying tissue, thereby reducing oxygen consumption and increasing $tcPO_2$ (Patel et al. 1989). Oxygen consumption in the tissue can be estimated from the rate at which $tcPO_2$ falls when blood flow is occluded, and blood flow in the tissue can be estimated from the rate at which $tcPO_2$ increases when the subject changes from breathing air to pure oxygen. Both these measurements have been made with Eugenol and distilled water as contact media. From these measurements it has proved possible to estimate the arterial oxygen tension (aPO_2) of healthy adults at a relatively low sensor temperature (43 °C). This method permits measuring the superficial blood flow when the subject starts inhaling pure oxygen.

6 Applications

6.1 Child Resuscitation

Basal $tcPO_2$ at 44 °C is used routinely in PaO_2 monitoring. It is the only means of detecting excessive PaO_2 (risk of retrolental fibroplasia) in premature babies in incubator. The probe must be moved every 4 h to avoid local burns.

6.2 Anesthesiology, Heart Surgery, Angiology

Basal $tcPO_2$ at 44 °C is a valuable means of measuring the tissue perfusion level distal to an arterial occlusion, and therefore to grade it (Agache et al. 1993). The basal $tcPO_2$ (foot, pretibial area, calf, thigh) in a supine subject both locates the vessel narrowing and assesses its severity. The latter can be improved by various maneuvers: reactive hyperemia, O₂ inhalation, standard exercise, passage from lying to standing position to evaluate the prognosis at stage IV (no increase indicates poor prognosis). When the $tcPO_2$ is low, in order to rule out a

respiratory cause, a concomitant measurement of the chest or arm tcPO₂ is recommended, in order to use the distal/chest or distal/brachial tcPO₂ ratio (Hauser and Shoemaker 1983). A basal tcPO₂ below 20 torr and a ratio below 0.2 would be incompatible with stump healing if amputation were carried out at the site of measurement (Kram et al. 1989).

Continuous tcPO₂ monitoring during a surgical operation helps detect bursts of hypoxia and pulmonary embolism (Bourgain and Grenouillet 1985). Under artificial breathing during anesthesia, it is an indicator of efficacy and a means of early detection of respiratory failure (Bourgain and Grenouillet 1985). In vascular surgery, it provides a continuous follow-up of the downstream blood flow and accordingly of the success of the operation (Neidhardt et al. 1987).

6.3 Dermatology

Basal 44 °C tcPO₂ was found reduced in all conditions investigated to date (Takiwaki 1994): lipodermatosclerosis with or without leg ulcer (Agache 1998) (perhaps due to perivascular sclerosis), morphea (perhaps from vascular atrophy), malignancies, inflammatory disorders, and diseases with acanthosis. Accordingly, the reduction was found even in conditions showing an expansion of the superficial vascular plexus. In psoriasis, tcPO₂ was found reduced by about 40 % (Patel et al. 1989; Duteil et al. 1993; Dodd et al. 1985; Agache et al. 1993; Bongard et al. 1992; Severinghaus et al. 1978; Kram et al. 1989; Neidhardt et al. 1987; Agache 1998; Kalis et al. 1990; Tronnier et al. 1979; Ott and Stüttgen 1984; Schalla 1986) and this reduction was alleviated along the improvement of the plaque (Duteil et al. 1993; Ott and Stüttgen 1984). To interpret these data, it is essential to point out what applies to the three main factors involved with the skin tcPO₂: superficial blood flow, epidermal metabolism, and O₂ diffusion rate through the epidermis.

Using tcPO₂ the measurement of the epidermal consumption of O₂, a well as the epidermal metabolism, is made possible by the combination of simple operations: measurement of the tcPO₂

reduction rate under occlusion and oxygen inhalation, with or without tape stripping. Seemingly this has been tried only in psoriasis, where an abnormally fast tcPO₂ decrease has been observed following vascular occlusion (187 torr min⁻¹ in diseased skin and 111 torr min⁻¹ in normal skin), suggesting an increase in the epidermal consumption of O₂ (the calculation gives 5.39 10⁻³ ml g⁻¹ min⁻¹ in diseased skin and 3.2 10⁻³ ml g⁻¹ min⁻¹ in normal skin), and thus of the epidermal metabolism (Ott and Stüttgen 1984). (P. Agache: it is obtained by multiplying the O₂ consumption by the thermal coefficient of O₂, evaluated at 20.27 kJ/l for a usual respiratory quotient (0.84) (Houdas and Guieu 1977). Using the above-mentioned figures, the results are 0.91 10⁻³ W cm⁻² for healthy skin at 44 °C and 1.08 10⁻³ W cm⁻² for lesions at 44 °C. Assuming that the cellular metabolism increases by 4 % per degree (Severinghaus et al. 1978), at 37 °C for psoriasis it is 0.71 10⁻³ W cm⁻² in healthy skin and 0.87 10⁻³ W cm⁻² in pathological skin (warmer by 1 °C) (healthy skin at 37 °C, 0.65 10⁻³ W cm⁻² (Houdas and Guieu 1977)). The basal metabolic rate in young adults is approximately 4.3 10⁻³ W cm⁻².)

The absolute measurement of the subepidermal blood flow is also made possible using two methods, as suggested by Severinghaus et al. (Severinghaus et al. 1978). This is of great interest a priori, because the only other absolute measurement method of cutaneous blood flow, namely by epicutaneous xenon clearance, involves the whole skin. But further theoretical as well as experimental studies are needed before advising routine use.

In the first method, the flow is estimated from the equation: Flux = E_{O₂}/(aO₂ - vO₂), where E_{O₂} is the epidermal O₂ consumption and (aO₂ - vO₂) the difference of O₂ concentration in arterioles and venules. E_{O₂} is calculated as described in the paragraph above. Assuming that the capillary PO₂ is midway between arteriolar and venular PO₂ and considering that arteriolar and arterial PO₂ are identical (600 torr), venular PO₂ is calculated, hence its difference (PO₂ with arteriolar PO₂). The difference is converted into difference in concentrations, using the hemoglobin dissociation

curve at 44 °C and Hb = 14 g/dl. With this method, the authors found subepidermal blood flow at 44 °C to be 0.475 ml g⁻¹ min⁻¹, a figure nine times higher than using xenon-133 clearance at the same site (volar forearm) at current skin temperature, showing how much the blood flow can be increased when the skin temperature is raised.

The second method is a blood flow measurement during reactive hyperemia, from the tcPO₂ recovery rate at 44 °C after occlusion, during pure oxygen inhalation. The tcPO₂ recovery rate fits an ascending exponential curve of formula $y = A(1 - \exp^{-t/\tau})$ where y is the tcPO₂ on each point of the curve, A is the final tcPO₂ and τ the time constant. The logarithmic transformation makes it possible to obtain τ (seconds). Then the blood flow rate Q is obtained by the formula $Q = 60\lambda/\tau$ where $\lambda = 0.9$ is the O₂ skin/blood partition coefficient, supposedly identical to the O₂ water/blood partition coefficient at the same temperature and with the same pressure. The authors found 1.2 ml g⁻¹ min⁻¹ for the skin blood flow at 44 °C during reactive hyperemia: a very high figure that should be confirmed.

According to the same authors, the measurement of the blood flow rate at 37 °C from the tcPCO₂ decreasing rate following occlusion release at 37 °C might also be performed using this method.

6.4 Toxicology

The 44 °C tcPO₂ has been shown to be significantly reduced in smokers, as a consequence of the reduced oxygen supply to the tissues in relation to the blood higher HbCO level (Lucas et al. 1989).

7 Practical Advice for Using tcPO₂

Calibration in relation to the atmospheric oxygen pressure must be carried out once or twice a day, depending on frequency, because there is a risk of the probe shifting (Winberley et al. 1990).

Theoretically, $PO_{2atm} = 0.2093 P_{atm} - PH_2O_{atm}$, where 0.2093 is the O₂ fraction in the air. PH_2O_{atm} is obtained by multiplying the relative humidity by the absolute pressure of water vapor at room temperature (provided by tables). In practice, it is only necessary to check that the oxygen atmospheric pressure used by the device is 159 torr. Variations in barometric pressure within the interval 760 ± 15 torr can be ignored.

If a gas control is used for calibration, its value displayed by the device should vary from the standard value by less than 0.5 %.

Before measuring, any trace of ointment or cream must be removed (it would hamper the oxygen passage). Hairy skin should be shaved. A thin layer of electrolytic solution (usually provided by the manufacturer) is applied in order to ensure maximum contact between the electrode and the skin, to facilitate the oxygen transfer and to avoid any air intrusion. When the sensor is placed, 15–20 min are necessary until a stable value is obtained.

A number of concerns should be heeded:

- Heating to 44 °C is harmful for the tissues; therefore use of tcPO₂ at a same site must not exceed 4 or 5 h to avoid burns.
- When a tcPO₂ decrease is expected because of a PaO₂ decrease, the latter must be measured either through blood sampling or noninvasively by pulse oximetry. However, this technique is approximate, as it indicates only the Hb saturation level.
- Results are different depending on the probes.

1 Introduction

Systemic sclerosis (SSc) is a rare and progressive connective tissue disease of multifactorial origin, characterized by vascular abnormalities and diffuse fibrosis in the skin and internal organs. The pathogenetic cornerstones of the disease are the activation of the immune system, vascular involvement, and increase of extracellular matrix deposition (Black et al. 2009).

Vasculopathy is a central feature of the disease, and structural abnormalities of the microvascular lining are evident in visceral organs as well as in the skin in the earliest stages of the disease (Kahaleh 2004).

Clinical and histologic findings suggest a key role for these alterations especially at the outset of the disease. Both permeability and vasomotility alterations might be due to an imbalance consisting of an increase of vasoconstricting factors (thromboxane, endothelin) associated to a relative decrease of vasodilator substances (prostacyclin and nitric oxide) (Flavahan 2008). The innate and adaptive immune system is activated in the perivascular areas and releases cytokines and growth factors (transforming growth factor beta

(TGF- β), platelet-derived growth factor (PDGF)), and extensive fibrosis of the dermal and subcutaneous layers develops (Abraham et al. 2009).

The progressive losses of capillaries on one hand, and the vascular remodeling of arteriolar vessels on the other, result in insufficient blood flow, causing severe and chronic tissue hypoxia. Hypoxia is one of the most important stimuli of angiogenesis, leading to the expression of pro-angiogenic molecules, mainly of vascular endothelial growth factor (VEGF), which fosters the angiogenic process. Nevertheless, in SSc patients, there is evidence for defective adaptive angiogenesis. Failure of the angiogenic process in this disease largely depends on alteration in the balance between pro- and anti-angiogenic factors as well as on functional alterations of the molecular and cellular players involved in the angiogenic and vasculogenic program (Cipriani et al. 2011; Manetti et al. 2011).

Given these observations, it stands clear that microvascular involvement has a pivotal importance for the clinician involved in the management of SSc.

Peripheral microvascular damage in this disease is characterized by dynamic alteration of the capillaries that carries a progressive decrease in their density. Microvascular changes are typically observed in the nailfold bed by capillary microscopy and are in fact exploited for the early diagnosis of SSc and prognostication of disease evolution (Cutolo et al. 2010a).

However, capillaroscopy provides mostly static information, and no or few data on the dynamic of microvessels are given by this technique. On the other hand, a number of efforts have been made in the last few years, to explore the dynamic variations of skin blood flow in SSc-related disorders, in order to unveil the earliest alteration of the disease and to provide useful information on the variation of vascular response according to the stage of the disease and to treatment.

In this chapter we will review data about skin blood flow measurement in systemic sclerosis, with particular reference to laser techniques.

2 Techniques for Evaluating Skin Blood Flow

2.1 Clinimetric Methods

2.1.1 Thermometry and Thermal Imaging

Thermometry was introduced for the first time by T. Lewis as a quantitative index of skin blood flow. The measurements are obtained with or without skin contact. The surface temperature can be mapped with infrared cameras or through contact with crystal liquid. Skin temperature is representative of underlying blood flow, with both muscle and skin perfusion believed to contribute to the signal. These methods are seldom used nowadays, due to a number of limitations, such as the lack of discrimination between nutritional and thermoregulatory blood flow, the poor sensitivity for important variation of blood flow and the slow reactivity, and the poor spatial resolution (Imbert et al. 2010).

In clinical practice, thermal imaging is mainly used for the evaluation of Raynaud's phenomenon (Fig. 1). It has been shown that local cold exposure of the hand inhibits the postischemic hyperemic response in patients but not in normal controls; thermal imaging can detect this difference with a fair sensitivity, but it does not seem to discriminate between primary and secondary Raynaud's phenomenon (Imbert et al. 2010; Murray et al. 2009).

3 Global Microvascular Measurements

Different physical sensors are able to evaluate the microcirculation in superficial tissues. They can do this directly, such as the laser techniques, indirectly through nutritional efficacy with transcutaneous oxygen pressure (pO₂) measurements, or globally as volume flow in plethysmographic methods (Imbert et al. 2010; Cracowski et al. 2006).

Fig. 1 Thermography images after cold challenge: healthy subject(*left side*) vs. Raynaud's phenomenon(*right side*)

4 Photoplethysmography

Photoplethysmography is an optical measurement technique that can be used to detect changes in blood volume in the microvascular bed of superficial tissues. Up to date photoplethysmography sensors are based on semiconductor technology with LED and matched photodetector devices working at the red or near-infrared wavelengths (Imbert et al. 2010; Allen 2007). Blood test vasoreactivity during cold challenge has been explored in Raynaud's phenomenon; the loss of dicrotic notch has been claimed as a typical sign of Raynaud's phenomenon secondary to systemic sclerosis, due to the reduction of vascular wall compliance (Cooke et al. 1993).

5 LDF and LDI

5.1 LDF

LDF is based on Doppler effect produced by red blood cells as they flow through superficial microvessels, when they reflect laser illumination. Low-power lasers are utilized with a probe able to detect and elaborate Doppler signal (Imbert et al. 2010; Rajan et al. 2009). It is a one-point measurement method, which records the integrated perfusion in a sampling volume in real time. It needs contact of the skin surface to

explore by a sensor, fixed to the skin by a double-adhesive transparent tape. The depth of the measurement depends on the laser wavelength and the fiber separation. With standard fiber separation (0,25 mm), a wavelength of 780 nm has a measuring depth of 0,5–1 mm and an approximate volume of 1 mm³.

In early studies HeNe lasers (632,8 nm) dominated; however, longer wavelengths (780–810 nm) are now preferred due to increased penetration depth and lower absorption by melanin, which shows less dependence on skin color and also a more efficient and stable process in the industrial production, using solid-state laser sources. Moreover, with these wavelengths, any dependence on oxygen saturation is eliminated. The signal captured is proportional to the mean velocity and to the number of red blood cells moving through the sampled tissue volume. Since the volume explored is not precisely determined, the measure is semiquantitative. Moreover, the vessels explored are not only the superficial skin capillaries but also the arterial and venous vessels of superficial and mid-dermis; other "parasite" movements can also influence the measurements. The physiological interpretation of the measurements obtained is thus not always univocal (Imbert et al. 2010; Li et al. 2006).

A number of refinements have improved this type of physiological signal, such as special software to analyze the velocimetric and volumetric

components of the signal or dual wavelength sensors that provide simultaneous measurements at two different depths (Imbert et al. 2010).

The main advantage of this method is its high sensitivity, which allows the recording of perfusion changes over time induced by spontaneous arteriolar vasomotion, as well as those occurring during the influence of physiological stimuli, such as post-occlusive reactive hyperemia (PORH), the venoarteriolar reflex, the reactivity to the administration by iontophoresis of vasoactive substances, or the systemic administration of medications (Fig. 2) (Salvat Melis et al. 2006; Rossi et al. 2012; Fries et al. 2005). Patients with SSc are characterized by either lower or normal peripheral blood perfusion as compared to healthy subjects (Correa et al. 2010; Cracowsky et al. 2002; Cutolo et al. 2010). Finger blood perfusion correlates negatively with the extent of nailfold microvascular damage evaluated by capillaroscopy and improves with i.v. iloprost treatment (Cutolo et al. 2010b; Sulli et al. 2014, 2013).

