

# Textbook of Clinical Neuropsychology

SECOND EDITION

Edited by  
Joel E. Morgan and  
Joseph H. Ricker

# Textbook of Clinical Neuropsychology

“Simply superb! Kudos to the Editors for producing a sequel that outshines the original and continues to set the standard for textbooks in clinical neuropsychology in its scope and scholarship. Morgan and Ricker have amassed an all-star cast of contributors who present a well curated coverage of the essential aspects of contemporary evidence-based neuropsychological practice with the expertise and depth that will satisfy the ardent graduate student as well as the seasoned academic and clinician. Every neuropsychologist should have the *Textbook of Clinical Neuropsychology* on his or her bookshelf.”

– Gordon J. Chelune, University of Utah School of Medicine

The first edition of the *Textbook of Clinical Neuropsychology* set a new standard in the field in its scope, breadth, and scholarship. This second edition comprises 50 authoritative chapters that will both enlighten and challenge readers from across allied fields of neuroscience, whether novice, mid-level, or senior level professionals. It will familiarize the young trainee through to the accomplished professional with fundamentals of the science of neuropsychology and its vast body of research, considering the field’s historical underpinnings, its evolving practice and research methods, the application of science to informed practice, and recent developments and relevant cutting-edge work. Its precise commentary recognizes obstacles that remain in our clinical and research endeavors and emphasizes the prolific innovations in interventional techniques that serve the field’s ultimate aim: to better understand brain-behavior relationships and facilitate adaptive functional competence in patients.

The second edition contains 50 new and completely revised chapters, written by some of the profession’s most recognized and prominent scholar-clinicians, broadening the scope of coverage of the ever-expanding field of neuropsychology and its relationship to related neuroscience and psychological practice domains. It is a natural evolution of what has become a comprehensive reference textbook for neuropsychology practitioners.

Dedicated to the memory of  
Manfred F. Greiffenstein, PhD, ABPP (CN, FP),  
scientist, scholar, clinician, devoted husband and  
father, and generous friend. His wit, intellectual  
integrity, and fearless pursuit of truth are indelibly  
etched in our minds and hearts.

## About the editors

**Joel E. Morgan, PhD, ABPP**, was Director of Training at the Veterans Administration New Jersey Healthcare System and Clinical Associate Professor of Neurosciences at Rutgers New Jersey Medical School prior to entering full-time private practice in 2001. Dr. Morgan maintains a life span private practice in clinical and forensic neuropsychology. He is licensed as a psychologist in New Jersey and is board certified by the American Board of Professional Psychology in both Clinical Neuropsychology and the subspecialty of Pediatric Neuropsychology. Dr. Morgan has served as a member of the editorial boards of four peer-reviewed journals and was an Oral Examiner for the American Board of Clinical Neuropsychology for ten years. He has more than 50 scholarly publications as book editor and chapter author, and has presented more than 25 invited addresses at national conferences.

**Joseph H. Ricker, PhD, ABPP (CN, RP)** is the Director of Psychology for Rusk Rehabilitation at New York University

Medical Center and is a Professor in the departments of Rehabilitation Medicine, Psychiatry, and Radiology at New York University School of Medicine. He has been licensed as a psychologist in five states and is board certified by the American Board of Professional Psychology in both Clinical Neuropsychology and Rehabilitation Psychology. He has served as a member of the editorial boards of five peer-reviewed journals (*Journal of Clinical & Experimental Neuropsychology*, *Journal of Head Trauma Rehabilitation*, *The Clinical Neuropsychologist*, *Rehabilitation Psychology*, and *Archives of Clinical Neuropsychology*). Dr. Ricker has a long record of federally funded research examining cognitive impairment, recovery, and rehabilitation following traumatic brain injury. His current research interests include the examination of altered cerebral blood flow and functional connectivity as they relate to cognitive impairment after brain injury, using modalities such as functional MRI, positron emission tomography, and diffusion tensor imaging.

# Contributors

**Lenard A. Adler, MD**, Professor of Psychiatry and Child and Adolescent Psychiatry, Director, Adult ADHD Program, New York University (NYU) School of Medicine, New York

**Samuel Alperin, MD**, Hofstra Northwell School of Medicine, Hempstead, New York

**Jim Andrikopoulos, PhD, ABPP (CN)**, Northwestern Medicine Regional Medical Group /Neurosciences, Winfield, Illinois

**Patricia M. Arenth, PhD**, Department of Physical Medicine and Rehabilitation, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

**Peter A. Arnett, PhD**, Professor and Director, Neuropsychology of Sports Concussion and MS Programs, Pennsylvania State University, Psychology Department, University Park

**Breton Asken, ATC, MS**, Department of Clinical and Health Psychology, University of Florida, Gainesville

**Ida Sue Baron, PhD, ABPP (CN)**, Independent Private Practice Professor, Departments of Pediatrics and Neurology, University of Virginia School of Medicine, Charlottesville, VA & Clinical Professor, Department of Pediatrics, The George Washington School of Medicine, Washington, DC.

**William B. Barr, PhD, ABPP (CN)**, NYU School of Medicine, New York

**Hunt Batjer, MD, FACS, ABNS**, Professor and Chairman of Neurological Surgery, University of Texas Southwestern Medical Center, Dallas

**Russell M. Bauer, PhD, ABPP (CN)**, Department of Clinical and Health Psychology, University of Florida, Gainesville

**Kathleen T. Bechtold, PhD, ABPP (CN, RP)**, Associate Professor, Department of Physical Medicine and Rehabilitation, The Johns Hopkins University School of Medicine, Baltimore, Maryland

**Heather G. Belanger, PhD, ABPP (CN)**, James A. Haley Veterans Hospital and University of South Florida, Tampa

**Kevin J. Bianchini, PhD, ABN**, Independent Practice, Jefferson Neurobehavioral Group, Metairie, Louisiana

**Linus A. Bieliauskas, PhD, ABPP (CP, CN)**, Professor, University of Michigan Health System and Staff Psychologist, Ann Arbor Veterans Administration Healthcare System, Ann Arbor

**Erin D. Bigler, PhD, ABPP (CN)**, Professor of Psychology and Neuroscience, Brigham Young University, Provo,

Utah; Adjunct Professor of Psychiatry, University of Utah, Salt Lake City

**Robert M. Bilder, PhD, ABPP (CN)**, Michael E. Tennenbaum Family Professor of Psychiatry and Biobehavioral Sciences and Psychology, University of California, Los Angeles

**Olivia Bjorkquist Harner, PhD**, Northwestern University, Feinberg School of Medicine, Chicago, Illinois

**Kyle Brauer Boone, PhD, ABPP (CN)**, California School of Forensic Studies, Alliant International University, Los Angeles, California

**Steven T. Brewer, PhD**, Angelo State University, San Angelo, Texas

**Brian L. Brooks, PhD**, Neurosciences program, Alberta Children's Hospital; Departments of Pediatrics, Clinical Neurosciences, and Psychology, University of Calgary; and Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada

**Andrew Burleson, MS**, National Jewish Health, Denver, Colorado

**Shane S. Bush, PhD, ABPP (CN, CP, RP, GP)**, Independent Practice, Long Island Neuropsychology, PC, Lake Ronkonkoma, New York

**Alissa Butts, PhD**, Department of Psychiatry and Psychology, Mayo Clinic, Rochester, Minnesota

**Dominic A. Carone, PhD, ABPP (CN)**, State University of New York (SUNY) Upstate Medical University, Syracuse

**Alison N. Cernich, PhD, ABPP (CN)**, Department of Veterans Affairs, Defense Centers of Excellence for Psychological Health and Traumatic Brain Injury, Washington, DC

**Michael Chafetz, PhD, ABPP (CN)**, Independent Practice, Algiers Neurobehavioral Resource, LLC, New Orleans, Louisiana

**Ronald A. Cohen, PhD, ABPP (CN)**, Evelyn McKnight Chair for Cognitive Aging and Memory; Professor, Departments of Neurology, Psychiatry and Aging; Director, Center for Cognitive Aging and Memory, University of Florida, Gainesville, Florida

**Denise D. Correa, PhD, ABPP (CN)**, Department of Neurology, Memorial Sloan Kettering Cancer Center, New York, New York

**C. Munro Cullum, PhD, ABPP (CN)**, Professor of Psychiatry, Neurology, and Neurological Surgery, University of Texas Southwestern Medical Center, Dallas, Texas

**Robert L. Denney, PsyD, ABPP (CN, FP)**, Neuropsychological Associates of Southwest Missouri, Springfield

**Jacobus Donders, PhD, ABPP (CN, RP)**, Chief Psychologist, Mary Free Bed Rehabilitation Hospital, Grand Rapids, Michigan

**Eric Ecklund-Johnson, PhD, ABPP (CN)**, Department of Neuropsychology, University of Kansas Hospital, Fairway, Kansas; Departments of Neurology and Psychiatry, University of Kansas Medical Center, Kansas City, Kansas

**Josephine Elia, MD**, Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania; Nemours Neuroscience Center, Wilmington, Delaware; Department of Pediatrics and Psychiatry, Sidney Kimmel Medical College, Thomas Jefferson University; A.I. DuPont Hospital for Children, Wilmington, Delaware

**Rachel L. Fazio, PsyD**, Private Practice, Bradenton, Florida

**Deborah Fein, PhD, ABPP (CN)**, University of Connecticut (UConn) Board of Trustees Distinguished Professor, Department of Psychology, Department of Pediatrics, University of Connecticut, Mansfield

**Joanne R. Festa, PhD**, Department of Neurology, Icahn School of Medicine at Mt. Sinai, New York, New York

**Christopher M. Filley, MD**, Director, Behavioral Neurology Section, Professor of Neurology and Psychiatry, University of Colorado School of Medicine, Senior Scientific Advisor, Marcus Institute for Brain Health

**Yitzchak Frank, MD**, Pediatric Neurologist and Clinical Professor in Pediatrics, Neurology and Psychiatry at the Icahn School of Medicine, Mount Sinai in New York

**Louis M. French, PsyD**, Walter Reed National Military Medical Center, Bethesda, Maryland

**Robin Garrett, PsyD**, Movement Disorders Center of Arizona, Scottsdale, Arizona

**Daniel J. Goldman, PhD**, Independent Practice, Edina, Minnesota

**Tad T. Gorske, PhD**, Assistant Professor, Director of Outpatient Clinical Neuropsychology, Division of Neuropsychology and Rehabilitation Psychology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

**Manfred F. Greiffenstein, PhD, ABPP (CN, FP)**, Psychological Systems Inc., Royal Oak, Michigan

**Kevin W. Greve, PhD, ABPP (CN)**, Independent Practice, Jefferson Neurobehavioral Group, Metairie, Louisiana

**Leslie M. Guidotti Breting, PhD, ABPP (CN)**, Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Pritzker School of Medicine, Chicago; Department of Psychiatry and Behavioral Sciences, North Shore University Health System, Evanston, Illinois

**Kathleen Y. Haaland, PhD, ABPP (CN)**, Professor, Departments of Psychiatry and Behavioral Sciences and Neurology, University of New Mexico, Albuquerque

**Marc W. Haut, PhD, ABPP (CN)**, Departments of Behavioral Medicine and Psychiatry, Neurology, and Radiology, West Virginia University School of Medicine, Morgantown

**David E. Hartman, PhD, MS, ABN, ABPP, (CP)**, Medical and Forensic Neuropsychology, Chicago, Illinois

**Jennifer Wiener Hartzell, PsyD, ABPP (CN)**, Departments of Supportive Oncology and Neuropsychology, Levine Cancer Institute, Carolinas HealthCare System, Charlotte, North Carolina

**Ramona O. Hopkins, PhD**, Professor of Psychology and Neuroscience, Psychology Department, Brigham Young University, Provo, Utah; Department of Medicine, Pulmonary and Critical Care Medicine, Intermountain Medical Center, Murray, Utah

**Megan M. Hosey, PhD**, Assistant Professor, Division of Rehabilitation Psychology and Neuropsychology, Department of Physical Medicine and Rehabilitation, The Johns Hopkins University School of Medicine, Baltimore, Maryland

**Laura L. Howe, JD, PhD**, Veterans Administration Palo Alto Health Care System, Palo Alto, California

**Richard F. Kaplan, PhD, ABPP (CN)**, Professor of Psychiatry and Neurology, Department of Psychiatry, University of Connecticut Health Center, Farmington

**Paul M. Kaufmann, JD, PhD, ABPP (CN)**, University Compliance Officer, University of Arizona, Tucson

**S. Joshua Kenton, PsyD**, Commander, U.S. Navy; Neuropsychologist, Naval Hospital, Camp Pendleton, Oceanside, California

**Michael W. Kirkwood, PhD, ABPP (CN)**, Department of Physical Medicine and Rehabilitation, Children's Hospital, Colorado and University of Colorado School of Medicine, Aurora

**Elizabeth Kozora, PhD, ABPP (CN)**, Professor, Department of Medicine, National Jewish Health Professor, Departments of Psychiatry and Neurology, University of Colorado School of Medicine, Denver

- T. Andrew Zabel, PhD, ABPP (CN)**, Clinical Director, Department of Neuropsychology, Kennedy Krieger Institute, Associate Professor of Psychiatry & Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland

# Preface

The second edition of the *Textbook of Clinical Neuropsychology* brings changes in the form of updated and new chapters and eliminates any that are no longer considered contemporary. As in the first edition, we strove to provide readers with the fundamentals of the science of neuropsychology, its historical underpinnings, the application of science to informed practice, and a look at recent developments and relevant cutting-edge work. Readers will take note that some chapters from the first edition have been combined into larger,

integrated discussions of related concepts and domains, providing more depth. The addition of new chapters broadens the scope of coverage of the ever-expanding field of neuropsychology and its relationship to related neuroscience and psychological practice domains. This second edition is a natural evolution of what has become a comprehensive reference textbook for neuropsychology practitioners.

*Joel E. Morgan and Joseph H. Ricker*

November 2017

# Foreword

There can be no more meaningful a volume in neuropsychology today than one that has embraced the essential importance of a life span focus while providing essential and contemporary knowledge about both classic and nascent segments of the broadening profession of neuropsychology. Editors Joel Morgan and Joseph Ricker made a significant contribution to the scientific literature with publication of the *Textbook of Clinical Neuropsychology* (2008). With the newest edition they entrusted their vision for this volume to extraordinarily gifted contributors, each of whom has produced authoritative chapters that will both enlighten and challenge readers from across allied fields of neuroscience, whether novice, mid-level, or senior-level professionals.

While one can selectively read a chapter in one's particular area of interest, the reader who considers the merits of all 50 chapters will come to realize that this volume is superlative in both the quality and breadth of its coverage. Further, there is a unifying message about the practice of neuropsychology and the populations served by members of the profession. Most notably is the extensive range of topics covered outside the constraints of the sometimes inflexible and artificial lines dividing pediatric from adult neuropsychology. Blurring these lines allows the reader to truly understand an individual's developmental course over his or her lifetime. This analytical posture can and should make a meaningful difference for the individual, the family, and, more broadly, society. This exemplary textbook should be mandatory reading.

One is struck in reading this second edition that there is a richness associated with the numerous and rapid gains made in the accumulation of neuropsychological knowledge over decades that is foundational. The efforts of many, well cited in this volume, served to move forward intentions to advance rigorous research protocols, extend clinical diagnostic methods, introduce effective interventions, and sharpen practitioners' clinical acuity for the effects of central nervous system and systemic disease and disorder, or lack thereof. This volume is a testament to the vital contributions of colleagues past and present to whom are owed an enormous debt of gratitude, and to those in the profession who pursue study cognizant of these achievements.

The advances documented throughout this volume highlight vividly the contrast between a less well-understood

profession that endorsed early the scientist-practitioner model of neuropsychology but had yet to define many of its fundamental tenets and neuropsychology's current expanded position and range of accomplishments. Each chapter author engages the reader with an intellectual depth for the content in his or her respective area of expertise but also highlights the more global and pragmatic strengths that are inherent to our field. This combination of established knowledge and pursuit of knowledge has sustained rapid and remarkable growth, passion, and collegiality among neuropsychologists who have diverse but compatible interests, experiences, and openness to the teachings of their colleagues. The second edition goes far to support these objectives.

The second edition will familiarize the young trainee through to the accomplished professional with a now vast and at times overwhelming database that places neuropsychology within its correct context of historical growth, evolving practice and research methods, and therapeutic gains. Yet, it contains precise commentary that recognizes obstacles that remain in our clinical and research endeavors along with a hopeful emphasis on the prolific innovations in interventional techniques that fully serve an ultimate aim, to better understand brain-behavior relationships and facilitate adaptive functional competence in patients. An objective to provide ethical, evidence-based, and compassionate care for our patients who entrust us to be knowledgeable in order to improve their health and well-being is truly supported by this volume's content, which considers the past yet sets standards for how the field might advance critical future directions for the whole person across their life span, and that will further support magnificent growth and accomplishment by those who pursue their career in the specialty of neuropsychology.

# Acknowledgments

No project of this size and scope is possible without considerable collaboration and assistance. We are indebted to our many contributors for their generous work on this volume and are grateful for their scholarship. They truly embody the 'scientist-practitioner.' We would like to thank our editors, Georgette Enriquez and Paul Dukes, for their guidance and publication acumen, and Renata Corbani, our production

editor, for her extraordinary organizational skills and for actually producing this book. Finally, we wish to thank our editorial assistant, Denise Krouslis, for her tireless devotion to seeing this project through and coordinating our large cadre of contributors. We could not have done this without all of you!

# 1 Historical Trends in Neuropsychological Assessment

*William B. Barr*

Clinical neuropsychology continues to be one of the most popular and fastest growing fields of psychological practice. At last look, the Society of Clinical Neuropsychology (Division 40) has vaulted over the past several years into the role as the largest division of the American Psychological Association (APA) (Barr, 2011). The number of clinical neuropsychologists who have gone on to receive board certification through the American Board of Clinical Neuropsychology (ABCN) has recently exceeded the landmark number of 1,000, making it the fastest growing specialty of the American Board of Professional Psychology (Stringer & Postal, 2015). The number of published studies using neuropsychological methods continues to grow exponentially.

To accompany its growth, clinical neuropsychology also faces a growing number of obstacles as a profession. In the age of health care reform, there are increasing pressures for clinical neuropsychologists to increase clinical productivity and to streamline the methodology they use for patient assessment (Puente, 2011). Based on developments with computers and the Internet, there is a call to adapt assessment technology in a rapid manner with the goal of meeting growing technological and marketing demands. There is also a demand to extend the reach of neuropsychological testing to reach all individuals in our communities, including those who do not speak English as a native language (Rivera-Mindt, Byrd, Saez, & Manly, 2010). However, before moving on to developing any “new” or “advanced” approaches to neuropsychological assessment, it is important to come to a full understanding of how our field arrived at this point in its development, by examining its history.

There are numerous clichés on the need to study history, such as the avoidance of being doomed to repeat it. Some argue that studying the history of one’s profession can be a fascinating and rewarding experience in its own right (Henle, 1976). The goal of this chapter is to focus on the development of various approaches to neuropsychological assessment as they developed from the middle part of the 20th century. There exist a number of excellent summaries of the origins of specific tests and accounts of neuropsychology’s pioneers (Boake, 2002; Goldstein, 2009; Meier, 1992; Reitan, 1994; Stringer, Cooley, & Christensen, 2002). This chapter will differ from those contributions by emphasizing the development of neuropsychological assessment and some

of the major approaches developed in North America that are used today in modern-day practice.

## **Development of Assessment Methods in Clinical Neuropsychology**

Neuropsychological assessment developed as a methodology from extending the use of clinical test batteries that had been developed for the purpose of experimentation or the evaluation and characterization of a more broadly defined category of psychopathology. The professional field of clinical neuropsychology has held debates over the years on a variety of issues that are not unlike those that were mounted for years in the field of clinical psychology, regarding “statistical” versus “clinical” approaches to assessment (Meehl, 1954). Ongoing debate between practitioners of these two approaches has continued for a half-century (Grove, Zald, Lebow, Snits, & Nelson, 2000) and similar debates continue in neuropsychology to the present day (Bigler, 2007).

On the one hand, there is one view of neuropsychological assessment that emphasizes quantification. It is characterized by the use of a fixed battery of tests and the application of empirically based cutoff scores to aid in decision making. There are other approaches typified by a more flexible battery with a selection of tests resulting from clinical hypotheses, the referral question at hand, or by characteristics of the patient’s behavior during the interview or in the solution of various tasks. Some might consider this second approach to be more “qualitative” in nature. When viewing these two approaches together, they appear to be so different as to possibly representing separate schools or systems of neuropsychology. The goal in the following pages is to summarize the historical origins of these different approaches to neuropsychological assessment and discuss how the issues of quantification versus characterization continue in the contemporary practice of neuropsychology.

## **Quantitative Approaches to Neuropsychological Assessment**

The interest of psychology as a science to the study of brain disorders in human beings dates back to the mid-19th century (Boring, 1950). **Wilhelm Wundt’s** (1832–1920)

laboratory in Germany provided the first experimental approach to psychology, characterized by rigorous quantification and analysis of consciousness. This methodology was taken outside of the psychology laboratory by Wundt's student, the famous psychiatrist **Emil Kraepelin** (1856–1926), who is known to have used some of the first applications of experimental psychological methods to study basic traits such as memory, fatigue, and learning ability associated with psychopathology.

The American **James McKeen Cattell** (1860–1944) imported **Wilhelm Wundt's** methods from Germany, but with less interest in laboratory studies and more of an emphasis on using psychological instrumentation for the study of individual differences. Cattell is credited for having first used the term *mental tests* and for being the first proponent for developing a standardized psychological test battery that could be used to compare results obtained in experiments performed by different investigators (Cattell, 1890). His student **Shepard Ivory Franz** (1874–1933) is credited for being the first to take an extended battery of psychological tests for use in a clinical setting. Franz developed what is likely to be the first neuropsychological test battery (see Table 1.1) given to patients in the United States (Franz, 1919). The battery was developed when he worked at McLean Hospital of Boston and followed him with use at St. Elizabeth's Hospital in Washington, DC. Many consider Franz to have been the first clinical and experimental neuropsychologist in the United States (Colotla & Bach-y-Rita, 2002). His work is known to have also included early studies of neuropsychological rehabilitation in addition to defining the psychologist's to clinical interviewing.

#### *Origins of the Halstead–Reitan Neuropsychological Test Battery*

The development of neuropsychological methodology was influenced subsequently by academic and research activities at the University of Chicago, beginning with studies on the physiological basis of behavior that extended well into the middle portion of the 20th century. **Karl Lashley** (1890–1958) was a member of that faculty from 1929 to 1935, where he was joined by a group of students that would go on to have a significant impact on the early development of psychology (Dewsbury, 2002). With more specific regard to neuropsychology, the students at that time included **Donald O. Hebb** (1904–1985), who was the author of the classic book *Organization of Behavior: A Neuropsychological Theory* (Hebb, 1949) and is now regarded as the founder of cognitive neuroscience.

In Chicago, members of the university's medical faculty were also becoming interested in the study of psychological phenomena in the patients they were treating. Interactions between the university's medical and psychology faculty led to the collaboration of **Heinrich Kluver** (1897–1979) and **Paul Bucy** (1904–1993) and their famous observations on the

psychological effects of bilateral medial temporal resection in monkeys (Kluver & Bucy, 1937).

**Ward Halstead** (1908–1969) joined the medical faculty at Chicago in 1935 after completing his graduate study in the psychology department at nearby Northwestern University. Halstead is now regarded as one of the major pioneers, if not the “founding father” of the field of neuropsychology as practiced by many in the United States (Goldstein, Weinstein, Reed, Hamsher, & Goodglass, 1985; Reitan, 1994). His name is associated with the creation of the first laboratory

devoted to the study of brain and behavior relationships in human beings. He is also known for providing the origins of the Halstead–Reitan battery (HRB; see Reitan & Wolfson, 1985), which was one of the most influential approaches of clinical neuropsychological assessment to have evolved in the 20th century.

Many of Halstead’s aims are outlined in the introductory chapters of his classic work, *Brain and Intelligence: A Quantitative Study of the Frontal Lobes* (Halstead, 1947). In the book’s introductory chapters, he clearly states that his goal was to study a form of biological intelligence that differed from the type intelligence that was measured by standard IQ tests. He sought to determine whether this form of intelligence contributed to man’s survival as an organism. He wanted to know if it was similar or different to the mental functions possessed by other organisms. Attempts to study this form of intelligence through a battery of psychological tests was the result of his desire to know whether biological intelligence could, in fact, be measured quantitatively and whether it was composed of unitary or multiple factors. He was also interested in knowing whether quantitative indices developed as a measure of biological intelligence would be helpful in furthering our understanding of normal and pathological ranges of human behavior.

Halstead assembled a combination of 27 indices, taken from 21 separate tests, in an effort to develop a battery used to provide a quantitative measure of biological intelligence. The test battery (listed in Table 1.2) included a number of measures created by Halstead as well as those developed by others. The selection of tests was based on their ability to distinguish between “brain-injured” and “normal” individuals or through their capacity to measure various aspects of

psychometric intelligence, personality, or basic sensory abilities. He acquired test data from 237 individuals, with each of them examined in his laboratory over a period of two days.

The experimental sample for Halstead’s test battery included neurosurgical patients who had undergone cerebral lobectomies, head-injured patients, and some control subjects (Loring, 2010). The test scores were subjected to a factor analysis, which was a new statistical method that had been developed by Chicago colleague **L. L. Thurstone** (1887–1955). Halstead’s analysis is, in fact, one of the first applications of this new analytic technique. The resulting solution was composed of four factors, with the first characterized as a central integrative factor, which Halstead labeled as Factor C. This was accompanied by separate factors for abstraction (Factor A), power (Factor P), and differentiated abilities (Factor D). Halstead’s book concludes with chapters reviewing how these four factors coincide with what was known in the existing literature (Halstead, 1947).

It must be emphasized that Halstead assembled his battery of tests in an effort to conduct an experimental analysis of biological intelligence. He did not originally intend its clinical use in a medical or psychiatric setting. He left the development of these clinical applications in the capable hands of his students, with **Ralph Reitan** (1922–2014) as the most successful among them. In his initial work, Reitan used Halstead’s test battery to examine brain functioning in brain-injured soldiers from World War II and continued with the study in various forms of medical and psychiatric illness (Reitan, 1989; Russell, 2015). After moving to the University of Indiana in 1951, Reitan continued to modify the test battery for more extended use in diagnosing the presence of brain damage as well as etiology and location of various brain lesions (Reed & Reed, 2015). This was accomplished by reducing the number of tests to those most sensitive for identifying the presence of brain disorders as well as including other tests that were proven useful for clinical analysis (Reitan, 1974). The final selection of tests used in the HRB is provided in Table 1.3.

Reitan and his followers argued that a fixed battery of tests has the clinical advantage of employing a central “impairment index” that can be used in a quantitative manner to

identify the presence or absence of brain damage (Goldstein, 1984; Reitan & Wolfson, 1985; Russell, Neuringer, & Goldstein, 1970). Validating and co-norming a set of procedures together also enables the clinician to determine how interrelations among various tests can be used to identify more specific patterns of brain dysfunction. Reitan's followers, using variants of the HRB and other fixed clinical batteries (see Table 1.4), have continued with successful ventures into the study of epilepsy, traumatic brain injury, and stroke. The HRB was one of the first neuropsychological tests to have been used in conjunction with a computerized scoring system (Russell et al., 1970) and one of the largest normative databases in the field has been conducted on a modified version of the HRB in conjunction with other tests (Heaton, Grant, & Matthews, 1991). While other quantitative test batteries have come and gone (Golden, Purisch, & Hammeke, 1979), Halstead and Reitan's battery continues currently as the most successful example of using a fixed battery of neuropsychological tests.

## Qualitative Approaches to Neuropsychological Assessment

The roots of a more qualitative approaches to neuropsychological assessment, characterized by the use of flexible test batteries, can be traced back to a more descriptive European approach to clinical assessment, as exemplified by **Jean-Martin Charcot's** (1825–1893) method of eliciting and describing complex psychological phenomena in asylum patients. The major difference is that, as opposed to relying solely on clinical impression, psychologists extended the use of these methods by submitting them to empirical analysis through the use of standardized tests.

Among the first systematic clinical applications of a more qualitatively oriented test battery can be seen in the work of **Kurt Goldstein** (1878–1965) in collaboration with psychologist **Adhemar Gelb** (1887–1936). Goldstein obtained a medical degree and developed an interest in brain disorders, especially aphasia, after an introduction to the topic by **Karl Wernicke** (1848–1904) (Eling, 2015; Goldstein, 1967; Goldstein, 2009; Simmel, 1968). In contrast, Gelb was a psychologist colleague of Wertheimer's who performed a number of influential experimental studies on the perception of color constancy. These investigators together provided a number of detailed descriptions of the effects of focal brain lesions on behavior in German soldiers injured during World War I (Goldstein & Gelb, 1918). Their view was that neurological syndromes such as aphasia and agnosia were based on a basic impairment in "abstract behavior," a characteristic that could be elicited reliably through administration of standardized assessment techniques.

Like many others, Goldstein fled Europe in the 1930s and continued his work in the United States. He was known in this country as a proponent of a holistic view of brain functioning that was consistent with findings reported in laboratory studies by Karl Lashley and through clinical descriptions by the English neurologist **Henry Head** (1861–1940). He was also recognized for an approach emphasizing the effects of psychopathology on the organism as a whole including not only cognition, but also various aspects of personality.

Goldstein's collaboration with psychologist **Martin Scheerer** (1900–1961) led to further refinement of the psychological test methods that he had initially developed in Germany (Eling, 2015; Goldstein, 2009). The monograph describing the use of the test battery listed in Table 1.5 provides one of the first systematic descriptions of how to

*Table 1.5* Goldstein–Scheerer battery (Goldstein & Scheerer, 1941)

-

examine patients for psychological signs of brain dysfunction (Goldstein & Scheerer, 1941). Included in this methodology is the view that the effects of brain dysfunction cannot be captured adequately through analysis of test scores as found in standard approaches to quantitative testing. Their view was that “test results can be evaluated only by analyzing the *procedure* by which the patient has arrived at his results” (Goldstein & Scheerer, 1941).

During the 1930s **Molly Harrower** (1906–1999), one of the lesser-known pioneers in the field of clinical neuropsychology, began to explore the use of psychological tests with neurosurgical patients in **Wilder Penfield’s** (1891–1976) neurosurgical unit in Montreal (Harrower, 1939). Harrower was influenced greatly by Gestalt psychology, having studied with **Kurt Koffka** (1886–1941), one of its founders, for her doctoral degree at Smith College. She also spent an influential three-month period with Kurt Goldstein before joining Penfield’s group. Harrower is known for adapting Rubin’s reversible figures for clinical purposes as a means to study the disruption of perceptual organization processes in patients with brain disorders and other forms of psychopathology (Harrower, 1939). Her formal work in neuropsychology terminated for the most part upon leaving Penfield’s unit in 1941. Harrower went on in her career to become a major influence on clinical psychology and an expert on use of psychological tests in appraising both normal and pathological personality (Dewsbury, 1999).

The influence of training in clinical psychology on the development of neuropsychology during that period is also seen in **Arthur Benton’s** (1909–2006) early work, with the test battery used in his first publication in the field of neuropsychology (Benton & Howell, 1941). Benton went on to have a profound influence on the development and maturation of the field of neuropsychology. He had obtained his first clinical experience working with patients at the New York State Psychiatric Institute while a graduate student at Columbia University in the late 1930s (Goldstein, 2009; Levin, Sivan, & Hannay, 2007). Exposure to neuropsychology was obtained through his attendance at Kurt Goldstein’s weekly Saturday lectures at Montefiore Hospital (Goldstein, 2009; Meier, 1992). His interest in the brain and behavior was solidified in World War II when he began to conduct evaluations on brain-injured soldiers at the Naval Hospital in San Diego with **Morris Bender** (1905–1983) a neurologist who was known for an interest in the study of higher-order cerebral functions (Hamsher, 1985; Meier, 1992). Bender had exposed Benton to the classic literature in neurology, forming a long-standing interest in an historical approach to the study of well-known neurological syndromes.

Benton originated some of the neuropsychological tests bearing his name to meet the demands of clinical practice. For example, he developed what eventually became the Benton Visual Retention Test as a set of designs drawn informally out of the immediate need for a reliable measure of nonverbal memory. The designs were eventually redrawn by a graphic

artist and later published by The Psychological Corporation (Benton, 1997). Benton moved to the University of Iowa in 1948, after spending a brief period of time at the University of Louisville. His initial role at Iowa was the Director of the Graduate Training Program in Clinical Psychology. He established a clinical assessment service for the Department of Neurology in 1950. His research efforts during that period focused on the study of somatosensory processes associated with Gerstmann’s syndrome. His research program expanded significantly in 1957 when research funding enabled him to establish a full-time neuropsychological laboratory.

Benton criticized the classic neurological literature for its lack of standardized methodology. His research goals consisted of the study of well-known neurological syndromes such as aphasia, apraxia, and agnosia through the use of well-validated test procedures that enabled him to factor out the influence of unspecified variables such as age and education. A list of the procedures developed in Benton’s laboratory for use in experimental studies is provided in Table 1.6 (Benton & Hamsher, 1989; Benton, Hamsher, Varney, & Spreen, 1983). Many of these measures are now standard components of neuropsychological test batteries used by those employing a hypothesis-testing approach to clinical assessment.

A similar approach to neuropsychological assessment is seen in the work of Benton’s contemporary **Hans Lukas Teuber** (1916–1977). Teuber was born in Germany and came to

the United States in 1941 (Hurvich, Jameson, & Rosenblith, 1987). He received his PhD in psychology from Harvard University in 1947. He had an indirect link to Gestalt psychology: his father was Director of the scientific station for the study of primates on the island of Tenerife when the Gestalt psychologist **Wolfgang Köhler** (1887–1967) arrived there in 1913 to conduct his famous studies of problem-solving abilities in apes (Köhler, 1925). Teuber's initial exposure to neuropsychology was at Harvard, where he interacted with Karl Lashley and attended lectures given by Kurt Goldstein, who was a visiting professor there in 1941 (Goldstein, 2009). In an interesting coincidence, Teuber also worked at the San Diego Naval Hospital in 1944 with Morris Bender, where he was exposed to working with patients with brain damage and to the classical literature in neurology. Following the war, Bender helped him develop a laboratory for the study of brain disorders at New York University (NYU). It was there that he went on to conduct a number of classic studies on perceptual disturbances of visual and somatosensory regions in brain-injured subjects in collaboration with Bender and a host of psychologist colleagues (Semmes, Teuber, Weinstein, & Ghent, 1960; Teuber, Battersby, & Bender, 1960).

Teuber, much like Benton, advocated the use of standardized procedures developed for conducting a reanalysis of many of the classical neurobehavioral syndromes described by 19th century investigators (Teuber, 1950). However, Teuber also demonstrated an interest in using the knowledge obtained from these investigations for understanding the basis of “normal” brain functioning. He is known for developing the concept of “double dissociation,” which has become a standard method for verifying the relationship between a given deficit and a specific lesion site (Teuber, 1955). He also advocated using a battery of tests “to analyze numerous specific performances in an individual patient” rather than devising “omnibus instruments purporting to detect ‘the’ brain injured patient as such” (Teuber, 1950 p. 31. An example of the battery used in his laboratory is provided in Table 1.7. For Teuber, neuropsychological tests provided a valid means of assessing brain–behavior relationships. His interests extended from the study of perceptual processes to include a means to solve the “riddle” of frontal lobe functioning (Teuber, 1964). He moved from NYU to the Massachusetts Institute of Technology in 1961 where he was responsible for establishing the foundation for the institute's strong reputation as a center for the study of cognitive neuroscience.

Our discussion of flexible test batteries extends above the U.S. border, into Canada, to the Montreal Neurological Institute (MNI). Neuropsychological studies have continued to flourish at the center as a result of **Wilder Penfield's** interests in behavior and his early collaborations with **Molly Harrower** and **Donald Hebb** on the surgical treatment of epilepsy (Loring, 2010). **Brenda Milner** arrived at MNI following World War II as a graduate student at McGill after having studied with **Oliver Zangwill** (1913–1987) in

Cambridge, England (Meier, 1992). She conducted her doctoral thesis on the neuropsychological effects of temporal lobectomy (Milner, 1954). She is best known for a series of studies on the behavioral effects of left versus right temporal lobe ablation on memory and other psychological functions (Milner, 1967). She also made important observations on the differences between patients with temporal and frontal lobe dysfunction, particularly as it applies to the effects of surgery (Milner, 1964).

While the focus of the work was on experimentation, Milner and her colleagues at MNI have developed and utilized a number of neuropsychological methods that have been

incorporated for use by other psychologists. An example of the clinical and experimental test battery developed and used at MNI is provided in Table 1.8 (Jones-Gotman, 1987; Kolb & Whishaw, 1989). The popularity of measures such as the Design Fluency Test (Jones-Gotman & Milner, 1977) and the Recurring Figures Test (Kimura, 1963), which were developed for neurosurgical studies, provides an excellent example of how experimentally derived measures can be incorporated into a flexibly defined battery of clinical tests.

### Origins of the Boston Process Approach

Many associate the type of flexible battery used today with the work of neuropsychologists at the Boston Veterans Administration (VA) Medical during the 1960s through the 1980s and the development of what now called the *Boston Process Approach* to neuropsychological assessment (Kaplan, 1988). The theoretical origins of the Boston Process Approach, with its emphasis on qualitative analysis of test behavior, are commonly attributed to the writings of **Heinz Werner** (1890–1964). In a classic paper published in 1937, Werner argued that the analysis of test scores or achievements is useful only when it is “supplemented by an analysis of the mental processes which underlie the achievements themselves” (Werner, 1937). Werner was raised in Vienna and developed interests in philosophy and science early in his life. After receiving his degree at the University of Vienna, he moved to Hamburg where he worked under the direction of **William Stern** (1871–1938). Stern is known for his work in

child development and is regarded as the originator of the concept of the IQ. It is interesting to note that Goldstein’s collaborator, **Martin Scheerer**, was a junior collaborator of Stern’s at Hamburg during the same time period.

Werner immigrated to the United States in the 1930s and held initial positions at the University of Michigan and Harvard before moving on to Brooklyn College and Clark University. He gained a reputation for a series of studies on “feeble-minded” children at a state institution located outside of Detroit, Michigan. His view was that normal and pathological development proceeded in terms of a qualitative change in patterns of functions rather than quantitative increases in accomplishments, as measured by the IQ (Werner, 1948). Werner drew parallels between his work and the work of Soviet psychologists **Alexander Romanovich Luria** (1902–1977) and **Lev Vygotsky** (1896–1934). While Luria is known for his structured approach to using qualitative methods for analyzing brain disorders (Luria, 1962), Vygotsky is known for his approach to analyzing mental growth by studying an individual’s *zone of proximal development*, which is the precursor to the method that is currently called *testing the limits* (Vygotsky, 1978).

The group at the Boston VA Hospital was comprised of a number of talented physicians, psychologists, and linguists who would challenge the holistic orientation to brain functioning and its disruption that was prominent in the field of neurology for much of the century. The group was led by neurologist **Fred Quadfasel** (1902–1974), who had been exposed to the 19th-century European literature in neurology while receiving his medical training in Germany. Quadfasel made an effort to expose his younger colleagues to this classic literature. **Norman Geschwind** (1916–1984) was the most prominent of these individuals. Geschwind is known in the field of neurology for reviving study of the neuroanatomic basis of language and other higher-order processes. He also exposed a new generation to detailed clinical investigative methods of observation and analysis, as popularized by Charcot and his colleagues in Europe before the turn of the century.

Geschwind was joined at the Boston VA by a rather large and talented group of clinical and research psychologists. The list included **Harold Goodglass** (1926–1984), who had an ongoing interest in studying the psychological and linguistic basis of aphasia as well as **Edith Kaplan** (1924–2009) who had an interest in the analysis of development through interactions with her undergraduate and graduate school mentor, Heinz Werner (Delis, 2010). **Sheila Blumstein**, **Edgar Zurif**, and others conducted a number of neurolinguistic studies of language and aphasia. **Nelson Butters** (1937–1995) was another student of Werner’s who made a transition from the study of primates to humans. Butters, in collaboration with his colleague, **Laird Cermak** (1942–1999), conducted a number of influential studies on the psychological processes disrupted in memory disorders, combining the use of neuropsychological methods and those developed in

the cognitive psychology laboratory (Butters & Cermak, 1980). Butters later moved to the University of California, San Diego, where he formed a group that performed studies on dementia and other neuropsychological conditions in a manner that was consistent with the Boston tradition. Cermak remained at the Boston VA to establish the Memory Disorders Research Center.

Goodglass and Kaplan worked together to develop what was a rather unique approach to neuropsychological assessment characterized by a combination of neurological investigative methods combined with Werner's emphasis on the study of process over achievement (Goodglass & Kaplan, 1979). This culminated in the introduction of the Boston Diagnostic Aphasia Examination (BDAE), which provided a systematic means of measuring and classifying aphasic disorders in a manner that was consistent with the clinical investigative model (Goodglass & Kaplan, 1972). An emphasis on performing a systematic analysis of behavior during testing led the group to develop specifications and materials for adapting commonly used tests such as the Wechsler Adult Intelligence Scale (WAIS) and Wechsler Memory Scale (WMS) and other tests, such as the Rey-Osterrieth Complex Figure and Clock Drawing Test, to enable clinicians to elicit and observe behaviors that are not easily captured through standard test administration guidelines. An example of the clinical test battery used at the Boston VA is provided in Table 1.9. Some of the methods developed at Boston for "testing the limits" during administration of routine tests have been incorporated for standardized use by publishers of tests including the WAIS-III and WAIS-IV (Wechsler, 1997; 2008).

Kaplan went on to coin the term *process approach* based on her use of qualitative observations (Kaplan, 1988). Although similar to what provided in observations of her predecessors, Goldstein and Scheerer (1941), the methods recommended by Kaplan are more systematic in nature. It

Table 1.9 Neuropsychological test battery used at the Boston VA (Goodglass & Kaplan, 1979)

would not be accurate to characterize the process approach as "solely qualitative" or with the goal of simply noting a patient's behavior when administering tests. The process approach, in its true form, calls for developing standardized methods for observing, scoring, and analyzing qualitative features of behavior in addition to interpreting traditional test scores (Kaplan, 1988). The approach is seen most clearly in a number of tests developed by Kaplan and her colleagues, including the California Verbal Learning Test (CVLT; see Delis, Kaplan, Kramer, & Ober, 1987) and the Delis-Kaplan Executive Function System (DKEFS; see Delis, Kaplan, & Kramer, 2001). The process approach, in its intended form, provides a means of observing the behavior of clinical subjects systematically in a manner that qualifies it as a qualitative analysis using quantitative methods.

### Update on Today's Trends

Proponents of the quantitative methods used in neuropsychology continue to argue that fixed test batteries, such as the HRB, are the only ones that have been fully validated for clinical decision making and diagnosis (Hom, 2003; Russell, Russell, & Hill, 2005). They also issue the criticism that the flexible nature of other test batteries, with their focus on qualitative aspects of behavior, is "unscientific." Some have gone as far as to argue that the methodology used in flexible test batteries does not meet *Daubert* standards (*Daubert v. Merrell Dow*, 1993) to be admissible in court for scientific testimony (Reed, 1996).

Opponents of fixed test batteries argue that those batteries take too long to administer and contain a number of redundant measures that offer little to address the clinical question at hand. They also argue that the validation studies performed on fixed batteries are outdated. Using today's standards for identifying the presence of brain damage through modern imaging techniques, combined with development of tests enhancing our ability to rule out the presence of motivational factors, the accuracy of the diagnoses used in those original validation studies and their relevance to modern-day practice becomes unclear. There are ample data from clinical and research studies indicating that, properly administered and interpreted, flexible test batteries do meet legal standards for neuropsychologists involved in forensic work (Bigler, 2007; Larrabee, Millis, & Meyers, 2008).

Lessons from social psychology inform us that it is normal to perceptually widen the gap between our personal views and those of our opponents. It is unlikely that those emphasizing a quantitative approach to assessment have no interest in observations of test behavior. In fact, Halstead himself is known to have regarded discrepancies between test scores and abilities in brain-damaged subjects to be a "patent absurdity" (Halstead, 1947). This chapter has also pointed out that followers of the process approach to assessment are not disinterested in the analysis of test scores and are, in fact, more interested in developing new ones, emphasizing a

Careful analysis of test behavior. A continuation of competing approaches to neuropsychology perpetuates a negative “us” and “them” mentality that has been carried into our professional organizations and boards. A failure to understand and address divisions in neuropsychology not only hinders scientific progress but also delays development of the field at large.

There is now ample evidence indicating that neuropsychologists are moving away from polarized positions to one that combines features from both quantitative and qualitative approaches to clinical assessment. In the most recent survey conducted by the AACN, it was found that the majority of neuropsychologists are now using a “fixed flexible battery” approach to assessment, consisting of a relatively standard set of tests in evaluations of diagnostically related groups, combined with some flexibility to add or subtract tests from the battery to meet individual needs of the patient (Sweet, Meyer, Nelson, & Moberg, 2011).

The results of recent survey data also indicate that neuropsychologists have remained rather stagnant in their development and utilization of new test methodology over the past ten years (Rabin, Paolillo, & Barr, 2016). Based on these results, it appears that most neuropsychologists are particularly reluctant to utilize computer technology for existing tests or to develop new tests based on more novel conceptions of brain and behavior (Bilder, 2011; Rabin et al., 2014). There are also indications that much of the methodology currently in use fails to meet society’s needs based on ongoing changes in culture and demographics, particularly with regard to our country’s Spanish-speaking population (Elbulok-Charcade et al., 2014; Rivera-Mindt et al., 2010). It is clear that the field needs to initiate efforts to update its assessment methodology. However, returning to the aim of this chapter, it is important for those individuals tasked with developing “new and better” assessment methodology to gain some knowledge of the rich and interesting history of neuropsychology and the lessons it teaches us to ensure clinical neuropsychology’s successful move into the future.

## 2 Specialty Training in Clinical Neuropsychology

### History and Update on Current Issues

*Linus A. Bieliauskas and Erin Mark*

Since its nascence in the experimental work of Lashley, Hebb, and Halstead, and early development of clinical applications by Reitan, Goldstein, and Benton (Meier, 1992), clinical neuropsychology can be justifiably proud of having become one of the most developed and formalized fields of practice within psychology. This is most apparent in the evolution of a training model that gives the profession a recognizable roadmap providing a rational basis for the construction and composition of education and training programs.

As described by Meier (1992), “the organizational structure for clinical Neuropsychology originated as much with the formation of the International Neuropsychological Society (INS) as any other single development” (p. 556). INS was formed in 1966 and held its first formal meeting in New Orleans in 1973. As Meier indicated, at the time, there was not sufficient support for clinical neuropsychology to form a division within the American Psychological Association (APA). Interest in clinical neuropsychology continued to grow, however, and in 1980, the Division of Clinical Neuropsychology (Division 40) was formed and is now one of the largest divisions within the APA. In 2013, the division changed its name to the *Society of Clinical Neuropsychology*.

Education and training in clinical neuropsychology were undergoing continued development during this period, though not all of it was systematic and much of it came from different points of view. It was not at all uncommon for individuals to enter the practice of clinical neuropsychology coming from a primary training background in animal Neuropsychology, education, or human development. More extensive reviews of the evolution of training in clinical neuropsychology during this time can be found in Meier (1981) and Bieliauskas and Steinberg (2003). Milestones in the development of a formalized training model in clinical neuropsychology, as well as more recent advances in the maturation of the field, and contemporary issues and challenges are summarized below.

A large number of acronyms for training bodies and other organizations with ties to clinical neuropsychology have developed and reference to these will be made throughout this chapter. For ease of use by the reader, a glossary of these acronyms is appended to the conclusion of this chapter.

#### Developments in the 1980s

In 1977, INS formed a task force on education, accreditation, and credentialing that began a systematic exploration of current training practices in clinical neuropsychology with the goal of establishing guidelines. This effort was joined by Division 40 in 1980, and in 1984, the Joint APA Division 40/INS Task Force on Education, Accreditation, and Credentialing in Clinical Neuropsychology issued a report describing current training practices in clinical neuropsychology (INS/APA, 1984). That report concluded that “training in clinical neuropsychology was far from standardized and that there was an increasing number of individuals who claimed competency in this area without indication of effective background or training” (p. 21, Bieliauskas & Matthews, 1987). One outcome of the existence of multiple routes toward obtaining competence in clinical neuropsychology was the establishment of the American Board of Clinical Neuropsychology (ABCN) board certification procedures so that the public and other professionals would have a recognizable standard by which to judge the capabilities of those calling themselves clinical neuropsychologists.

The task force then issued a series of reports in order to further identify the essential components of training programs at various levels and to provide guidelines for the further development of such training programs. These reports were consolidated in the INS/APA Guidelines report (1987), and included guidelines for clinical neuropsychology training programs at the doctoral, internship, and postdoctoral levels. Consideration was given to clinical and experimental psychology core knowledge areas, training in the neurosciences, desirable didactic and experiential training, and exit criteria from each of the levels of training. These guidelines were eventually adopted as official documents by Division 40 of APA and were employed as a guide to create a list of those programs at each level (i.e., doctoral, internship, and postdoctoral) that purported to be in compliance with these guidelines. It was the goal of Division 40 to provide a central listing of programs in response to increasing demand from students who wished to explore such training, as well as to provide some guidance to programs wanting to develop training programs in clinical neuropsychology. A listing of graduate, internship, and postdoctoral programs that report

they are in compliance with the Division 40 guidelines can be found online at [www.Div40.org](http://www.Div40.org) and is regularly updated. As of the writing of this chapter, Division 40 listed 40 doctoral programs, 50 internships, and 96 postdoctoral programs claiming adherence to Division 40 training guidelines. It should be noted, however, that like other program listings, a program's adherence to the Division 40 guidelines is purely by self-report.

In 1988, Division 40 adopted a "Definition of a Clinical Neuropsychologist" that broadly outlined training expectations for those wishing to identify themselves as specialists in the field. Basically, it indicated that clinical neuropsychologists need to have acquired systematic didactic and experiential training in neuropsychology and neuroscience and that his or her competencies had been reviewed by their peers and found acceptable, with board certification through the American Boards of Professional Psychology (ABPP) showing the clearest evidence of such. In 2006, the Division 40 Executive Committee decided to reevaluate and update a definition of neuropsychology that had been adopted by the Division some years earlier. To that end, the Executive Committee published a survey seeking the views of Division 40 members on this topic and also appointed a group to review the responses, formulate a proposed course of action, and report back to the Executive Committee. At its August 2007 meeting, the Executive Committee reviewed the work of that group, including a proposed revised definition of neuropsychology. After conferring with APA staff, the Executive Committee decided to proceed with a broader approach to provide guidance both to the public and the profession regarding the specialty of neuropsychology, through promulgation of guidelines for neuropsychology. These proposed guidelines for neuropsychology will be drafted in accordance with governing policy regarding both practice and education guidelines.

As training became more organized, another significant development was the establishment of training organizations for each of the different levels of training in clinical neuropsychology. This permitted the various training programs to come together to discuss areas of mutual interest and concern and lead to increased standardization of training experiences across the United States and Canada. The first of these organizations to form was the Midwest Consortium of Postdoctoral Programs in Clinical Neuropsychology in 1988, which eventually developed into the Association of Postdoctoral Programs in Clinical Neuropsychology (APPCN) in 1994. The Midwest Consortium, and then APPCN, developed formal bylaws, criteria for postdoctoral program membership, and devised self-study forms to better identify a uniform training standard. APPCN has also been active in developing accreditation standards for specialty postdoctoral training while working closely with APA, a process that is discussed in more detail on p. 18. At the time of this writing, APPCN listed 67 member programs on its website ([www.appcn.org/member-programs](http://www.appcn.org/member-programs)), of which many are also listed by Division 40.

As indicated earlier, the ABCN was established in 1981 and was subsequently incorporated into the parent board of the ABPP in 1983. ABCN has always employed the generally accepted guidelines adopted by Division 40 as its basic credentialing requirements for taking the board specialty examination, a practice that is becoming increasingly common, especially among clinical neuropsychologists who have recently completed their training. As of April 2016, 1,141 individuals have become board certified clinical neuropsychologists (i.e., ABPP-CN) from across the United States and Canada. APPCN requires that the director of postdoctoral training of its member programs be board certified through ABCN. Initial descriptions of the formation of the history of the board can be found in Bieliauskas and Matthews (1987), with an update of ABCN policies and procedures in Yeates and Bieliauskas (2004), and in Lucas, Mahone, Westerveld, Bieliauskas, and Barron (2014). Further information about ABCN can be found online at [www.theabcn.org](http://www.theabcn.org).

The membership organization associated with ABCN is the American Academy of Clinical Neuropsychology (AACN). Full AACN membership is restricted to individuals who have been board certified by ABCN, though anyone with an interest in clinical neuropsychology who is not board certified may join AACN as an affiliate member. Whereas ABCN is strictly an examining body for board certification, AACN offers a continuing education program, develops position statements related to the field of clinical neuropsychology, and advocates for the maintenance of quality standards of practice. AACN hosts an annual meeting and sponsors regional neuropsychology educational presentations. More information about AACN can be found online at [www.theaacn.org](http://www.theaacn.org).

### Developments in the 1990s

In the 1990s, doctoral and internship programs that provided specialty training in clinical neuropsychology also began to organize in response to the Houston Conference guidelines. The Association for Doctoral Education in Clinical Neuropsychology (ADECN; [www.adecnonline.org](http://www.adecnonline.org)) and the Association of Internship Training in Clinical Neuropsychology (AITCN; [www.aitcn.org](http://www.aitcn.org)) were in place by 1995. Fifty internship programs identifying clinical neuropsychology as a special emphasis are listed on the Division 40 website, with approximately half of these also belonging to AITCN (listed online at [www.aitcn.org/member\\_programs](http://www.aitcn.org/member_programs)). Those programs that are APA-accredited are designated as internships in clinical *psychology*, even though they offer significant specialty training in clinical neuropsychology. According to the Division 40 guidelines (INS/APA, 1987), 50% of an intern's training should include supervised experiences in clinical neuropsychology in order for an internship program to be viewed as a specialty training program.

In 1995, the Clinical Neuropsychology Synarchy (CNS) was formed to provide a unified forum for all major organizations

in clinical neuropsychology to discuss training and professional issues and the CNS continues to meet for this purpose on a regular basis. The members of CNS include APPCN, ADECN, and AITCN, as well as the ABCN, AACN, Division 40, the National Academy of Neuropsychology (NAN), and the Association of Neuropsychology Students in Training (ANST). The impetus for development of the CNS was, in part, based on the recognition of clinical neuropsychology as a specialty by the APA and, in part, a decree of the Inter-organizational Council for Accreditation of Postdoctoral Programs in Psychology (IOC)—an organization composed of all the regulatory bodies in professional psychology in North America and representatives of the specialties. Both of these organizations recognized that as new psychology specialties developed and were recognized, a consensus voice of the specialty would be needed to foster standards of education and credentialing. Thus, development of a *synarchy*, which means “governance through joint sovereignty,” was encouraged for each specialty. While CNS has served this purpose for clinical neuropsychology, similar synarchies/specialty councils exist for 13 other specialties in professional psychology. The INS sends an observer to CNS meetings, but does not consider itself a participating member of CNS since it is a scientific rather than professional organization and it is not discipline-specific in its membership (i.e., its membership is multidisciplinary). Typically CNS summit meetings of the organizational representatives are held two or three times annually. To date, CNS has opted not to develop bylaws and instead, decision making is by consensus. More information about CNS can be found on the organization’s website ([www.appcn.org/clinical-neuropsychology-synarchy](http://www.appcn.org/clinical-neuropsychology-synarchy)).

In 1996, after an approximately ten-year application process, clinical neuropsychology was the first psychology specialty to be formally recognized as such by the APA. The 14 psychology specialties currently recognized by the APA with their respective year of initial recognition are listed in Table 2.1. Division 40 has since led the necessary periodic reapplication process for clinical neuropsychology specialty status, which is currently approved until 2017. A listing of APA-recognized psychological specialties and proficiencies can be found online at the organization’s website ([www.apa.org/ed/graduate/specialize/recognized.aspx](http://www.apa.org/ed/graduate/specialize/recognized.aspx)).

### The Houston Conference

With the recognition of specialty status in 1996, there came the realization that clinical neuropsychology had now matured as a profession and that the model of training should be specified. Julia Hannay proposed a consensus conference and, with the support of the University of Houston, the conference was organized in the fall of 1997. A planning committee was formed by the CNS and the Houston Conference was organized with the co-sponsorship of the University of Houston, the board of Educational affairs of APA, AACN, ABCN, Division 40, APPCN, and NAN. All members of

Table 2.1 APA-recognized specialties in professional psychology

<i>Specialty Name</i>	<i>Year Initially Recognized</i>
Clinical Neuropsychology	1996
Industrial-Organizational Psychology	1996
Clinical Health Psychology	1997
Clinical Psychology	1998
Clinical Child Psychology	1998
Counseling Psychology	1998
Psychoanalysis in Psychology	1998
School Psychology	1998
Behavioral and Cognitive Psychology	2000
Forensic Psychology	2001
Family Psychology	2002
Geropsychology	2010
Police and Public Safety Psychology	2013
Sleep Psychology	2013

Information from APA’s web page listing specialties in psychology (APA, n.d.)

Division 40 and NAN and all training programs in the Division 40 listing were invited to submit applications to attend the conference. From these submissions, 40 delegates were chosen by the planning committee, bringing the total number of conference participants to 46 (including the planning committee). Delegates to the conference were chosen to be broadly representative of the field based on such parameters as geographic region, practice setting, level of training, gender, cultural diversity, subspecialization within the field, and seniority. Delegate selection and the format of the conference were modeled on earlier successful training conferences in psychology such as the Conference on Postdoctoral Training (Belar et al., 1993) and the Conference on Internship Training (Belar et al., 1989). The Houston Conference produced a policy statement formally recognizing training appropriate to the development of specialization in clinical neuropsychology. The statement can be accessed at the Division 40 or AACN website ([www.theaacn.org/position\\_papers/Houston\\_Conference.pdf](http://www.theaacn.org/position_papers/Houston_Conference.pdf)), though the reader is encouraged to read the proceedings of the conference to achieve a full appreciation of the development of the document (Hannay et al., 1998). While there was considerable discussion and debate at the Houston Conference regarding training models, a consensual training model was eventually developed that acknowledged the need for both specialized and generalized clinical training throughout a systematic program of doctoral studies, internship, and postdoctoral residency. For example, education and training were to be completed at accredited training programs, a provision that will be further discussed later in this chapter. Clinical neuropsychology was acknowledged as a postdoctoral specialty, with residency training viewed as an integral part of the training background, leading to eligibility for specialty board certification through the ABPP, the parent board of ABCN. There was clear consensus that while *continuing education*, such as that

provided by workshops, lectures, online learning, etc., was an expected activity for all specialists, continuing education was *not* seen as sufficient for establishing core knowledge or skills or for primary career changes. Concern was raised at the time about whom the recommended training should affect and it was agreed that the policy would apply to future training in clinical neuropsychology (i.e., to those *entering* training after the document was to be implemented) and was not intended to be retroactive. CNS and all its member organizations, endorsed the Houston Conference document within one year, such that the Houston Conference model of training became the recommended route to becoming a clinical neuropsychologist for those *beginning* their training in 1999 or later.

### **The Houston Conference Guidelines for Training in Clinical Neuropsychology**

The Houston Conference guidelines laid out a recommended sequence of training, starting at the undergraduate level, for students wishing to eventually specialize in clinical neuropsychology. At the undergraduate level, student typically complete an undergraduate degree in psychology, with emphases on the biological bases of behavior, cognition, and basic neuroscience (although a psychology major continues *not* to be an absolute requirement to enter graduate training). Students then enter a graduate program in applied psychology, most often clinical psychology, which provides either specialty *track* training in clinical neuropsychology or substantial training opportunities in subject areas germane to clinical neuropsychology. Next, the graduate student typically completes an internship offering at least some specialty training in clinical neuropsychology. Finally, the student attends a two-year postdoctoral residency specializing in clinical neuropsychology. The completion of a postdoctoral residency, though a relatively new aspect of specialty training, is now a credentialing *requirement* for candidates seeking board certification by ABCN who completed their training as of January 1, 2005 or later. While the residency requirement may seem unnecessary to some, it places specialists in clinical neuropsychology at the same level of training as their counterparts in the medical specialties of neurology or psychiatry and further eliminates distinctions that can be perceived as markers of second-class professional status.

In addition to specifying the recommended training sequence for specialization in clinical neuropsychology, the Houston Conference also specified a *knowledge base* and *skill base* thought to be necessary for specialization in clinical neuropsychology. The knowledge base includes training in core general psychology topics (e.g., statistics, learning theory, biological bases of behavior), core clinical psychology topics (e.g., psychopathology, psychometrics, interview and assessment techniques, intervention, ethics), foundations of brain-behavior relationships (e.g., functional neuroanatomy, neurological and related disorders, neuroimaging

techniques, neuropsychology of behavior), and foundations for the practice of clinical neuropsychology (e.g., specialized neuropsychological assessment and intervention, research design and analysis, practical implications). The skill base is comprised of the following areas: assessment; treatment and intervention; consultation to patients, families, and institutions; research; and teaching and supervision. It is worth noting here that the Houston Conference guidelines permitted some degree of flexibility with respect to when in the training sequence students could acquire their knowledge and skill base. Thus, for example, students may acquire their knowledge base in brain-behavior relationships during their graduate, internship, or postdoctoral training. The Conference also placed importance on research activities and recommended that students' research skills go beyond basic skills (i.e., research design, literature review) and include the ability to execute research, monitor its progress, and evaluate its outcome. Thus, per the Houston Conference Guidelines, clinical neuropsychologists were expected to be not just consumers of research but also to be capable of producing research. From start to finish (including undergraduate education), the typical time to completion of specialty training in clinical neuropsychology is approximately 11 years, which is similar to the training period in medical specialties.

Effectively, the Houston Conference produced a formal model for training in clinical neuropsychology that is essentially equivalent to models developed for specialties in medicine. The model specified general and specific training at the doctoral, internship, and postdoctoral level. Board certification in clinical neuropsychology, through the parent body of ABPP, was identified as the desirable exit goal—again, making the specialty similar to medical specialties. In actuality, the model stipulated by the Conference guidelines did not *create* novel training requirements for neuropsychologists, but rather codified the kind of training that most clinical neuropsychologists had already undergone. Nevertheless, with the Houston Conference guidelines, clinical neuropsychology became the first of psychology's specialties to forward such a detailed training model.

### **Later Developments: APA Accreditation and Postdoctoral Residency**

The Houston Conference, which identified clinical neuropsychology as a postdoctoral specialty, also specified that training should occur in *accredited* programs. APA has long accredited doctoral and internship training programs in professional psychology (APA, 2013a; APA, 2013b), the current listing of which can be found online at [www.apa.org/ed/accreditation/programs](http://www.apa.org/ed/accreditation/programs). Accreditation of postdoctoral programs, however, has started to occur relatively recently. APA has moved to accrediting postdoctoral residency programs by two designations. First, programs can be accredited as providing training in professional psychology. This designation covers programs that offer training in multiple areas

of concentration, though without having being accredited as offering “substantive” training in a designated specialty area. Such programs may offer training in clinical neuropsychology as part of their curriculum, but their graduates may not designate themselves as having completed an accredited postdoctoral residency in clinical neuropsychology. Their designation reflects completion of an accredited postdoctoral residency in professional psychology.

Second, APA offers accreditation of postdoctoral residencies in substantive specialty areas, including clinical neuropsychology. These programs must meet specialty-specific criteria as well as more general criteria for training in professional psychology. APA is steadily moving forward with formal accreditation under both designations, but the development has been recent, and its accreditation criteria for clinical neuropsychology largely derive from the Houston Conference (Hannay et al., 1998). Since the publication of the first edition of this volume, the number of accredited postdoctoral residency programs has increased dramatically, almost quadrupling. At the time of this writing, APA listed 22 formally accredited postdoctoral programs offering specialty training in clinical neuropsychology (APA, 2013b).

The recommendation by the Houston Conference, that training occur at accredited programs, was not intended to restrict training opportunities. Indeed, the Houston Conference document simply indicates that postdoctoral programs will *pursue* accreditation according to specific criteria. As such, ABCN currently requires that training in clinical neuropsychology be in conformity with the Houston Conference document and does not currently require that the postdoctoral residency be accredited by APA.

Although the number of APA-accredited postdoctoral programs offering specialty training in clinical neuropsychology has increased significantly in the last decade, the previously slow pace of formal accreditation necessitated alternative means of specialty designation. The earliest was a general designation for postdoctoral programs instituted by the Association of Psychology Postdoctoral and Internship Centers (APPIC) in 1968. APPIC criteria for membership as a postdoctoral training center includes general requirements (including organized training experiences), supervision requirements, and a minimum of 25% time in providing professional services (APPIC Directory, 2013). APPIC criteria was most recently revised in May 2006, with later clarification of the criteria occurring in June 2011. As of June 2014, APPIC listed 163 agencies as offering postdoctoral training, 100 of which described themselves as offering “supervised experiences” in adult or child clinical neuropsychology (<https://membership.appic.org/directory/search>).

Designation of postdoctoral programs as offering specialty training in clinical neuropsychology has been offered by APPCN since 1994. While APPCN initially considered the development of an accreditation process, it chose not to pursue this when it became clear that APA was ready to formally accredit specialty postdoctoral training in clinical

neuropsychology. APPCN has always required, and continues to require, that each member program complete a self-study covering specific training criteria. APPCN has cooperated with APA in developing accreditation criteria and APPCN’s self-study guide has been largely incorporated by APA into its accreditation procedures. As mentioned earlier, there are currently 67 postdoctoral training programs listed by APPCN. Both their listing of programs and the self-study guide can be found at the AAPCN’s website ([www.appcn.org](http://www.appcn.org)).