Moreover, SSc patients have impaired microvascular responses as compared with controls. Ischemic challenge and cold test have yielded similar results, where some studies reported no consistent differences in these tests between primary and secondary RP, while others contradicted these results (Cracowsky et al. 2002; Correa et al. 2010; Rajagopalan et al. 2003). A different kinetic of response to ischemic challenge and cold stimulus has been claimed within SSc cutaneous subsets, diffuse disease showing a distinct alteration of ischemic test and limited disease with a prevalent modification of the response to cold (Grattagliano et al. 2010).

SSc shows abnormal neurovascular response to local heating that is not related to the severity of skin involvement (Salvat Melis et al. 2006; Roustit et al. 2008; Boignard et al. 2005). Local release of vasodilator substances has yielded contradictory results; some authors claimed an alteration of endothelial dependent but not endothelial independent vasodilatation (Anderson et al. 1999), whereas others have reported an impairment of both responses (Rossi et al. 2008).

Fig. 2 Laser flow measurement: a probe detects Doppler shift of a low power laser beam as red blood cells flow through microcirculation. Iontophoresis allows local application of vasodilator substances. Tracings of blood flow are depicted on the screen (Courtesy of A. Moneta, Perimed Italia srl)

6 Laser Doppler Perfusion Imaging

Laser Doppler imaging (LDI) is a relatively new method that allows an objective assessment of skin perfusion over a wide skin surface. This is currently performed by a scanning beam and point by point perfusion measurements, which consequently lead to imaging times of several minutes. The measurement is noncontact and can register chronic changes or measure repetitively in quick succession. The LDI uses normally a low-power laser beam (1 mW) with a wavelength of 633 nm. Perfusion signals are combined to form a color-coded map, with a color scale ranging from dark blue (lowest value) to red (highest value) (Fig. 3). The size of the scanned area may range from 5×5 to 50×50 cm, depending on the distance of the scanner. The blood flow is expressed in arbitrary perfusion unit, since also in this case the volume sampled is not accurately determined. This technique, although limited by the slowness of imaging acquisition, has the advantage of conjugating the possibility of scanning a large surface area and evaluating dynamic changes over time (Imbert et al. 2010).

Fig. 3 Laser Doppler perfusion imager. Intensity signal from a color-coded scale ranging from *dark blue* (lowest value) to *red* (highest value) (Courtesy of A. Moneta, Perimed Italia srl)

It is a valuable tool for refining the differential diagnosis of Raynaud's phenomenon (Szabo et al. 2008; Rosato et al. 2009a) and for the evaluation of the dynamic changes of microcirculation after the local administration of vasoactive substances by iontophoresis or the systemic administration of drugs (Anderson et al. 2004; Rosato et al. 2010; Shah et al. 2013). Through intensity imaging and colorimetric scale, it is possible to evaluate the distribution and homogeneity of flux and regional differences between different skin areas; an association of dyshomogeneous perfusion and lack of proximal distal perfusion gradient was observed in SSc patients. This contrasts with healthy subject, where the gradient was maintained and the flux was homogeneous, and primary Raynaud's subjects, where lack of proximal distal gradient was combined with homogeneity of flux (Rosato et al. 2009a). Moreover, laser imaging alone can provide an indirect provisional estimate of possible digital artery obstruction (Rosato et al. 2009b).

7 Laser Speckle Contrast Imaging

A newer method to dynamically explore a relatively large skin area is laser speckle contrast imaging (LASCA). Like LDI, LASCA

(or Perfusion Speckle Imager, PSI) is a noncontact method and can register blood flow over an area that may range from a few millimeters to several centimeters depending on the type of scanner and the distance of the head of the scanner from the skin surface. A laser-diffused light, with a wavelength of 785 nm, illuminates the area of interest, producing a speckle pattern of the whole scanned skin area, without the need of a point-to-point scanning, like in LDI described above. When a surface is illuminated by laser light, the backscattered light will generate a random interference pattern, consisting of dark and bright "dots." This pattern is called a speckle pattern. If the illuminated surface is static, the speckle pattern is stationary, and dots have a high contrast between each other. When there are moving particles, such as red blood cells in the living tissue, the speckle pattern will change over time, since the contrast between dots decreases inversely to the speed of the moving objects. These dynamic changes in the contrast are instantaneously recorded by a special camera positioned in the scanner head, with a high spatial resolution. Therefore, the PSI system presents the same advantages of LDI, with a higher speed of imaging acquisition and a better resolution. It is therefore possible to produce colored maps representing the blood flow distribution and also

Fig. 4 Perfusion images are useful to detect regional differences in perfusion distribution and homogeneity of flux: i.e., presence of proximal distal gradient (**a, b**) with homogenous (**a**) vs. inhomogenous flux distribution (**b**), absence of proximal distal gradient (**c, d**) with homogenous (**c**) vs. inhomogenous flux distribution (**d**) (Pericam PSI, Perimed, Jarfalla)

to record continuously the blood flow changes, with movies owing a frame rate up to 90 frames per second (depending on the size of the scanned area) (Imbert et al. 2010; Briers 2006). In analogy with laser Doppler imaging, it is possible to evaluate the distribution and homogeneity of flux and regional differences between different skin areas (Fig. 4) (Della Rossa et al. 2013; Ruaro et al. 2013); at the same time, it is possible to explore the dynamic of microcirculation after physiological stimuli (Fig. 5), as well as the response to topical application of vasodilator substances by iontophoresis (Ruaro et al. 2013; Roustit et al. 2010).

Within SSc patients, difference in the ischemic challenge may help to better refine disease sub-setting, as early disease seems to show exaggerated POHR as compared to established disease. Peripheral blood perfusion is lower in SSc patients as compared to healthy subjects; moreover, skin blood flow linearly decreases with the increase of severity of microangiopathy assessed

by capillaroscopy (Ruaro et al. 2013). When measuring basal skin blood flow, LASCA was found significantly less time-consuming than LDF; LASCA and LDF are highly correlated (Ruaro et al. 2013; Roustit et al. 2010), but LASCA shows lower intraoperator variability versus LDF analysis and is much better accepted by patients (Roustit et al. 2010).

8 Summary

Laser techniques have gained a growing attention as reliable and noninvasive methods to assess vascular reactivity in SSc patients.

LDF is a contact laser with single-point sampling; it is very sensitive and allows reliably to assess in real time small and rapid variation in skin blood flow, in response to physiological stimuli or to the application of vasodilator substances by iontophoresis or the administration of systemic drugs. The disadvantages of this technique are

Fig. 5 Tracings of the postocclusive hyperemic response in a healthy subject as compared to limited SSc and early SSc (36) (Pericam PSI, Perimed, Jarfalla)

related to the need of contact with the skin (needs skin integrity) and the study of a single point that does not enable to explore larger areas.

LDI permits the mapping of a larger area and does not need contact, allowing the evaluation also of areas of injured skin. Through intensity color scales, it enables the assessment of regional differences in flow distribution, and it can consent the dynamic evaluation of flow after different kinds of stimuli (physical, pharmacological, local, or systemic). The main disadvantage is related to the relatively high scanning time that might not enable to detect shorter variations of flux.

LASCA is a newer whole field imaging tool that combines the rapidity of acquisition to the possibility of mapping a relatively large skin area without contact. It allows both qualitative evaluation of skin blood flow and assessment of flux distribution according to different areas. Dynamic variation after physiological or

pharmacological stimuli can be assessed as well. It is reproducible, rapid, and much better accepted by patients than LDF.

Port-wine stains (PWSs) are cosmetically disfiguring, congenital capillary and venular malformations that affect 0.3–0.5 % of newborns (Jacobs and Walton 1976; Lorenz et al. 2000). The lesions are most frequently located on the face (often in a trigeminal dermatomal distribution) and the neck, which cannot disappear spontaneously. At birth, lesions are first noted as subtle, light pink patches. Delayed or inadequate treatment may result in nodularity, hypertrophy, and soft tissue overgrowth, causing dysmorphism, asymmetry, and occasional spontaneous bleeding (Kira et al. 2009). These changes in color and contour are attributed to progressive ectasia of the abnormal dermal vascular plexus. So it is essential to treat PWS as early as possible and maintain treatment to prevent the development of vascular nodules and hypertrophy in later years.

There appears to be no hereditary predilection for PWS within families and no certain risk factors for PWSs as well as no known ways to prevent them. The development of PWS is hypothesized that the deficiency or absence of surrounding neurons regulating blood flow through the ectatic postcapillary venules. The blood vessels are unable to constrict normally and remain permanently dilated. It is believed that PWSs develop within the first 2–8 weeks of gestations (Schneider et al. 1988). In addition, PWSs may occasionally develop progressive lymphangiectasia, soft tissue hypertrophy (Klippel-Trenaunay-Weber syndrome), Cobb syndrome, and Proteus syndrome (PS).

On histopathology, PWSs consist of dilated, ectatic capillary, and venule-sized vessels in both papillary and reticular dermis. These vessels, unlike capillary hemangiomas, are not proliferative and therefore only grow proportionally with the individual. While hemangiomas tend to spontaneous regression, PWS vessels become progressively tortuous and dilated over time. The pathogenesis is still not fully understood. One hypothesis is a lost capacity of vessel constriction and thus an abnormal regulation of blood flow. Recent studies indicate that RASA1 mutations cause capillary and arteriovenous malformations and hereditary capillary malformations and limb enlargement without arteriovenous malformation (Revenu et al. 2008; Boon et al. 2005; Hershkovitz et al. 2008). Vascular endothelial growth factor (VEGF) and VEGF-receptor 2 expression are significantly increased in PWS compared to controls, indicating that VEGF and VEGF-R2 may contribute to vessel proliferation and vasodilatation (Vural et al. 2008).

Traditional therapies including excision, cryotherapy, skin grafting, dermabrasion, and radiation therapy were reported to be inefficient and had many unacceptable side effects. In recent decades, laser therapies such as pulsed dye laser (PDL) have gained great popularity for PWS (Landthaler and Hohenleutner 2006). Other light-based devices, including alexandrite lasers, intense pulsed light (IPL), and combined 585/1064-nm devices, are also used to achieve desired lesion lightening. The basic principle is selective photothermolysis (SP). The preferential absorption of laser light is absorbed by hemoglobin and the subsequent conversion of the absorbed light into thermal energy that leads to the coagulation of blood vessels.

Furthermore, the thermal relaxation time (T_r) for skin blood vessels 50–150 μm in diameter is between 1.4 and 12.8 ms, so the 0.45–50 ms pulse duration produced by these lasers matches the T_r for dermal blood vessels, which confine the laser energy to the targeted vessel before much heat is lost by thermal diffusion out of the exposure field (Nelson et al. 1995).

It was shown that the penetration depth of 585-nm PDL is 1.2 mm, comparing to 0.5 mm at 577-nm PDL, below the basal membrane while retaining vascular selectivity (Tan et al. 1989). Histological studies (Fiskerstrand et al. 1996; Hohenleutner et al. 1995) showed that using 585-nm PDL treatment at 0.45-ms pulse duration, 5-mm spot size, and 6–8 J/cm^2 radiant exposure, the photocoagulation occurred at a depth of approximately 0.65 mm. Moreover, complete photocoagulation of the vessel lumen occurs in superficial vessels up to approximately 150 μm in diameter. However, larger and deeper vessels, owing to both shielding by superficial vessels and inadequate penetration depth, remain resistant (Lucassen et al. 1996), so longer PDL wavelengths are needed to further enhance the depth of photocoagulation and clearance (Geronemus et al. 2000). New-generation of long-pulsed tunable dye lasers (LPTDLs) offer potential advantages over conventional PDL. The LPTDL offers a pulse length of 1.5 ms and tunable wavelengths from 585 to 600 nm. These parameters are more useful in PWS that consist of more ectatic and deeper located vessels. The absorption coefficient of oxygenated hemoglobin is substantially lower at 595 nm than at 585 nm (Greve and Raulin 2004; Chang et al. 2002; Prah 1999). Therefore, higher fluence and longer pulse durations are necessary when using a wavelength of 595 nm.

1 Treatment

1.1 PDL

PDL devices (577 nm, 585 nm, or 595 nm) are the most frequently used lasers to treat PWSs. Yellow light produced by PDL is preferentially absorbed by hemoglobin in the PWS blood vessels where, after being converted to heat, it causes thermal

1.2 Pulsed Nd:YAG Laser (1,064 nm)

The penetration depth of 1,064 nm Nd:YAG laser pulses is deeper than PDL. Theoretically, it can be used to impact thicker and deep-lying blood vessels, which have particularly advantage in matured or hypertrophic PWSs. However, thermal injury of deeper blood vessels may lead to necrosis of

surrounding dermis and increase the risk of scarring compared to PDL. Yang et al. (2005) reported that 1,064 nm Nd:YAG laser was as effective as the PDL in the treatment of PWSs with the minimum purpuric dose. The 1,064-nm Nd:YAG laser also showed to be safe and effective for treating hypertrophic PWS of the lip (Kono et al. 2009).

In conclusion, the 1,064-nm Nd:YAG laser is an important device in the armamentarium of treatment options for PWS, particularly in the case of nodularity and hypertrophy.

1.3 A Dual-Wavelength Laser System (595-nm PDL and 1,064-nm Nd:YAG Laser)

The exact nature of the synergy for vascular lesions between PDL and Nd:YAG lasers remains unclear. One possible explanation is the shift in the light-absorption properties of blood during coagulation. The dual-wavelength laser system targets oxyhemoglobin by the 595-nm wavelength and then targets the methemoglobin (converted from oxyhemoglobin) by the latter 1,064-nm wavelength, because methemoglobin has a significant absorption peak near 1064 nm (Alves and Wajnberg 1993; Randeberg et al. 2004). In 2009, Alster and Tanzi (2009) reported that the dual-wavelength laser system was superior to PDL alone in the treatment of recalcitrant and hypertrophic PWS. Side effects were limited to mild purpura and vesicle formation in one patient that resolved without sequelae in 6 days. The synergies between PDL and 1064-nm Nd:YAG laser have also been evaluated by other authors and proved to be effective (Borges da Costa et al. 2009).

1.4 IPL

IPL devices emit polychromatic incoherent high-intensity pulsed light with an emission spectrum ranging from 500 to 1,400 nm, and pulse durations are in millisecond range. Therefore, IPL systems have a potential advantage over other laser systems because they incorporate the highly oxyhemoglobin selective wavelengths around

577–600 nm and also emit longer wavelengths allowing deeper penetration into the dermis and deeper capillary destruction (McGill et al. 2008).

IPL provides an alternative choice for PWS, owing to its broad-spectrum, lesser frequency of complications, and economic consideration. In some cases, fresh or laser-resistant PWS was effectively treated by IPL sources (Raulin et al. 1999; Bjerring et al. 2003; Ozdemir et al. 2008). Recently, Wang et al. (2013) have reported that 29 Chinese neck PWS patients (without any treatments before) received IPL therapy for five times at intervals of 4–5 weeks. Over 60 % patients achieved more than 50 % improvement.

1.5 Alexandrite Laser

The 755-nm alexandrite laser has been proven particularly useful in the treatment of hypertrophic and PDL-resistant PWS (Li et al. 2008; Izikson et al. 2009), especially when used in combination with PDL. The alexandrite laser has selective absorption of deoxyhemoglobin over oxyhemoglobin, so in theory it should preferentially damage venules (i.e., PWS vasculature) over arterioles and has 50–70 % deeper tissue penetration than PDL. We also need to tell patients that permanent hair reduction may occur with the alexandrite laser. Owing to the deeper tissue penetration and decreased absorption by hemoglobin of longer wavelength lasers, the alexandrite laser are associated with elevated risk of adverse effects such as pigmentary changes and scarring.

1.6 Photodynamic Therapy (PDT)

The basic principle of PDT is the intralesional or intracirculatory addition of an exogenous chromophore into the ectatic capillaries, serving as a photosensitizing drug. The tissue-localized drug is irradiated at an appropriate wavelength for selective absorption by the photosensitizer. This leads to the generation of reactive oxygen species, inducing intracapillary photothermal and photochemical effects and the destruction of the

vascular lesions in the dermis without damage to the normal overlying epidermis.