In addition to providing a list of designated training programs, APPCN also organizes an annual postdoctoral match (i.e., “the match”) that matches candidates to programs. Prior to the advent of the match, neuropsychology postdoctoral programs relied on advertising, word-of-mouth, organizational listing, and other informal methods for recruitment of postdoctoral candidates. Candidates generally completed multiple program applications, traveled for invited interviews, and then received offers when the candidate and the program agreed that there would be a good match. It was becoming clear in the 1990s that the growing number of candidates and programs made this informal process unwieldy and inefficient. In 2001, APPCN established a match system for candidates seeking specialty postdoctoral training. This system approximated the match system employed for specialty training in medical residencies and psychology internships and established a central listing of available postdoctoral programs, a uniform application form, a uniform application date, and a uniform match date, which occurs in February. Once candidates and programs commit to the match, they are bound by its results, avoiding the older method of scrambling phone calls, offers and counter-offers, and anxiety-inducing delays. A standard interview time and space has been provided at the annual North American meeting of the INS, which takes place in February at an annual meeting (meeting information for INS can be obtained at its website: [www.the-ins.org/](http://www.the-ins.org/)), affording programs and candidates an opportunity to meet without being limited by time, expense, and the inconvenience of traveling to multiple long-distance on-site interviews. It should be noted, however, that not all programs participate in the match, which may complicate the application process for program directors bound by match-imposed timelines, and candidates who are receiving competitive offers from programs not participating in the match.

Acknowledging the possibility that not all programs and candidates would find suitable matches during the initial match process, the APPCN created a secondary “clearinghouse.” This clearinghouse service provides a listing of both candidates and programs that did not find a suitable match on match day. A description of these match-related services can also be found on the APPCN website.

Another service offered through APPCN is the residency examination, an objective examination for postdoctoral students-in-training. The examination is designed to identify whether the student is progressing effectively in the different

areas of clinical neuropsychology and moving toward success on the board certification examination. The residency examination provides effective feedback for postdoctoral training programs and can be used to assess overall effectiveness of APPCN programs when test results are aggregated.

### Recent Developments and Continuing Controversies

The movement toward board certification has steadily gained momentum in the last decade, and among early career neuropsychologists board certification is becoming increasingly more commonplace. In an effort to increase rates of board certification among newly trained neuropsychologists, ABPP provides students with an opportunity to start the board certification process before completion of their training by allowing students to submit and maintain their credentials for a one-time fee of \$25.00.

Multiple support resources exist for neuropsychologists interested in pursuing board certification in clinical neuropsychology. As mentioned earlier, neuropsychologists interested in pursuing board certification should go to ABPP.org for more information about starting the certification process. Additional resources can be found on the AACN website Study Materials page, which has links to useful resources, including information about the AACN membership program. The AACN membership program offers candidates (i.e., individuals who have had their credentials accepted by ABPP/ABCN) the opportunity to request a mentor to assist them through the various stages of the process. Individuals interested in textbooks on the subject of board certification in clinical neuropsychology will surely find the following two volumes helpful: *Board Certification in Clinical Neuropsychology: A Guide to Becoming ABPP/ABCN Certified Without Sacrificing Your Sanity* (2008) by Kira Armstrong, Dean Beebe, Robin Hilsabeck, and Michael Kirkwood; and *Clinical Neuropsychology Study Guide and Board Review* edited by Kirk Stucky, Michael Kirkwood, and Jacobus Donders (2013). Finally, an excellent resource that acts both as a study group and as a source for free neuropsychology-related study materials is the BRAIN group (i.e., Be Ready for ABPP in Neuropsychology). BRAIN is a peer-based support and study group that was started in 2002, has grown over time, and is now partnered with AACN. See BRAIN's Wikipedia page for more information ([www.brain.aacnwiki.org](http://www.brain.aacnwiki.org)).

The most recent development to effect board certification opportunities came early in 2014 when the ABCN announced the creation of its first subspecialty board: Pediatric Clinical Neuropsychology. The creation of this subspecialty board is the result of many years of effort on the part of many committed pediatric neuropsychology professionals. At the time of this writing, application for ABCN subspecialty certification in pediatric clinical neuropsychology is available only to those *currently* board certified in clinical neuropsychology through ABPP/ABCN. Further details concerning

subspecialty certification can be obtained from the ABCN website.

Another important aspect of training that continues to evolve is the role of technologies, such as functional imaging techniques and computerized testing batteries. Some practitioners are apprehensive about the potential negative impact of such technological advances on the practice of clinical neuropsychology. Innovation in this context, however, is not something to fear. On the contrary, neuropsychologists, with their strong background in the neurosciences, and continually updated training programs, are well poised to take advantage of continuing developments in the field of health care.

As with any efforts at formalization and establishment of standards, some controversies have arisen. Some have objected to the establishment of the training model specified by the Houston Conference. In particular, there remains some questioning of the need for formal postdoctoral training and the specification that specialty training cannot be established through continuing education (CE) activities. As described earlier (Bieliauskas, 1999), the rightful aspiration of the professional specialty of clinical neuropsychology to command respect and be equally regarded by other professional specialties, such as those in medicine, requires that it behave in a similar way. A profession without a model will command no respect. Just as a patient has the right to expect that his or her medical specialist has completed recognized residency training and does not profess to have developed her or his diagnostic and treatment capability online, or in weekend workshops, so does a patient have the same right to expect residency training when he or she seeks specialist services from a clinical neuropsychologist. Just as a patient has the right to expect his or her medical specialist to have demonstrated the competence established during her or his training by undergoing examination for recognized board certification, the patient has the right to expect no less of his or her specialist in clinical neuropsychology. Again, the establishment of the two-year postdoctoral residency requirement for the field puts clinical neuropsychology on par with fellow medical specialties.

There are numerous opportunities to obtain CE in clinical neuropsychology and related areas of interest. Extensive workshop programs are sponsored by AACN during its annual meeting and in regional presentations ([www.theaacn.org](http://www.theaacn.org)). The National Academy of Neuropsychology also provides an extensive workshop program at its annual meeting and provides online opportunities for CE (<http://nanonline.org/>). The American Academy of Neurology (AAN) offers many behaviorally related neurology educational offerings at its annual meeting as well ([www.aan.com/professionals/](http://www.aan.com/professionals/)). APA and many other organizations also offer multiple CE opportunities. The perspective developed at the Houston Conference is that CE is a valuable and necessary method of keeping updated in one's specialty and keeping abreast of current developments. It is *not*, however, an appropriate means for establishing the basis for specialization.

The argument has also been raised that formalization of training in clinical neuropsychology unnecessarily restricts the number of training opportunities for students and short-changes public needs for clinical neuropsychology services. Hopefully, from the review in this chapter, it is apparent that the field has grown considerably, most notably with respect to the number of designated postdoctoral programs in the last decade, and that numerous training opportunities are available. To repeat, the Division 40 website lists 40 doctoral programs, 50 internship programs, and 96 postdoctoral training programs. Along with the other listings described in this chapter, this does not appear to represent a shortage.

Finally, some have said that the establishment of a training model such as that represented by the Houston Conference is premature. That argument is obviated by the formal recognition by APA of clinical neuropsychology as a specialty. Once a specialty is thus formally established, it is important that it can reliably and validly describe the training and experience required to attain it. Any model for training to standards is, by nature, a living entity and, thus, a work in progress, and there is no doubt that further refinements and modifications in training will take place in the future. This is true for all the specialties in psychology, including, for example, clinical psychology, which has had major training conferences and emerging policies dating from the Boulder Conference in 1949 (Kelly, 1950) to the Conference on Postdoctoral Training in Professional Psychology in 1992 (Larsen et al., 1993). If one were to call the Houston Conference policy a “work in progress,” it should be noted that the same can be said for the government of the United States, which continually amends its constitution, the latest amendment (27th) being ratified in 1992 after being initially proposed in 1789.

The evolution of training for the specialty of clinical neuropsychology has been remarkable in terms of its exciting beginnings, gradual coalescence, and systematic development toward a formal model. Students benefit by having a clear roadmap to becoming a clinical neuropsychologist, training programs benefit by having guidance on establishing curricula and training experiences that meet consensual standards, and the profession benefits by having a degree of confidence that its members have undergone a specific program of didactic and experiential training. There is a need to respect this systematic development (Bieliauskas, 1999) and the aspirations it represents for the good of our patients and the health of our profession. clinical neuropsychology can certainly be proud of its current professional status, which is due, in large part, to the development of its training model. Ongoing evolution is the mark of the health of the profession and exciting developments in this regard await all of us.

# 3 Psychometric Foundations of Neuropsychological Assessment

Glenn J. Larrabee

## Plan of Chapter

The present chapter reviews the psychometric foundations of neuropsychological assessment. The reader is referred to Chapter 1 by William Barr for a review of the historical underpinnings of modern neuropsychological assessment. The current chapter begins with an overview of basic definitions of what a test is, and what psychometrics entails. This is followed by discussion of reliability, validity, normative issues, and data on test score variability pertinent to the interpretation of neuropsychological test results.

## What Is Psychometric Testing?

Cronbach (1990) defines a *test* as a systematic procedure for observing and describing behavior with the aid of numerical scales or fixed categories. In other words, observations are quantified, then assigned some meaningful values that can be ranked as representing more or less of some trait, ability, or behavior. In neuropsychological assessment, tests comprise measures of abilities, such as language, perception, motor skills, working memory, processing speed, and learning and memory, as well as questionnaires completed either by the examinee (MMPI-2-RF, Tellegen & Ben-Porath, 2008/2011; Postconcussion Checklist, Gardizi, Millis, Hanks, & Axelrod, 2012) or by someone who knows the examinee, rating them on various traits or behaviors (Behavior Rating Inventory of Executive Function—Adult Version, Roth, Isquith & Gioia, 2005; note that self-report ratings are also available with this scale). Irrespective of whether the test is a measure of ability or a symptom questionnaire, the quantification and scaling of behaviors and responses captured by the test allows a meaningful ranking of a person's behavioral characteristics that are being assessed. Cronbach (1990) describes psychometric testing as summing up performance in numbers, and follows what he refers to as “two famous old pronouncements: If a thing exists, it exists in some amount; if it exists in some amount, it can be measured” (p. 34).

Nunnally and Bernstein (1994) discuss the role of measurement in science as consisting of rules for assigning symbols (e.g., numbers) to objects (in the case of psychology, attributes) so as to (a) represent quantities of attributes numerically (scaling) or (b) define whether the objects fall in the

same or different categories regarding a given attribute. They note that much of what is historically called *measurement* involves scaling, and therefore properties of numbers, but classification can be of equal importance. Of course, neuropsychological examples exist wherein a collection of scaled attributes can be subjected to cluster analysis to yield different categories as defined by differential patterns of strengths and weaknesses on those attributes; for example, profiles of scaled attributes that characterize subtypes of learning disabilities (Fletcher & Satz, 1985).

Both Cronbach (1990) and Nunnally and Bernstein (1994) emphasize the importance of standardization. Measures are standardized to the extent that the rules for use are clear, practical to apply, do not demand great skill of administration beyond the initial learning period, are not dependent upon the specific test administrator, and include some form of norms that describe the numerical scores obtained in a population of interest, by quantifying how much of the attribute is present. The fundamental purpose of standardization is that users of a particular test should obtain similar results; in other words, absent practice effects, the same intelligence test administered to the same patient, but by different examiners should yield the same overall IQ score.

Nunnally and Bernstein (1994) review four different levels of measurement, originally proposed by Stevens (1951).

- 1 Nominal (equal vs. not equal): Permissible statistics include numbers of cases and mode, e.g., handedness.
- 2 Ordinal (> versus <): Permissible statistics include median, percentiles, order statistics, e.g., class rank.
- 3 Interval (equality of intervals or differences): Permissible statistics include arithmetic mean, variance, Pearson correlation, e.g., Wechsler Adult Intelligence Scale–IV (Wechsler, 2008) Index scores or Halstead-Reitan Battery (HRB) T scores (Heaton, Miller, Taylor, & Grant, 2004).
- 4 Ratio (equality of ratios), permissible statistics include geometric mean, e.g., temperature (Kelvin).

The level of measurement that best characterizes most neuropsychological test scores is the interval level, which allows general linear transformations of the type  $x' = bx + a$ .

Test procedures are typically designed to yield scores that follow the standard normal distribution with mean of 0 and standard deviation of 1. Through linear transformation one can obtain different descriptive mean scores and standard deviation units such as scores that follow an IQ metric, with a mean of 100 and standard deviation of 15, or IQ subtests with mean of 10 and standard deviation of 3. Other familiar transformations of mean and standard deviation values include the use of T scores with mean of 50 and standard deviation of 10 (Heaton et al., 2004). For test scores that do not approximate the standard normal distribution but rather yield a skewed distribution, performance is ranked following ordinal scaling using percentiles based on the frequency distribution of scores (e.g., many measures from the Benton Neuropsychology Laboratory are scored in this fashion; Benton, Sivan, Hamsher, Varney, & Spreen, 1994).

### Reliability, Measurement Error, and Reliable Change Scores

*Reliability* refers to the consistency or stability of a test score; it is the degree to which an experiment, test, or any other measurement procedure yields the same results on repeated trials (Carmines & Zeller, 1979). In classical test theory, an observed test score is considered to be comprised of a true score component (i.e., the actual amount of the attribute being measured) as well as a component that is due to error (i.e., any component condition that is irrelevant to the purpose of the test; Anastasi & Urbina, 1997). Over several observations, the variance in observed scores is comprised of both true score and error variance. Reliability can then be considered as the ratio of true score variance to the observed score (total) variance (true score variance + error variance), or  $r_{tt} = \text{True-score variance} / \text{Observed score variance}$  (Cronbach, 1990).

There are four main ways of computing reliability (Anastasi & Urbina, 1997; Cronbach, 1990): (a) test-retest reliability, in which the same test is repeated following a temporal delay with scores at Time 1 correlated with scores at Time 2; (b) alternate or parallel form reliability, in which two (or more) equivalent test forms are administered, following a temporal delay, with correlations computed between scores obtained on the alternate forms (note, there is usually counterbalancing of alternate form order to control for practice effects, something that cannot be controlled in the test-retest paradigm); (c) split-half reliability, computed by correlating the score on both halves of the test (e.g., odd-even; obviously inappropriate for a speeded test such as Digit Symbol or Trail Making); and (d) internal consistency based on the consistency of responses to all items in the test.

Calamia, Markon, and Tranel (2013) have published a meta-analysis of the test-retest reliabilities of several commonly used neuropsychological tests, including the Wechsler Adult Intelligence Scale (WAIS), Auditory Verbal Learning

Test (AVLT), California Verbal Learning Test (CVLT), Complex Figure Test (CFT), Trail Making Test (TMT), Benton Visual Retention Test (BVRT, Administration A), Boston Naming Test (BNT), Controlled Oral Word Association Test (COWA), and the Wisconsin Card Sorting Test (WCST) perseverative error count. The magnitude of these retest correlations was adequate to high, with several exceeding .70. Retest correlations were robust and related to the effects of age (estimated reliability increases slightly with increase in age), use of alternate forms (decreasing test-retest correlations based on alternate forms), and duration of retest interval (decreasing test-retest correlations in association with longer retest intervals). For the tests studied, retest correlations ranged from .706 for Matrix Reasoning to .915 for Information for the WAIS, .284 (recognition) to .881 (long delay) for the AVLT, .505 (Trial 1) to .749 (trials 1–5 total) for the CVLT, .500 (copy) to .741 (immediate recall) for the CFT, .658 (Trail A) to .769 (Trail B) for the TMT, .797 for BNT; .632 for BVRT, .794 for COWA, and .616 for WCST.

The correlation computed between split halves must be corrected for being based on only one-half of the total test items; all other things being equal, the longer a test the more reliable it will be (Anastasi & Urbina, 1997). The effect that lengthening or shortening a test can have on the reliability coefficient can be estimated by the Spearman-Brown formula, wherein  $r_{nn} = nr_{tt} / 1 + (n - 1)r_{tt}$ , in which  $r_{nn}$  is the estimated coefficient,  $r_{tt}$  is the obtained coefficient, and  $n$  is the number of times the test is lengthened or shortened; e.g., if the number of test items is increased from 25 to 100,  $n = 4$  (Anastasi & Urbina, 1997). When applied to a split-half computation, the formula simplifies to  $r_{tt} = 2r_{hh} / 1 + r_{hh}$  where  $r_{hh}$  is the correlation of the half-tests (Anastasi & Urbina, 1997).

The interitem consistency upon which internal consistency reliability applies, is influenced by two sources of error variance: (a) content sampling (which also influences alternate form and split half reliability), and (b) the heterogeneity of the behavior domain being sampled (Anastasi & Urbina, 1997). Domains in which the content is homogeneous will have higher interitem consistency and greater internal consistency reliability coefficients. Anastasi and Urbina (1997) note that the most common procedure for finding interitem consistency was developed by Kuder and Richardson (1937) and is known as *Kuder-Richardson Formula 20*. The formula for Kuder-Richardson 20, provided by Anastasi and Urbina (1997) is:

$$r_{tt} = (n / n - 1) (SD_t^2 - \sum pq) / SD_t^2$$

where  $r_{tt}$  is the reliability of the whole test,  $n$  is the number of items in the test, and  $SD_t$  is the standard deviation of total scores on the test. The value,  $\sum pq$ , is found by multiplying the number of persons who pass each item ( $p$ ) multiplied by the number who fail each item ( $q$ ) summing these item products over all items to give  $\sum pq$ . Anastasi and Urbina (1997) note that since  $p$  for each item is often recorded during

test development to find the difficulty level of each item, the Kuder-Richardson Formula 20 involves little additional computation. They also report that Cronbach (1951) demonstrated mathematically that the Kuder-Richardson reliability coefficient is actually the mean of all split-half coefficients resulting from different splittings of a test.

Dick and Haggerty (1971) discuss an alternate to Kuder-Richardson Formula 20: *Kuder-Richardson 21*, which can substitute for Formula 20 when individual item statistics are unavailable. This formula is:

$$r_{tt} = (n/n - 1) / (SD_i^2 - np_{av}q_{av}) / SD_t^2$$

where  $p_{av}$  is the mean difficulty level (ratio of total test mean to the total number of test items) and  $q_{av}$  is  $1 - p_{av}$ . Dick and Haggerty note that Kuder-Richardson 21 yields a lower-bound estimate of internal consistency, i.e., a conservative or low estimate of test reliability.

A more general internal consistency formula is coefficient alpha ( $\alpha$ ; Cronbach, 1951). This is presented in Anastasi and Urbina (1997) as  $\alpha = (n/n - 1) (SD_t^2 - \sum (SD_i^2) / SD_t^2$ , where  $SD_i^2$  is the sum of the variances of item scores, replacing  $\sum pq$ . Cronbach (1990) notes that what testers call  $\alpha$  statisticians refer to as an *intraclass correlation*.

Although internal consistency reliabilities are not typically thought of as providing evidence of validity, there are times when validity is also addressed by demonstration of internal consistency, particularly when the test contains an apparently heterogeneous set of items. An example of this is the investigation by Butcher, Arbisi, Atlis, and McNulty (2003) of the MMPI-2 Symptom Validity Scale (FBS; Lees-Haley, English, & Glenn, 1991). These authors noted the original heterogeneous nature of the scale, designed to capture both faking good and faking bad self-report characteristics of personal injury malingerers (cf. Lees-Haley et al., 1991). Butcher et al. computed Cronbach's  $\alpha$  for the FBS for a variety of subject groups, including psychiatric patients, medical patients, chronic pain, and forensic samples of personal injury litigants and correctional facility inmates. Excluding the personal injury sample, Cronbach's  $\alpha$  ranged from a low of .47 for chronic pain patients to a high of .64 for psychiatric inpatients, reflecting the heterogeneous nature of the items comprising FBS. By contrast, Cronbach's  $\alpha$  for the personal injury sample was substantially higher, .85, providing supporting evidence for the original test development strategy of Lees-Haley et al. (1991) that emphasized a hybrid pattern of personal injury exaggeration, mixing fake good and fake bad self-report.

Reliability is an important property of psychometric tests, for it places an upper limit on the validity of a test that cannot exceed the square root of the reliability of the test (Dick & Haggerty, 1971). Thus, for a test with a reliability of .81, the validity coefficient cannot exceed .90. Reliability is also directly related to the measurement error of a test.

The standard error of measurement (SEM) is equal to  $SD_t \sqrt{1 - r_{tt}}$ , where  $r_{tt}$  is the reliability of the test, and  $SD_t$

is the standard deviation of the test. The SEM is informative for interpretation of test scores, since tests are always less than perfectly reliable. Consequently, several different examinations of the same person would yield a normal distribution of performance, with the mean of this distribution likely representing an individual's true score. Like any other standard deviation, the SEM can be interpreted relative to the standard normal distribution, such that  $\pm 1$  SEM would encompass approximately 68% of the distribution. For example, using Trail Making B, the Heaton et al. (2004) T score normative data (mean = 50, SD = 10), and the .769 reliability for Trail Making B reported by Calamia et al. (2013), for an individual who obtains a T score of exactly 50 on Trail Making B, representing her or his true score, actual obtained scores will fluctuate  $\pm 1$  SEM,  $10\sqrt{1 - .769}$ , or  $\pm 4.81$ , 68% of the time.

Measurement error also impacts comparisons of score differences between two different tests. The standard error of the difference between two scores is  $SE_{diff} = \sqrt{(SEM_1)^2 + (SEM_2)^2}$ . Since  $SEM_1^2 = SD_t \sqrt{1 - r_{11}}$ , and  $SEM_2^2 = SD_t \sqrt{1 - r_{22}}$ , the formula can be rewritten to:  $SE_{diff} = SD_t \sqrt{2 - r_{11} - r_{22}}$  (see Anastasi & Urbina, 1997). So, if the  $SE_{diff}$  for a comparison of two scores equals five T score points, for a score difference to be significant,  $p = .05$  two-tail (nondirectionally), it must exceed  $(5)(1.96)$  or  $\pm 9.8$  T score points.

Most modern test manuals contain not only data on test reliability, but also data on the SEMs of tests such as the WAIS-IV (Wechsler, 2008), and Wechsler Memory Scale IV (Wechsler, 2009). These manuals also contain data on the frequency of normative subjects who obtain various differences between test scores from different domains of performance, for example, Table B-11 of the Wechsler Memory Scale-IV (WMS-IV) manual shows the percentage of the theoretically normal distribution (base rates) of varying magnitudes of difference scores between the WAIS-IV General Ability Index (GAI) and various WMS-IV Indexes. It is noteworthy to compare the values in Table B-11, representing the actual frequency distribution of difference scores, to the data presented in Table B-10, which displays the values needed to obtain a significant difference between the WAIS-IV GAI and the WMS-IV Indexes. Take the comparison of the WMS-IV Auditory Memory Index, for example, which in Table B-10 shows a difference of 10.95 is needed to reach the .01 level of significance using the formula for the SEM for comparison of two difference scores. By contrast, Table B-11 shows that a WAIS-IV GAI minus WMS-IVAMI difference of 10 points occurs in 19% of theoretically normal subjects, and that a person must achieve a WAIS-IVGAI minus WMS-IVAMI difference of 34 points for this to occur in the bottom 1% of the normal population.

This apparent discrepancy is best understood by returning to classic test theory, which considers test scores as being comprised of both true score variance and error. The data in B-10 reflect the effects of measurement error alone, whereas the base rate data in Table B-11 reflect both true

score variance (variability of the abilities of individual subjects) and error effects, for the difference scores reported. It is this author's opinion that the more informative data are those presented in tables reflecting the actual base rate of test score differences, such as contrasts between the GAI and AMI, rather than relying upon the statistical significance of this contrast as related to the combined measurement error of the two tests.

Since a common use of neuropsychological testing is to evaluate change over time, either in someone who is recovering from a cerebral insult, such as severe traumatic brain injury (TBI), or to monitor the deterioration over time that can occur with a dementing condition, it is important to understand the statistical and measurement issues attendant to evaluating change scores. Jacobson and Truax (1991) have proposed a reliable change index (RC) for determination of change in performance from Time 1 ( $x_1$ , baseline) to Time 2 ( $x_2$ , follow-up), which is divided by the standard error of the difference ( $SE_{diff}$ ).  $SE_{diff}$  is defined as  $\sqrt{2(SEM)^2}$ . SEM is defined as  $SD\sqrt{1 - r_{xx}}$ , with  $r_{xx}$  representing the reliability of the test used as the baseline and follow-up measure; so,  $RC = x_2 - x_1 / \sqrt{2(SEM)^2}$ . If this value exceeds a z value of 1.98, it represents a reliable (significant) change (note that this formula is a variation of the formula for determining whether differing scores on two *different* tests, such as WAIS-IV GAI and WMS-IV AMI represent a reliable difference; in the case of RC, the change being compared is based on a second administration of the *same* test).

Chelune, Naugle, Luders, Sedlak, and Awad (1993) proposed a modification to the RC index of Jacobson and Truax (1991), taking into account the average practice effect that occurs on neuropsychological tests that are repeated. Chelune et al. determined practice effect size by repeat assessment of seizure disorder patients undergoing medical management of their seizures, with both the WAIS-R and WMS-R. They then used this practice effect information and the RC index for determination of significant change in seizure patients undergoing either left or right temporal lobectomy, finding better detection of change when the average practice effect was included in the RC formula. In Chelune et al.'s modification, the average practice effect is subtracted from the score difference in the numerator of the Jacobson and Truax formula, so that  $RC = x_2 - x_1 - pe_{avg} / \sqrt{2(SEM)^2}$ , where  $pe_{avg}$  is the mean practice effect.

McSweeney, Naugle, Chelune, and Luders (1993) have taken an alternative approach for detection of change on repeat assessments. Using expanded samples of the seizure patients studied by Chelune et al., they determined T scores for change based on regression equations that utilized baseline performance on the WAIS-R or WMS-R, to predict follow-up performance on these measures, using the medically treated but nonoperated seizure patients for determination of the T scores. Simply, the equation becomes  $y_p = \beta x + c$ , where  $y_p$  is the predicted score on follow-up,  $\beta$  is the slope of the regression equation,  $x$  is the baseline score, and  $c$  is

the regression constant. Predicted scores are then converted to T scores for change, with  $T = 50 + [10(y_o - y_p) / SE_{est}]$ . In this equation,  $y_o$  is the observed score on retest,  $y_p$  is the predicted score, and  $SE_{est}$  is the standard error of estimate. Better characterization of change over time was obtained using the regression estimated T scores for change, than using the unadjusted WAIS-R and WMS-R scores alone. In this regression procedure,  $SE_{est}$  replaces SEM and  $SE_{diff}$ , but returning to classical test theory, the scores entered into the regression equation include both true score and error score variance, so these factors are implicitly present in the model. Moreover, the regression approach also takes into account regression to the mean, an important factor in considering change scores for persons whose baseline performance is extreme relative to the mean score; scores at the extreme have greater regression effects than those closer to the mean.

Duff (2012) provides a comprehensive review of the evaluation of change scores in neuropsychological assessment, including RCI, RCI adjusted for practice effect, and both simple and complex regression equations for estimation of change. RCI proved inferior to both RCI adjusted for practice effect and regression-based approaches, which did not differ substantially from one another.

### Validity, or Does the Test Measure What It Is Intended to Measure?

Generally defined, *validity* characterizes the scientific utility of a measuring instrument, in terms of how well it measures what it purports to measure (Nunnally & Bernstein, 1994). There are three main types of validity: content validity, criterion or predictive validity, and construct validity (Anastasi & Urbina, 1997; Cronbach, 1990; Nunnally & Bernstein, 1994). Content validity refers to how well the test that has been constructed was sampled from the items relevant to performance on that test; for example, did the Wide Range Achievement Test-IV (WRAT-IV) Arithmetic subtest adequately sample the domain of basic calculational ability? Criterion validity refers to how well the test predicts some external criterion, either at or near the same time the test is administered (concurrent validity, e.g., how well does the test predict ability to drive a car) or at some point in the future (predictive validity, e.g., how well does this test predict future development of dementia).

Construct validity is a more abstract concept. Cronbach and Meehl (1955) define a *construct* as some postulated attribute of people, assumed to be reflected in test performance. Anastasi and Urbina (1997) define the construct validity of a test as the extent to which the test may be said to measure a theoretical construct or trait. Neuropsychologically relevant examples of constructs include working memory, processing speed, verbal learning and memory, etc. Construct validity can be tested various ways: for example, comparison of groups that are expected to show low levels of a particular attribute in the context of evidence for preserved ability on

unrelated attributes, such as persons behaviorally identified as amnesic scoring poorly on a verbal memory test, but normally on measures of intelligence and working memory. Correlational methods are also appropriate for the investigation of construct validity. Campbell and Fiske (1959) argued that construct validity is established not only by showing the relationship of measures of a construct to other measures of the same construct, but also by showing no relationship with measures not related to the construct—in other words, showing both convergent and discriminant validity. They proposed a method for analysis of construct validity by use of a multitrait–multimethod matrix of correlations. Another common way to evaluate the construct validity of a test is to factor analyze a data set containing the test and other tests that define the purported construct the test is hypothesized to measure, as well as tests unrelated to the purported construct, again, addressing both convergent and discriminant validity. (e.g., memory tests should load on a memory factor, but not on a factor defined by measures of intelligence and problem solving).

The remaining discussion of neuropsychological test validity draws heavily from a recent paper that presents a framework for developing a core neuropsychological test battery (Larrabee, 2014). This framework recommends reviewing previously conducted factor analyses to identify a core set of neuropsychological domains of performance, thereby determining the construct validity of test procedures. The patient groups recommended for investigating criterion validity include moderate and severe TBI, Alzheimer-type dementia, and unilateral left and right hemisphere stroke. Analysis of test performance in the TBI and Alzheimer groups can be used to address different criteria including sensitivity to the presence of neurological trauma or disease, identification of those tests most sensitive to the severity of cerebral injury or disease, and identification of those tests that are the best predictors of activities of daily living, including financial competency, ability to drive a motor vehicle, and ability to work. The unilateral left and right hemisphere groups can be used to evaluate the best procedures for identification of lateralized neuropsychological impairment, as well as for evaluation of the moderating effects of language comprehension impairment in left hemisphere stroke and neglect in right hemisphere stroke on specific neuropsychological abilities. Finally, as part of the validity section of this chapter, I will describe a hypothetical core neuropsychological battery based on these various aspects of test validity that I have proposed (Larrabee, 2014), which also incorporates embedded/derived measures of performance validity (a topic discussed in detail in Dr. Boone's chapter in the current volume).

### ***Factor Analyses of Neuropsychological Tests***

Factor analysis is frequently used to determine the construct validity of neuropsychological test procedures (Delis, Jacobson, Bondi, Hamilton, & Salmon, 2003; Floyd &

Widaman, 1995; Larrabee, 2003a). Factor analysis can be used to summarize patterns of correlations among observed variables, reduce a larger number of observed variables into a smaller number of factors, provide an operational definition for an underlying process (e.g., memory) by using observed variables (i.e., memory test scores), and test a theory about the nature of underlying processes (Floyd & Widaman, 1995; Tabachnick & Fidell, 2005). A basic assumption is that tests loading on a particular factor (i.e., correlated with that factor) are explained by the underlying factor. For example, if a test is truly a measure of the construct of verbal memory, then it should load primarily on a factor defined by other tests known to be measures of verbal memory; conversely, the test should not show primary loadings on either a verbal symbolic factor or working memory factor, otherwise the purported verbal memory test is nothing more than another way of measuring verbal symbolic abilities or working memory.

As I have described in another paper (Larrabee, 2014), factor analyses of neuropsychological test batteries (Holdnack, Zhou, Larrabee, Millis, & Salthouse, 2011; Larrabee, 2000; Larrabee & Curtiss, 1992, 1995; Leonberger, Nicks, Larrabee, & Goldfader, 1992; Tulskey & Price, 2003) generally define six domains of function:

- 1 *Verbal symbolic abilities* including measures of word definition, word knowledge, and general facts such as measured by the WAIS-IV Vocabulary subtest, Similarities and Information subtests (Wechsler, 2008), and measures of word-finding ability such as Controlled Oral Word Association (COWA), and the Benton Visual Naming test (Benton, Hamsher, & Sivan, 1994). Also loading on this factor are measures of academic achievement such as the Wide Range Achievement Test–Revised (Jastak & Wilkinson, 1984) Arithmetic, Spelling and Reading, subtests (Greenaway, Smith, Tangalos, Geda, & Ivnik, 2009; Larrabee, 2000; Larrabee & Curtiss, 1992).
- 2 *Visuoperceptual and visuospatial judgment and problem solving abilities* including measures such as Visual Form Discrimination, Facial Recognition, and Line Orientation, (Benton et al., 1994; Greenaway et al., 2009; Larrabee, 2000; Larrabee & Curtiss, 1992). This factor also includes the subtests defining the Perceptual Reasoning Index of the WAIS-IV, including Visual Puzzles, Block Design, and Matrix Reasoning (Wechsler, 2008).
- 3 *Sensorimotor function* includes procedures such as Finger Tapping, Grip Strength, Purdue Pegboard, Grooved Pegboard, and Benton Finger Localization and Tactile Form Perception. There are very few factor analyses of these tests in the context of a larger set of nonsensorimotor neuropsychological procedures. Curtiss and I have reported loadings of Grooved Pegboard and Purdue Pegboard on a

*visuoperceptual visuospatial* factor, along with Benton Tactile Form Perception and WAIS-R Performance IQ subtests such as Block Design and Object Assembly, with a separate motor factor on which Finger Tapping and Grip Strength loaded (Larrabee & Curtiss, 1992; see Larrabee, 2000). In another investigation, Finger Tapping loaded with processing speed measures such as Trail Making B and Digit Symbol (Leonberger et al., 1992; also see Larrabee, 2000). Carroll (1993) has also reported loadings of sensorimotor variables on a psychomotor ability factor.