In 2013, Gao et al. (2013) reported a side-by-side comparison of PDT and PDL in the treatment of PWS birthmarks. 585-nm pulsed PDT was carried out with a combination of hematoporphyrin monomethyl (HMME) and a low-power copper vapor laser (510.6 and 578.2 nm). For red PWS, the blanching rates of PDL and PDT at 2 months ranged from 11–24 % to 22–55 %, respectively. For purple PWS, blanching rates of PDL and PDT ranged from 8–33 % to 30–45 %, respectively, which meant PDT is at least as effective as PDL and, in some cases, superior. Other authors did not find any significant benefit in combining PDT with PDL compared to PDL alone (Evans et al. 2005). However, other authors found a beneficial effect in combining benzoporphyrin derivative monoacid ring PDT with PDL in contrast to PDL alone [34].

In conclusion, PDT might offer additional therapeutic benefits in the treatment of PWS, but sometimes prolonged systemic visible light sensitivity after intravenous administration of porphyrin derivatives et al. practical problems limit its clinical application.

1.7 Dye Pulsed Light (Dye-PL)

Very recently, dye-PL has been introduced to treat PWS. The wavelength of dye-PL is from 500 to 600 nm, which incorporate the highly oxyhemoglobin selective wavelengths at 542 nm and 577 nm. The wavelength of dye-PL is close to 585/595-nm PDL. Theoretically, it is supposed to be suitable for the treatment of PWS. Further clinical and basic researches are needed to evaluate its efficacy.

2 Conclusion

Many different laser/light systems, as well as alternative treatment strategies, have been used to treat PWS. The 585–600 nm PDL with variable pulse widths (ranging from 0.45 to 10 ms) in combination with epidermal cooling modality

proved to be safe and effective. However, blood vessel size and depth of PWS as well as revascularization make it difficult to completely eradicate lesions with current laser/light technology. Newer approaches and further randomized controlled trials are needed to establish the role of incoherent light sources and lasers other than the PDL.

1 Rating Port-Wine Stains

- Color (hue and lightness)
 1. Normal skin
 2. Pale pink
 3. Pale red or bright pink
 4. Pale purple or dark pink
 5. Dark red
 6. Bright purple or dark red
 7. Dark purple
- Patchiness
 1. Not at all patchy
 2. A little patchy
 3. Rather patchy
 4. Very patchy
- Boundary
 1. Vague
 2. Fairly sharp
 3. Very sharp
- Size
 1. Nonexistent
 2. Very small
 3. Small
 4. Medium
 5. Large
 6. Very large
- Shape
 1. Regular
 2. Somewhat irregular

This chapter was originally published under the ISBN 978-3-540-01771-4 with the following book title *Measuring the Skin*. The content has not been changed.

- 3. Very irregular
- Surface
 - 1. Smooth
 - 2. A little uneven
 - 3. Rather uneven
- Hypertrophy
 - 1. Not hypertrophic
 - 2. A little hypertrophic
 - 3. Rather hypertrophic
 - 4. Very hypertrophic

This rating was evaluated on 90 patients. Color and boundary were correlated as well as size and hypertrophy. Shape and patchiness were found to

be difficult to distinguish (irregular shaped port-wine stains were often judged as patchy) (Koster et al. 1998).

Using morphometry, size, contour length, and shape regularity are easily and quickly assessed without a device. Accordingly, this classification might be easily replaced by a measurement.

1 Introduction

In the human skin, sweat is produced by specialized glands. In the sweat apparatus, the constitutive cells are not destroyed in the secretion process. Cutaneous sweat glands correspond to two main types, namely, the eccrine (ESG) and apocrine (ASG) sweat glands. They are commonly distinguished by histomorphology (Saga 2001; Noël et al. 2013). The presence of putative apoeccrine sweat glands (AESG) has been further suggested (Sato et al. 1987). The sweat secretion is altered in both its amount and composition by various physiological and pathological events. The densities in ESG, ASG, and putative AESG differ over different body regions. In addition,

morphological and functional variations exist according to age and nature of specific stimuli. The skin surface bacterial microflora (biocene) plays a major role in causing sweat malodor.

Despite social and cultural differences among the world populations, excessive sweating and body malodors are usually perceived as unpleasant conditions (Sato et al. 1989). By contrast, regional hypohidrosis and anhidrosis appear less disturbing, although they impair the thermoregulation and commonly represent warning signs for several systemic diseases.

Although the morphologic microanatomy remains the basis of sweat gland classification, molecular phenotyping and functional characteristics should be combined when possible. In some conditions in humans, it is uncertain whether some glands are ESG or ASG depending on the selected criteria. Various immunohistochemical markers including cytokeratin (CK) phenotyping, as well as the epithelial membrane antigen (EMA), the carcinoembryonic antigen (CEA), and others, were introduced for this purpose (Noël et al. 2013; Wollina 1991; Saga 2002; Wilke et al. 2004). In addition, the identification of glycoconjugates was used to characterize sweat glands in health and disease (Wollina et al. 1989; Sames et al. 1999; Li et al. 2009).

2 Sweat Gland Structure

2.1 Eccrine Sweat Glands

Each ESG is composed of a deep coiled portion in continuation with a straight excreting intradermal duct ending as a spiral intraepidermal acrosyringium. The secretory portion represents about two-thirds of the coiled structure. It consists of an epithelial layer composed of large clear (secretory) cells admixed with smaller granular dark (mucoid) cells, and they are cuffed by spindle-shaped myoepithelial (contractile) cells. Clear cells contain glycogen and mitochondria in abundance. They produce the eccrine sweat. Fine canaliculi collecting the secreted sweat are squeezed between adjacent clear cells. Each of the canaliculi represents a pouch extending from

the luminal space. The granular dark cells exhibit pyramidal conformation with a narrow base near the peripheral basement membrane. The intraepidermal acrosyringium is lined by epithelial cells similar to those of the straight intradermal duct.

The two to four million ESG are distributed over the human body reaching in average 60–200 per cm². They reach higher densities (about 600/cm²) on the palms and soles (Xhaufflaire-Uhoda et al. 2010a). Every single ESG opens directly at the skin surface through an individual acrosyringium. ESG are absent from the lips, nail bed, and some portions of the genitalia. ESG activity is controlled by a unique cholinergic orthosympathetic innervation. Various thermal, emotional, intellectual, and gustatory stimuli activate dedicated centers of the brain controlling the ESG production. In addition, hypoglycemia, hyperthyroidism, and hypercapnia represent other stimuli for ESG production (Xhaufflaire-Uhoda et al. 2010a). The global excretory ESG activity is low compared with that of the kidneys.

Eccrine sweat is the exocrine product of the deep coiled segment of the gland. The secretory sweat coils produce an isotonic ultrafiltrate of plasma. It corresponds to a clear, colorless, and odorless watery fluid enriched in organic and inorganic electrolytes. The eccrine sweat composition varies according to the secretion rate, the transit time inside the excretory duct, the aldosterone activity, the physical training, and the acclimatization to the environmental moisture and temperature. Indeed, during the eccrine sweat migration inside the intradermal duct, partial selective resorption of ions, particularly Na⁺ and Cl⁻, takes place. Other electrolytes are also reabsorbed, particularly in extreme sweating conditions. Eccrine sweat becomes hypotonic and contains much less electrolytes and minute amounts of glucose. By contrast, lactate increases in abundance. In the distal duct portion, sweat evaporates partially inside the acrosyringium, producing a mixture of vapor and liquid at the stratum corneum (SC) surface depending upon the rate of sweat production (Sato et al. 1989). The amount and composition of eccrine sweat at the SC surface show interindividual variations

modulated over time by the body site (Sato et al. 1989). Of note, eccrine sweat contains compounds of clinical importance, including heavy metals, some drugs, other organic compounds, and (photo-) allergens.

In regular conditions, the ESG activity appears intermittent over a large part of the body. Apparently, cyclic periodic outputs alternate with pauses. The pulsating rhythm is about 0.3–12 sweat outputs per minute. Such a rhythmic activity shows interindividual variations according to circumstances and body sites. It possibly results from spasmodic contractions of periluminal myoepithelial cells once distended by the sweat flow. In general, contiguous ESG appear active alternately. Even in case of profuse sweating, it is assumed that only about 50 % of the ESG release sweat simultaneously. Such functional feature is not present on the palmoplantar sites where sweat production is largely synchronized involving the vast majority of ESG (Sato et al. 1989; Xhauffaire-Uhoda et al. 2010a).

Sweating evaporation from ESG pores (Uhoda et al. 2005; Xhauffaire-Uhoda et al. 2010b) is a mechanism involved in body thermoregulation during exposure to either warm environment or body hyperthermia. By contrast, running sweat droplets over the skin surface has little or no thermoregulatory effect. Blood flow regulation and vasodilation of the superficial vasculature largely contribute to the homeothermic control. At rest, discrete water evaporation from each single sweat pore at the SC surface is added to the actual transepidermal water loss (TEWL) to form the global insensible perspiration reaching about 600 g daily for the whole body.

2.2 Apocrine Sweat Glands

Most ASG are located in the armpits and groins. They are fewer around the umbilicus, in the perineal region, and in the mammary areola. Each ASG consists of a deep coiled secretory portion connected to a duct. The glandular portion is formed by cuboidal or columnar cells containing granules and vacuoles in part pigmented. The apocrine excretory duct closely resembles the

eccrine duct. It consists of a double or triple layer of rather similar cuboidal cells. Those forming the inner layer exhibit a faint luminal fringe. The peripheral basal layer contains numerous mitochondria and microvilli. The apocrine sweat is scanty and sticky in consistency.

ASG remain quiescent during childhood, and they become functionally mature under androgen stimulation at puberty. Afterward, the hormonal control is apparently no more operative, being replaced by both adrenergic and cholinergic stimuli.

Apocrine sweat consists of a lipid-rich liquid produced inside large ASG acini located deep in the dermis and hypodermis. It is released into apo-pilosebaceous ducts of adjacent hair canals before reaching the SC surface. Apocrine sweat is slightly viscous and milky, enriched in lipids, nitrogen, lactates, and various other ions including Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , and HCO_3^{3-} . The apocrine secretion appears to be derived from pinching off the apical cytoplasm of the secretory cells. Moll's glands on the lids, ceruminous glands in the ear canal, and pseudomammary anogenital glands are specially adapted ASG (Van Der Putte 1994).

2.3 Apoeccrine Sweat Glands

AESG were tentatively identified in the armpits where they were estimated to outnumber 25,000. It was assumed that the axillary skin contained approximately equal numbers of ESG, ASG, and AESG. The AESG were described to share some features in common with both the ESG and ASG (Sato et al. 1987). Their presence remains however a controversial issue (Sato et al. 1987; Hermanns-Lê et al. 2004). The distinction between AESG and both the ESG and ASG was mainly assessed on gross morphology (Uhoda et al. 2005). Their physiologic and pharmacologic stimulation appeared to be distinct from those controlling ASG. They possibly open directly onto the skin surface. They seemingly respond quickly to psychological stress, and they were considered to largely contribute to the abundant sweat produced in the armpit.

3 Sweat Gland Immunohistochemistry

A multipronged immunohistochemical approach is helpful in the study of human sweat glands. Although the excretory ducts appear phenotypically similar in the distinct sweat glands, the deep secretory coils show distinctive differentiation patterns.

The secretory coil and at a lesser extent the ductal cells of the ESG were identified by the CAM 5.2 antibody. All segments of the ASG including secretory and ductal cells were decorated by this antibody. The monoclonal CAM 5.2 CK antibody strongly reacts with CK 8 and at a lower extent with CK 7 (Noël et al. 2013). No reactivity has been disclosed with CK 18. The different ESG portions contain a cytoskeleton made of several distinct CK (Metze and Luger 1996; Metzler et al. 1990). They include CK 7, CK 8, CK 14, CK 18, and CK 19, as well as EMA and CEA (Li et al. 2009). It was reported that the expression intensity of CK 7, CK 18, and CK 19 was stronger than that of CK 8 and CK 14 (Li et al. 2009). A controversy exists about the presence of CK 10 (Li et al. 2009; Demirkesen et al. 1995).

The polyclonal S100-B protein antibody detects one of the 19 Ca²⁺-binding proteins of the S100 family. The S100-B protein predominates inside the cytoplasm of ESG secretory cells. The monoclonal antihuman EMA antibody (Li et al. 2009; Metze and Luger 1996) and the polyclonal antihuman CEA antibody (Li et al. 2009) typically label sweat glands (Noël et al. 2013). EMA is located in the luminal coating of the eccrine secretory segment and in the dark cells as well. The ASG contain EMA in different segments including the glomerular structure and the excretory duct (Noël et al. 2013). CEA is present at all levels of the ESG. The ASG showed a heterogeneous CEA labeling on the luminal coating of the duct. UEA-1 is a lectin specifically binding to α -L fucosyl moieties. The anti-UEA-1 antibody reveals the lectin-binding sites corresponding to oligosaccharides with terminal α -fucose, some of which are present in sweat glands (Noël et al. 2013; Metzler et al. 1990). In the ESG secretory segments, clear

cells exhibit strong cytoplasmic UEA-1 staining. ASG globally appear intensely labeled. A variable number of cells of the secretory ESG segment were strongly positive. The monoclonal antihuman CD138 detects the transmembrane syndecan-1 proteoglycan (Noël et al. 2013). A variable number of ESG secretory cells are strongly positive for this antibody. The monoclonal antibody to CD63 (NKI-C3) detects various proteins whose molecular weights range 25–100 kd. They are probably part of some lysosomal antigens located in cytoplasmic vacuoles (Noël et al. 2013). In ESG, CD63 immunostaining is present in the apical part of secretory cells. A positivity for the gross cystic disease fluid protein-15 appears typical for the ASG (Uhoda et al. 2005).

So far, AESG were not clearly and specifically distinguished using immunohistochemistry, and publications about this topic remain scanty and controversial (Sato et al. 1987; Hermanns-Lê et al. 2004). However, recent findings suggest that the immunoreactivity to the S100-B protein, CEA, and CD63 possibly helps identifying some AESG (Noël et al. 2013).

The functional activities of the eccrine sweat glands (ESG) and apocrine sweat glands (ASG) are clearly distinct in humans. The appropriate noninvasive methods assessing their excretion activities at the skin surface are distinct.

1 Biometrology of Eccrine Sweat Excretion

Eccrine sweating is the response to thermal, emotional, and gustatory stresses. It is under the control of acetylcholine from the cholinergic sympathetic innervation. ESG activity plays an essential role in regulating body temperature in physiological conditions. Such a function is altered by a series of systemic diseases. For instance, diabetic neuropathy frequently involves the distal sensorimotor innervation. The resulting

peripheral sweating deficit is commonly responsible for unequivocal alterations in the length-dependent thermoregulatory sweating (Piérard 2003). Hence, legs affected by diabetic neuropathy are commonly hypohidrotic with a “compensatory” hyperhidrosis over the upper body regions (Xhaufaire-Uhoda et al. 2011). Other possible sweating alterations in diabetes include segmental hypohidrosis and more rarely isolated dermatome involvement. Some patients suffer from a combination of two or more of these patterns and even from global anhidrosis (Piérard 2003). The extent in body surface anhidrosis was reported to be correlated with the severity of clinical dysautonomia (Piérard 2003). Fine-tuning objective assessments of discrete aspects of the sweat gland dysfunction have been rarely explored so far using recent sensitive biometrological methods (Xhaufaire-Uhoda et al. 2011). However, considering the impact of ESG activities in a variety of physiopathological conditions, diverse methods are available for recording the ESG numbers and assessing their functional status (Piérard 2003). The *in vivo* tests belong to two major categories (Noël et al. 2012).

The first group of methods provides an overall information about the amount of excreted sweat, irrespective of the number of active ESG. Such assessments include the gravimetric method of collecting and weighing sweat at the skin surface. The global decrease in body weight over a couple of hours was used as an indication of the amount in sweat output over the selected period of time. Microcannulation of individual sweat ducts represented an ancillary cumbersome method. Global assessments of water evaporation from the skin surface were advocated using a variant of transepidermal water loss (TEWL) measurement. Electrometric procedures quantifying the stratum corneum (SC) moisture was expected to represent an indirect indication of the ESG production.

The second group of methods assesses the density of active ESG over a given skin surface area (Noël et al. 2012; Hermanns-Lê et al. 2004). In particular, skin capacitance mapping/imaging (SCMI) visualizing any tiny individual sweat output conveniently provides a real-time noninvasive information.

1.1 Gravimetric Method

The gravimetric method was formerly developed for quantifying the actual amount of eccrine sweat produced in excess under controlled conditions (duration, temperature, site, etc.) during defined time intervals. Thermal sweating was thus explored on absorbent filter papers or pads of defined dimensions placed under occlusion (Leyden et al. 1981). Any pharmacological stimulation or inhibition of ESG was possibly performed. In these procedures, the sampling material was weighed before and immediately after the collection period of sweat. A minimum amount of about 100 mg of sweat was necessary for reliable quantifications. A well-acclimatized person can produce up to 10 l of eccrine sweat over a single day.

1.2 Water Evaporation Quantification

Regular TEWL measurements are typically used for testing the SC barrier function. Such evaluations are performed in the absence of active sweating. However, such expectation proves to remain invalid in some circumstances. Indeed, the same devices designed for TEWL measurements in resting conditions are alternatively used for assessing the insensible perspiration with contribution of the discrete eccrine sweat evaporation at rest. The quantification of minute amounts of sweat vapor production in the instrumentally measured TEWL values has rarely been identified in the literature (Rennie et al. 1991) and remains commonly neglected in the interpretation of TEWL data. However, it is acknowledged that any physical, thermal, and emotional stress influences the regular TEWL through sweat production.

TEWL measurements are time consuming and typically confined to small skin areas. However, it is possible to perform continuous recordings, particularly with the open chamber method. This method is suitable for detecting moderate physiological changes in sweat evaporation. Of note, it is not convenient when sweat in excess is running at the skin surface without complete evaporation.

1.3 Sweat Visualization by Staining Procedures

Several simple methods advocated for sweat detection used specific dyes *in vivo*. The skin had first to be wiped for removing any residual sweat before performing the test procedure. The skin was then painted with the reactive dye or covered by a sweat-absorbing material soaked with the reagent. According to the dyes applied either singly or in combination, detection of sweat was rendered possible. The painting method conveniently allowed serial image recordings and image analysis of spontaneous sweating.

One procedure relied on filter paper impregnated with a 1 % bromophenol blue alcoholic solution. The material was deposited onto the sweating SC surface for a few seconds. The gray powder turned blue following contact with watery fluid at a pH above 4.6 which is consistent with sweat. After removal, a series of blue spots appeared at the site of sweat droplets. Alternatively, the skin was powdered with bromophenol blue, or the dye was dispersed in an oily vehicle to be applied as a thin film to the SC surface.

By far, the most simple and safe staining method relied on the iodine starch reaction. A 2 % iodine ethanol solution was painted on the skin. After spontaneous evaporation of the solvent, sheets of starch-enriched filter paper were held against the skin surface for a few seconds. Upon removal of the material, a dark blue imprint became apparent wherever sweating was active. As a variant method, a filter paper was dipped into ethanol solution of iodine and castor oil. After air drying, the paper was placed for 1 min onto the skin, lifted off, and powdered by starch in order to reveal blue dots. Another variant consisted in the application of starch dispersed in castor oil onto the iodine-painted skin. Active sweat pores appeared as dark blue spots at the skin surface. Image analysis allowed the assessment of the ESG numbers and activities.

The simplest and most versatile iodine starch method consisted of a single step procedure based on iodinated starch sprayed onto the SC. Sweat drops were visualized directly at the skin surface as dark blue/purple spots. This method was

possibly repeated on the same site after wiping the iodinated starch from the skin surface. Safety procedures had to be guaranteed because inhalation of iodinated starch is hazardous. Several other dyes such as rhodamine were possibly used as well as Prussian blue powdered on a self-adhesive transparent tape turning blue after contact with sweat.

The sweat droplets were assumed to be hemispherical ($2/3 \pi r^3$) or almost a sphere (πr^3) upon dripping. Calculating the sweat excretion rate over given skin areas was attempted by adding the estimated volume of each sweat droplet.

The aforementioned staining methods were probably prone to various flaws. A pitfall occurred with residual surfactants on SC altering sweat rheology. Dot merging resulted from sideways movement during the imprint stage or due to intense sweating, causing droplet running at the skin surface prior to imprint. In some circumstances it remained difficult to accurately delimit the area of skin from which the print was taken.

1.4 Staining Methods for Specific Organic Sweat Compounds

Some powder or liquid dyes applied onto the skin allowed detecting specific organic sweat compounds. For instance, astra blue revealed various organic ions. Quinizarin turned black in the presence of carbonates. Painting the skin with 5 % orthophthalaldehyde in xylene revealed within 2–3 min a black reaction product following contact with ammonia at the ESG pores.

Ninhydrin turned purple-blue in contact with amino acids. This chemical proved to be irritant for skin and was forbidden for local applications. A safer procedure used a filter paper dipped in 1 % ninhydrin acetone and heated for a few minutes at 120 °C in an incubator before application to the skin. A violet stain appeared at the site of sweat deposits.

1.5 Casting Methods

Silicone rubber methods relied on the hydrophobicity of the material. It was assumed that after application of the casting material to the skin

surface, any sweat droplets released from ESG pores would prevent deposition of the hydrophobic material, leading to imprints at the surface of the casting material.

The silicone rubber material is readily available, simple, and safe to be applied to any part of the body surface. This material admixed to the polymerizing agent forms a cast that is peeled off carefully from the skin surface before visualization under the microscope. A possible flaw with the replica technique is the inclusion of air bubbles under the casting material.

When the silicone rubber material is thin, sweat droplets appear as holes in a membrane. The number of ESG over the defined skin surface area is conveniently counted. A variant of the casting method relies on the application of a thin layer of petrolatum jelly to the skin surface. Beading of sweat droplets is recorded and image analysis determines the ESG density per SC unit area (Piérard 2003).

1.6 Electrometric Methods

Skin electric properties are altered by the SC moisture. Hence, skin capacitance and conductance are increased in the presence of sweat (Piérard 2003). These methods represent screening tools. However, they are infrequently used in functional assessments of sweat production because measures are only relative and indirect. In addition, a saturation effect of the SC rapidly occurs when sweating is abundant.

1.7 Skin Capacitance Mapping/Imaging

In physiological conditions, water is distinctly lost by minimal evaporation through the interadnexal epidermis and sweat glands. Basically, three distinct conditions are encountered regarding skin capacitance mapping/imaging (SCMI) aspects of the sweat gland activity (Xhaufaire-Uhoda et al. 2010a, b, 2011; Noël et al. 2012; Batisse et al. 2006; Lévêque et al. 2006; Piérard-Franchimont, Piérard 2015; Piérard-Franchimont

et al. 2016). The SkinChip[®] and Sweatchip[®] devices as well as the Moisture Map HM100 device (CK Technology, Vise, openate...) (L'Oréal, Paris) operates through a multisensor probe generating detailed capacitance measurements at 50 μm resolution over the SC. The SCMI picture is displayed in a range of gray levels according to each capacitance value. Thus, a nonoptical capacitance map of the skin surface is created. The darker pixels represent high capacitance spots, while the clear ones correspond to lower capacitance values. Skin capacitance is considerably influenced by sweat. Any prolonged contact time over 5 s between SC and the SCMI probe increases the density in darker pixels, owing to accumulation of sweat, TEWL, and water saturation of the SC.

First, the sweat quiescent stage does not show any obvious SCMI manifestation. Second, sweat glands become discretely active even in the absence of visible sweating, in which case they emit only discrete amounts of water vapor. Such aspect of the imperceptible (insensible) perspiration through sweat pores is conveniently observed using SCMI when the subject is in a quiet condition without any overheating. Tiny black dots mark the joining up of each discretely active ESG at the SC surface. The tiny black dots correspond either to open ESG ducts or to soft cornified and moisturized caps of SC cuffing the sweat pores. Such structures probably exhibit a sweat-holding capacity capturing the sweat vapor. There is no running sweat at that stage of the ESG activity. In such a condition, sweat vapor is apparently emitted in minimal amounts and the casual TEWL nearly remains unaffected. However, this condition is also present in association with an overall increase in interadnexal SC moisturization (Noël et al. 2012). In such instance, TEWL is commonly increased (Noël et al. 2012). Third, watery sweat is poured out through active ESG, implying that the skin surface water loss (SSWL) reaches much higher values than the regular TEWL. When sweating is more active, SCMI black dots enlarge and some of them merge to form irregular black "puddles." This aspect is more closely related to SSWL than to TEWL. Because sweat appears as black dots, it is possible

to measure its contribution to the mean SCMI-derived gray level by thresholding the values under consideration (Noël et al. 2012).

SCMI after exercise shows the combination of two major changes affecting the sweat gland activity and the SC hydration (Xhaufflaire-Uhoda et al. 2011). On the one hand, a large number of tiny black dots reveal the presence of boosted ESG. Their size and distribution over the skin surface are relatively uniform. Some larger dark spots result from both the enlargement and merging of the tiny black dots. On the other hand, the SCMI background appears darker than before exercise, indicating an increased SC moisture. These features were reported to be particularly obvious at completion and during about 1 min after exercise, and they faded after about 5 min.

Thus, SCMI represents a convenient way for studying the versatile ESG activity. The method is sensitive enough for detecting early signs of ESG activity under various stimulations. The influence of autonomic neuropathies on ESG, including the diabetic type (Xhaufflaire-Uhoda et al. 2011; Noël et al. 2012), is possibly measured using the SCMI method. It must be stressed that some hyperkeratotic disorders interfere with sweat excretion. Tinea (pityriasis) versicolor and psoriasis represent such conditions where the sweat output is largely curbed (Uhoda et al. 2005; Xhaufflaire-Uhoda et al. 2006).

2 Biometrology of Apocrine Sweat Excretion

Human ASG is confined to the regions of armpits, perineum, umbilicus, and breast areolae. They become functional at puberty. Some ASG functions include an odoriferous role, a sexual attractant, a territorial marker, and warning signals. The ASG production of pheromones is established in many species.

2.1 Apocrine Sweat Cannulation

Apocrine sweat present inside the collecting intradermal apo-pilosebaceous duct is possibly

squeezed out in part at the skin surface by contracting smooth muscle cells with adrenaline 1:2,000 in physiologic saline. Such a procedure is painful. It is possibly performed after collecting apocrine sweat by capillary tubes from the apo-pilosebaceous duct. Approximately 1 μ l of milky apocrine fluid is obtained from each ASG pore. However, only a limited number of apo-pilosebaceous ducts within the visibly adrenaline-blanching area actually release sweat.

2.2 Axillary Malodor Assessment

Studying axillary malodor requires controls of local shaving, previous applications of cleansing agents, deodorants, perfumes, and frequency of their respective applications in the armpits (Piérard 2003). In a common procedure, cotton gauze pads thoroughly cleaned and autoclaved are held in place in the target armpit for 6–9 h. Chromatographic analytic analysis allows detection of various chemicals responsible for malodor. However, there are limitations because of the complex nature and variable individual composition of axillary malodor chemistry. In addition, the analysis does not yield a quantitative malodor assessment.

In vitro microbiological evaluations demonstrate the efficacy of any compound curbing the microorganism growth involved in malodor. Thus, these techniques represent an indirect assessment of the potential deodorant activity. The in vivo microbiological evaluation relies on the microflora collection from the SC. Counting colonies after culture or performing a viability test under flow cytometry is possible. The most difficult aspect of the quantitative methods resides in the rigorous controlled collection of the bacterial bioscene from the skin surface.

1 Introduction

Since the seminal work of Pharo Gagge at the John B. Pierce Foundation Laboratory (Gagge 1937), the measurement of skin wetness as a physical variable has received great attention, particularly for its role in the estimation of the body's heat balance under conditions of increased metabolic heat production (e.g., resulting from exercising muscles) and decreased gradient for heat loss to the environment (e.g., resulting from high ambient temperatures) (Nadel and Stolwijk 1973; Candas et al. 1979; Havenith 2001; Havenith et al. 2013). However, although much is known on the biophysical role of skin wetness in contributing to thermal homeostasis, surprisingly little has been done to elucidate how humans sense wetness on their skin and how the level of *physical* skin wetness relates to the level of *perceived* skin wetness.

Expanding the knowledge on how humans perceive skin wetness has both a fundamental and an applied significance. On the fundamental side, this could contribute to a better understanding of how the peripheral and central nervous systems interact to generate complex

somatic perceptions (Craig 2003). On the applied side, this could be useful for its potential clinical as well as industrial implications. Within the clinical context, this knowledge could contribute to the development of diagnostic tests for patients with somatosensory disorders (e.g., multiple sclerosis and diabetic neuropathy) (Gin et al. 2011) as well as skin conditions (Mayrovitz and Sims 2001). Within the industrial context, this knowledge could contribute to the development of new strategies in clothing design aiming to improve thermal comfort as well as to the design and optimization sanitary products for personal and patient care. Indeed, local skin wetness has been repeatedly shown to play a critical role in the onset of thermal and clothing discomfort (Fukazawa and Havenith 2009) as well as to be a risk factor for pressure ulcers when individuals are bed rested and wear sanitary products (e.g., diapers) (Mayrovitz and Sims 2001).

This chapter will present the state of the current knowledge about the neurophysiological and psychophysical bases of humans' ability to perceive skin wetness, along with an overview of the most recent methods used to assess this sensory feature of the human skin.

1.1 Skin Wetness as a Physical Variable

As a physical variable, skin wetness was first introduced by Gagge (1937) who recognized its critical role in the heat balance of the body. Whether due to increases in metabolic heat production (e.g., as a result of exercise) or exposure to hot environments, body core overheating is prevented, and heat balance maintained, by means of sweating (Candas et al. 1979). Evaporative heat loss through sweating plays a critical role in cooling the skin, thus maintaining a favorable core to skin gradient for heat losses from the body to the environment (Kondo et al. 1997). Therefore, within environmental conditions that allow full evaporation, the level of physical skin wetness

represents an important parameter to ensure the evaporative efficiency of sweating (Candas et al. 1979). As such, skin wetness is defined as the fraction of the body covered by liquid at skin temperature (e.g., sweat), and it represents a physical measure of the degree of wetness involved in the process of evaporation (Gagge 1937). Skin wetness is usually expressed as a decimal fraction, with 1 representing the upper limit for a fully wet skin and 0.06 representing the minimal value due to insensible perspiration through the skin (Nishi and Gagge 1977).

Since Gagge's seminal work, the measurement of skin wetness as a physical variable has received great attention, particularly in the context of predicting the body's heat balance during conditions of increased metabolic heat production and decreased gradient for heat loss to the environment (Nadel and Stolwijk 1973; Candas et al. 1979; Havenith 2001; Havenith et al. 2013). However, although much is known on the biophysical role of skin wetness in contributing to thermal homeostasis, surprisingly little has been done to elucidate how humans sense wetness on their skin and how the level of *physical* skin wetness relates to the level of *perceived* skin wetness.

1.2 Skin Wetness as a Perceptual Variable

In contrast with insects, in which humidity receptors subserving *hygro-sensation* have been identified and widely described (Tichy and Kallina 2010), humans' largest sensory organ, i.e., the skin, seems not to be provided with specific receptors for the sensation of wetness (Clark and Edholm 1985). Thus, as human beings, we seem to *learn* to perceive the wetness experienced when the skin is in contact with a wet surface or when sweat is produced (Bergmann Tiest et al. 2012a) through a complex multisensory integration (Driver and Spence 2000) of thermal (i.e., heat transfer) and tactile (i.e., mechanical pressure and skin friction) inputs generated by the interaction

between skin, moisture, and (if donned) clothing (Fukazawa and Havenith 2009). However, until very recently, what was still unclear was the individual role of thermal and tactile cues and how these are integrated peripherally as well as centrally by our nervous system when experiencing the perception of skin wetness.

Investigating the neurophysiological and psychophysical bases of human skin wetness perception has represented a challenge which has attracted the interest of many scientists since the early days of the twentieth century. To our knowledge, the first scientist who has attempted to explain the sensory basis of this skin perception was Bentley, who in 1900, with his famous “synthetic experiment,” tested the perception of dipping a sheath-covered finger into a liquid; the results showed that the participants at first refused to believe that the finger was not actually wet (Bentley 1900). Based on these early observations, Bentley proposed a sensory-blending hypothesis which suggests the blend of pressure and coldness as responsible for evoking the perception of wetness.