- 4 *Attention/working memory* includes the subtests comprising the Working Memory Index for the WAIS-IV (Wechsler, 2008) and WMS-IV (Wechsler, 2009) including Digit Span, Arithmetic, Letter-Number Sequencing, and Symbol Span (Holdnack et al., 2011). This dimension also includes measures such as the Paced Auditory Serial Addition Test (PASAT), which measures both processing speed and working memory (Larrabee & Curtiss, 1992; 1995; also see Larrabee, 2000). WAIS-IV Arithmetic, which loads primarily on a working memory factor, has a secondary loading on the *verbal symbolic* factor (Holdnack et al., 2011).
- 5 *Processing speed* includes measures such as Coding and Symbol Search, which comprise the WAIS-IV Processing Speed Index (Holdnack et al., 2011). Also included in this domain is the TMT (Reitan & Wolfson, 1993; Larrabee & Curtiss, 1992, see Larrabee, 2000; and Leonberger et al., 1992) and the PASAT. The Stroop Test is also considered by Carroll (1993) as a measure of cognitive speed. Controlled Oral Word Association measures word-finding skills under time constraints and loaded equivalently on a *verbal symbolic* factor and on a *processing speed* factor in one investigation (Larrabee & Curtiss, 1992; Larrabee, 2000).
- 6 *Learning and memory* tests can actually be divided into separate domains of *verbal learning and memory*, and *visual learning and memory*. *Verbal learning and memory* tests include three basic paradigms: text recall, paired associate learning, and supraspan list learning tasks. Exemplars of the text recall and paired associate paradigms include WMS-IV Logical Memory and Verbal Paired Associates. Tests of supraspan list learning include the CVLT-II (Delis et al. 2000), the Rey AVLT (Rey, 1964; Schmidt, 1996), and the Verbal Selective Reminding Test (VSRT, Buschke, 1973; Larrabee, Trahan, Curtiss, & Levin, 1988). *Visual learning and memory* tests usually include measures of design reproduction from memory such as the BVRT (Sivan, 1992), WMS-IV Visual Reproduction, or the CFT (Meyers & Meyers, 1995; Rey, 1941). Visual learning and memory tests also include recognition memory measures such as the Continuous

Visual Memory Test (CVMT; Trahan & Larrabee, 1988), and the Faces subtest of the Recognition Memory Test (Warrington, 1984). On the one hand, factor analysis has shown that immediate design reproduction from memory is more closely associated with visuospatial/constructional tasks such as Block Design and Object Assembly, but that the delayed reproduction task causes a shift in loadings so that the stronger association is with memory, with a secondary association with visuospatial/constructional skills (Larrabee & Curtiss, 1995; Larrabee, Kane, Schuck & Francis, 1985). On the other hand, recognition memory tests such as the Continuous Recognition Memory test (CRM) for detection of recurring familiar figures such as insects and seashells (Hannay, Levin, & Grossman, 1979) show primary loadings with a memory factor for both the learning trials as well as for the delayed recognition trial (Larrabee & Curtiss, 1995). These data suggest that use of delayed reproduction attenuates the spatial/constructional confound inherent in assessing visual memory by having someone draw designs from memory. Visual recognition memory tasks appear to be purer measures of visual memory, from a factor analytic perspective.

Exceptions to the above six factors have been reported. A combined general memory factor, rather than separate verbal and visual learning and memory factors, has been reported using confirmatory factor analysis of WAIS-IV and WMS-IV subtests, including a hierarchical general ability factor in the model (Holdnack et al., 2011). Confirmatory factor analysis also provides evidence supporting separate verbal and visual memory factors, rather than a combined factor, when a hierarchical model is not specified and the factors are allowed to correlate with one another (Holdnack et al., 2011). In one investigation, academic achievement measures such as the Wide Range Achievement Test–Revised (Jastak & Wilkinson, 1984) demonstrated primary loadings for Reading, Spelling, and Arithmetic on a *verbal symbolic* factor, with secondary loadings on a factor defined by measures of processing speed, attention and working memory including Wechsler Memory Scale Mental Control, TMT–B, and the PASAT (Larrabee & Curtiss, 1992; see Larrabee, 2000). Tests described as measures of *executive function* (Lezak, Howison, Bigler, & Tranel, 2012) typically show loadings on factors of *processing speed* (TMT–B; COWA), *working memory* (Letter-Number Sequencing), or *visuoperceptual and visuospatial judgment and problem solving ability* (Category Test; WCST; see Larrabee, 2000; Leonberger et al., 1992), rather than on an *executive function* factor. Others have also found relationships between tests of executive function and tests of problem solving, general intelligence, and processing speed (Barbey, Colom, & Grafman, 2013; Keifer & Tranel, 2013; Salthouse, 2005). Last, the factor structure of collections of

neuropsychological tests appears to be relatively invariant of age over the adult years (Crook & Larrabee, 1988; Larrabee & Curtiss, 1995; Wechsler, 2008), demonstrating that the same constructs are identified over the adult age range.

### Criterion Validity

The original primary criterion for neuropsychological tests was sensitivity to the presence of brain damage or dysfunction, which was generally characterized by composing a sample of patients with a variety of different neurological disorders. In other words, “brain damage” was considered to be a *unitary* (present vs. absent) or *unidimensional* (more of or less of) construct. Early test batteries reinforced this assumed criterion by utilizing global impairment scores such as the Halstead Impairment Index, which used a cutting score to define presence or absence of brain damage (Reitan & Wolfson, 1993). Of course, this did not restrict further analysis of test data—for example, the analyses recommended by Reitan (1974) to include consideration of level of impairment, evaluation for pathognomonic signs, analysis of differential scores or patterns of ability, and comparisons of the functional efficiency of both sides of the body. Early investigations also compared the neuropsychological test performance of groups of subjects with diffuse, or left or right hemisphere damage (Russell, Neuringer, & Goldstein, 1970; Spreen & Benton, 1965). These groups, however, were comprised of subjects who had varying etiologies for their diffuse or lateralized brain damage with some cases likely including subjects who had both diffuse and lateralized damage, e.g., lateralized contusion or hematoma superimposed upon diffuse damage following severe TBI.

To better evaluate these original criteria for validity, as well as criteria that have evolved over time, it is helpful to use effect size analysis. The *standardized mean effect size*, generally defined, refers to the difference, in standard deviation units, between the mean performance of two groups on some dependent measure (Cohen, 1988). Typically, the standard deviation for this contrast is the pooled standard deviation of the control group and comparison group (Borenstein, Hedges, Higgins, & Rothstein, 2009), and the letter *d* is typically used to represent this effect size. The larger the effect size, the greater the separation of the test performance of the two comparison groups. Cohen (Table 2.2.1, p. 22, 1988) has provided percent nonoverlap for various magnitudes of *d*. Zakzanis, Leach, and Kaplan (Table 2.1, p. 13, 1999) have reported the percent of overlap as a function of the magnitude of *d*. For example, for a *d* of 1.0, the overlap percent is 44.6%, dropping to 18.9% for a *d* of 2.0, and 7.2% for a *d* of 3.0. As can be seen, the larger the value of *d*, the smaller the overlap percent, and the smaller the diagnostic error for both false positives and false negatives, resulting in an increase in both sensitivity (true positives) and specificity (true negatives).

The effect size is also related to the area under the receiver operating characteristic (ROC) curve. The ROC is derived by plotting the false positive error rate ( $1.0 - \text{specificity}$ ) on the x-axis and the true positive rate (sensitivity) on the y-axis for each potential cutting score comparing two groups on a diagnostic test (Hsaio, Bartko, & Potter, 1989; Swets, 1973). In ROC analysis, perfect discrimination is achieved at an area under curve (AUC) of 1.00, with chance discrimination falling at an AUC of .50, represented as the diagonal line traversing from zero false positive rate, and zero sensitivity, to perfect sensitivity and 100% false positives. AUC represents the probability of correctly classifying a randomly selected individual with the condition of interest as well as correctly classifying a randomly selected individual without the condition of interest. AUC of 0.7 to 0.8 have been characterized as acceptable, 0.8 to 0.9 as excellent, and 0.9 or more as outstanding (Hosmer & Lemeshow, 2000). When the distributions for the false positive errors and sensitivity each are normally distributed, there is a 1:1 correspondence between ROC AUC and the effect size, *d* (Rice & Harris, 2005). Thus, in studies where the effect size alone is either reported or calculable from the data presented, the effect size can serve as a proxy for the ROC AUC. In investigations where ROC AUC and the effect size are both reported, ROC AUC provides a more accurate quantification of diagnostic accuracy, as it encompasses the entire range of test scores for the two groups being compared (i.e., those with and those without the condition of interest).

ROC AUC can be used to compare the diagnostic accuracy of single tests, as well as of multiple measures utilizing the logit obtained from logistic regression analysis. Greve, Ord, Curtis, Bianchini, and Brennan (2008) demonstrated equal ROC AUCs for the Portland Digit Recognition Test, Test of Memory Malingering, and Word Memory Test, for discriminating nonmalingering patients with either TBI or chronic pain, from litigants characterized as malingering cognitive impairment of TBI or chronic pain. Loring et al. (2008) found a Cohen's *d* of .47 for the Rey AVLT (Rey, 1964) scores of right vs. left temporal lobe epilepsy, which was substantially higher than the *d* of 0.29 for the same comparison employing the CVLT (Delis, Kramer, Kaplan, & Ober, 1987). Comparing the performance of right versus left temporal lobe epilepsy groups on the BNT (Kaplan, Goodglass, & Weintraub, 1983) yielded a Cohen's *d* of 0.56, compared to a Cohen's *d* of 0.36 for the Benton Visual Naming Test (Benton, Hamsher, & Sivan, 1994). Colleagues and I reported a slightly greater ROC AUC derived from logistic regression for an ability-focused neuropsychological battery than for the primary HRB subtests in discriminating brain-injured patients from a pseudoneurologic control sample (Larrabee, Millis, & Meyers, 2008).

Loring and I (Loring & Larrabee, 2006) used Reitan's original validation data to derive effect sizes for contrasts of brain-impaired and nonimpaired subjects for subtests of the Wechsler-Bellevue. In some cases these effect sizes surpassed those of subtests comprising the HRB, although the HRB

did show the largest effect sizes overall. In the same paper, we reviewed subsequent publications that used the WAIS (Vega & Parsons, 1967; Kane, Parsons, & Goldstein, 1985) or WAIS-R (Sherer, Scott, Parsons, & Adams, 1994) that showed equal or superior effect sizes for the Wechsler scales in comparison to the HRB. For example, Sherer et al. found that the Full Scale IQ effect size,  $d = .92$ , was more than double that of the HRB Impairment Index,  $d = .43$ . Data analyzed from Kane et al. showed a WAIS Performance IQ (PIQ) effect size,  $d = 1.74$ , essentially equal to an HRB average T score,  $d = 1.63$ , and HRB Average Impairment Rating,  $d = 1.88$ . In a subsequent paper (Loring & Larrabee, 2008), we reported that the Verbal IQ (VIQ) effect size for the Kane et al. data,  $d = 2.40$ , was greater than any HRB effect size, as well as greater than the PIQ effect size.

As we emphasized (Loring & Larrabee, 2008), WAIS and HRB data that we reviewed show two interesting results. First, the similar and in some cases, greater effect sizes for the Wechsler scales versus the HRB in discriminating neurologically impaired from nonneurologically impaired subjects argues against the older notion that the HRB measures “biologic” intelligence whereas the Wechsler scales measure “psychometric” intelligence. These findings are best understood by the factor analyses of the WAIS-R, WMS-R, and HRB conducted by Leonberger et al. (1992), which showed that the HRB subtests loaded on the same factors as the subtests comprising the WAIS-R. The TPT and Category Test loaded on the same factor as the Picture Completion, Picture Arrangement, Block Design, and Object Assembly subtests. The Seashore Rhythm and Speech Sounds Perception tests loaded on the same factor as WAIS-R Arithmetic and WMS-R Digit Span and Mental Control. TMT-B split loadings between a perceptual organization factor and a processing speed factor, with Digit Symbol showing the same split in loadings, and Finger Tapping loading on the processing speed factor alone. Second, these data underscore that brain damage or dysfunction is not a unitary or unidimensional construct, otherwise why would WAIS VIQ show the largest effect size in the Kane et al. (1985) investigation, in comparison to PIQ and the HRB average impairment rating, and why would Sherer et al. (1994) find a PIQ effect size one-half of that reported by Kane et al., but double that found for the HRB Impairment Index in their own study?

Over the years, it has become obvious that “brain damage” is not a unitary or unidimensional construct, and in modern neuropsychology, the criterion is typically presence or absence of a particular *type* of brain dysfunction, and its differential impact on key neuropsychological abilities. For example, Zakzanis, Leach, and Kaplan (1999), reported larger effect sizes for measures of delayed recall for Alzheimer’s and depression, relative to other neuropsychological abilities. For subjects with Alzheimer’s disease, the delayed recall effect of 3.23 was nearly four times the effect of manual dexterity, 0.85, but in subjects who had Parkinson’s disease with dementia, the delayed recall effect size of 1.82

was less than the manual dexterity effect of 2.42, consistent with the primary effects of this disease on motor functions. These data show how different disorders differentially impact performance in the major domains of neuropsychological abilities.

The most commonly seen disorders include those resulting from TBI, stroke, and dementia (Lezak et al., 2012). TBI and dementia allow for analysis of the effects of diffuse brain dysfunction on neuropsychological domains of ability. TBI and dementia also allow for analysis of change in neuropsychological abilities over time, that is, recovery over time in moderate or severe TBI, and deterioration over time in dementia. Stroke allows for analysis of the effects of unilateral hemispheric dysfunction on both lateralized cognitive abilities, as well as on sensorimotor skills.

Certain modifiers of criterion validity are also important to consider, such as disease severity, and presence/absence of language comprehension impairment in left hemisphere stroke, and presence/absence of neglect in right hemisphere stroke. Tests that are sensitive to presence/absence of disease may not be the same tests that are sensitive to severity of disease in either TBI or dementia, nor may such tests show sensitivity to the everyday functional consequences of a particular disorder such as Alzheimer’s disease. On the one hand, failure of a task such as WAIS-III Block Design may represent a visuospatial problem solving deficit in a person with a right hemisphere stroke. On the other hand, patients with left hemisphere stroke may perform poorly on Block Design due to the effects of language comprehension impairment and disrupted verbal symbolic processes (employed by these subjects for problem solution, even on “nonverbal” tasks), rather than represent a purely visuospatial impairment.

In TBI, persisting impairments at one-year postinjury are not typically found, until the initial time to follow commands is between 1 to 24 hours (one hour to 24 hours of coma, Dikmen, Machamer, Winn, & Temkin, 1995). The only measures in a comprehensive neuropsychological battery that were sensitive to persistent deficit in this injury severity group were Verbal Selective Reminding (Buschke, 1973; Larrabee et al., 1988), a sensitive measure of verbal supraspan learning, and TMT-B (Reitan & Wolfson, 1993), a measure of psychomotor speed and set shifting. Additionally, the effect size for Verbal Selective Reminding, .46, was three times the effect size for TMT-B, 0.15, reflecting greater sensitivity of verbal memory than processing speed (Dikmen et al., 1995). Neuropsychological effects are clearly related to severity of TBI, as defined by time to follow commands, and using an overall test battery mean represented as an average z score (Dikmen et al., 1995; Rohling, Meyers, & Millis, 2003). In TBI, effect size for neuropsychological performance at one year posttrauma was  $d = -0.02$  for time to follow commands (TFC) of < one hour contrasted with the performance of an orthopedic trauma control group, increasing linearly to  $d = -0.22$  for 1–23 hours TFC,  $d = -0.45$  for 1–6 days TFC,  $d = -0.68$  for 7–13 days TFC,

$d = -1.33$  for 14–28 days TFC, and  $d = -2.31$  for > 28 days TFC (Rohling et al., 2003). The most severely injured group, which took more than one month to follow commands, produced an effect size of  $d = -2.31$ , more than two standard deviations worse than the least severely injured group, whose performance was basically identical to that of orthopedic trauma controls, with  $d = -0.02$ .

Similar results showing sensitivity of processing speed and memory to acquired deficits related to moderate and severe TBI have been reported for the WAIS-IV and WMS-IV (Wechsler, 2009). The WAIS-IV and WMS-IV index scores most sensitive to discriminating moderate to severe TBI subjects from demographically matched controls were Processing Speed ( $d = 1.32$ ) and all three WMS-IV primary indices (Auditory Memory Index,  $d = 1.25$ ; Visual Memory Index,  $d = 1.07$ , and Visual Working Memory Index,  $d = 1.26$ ).

Complimentary results have been reported by Miller, Fichtenberg, and Millis (2010), who evaluated the diagnostic discrimination of a group of subjects with mild, moderate, and severe TBI, as well as other neurologic disorders, from subjects who had cognitive complaints but no evidence for acquired neurological dysfunction (a “pseudoneurologic” control group). Miller et al. used an ability-focused battery covering five domains: language/verbal reasoning, visual-spatial reasoning, attention, processing speed and memory, using WAIS-III domain scores and select measures of neuropsychological function such as the CVLT-2, and TMT. ROC AUC was .89 based on the five domains, and .88 based on an average of the five domain scores. Based on processing speed and memory alone, the ROC AUC was .90.

In a neurological group that was comprised primarily of TBI and seizure disorder patients, performance on the AVLT Trial V (Rey, 1964; Lezak et al., 2012) was more sensitive to discriminating the neurologic group from a normal control group, than any other measure of performance, including tasks of verbal cognitive function, visual cognitive function, processing speed, attention/working memory, and visual memory function (Powell, Cripe, & Dodrill, 1991).

These data demonstrate that measures of verbal supraspan learning and processing speed are the most sensitive neuropsychological tests for detection of residual cognitive impairment following TBI. Effects of Alzheimer-type dementia also impact memory functioning and processing speed.

In Alzheimer’s disease (AD), the tests that are typically most sensitive to discriminating patients with AD from normal elderly are those measuring learning and memory, particularly tests involving a delayed recall trial (Larrabee, Largen, & Levin, 1985; Welsh et al., 1994; Zakzanis et al., 1999). On the WMS-IV (Wechsler, 2009), effect sizes for Auditory Memory ( $d = 2.24$ ) and Visual Memory ( $d = 2.00$ ) are substantial, with greater differences for delayed recall ( $d = 2.39$ ) than immediate recall ( $d = 2.16$ ), accompanied by effect sizes of similar magnitude for processing speed ( $d = 2.25$ ). Colleagues and I found a large effect size for WAIS Digit Symbol,  $d = 1.57$ , which was eclipsed by the effect size for

Verbal Selective Reminding of  $d = 2.53$  for words in consistent long-term retrieval, and  $d = 3.41$  for total words recalled (Larrabee et al., 1985).

Despite the sensitivity of memory tests to detection of cognitive impairment associated with AD in Larrabee et al. (1985), memory tests were not sensitive to severity of the disorder. In particular, we found that Verbal Selective Reminding, the most sensitive measure discriminating AD from normal elderly, did not correlate at all with severity of AD. By contrast, WAIS Information and Digit Symbol reflected significant correlation with disease severity, as measured by the Clinical Dementia Rating Scale (CDR; Hughes, Berg, Danziger, Coben, & Martin, 1982), or functional impairment, as measured by the Blessed, Tomlinson, and Roth (1968) dementia rating scale. Similarly, Griffith et al. (2006) found that subjects with Mild Cognitive Impairment (MCI), many of whom are likely in the beginning stages of AD, were discriminated from normal controls by the Hopkins Verbal Learning Test (HVLT; Brandt, 1991;  $d = 1.50$ ), but the HVLT did not discriminate MCI from AD ( $d = 0.06$ ); rather, it was semantic fluency that discriminated AD and MCI ( $d = 0.71$ ).

Studies of patients experiencing unilateral stroke allow not only for comparisons of the effects of lateralized brain insult on the six domains of function previously reviewed, but also allow for analysis of the moderating effects of conditions common to lateralized stroke. This includes analysis of the effects of auditory comprehension impairment consequent to aphasia following left-hemisphere stroke, and hemispatial neglect, which is common following right-hemisphere stroke.

Benton et al. (1994) have analyzed performance on a variety of visuo-perceptual and visuo-spatial tasks in relation to language comprehension impairment, and visual field defect. Performance on Facial Recognition, a task requiring the subject to match a black-and-white photograph of an unfamiliar person to photographs of the same person presented in different shading contrasts, is performed more poorly by patients with posterior right-hemisphere lesions (53% failure rate) than anterior right hemisphere lesions (26% failure rate). By contrast, Facial Recognition is passed by 100% of left-hemisphere stroke patients without aphasia (anterior and posterior), and 100% of left-hemisphere stroke patients with aphasia (anterior and posterior), but who have normal auditory comprehension. Before concluding that Facial Recognition performance can contribute to discrimination of lateralized brain dysfunction, however, it is important to note that 29% of anterior left-hemisphere stroke patients, and 44% of left-posterior stroke patients who have auditory comprehension impairment fail the Facial Recognition Test.

In an investigation of the effects of unilateral hemisphere damage on WAIS Verbal and Performance IQ, I found (Larrabee, 1986) that overall severity of language dysfunction in the group with left-hemisphere damage (LHD) was significantly correlated, at equal levels of magnitude, with WAIS Verbal IQ ( $-.77$ ) and Performance IQ ( $-.74$ ). Additionally, aphasia severity in the LHD group correlated significantly

with a number of so-called nonverbal subtests, including Block Design (−.44) and Object Assembly (−.72).

These data demonstrate that aphasia, in particular when accompanied by auditory comprehension impairment, is a moderating variable for performance on visual cognitive tasks, and must be considered in interpretation of what has traditionally been thought of as “nonverbal” performance in aphasic patients (e.g., WAIS-IV Block Design, Visual Puzzles). Benton, Sivan, et al. (1994) provide data showing that performance on Judgment of Line Orientation does not seem to be affected by presence/absence of auditory comprehension impairment, making this task important for the differential diagnosis of cognitive impairment secondary to one versus multiple infarctions. Hamsher (1991) also reported that performance on measures of global stereopsis was not disrupted by auditory comprehension impairment.

Hemispatial neglect, or inattention to the left hemispace in a right-handed individual, modifies the neuropsychological effects of right-hemisphere disease. Hemispatial neglect is a cognitive rather than a purely sensory phenomenon in that the lesions producing this condition need not involve sensory projection systems or primary sensory cortex (Heilman, Watson, & Valenstein, 2012). Neglect represents a failure of directed attention. Patients with a visual field cut without neglect will move the to-be-perceived object so that it will fall in the preserved visual field, whereas patients with neglect do not compensate for the field cut. On the Facial Recognition Test, patients with posterior right hemisphere stroke and field cut had a 58% failure rate, whereas those without field cut had a 40% failure rate (Benton, Sivan et al., 1994; note this difference was not statistically significant, and the authors did not differentiate the field cut group as to which subjects had or did not have neglect). Indeed, Trahan (1997) found that in particular, patients with left visual neglect showed impaired performance on the Facial Recognition Test. On the Line Orientation Test there was a nonsignificant trend toward a higher frequency of failure in patients with field defects (Benton, Sivan, et al., 1994). Although Benton, Sivan, et al. (1994) did not analyze the effects of neglect on the Visual Form Discrimination test, they do point out that the use of peripheral figures in both the right and left hemispace allows for analysis of neglect in the individual case.

The presence of neglect in association with right-hemisphere injury may reflect a more generalized attentional impairment following right-hemisphere stroke. Trahan, Larrabee, Quintana, Goethe, and Willingham (1989) reported a 56% rate of impairment for acquisition, and 48% rate of impairment for delayed recall on the Expanded Paired Associate Test (EPAT; Trahan et al., 1989) for left-hemisphere stroke patients, which was approximately double the failure rate of patients who had right-hemisphere stroke (25% for acquisition, and 23% for delayed recall). Performance on WAIS-R Digit Span, a measure of attention and working memory, was related to EPAT performance for the right- but not the left-hemisphere

stroke patients. This suggested that reduced attention may have contributed to poor EPAT test performance in the right hemisphere stroke group. Data were unavailable, however, to determine whether there was a higher rate of neglect in those right CVA patients with attentional impairment, who also performed poorly on the EPAT.

Criterion validity also is evaluated by correlation of neuropsychological performance with important activities of daily living such as working, driving a car, and making financial decisions. This has also been referred to as *ecologic validity*. Measures of working memory, processing speed, verbal fluency, visuospatial ability, and calculational skills appear to be particularly significant predictors of these activities of daily living.

Williams, Rapport, Hanks, Millis and Greene (2013) found that neuropsychological tests predicted outcome on the Disability Rating Scale, and return to work, independent of and in addition to predictions based on admission Glasgow Coma Scale, and presence of CT scan abnormalities. Particularly significant predictors were Trail Making A and B, Grooved Pegboard, the Symbol Digit Modalities test, and measures of visuospatial ability. Interestingly, verbal learning and memory skills measured by tests such as the AVLT or CVLT, were *not* sensitive predictors of important activities of daily living.

Driving ability has been correlated with performance on Trail Making B in patients who have suffered severe TBI (Novack et al., 2006), and in patients with questionable dementia (Whelihan, Dicarolo, & Paul, 2005). Rizzo and Kellison (2010) recommend that predictions of driving ability be made based on performance on raw scores that have not been demographically corrected for age and education, since what matters on the road is pure ability regardless of demographic characteristics.

Financial capacity in Alzheimer’s disease was related to performance on a variety of neuropsychological tests measuring working memory and oral calculational abilities (Earnst et al., 2001). Digits Forward was related to understanding a bank statement, whereas Digits Reversed related to all four aspects of basic monetary skills. WAIS-III Letter-Number Sequencing related to several domains of monetary capacity. The Arithmetic subtest related to basic monetary skills, and checkbook and bank statement management (Earnst et al., 2001). Sherod et al. (2009) found that written arithmetic skill (WRAT-3, Wilkinson, 1993) predicted financial capacity for control subjects, those with mild Alzheimer-type dementia, and those with amnesic MCI.

Marson, Ingram, Cody, and Harrell (1995) found that capacity to make medical decisions was related to word fluency (Controlled Oral Word Association), but not to memory performance or overall severity of cognitive impairment, in patients with AD. This was despite significant differences in global cognitive function, and memory function, between patients with AD and normal controls. This result is strikingly similar to the findings of Larrabee et al. (1985); Griffith

et al. (2006); and Earnst et al. (2001), showing that although memory tests are the most sensitive discriminators of AD and normal elderly, nonmemory cognitive skills, specifically, verbal symbolic abilities, are more sensitive to severity of dementia, and to accompanying impairments in activities of daily living.

### ***A Hypothetical Ability-Focused Neuropsychological Battery***

In Larrabee (2014) I proposed a hypothetical ability-focused neuropsychological battery based upon (a) factor analytic support for each test as measuring one of the six primary neuropsychological factors with (b) evidence showing sensitivity to presence of neuropsychological deficits, and/or (c) showing evidence of sensitivity to the severity of effects of a neurobehavioral disorder such as what occurs with moderate and severe TBI or AD, and/or (d) showing significant correlations with activities of daily living, and/or (e) containing an embedded/derived measure of performance validity. Choice of a particular test for inclusion in this battery would depend largely upon how many of these five criteria were met by the measure. Primary criterion groups would include moderate and severe TBI, probable AD, and left- and right-hemisphere stroke for analysis of lateralized neuropsychological deficits as well as for evaluation of moderating effects of language comprehension impairment in left-hemisphere stroke, and left unilateral neglect in right-hemisphere stroke.

With the exception of discussing tests of performance validity, I have reviewed much of the same validity literature in this chapter as I did in Larrabee (2014). The reader is referred to Boone (Chapter 4 in this volume) for in-depth discussion of embedded/derived measures of performance validity, and to Larrabee (2014) for more in-depth discussion of the framework for development of an ability-focused neuropsychological battery. I have previously made the distinction between performance validity tests (PVTs), which assess whether the examinee is providing an accurate measure of his or her actual ability, and symptom validity tests (SVTs), which assess whether an examinee is giving an accurate report of his or her actual symptom experience, as would be captured on omnibus personality inventory validity scales, pain scales, and scales assessing self-reported cognitive functions (Larrabee, 2012a). Embedded and derived PVTs typically capture extremely poor performance on simple motor skills, unrealistically low basic visual perceptual discrimination skills, extremely poor working memory, poor recognition compared to recall on memory testing procedures, and atypical errors on recognition memory scores and on problem solving tasks. In other words, performance is either atypically low/poor, or falls in a pattern that is atypical for what is seen in patients who have bona fide neuropsychological impairments from significant neurologic, developmental, or psychiatric disorders.

The hypothetical battery I proposed (Larrabee, 2014) included the following.

- *Verbal symbolic ability*: COWA, Animal Naming, WAIS-IV Information and Similarities, WRAT-IV Reading and Arithmetic
- *Visuoperceptual visuospatial judgment and problem solving ability*: Benton Visual Form Discrimination, WAIS-IV Block Design, Visual Puzzles, WCST
- *Sensorimotor skills*: Grip Strength, Finger Tapping, Grooved Pegboard
- *Attention/working memory*: WAIS-IV Digit Span, Arithmetic, Letter-Number Sequencing, WMS-IV Symbol Span
- *Processing speed*: TMT, WAIS-IV Symbol Search, Coding, and the Stroop
- *Learning and memory (verbal)*: the AVLT, WMS-IV Logical Memory and Verbal Paired Associates
- *Learning and memory (visual)*: WMS-IV Visual Reproduction, CVMT, CRM (Hannay et al., 1979)

This hypothetical ability-focused battery contains 27 measures (11 of which require 5 minutes or less to administer, with a total estimated time of administration of 4.5 hours). Additionally, this hypothetical core battery includes ten embedded and derived measures of performance validity based on the following tests: Visual Form Discrimination (Larrabee, 2003b), Finger Tapping (Arnold et al., 2005; Larrabee, 2003b), Logical Memory Recognition and Verbal Paired Associates Recognition (Pearson, 2009), AVLT (Barash, Suhr, & Manzel, 2004; Boone, Lu, & Wen, 2005; Davis, Millis, & Axelrod, 2012), Visual Reproduction Recognition (Pearson, 2009), CVMT (Larrabee, 2009), CRMT (Hannay et al., 1979; Larrabee, 2009), WAIS-IV Digit Span (Jasinski, Berry, Shandera, and Clark, 2011), and the WCST (Greve, Heinly, Bianchini, & Love, 2009; Larrabee, 2003b).

This compares to 34 measures if one were to administer all of the tests comprising the Heaton et al. (2004) normative data (23), plus all of the WAIS-R subtests (11) in this database, and 36 tests if the entire Neuropsychological Assessment Battery (NAB; Stern & White, 2003) is administered. The Meyers Neuropsychological Battery (MNB; Meyers & Rohling, 2004) contains 22 measures, with 11 embedded and derived PVTs, but uses single tests to represent motor and tactile ability, verbal and visual memory. Additionally, tests were selected for the MNB based upon their discrimination of various neurological groups; i.e., sensitivity to presence of disorder. Test selection was not also based on sensitivity to severity of impairment, or prediction of activities of daily living.

### **Psychometric Issues Related to Interpretation of Test Scores**

Neuropsychological test scores for test procedures falling in each of the domains of ability including *verbal symbolic*,

*visuoperceptual visuospatial judgment and problem solving, sensorimotor, working memory, processing speed, and learning and memory*, are measures of human capabilities and vary as a function of several factors that are independent of brain dysfunction, psychiatric, or developmental disorders, including age, education, sex, and ethnicity (Heaton et al., 2004; Holdnack & Weiss, 2013). Consequently, these factors that are independent of disease or clinical disorders must be taken into consideration in demographic adjustments to raw test scores. Otherwise, one runs the risk of overidentifying impairment (elevated false positive rate) in persons with low premorbid ability, and underidentifying impairment (elevated false negative rate) in persons with high premorbid ability. Key demographic factors include age, which shows greatest impact (cross-sectionally) on measures of *verbal and visual learning and memory, processing speed, and novel visuoperceptual visuospatial problem-solving* skills such as the Category Test (Heaton et al., 2004; Larrabee, 2014); educational and occupational attainment, which are most-strongly associated with *verbal symbolic and attention/working memory* abilities (Heaton et al., 2004; Holdnack & Weiss, 2013; Larrabee, 2014); and sex, which is correlated with performance on *verbal learning and memory* measures such as the VSRT (Larrabee et al., 1988), and CVLT (Delis et al., 1987), as well as related to performance on measures of *sensorimotor* skills such as Finger Tapping and Grip Strength (Heaton et al., 2004). Holdnack and Weiss (2013) present case examples of how appropriate adjustment for demographic factors can alter findings in two clinical cases.