Following this early work on the psychophysical bases of skin wetness perception, a number of studies have investigated the perception of skin wetness. By investigating the perceptual responses to either skin’s contact with external wet and dry stimuli (Sweeney and Branson 1990a, b; Li 2005; Daanen 2009; Niedermann and Rossi 2012; Bergmann Tiest et al. 2012a, b; Ackerley et al. 2012; Filingeri et al. 2013, 2014a, b, c, 2015) or to the active production of sweat (Fukazawa and Havenith 2009; Lee et al. 2011; Gerrett et al. 2013), these studies have provided insights about the potential mechanisms for which skin wetness is sensed in humans.

The majority of these studies have endorsed the use of quantitative sensory testing as the preferred methodology to measure human skin wetness perception. Therefore, before reviewing the main findings of the abovementioned studies and before providing practical examples of how QST is performed in the context of measuring skin wetness perception, an overview of the characteristics of these tests will be provided.

2 Quantitative Sensory Testing

Quantitative sensory testing (QST) represents a noninvasive sensory examination of somatosensory modalities such as light touch, vibration, thermal, and pain sensation (Chong and Cros 2004). The basic psychophysical paradigm on which this test is based is that of *stimulus-response*: by exposing the participant to a stimulus with prespecified physical properties (e.g., temperature), the resulting sensory response (i.e., the presence/absence of any perception of the stimulus; estimation of the intensity of the stimulus) is measured in order to investigate the target somatosensory function (e.g., thermal sensitivity) (Walk et al. 2009).

QST can be divided into threshold detection tests and stimulus intensity ratings. Threshold detection tests use a graded series of stimuli of increasing and decreasing intensities in order to determine the sensory threshold at which the participant detects or no longer detects a particular somatosensory stimulus. Stimulus intensity tests use a fixed standard stimulus of known properties in order to determine the participant’s ability to provide a quantitative rating of the stimulus’ intensity (Chong and Cros 2004; Walk et al. 2009).

During a QST, and in response to the stimuli, participants are usually instructed to either report the presence or absence of a particular sensation with a *Yes-No* method (Chong and Cros 2004) or to report the intensity of the perceived stimulus on psychometric scales.

2.1 Psychometric Scales

Two main types of psychometric scales are commonly used when QST is administered with a stimulus intensity paradigm: Likert scales and visual analogue scales.

Likert scales (or categorical scales) are psychometric scales which are characterized by 4–11 points with designated verbal descriptors and anchor points at the extremes of the scale which define the range of sensations/perceptions

specifically tested within the construct of the scale (Likert 1932). Visual analogue scales are psychometric scales which are characterized by a straight line whose extreme points represent the anchor points for the sensation/perception specifically tested (Scott and Huskisson 1976).

With regard to the specificity of each type of scale, and how appropriate their use is according to the experimental conditions designed, it is generally accepted that Likert scales are preferable for the benefits that the presence of verbal descriptors provides in helping individuals to describe their sensations. This is particularly true when external noise or other distracters can influence the subjective ability to define one's own sensations (Lee et al. 2010). With regard to visual analogue scales, these are generally considered as preferable when a higher sensitivity in the measurement of a particular sensation is needed. Also, by not restricting individuals' ability to rate their sensation based on specific verbal descriptors, these scales are thought to provide individuals with a greater flexibility and thus accuracy in their sensation discrimination (Lee et al. 2010).

With regard to the use of QST in the investigation of skin wetness perception, this method has been widely used in the context of testing skin wetness perception as a result of the contact with an external wet or a dry stimulus. In light of this, the following paragraphs present an overview of the most representative studies which have endorsed the use of QST when investigating skin wetness perception.

3 Assessing Skin Wetness Perception: Overview of the Literature

Most of the literature on skin wetness perception has focused on investigating the minimum amounts of wetness that individuals are able to discriminate between (i.e., *discrimination of skin wetness*) and whether individuals are able to characterize the level of skin wetness they experience during the skin's contact with external (wet or dry) stimuli (i.e., *magnitude estimation of skin wetness*).

3.1 Discrimination Studies

During a discrimination experiment, Sweeney and Branson (1990b) showed that, when cotton test fabrics (25 cm²) with different water content were applied to the upper back of 13 blindfolded female participants, these discriminated between moisture content with a discrimination threshold of 1.6 $\mu\text{l}\cdot\text{cm}^{-2}$ against a reference stimulus of 3.6 $\mu\text{l}\cdot\text{cm}^{-2}$ (Sweeney and Branson 1990b).

In line with this approach, Jeon et al. (2011) applied four 100 cm² specimens of different types of fabric (i.e., cotton, regular polyester, and two types of the so-called high-performance polyester) with a range of moisture contents (1–21 $\mu\text{l}\cdot\text{cm}^{-2}$) to the right and left inner forearm of ten blindfolded female participants (duration: 5 s). Test fabrics were applied simultaneously to two reference fabrics (with amounts of water of 5 and 15 $\mu\text{l}\cdot\text{cm}^{-2}$) and participants judged which stimulus caused greater wetness perception. This study found average discrimination thresholds which differed between the different materials (higher for, e.g., high-performance polyester) in the range of 1.9–2.6 $\mu\text{l}\cdot\text{cm}^{-2}$ against the 5 $\mu\text{l}\cdot\text{cm}^{-2}$ reference stimulus and from 3.6 to 5.4 ml against the 15 $\text{ml}\cdot\text{cm}^{-2}$ reference stimulus.

Similarly, in a study in which six males and six females (blindfolded) interacted with three different types of wet materials (i.e., 19.6 cm² thin and thick viscose and cotton wool), in two ways of exploring (i.e., the samples were either touched statically, flat on the table, in which case only thermal cues were available, or they were touched dynamically, picked up, and manipulated, in which case both thermal and mechanical cues were available), Bergmann Tiest et al. (2012a) found that discrimination thresholds ranged from ~ 25 to ~ 400 $\mu\text{l}\cdot\text{cm}^{-2}$ according to the type of contact with the stimuli (static vs. dynamic).

Overall, the abovementioned studies provided evidence in support of the individual ability to readily discriminate between higher and lower wetness levels. However, although endorsing the use of QST, by approaching the assessment of skin wetness perception with a *discrimination paradigm* (i.e., a forced choice between two options), these studies have provided limited

evidence on the potential sensory mechanisms involved in the subjects' ability to sense and discriminate skin wetness. In this respect, the studies which have approached the assessment of skin wetness with a *magnitude estimation paradigm* have provided more detailed insights on the potential sensory inputs underlying the human's ability to sense wetness on the skin, thus indicating this approach (i.e., QST with a magnitude estimation paradigm) as a potentially more effective method to assess skin wetness perception.

3.2 Magnitude Estimation Studies

The experimental studies that have investigated what sensory inputs contribute to skin wetness perception as a result of the contact with an external wet or dry stimulus have indicated that the thermal sense (and specifically cold sensations) could be the key player in driving the perception of wetness (Daanen 2009; Bergmann Tiest et al. 2012b; Ackerley et al. 2012). In support of this hypothesis, it has been proposed that, as we *learn* to perceive skin wetness, we tend to associate the cold sensations evoked by the drop in skin temperature occurring during the evaporation of moisture from the skin as a signal of the presence of moisture, and thus wetness, on the skin surface (Daanen 2009). Therefore, cold stimuli able to reproduce such skin cooling rates are suggested to suffice in evoking the perception of wetness (Bergmann Tiest et al. 2012b). In this respect, Daanen (2009) measured the temperature course of the skin (i.e., temperature's drop of 1–5 °C with a 0.05–0.2 °C·s⁻¹ cooling rate) when this was wetted with drops of water with volumes in a range of 10–100 µl. The author suggested that the cold sensations experienced when such skin cooling occurs can contribute to the perception of skin wetness. Therefore, exposing the skin to a cold-dry stimulus producing such skin cooling was hypothesized and tested effective in evoking an illusory perception of skin wetness (Daanen 2009).

The critical role of cold sensations in inducing the perception of wetness had been previously observed by Yamakawa and Isaji (1987) during a

magnitude estimation experiment performed with six different textiles in three wetness conditions and at three different temperatures (Yamakawa and Setsuku 1987). In this study the authors found that subjects' ratings in terms of perceived wetness correlated to the initial cooling rates occurring during the contact between the subjects' fingers and the test fabrics: a greater initial temperature drop was linked to a greater perception of wetness. In line with this, the role of coldness in sensing skin wetness has been further confirmed by Bergmann Tiest et al. (2012b), who showed that, when manipulating dry phase-change materials which induced cool sensations, participants perceived these as being wetter than non-treated dry fabrics.

Finally, Ackerley et al. (2012) have recently shown that nine blindfolded females readily discriminated between very small amounts of moisture (in the range of 1.6 µl·cm⁻²) applied with a tactile stimulator over different regions of the body. Although in the mentioned study no recordings of local skin temperature and thermal sensations were performed, the authors hypothesized that participants distinguished the greater from the smaller levels of moisture due to the resulting greater evaporative cooling which induced colder thermal sensations and thus wetter perceptions.

With regard to the potential contribution of other sensory modalities (than thermal) to the perception of skin wetness, Bergmann Tiest et al. (2012a) have recently provided evidence for the role of tactile inputs in the haptic perception of wetness. In their study, the authors observed that, during the interaction with wet materials (i.e., 19.6 cm² thin and thick viscose and cotton wool), wetness discrimination thresholds decreased significantly when individuals were allowed dynamic as opposed to the static touching. This indicated that individuals' skin wetness perception was increased by a higher availability of tactile information, as occurring during the dynamic exploration (as opposed to the static contact) of the wet materials. The authors concluded that, when thermal cues (e.g., thermal conductance of a wet material) provide insufficient sensory inputs, individuals seem to

use mechanical cues (e.g., stickiness resulting from the adhesion of a wet material to the skin) to aid them in the perception of wetness.

Overall, these magnitude estimation studies have provided more detailed insights on the sensory inputs which could significantly contribute to driving the perception of skin wetness during the contact with wet stimuli (e.g., thermal cold sensations). Furthermore, these studies have demonstrated that assessing the psychophysical processes involved in the perception of skin wetness by using QST with a magnitude estimation paradigm can provide reliable quantitative data about the neurophysiological mechanisms underlying this complex somatosensory experience. However, despite these studies having provided psychophysical evidence on the role of the different sensory cues involved in the perception of skin wetness during the skin's contact with external (dry or wet) stimuli, until very recently, still little was known on how this sensory information was then centrally integrated by the nervous system. Furthermore, the absence of a specific reference sensory model for the perception of skin wetness contributed to a lack of standardized procedures in the assessment of skin wetness perception.

In this respect, our group has recently performed a systematic experimental analysis of the neurophysiological and psychophysical factors which underpin human skin wetness perception, with the aim of developing a neurophysiological model which could be used as a frame of reference in the assessment of the perception of skin wetness (Filingeri et al. 2013, 2014a, b, c, 2015). In order to achieve this aim, we developed a structured and systematic methodology for the assessment of skin wetness perception. In light of this, and due to the practical implications that this systematic methodology might have in the context of standardizing the assessment of human skin wetness perception, an overview of this experimental work as well as of the sensory model for skin wetness perception, along with detailed information and practical examples of the methods and setups we used in these studies, will be presented below.

4 Quantitative Sensory Testing of Skin Wetness Perception: Empirical Framework

The aim of the experimental work performed by our group was to investigate the neurophysiological and psychophysical bases of humans' ability to perceive wetness on the skin (Filingeri et al. 2013, 2014a, b, c, 2015). The contact with an external wet or dry stimulus was considered as the scenario in which the perception of skin wetness can be experienced and assessed. Specifically, it was aimed to elucidate, from a mechanistic standpoint, the individual contribution as well as the interaction between the sensory cues which seem to drive the perception of skin wetness (i.e., cutaneous thermal and tactile inputs).

A QST with a magnitude estimation paradigm was used to investigate skin wetness perception as a result of the contact with an external stimulus. This approach has been previously shown to be more appropriate than a discrimination paradigm when investigating the sensory cues involved in the perception of skin wetness. A number of external stimuli, with different properties (i.e., temperature, pressure, level of wetness), were applied to different body regions (i.e., hairy and glabrous skin sites), during different activities (i.e., rest and exercise), during different environmental conditions (i.e., thermoneutral and warm), and during different sensory states (i.e., the presence/absence of a selective reduction in the activity of specific cutaneous nerve fibers). These studies provided evidence for and support to the development of a specific neurophysiological model for human skin wetness perception. As results of these studies, the following findings were obtained:

1. When the application of cold-dry stimuli on participants' hairy skin produced a drop in skin temperature ranging between 1.4 and 4.1 °C with a cooling rate of 0.14–0.41 °C·s⁻¹ (a similar cooling rate as the one induced by the evaporation of water from the skin), an illusion of skin wetness perception was evoked; when cold-dry stimulations produced a drop in skin temperature of 0.2–0.7 °C with a cooling rate of 0.02–0.07 °C·s⁻¹, skin wetness perception

Fig. 1 (a) Relative variations in skin temperature drop from baseline (ΔT_{sk}) and corresponding cooling rates as a result of six cold-dry stimuli with decreasing contact temperatures. (b) Wetness perception scores recorded as a result of each of the six cold-dry stimuli (phase B) and during the following bare skin phase (c) (* $p < 0.05$). Skin cooling rates corresponding to each stimulus are reported

between brackets. The point “1” of the wetness perception scale corresponds to the threshold set to identify perceived skin wetness (Reprinted from Neuroscience Letters, 551, Filingeri D, Redortier B, Hodder S, Havenith G, The role of decreasing contact temperatures and skin cooling in the perception of skin wetness, 65–69, Copyright (2013), with permission from Elsevier)

was little evoked and decreasing thermal sensations prevailed (Filingeri et al. 2013) (Fig. 1).
 2. Cold-dry stimulations inducing skin cooling rates of 0.06–0.4 °C·s⁻¹ were shown to evoke artificial skin wetness perceptions, with colder stimuli resulting in a higher frequency and magnitude of wetness perception. However, it was observed that the application of stimuli with a higher mechanical pressure on

the skin (10 vs. 7 kPa) reduced the frequency of the times artificial wetness perceptions were evoked. Also, it was found that cold-dry stimuli were perceived as being wetter during exercise performed in a warm environment than during rest in the same environment, as well as than during exercise in the thermoneutral one (Filingeri et al. 2014c) (Fig. 2).

Fig. 2 Frequency distribution of local wetness perception scores as a result of three cold-dry stimuli (i.e., 4, 8, and 15 °C below local skin temperature) applied with low and high pressure. The frequency of times the same cold-dry stimulus was perceived as “dry” or as “wet” is indicated as a fraction (%) of the total responses recorded for each stimulus. Differences are indicated as statistically ($*p <$

0.05) or as not statistically significant (i.e., ns) (Reprinted from Neuroscience, 258, Filingeri D, Redortier B, Hodder S, Havenith G, Thermal and tactile interactions in the perception of local skin wetness at rest and during exercise in thermo-neutral and warm environments, 121–130, Copyright (2014), with permission from Elsevier)

- The existence of regional differences in cutaneous thermosensitivity to cold has been shown to translate into significant regional differences in cutaneous wetness perception across the human torso. Interestingly, these regional sensory patterns were observed to be independent from the magnitude of local skin cooling caused by the stimulus. In other words, the regions in which the stimulus resulted in greater skin cooling (i.e., lateral chest) were not necessarily the ones in which the stimulus was perceived as colder, wetter, and more unpleasant (Filingeri et al. 2014a) (Fig. 3).
- Warm temperature stimuli were shown to suppress the perception of skin wetness during initial static contact with a wet surface (Filingeri et al. 2015) (Fig. 4).
- It was found that individuals perceived warm-wet and neutral-wet stimuli as significantly less wet than cold-wet ones, even when these were characterized by the same moisture content. Also, it was shown that when cutaneous cold and tactile sensitivity was diminished by a selective reduction in the activity of A-nerve afferents (subserving cold and light touch cutaneous

- sensitivity), wetness perception was significantly reduced. Finally, a trend was observed with the extent of perceived wetness being higher on the hairy than on the glabrous skin. This seems to be due to the structural (i.e., glabrous skin presents thicker stratum corneum and higher thermal insulation) and functional differences (i.e., glabrous skin presents higher density of mechanoreceptors, while hairy skin has a higher density of thermoreceptors) between hairy (more of a thermosensory organ) and glabrous skin (more of an organ for heat exchange) (Filingeri et al. 2014b) (Fig. 5).
- Based on a concept of perceptual learning and Bayesian perceptual inference, the first neurophysiological model of cutaneous wetness sensitivity centered on the multisensory integration of cold and mechanosensitive skin afferents was developed in order to explain how humans sense warm, neutral, and cold skin wetness (Filingeri et al. 2014b) (Fig. 6).

The above-listed findings were obtained during five experimental studies which were conducted to

Fig. 3 (continued)

investigate skin wetness perception as resulting from the contact with an external (dry or wet) stimulus. These outcomes provided evidence for the primary role of cold thermal cues as well as mechanical cues in the form of pressure and stickiness in driving the perception of skin wetness.

In this respect, it deserves mention that, as an alternative way of experiencing skin wetness perception, the active production of sweat (either as resulting from exposures to warm environments or from exercise) represents a condition in which this sensory experience can also be assessed. Although in this context, the possibility to implement a quantitative approach and to use QST to isolate the individual contribution of the different sensory cues (i.e., thermal and tactile) is limited by the difficulties in strictly controlling the characteristics of the stimulus used (i.e., the amount and location of sweat-induced skin wetness), in order to provide the reader with a more comprehensive picture of the theoretical framework behind the perception of skin wetness; the findings of the most representative studies which have assessed skin wetness perception as resulting from active sweating are summarized below.

4.1 Skin Wetness Perception: Sweat Production

In a study in which thermal comfort sensitivity was investigated in relation to locally manipulated

skin wetness (as resulting from exercise-induced sweat production), Fukazawa and Havenith (2009) found that the torso seems to have a lower sensitivity to wetness than the limbs. Similar findings were also reported by Gerrett et al. (2013) in a non-manipulated condition (natural sweat distribution across the torso during exercise). However, as sweat rates across the torso are much higher than on the limbs (Havenith et al. 2008; Smith and Havenith 2011, 2012), the skin wetness experienced in a non-manipulated condition is nevertheless higher for the torso (Gerrett et al. 2013). This is supported by Lee et al. (2011), who showed that individuals reported the torso (i.e., chest and back) to be the region more often perceived as wet during rest and moderate exercise in 25 °C and 32 °C ambient temperature and 50 % humidity.

Interestingly, in all these studies, skin temperature was always observed to increase significantly during the exercise protocols, suggesting that participants were able to both sense and regionally discriminate sweat-induced skin wetness, despite not experiencing any cold sensation, one of the main sensory cues which has been suggested to drive the perception of skin wetness (Filingeri et al. 2013, 2014a, b, c, 2015). It could therefore be suggested that in conditions of sweat-induced skin wetness, individuals rely more on tactile (e.g., stickiness of their clothing) than on thermal inputs (i.e., thermal cold sensations) to characterize their wetness perception. This

Fig. 3 Body maps showing the regional distribution of (a) local skin cooling (°C) caused by the application of the stimulus, (b) absolute mean votes for thermal sensation, (c) frequency of wetness perception, and (d) absolute mean votes for pleasantness sensation, as a result of the 10 s application of the relative cold-dry stimulus (15 °C lower than local T_{sk}) to each skin site, averaged over all conditions. Data were collected on the left side of the body and the body maps presented were developed assuming left-right symmetry (see Ouzzahra et al. 2012). Regions showing greater skin cooling, colder sensations, more frequent wetness perceptions, and more unpleasant sensations are represented in darker colors. Part of the rating scales used by the participants to score their absolute thermal and pleasantness sensations is reported next to the respective body maps. Two main tendencies are shown. First, the

regional differences in thermal, wetness, and pleasantness sensation present a similar pattern across the torso (e.g., as opposed to the chest, the lateral and lower back appears more sensitive to cold, wetness, and thermal displeasure). Second, these sensory patterns seem independent from the regional variations in skin cooling (i.e., regions which show greater skin cooling, such as the lateral chest, are not necessarily the ones in which the stimulus was perceived as colder, more often wet, or more unpleasant) (Reprinted from Journal of Applied Physiology, doi: 10.1152/jappphysiol.00535.2014, Filingeri D, Fournet D, Hodder S, Havenith G, Body mapping of cutaneous wetness perception across the human torso during thermo-neutral and warm environmental exposures, Copyright (2014))

Fig. 4 Wetness perception scores recorded before (pre-stimulation) and during (stimulation) the application of the warm-dry and warm-wet stimuli. Average changes in vote (Δ Votes) from pre- to poststimulation are also reported (Filingeri et al. 2015) (Reprinted from Skin Research and Technology, doi: 10.1111/srt.12148, Filingeri D, Redortier B, Hodder S, Havenith G, Warm temperature stimulus suppresses the perception of skin wetness during initial contact with a wet surface, Copyright (2014), with permission from John Wiley and Sons)

hypothesis could be supported by the fact that a swelling state of the skin (due to sweat production) has been previously suggested as to potentially affect the regional perception of skin wetness by increasing the skin's sensitivity to tactile stimulation (Gerrett et al. 2013).

The possibility that, in conditions of sweat-induced skin wetness, individuals rely more on tactile than on thermal inputs to characterize their wetness perception could be also in line with what previously shown for the skin's contact with an external stimulus (i.e., manual exploration of a wet material) by Bergmann Tiest et al. (2012a),

who reported that, when thermal cues (e.g., thermal conductance of a wet material) provide insufficient sensory inputs, individuals seem to use mechanical cues (e.g., stickiness resulting from the adhesion of a wet material to the skin) to aid them in the perception of wetness (Bergmann Tiest et al. 2012a). However, as in the abovementioned studies (Fukazawa and Havenith 2009; Lee et al. 2011; Gerrett et al. 2013), the mechanical interaction at the skin was neither manipulated nor controlled; these studies did not provide conclusive evidence on the potential link between the thermal and tactile changes occurring

Fig. 5 (continued)

locally at the skin's surface when this was wet due to sweating and the resulting sensory inputs used by the participants to characterize their perception of skin wetness.

In this respect, the studies performed by our group (Filingeri et al. 2013, 2014a, b, c, 2015), which focused on assessing skin wetness perception during the contact with an external dry and/or wet stimulus, were conducted with the aim of isolating the individual contribution of thermal and tactile cues to the perception of wetness, so that a sensory model for wetness could be developed and thus used as a frame of reference also in those studies in which skin wetness is induced by the active production of sweat. In doing so, we developed a structured and systematic methodology for the assessment of skin wetness perception. The following paragraph summarizes the methodology developed (including all the relevant equipment used) and provides a practical outline of a typical experimental protocol as used in the assessment of skin wetness perception.

5 Quantitative Sensory Testing of Skin Wetness Perception: Practical Framework

When investigating the perception of skin wetness, one of the aims of the sensory testing is to isolate the individual contribution of cutaneous thermal and tactile cues to the perception of wetness so that the participant's somatosensory ability to perceive skin wetness can be assessed.

In this respect, as other sensory modalities than thermal and tactile (e.g., vision) can represent a potential confounding factor in the assessment of skin wetness perception, specific setups are needed. For example, as in the abovementioned studies, we wanted to limit the contribution of vision to the perceptual experience of skin wetness (thus focusing on the somatosensory components of this perception); we therefore did not provide participants with any specific information about the type of stimuli we used. Furthermore, during the assessment of skin wetness perception, participants were blind to the site of stimulation. This approach was considered necessary to reduce the contribution of any expectation effect as well as of any confounding factor in the assessment of skin wetness perception. Hence, specific setups were designed. An overview of their characteristics is presented below.

5.1 Experimental Setup

For the first study investigating skin wetness during the contact with an external stimulus, the forearm was chosen as preferred site for stimulation (Filingeri et al. 2013). In this respect, participants were informed only about the body region subjected to the stimulation. No information was provided on the type and magnitude of the stimulation to limit any expectation effects.

To blind the participants to the site of stimulation, an S-shaped wooden panel (width, 81 cm; length, 74 cm; height, 60 cm) was placed on a

Fig. 5 Forearm and finger pad skin temperature ($^{\circ}\text{C}$) and corresponding ratings for thermal sensation and wetness perception (arbitrary units, a.u.) during the static (STAT), dynamic (DYN), and evaporation (EVAP) phases of contact with the warm-wet (35°C), neutral-wet (30°C), and cold-wet (25°C) stimuli. Panels **a** and **b**, panels **e** and **g**, and panels **i** and **k** show skin temperature, thermal sensation, and wetness perception data, respectively, as recorded during the NO-BLOCK trial for the forearm and finger pad. Panels **b** and **d**, panels **f** and **h**, and panels **j** and **l** show skin temperature, thermal sensation, and wetness perception data, respectively, as recorded during the BLOCK trial for the forearm and finger pad. Two tendencies are illustrated. In the NO-BLOCK trials, thermal sensations matched the variation in skin temperature, and wetness

perceptions increased with decreasing contact temperatures (static phase) and from static to dynamic to post contact (evaporation). In the BLOCK trials, cold sensitivity was reduced in the forearm, and both warmth and cold sensitivity were reduced on the finger pad. This resulted in a significant decrease in wetness perceptions during all temperature stimulations (and particularly during the cold one) and during all phases of interaction. Data are reported as mean (group average $n = 13$) and SD (vertical lines) (Reprinted from Journal of Neurophysiology, doi: 10.1152/jn.00120.2014, Filingeri D, Fournet D, Hodder S, Havenith G, Why wet feels wet? A neurophysiological model of human cutaneous wetness sensitivity, Copyright (2014))

Fig. 6 Neurophysiological model of cutaneous wetness sensitivity. Mechano Aβ, cold Aδ, and warm C-sensitive nerve fibers and their projections from the skin, through the peripheral nerve, spinal cord (via the dorsal column-medial lemniscal pathway and the spinothalamic tract), thalamus, and somatosensory cerebral cortex (including the primary and secondary somatosensory cortices SI and SII, the insular cortex, and the posterior parietal lobe), are shown. Panels **a** and **b** show the neural model of wetness sensitivity (consisting of Aδ and Aβ afferents) under normal and

under selective reduction in the activity of A-nerve fibers, respectively. Panels **c**, **e**, and **g** show the pathways for wetness sensitivity during static contact with warm, neutral, and cold moisture. Panels **d**, **f**, and **h** show the pathways for wetness sensitivity during dynamic contact with moisture (Reprinted from Journal of Neurophysiology, doi: 10.1152/jn.00120.2014, Filingeri D, Fournet D, Hodder S, Havenith G, Why wet feels wet? A neurophysiological model of human cutaneous wetness sensitivity, Copyright (2014))

table. A hole (width, 12 cm; height, 13 cm) in the panel allowed participants to enter their left forearm and lay it down with the palm facing upward. This setup did not allow the participants to see the stimuli that were applied on their forearm (Fig. 7).

For the second and third studies investigating skin wetness during the contact with an external stimulus, the upper and lower back were chosen as preferred sites for stimulation, as participants were tested either resting or exercising (cycling) (Filingeri et al. 2014c, 2015). In this respect,

Fig. 7 The S-shaped wooden panel used to blind the participants to the site of stimulation

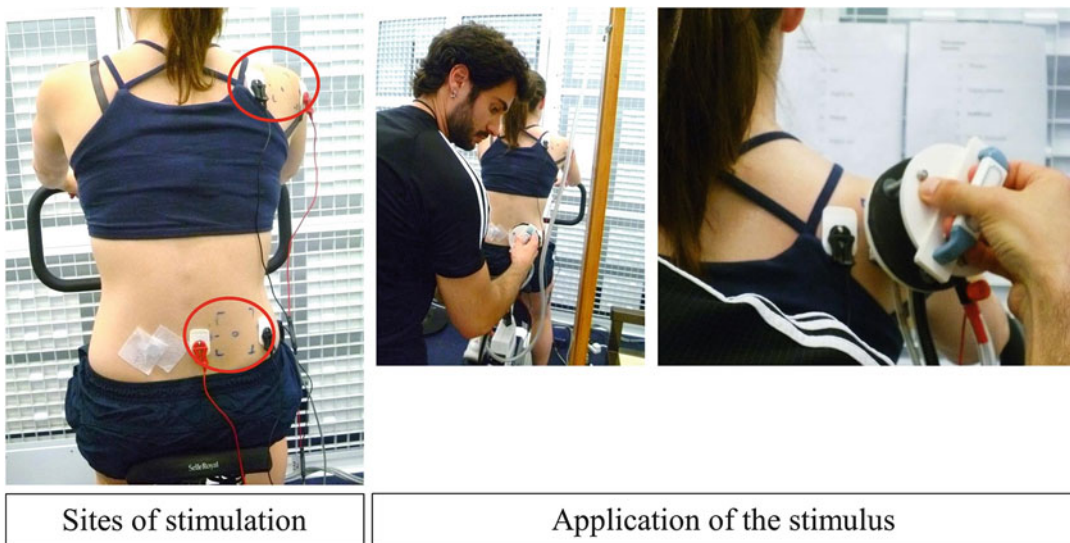

Fig. 8 The experimental setup adopted by Filingeri et al. (2014c, 2015)

participants were informed only about the body region subjected to the stimulation. No information was provided on the type and magnitude of the stimulation to limit any expectation effects. Being this their back, participants were naturally blind to the site of stimulation (Fig. 8).

For the fourth study investigating skin wetness during the contact with an external stimulus, as the

regional sensitivity to skin wetness perception was investigated, 12 regions of the front and back of the torso were chosen as preferred sites for stimulation (Fig. 9) (Filingeri et al. 2014a). In this respect, participants were informed only about the body region subjected to the stimulation. No information was provided on the type and magnitude of the stimulation to limit any expectation effects.

Fig. 9 The 12 skin sites of the front and back of the torso chosen for stimulation

Fig. 10 The experimental setup adopted by Filingeri et al. (2014a)

To blind the participants to the sites of stimulation, the following setup was designed (Fig. 10). When the front torso was stimulated, participants were asked to lie on a bench on their back, with their arms alongside the body and a rectangular-shaped textile screen (length, 81 cm; height, 67 cm) was placed above the participants' neck. The screen was adjusted until each participant confirmed that they could not see either their front torso or the investigator. When the back torso was stimulated, participants were asked to lie on their front, with their arms alongside the body, and to face toward the left, while the investigator was standing on their right-hand side (Filingeri et al. 2014a).

For the fifth and last study investigating skin wetness during the contact with an external stimulus, the forearm and index finger pad were chosen as preferred sites for stimulation (Fig. 11) (Filingeri et al. 2014b). In this respect, participants were informed only about the body region subjected to the stimulation. No information was provided on the type and magnitude of the stimulation to limit any expectation effects.

To blind the participants to the site of stimulation, an S-shaped wooden panel (width, 81 cm; length, 74 cm; height, 60 cm) was placed on a table. A hole (width, 12 cm; height, 13 cm) in the panel allowed participants to enter their left forearm so that they could interact with the stimuli.

Fig. 11 The two skin sites chosen for stimulation

This setup did not allow the participants to see the stimuli that were applied on their forearm. Furthermore, as in this study a compression ischemia protocol was used to selectively reduce cutaneous cold and tactile sensitivity; during the experimental tests in which this protocol was performed, a blood pressure cuff was applied on the participants' forearm (Fig. 12).

In summary, the experimental setups presented above provide practical examples on how to meet the conditions required for the assessment of skin wetness perception across different regions of the body as well as during different experimental conditions.

Meeting these experimental conditions with the appropriate setup is just one of the steps which are required when performing a QST of the perception of skin wetness. Indeed, the choice of the appropriate stimulator for delivering the specific stimuli required, as well as the choice of the appropriate physiological and psychometric measurements, and finally the design of an appropriate experimental protocol all represent factors which are essential to effectively assess this perception. An overview of these factors is presented below.