Demographic adjustments are typically done in one of two ways. The first is to simply aggregate normative (i.e., nonclinical) subjects into groups with similar demographics (e.g., adult males with less than high school education, in ten-year increments of age, with age groups repeated for males with high school education, etc., with the same done separately for females). Numerous examples of this type of normative process are reported in Strauss, Sherman, and Spreen (2006). A second major approach uses multiple regression to predict test scores by the relevant demographic characteristics, with norms based on the residuals that remain after adjustment for the demographic factors (e.g., Heaton et al., 2004; also see Mitrushina, Boone, Razani, & D'Elia, 2005, for a regression approach based on meta-analytically derived normative data).

A third way, at least for WAIS-IV scores, is to administer a measure of accuracy of sight reading, the Wechsler Test of Premorbid Function (TOPF; Pearson, 2009), which is used in conjunction with demographic factors to estimate premorbid level of function for the four WAIS-IV Index scores, and compare the examinee's current level of function to his or her premorbid estimates. This is based on the long-supported evidence that sight reading—in particular, sight reading of irregularly spelled words such as *corps*—is relatively preserved even in patients with disorders such as early stage Alzheimer-type dementia (Holdnack, Schoenberg, Lange, &

Iverson, 2013; Pearson, 2009). Of course, one must compare current reading ability to demographically estimated level, to ensure that reading ability itself is not affected by suspected acquired impairment; if this is the case, prediction is recommended based on demographics alone (Pearson, 2009). This approach is best reserved for the WAIS-IV, as the premorbid estimates for the WMS-IV have relatively large errors of estimate, and there is only a predictive relationship when demographic factors are included with the TOPF; demographic factors alone (e.g., educational and occupational attainment) do not predict WMS-IV performance (Holdnack et al., 2013), with the obvious exception of age. Holdnack et al. (2013) also discuss use of the Oklahoma Premorbid Intelligence Estimate (OPIE), which includes current performance on WAIS-IV subtests, as well as demographic factors to predict premorbid level of function. Of course, this approach results in a contamination of predictor with criterion, in which subtests comprising Full Scale IQ are also used to predict IQ, referred to by Holdnack et al. as inflation of prediction due to auto-correlation of the test with itself.

Thus, someone using demographically corrected index scores for the WAIS-IV is already adjusting for premorbid level of function, in contrast to using unadjusted (with the exception of age) scores, in comparison to estimated premorbid level of function. An interesting comparison, which I do not think has been conducted, would be to see whether demographically corrected WAIS-IV index scores are comparable in sensitivity to mild Alzheimer-type dementia, contrasted with an approach using demographically uncorrected (with the exception of age-correction) scores which themselves are compared to TOPF-estimated premorbid level of function.

Some have recommended comparing current level of performance for all neuropsychological tests to estimated premorbid level of intellectual function (i.e., premorbid IQ; Tremont, Hoffman, Scott, & Adams, 1998; Miller & Rohling, 2001). This approach would be expected to work better, that is, be more accurate, for those abilities more closely associated with IQ, including *verbal symbolic ability and visuoperceptual visuospatial judgment and problem solving ability, working memory, and processing speed*. Such an approach would work less well with abilities such as memory, which are less strongly related to traditional IQ scores (Holdnack et al., 2013; Larrabee, 2000), but show their strongest associations with age (Larrabee, 2014).

Scores on individual tests that have been scored using the appropriate normative base are typically interpreted, on a test-by-test basis, in reference to their standing in comparison to the normative group, either relying upon z or T scores relative to the standard normal curve, or by percentile rank for test scores that do not follow a normal distribution. This interpretive approach is somewhat akin to that in clinical medicine in which ranges of performance for normal and abnormal results are described for various laboratory values (e.g., white blood cell count, hematocrit, etc.). In the case of neuropsychological test score interpretation, the focus

is a deficit-based approach. Different authors have recommended different interpretive schemes. For example, Heaton et al. (2004) use a T score based approach (mean = 50, SD = 10) to define 55+ as *above average*, 45–54 as *average*, 40–44 as *below average*, 35–39 as *mild impairment*, 30–34 as *mild to moderate impairment*, 25–29 as *moderate impairment*, 20–24 as *moderate to severe impairment*, and 0–19 as *severe impairment*. Using a global composite score, the Average Impairment Rating, Heaton et al. (2004) reported that defining impairment as a cutting score of T < 40 correctly classified 85.6% of 1,212 normal subjects as nonimpaired (85.6% specificity), and 77.1% of 436 brain-damaged patients as impaired (77.1% sensitivity). Benton, Sivan, et al. (1994) define *defective* as the bottom 5%, with scores in the bottom 1% as *severely defective*, and scores in the range of the sixth to 16th percentile considered to be *borderline*. On the WAIS-IV (Wechsler, 2008), scores in the range of 70–79 (third to 10th percentile) are considered to be *borderline*, with scores of 69 and below (second percentile) considered to be *extremely low*.

Heaton et al. (2004) caution against overinterpreting performance on the HRB as impaired, based solely on tabulating the number of scores falling in the impaired range. They report that in a large sample of 1,189 neurologically normal individuals, only 13.2% had no T score in the impaired range, and the group median was three abnormal scores out of 25. Binder, Iverson, and Brooks (2009) review the extensive literature on this topic, noting that it is common not only to find multiple impaired scores consequent to administering batteries of individual tests, but also to find large discrepancies between separate neuropsychological skills such as *verbal symbolic functions* and *verbal learning and memory*. Binder et al. (2009) conclude that abnormal performance on some proportion of tests in a battery is psychometrically normal, thus several abnormal scores in a large test battery do not necessarily imply the presence of acquired brain dysfunction. They also conclude that although people with higher IQ scores tend to have fewer low scores than people with lower IQ scores, normal persons of high intelligence often have some low test scores, large variability between highest and lowest scores is psychometrically normal, and the degree of normal variability is greater in those people with higher IQ scores.

In order to minimize the error of misinterpreting low scores or large variability between scores as showing impairment when such patterns are normal, Binder et al. (2009) recommend looking for consistencies across the data, and checking to see if the data match with the clinical history, neurodiagnostic data, and other clinical information. For example, consider two cases that each show three poor performances. The first is a 70-year-old man with a two-year history of memory decline, who produces poor performance on WMS-IV Logical Memory, Verbal Paired Associates, and the AVLT. The second case is a 25-year-old man who has vague cognitive complaints leading to referral, and produces

poor performance on Finger Tapping, WAIS-IV Arithmetic, and Animal Naming, with normal Grooved Pegboard, Trail Making B, and AVLT performance. The history and context for evaluating these two sets of poor scores lead to different conclusion regarding the consequences of the three poor performances in each of these two cases. I have offered a four-part model for analysis of consistency of test performance (Larrabee, 1990; Larrabee, 2012b):

- 1 Are the data consistent within and between domains?
- 2 Is the neuropsychological profile consistent with the suspected etiology?
- 3 Are the neuropsychological data consistent with the documented severity of the injury (or illness)?
- 4 Are the neuropsychological data consistent with the subject's behavioral presentation?

Crawford, Garthwaite, and Gault (2007) provide a statistical approach based on the Monte Carlo simulation, which allows determination of the number of “impaired” scores occurring by chance, as a function of the number of tests administered, and the average intercorrelation between those tests. The Crawford et al. (2007) procedure also allows determination of the significance of large discrepancies occurring in a battery of tests as a function of the number of tests administered. While this provides very helpful statistical guidance, one must still analyze the clinical history and other contextual information to arrive at the most appropriate interpretation of the data.

Co-normed batteries such as the comprehensive norms for an expanded HRB (Heaton et al., 2004), the NAB (Stern & White, 2003), and the WAIS-IV/WMS-IV (Wechsler, 2009) allow for direct comparisons using different subtests with a common normative basis. Rohling and colleagues have developed an approach for aggregating individually normed tests: the Rohling Interpretive Method (RIM; Miller & Rohling, 2001; Rohling, Miller, & Langhinrichsen-Rohling, 2004), which is derived from effect size methodology with creation of linear composite scores including an Overall Test Battery Mean, and domain means for *verbal comprehension*, *perceptual organization*, *executive functions*, *memory*, *attention concentration*, and *processing speed*, with separate measurement of *symptom validity*, *personality factors*, *premorbid level of function*, *language comprehension*, and *sensory perceptual skills* (Miller & Rohling, 2001; Rohling et al., 2004). This procedure has been incorporated into the MNB, to aggregate norms developed independently for separate tests such as the AVLT and the TMT. The MNB norms, based on aggregated norms across different samples, are smoothed for demographic effects of age, gender, and education, based on a large sample of neurological, pain, and psychiatric patients (i.e., the norms are based on non-clinical subjects, with further smoothing of the norms using multiple regression to account for any additional effects of age, gender, and education, as based on clinical patient

performance, essentially creating a normative “hybrid”). In a recent comparison of normative databases for tests common to the MNB, expanded HRB (Heaton et al., 2004), and the normative data presented by Mitrushina et al. (2005), there were essentially identical results for the performances scored using the co-norms of Heaton et al. (2004), meta-analytic (composite) norms of Mitrushina et al. (2005), and the hybrid (composite and regression smoothed) norms of the MNB (Rohling et al., 2015). Similarly, the hybrid normative database yielded essentially identical overall effect size and correlation with severity of TBI comparing an independent sample of TBI patients to the TBI sample investigated by Dikmen et al. (1995) using an expanded HRB, that included additional measures of memory and intellectual function (Rohling et al., 2003). This direct comparison of the aggregated norm approach characteristic of flexible battery approaches to the co-normed approach characteristic of fixed batteries supports the comparability of aggregated norm approaches, particularly when employing a statistically based approach such as the RIM (Miller & Rohling, 2001; Rohling et al., 2004).

In contrast to the earlier discussion regarding the importance of using demographically corrected scores in assessment and diagnosis of brain dysfunction, there is evidence suggesting that for prediction of functional outcome in activities of daily living, uncorrected or “absolute” scores can provide information above and beyond that provided by the corrected scores. As already noted, Rizzo and Kellison (2010) found that raw scores may be better predictors of driving ability than are scores corrected for age and education. Silverberg and Millis (2009) reported that absolute scores (Heaton et al., 2004)—norms for a general healthy adult population—predicted selected measures of functional outcome and functional status better than demographically adjusted scores (adjusted for age, gender, education, and race) for patients with TBI (median Glasgow Coma Scale [GCS] of 9).

## Summary

This chapter reviewed the psychometric foundations of neuropsychological assessment, starting with the definition of what a test entails. This was followed by discussion of reliability and validity. The discussion of validity followed a recent paper (Larrabee, 2014) that provided a framework for comprising an ability-focused neuropsychological battery that is based on factor-analytically derived domains of performance, populated by procedures showing sensitivity to presence of impairment, sensitivity to severity of impairment, and prediction of instrumental activities of daily living, and containing embedded/derived measures of performance validity. In the final section of the chapter, psychometric issues related to normal test score variability were considered, as well as issue related to utilization of co-normed versus individually normed tests.

## 4 Assessment of Neurocognitive Performance Validity

*Kyle Brauer Boone*

Prior to the 1990s, little literature existed on psychometric methods to document noncredible performance during neurocognitive testing, but in the intervening decades there has been an explosion in the development and validation of techniques to objectively identify failure to perform to true ability (see Boone, 2007, 2013; Larrabee, 2007; Victor, Kulick, & Boone, 2013a,b), termed *performance validity tests* (PVTs; Larrabee, 2012). Practice recommendations indicate that PVTs are to be interspersed “throughout the evaluation” (National Academy of Neuropsychology, Bush et al., 2005), and that both “embedded” and “freestanding” PVTs should be utilized (American Academy of Clinical Neuropsychology; Heilbronner et al., 2009).

Freestanding PVTs serve a single purpose in assessing for negative response bias, while embedded indicators are derived from standard neurocognitive tests, and thus serve “double duty” both as measures of performance validity but also as techniques to evaluate neurocognitive function. The field of clinical neuropsychology will likely move to primary, if not exclusive, use of embedded PVTs because they do not require extra test administration time, and are more shielded from attempts at coaching and education because of their main purpose as measures of neuropsychological function. Further, they allow for evaluation of performance validity in “real time” rather than requiring that results from PVTs administered at one point in the exam be used to determine validity of neurocognitive test performance at a different point in the testing. Unfortunately, embedded indicators have developed a reputation as “second-rate” PVTs because it has been widely believed that they are less sensitive in identifying noncredible performance than “dedicated” PVTs. However, this is not entirely accurate: While overall sensitivity rates are probably lower for embedded PVTs as a group, as shown in tables in Boone (2013), dedicated and embedded PVTs both have sensitivity rates within the range of >20% to 80%. For example, at cutoffs recommended by the test developer, sensitivity of the Test of Memory Malingering (TOMM; Tombaugh, 1996) to noncredible performance in traumatic brain injury is only 48% to 56% (Greve, Ord, Curtin, Bianchini, & Brennan, 2008). While many embedded indicators also have sensitivity rates that approximate 50% (Digit Span variables, Babikian, Boone, Lu, & Arnold, 2006; Finger Tapping, Arnold et al., 2005; CVLT-II; Donders & Strong, 2011, Wolfe

et al., 2010; Stroop A and B, Arentsen et al., 2013), others equal or exceed 65% (Picture Completion Most Discrepancy Index, Solomon et al., 2010; RAVLT effort equation, Boone, Lu, & Wen, 2005), while still others achieve at least an 80% detection rate (Digit Symbol recognition; Kim, N., et al., 2010; RO effort equation, Reedy et al., 2013).

Negative response used to be viewed as a unitary and static characteristic of the test taker, but available data indicate that only a minority of noncredible patients engage in negative response bias on every measure administered during a neuropsychological exam. Rather, the large majority (>80%; Boone, 2009) “pick and choose” tests on which to demonstrate impairments, under the apparent belief that poor performances on all tasks will not be credible. Test takers may elect to underperform at particular times during the exam (e.g., at the end when “fatigued,” at the beginning to illustrate that they do not function early in the day, etc.). Alternatively, they may decide to display deficits on particular types of tasks that they believe are consistent with their claimed condition. For example, research suggests that test takers performing in a noncredible manner in the context of claimed mild traumatic brain injury (mTBI) overselect verbal memory tests on which to underperform, whereas individuals feigning cognitive impairment in the setting of claimed psychiatric disorder appear to target timed, continuous performance test (CPT)–type tasks on which to perform poorly (Nitch, Boone, Wen, Arnold, & Warner-Chacon, 2006; Roberson et al., 2013). Further, even within the same claimed condition, test takers may adopt differing approaches to underperformance. The following two cases illustrate examples of differing strategies of feigning in the context of claimed mTBI.

### **Case #1: Feigned Verbal Memory and Math Impairment**

This 41-year-old female litigant worked in public relations and had completed an AA degree. She was tested five years after a motor vehicle accident in which she, at most, sustained a mTBI; any loss of consciousness was equivocal, there was no retrograde or anterograde amnesia, and she was alert and oriented in the hospital and released the same day. She continued to work, and handled all activities of daily

living (ADLs) independently. At the time of the exam she was reporting headaches, back pain, numbness/tingling in her right arm, cognitive difficulties including “struggles” with memory, and anxiety/depression.

She failed PVTs confined to verbal memory: Warrington Words: (total = 32; time = 201"; failed cut-offs for women; Kim, M., et al., 2010) and RAVLT (recognition false positives = 5 [failed]; effort equation = 13 [passed]; Boone et al., 2005). However, she passed indicators from nine other tests mostly tapping other cognitive domains: b Test (E-score = 42; Roberson et al., 2013), Rey Word Recognition (12; Bell-Sprinkel et al., 2013), Digit Symbol recognition (178; Kim, N., et al., 2010), Picture Completion Most Discrepant Index (5; Solomon et al., 2010), Digit Span variables (Age-Corrected Scale Score [ACSS] = 11; Reliable Digit Span [RDS] = 10; three-digit time = 1.5"; Babikian et al., 2006), Rey-Osterrieth (RO) Effort equation (61; Reedy et al., 2013), Logical Memory equation (64.5; Bortnik et al., 2010), and Trails A (18"; Iverson, Lange, Green, & Franzen, 2002), and Stroop A and B (A = 39"; B = 56"; Arentsen et al., 2013).

Across the neuropsychological battery, all scores were within the average range or higher with the exception of a borderline score in math calculation ability and a low average score in delayed verbal recall (verbal memory scores ranged from low average to average). On previous testing six months after the injury, math calculation ability was average, and verbal memory was average to high average. Thus, the weaknesses observed on current testing were not corroborated on testing completed closer in time to the injury. Minnesota Multiphasic Personality Inventory – 2 – Restructured Form (MMPI-2-RF) scales were unelevated with the exception of sanitizing of negative personal characteristics (L-r = 66T). The patient attributed her headaches to the mTBI, but chronic headache is not found post-mTBI in countries without a tort system (Mickeviciene et al., 2004), and the patient in fact had well-documented headaches, as well as an extensive history of chronic pain and vague medical symptoms, prior to the accident.

### **Case #2: Feigned Impairment in Visual Memory, Vigilance/Processing Speed, and Sensory Function**

This 59-year-old female litigant worked as a mid-level executive and had completed an MBA. She was tested four years after a motor vehicle accident in which she sustained equivocal loss of consciousness. She called emergency personnel to the scene but did not seek medical attention except for chiropractic care. She continued to be active in her profession and church, and to handle all ADLs independently. When asked as to symptoms related to the accident, the patient reported multiple cognitive difficulties including lack of focus, mental slowness, difficulty processing information, “dyslexia,” problems in multitasking, and becoming “visually lost,” as well as orthopedic pain, difficulty hearing, development of sleep apnea, and emotional dyscontrol.

She failed PVTs involving processing speed/vigilance, such as b Test time (805"; E-score = 58 [passed]; Roberson et al., 2013), Dot Counting Test E-score (23; Boone, Lu, & Herzberg, 2002), Stroop (A = 98"; B = 123"; Arentsen et al., 2013), and Digit Symbol (ACSS = 4 [failed]; recognition equation = 80 [passed]; Kim, N., et al., 2010), as well as PVTs involving visual perception/spatial skill/memory (Picture Completion Most Discrepant Index = 2, Solomon et al., 2010; RO effort equation = 49, Reedy et al., 2013), basic attention (Digit Span: mean time per digit = 1.05" [failed], ACSS = 7 [passed], and RDS = 8 [passed]; Babikian et al., 2006), and finger speed and sensation (Tapping dominant = 26, Arnold et al., 2005; Finger Agnosia errors = 4, Trueblood & Schmidt, 1993). In contrast, she passed all verbal memory PVTs (Warrington Words = 50, 82," Kim, et al., 2010; Rey Word Recognition = 9, Bell-Sprinkel et al., 2013; RAVLT effort equation = 18, Boone et al., 2005), as well as Trails A (45"; Iverson et al., 2002) and Rey 15-item plus recognition (30; Boone, Salazar, Lu, Warner-Chacon, & Razani, 2002).

Across the neuropsychological exam, impaired scores were observed in motor dexterity, while impaired to low average scores were documented in processing speed and visual perceptual/constructional skill, and basic attention was low average; all other scores were average or higher. The failed PVT performances predicted which standard cognitive scores were lowered. The abnormal neurocognitive scores, if accurate, would be inconsistent with the patient’s functionality in all activities of daily living. Further, on testing completed two years after the injury, all scores on measures of attention, processing speed, and motor dexterity were average; thus, low scores on current exam were not corroborated on the exam closer in time to the injury. On the MMPI-2-RF, the only elevated validity scale was FBS-r (80T), suggestive of noncredible overreport of physical and cognitive symptoms, and substantive scales involving physical symptom report were also elevated. In addition, multiple scales were elevated reflecting anxiety, depression, cycling mood disorder, and anger-related disorder. Such psychiatric symptoms are not empirically verified sequelae of remote mTBI (Panayiotou, Jackson, & Crowe, 2010), nor are the patient’s complaints of chronic headache, loss of hearing, and development of sleep apnea.

In these cases, if PVTs had not been administered that covered a wide range of cognitive domains, the nature and extent of the negative response bias would not have been documented. Fortunately, numerous PVTs have now been validated within each of the cognitive domains (i.e., attention, processing speed, verbal and visual memory, executive, motor dexterity, sensory, visual perceptual/spatial, and language), and are listed and described in tables found in Boone (2013) and Victor et al. (2013a, 2013b).

### **Interpretation of Data From Multiple PVTs**

Given that the recommendation is now to check for performance validity repeatedly during neuropsychological exams and within each cognitive domain (with the eventual goal

of performance validity indicators for every task to check for performance veracity in real time), it is imperative to develop sound methods for interpreting the data from the various measures in combination. PVT cutoffs are traditionally set to allow a false positive rate of <10%. If a single PVT is administered, credible patients are not adequately protected (i.e., if they perform abnormally, they could be within the 10% of credible patients who fail the measure, yet they will be determined to be noncredible). The best method to protect credible patients is to administer multiple PVTs because while a single failure is not particularly unusual across several PVTs administered (i.e., 41% of credible neuropsychology clinic outpatients with various neurologic and psychiatric diagnoses fail a single PVT; Victor, Boone, Serpa, Beuhler, & Ziegler, 2009; see also Schroeder & Marshall: 19% of psychotic and 17% of nonpsychotic psychiatric patients failed a single PVT), failure on multiple PVTs is relatively rare. For example, Victor et al. (2009) found that only 5% of their credible sample failed two PVTs (out of four), Schroeder and Marshall (2011) reported that 5%–7% of psychiatric patients failed two PVTs (out of seven), and Larrabee (2003) observed that 6% of his credible moderate to severe traumatic brain injury sample failed two validity measures (out of four PVTs and one SVT), a remarkably consistent pattern of findings. Victor et al. (2009) further reported that only 1.5% of their sample failed three PVTs, and zero failed four, while Larrabee (2014) reported that 4% of his sample failed three measures (out of six PVTs and one SVT), with no false positive identifications after three failures. Other researchers have documented that two to three PVT failures are associated with 100% specificity (Chafetz, 2011; Davis & Millis, 2014; Meyers & Volbrecht, 2003; Meyers et al., 2014; Schroeder & Marshall, 2011; Sollman, Ranseen, & Berry, 2010; Vickery et al., 2004). Larrabee (2008) demonstrated that, using posterior probabilities, the probability that a test taker who fails three PVT cutoffs is in fact noncredible is essentially 99%, a finding recently confirmed by Meyers et al. (2014).

Berthelson, Mulchan, Odland, Miller, and Mittenberg (2013), citing results from a Monte Carlo simulation, argued that if PVTs are correlated at approximately .3 (as documented by Davis & Millis, 2014; Nelson et al., 2003), the false positive rate for two PVT failures (with cutoffs set to 90% specificity) in a credible population is 11.5%. They further assert that if PVT cutoffs are adjusted to result in 85% specificity, two failures occur in nearly 20% of credible patients. However, cutoffs typically are selected to achieve a false positive rate of <10%, precisely so that credible patients are adequately protected. To check the accuracy of Berthelson et al.'s (2013) simulation, Davis and Millis (2004) subsequently examined PVT false positive rates in a neurologic population with no motive to feign impairment, and observed that when six to eight PVTs are administered (with cutoffs set to 90% specificity), the actual occurrence of one or two failures was lower than predicted by Berthelson et al. (2013), and there was no significant relationship between number of

PVTs administered and number failed ( $r = .10$ ). Similarly, Larrabee (2014) also found that the Monte Carlo simulation overestimated that rate of multiple PVT failures in credible populations, likely because PVT data do not have normal score distributions required for use of the simulation model.

The question arises as to whether “passed” PVTs “cancel out” any failures. However, there is an inverse relationship between test sensitivity and specificity, such that when test cutoffs are selected to enhance specificity (i.e., allowing only a 10% failure rate), sensitivity will be lowered, thereby rendering failed performances more informative than passing scores. That is, if specificity of individual PVTs is >90%, and sensitivity rates range from <50% to 80%, scores on individuals PVTs will be more effective in ruling in than ruling out noncredible performance. Further, as discussed earlier, noncredible test takers are likely selecting specific tasks, and particular times, during the exam on which to underperform, rather than electing to fail to perform to true ability on all tests administered. As such, it is expected that they will pass some PVTs during the portions of the exam that they are choosing not to perform poorly.

To summarize, the current recommendation in the field of clinical neuropsychology, particularly in the context of a forensic exam in which there is compensation seeking or other external motive to present oneself as more impaired than is actually the case, is that multiple PVTs are to be administered, interspersed throughout the exam, to cover multiple cognitive domains (if not for every task administered), so that performance validity is repeatedly sampled.

In addition to failing scores on PVTs, additional confirming evidence of a noncredible presentation is typically present, including: (a) nonsensical change in scores on sequential neuropsychological examinations, particularly dramatic declines in scores remote from the injury; (b) mismatch between performance on PVTs and evidence as to how the test taker actually functions in activities of daily living; (c) report of nonplausible symptoms (inability to recall birth date and other overlearned personal and family information; chronic headache, loss of hearing, development of sleep apnea, etc., in the context of mTBI); and (d) evidence from personality inventories, such as the MMPI-2-RF, of noncredible cognitive symptom overreport (e.g., MMPI-2-RF RBS and FBS-r), often in conjunction with denial of antisocial and exploitive behaviors (Cottingham et al., in press). In most cases, observations gleaned from these sources of information and PVT data render conclusions straightforward.

However, there are two noteworthy exceptions: individuals with dementia and individuals with very low intellectual scores (Full Scale IQ [FSIQ] <70). As discussed earlier, multiple failures on PVTs virtually never occur in credible populations, but patients with dementia and low IQ have been documented to fail PVTs at a high rate despite performing to true ability (Dean, Victor, Boone, & Arnold, 2008; Dean, Victor, Boone, Philpott, & Hess, 2009; Meyers & Volbrecht, 2003; Rudman, Oyeboode, Jones, & Bentham, 2011; Victor & Boone, 2007). For example, Dean et al. (2009) reported that in individuals with diagnosed dementia, 36% of PVTs were failed in

those patients with Mini-Mental State Exam (MMSE) >20, 47% were failed when MMSE scores were 15 to 20, and 83% of PVTs were failed with MMSE <15. Similarly, in neuropsychology clinic patients with an IQ range of 60–69, 44% of administered PVTs were failed, while the failure rate was 60% in those with IQ of 50–59 (Dean et al., 2008). Performance validity indicators are based on the premise that simple tasks that appear relatively difficult will be passed by actual patients with brain injury, but failed by noncredible test takers. However, in patients with dementia or low IQ, most “simple” tasks are in fact difficult. The question then arises as to how to arrive at an accurate differential diagnosis of actual versus feigned dementia or intellectual disability.

The remainder of this chapter will address determination of performance validity in the context of possible dementia. The following case illustrates some of the techniques available in this endeavor.

### **Differential Diagnosis of Actual Versus Feigned Dementia**

This 69-year-old patient with eight years of education and subsequent attainment of a GED sustained at most a mTBI in a motor vehicle accident five years prior to evaluation. Medical records indicate that he self-extricated at the scene and was standing at the accident site upon arrival of emergency medical personnel. The patient was described as alert and oriented with no loss of consciousness (Glasgow Coma Scale [GCS] was 15), although subsequently he displayed some mild confusion and was amnesic for the event. He required suturing of a laceration on his head, and was found to have a left hand fracture. Brain CT was normal, but brain MRI obtained two days later showed an area of acute infarction/ischemia in the left basal ganglia and left cerebral peduncle region, as well as mild atrophy with mild nonspecific periventricular and deep white matter changes judged likely related to chronic ischemic white matter disease. He was discharged to home after three days. He filed a lawsuit alleging reduced cognitive function secondary to direct effects of traumatic brain injury, as well as the effect of stroke, which was claimed as caused by the traumatic brain injury, and that precluded him from returning to work as a taxi driver. Symptoms reported at the time of evaluation included decline in memory, reduced balance, back and right leg pain, pain at the fracture site, periodic headaches, insomnia, and depression and anxiety.

The patient’s medical history was rather extensive, including chronic hypertension (with associated borderline hypertrophy on echocardiogram and calcification of the aorta), high cholesterol, elevated blood sugar levels, low testosterone, possible sleep apnea, lengthy smoking history, treatment for gastrointestinal (GI) cancer in the year prior to the accident including six months of chemotherapy, chronic depression, thyroid and parathyroid dysfunction, and possible excessive alcohol use (current use of two glasses of wine three to four nights per week). Additionally, the patient had performed

poorly in school due to difficulty “concentrating,” but he stated that he did not know whether he had an actual learning disability or attention deficit disorder. Family history was noteworthy for a disabling psychiatric condition in his only child (a daughter), and apparent substance abuse in at least one parent. He resided with his wife and adult daughter, and no concerns were expressed regarding his ability to function within the community. He had an active driver’s license.

Scores from the neurocognitive exam are reproduced in the Table 4.1.

The patient in fact failed 100% of PVTs administered (15 of 15 separate tests); the graphs in Figures 4.1, 4.2, and 4.3 contrast the patient’s PVT scores against mean scores for credible and noncredible groups.

Results of neurocognitive testing revealed impaired scores in finger dexterity, visual perceptual/spatial skills, visual memory, and word retrieval; impaired to borderline scores in processing speed; impaired to low average scores in verbal memory; and low average performance in basic attention. In a test taker in the patient’s age range who has documented evidence of small strokes and multiple medical illnesses, the question arises as to whether he has developed cognitive deterioration to the level of a dementia, and if this accounts for the widespread PVT failures.

The determination as to whether a patient’s performance validity failures reflect noncredible performance versus the effects of an actual dementia is made by examining (a) the patient’s functionality in ADLs to see if it is consistent with dementia; (b) the patient’s test scores and spontaneously displayed skills for evidence of consistency of impairment; (c) whether performance on PVTs matches that expected for dementia, and (d) whether the patient still fails PVTs when cutoffs are selected that adequately protect against false positive identifications of malingering in credible dementia patients. Additionally, when a patient has been repeatedly tested, consistency of test scores across exams can be analyzed.

As outlined below, the evidence in the current case indicated that the patient did not in fact have a dementia and that his neuropsychological test performance was noncredible.

#### *Evidence From PVT Performance*

- The patient obtained a MMSE score of 19 (out of 29 possible points), which would suggest a mild/moderate dementia. Yet, he failed 100% of PVTs administered, which is markedly higher than that expected for this MMSE score. Specifically, Dean et al. (2009) found that with a MMSE score of 15 to 20, an average of 47% of PVTs are failed (in contrast to 36% with MMSE score of >20, and 83% with MMSE scores <15).
- The only PVT employed in the Dean et al. (2009) study that maintained 90% specificity in dementia at published cutoffs was mean time to recite four digits on forward Digit Span (cutoff >4"); the patient’s score markedly exceeds this cutoff.

Table 4.1 Neuropsychological test scores in noncredible test taker

<b>Gross Cognitive Function</b>

Figure 4.1 Scores on dedicated PVTs

Figure 4.2 Scores on embedded PVTs involving attention, visual perception/spatial skills, motor dexterity, and verbal and visual memory

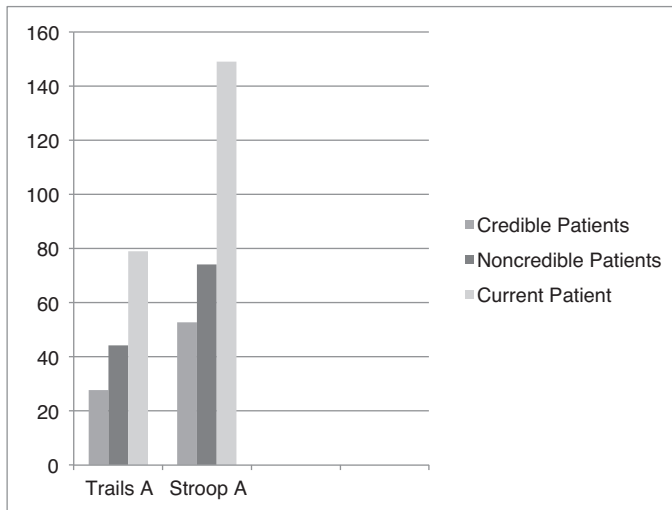

Figure 4.3 Scores on embedded PVTs involving processing speed

- When cutoffs were adjusted per the Dean et al. (2009) study to maintain a <10% false positive rate in dementia patients, the patient still failed the Warrington Words (cutoff <26), finger tapping dominant hand (cutoff <21), and Rey Word Recognition (cutoff <5).
- As shown in Figure 4.4, the patient's scores on the Dot Counting Test, Rey 15-item total recall, and TOMM Trial 1 were worse than mean scores obtained by patients with mild dementia, and most scores (with the exception of Rey 15-item recall and mean ungrouped dot counting time) were worse than mean scores obtained by patients with moderate to severe dementia who were residing in a locked residential facility.
- On a forced choice measure (Warrington–Words), the patient obtained a score significantly below chance (19/50). This performance would suggest that the patient knew correct answers that he did not provide, in contrast to patients with significant dementia (i.e., who have little to no ability to learn new information), and who would be expected to perform at worst at chance levels on the test.