5.2 Stimulator

With regard to the type stimulator to be used to assess the perception of skin wetness, this has to satisfy specific criteria which are essential to effectively investigate the thermal and tactile components involved in the perception of skin wetness. The stimulator has to be:

- Controllable in terms of its temperature, in terms of the mechanical pressure this can generate on the skin, and in terms of its wetness level
- Relatively small and easily applicable to different parts of the body, during different conditions (e.g., rest and exercise)

In our studies, these criteria were found to be satisfied by the Physitemp thermal probe (Physitemp Instruments, Inc., USA). This thermal stimulator presents a thermal probe with a contact metallic surface of 25 cm² and a weight of 269 g (Fig. 13a). The thermal probe is driven by a thermoelectric (Peltier effect) module. The system is composed of a controller (readout unit) to which the thermal probe is connected. For stable operation, the thermoelectric module requires a trickle of cooling water. This is supplied by a pump and tank unit connected to the controller (Fig. 13b).

The thermal probe we used had a base adjustable temperature range of 20–30 °C. According to the base temperature, a temperature control range of ± 20.5 °C is allowed. The thermal probe has a response time of <4 s in heating and cooling.

As it stood, the thermal probe assured that some of the requirements needed (i.e., having a controllable temperature as well as being relatively small and easily applicable to different parts of the body) were met. However, specific modifications were needed to assure that the same stimulator could allow the application of stimuli with different levels of wetness, as well as to control the mechanical pressure applied to the skin.

Fig. 12 The S-shaped wooden panel used to blind the participants to the site of stimulation

With regard to the first requirement, to make the contact with the probe's surface either dry or wet, test fabrics (100 % cotton) with a surface of 100 cm² were placed on the thermal probe and

fixed by an elastic band (Fig. 14). According to the test, these were wetted with water at ambient temperature (~23 °C), using a variable volume pipettor (SciQuip Ltd., Newtown, UK).

Fig. 13 The thermal probe used for the application of the external stimuli. Panel **a** shows the control unit with the three dials allowing control of the probe's temperature (step changes of ± 5 °C, ± 1 °C, or ± 0.1 °C) and the thermal probe with the contact metallic surface of 25 cm² (in the *red circle*). Panel **b** shows a schematic diagram of how the control unit was connected to the pump and tank unit

Fig. 14 The test fabrics used to make the probe's contact surface either dry or wet

To ensure that the wet fabric would reach the required probe's temperature, the contact temperature between the probe and the test fabric was monitored with a thin thermocouple (0.08 mm wire diameter, 40 gauge; 5SRTC-TT-TI-40-2M, Omega, Manchester, UK) placed on the thermal probe's surface. Probe-fabric temperature was then monitored online using a Grant Squirrel SQ2010 data logger (Grant Instruments Ltd., Cambridge, UK).

With regard to the second requirement, to manipulate and control the mechanical pressures applied by the thermal probe, we designed and developed a pressure control system (Fig. 15). The system consisted of an air bladder, inserted into a frame attached to the thermal probe, which was connected to a manometer (containing water) throughout a silicon tube. The frame consisted of

two wooden disks laid one upon the other and coupled by three springs which allowed the top disk to scroll down freely. A handle was attached to the top disk so that the probe could be applied to the skin. When this happened, the air bladder deformed, producing a pressure change in the system which resulted in displacing the water in the manometer from its set "null" point (no pressure applied). The point reached by the water in the tube as a result of the pressure change was used as an indicator to control the mechanical pressure. To calibrate and standardize this last one, a digital scale (Mettler Toledo, Inc., USA) was used to measure the force resulting from the application of the probe.

The range between the lowest and the highest pressure applicable and measurable by the system resulted in 7–55 kPa. Tests were performed during

Fig. 15 The pressure control system developed to manipulate and control the mechanical pressures applied by the thermal probe. The system consists of an air bladder, inserted into a frame and attached to the thermal probe. The air bladder is connected to a manometer (containing water) throughout a silicon tube (a). When no pressure is applied to the system, the water in the manometer sets to its “null” point (b). When pressure is applied, the air bladder deforms, producing a pressure change in the system which displaces the water in the manometer from its set “null”

point (c). The point reached by the water in the tube, as a result of the pressure change, is used as an indicator to control the mechanical pressure applied to the skin (Reprinted from Neuroscience, 258, Filingeri D, Redortier B, Hodder S, Havenith G, Thermal and tactile interactions in the perception of local skin wetness at rest and during exercise in thermo-neutral and warm environments, 121–130, Copyright (2014), with permission from Elsevier)

the development of the prototype to check the accuracy and repeatability of the nominal pressures applied with the pressure control system. One hundred trials were conducted. These consisted of measuring the force resulting from the application of the probe on a digital scale (Mettler Toledo, Inc., USA) while controlling that the water displacement on the manometer was the one required for the pressures selected. Ninety-five percent confidence interval values were calculated for the two reference pressures (i.e., 7 and 10 kPa) and resulted as follows: 7 kPa = 7.1 kPa (lower bound), 7.2 kPa (upper bound); 10 kPa = 10.4 kPa (lower bound), 10.6 kPa (upper bound).

It deserves mention that, although the stimulator described above was found to satisfy the criteria required for the assessment of skin wetness perception, alternative options to this device

are available and have previously found to be effective in delivering controlled local dry and/or wet stimuli to the skin. An example of such devices is represented by the automated rotary tactile stimulator (Dancer Design, Wirral, UK) used by Ackerley et al. (2012) in their investigation of skin wetness sensitivity across different body sites.

The rotary tactile stimulator has four radial arms with a smooth, slightly rounded plastic surface at each end (length, 6 cm; width, 3 cm), on which test fabrics can be applied, e.g., by means of pieces of VELCRO®. The authors used this automated rotary tactile stimulator to deliver controlled moving stimuli at a predetermined force, direction, and speed to the skin sites, using custom-written scripts in LabVIEW (National Instruments, Austin, USA).

5.3 Measurement of Skin Temperature

In order to overcome previous limitations observed in the literature (i.e., the absence of specific physiological measurements of local changes at the skin during application of the external stimuli), for the assessment of skin wetness perception as performed in our recent studies, it was decided to monitor: (1) the local changes in skin temperature when the skin was stimulated with the probe and (2) the whole-body changes in mean skin temperature when participants were exposed to different environmental and exercising conditions.

Local skin temperature before or after the contact with the stimuli was measured by using a single-spot infrared thermometer (Fluke

566, Fluke Corporation, USA) with a temperature range of $-40\text{ }^{\circ}\text{C}$ to $800\text{ }^{\circ}\text{C}$ and an accuracy of $\pm 1\text{ }^{\circ}\text{C}$ (Fig. 16). In order to maximize the accuracy of the temperature reading, during all testing the infrared thermometer was calibrated against a matte black plate whose temperature was monitored with a thermistor (Grant Instruments, Cambridge, UK).

Local skin temperature during the contact with the stimuli was measured by using a thin thermocouple (0.08 mm wire diameter, 40 gauge; 5SRTC-TT-TI-40-2M, Omega, Manchester, UK). This was applied either on the ventral side of the forearm or index finger pad using Transpore tape (3M, Loughborough, UK), with the sensor tip touching the skin, but not covered by tape (Fig. 17). To monitor (online) and record contact temperatures, the thermocouple was plugged in

Fig. 16 The infrared thermometer used to measure local skin temperature before or after the contact with the stimuli

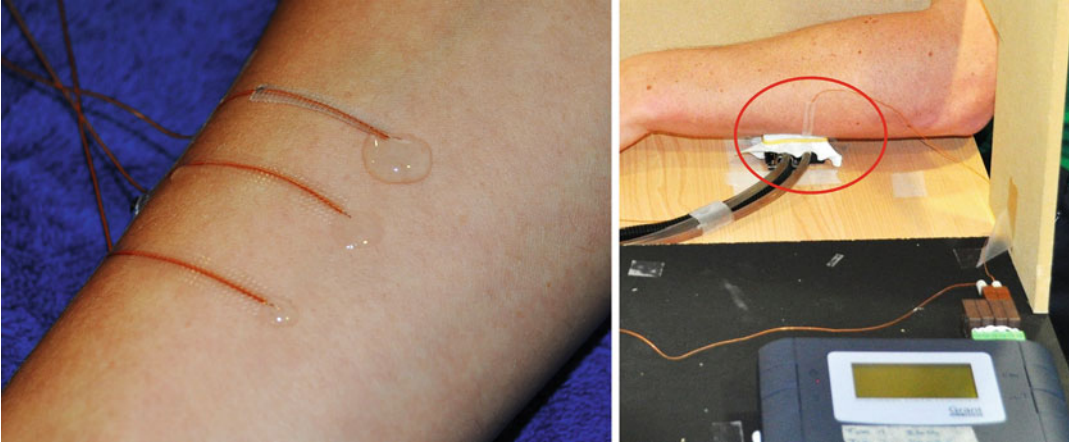

Fig. 17 The thin thermocouples used to measure local skin temperature during the contact with the stimuli

Fig. 18 The iButton (wireless temperature loggers) used to measure local skin temperature to be used for the estimation of mean skin temperature

Grant Squirrel SQ2010 data logger (Grant Instruments Ltd., Cambridge, UK).

Finally, to estimate mean skin temperature, iButton wireless temperature loggers (Maxim, San Jose, USA) with a temperature range of -55 to 100 °C, resolution of 0.5 °C, and response time of 2 s were used. These were taped to five skin sites on the left side of the body (i.e., cheek, abdomen, upper arm, lower back, and back lower thigh) to record local skin temperature (Fig. 18). Mean skin temperature (T_{sk}) was calculated according to the work of Houdas and Ring (1982) as follows:

$$\begin{aligned} \text{Mean } T_{sk} = & (\text{cheek} \times 0.07) \\ & + (\text{abdomen} \times 0.175) \\ & + (\text{upper arm} \times 0.19) \\ & + (\text{lower back} \times 0.175) \\ & + (\text{back lower thigh} \times 0.39) \end{aligned}$$

5.4 Measurement of Skin Wetness Perception

In order to measure skin wetness perception, two main types of psychometric scales were used within the experimental work we performed:

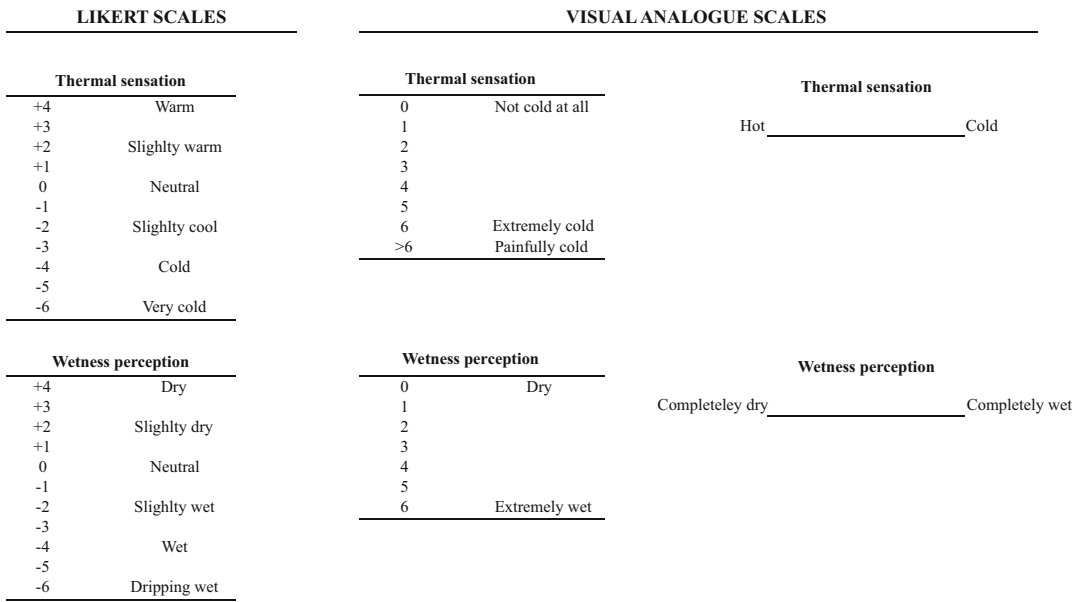

Fig. 19 Overview of the Likert scales and visual analogue scales used by Filingeri et al. (2013, 2014a, b, c, 2015) for the assessment of thermal sensation and skin wetness perception

Likert scales and visual analogue scales. These were used in conjunction with similar scales for the assessment of thermal sensation (Fig. 19).

With regard to the specificity of each type of scale, and how appropriate their use is according to the experimental conditions designed, it is generally accepted that Likert scales are preferable for the benefits that the presence of verbal descriptors provides in helping individuals to describe their sensations. This is particularly true when external noise or distracters can influence the subjective ability to define one’s own sensations (Lee et al. 2010). In line with this point, and with regard to our experimental work, Likert scales were mainly used for those conditions in which skin wetness perception was assessed while participants were exercising or when they could not mark their sensation by handwriting due to a particular experimental setup.

With regard to visual analogue scales, these are generally considered as preferable when a higher sensitivity in the measurement of a particular sensation is needed. Also, by not restricting individuals’ ability to rate their sensation based on specific verbal descriptors, these scales are

thought to provide individuals with a greater flexibility and thus accuracy in their sensation discrimination (Lee et al. 2010). In line with this point, we primarily used visual analogue scales for those conditions in which skin wetness perception was assessed and a greater accuracy in wetness discrimination was needed by the participants, due to the large number of different stimuli these were exposed to (e.g., stimuli characterized by a wide range of temperatures).

6 Protocol for the Assessment of Skin Wetness Perception

Once the necessary requirements for the assessment of skin wetness perception are met (i.e., appropriate experimental setup, stimulator, physiological and psychometric measurements) the QST can be performed. However, in order to assure an effective and reliable assessment, a standardized experimental protocol must be performed. In this respect, and based on the experimental studies we have performed (Filingeri et al. 2013, 2014a, b, c, 2015), here we present

an example of a generic protocol to be used in the assessment of skin wetness perception:

1. The participant arrives to the laboratory or testing site 30 min before the time scheduled for the test to allow preparation procedures. Anthropometric parameters (i.e., seminude body mass, height, and skinfold thickness for body composition calculation) can be recorded to help characterize the participant.
2. The participant changes into comfortable clothing appropriate for the type of assessment. For example, if the participant is required to exercise during the assessment of skin wetness perception, clothing such as t-shirt, running shorts, socks, and running shoes will be required.
3. At this point, five iButton (Maxim, USA) are taped to five left skin sites (cheek, abdomen, upper arm, lower back, and back lower thigh) to record local skin temperature. The five temperature measurements can be recorded at 1 min intervals throughout the tests; these can then be averaged every 5 min and weighted according to the work of Houdas and Ring (1982), to give an estimate of mean skin temperature for the entire body. This approach is particularly useful when the assessment of skin wetness perception is performed in relation to the exposure to different ambient conditions which could potentially change the thermal state of the body.
4. The skin sites targeted for stimulation are then marked with a washable marker to assure consistency in the location of stimulation. These can be on any site of the body (examples from our experimental work include forearm, front and back of the torso, and index fingertip).
5. After preparation, the participant enters the testing room (or environmental chamber if the test is performed in different ambient conditions), and 10 min is allowed for stabilization and acclimation to the new environment. During this period, the participants familiarize with the psychometric rating scale designed to record individual thermal sensations and wetness perceptions. Specific instructions are

provided on how to interpret and use the scale. For example, when using Likert scales (see Fig. 19), the following can be said to the participant:

During the test, I will ask you to rate your local thermal sensation and wetness perception. As soon as I apply the stimulus on your skin, try to report your local and very first sensation / perception using whatever number in the scales seems more appropriate to you

Also, when using visual analogue scales (see Fig. 19), the following instructions can be provided:

When reporting thermal sensations, I would like you to associate the anchor point “Hot” (on the left of the scale) to the idea of a burning hot pan, and the anchor point “Cold” (on the right of the scale) to the idea of an ice cube, and to mark a point on the scale which corresponds to the level of warmth or coldness you experience when the stimulus will be applied on your skin. Please consider the midpoint of the scale as a neutral point (to be marked if neither hot nor cold sensations are experienced). When reporting wetness perceptions, I would like you to associate the anchor point “Completely dry” (on the left of the scale) to the absence of any wetness. Thus, any marked point which is not on the left edge of the scale is considered to correspond to the perception of skin wetness, with the closer this is to the anchor point “Completely wet” (on the right of the scale), the greater the level of wetness you are experiencing during the application of the stimulus on your skin

6. After the stabilization and acclimation period, and according to the conditions (e.g., resting or exercising), the participant is asked to maintain a seated position or to move to an electromagnetically braked cycle ergometer (e.g., Lode Excalibur, the Netherlands) and start cycling at any required exercise intensity.
7. At this point the QST of the perception of skin wetness can be initiated. First, the participant is asked to rate thermal sensation and skin wetness perception just before the application of the stimulus in order to provide an indicator of baseline sensation for the skin site targeted for stimulation. At the same time, local skin temperature of the skin site targeted for stimulation is either measured with the infrared

thermometer or continuously monitored with a thermocouple at the contact site.

Secondly, the thermal probe is set with the required level of wetness (i.e., a fabric with known moisture content is applied on the probe as described in the *Stimulator* paragraph), set to the required temperature, and then applied by hand to the skin site with the set pressure. To avoid an effect of surprise on the transient sensations, a verbal warning is given prior to stimulation. The application of the probe can vary from a short (e.g., 10 s) to a longer contact (e.g., 30 s) according to whether an initial and transient sensation or a steady-state sensation is assessed.

During the stimulation, the probe is not moved and (according to the specific experimental setup) the participant cannot see the stimulated area.

At the end of the stimulation, the participant is instructed and encouraged to verbally report his/her local sensation and perception using whatever number in the Likert scale seems appropriate (integers only) or to mark a point on the visual analogue scale. Immediately after this, the probe is removed and, if skin temperature is measured with an infrared thermometer, the temperature of the stimulated area is recorded. This method allows perceptual rating to be made consistently close to the time when poststimulation skin temperature is recorded.

8. The above-outlined protocol can be then repeated if more than one stimulus is tested, allowing at least 1 min in between them. In case of multiple stimuli, and multiple tests, endorsing a balanced order of application will be useful in reducing to a minimum any learning and expectation effect.

As a potential alternative to the above-outlined protocol, the same procedure can be performed and skin wetness perception assessed, by having the participant actively interacting with stimuli instead of being passively exposed to it. The benefit of this approach is in the possibility of asking the participant to interact dynamically (as opposed to statically) with the stimulus, thus enabling the

assessment of the tactile component (i.e., skin friction) of skin wetness perception.

In this respect, an example of this protocol, involving the use of the same experimental setup as shown in Figs. 7 and 11 (i.e., stimulation of the forearm or index finger pad), is presented below:

1. The thermal probe is secured with surgical tape on the side of the table which is not visible to the participant, with the thermally controlled surface facing upward.
2. Prior to interacting with the stimulus, and in order to set a specific baseline skin temperature, the participant is asked to insert their arm through the hole in the panel and place the forearm or index finger pad for at least 30 s on the thermal probe.
3. The participant then removes the arm from the thermal probe, places it on the side of the table visible to him/her, and waits 1 min for the stimulus to be prepared.
4. During this time, the probe is set to the required temperature, and the test fabric is secured to the probe and then wetted with the required amount of moisture with a pipettor. An average time of 1 min is usually required for the wet test fabric to reach the selected temperature.
5. Once the stimulus preparation is completed, the interaction with the wet stimulus is initiated. If both thermal and tactile cues are assessed, this interaction can consist of two phases: static and dynamic.
6. First, the participant is instructed to insert his/her left arm through the hole in the panel and to lower it until the forearm or index finger pad is in full contact with the thermal probe. As soon as in static contact, the participant is encouraged to rate his/her local thermal and wetness perceptions, e.g., by marking a point on the thermal and wetness scales he/she is provided with on the side of the table which is visible to him/her (response time ~ 5 s).
7. Secondly, the participant is asked to move the forearm or index finger pad forward (~ 2.5 cm) and backward (~ 2.5 cm) twice while maintaining full contact with the thermal probe. At the end of this dynamic interaction, he/she is asked again to rate his/her local

thermal and wetness perceptions (response time ~ 5 s).

8. This sequence (i.e., setting the baseline skin temperature, preparing, and then interacting with the wet stimulus) can be repeated for each stimulus intended to be assessed, however assuring a balanced order in the administration, with at least 1 min in between successive applications.

Note: As no visual feedback is available during the stimulation, to assure consistency in the interaction with the stimuli (i.e., pressure applied to the probe and horizontal displacement during the dynamic phase), the investigator is supposed to gently guide the participants' arm throughout the interaction with each stimulus and to provide verbal instructions on when to change the interaction (e.g., from static to dynamic). Also, assure participants are familiarized with the experimental protocol prior to testing.

7 Conclusion and Recommendations

This chapter has presented the state of the current knowledge about the neurophysiological and psychophysical bases of humans' ability to perceive skin wetness, along with an overview of the most recent methods used to assess this sensory feature of the human skin.

The ability to perceive skin wetness represents one of the numerous somatosensory features of the skin. As humans seem not to be provided with specific humidity receptors on their skin, the ability to sense skin wetness has been shown to rely on a complex multisensory integration of thermal (i.e., heat transfer) and tactile (i.e., mechanical pressure and skin friction) inputs generated by the interaction between skin, moisture, and (if donned) clothing. Therefore, when assessing skin wetness as a perception, these parameters (i.e., cutaneous thermal and tactile sensitivity) should be measured and controlled within specific testing conditions.

Quantitative sensory testing has been shown to be a reliable method to assess the perception of skin wetness. However, this method has to be

implemented within a specific experimental setup and performed according to a standardized protocol. In this respect, this chapter has provided an empirical framework for the perception of skin wetness as well as the first available sensory model which can be used as a frame of reference in the assessment of this perception. Furthermore, and in light of the latter, a practical framework for the assessment of this perception has been provided in order to standardize the procedure and assure consistency in the evaluation of skin wetness perception.

Still little is known on the complex sensory integration underpinning skin wetness perception as a somatosensory feature of the skin. However, due to the fundamental as well as practical implications that the ability to sense skin wetness has on everyday life, the possibility to develop and standardize specific testing procedures (as proposed in this chapter) is critical, not only to further the understanding of this sensory experience but also to design specific diagnostic tests which can be confidently and widely used within industrial as well as clinical contexts.

Hyperhidrosis (HH) • Gravimetry • Objective evaluation

1 Background

Though hyperhidrosis is generally considered a subjectively perceived disease, it seems more and more doubtful that merely subjective evaluation is sufficient to qualify the patient to surgery (Haider and Solish 2005). Vapometry provides valuable and reliable method of assessment; nevertheless, it is not possible to be performed in multiple localizations (face, hands, armpits, trunk, feet) in more than one patient at the same time (Larson 2011). Moreover, the equipment for this assay is rather expensive and cannot be considered a standard instrument for a surgical clinic. In contrary, gravimetry is a simple, cheap, and fast method of objective evaluation of sweating (Heckmann et al. 2001; Hund et al. 2002; Stefaniak et al. 2011). Gravimetry is a short and easy method of objective measurement of sweating. It is performed by 1 min collection of sweat with 3-weighted cotton swab. Net weight is calculated as the difference between brutto and tara weights. To include individual differences determined by the area in which the sweating is preferred, the net weight is divided by the total body surface and therefore standardized. Adequate and objective evaluation of intensity of sweating plays an essential role in proper qualification to surgery and,

further, for reliable assessment of the results of intervention. In some anecdotal cases, despite obvious anhidrosis, the patients may still demand further treatment (Kreyden et al. 2002), which may arise from psychiatric conditions, such as body dysmorphic syndrome. In those patients, invasive treatment may lead not only to dissatisfaction but also to severe psychiatric disturbances or even suicide. Thanks to regular introduction of the quantitative evaluation of sweating prior and after surgery, it is possible to provide the patients with information on their sweating compared to the reference values.

Epidemiological studies concerning HH are based solely on subjective data gathered from questionnaires. Based on such data, Strutton et al. (2004) have shown that HH affects approximately 2.8 % of the population and that palmar HH occurs most often at approximately 13 years of age. Large Chinese studies (Tu et al. 2007), again solely based on subjective questionnaires and conducted in a group of 33,000 people, between the age of 11 and 22 years, have shown that HH occurs in 4.36 % of the general Chinese population. A similar questionnaire-based study has been conducted in the USA, finding HH in 1.4 % of the respondents (Adar et al. 1977). Another questionnaire-based study by Westphal et al. (2011) has shown a high HH prevalence, of up to 5.5 %, among the Brazilian population.

In most studies presented in the literature, the authors concentrate on relative impact of different forms of treatment on gravimetrically measured sweating (Heckmann et al. 2001; Hund et al. 2002; Hong et al. 2012; Lowe et al. 2007; Proebstle et al. 2002). Mostly, such measurements were performed in dermatological settings and concerned the results of local methods of treatment such as Botox treatment or iontophoresis. In those methods of treatment, associated with low level of transient complications or side effects, even less stringent approach to qualification will not cause long-term harm to the patients. Thanks to regular introduction of the quantitative evaluation of sweating prior and after surgery, it is possible to provide the patients with information on their sweating compared to the reference values. Due to that it was possible to confirm that the

preoperative values of abdomino-lumbar sweating in the PHH patients are very low. The increase in sweating in this area is very often subjectively experienced by the patients. Nevertheless, in our experience the post-op abdomino-lumbar sweat rate remains low and not above the reference value found in our control subjects (Stefaniak 2013).

2 Technique to the Evaluation

Gravimetric assays have been performed similarly to the procedure described by Heckmann et al. (2001) and Hund et al. (2002). In short, after 15 min rest in sitting position, the patients were invited into the air-conditioned measure room in standardized temperature (24–25 °C) and humidity 15–17 %. The subjects were not allowed to consume alcohol 48 h prior to the assessment and had their last meal at least 6–8 h prior to testing. All tests were performed in disposable gloves.

A standard small cotton gauze pad has been weighted on a precise ($d = 0.5$ mg) weight scale (Radwag, Poland – scale type WPS 110/C/S, Poland). Then the pad was given to the participant who was asked to wipe carefully the area under evaluation. The procedure in each localization lasted 1 min. Then the pad was weighted again and a difference was calculated. To avoid a bias associated with different body areas of participants, the difference was standardized by division by body area calculated with the height of the participant (according to Mosteller, body area [m^2] = $0.01667 \times \text{height [cm]}^2 \times \text{mass [kg]}$) (Verbraecken et al. 2006). An Internet tool has been developed in order to simplify transcoding raw data into results adjusted to body surface of the patients (www.chirurgiapomorska.edu.pl/gravimetrickool).

Mean gravimetric intensity of sweating in PHH patients prior to surgery was 24.49 ± 45.64 mg/min/ m^2 for facial, 153.37 ± 160.39 mg/min/ m^2 for palmar, 66.23 ± 56.18 mg/min/ m^2 for axillary, and 31.24 ± 72.97 mg/min/ m^2 for abdomino-lumbar localizations (Stefaniak 2013). After surgery it was 14.48 ± 11.64 mg/min/ m^2

for palmar, 23.63 ± 24.56 mg/min/m² for axillary, and 28.86 ± 56.05 mg/min/m² for abdomino-lumbar localizations (Stefaniak 2013). In another study by our team (Stefaniak et al. 2013) performed on healthy volunteers, mean value of gravimetrically evaluated intensity of sweating was, respectively, 19.15 ± 14.97 , 18.49 ± 14.06 , 42.39 ± 47.08 , and 15.77 ± 16.87 mg/min/m².

The overall test–retest correlation was 0.71 (Stefaniak et al. 2013). Test–retest values measured in volunteers for different localizations were facial 0.64, palmar 0.54, axillary 0.84, and abdomino-lumbar 0.70. In follow-up patients it was, respectively, 0.82, 0.81, 0.79, and 0.66 (only follow-up results were included in test–retest evaluation).

As mentioned in the background of this chapter, the epidemiology of HH identifies about 1–4 % of population to suffer from intractable symptoms that should be considered a qualification to surgery. In normal distribution, it is calculated that 95.5 % of observations are within mean ± 2 SD. Considering that only the upper limit of normative value is important for diagnosing hyperhidrosis, it can be calculated that 2.25 % of cases will be within the range higher than mean ± 2 SD. This percentage is in accordance with epidemiological data on predominance of PHH in population, which has been reported to reach 2.8 % (Haider and Solish 2005; Strutton et al. 2004). Therefore, in order to obtain threshold for diagnosis of hyperhidrosis, double standard deviation was added to the mean from general population. Those thresholds are presented in the table below (Table 1).

3 Comment

It has to be underlined that gravimetric assessment, as a qualification standard, allows minimization of the risk of qualifying people for surgery who have a psychological problem with HH rather than a biological one. It is often that subjective HH assessment does not match the results of objective tests. This is usually so because patients tend to compare themselves to their peers, rather than looking upon themselves objectively. Another reason for “subjective–objective” discrepancies is through comparing the “ideal me” with the “real me.” Bearing those discrepancies in mind, when assessing patients, we can often see that he or she has an overestimated subjective HH assessment, even though the objective test shows otherwise. On the other hand, patients that often meet the criteria for surgical treatment of HH tend not to see the real problem.

Considering what has been written above, the more important it seems to conduct additional objective assessments, which are characterized by high sensitivity, and allow screening for patients who actually suffer from intensive HH. Performing objective HH assessment also allows avoiding qualifying patients for surgery who, in fact, have mild HH and could benefit from other types of treatment such as iontophoresis or botulinum toxin therapy. It should also be mentioned that gravimetry can additionally add to qualitative evaluation of hyperhidrosis. This can be achieved by five-point evaluation (face, hands, armpits, abdomino-lumbar area, and feet). In primary hyperhidrosis, two out of five localizations will be increased (hands and feet), while the others

Table 1 Reference values of sweating in different areas of the body measured by gravimetry and suggested thresholds for qualification for sympathectomy (Stefaniak and Proczko 2013)

Threshold for qualification for sympathectomy (mg/min/m ²)	Mean value in 1-min gravimetric test divided by body surface (mg/min/m ²)	Localization
49	19	Face
46	18	Hands
136	42	Armpits
Not applicable ^a	16	Abdomino-lumbar
46	18	Feet

^aHyperhidrosis in this localization is not a qualification to sympathectomy

will be low, especially in abdomino-lumbar area. Increased values in all five areas will rather point to generalized hyperhidrosis due to endocrine problems, such as menopause, obesity, or sexual hormone disturbances (Stefaniak et al. 2012).

To sum up, basing ETS qualification solely on subjectively reported intensity of sweating may create the risk of qualifying for surgery patients in whom sweating does not exceed the normative value for the specific population or is a symptom of other underlying diseases. Taking into account the occurrence of post-ETS compensatory sweating (Lyra et al. 2008), as well as its unpredictable intensity (Lyra et al. 2008), qualifying patients that do not meet the objective HH criteria should be considered a mistake. The key message of this study is that when assessing patients suffering from HH, it is necessary to use both objective and subjective methods of evaluation.

4 Conclusion

Gravimetry is an easy, reproducible, cheap, and fast method of evaluation of sweating. The reference values are stable and can serve as a qualifying and follow-up tool for evaluation of the patients with PHH in any localization.

subcutaneous tissue • adipose tissue • subcutis
connective tissue

Between the dermis (syn: cutis) and the underlying bones, muscles, or fasciae lies a tissue of uneven thickness according to body sites and individuals, called subcutaneous tissue or subcutis (syn: hypodermis). The term “subcutaneous fascia” is sometimes used as a synonym for subcutaneous tissue, although this definition is the subject of current debate as outlined below. From an anatomical and physiological viewpoint, subcutaneous tissue contains two components which, although intricate, have different functions: the interstitial tissue and the adipose tissue.

1 The Interstitial Connective Tissue

1.1 Histomorphology

Subcutaneous interstitial connective resembles dermis in structure but is much looser. As such, it is a network of collagen and elastic fibers embedded in a ground substance made of a mucopolysaccharide gel sequestering a large amount of water and an additional small amount of “free” interstitial liquid (Brace and Guyton 1979). On its outer side, subcutaneous tissue is in direct contact with the dermis. The dermo-hypodermal junction is irregular, the dermis being attached to