#### *Mismatch Between Test Scores and Demonstrated Functionality*

- The patient was able to provide detailed information regarding the accident and his symptoms/treatment in his deposition and on interview, and showed no memory lapses in his interactions with the examiner (e.g., did not re-ask questions already asked, did not require test instructions be repeated, etc.), behaviors that would be inconsistent with his dementia-level word recall scores on the RAVLT. He scored below chance levels on one forced choice recognition memory test, arguably performing worse than a blind person (who would be predicted to perform at chance levels).

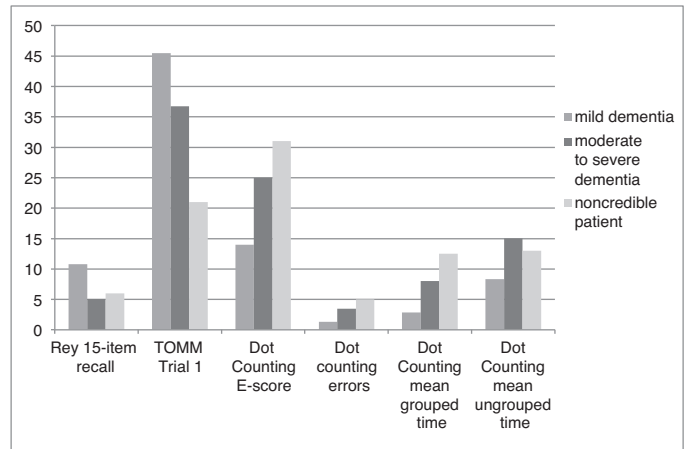

Figure 4.4 PVT Performance as compared to patients with mild and moderate/severe dementia

data for rey 15-item, TOMM Trial 1, and Dot Counting errors, mean grouped time, and mean ungrouped time from Rudman et al. (2011); data for Dot Counting E-score from Boone et al. (2002)

- His very low scores on measures of visual perceptual/constructional skills, visual memory, and processing speed would likely preclude ability to drive, yet he was driving at the time of the exam.
- His low confrontation naming score would be indicative of a significant word-retrieval difficulty, yet no such expressive language difficulties were observed in spontaneous speech.
- He obtained very low finger tapping scores yet used his fingers normally during the exam (to turn booklet pages, hold and use a pen, etc.), and did not report dysfunction of his fingers when asked regarding physical symptoms.
- He made excessive errors in counting (on the Dot Counting Test), a preschool level skill, but in his deposition he was able to provide detailed information regarding the amount and source of his income.
- He scored within the markedly impaired range in rapid word reading, yet he was able to complete the 338-item MMPI-2-RF in less than an hour. No significant over-report was documented on validity scales; however, of note, he obtained a below average score on VRIN-r (39T), which measures consistency in answering similar sets of items. His low score, reflecting more carefulness and consistency in responses than the typical test taker, would not be likely in an individual with actual dementia.

#### *Marked Inconsistency in Test Scores Across Cognitive Exams*

- Three years prior to current testing (but after the accident at issue in the lawsuit), the patient scored in the high average range on a visual spatial reasoning task, in contrast to the impaired scores obtained on current testing.

- Two years prior to current exam, the patient scored in the average range in processing speed, in contrast to the borderline to impaired scores obtained on current exam.
- Six months prior to current exam, the patient scored in the average range on visual memory testing, in contrast to the impaired visual memory scores observed on current testing.
- MMSE scores were widely discrepant across evaluations by different neurologists: One to two years after the accident the patient was described as displaying intact memory and concentration, but in the following year MMSE scores ranged from 15 to 18, and rose to 25 the year after that.
- Particularly poor finger tapping performance was documented on current exam and two years previously, but no neurologist or other physician had reported dysfunction of the patient's fingers.

### Literature on PVTs in Dementia

The review of PVT performance in dementia provided by Dean et al. (2009), and the empirical data reported by Dean et al. (2009), Duff et al. (2011), Rudman et al. (2011), and Bortnik, Horner, and Bachman (2013), show that most PVTs (e.g., TOMM, Digit Span indices, Warrington, Digit Memory Test, Victoria Symptom Validity Test, Word Memory Test [WMT], Medical Symptom Validity Test [MSVT], Nonverbal Medical Symptom Validity Test [NVMSVT], Rey 15-item, Dot Counting, Amsterdam Short Term Memory Test, b Test, Rey Word Recognition, RAVLT effort equation, RO effort equation, RAVLT/RO discriminant function, RBANS Effort Index, Trailmaking Test Ratio) are found to have high false positive identification rates in dementia samples. For example, Rudman et al. (2011) reported specificity rates of 64% for TOMM (Trial 2 and retention <45), 54.8% for Rey 15 total (<8), 45.2% for MSVT, and 33.3% for NV-MSVT. Attempts have been made to identify a unique performance pattern on the WMT ("general memory impairment profile" [GMIP]) and MSVT ("severe impairment profile") that can be used to flag patients with actual severe cognitive dysfunction and thereby reduce the test false positive rate in these patients (Green, Montijo, & Brockhaus, 2011). However, Chafetz and Biondolillo (2013) showed that noncredible patients can easily produce the severe impairment profile, and others have argued that the requirement that the severe impairment profile only be considered if there is a probability that the patient has true impairment is circular (Axelrod & Schutte, 2010). Further, when impairment profiles are employed, specificity does increase, but sensitivity declines; for example, Fazio, Sanders, and Denney (2015) documented 95.1% sensitivity and 68.4% specificity for the WMT in a criminal forensic population, and with use of the GMIP, specificity was increased to 94.7%, but sensitivity declined to 56.1%. However, as discussed later, sensitivity rates of approximately 50% or less may be typical for techniques used to differentiate actual versus feigned dementia.

Perhaps the most research on performance validity in dementia populations has involved the RBANS. Silverberg, Wertheimer, and Fichtenberg (2007) developed an Effort Index (EI) using weighted scores from the Digit Span and List Recognition subtests of the RBANS. Using a cut-off of >3, specificity in a mixed clinical sample was 94%, while sensitivity in a noncredible mTBI sample was 53.3%. Similar sensitivity rates have been reported in geriatric suspect effort groups (51.1% to 64.4%; Barker, Horner, & Bachman, 2010). However, research has demonstrated excessive false positive rates for the EI in geriatric samples that included patients with mild cognitive impairment and Alzheimer's disease (e.g., 69% specificity; Hook, Marquine, & Hoeszle, 2009). The EI appears to have good specificity in geriatric patients who are cognitively intact or have only mild impairment (97%), but specificity declines to unacceptable levels in nursing home residents and in patients with Alzheimer's disease (63% to 66%; Duff et al., 2011). Further, older age and less education negatively impacts EI scores in cognitively intact geriatric patients (Duff et al., 2011).

Because of the elevated false positive rates for the EI in dementia samples, Novitski, Steele, Karantzoulis, and Randolph (2012) developed the RBANS Effort Scale (ES) for use in an amnesic population. The ES involves calculation of the discrepancy between performance on list recognition and recall subtests, to which is then added the digit span subtest score. The authors cautioned that while this equation would result in lowered false positive identifications in truly amnesic patients, false positive identifications would be elevated in patients with normal memory. Several subsequent publications have confirmed lowered false positive rates for an ES cut-off of <12 as compared to the EI in dementia patients. For example, Dunham, Shadi, Sofko, Denney, and Calloway (2014) observed that EI specificity in a genuine memory impairment group was 41% as compared to specificity of 81% for the ES. However, in line with the cautions provided by Novitski et al. (2012), further analyses revealed that specificity was moderated by level of impairment; specificity was higher for the EI (75%) when the RBANS total score was average to mildly impaired, while ES specificity was 96% when RBANS total score was severely impaired, leading the authors to conclude that selection of which RBANS performance validity score to use depends on level of impairment. Burton, Enright, O'Connell, Lanting, and Morgan also reported higher specificity for ES (86%) as compared to EI (52%) in a mixed dementia sample, but noted that specificity rates depended on dementia type; ES specificity was 96% in patients with Alzheimer's disease, but only 69% in non-Alzheimer's dementia. In this vein, examination of performance validity RBANS scores in patients with Parkinson disease revealed an 8% false positive rate for the EI, but a 62.6% false positive rate for the ES (Carter, Scott, Adams, & Linck, 2016). Thus, the ES scale appears to be most appropriate for use in patients with prominent amnesia, but false positive rates are problematic in other types of dementia.

In the Dean et al. (2009) study, mean time to recite four digits in forward order on Digit Span maintained 90% specificity at established cutoffs in 48 dementia patients, although sensitivity has been reported as low (28% to 37%; Babikian et al., 2006). In the Dean et al. (2009) study, specificity for finger tapping cutoffs was low in the overall sample of 55 dementia patients with finger tapping scores, but was 100% in subgroups of patients with Alzheimer's disease and fronto-temporal dementia (but only 43% in vascular dementia), although subgroup sample sizes were small. Sensitivity levels for dominant finger tapping cutoffs are at least moderate (50% to 61%; Arnold et al., 2005). Finally, a recent study showed that use of Digit Span RDS <7 and RAVLT recognition <10 in combination only misclassified 5% of 178 early Alzheimer's dementia patients (Loring et al., 2016), although sensitivity of these cut-offs is unknown.

Additionally, other measures appear to have promise in distinguishing actual versus feigned dementia. Schindler, Kissler, Kuhl, Hellweg, and Bengner (2013) described performance on a yes/no recognition task (presentation of 20 unfamiliar faces, followed by a recognition trial in which the 20 faces are interspersed with 20 new faces, with the test taker instructed to report whether each face was previously seen) in a small sample of dementia patients ( $n = 13$ ) and suspected malingerers ( $n = 11$ ) as well as other groups. The dementia patients exhibited an inflated "yes" response bias, while the suspected malingerers displayed an increased "no" response bias. At a cutoff of nine false negative responses, sensitivity was 54% and specificity was 100%. Schroeder, Peck, Buddin, Heinrichs, and Baade (2012) reported data on the forced choice Coin-in-the-Hand Test in 45 hospitalized patients with moderate to severe cognitive deficits (mean RBANS Global score = first percentile; mean MMSE score = 21.47). More than one error (out of ten possible) occurred in 11% of the sample, and a cutoff of >2 errors resulted in 96% specificity, while specificity was 100% at a cutoff of >4 errors. Dementia subtype was not related to test performance. Rudman et al. (2011) had reported somewhat lower specificity for this measure in 42 patients of varying types of dementia; using a cutoff of <7, specificity was 88.1%, although it achieved the second highest specificity rate among various PVTs examined. The highest hit rate (100%) was observed for the discrepancy between grouped and ungrouped dot counting times on the Dot Counting Test (failure was defined as total ungrouped dot counting time < total grouped dot counting time).

These measures appear to warrant further study in the differential of actual versus feigned dementia, although, for the latter two indicators, while specificity may be relatively high, information as to whether they are in fact effective (i.e., have adequate sensitivity rates in real world settings) is lacking. As a caution, Vocabulary minus Digit Span was initially reported to be a useful PVT (Miller, Ross, & Ricker, 1998), and was documented to have a specificity rate of 97% in 38 patients with probable Alzheimer's disease (Dean et al., 2009). However, other research has demonstrated that this index does not discriminate credible and noncredible groups

(Curtis, Greve, & Bianchini, 2009) and has low sensitivity (Harrison, Rosenblum, & Currie, 2010), thereby indicating that it has virtually no clinical utility. Thus, without real world sensitivity data for the Coin in Hand Test and the Dot Counting discrepancy score, it is unknown whether they are in fact effective PVTs in dementia evaluations.

Other avenues that might warrant exploration in distinguishing actual versus feigned dementia are development of PVTs that rely on old, overlearned information and implicit memory, which are relatively intact in patients with dementia. For example, Cuddy and Duffin (2005) reported spared recognition for music in a woman with advanced dementia (MMSE = 8) as measured by recognition of familiar from unfamiliar melodies, and detection of "wrong" notes in known melodies as well as distinguishing distorted versus correctly played melodies. Horton, Smith, Barghout, and Connolly (1992) observed that normal individuals and amnesic patients both showed typical priming effects on word or fragment completion tasks, in contrast to an amnesia simulation condition in which word completion rates were substantially below baseline performances. Hilsabeck, LeCompte, Marks, and Grafman (2001) subsequently reported data for a PVT involving priming, the Word Completion Memory Test, that requires test takers to complete word stems with previously studied words (Inclusion subtest), and then after exposure to a new list of words, test takers are asked to complete word stems *without* using these latter words (Exclusion subtest). Normal controls and a small group of memory disordered patients ( $n = 14$ ), including two patients with dementia, used more list words on the first task than on the second, while simulators showed the opposite pattern, obtaining a mean difference score that was negative.

Considered as a whole, the available literature suggests that recognition memory tasks, time scores for simple tasks (number repetition and counting), finger speed (except in vascular dementia patients), and implicit memory measures and those involving overlearned information, appear to show the most potential as PVTs in dementia populations, in that these tasks are performed relatively normally by these patients. Additionally, recognition techniques that capitalize on the "yes" response bias found in dementia patients and the "no" response bias that appears to characterize noncredible subjects may also be a fruitful avenue of investigation. Severity of dementia requires consideration in that patients with mild dementia are consistently found to outperform patients with more severe dementia on virtually all PVTs (see Dean et al., 2009). Use of multiple PVTs with cut-offs set to achieve at least 90% specificity for dementia will likely be shown to be adequately protective of dementia patients; as a model, Smith et al. (2014) demonstrated that when PVT cut-offs are selected to result in 90% specificity in a credible population with low intellectual level (FSIQ <75),  $\geq 2$  failures (across seven PVTs most sensitive in detecting likely feigning of intellectual disability) was associated with 85.4% specificity and 85.7% sensitivity, while a cut-off of  $\geq 3$  failures resulted in 95.1% specificity and 66.0% sensitivity.

In conclusion, the field of neuropsychology has made considerable strides in developing methods to accurately identify noncredible neurocognitive test performance, and a next important step will be to refine and perfect techniques to assist in distinguishing actual versus feigned dementia.

# 5 Differential Diagnosis in Neuropsychology

## A Strategic Approach

David E. Hartman

The word *diagnosis* dates from the late 1600s, a latinized derivation of the Greek *διάγνωσις* from the root word *διαγιγνώσκειν* (*diagignoskein*) generally translated as to “discern” or “distinguish.” The *practice* of medical diagnosis was performed from ancient times, with differential diagnostic formulations filtered through prevailing theories of disease causation. Hippocrates, for example, understood that different imbalances among various bodily fluids or “humors” caused the spectrum of diseases, and in order to obtain the clearest picture of disease patterns, he proposed a diagnostic protocol that included tasting the urine, listening to the lungs, and noting skin color and other appearance changes (Berger, 1999). While neuropsychology has its own history of measurement and classification, aphasia insights and phrenological dead-ends, the focus of this chapter is an attempt to deconstruct the process of diagnosis as it is used in present-day clinical neuropsychology.

In contrast with the medical profession, it is not clear that neuropsychological “diagnosis” has consistent meaning or methodology within the profession. In medicine, there is a reasonably well established approach to diagnosis, where symptom complaints are mapped on to medical disorders; it has been proposed that 36 symptoms account for more than 80% of patient complaints and “the physician who has mastered the differential diagnosis of these symptoms will be able to diagnose accurately almost all the problems seen in a typical medical practice” (Seller & Symons, 2007, p. v).

No such agreement is found for *diagnosis* as it is practiced within neuropsychology. A PUBMED search of the phrase *neuropsychological diagnosis* elicited 55 results: 28 investigated brain abnormality, ten examined medical or substance-caused patterns of test abnormality, two described neuropsychological correlates of a psychiatric disorder, three discussed learning and educational issues, three reviewed aspects of neuropsychological rehabilitation, and nine described test development or test pattern research. Only one of these, “Syndrome Analysis” (MacFarland, 1983) suggested the need to identify symptom clusters in neuropsychology, but restricted symptoms to behavioral evidence of brain syndromes, e.g., aphasia, apraxia, perseveration.

The ambiguity of the term *neuropsychological diagnosis* suggests that the term is used differently according to both job characteristic and perhaps the orientation of the

practitioner. Examining the ways that neuropsychologists use the term *diagnosis* suggest that the word describes a clinical methodology of varying complexity, level of information integration, and even accuracy.

The purpose of this chapter is an attempt to deconstruct the meanings of *diagnosis* in a neuropsychological context, to guide the student and practitioner into a general clinical approach to patient examination, and to recognize the multiple meanings of the word *diagnosis* and learn to distinguish the appropriate clinical strategy and pitfalls of each approach.

Perhaps the most basic meaning of the word *diagnosis* in neuropsychology is what might be termed *descriptive diagnosis*. Descriptive diagnosis involves the use of neuropsychological procedures to detect the existence or measure the severity of a single, known/assumed brain syndrome. The neuropsychologist who examines individuals for entry into a dementia treatment program is performing descriptive diagnosis; the patient’s a priori diagnosis of dementia is required to merit entry into the program. It is the task of the neuropsychologist to measure the degree of dementia—either to provide additional justification for program entry, gauge the need for services, or shape the pattern of services to be provided.

Descriptive Diagnosis is synonymous with *measurement*. “Diagnosis” in this sense of the word does not require consideration of alternatives, but measurement of an agreed upon construct. Neuropsychologists asked to measure the severity of Parkinsonism, for example, might choose tests that explicate the Parkinsonian fronto-striatal axis of dysfunction with tests of fronto-executive ability, bradyphrenia, memory impairment, and motor signs. Basal ganglia damage would produce impairments of procedural memory, perceptual learning, and skill acquisition (Robbins & Cools, 2014); the neuropsychologist chooses tests appropriate to measuring the range of expected dysfunction.

Figure 5.1 Descriptive diagnosis

This is typically a noncontroversial, common and necessary neuropsychological diagnostic task. However, clinicians asked to provide neuropsychological syndrome measurement are expected to familiarize themselves with available research and to determine expectable diagnostic patterns, range of severity, and even the viability of the construct. Neuropsychologists employed by a brain injury facility and requested to examine *postconcussion syndrome* should be familiar with expected acute symptomatology, neuropsychological severity levels, and recovery time. Finding severe test impairment and chronic or worsening neuropsychological dysfunction should prompt the neuropsychologist, not simply to conclude that tests reflect “severe, worsening postconcussion syndrome” but to consider that postconcussion complaints overlap with non-head-injury-based symptom complaints (Lees-Haley & Brown, 1993) including preexisting psychopathology or malingered impairment (Gunstad & Suhr, 2002; Satz et al., 1999) that the World Health Organization has criticized the diagnosis for its nonspecificity (Carroll et al., 2004) and that *severe worsening postconcussion syndrome* is almost certainly something *other* than postconcussion syndrome. Similarly, neuropsychologists examining athletes for *chronic traumatic encephalopathy* should understand that their neuropsychological tests may actually be measuring a multifactorial (Solomon & Zuckerman, 2014), or even an inappropriately diagnosed, condition (Andrikopoulos, 2014). Neuropsychologists asked to measure a single syndrome should investigate the origin of the referral. Is the referral source a clinician who advocates for the existence of a particular disorder? One physician’s website likened her own personal reaction to toxic exposures as that of “canary in a coal mine,” alluding to caged birds that miners took into their tunnels, to provide early warning of carbon monoxide exposure. The website of this physician stated that

We ‘human canaries’ are here to warn the rest of you that, unless you become informed and start making changes to avoid as many toxic chemicals as possible, you too may become very ill, or even die, from the consequences.

(Gilbere, 2000)

It is often useful to ask patients how they “discovered” their diagnosis, including asking about whether they have researched literature or particular Internet sites that support the diagnosis. Neuropsychologists should be wary when asked to validate what have been termed *fashionable illnesses*, typically characterized by vague fluctuating, multisystem psychosomatic complaints, buttressed by pseudoscientific explanations (Ford, 1997).

The greatest risk for neuropsychologists who perform descriptive diagnosis is *confirmatory bias*— assuming both the validity of the working diagnosis and the imprimatur to “measure” it. In fact, for many cases the diagnostic question may be incorrect, poorly worded, or completely irrelevant, given the patient’s actual difficulties (Lezak, 1995, p. 110).

Neuropsychologists would do well to recall Rosenhan’s classic experiments during the 1970s, where healthy volunteers were asked to feign mental illness symptoms in order to gain admission to a psychiatric hospital. Once admitted, they were told to act completely normally. All were diagnosed with a psychiatric disorder, all told they required antipsychotic drugs, and all but one were diagnosed with schizophrenia “in remission” prior to their release (Rosenhan, 1973).

A simple rule to lessen confirmatory bias is to always view the referral question as a *hypothesis*, rather than the *presumptive diagnosis*. Referral sources may have limited access to information or propose their diagnosis from a circumscribed professional skill set. The fact that a diagnosis has been written in a chart does not necessarily make it correct. This author recalls a referral where the only question of concern was “degree of depression.” The patient’s chart repeatedly referenced the patient’s “depressive demeanor.” In my office, the patient proved to be a very pleasant older woman with no signs of depression. Her masked facies, lack of initiation, flat affect, and loss of executive function had been charted as “withdrawal” and “reactive depression,” rather than, as proved to be the case, early signs of dementia and advancing parkinsonism.

In another case, the referral question was a single question to be measured, and was not neuropsychological but personality-related. A surgeon was referred by his hospital practice for loud and aggressive arguments with colleagues. He appeared to show insight on clinical interview that his behaviors had been truculent and argumentative, but attributed staff reactions to their unfamiliarity with his “urban” interpersonal style.

He did not appear immediately abrasive or unusual during the initial interview, but created a disturbing scenario on the elevator up to the testing laboratory. Here the doctor began to speak with a young child riding in the elevator with mother. He told the girl how “pretty” her coat was, and then bent over to feel the fabric on the coat’s lapel. He was oblivious to her mother’s surprised and horrified reaction.

This physician produced unremarkable results on personality tests, but failed several tests of executive function. My report to the referral source concluded that his “interpersonal pathology” better resembled frontal lobe abnormality and a neurological evaluation was strongly recommended. The doctor’s brain MRI was found to demonstrate a lemon-size slow-growing tumor immediately posterior to the frontal lobe, which had the effect of degrading frontal lobe function without obvious sensory-motor or posterior impairment; in effect, inducing a very slow “frontal lobotomy.” Surgery was reportedly performed immediately.

Another risk for neuropsychologists in a practice that is that while they are “often well practiced in the integration of findings from multiple test within multiple cognitive domains in an ongoing hypothesis-testing model” this approach may be “abandoned in favor of a unitary analysis of a single data source when psychological findings are addressed in the evaluation” (Allen, 2004, p. 17).

Figure 5.2 Domain-specific differential diagnosis

A more complex layer of diagnostic inference could be termed *domain-specific differential diagnosis*. Here the diagnostic task is to differentiate between patterns of at least two brain-based disorders: e.g., Alzheimer’s disease versus vascular dementia, or traumatic brain injury versus stroke. The preparatory task is similar to that of descriptive diagnosis, with required understanding as to whether test patterns resemble one or more diagnostic entities; this level of diagnosis now includes *syndrome analysis*. While there is always processing overlap and interdependence of cognitive functions at the behavioral level of neuropsychological tests, syndrome analysis is frequently possible. Neurodegenerative dementias differ in their neuropsychological profiles. Compared to Alzheimer’s disease, a vascular dementia profile “is characterized by better verbal memory performance worse quantitative executive functioning and prominent depressed mood” (Levy & Chelune, 2007). Compared to Alzheimer’s, both dementia with Lewy bodies and Parkinson’s disease can produce impaired visual information processing, degraded executive function, and mood-congruent hallucinations (Levy & Chelune, 2007).

Neuropsychological reports that require domain-specific differential diagnosis should outline the factual basis for concluding that a particular pattern of test results and history can be differentially diagnosed. Including research citations as scientific support is appropriate.

A third layer of diagnostic consideration includes differential functional localization-specific diagnoses while also considering the influence of medical disorders and their medications. This three-layered approach to diagnostic decision-making might be labeled *multidomain neuropsychological diagnosis*, where diagnostic considerations transcend focal central nervous system phenomena to include areas of non-central nervous system “medical” illness, along with the medications that are used to treat those same conditions.

Multidomain neuropsychological diagnosis requires the perspective that “many diseases affect behavior and cognitive without directly involving brain substance” (Lezak, 2012, p. vii) and more clearly mandates neuropsychological expertise at the level of medical neuropsychology. Interaction of organ system disease, metabolic disorder, genetic aberration, infection, autoimmune condition, or toxicant exposure with neuropsychological function make this level of diagnosis far more complex and challenging, but absolutely essential for neuropsychologists who diagnose as health care providers. While neuropsychologists may take the position that their

Figure 5.3 Multidomain neuromedical diagnosis

referral questions address brain–behavior phenomena, the fact is that patients sent for diagnosis are: (a) rarely perfectly healthy, and (b) rarely exhibit pathological patterns of behavior that are uniquely caused by central nervous system dysfunction. More typically, the patient’s “neuropsychological” condition is influenced by layers of pathology and patients entering the neuropsychologist’s office have diseases that “are actually relatively common, yet their neuropsychological symptoms and mechanisms are not often examined closely” (Armstrong, 2012, p. xii). Not only the type, but also the number of medical disorders may affect neuropsychological function. Patients with an aggregation of medical pathologies show cumulative deterioration that predicts cognitive deficits over and above age, mood, neuropathology, or psychiatric status (Patrick, Gaskovski, & Rexroth, 2002).

Neuropsychological pathology at a multidomain level of differential diagnosis requires appreciating that, referral question to the contrary, the influence of medical disorders may be additive or even primarily explanatory vis-à-vis test results, and also that these disorders are extremely common among patients who are referred for something more “neuropsychological.” For example, the National Health and Nutrition Examination Survey (NHANES) data from 2005–2008 suggest age-standardized hypertension prevalence of 29.8 but rate of hypertension control at only 45.8% (Crim et al., 2012). Subpopulations (i.e., Mexican Americans) have higher rates and lower treatment levels (Burt et al., 1995). and prevalence of hypertension among African Americans at is considered to be “among the highest in the world and increasing” (Hall, Duprez, Barac, & Rich, 2012, p. 302). Hypertension contributes to progressive cognitive impairment (Birns, Morris, Jarosz, Markus, & Kalra, 2009) and elevates risk for stroke and myocardial infarction. Long-standing hypertension causes reductions in cerebral blood flow, metabolism, and cognitive function (Fujishima, Ibayashi, Fujii, & Mori, 1995). Hypertension is associated with greater degrees of cortical atrophy in older adults and is a risk factor for cognitive decline (Meyer, Rauch, Rauch, & Haque, 2000). Neurochemical disturbances are found among hypertensives, particularly in central nervous system catecholamines that mediate attention and memory (Waldstein,

Manuck, Ryan, & Muldoon, 1991). Hypertensives perform consistently more poorly than individuals with normal blood pressure on neuropsychological tests of memory, attention, and abstract reasoning.

Migraine headache history, in the absence of brain lesions or trauma, and typically seen as a “nuisance” symptom, reduces both cerebral blood flow and metabolism, producing transient cognitive impairments lasting for about an hour (Meyer, 2012) but chronic migraine sufferers may suffer orbitofrontal cognitive impairments from medication overuse, with a neuropsychological profile similar to substance abusers (Biagianni et al., 2012). Chronic cluster headache sufferers can be impaired on executive tasks, (e.g., Trails, Stroop), consistent with proposed prefrontal involvement in this headache syndrome (Dresler et al., 2012). It is almost impossible to obtain a complete medical history from clinical interview. Use of a checklist (see Table 5.1) prior to the evaluation, may allow additional inquiry and alert the neuropsychologist to possible diagnostic rule-outs.

Table 5.1 Disease/health history

**Please check if you have a history of, have been told you have, or have been diagnosed with any of the following:**

- Abuse: Physical, Sexual, or Verbal
- Addiction (Any)
- Attention deficit/hyperactivity disorder (ADHD)
- Adverse Childhood Experiences (Describe on Back Page)
- AIDS (Acquired Immune Deficiency Syndrome)
- Alcohol Abuse/Dependence
- ALS (Amyotrophic Lateral Sclerosis)
- Alzheimer’s Disease
- American Trypanosomiasis/Chagas Disease
- Anemia
- Anthrax
- Anxiety or Panic
- Aortic Aneurysm
- Aortic Dissection
- Arthritis
- Childhood Arthritis
- Lupus (SLE) (Systemic Lupus Erythematosus)
- Osteoarthritis (OA)
- Rheumatoid Arthritis (RA)
- Aspergillus Infection (Aspergillosis)
- Asthma
- Autism Spectrum Disorder
- Bacterial Meningitis
- Balance Problems
- Bioterrorism Agents/Diseases
- Bipolar disorder
- Birth Defects
- Black Lung (Coal Workers’ Pneumoconioses)
- Blast Injuries
- Blood disorders
- Botulism (Clostridium Botulinum)
- Bovine Spongiform Encephalopathy (BSE)

---

Neuropsychological diagnosis which includes these four layers of information is enhanced by reviewing and ordering laboratory blood and urine tests. Lab tests can provide useful clues to neuropsychological diagnosis at the medical symptom level, and are important to identify pathognomonic signs, monitor medication levels, detect drug or alcohol abuse, and consider the possible influence of lab result abnormality upon neuropsychological diagnosis (McConnell, 2014). While most lab testing is performed by hospital

or medical personnel, psychologists licensed to prescribe medications, depending upon state law, may order such tests directly. In either case, neuropsychologists practicing at this level of differential diagnostic expertise have the responsibility to collaborate with medical providers by reviewing and even requesting such tests.

Just as medical diagnosis influences neuropsychological diagnosis, prescription medications can significantly alter neuropsychological presentation and require the influence effects of medications prescribed to treat a medical diagnosis requires consideration in neuropsychological diagnosis. The influence of medication on neuropsychological diagnosis is as ubiquitous as are patients taking medication, and increases with age. Ninety percent of persons aged 65 and older take at least one prescription medication, and almost half are given five drugs or more (Tannenbaum, Paquette, Hilmer, Holroyd-Leduc, & Carnahan, 2012). Consideration of medication effects and their interactions by neuropsychologists is still relatively rare, even though “consumption of medication that can negatively affect cognition is an alternate explanation that may be under-recognized” (Tannenbaum et al., 2012, p. 640). Neuropsychologists are responsible for understanding the individual and interactive effects of medications in terms of dose, frequency of occurrence, and severity with respect to the patient’s overall cognitive and emotional status. Some medication effects are fairly common, e.g., the effects of acute benzodiazepine ingestion upon memory. Alternatively, a neuropsychologist who routinely “finds” statin-related cognitive impairment is likely overdiagnosing a rare occurrence (Rojas-Fernandez & Cameron, 2012). Diagnostic conclusions should include possible neuropsychological medication effects and drug interactions; websites such as epocrates ([www.epocrates.com](http://www.epocrates.com)) offer free drug interaction checks to professionals. Arguably, neuropsychologists should be aware of potentially dangerous or even lethal effects of medications, doses, and interactions, since prescriptions may be obtained from multiple physicians who are not in communication with one another and are unable to observe the patient outside the office. Patients themselves may fail to appreciate drug-related dangers that develop over time.

The next layer of neuropsychological diagnostic inference, *multidomain neuromedical diagnosis*, includes the influence of psychiatric disorder, both active and historical. Patients who are being evaluated for neuropsychological impairment may or may not have discussed their psychiatric history with the same health care practitioners who are treating them for neurologic or general medical concerns. As is the case with medical conditions, a comprehensive interview and/or history questionnaire concerning personal and familial psychiatric morbidity may suggest additional testing, neuropsychological inquiry, and psychiatric/psychological referral. Due to the high genetic loading of many psychiatric disorders (e.g., bipolar disorder), obtaining a family history of psychiatric presentation may guide questions addressed to the current patient. Psychiatric history is directly germane to

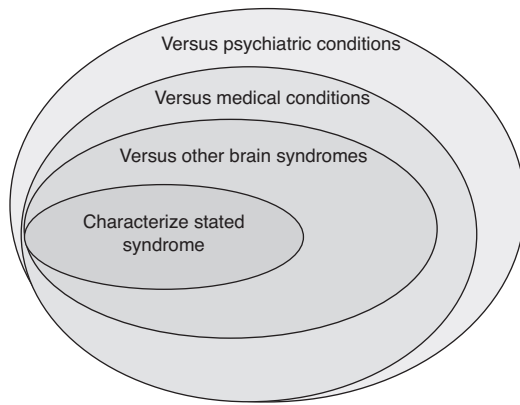

Figure 5.4 Neuromedical psychiatric diagnosis

neuropsychological conclusions since cognitive impairment profiles are common among individuals with certain psychiatric disorders, and may differ according to diagnosis. Patients with certain schizophrenic disorders, for example, may be neuropsychologically impaired, but stable, over the first ten years of illness (Bozikas & Andreou, 2011). In contrast, pre-morbid neuropsychological function in patients diagnosed with bipolar disorder is relatively normal, but deteriorates over time until chronic bipolar disorder patients “may be virtually indistinguishable” from patients with schizophrenic disorder (Woodward, 2016). Patients with bipolar disorder continue to display neuropsychological impairments that persist even during euthymic (normal mood) intervals.

Cognitive deficits involving attention, executive function, and verbal memory are evident across all phases of bipolar disorder. . . . differentiating medication- from illness-induced cognitive dysfunction requires comprehensive assessment with an appreciation for the cognitive domains most affected by specific medications. No current pharmacotherapies substantially improve cognition in bipolar disorder.

(Goldberg & Chengappa, 2009, p. 123)

Diagnostic history, family history of psychopathology, and use of objective psychological assessment instruments (e.g., Minnesota Multiphasic Personality Inventory-2 Restructured Form; Personality Assessment Inventory, Millon Clinical Multiaxial Inventory IV) provide valuable normative comparisons and symptom validity measurement as well.

The fifth layer of diagnostic consideration includes objective assessment of effort and motivation. Perhaps more than any other layer of influence, this may be a unique neuropsychological contribution to the understanding of patient symptoms. Clinicians listening to self-report may do little more than reify that self-report in the medical record. This does not advance accurate diagnosis unless the pattern of self-report provides reliable clinical data. Psychologists and neuropsychologists have the best and most widely researched procedures to provide objective assessment of response pattern credibility.

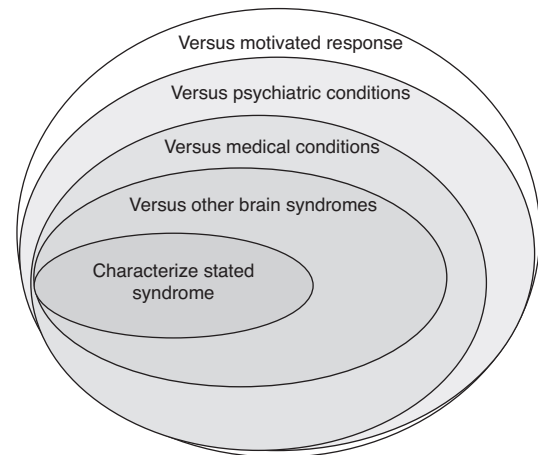

Figure 5.5 Forensic neuromedicopsychiatric diagnosis

The fifth layer of diagnostic inference, gradual and growing acceptance by the neuropsychological community that: “malingering or deficit exaggeration must be specifically addressed to support either a conclusion of faking bad or putting forth good effort at task performance” (Loring, 1995). Most neuropsychologists now agree that any neuropsychological evaluation is incomplete without the careful consideration of patient motivation (Iverson, 2003), and the specialized methodology employed to measure motivation has proven demonstrably superior to clinical judgment. Subjective clinical judgment in the absence of tests that determine motivation and effort do

not make optimal or near-optimal use of information bearing on malingering when evaluating cases, for it that were so, clinicians [not making use of such tests] would at least be matching, if not outperforming, formal decision rules and success, which they are not doing.

(Faust & Ackley, 1998, p. 2)

In one study, three-quarters of neuropsychologists who did not have access to formal tests of exaggeration indicated moderate or greater confidence in their *wrong* conclusions and “not a single neuropsychologist identified malingering in those patients who were instructed to fake brain injury” (Binder, 1997, p. 226).

There is no reasonable rationale to remove consideration of motivation distortion just because there is no active lawsuit. Poor effort and exaggeration occur for nonlitigious reasons: The patient may wish to be taken care of, avoid adult responsibility, or obtain family support; these may not require litigation, just formal validation of clinical disability.

The *National Academy of Neuropsychology*, representing the neuropsychological community, concluded that symptom validity testing was necessary in both medical and forensic contexts.

Symptom exaggeration or fabrication occurs in a sizeable minority of neuropsychological examinees, with greater

prevalence in forensic contexts. Adequate assessment of response validity is essential in order to maximize confidence in the results of neurocognitive and personality measures and in the diagnoses and recommendations that are based on the results. . . . Assessment of response validity, as a component of a medically necessary evaluation, is medically necessary. When determined by the neuropsychologist to be necessary for the assessment of response validity, administration of specific symptom validity tests is also medically necessary.

(Bush et al., 2005, p. 419)

Specific test measures of effort and symptom distortion are not simply an adjunct to clinical impression, but must be *part* of that clinical impression. There is no corpus of data to suggest that motivation effects disappear if patients are not engaged in lawsuits. Apparently nonlitigating patients may be intending to litigate *after* testing; others may deny active litigation and attempt to route their referral through a treating physician, in order to have the evaluation covered as a clinical procedure. They may intend to have the neuropsychologist testify as a *fact* witness, unwittingly colluding with their search for disability. Some patients may not reveal litigation participation because their evaluation would be covered by insurance if it was a clinical procedure but *not* as part of a legal claim. Others who have no intention to sue shape their behavior for nonlitigation-related reinforcers, e.g., avoiding adult responsibilities. One frequently sees reports and studies where individuals are concluded to be well-motivated if *they have already obtained disability benefits*, as though the reason to feign impairment disappears when benefits are granted. More likely, because such patients undergo periodic disability review, they are well aware that the disability pretense must continue to ensure the continuation of benefits.

Others patients deliberately self-injure to *become* medically disabled. Some are obsessed with obtaining mutilating surgeries, which may actually occur unless they are correctly diagnosed with a *factitious* disorder. I asked one such patient, who had recurring episodes of lymphedema, infection, and sepsis in a leg, what he understood as a plan for treatment. He replied, with a fascinated expression,

well, the doctor says that if my infection and lymphedema continues, they may have to amputate the leg at the knee . . . but that may not be enough, so they may have to amputate the leg at the thigh . . . but *that* may not be enough and they may have to amputate the leg above the thigh, all the way above the hip!

He described these morbid possibilities like that of a child being offered ever more desirable toys. The patient's medical record contained numerous exploratory operations, some of which found objects, such as broken-off pencil points, in muscle or joint tissue. Surgeons blithely recorded the patient's explanations, e.g., "He thanked us for removing the object, which had been embedded in his leg since childhood."

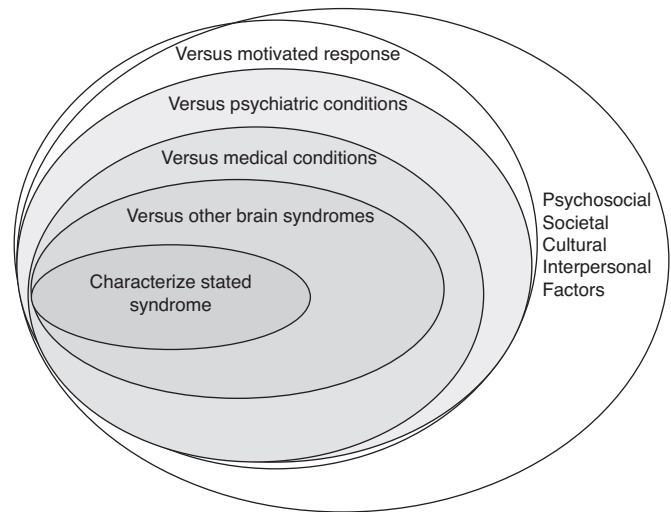

Figure 5.6 Differential forensic biopsychosocial diagnosis

The final layer of diagnostic consideration *differential forensic biopsychosocial diagnosis* includes a culture-fair biopsychosocial assessment as to how a particular diagnosis may be shaped by the patient's culture, language facility, societal differences, and attitude toward the examination. It is tempting for neuropsychologists to assume that their tests measure concrete, invariant aspects of brain function but of course, they do not. This author recalls the rather horrifying conclusion of one self-identified neuropsychologist who pronounced that a low IQ score per the Bell Curve was evidence, *ab aeterno*, of defective brain function; he indicated that it did not matter whether the patient given the IQ test was English- or Spanish-speaking, poorly or well-educated. Contrary to this egregiously incorrect understanding of what tests measure across languages and cultures, the *Ethical Principles of Psychologists and Code of Conduct* (American Psychological Association, 2010) requires psychological practitioners to respect the rights and welfare of all populations, and attempt to eliminate biases related to age, cultural, ethnicity, race, religion, sexual orientation, disability, language, and socioeconomic status (*Ethical Principles—Preamble: General Principle E*, 2010). For neuropsychological diagnosis, such respect comes with the understanding that neuropsychological differences are not indicia of immutable brain function, but may be related to health disparities, cultural approach to authority and testing, and many other factors. Even tasks as simple and universally administered as Digit Span are affected by linguistic and cultural differences (Ostrosky-Solis & Lozano, 2006).

The reasons behind cultural differences in neuropsychological test responses may be linguistic or cultural. Other authors have suggested that such differences reflect evidence of a "different" brain. Chee, Zheng, Goh, Park, and Sutton (2011) found young predominantly White American adults had higher cortical thickness in frontal, parietal, and medial-temporal polymodal association areas in both hemispheres,

compared with Chinese residents of Singapore. They proposed that varying gray matter patterns could be the result of ethnic-cultural cognitive differences, genetics, or environmental factors. Regardless of whether neuropsychological differences are structural or psychosocially derived, neuropsychological diagnosis, in the largest sense, requires consideration of whether these influences shape or even change the diagnosis.

In conclusion, neuropsychological diagnosis requires a strategic approach with layered consideration of causal influences upon neuropsychological behavior. Detailed test measurement is only the most basic layer of that diagnostic inference. Depending upon the referral question and the complexity of the case, neuropsychological diagnosis can require detailed understanding, not only of brain-behavior relationships, but also brain-behavior-medical and medication-relationships. Neuropsychological diagnosis additionally requires the appreciation of mental health history, motivation, and psychosocial influences upon the final interpretation of what our tests measure, and what the patient actually “has.” Neuropsychological test selection and numerical result interpretation is just the beginning.

If I have any final advice about *how to diagnose*, it is to explicitly justify one’s diagnostic conclusions in the body of the report. Be clear about sources of data and how those data were integrated into final conclusions. The reader of a neuropsychological report should be clear as to each link in the chain of diagnostic inference. Footnotes to research and decision-making strategy included in the report allow the reviewer to trace or dispute your reasoning. A well crafted report should be clear, in and of itself. There should be no question in the mind of the reader why you made a particular diagnosis.

The following brief ABCDE of neuropsychological diagnosis could be considered an initial checklist when determining the influence of neuropsychological test results on behavior.

**A**(scertain) which level of diagnostic inference is required. Does “diagnosis” require measurement of an agreed-upon construct, or differential diagnosis at a more complex level of consideration? Is the construct generally agreed upon, e.g., Degree of Alzheimer’s Dementia, or is the diagnostic request itself controversial or implausible, e.g., chronic postconcussion syndrome, multiple chemical sensitivity, chronic lime disease, toxic mold encephalopathy, etc.

**B**(ase) rate consideration of diagnostic influences and whether they are supported by peer-reviewed research. The effect of Benzodiazepines on neuropsychological function is generally agreed upon; statin effects upon neuropsychological function are probably rare. Ascribing Autism to vaccination is junk science.

**C**(onsideration) of reasonable alternatives and aggregate influences upon diagnosis. There should be an explicit set of considerations leading to your diagnosis.

**D**(e-bias) conclusions and reports. Sweet and Moulthrop (1999) remind the diagnostician that reports should be written to a standard that a panel of neuropsychological peers would find acceptable. The report should be reviewed for emotional or scientific bias and even if the report has no likelihood of being professionally critiqued, the diagnosing neuropsychologist should be prepared to dispassionately explain how diagnosis flows from data, rather than clinical lore or personal belief system.

**E**(ffort) examination is critical to understanding whether results are actual clinical neurobehavioral patterns or whether those same results are overridden by motivational

*Table 5.2* Sample biopsychosocial questions. Each of these questions has potential import for understanding test results and diagnostic considerations

---

Is anyone in your family currently disabled, or has been disabled in the past? If so, who?
Have you or any members of your family been physically, sexually or chronically verbally abused?
Are you a member of any group with a diagnosis like yours?
Have you read any books that influence the way you understand your condition?
Are there any Internet sites that you particularly recommend in understanding your condition?
If you have limitations in your daily activities, who helps you?
How much coffee, tea or other caffeinated beverage do you drink each day?
How many alcohol drinks will you typically drink each week?
Do you take supplements, health foods, herbs or other nonprescribed treatments for your condition(s)?
What are you current favorite activities?
Have there been any major changes in your life or family in the past several years? (e.g., death, marriage, divorce, financial problems, addiction, violence) Please list _____
Were you ever in the military or National Guard? Were you honorably discharged? At what rank? Do you have a military disability?
What is your primary language spoken at home? What languages do you speak?
Does anyone in your family have a history of depression, bipolar disorder, thyroid disorder, schizophrenic disorder, attention deficit, alcohol or drug abuse, attempted or completed suicide, tics, problems with the law, anxiety or panic, posttraumatic stress disorder, heart attack, high blood pressure, stroke, dementia, learning disability. Please explain.
Have you been sued or have you sued anyone? If yes, please describe each lawsuit and date.
If you are in a current lawsuit, how much stress does this cause you? 0(none)_____ 10(extreme) _____

---

distortion. While poor effort is not the same as malingering, neither describes an accurate pattern of brain-behavior relationships. Given the preponderance of research and professional statements regarding this issue, examination of effort and motivation should be considered standard procedure for almost every diagnostic evaluation. It is arguably unethical to perform evaluations (e.g., Social Security Disability evaluations) that actually forbid the use of effort measures.

To conclude, neuropsychological diagnosis requires a *strategy*; specifically a multilayered series of considerations which lie between the initial referral question and the final diagnosis. Utilizing this methodology does not ensure perfect diagnosis, but using a multi-layered strategic approach increases the likelihood that appropriate influences diagnosis are weighed before conclusions are drawn. We strive for understanding of our complex selves, and if we cannot yet understand a grand design, we can at least, be clear about the path we have taken.

# 6 Neuroanatomy for the Neuropsychologist

*Christopher M. Filley and Erin D. Bigler*

## Introduction

The details of human neuroanatomy are vast, intricate, and continually expanding. As a result, the study of neuroanatomy may seem forbidding to clinicians and researchers whose focus is on clinical behavioral assessment. Nevertheless, a working knowledge of neuroanatomy is fundamental for neuropsychologists. This chapter will endeavor to develop such an understanding, presenting an overview of human neuroanatomy while emphasizing the most relevant aspects for those engaged in the neuropsychological study of higher functions.

## Historical Background

The origins of human behavior and consciousness are an enduring source of fascination. Few have not had occasion to ponder the sources of thought and feeling, and the personal immediacy of daily conscious experience is an inescapable aspect of human existence. Whereas richly descriptive literary and artistic accounts of mental life have been offered by the humanities for generations, the biomedical sciences have also advanced our understanding of these phenomena through formal investigation of the nervous system. From ancient times, physicians have been intrigued by the role of the brain in human behavior. In the fifth century B.C., Hippocrates held that the brain was the seat of all mental faculties, and that afflictions of the brain led to a wide range of mental and emotional disorders. Galen, in the second century A.D., believed that the brain was the primary modulator of mental capacities, although he and many medieval physicians asserted that these capacities were to be found within the ventricles. With the appearance of detailed studies of the brain by the Renaissance anatomist Vesalius in the 16th century, the identification of the brain as the site of cognition and emotion steadily gained credence. The rise of neurology and its allied basic neuroscience disciplines in the last two centuries buttressed this association with descriptive data on the clinical phenomenology of normal and abnormal brain functions. Even the psychoanalytic thinking of Sigmund Freud in the early 20th century acknowledged that the ultimate goal of

psychological research was to establish a scientific basis for human behavior. Today, with the advent of sophisticated methods in neuroscience including modern neuroimaging, no doubt exists in the scientific community that the brain is the organ of the mind (Filley, 2011; Mesulam, 2001; Cummings & Mega, 2003).

## Philosophy and the Brain

Despite the identity of brain and mind that is widely accepted among neuroscientists, considerable debate on this question remains in society as a whole. Many people are reluctant to attribute the extraordinary phenomena of human behavior to the activity of such physical entities as nerve cells and chemicals in the brain. This uncertainty stems from a long and persisting controversy in Western philosophy known as the mind-brain problem (Filley, 2011). Most closely linked with the work of the 16th century French philosopher Rene Descartes, this debate centers on the relationship of the mental and physical worlds. Descartes, sometimes called the father of modern philosophy, acknowledged that both mental and physical realities exist (*res cogitans* and *res extensa*, respectively), but maintained that they are strictly separated (Searle, 2000). For Descartes, the mental world is represented by the soul, an inherently subjective entity, whereas the physical world is an objective reality to which the soul cannot be reduced. This view, known as *dualism*, has dominated much of philosophical thinking for hundreds of years, and finds many adherents today. The soul, however, does not lend itself to scientific scrutiny, and postulation of its existence is not helpful to those wishing to study a physical phenomenon. Whereas proof that a soul does not exist is most difficult to acquire, there is also no evidence to support that it does. On the contrary, much information favors the idea that the brain makes an essential contribution to all aspects of mental existence. As modern neuroscientific data on the brain accumulate, it is increasingly apparent that both cognition and emotion—thinking and feeling, respectively—may be completely explained by brain science. Even consciousness, a formidable concept that until recently intimidated neuroscientists, appears to be nothing more—or less—than a product of the brain at work (Searle, 2000).

### The Neuroanatomy of Higher Function

Neuroanatomy is the study of the structure of the nervous system, the major integrative organ system in the human body. The nervous system is an exceedingly complex assembly of excitable cells and their supporting structures, and is most usefully considered in terms of its major divisions (Table 6.1). As a first step, the major division in neuroanatomy is between the central nervous system (CNS), which is made up of the brain and the spinal cord, and the peripheral nervous system (PNS), consisting of numerous spinal and cranial nerves (CNs) with branches that reach virtually the entire body and transmit information to and from the CNS. The autonomic nervous system, organized to regulate many aspects of visceral function, is made up of selected components of both the CNS and the PNS. For clinicians primarily engaged in the assessment and care of individuals with disorders of the brain, the anatomy of the brain is the most critical portion of neuroanatomy. In this chapter, therefore, a clinically relevant depiction of brain anatomy will be provided. Special attention will be devoted to the representation of the singular mental capacities of *homo sapiens*, often referred to as the higher cerebral or *cognitive functions*, or simply the *higher functions*.

The first task will be to develop a thorough understanding of the structure of the brain. This foundation is a necessary basis for a basic task of clinical neuroscience: the localization of normal and disturbed brain function. For this process,

not only do brain areas devoted to higher functions deserve attention, but also those anatomically related regions that enable identification of behaviorally relevant areas by virtue of their “neighborhood” proximity. With this background, a brief discussion will follow on major unifying themes in brain-behavior relationships, including the phylogenetic organization of the brain; the functions of cortical, subcortical, and white matter regions; and cerebral lateralization. These considerations will lead directly to the concept of neural networks, a notion that offers a comprehensive organizing principle for understanding all the domains of cognition and emotion. Finally, a synopsis of the major functional affiliations of the four cerebral lobes will be presented.

### Neuroanatomy Through Neuroimaging

Since the introduction of computed tomography (CT) in the early 1970s, the fidelity of brain imaging to visualize gross brain anatomy has improved at a rapid pace hastened by the development of magnetic resonance (MR) imaging (MRI). Today much of neuroanatomy is now taught via neuroimaging methods (Leichnetz, 2006; Nowinski & Chua, 2013). This chapter will use the basic information from the first edition of this book, as the fundamentals of neuroanatomy have not changed, and fuse this traditional approach with MR methods of imaging that highlight neuroanatomical detail. For example, the middle and right-hand images in Figure 6.1 are from an axial MRI section of the brain, which has the appearance of an actual gross postmortem neuroanatomical specimen as shown on the left. The distinct boundaries between white and gray matter are readily visualized with this type of MRI sequence as well as key major structures, which are identified in the scan on the right. The

Figure 6.1 The postmortem stained horizontal (also referred to as axial) section on the left appears very similar to the living, in vivo T1-weighted axial MRI next to it (middle image). Used with permission from (Roberts & Hanaway, 1970). The similarities between the postmortem brain and MRI clearly demonstrates how MRI approximates gross anatomy. A duplicate of the middle image on the far right identifies common brain regions at this level: (1) cingulate gyrus, (2) corpus callosum (forceps minor), (3) internal capsule, (4) thalamus, (5) atria of the lateral ventricle, (6) visual cortex, (7) posterior fornix (crus forni), (8) septum pellucidum.

cortical ribbon of gray matter is clearly demarcated from white matter as are the ventricles, filled with cerebrospinal fluid (CSF) in both the histologically stained postmortem brain as well as the very much alive, in vivo brain image in the middle and right. Throughout this chapter various MR imaging techniques will be used to highlight neuroanatomy. An appendix to this chapter overviews CT and MRI methods for neuroanatomic identification.

## The Structure of the Human Brain

Neuroanatomy is an enormous and growing area of neuroscience, and a complete description of the human brain alone is far beyond the scope of this chapter. However, the goal in this section is to provide a focused consideration of the brain that is useful for the purposes of clinical and research neuropsychologists. Additional details to amplify the account of general neuroanatomy can be found elsewhere (Blumenfeld, 2011; Brodal, 1981; Catani & Thiebaut de Schotten, 2012; DeArmond, Fusco, & Dewey, 1989; Kandel, Schwartz, & Jessell, 2000; Nolte, 2002; Paxinos, 1990).

## Gross Anatomy

The human brain is a roughly spherical organ situated within the cranium and weighing about 1,400 grams (three pounds) in the adult. It has a soft, gelatinous consistency, and its visibly obvious delicacy immediately explains the protective role of the rugged skull in which it is encased. The surface of the brain is folded into many rounded ridges called *gyri*, between which are grooves known as *sulci* or *fissures*. At its base, the brain is continuous with the spinal cord, as the medulla oblongata of the brain stem merges into the cord as it exits the skull through an opening called the *foramen magnum*. A prominent external feature of the brain is its trio of three covering layers: the thick, fibrous *dura mater* just below the inner table of the skull, the weblike *arachnoid* that attaches itself to the inner surface of the dura, and the thin *pia mater* that directly invests the brain surface.

The brain is ordinarily divided into three gross anatomic segments: the cerebrum, cerebellum, and the brain stem (Figure 6.2). The cerebrum is made up of the paired cerebral hemispheres, joined by a large white matter tract called the *corpus*

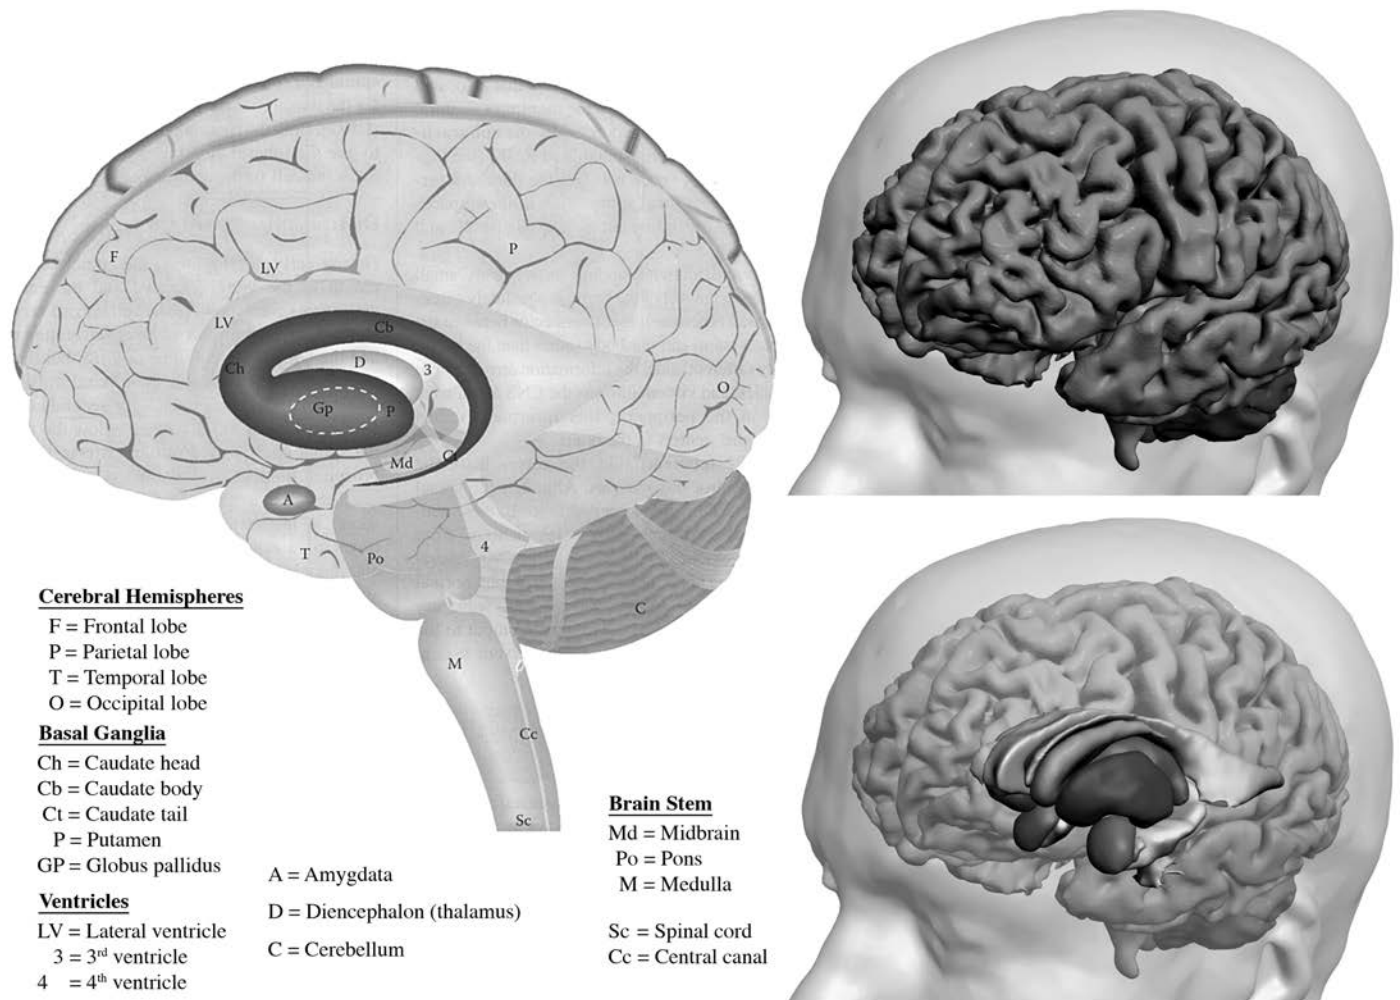

Figure 6.2 Left: overview of major brain structures (© Hendelman 2006; reproduced by permission). Top right: This image is not a drawing but a three-dimensional rendering of the MRI of one of the authors (EDB) showing the cortical gyri. Bottom right: Using see-through technology, each major region of interest can be isolated and classified. A color version of this figure can be found in Plate section 1

*callosum*, and the *diencephalon*, which includes the *thalamus* and *hypothalamus*. The cerebellum is a relatively large and discrete structure situated posterior to the brain stem. The brain stem itself consists of the *midbrain*, *pons*, and *medulla* (commonly used as a synonym for the *medulla oblongata*). Within the brain are four cavities known as *ventricles*—the two lateral ventricles in the cerebral hemispheres, the third ventricle lying between the two thalami, and the fourth ventricle between the brain stem and cerebellum—each filled with CSF. Numerous blood vessels are also visible grossly. Four major arteries in the neck provide a rich and constant flow of oxygenated blood to meet the high oxygen demand of the brain. These are the two carotid arteries and the two vertebral arteries, which link at the base of the cerebrum in a complex anastomotic structure, called the *circle of Willis*, where major arteries irrigating specific cerebral regions originate. On the venous side of the circulation, a widespread network of venous sinuses returns deoxygenated blood to the paired internal jugular veins in the neck.

Despite its relatively small size (about 2% of the total body weight in adults), the brain houses an extraordinary number of cells. The cellular composition of the brain includes neurons (nerve cells), the basic functional units of the nervous system, and glial cells (glia), that perform a variety of supporting roles. Although estimates differ, it is possible that the brain contains 100 billion neurons and as many as ten times as many glial cells. Even more impressive is the fact that neurons are believed to connect with at least 1,000 others via contacts known as *synapses*. Neurons are excitable cells that function to integrate signals they receive and transmit impulses to other cells, and the brain can thus be considered a densely interconnected electrical organ. The computational power conferred by the enormous number of neurons and synapses is thought to account in large measure for the singular capacities of the human brain.

Another important anatomic distinction in the brain can be drawn between the gray matter and white matter. These two components can be clearly discerned in the freshly cut brain because of the glistening white appearance of the latter that is imparted by its major constituent, myelin. Whereas the gray matter largely consists of the cell bodies of neurons and their synaptic connections, the white matter is the collective mass of myelin-coated axons that travel within and between the hemispheres to link cortical and subcortical gray matter areas. The white matter in the brain, which constitutes roughly half its volume and weight, thus enables connectivity between all brain areas, and is a crucial component of the many neural networks that are believed to subservise neurobehavioral functions.

### Microscopic Anatomy

At a microscopic level, the brain can be regarded as a collection of neurons, glial cells, and blood vessels. The essential elements for neurobehavioral function are the neurons, but the glia and vasculature also perform important supportive roles.

**Figure 6.3** Upper left: drawing of a typical neuron, showing its characteristic cell body, dendrites, and axon. Upper right: The simplicity of the diagram to the left belies the true complexity of neurons, axonal projections, and dendritic fields. This is an actual photomicrograph of a hippocampal pyramidal cell in the pigeon. The arrow points at the axon with all of the other appendages being dendrites. The horizontal unit bar is 50 $\mu$ . (Used with permission from Atoji, Wild, & Wiley, 1956). A color version of this figure can be found in Plate section 1.

Neurons are the fundamental units of the nervous system (Figure 6.3). These are cells that are anatomically and physiologically specialized to transmit or process information. Neurons are thus responsible for transmitting sensory stimuli to the brain from the periphery, for sending motor signals from the brain destined to produce movement in a muscle, and for the intermediary processing of information between stimulus and response. In the brain, the great majority of neurons are called *interneurons* because they are structurally interposed between sensory input and motor output; these cells mediate all the cognitive and emotional operations traditionally subsumed under the headings of mentation, higher function, and behavior. To accomplish these objectives, neurons have a typical arrangement that includes a cell body, a variable number of dendrites, and an axon as schematically shown in Figure 6.3. The cell body, also known as the *soma* or *perikaryon*, houses the cell's nucleus and other organelles that maintain the metabolic status of the neuron and synthesize its essential macromolecules. Dendrites are relatively short neuronal processes that extend from the cell body and receive input from other neurons via synaptic contacts. The axon, in contrast, is a long, cylindrical process that provides for the output of the neuron, again by means of synaptic contact with adjacent neurons.

Information transfer within the nervous system is both electrical and chemical in nature. In an individual neuron, the signal is electrical and takes the form of an action potential.

This electrical impulse, often referred to as a *spike* because of its characteristic appearance when recorded experimentally, is propagated along the axon by virtue of a sudden influx of sodium ions that transiently reverses the polarity of the axonal membrane. After the action potential passes, a short refractory period occurs and then another spike can be propagated. An important feature of the action potential is that it is an “all or none” phenomenon, so that its generation depends on the balance between the excitatory and inhibitory inputs received by neuronal dendrites. At the synapse, however, neuronal information transfer is chemical. The synapse is a specialized region of the neuron where a chemical messenger known as a *neurotransmitter* diffuses from one neuron (presynaptic) across a narrow synaptic cleft to activate another neuron (postsynaptic). When the neurotransmitter binds with its receptor on the postsynaptic membrane of the adjacent neuron, it may produce either a depolarization (excitatory stimulus) or a hyperpolarization (inhibitory stimulus), and the summation of these competing influences determines whether an action potential is generated in the postsynaptic neuron. Neurotransmitters are typically small amines, amino acids, and neuropeptides, the pharmacology of which promises many avenues for the successful manipulation of abnormal physical and mental states.

Returning to Figure 6.3, it must be emphasized that this schematic figure merely represents a characterization of a neuron. Actual neurons are far more complex, delicate, and intertwined with adjacent neurons and glia cells than what may be appreciated in the schematic. The diameter of axons is but a few microns, with axon membranes and synaptic gaps measured in nanometers. As will be shown in later illustrations, axon projections may be very short, some under a millimeter in length. However, some axons are very long and aggregate together to form distinct and identifiable tracts. The longest projecting axons within a distinct, well-identified tract are found within the corticospinal tract. In a tall basketball player, some axons from cortex to spine may be more than a meter in length! Axons within complex neural systems, such as those involved in working memory that connect parietal attentional networks with frontal areas involved in executive control and interhemispheric integration, vary in length from a few to several centimeters. Except for the shortest projections, axons course within the brain parenchyma in circuitous nonlinear pathways through densely compacted cellular arrays. Appreciating the microscopic size of the individual neuron, and the complex environment of billions of cells within which each neuron must navigate from origin to terminus, underscores the intricacy of these fundamental units of the brain. The histological staining techniques in Figure 6.3 show how projecting axons interlace one with another. As demonstrated in this figure, the interlacing of projecting axons only a few microns in length constitutes the basis of an extremely complex neuronal network (note that the horizontal bar in the upper right of Figure 6.3 indicates a micron scale—a millionth of a meter).

Glial cells are far more abundant in the CNS than neurons. Glia are classified into four types: *astrocytes*,

*oligodendrocytes*, *microglia*, and *ependymal cells*. Each type of glial cell has special functions in the brain. Astrocytes are star-shaped cells found in both gray and white matter that participate in the mechanical support of neurons, the metabolic regulation of the microenvironment, and the response of the brain to injury. Oligodendrocytes are located mainly in white matter, where they are responsible for the myelination of central axons, just as Schwann cells carry out this function in the PNS. Microglia are small cells found in gray and white matter that serve as phagocytes, migrating as needed to damaged areas where they dispose of pathogens and neuronal debris. Ependymal cells line the ventricular system, and at a specialized structure known as the *choroid plexus*, one of which is located in each ventricle, ependymal cells form a secretory epithelium that produces CSF; this fluid fills the ventricles and also bathes the entire CNS.

The major vessels that transport blood to and from the brain are the arterial and venous structures discussed in the next section. At the microscopic level, numerous cerebral capillaries serve as the bridging vessels between the arterial and venous systems. These capillaries consist of tightly packed endothelial cells where blood containing oxygen and glucose is delivered to the brain, and then recirculated after these nutrients are extracted. An important feature of the capillaries is that they make up a major part of the blood-brain barrier, which protects the brain from the entry of many pathogens that may circulate in the bloodstream.

### **Blood Supply**

The steady delivery of well-oxygenated blood to the brain is vital. Brain ischemia or anoxia causes neurologic symptoms within seconds, and irreversible neuronal damage and ultimately death will occur if either condition lasts for minutes. A complex system of arteries and veins transports blood to and from the brain, and a working knowledge of this vasculature is necessary for understanding the neurobehavioral effects of many neurologic disorders, including the common and often devastating stroke.

The arterial supply of the brain comes entirely from four large arteries, sometimes called *great vessels of the neck*, all of which ultimately derive from the aorta. The right and left common carotid arteries arise from the right subclavian artery and the ascending aorta, respectively, and within a few centimeters of its origin, each bifurcates into an external branch that supplies extracranial structures, and an internal carotid artery (ICA) that irrigates a substantial portion of the brain (Figure 6.4). The paired vertebral arteries, somewhat smaller than the common carotids, arise from the subclavian arteries and ascend in parallel to a level just below the pons, where they merge to form the single basilar artery. The four great vessels then combine to form the circle of Willis, a vascular loop at the base of the brain from which arise all the arteries supplying the cerebrum. As shown in Figure 6.4a, the

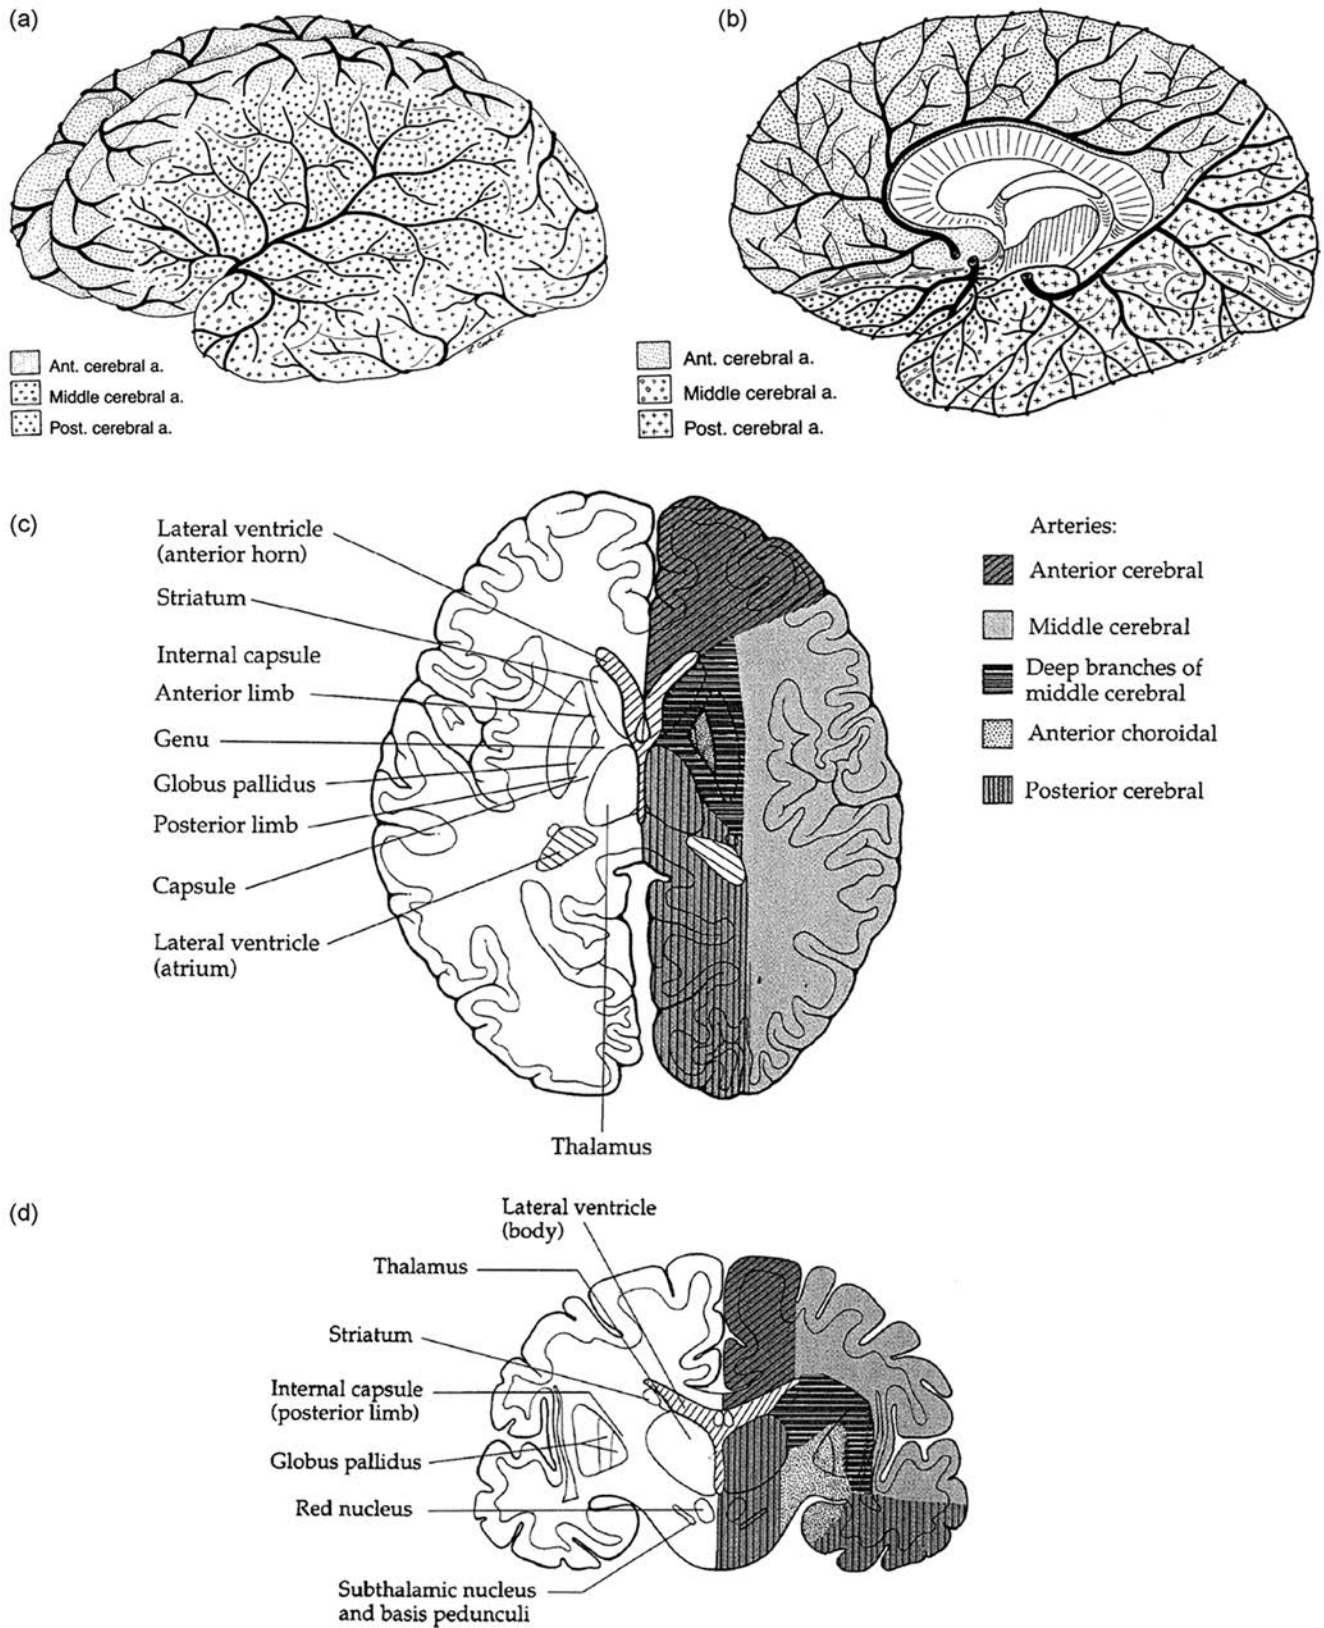

Figure 6.4a Left: the blood supply of the brain, showing the major arteries of the neck and their relationship to the circle of Willis. Right: (A) lateral, somewhat oblique, view of the convex surface of the left cerebral hemisphere and the paramedian portion of the right cerebral hemisphere showing the anterior, middle, and posterior cerebral arteries and their territories (reprinted with the permission of Cambridge University Press); (B) sagittal section of the right cerebral hemisphere showing the anterior, middle, and posterior cerebral arteries and their territories (reprinted with the permission of Cambridge University Press); (C and D) arterial circulation of deep cerebral structures illustrated in this schematic horizontal (c) and coronal (d) section. (The figure on the left is from Martin 1996, while the figure on the right is adapted from Lim & Alexander, 2009.)

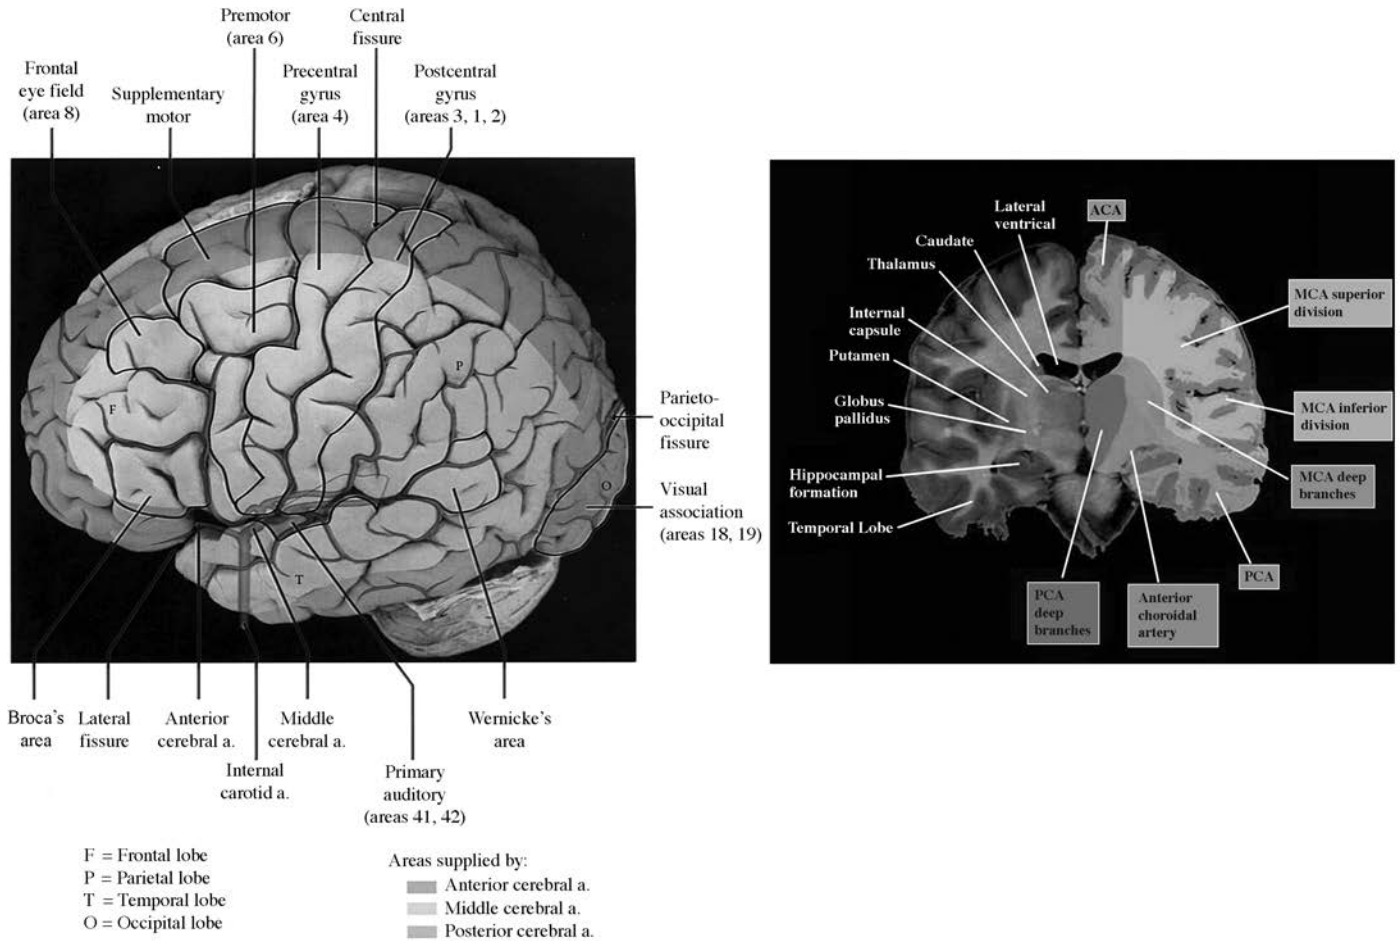

Figure 6.4b Left: coronal MRI section at the level of the thalamus depicting the differences in vascular distribution. Right: the distributions of the anterior, middle, and posterior cerebral arteries as depicted on the dorsolateral surface of the cerebral hemisphere. (© Hendelman 2006; reproduced with permission.) A color version of this figure can be found in Plate section 1.

circular appearance of the paired posterior cerebral arteries (PCAs) that bifurcate from the top of the basilar artery and proceed to supply posterior cerebral regions, the paired posterior communicating arteries (PCoAs) that connect the PCAs with the ICAs, the paired anterior cerebral arteries (ACAs) that arise from the ICAs and go on to irrigate anterior regions of the cerebrum, and a single anterior communicating artery (ACoA) that joins the two ACAs form what is referred to as the 'Circle of Willis', as depicted in Figure 6.4. Another important artery that arises from the circle of Willis is the middle cerebral artery (MCA): One MCA is found on each side, and each one ascends to the ipsilateral hemisphere to nourish the lateral aspect of the cerebrum. Whereas vascular disease of many kinds can affect any of these vessels and dramatically disrupt neurologic function, the MCA, ACA, and the PCA are most important arteries in terms of neurobehavioral function because these are the arteries that supply the cerebral hemispheres (see Figures 6.4b and 4c).

The venous drainage of the brain is accomplished by a richly anastomosed system of cerebral veins, conventionally

divided into superficial and deep groups, both of which empty into a network of dural sinuses. Superficial veins near the brain surface typically drain into the superior sagittal sinus, a long, tubular structure that runs in the interhemispheric fissure at the top of the brain. Deep veins drain into the paired straight sinuses that are found superior to the cerebellum. The major dural venous sinuses merge at the confluence of sinuses, and then the straight sinuses drain into the internal jugular veins to return blood to the heart. Vascular disorders involving the cerebral venous system are far less common than those of the arterial system, but the outcome can be similarly catastrophic.

### Ventricles and Cerebrospinal Fluid

Within the brain, there are four internal cavities called *ventricles* (Figure 6.5). These cavities are filled with CSF, a watery fluid produced within the ventricles that surrounds the entire CNS. The ventricular system is important in governing the pressure and fluid dynamics of the brain. The CSF plays a

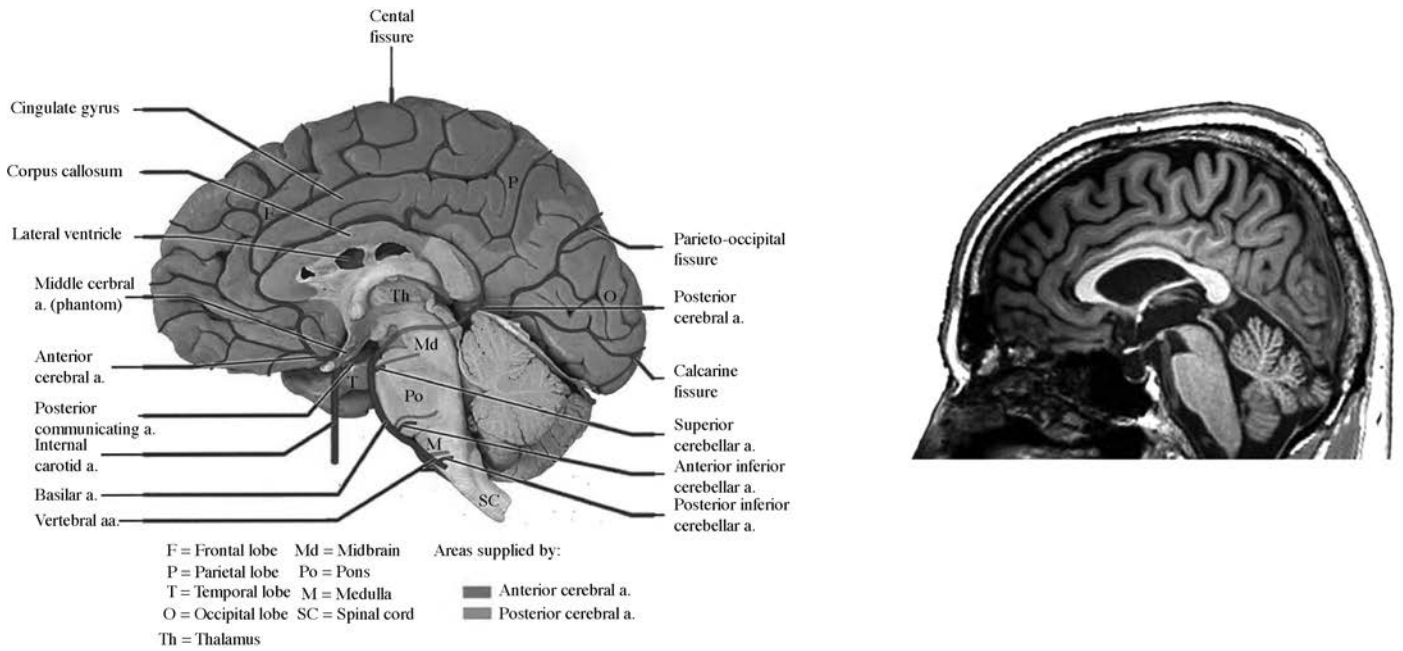

Figure 6.4c Left: the distributions of the anterior and posterior cerebral arteries on the medial surface of the cerebral hemisphere (copyright © Hendelman 2006; reproduced with permission). Right: MRI of one of the authors (EDB) at approximately the same level of the colorized postmortem sagittal section with the vasculature colored in on the left. The cut through the cerebral hemisphere is slightly off center so that the cortical gyri may be observed; these gyri are covered in part by the falx cerebri, an extension of the dura mater that is situated between the two cerebral hemispheres. A color version of this figure can be found in Plate section 1.

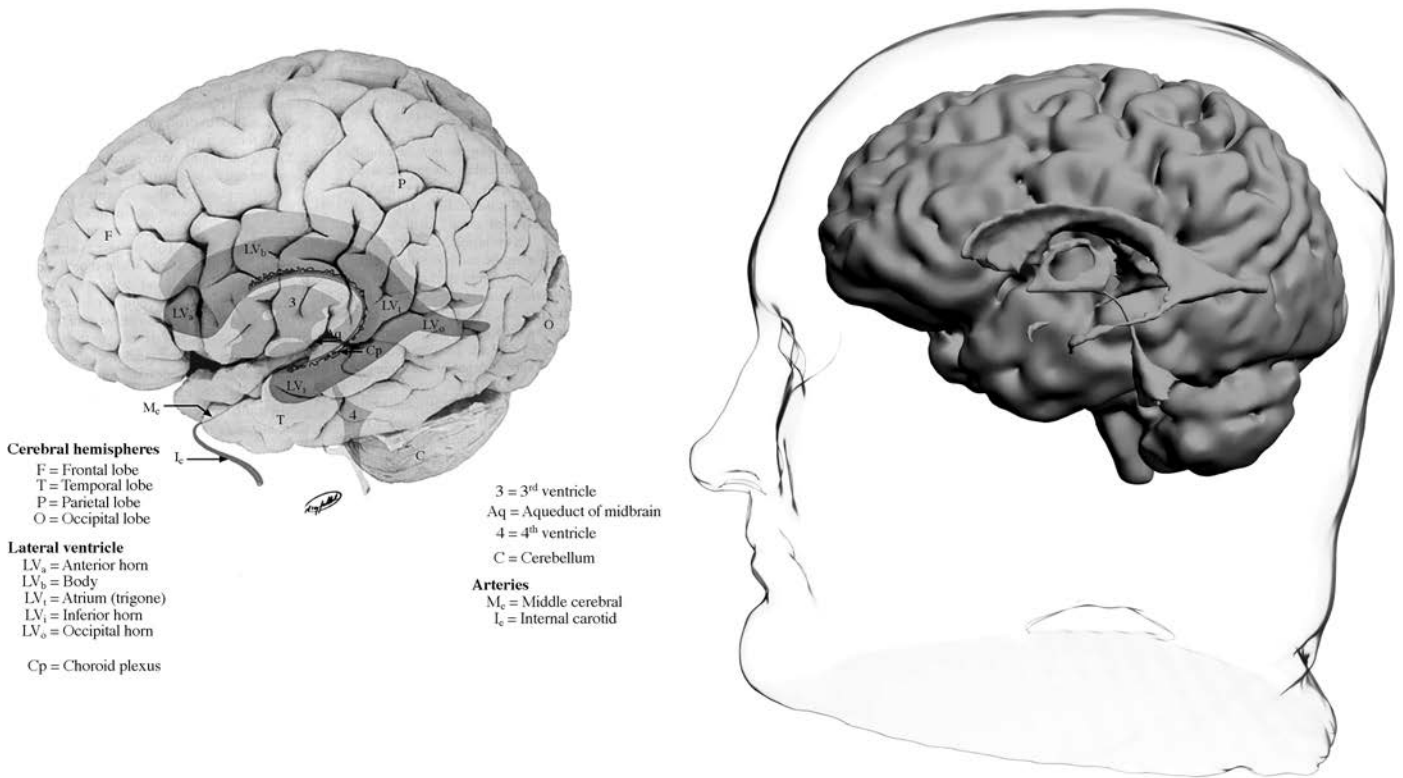

Figure 6.5 Left: the position of the four ventricles within the brain. (copyright © Hendelman 2006; reproduced with permission.) Right: three-dimensional MRI rendering of the ventricular system of one of the authors (EDB). To highlight the ventricular system, the surface of the brain has been smoothed to some extent. A color version of this figure can be found in Plate section 1.

supportive role in normal CNS function, and abnormalities of the CSF are critical in the diagnosis of many neurologic disorders.

The two largest ventricles are the lateral ventricles, one in each hemisphere, which are situated deep to the frontal, temporal, parietal, and occipital lobes. These communicate with a single third ventricle, which is narrow and located between the two thalami, via an opening in each lateral ventricle called the *foramen of Monro*. The tent-shaped fourth ventricle lies just dorsal to the brain stem and is connected to the third ventricle by a small conduit in the midbrain known as the *cerebral aqueduct*. In turn, the fourth ventricle empties into a region of the subarachnoid space called the *cisterna magna* through three apertures, the midline *foramen of Magendie* and the two lateral *foramina of Luschka*. The CSF then circulates caudally to the lower end of the spinal canal and then rostrally to the convexities of the brain, where it is eventually absorbed into the cerebral venous sinuses through structures called the *arachnoid villi*.

CSF is steadily produced by the choroid plexus in all four ventricles. The total volume of CSF in and around the CNS is approximately 140 ml, whereas the volume of CSF within the ventricles is a small fraction of this, about 25 ml. As the CSF is produced at a rate of about 450 ml per day, the CSF volume turns over about three times daily. The neuroanatomical importance of the CSF is twofold: In structural terms, it serves a supportive role in providing a buoyancy that prevents the brain from settling down upon the rigid bony protuberances of the skull, and functionally, the CSF takes part in regulating the chemical environment of brain neurons.

Clinically, the ventricular system and the CSF have many important implications. Enlargement of the ventricular system from an excess of CSF, as occurs with hydrocephalus and certain mass lesions, can have major neurologic consequences. Analysis of the constituents of the CSF after lumbar puncture is crucial for diagnosis of many neurologic disorders, such as meningitis and encephalitis. In disorders associated with parenchymal volume loss, such as many neurodegenerative diseases or moderate to severe traumatic brain injury, reduction of brain volume is accompanied by a compensatory increase in ventricular size, often readily identifiable on MRI or CT imaging.

### **Cranial Nerves**

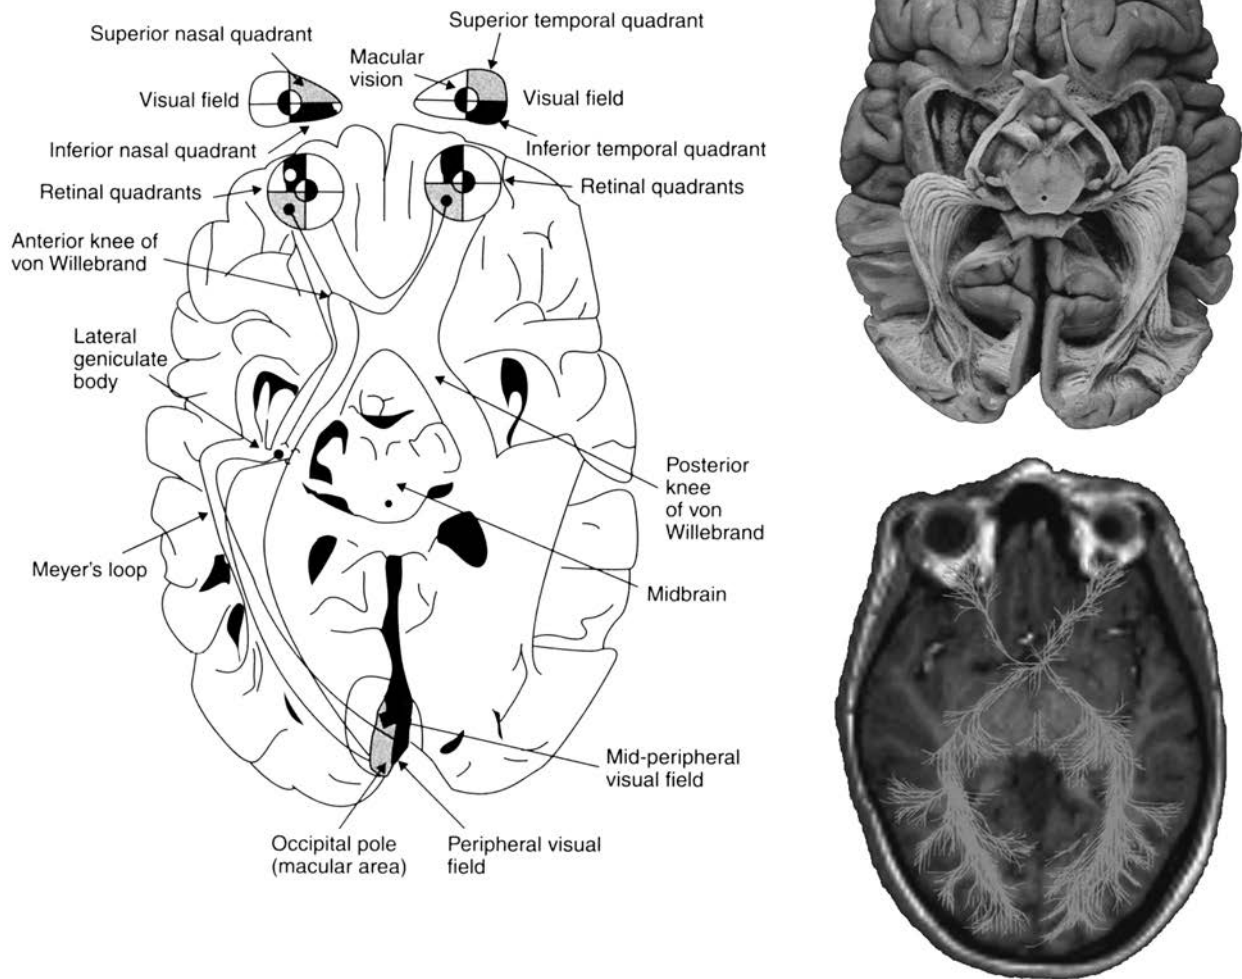

The 12 CNs provide for motor and sensory innervation of the head and neck, and their anatomy is inextricably associated with that of the brain. All of the CNs are regarded as components of the PNS, with one exception: The second CN, the optic nerve, is actually a tract of the brain. The CNs each exist in pairs, and their crossed and uncrossed connections with central structures are important in understanding the anatomy of the brain.

The first CN is the olfactory nerve, which subserves the sense of smell. Olfaction is far more highly developed in lower animals, but this chemical sense exists in humans as a reminder of the evolutionary background of *homo sapiens*. The olfactory system originates as a collection of olfactory receptor cells called the *olfactory epithelium* in the roof of the nasal cavity. The olfactory nerve consists of the collected axons of these cells. Ascending through the cribriform plate of the ethmoid bone, the olfactory nerve terminates in the olfactory bulb at the base of the frontal lobe. From there, the olfactory tract projects to the olfactory cortex in the medial temporal lobe.

The sense of vision is of central importance in human life, as signified by the large number of CNS neurons devoted to it. Incoming visual stimuli are initially processed in the eye, where photoreceptor cells in the retina—known as *rods* and *cones*—transduce patterns of light into electrical signals that are sent to the brain. The optic nerve can be seen by physicians at the back of the eye, where examination with an ophthalmoscope permits visualization of the optic disc. The optic disc contains the axons of neurons that transmit visual information to the lateral geniculate nucleus of the thalamus. From there, additional relays through the temporal and parietal lobes project to the primary visual cortex in the occipital lobes (Figure 6.6). On its way to the thalamus, the optic nerve divides into two components, one remaining on the same side as the eye from which it came and the other passing over to the other side of the brain. This neuroanatomical feature is important because it results in each hemisphere receiving input from the contralateral visual field. Thus the left hemisphere receives input from the right visual field and vice versa. Crossed function such as this is typical of a number of systems in the brain and has many clinical and neurobehavioral implications. In Figure 6.6 the neuroanatomical dissection next to the schematic shows the visual projections emanating from the lateral geniculate nuclei and how they fan through the temporal and parietal lobes to their destination in the visual cortices. The gross projections from the optic nerves to the visual cortices may now be identified *in vivo* using structural MRI along with the newer technique of diffusion tensor imaging (DTI).

CNs three, four, and six are typically considered as group because of their exclusive role in eye movements. These three nerves—the oculomotor (CN III), the trochlear (CN IV), and the abducens (CN VI)—arise from the brain stem and allow for normal conjugate gaze by linking the movement of the two eyes so that a single visual image is presented to the brain. CN III also provides the afferent limb of the important pupillary light reflex, which has much localizing value in neurologic diagnosis.

CN V, the trigeminal nerve, has both motor and sensory functions. It is the general sensory nerve of the face, mediating ipsilateral somatic sensation via three divisions: ophthalmic (V1), maxillary (V2), and mandibular (V3).

**Figure 6.6** The course of the visual image is shown from the retina through the optic nerve, optic tract, lateral geniculate body, and optic radiation, to the visual cortex (reproduced with permission from Arslan, 2001). Top right: meticulous dissection of the visual projections from the optic chiasm to the visual cortex (reproduced with permission from Glubegovic & Williams, 1980). Bottom right: DTI of aggregate tracts from the visual projection system, plotted on a T1-weighted image (from Staempfli et al., 2007, and reproduced with permission from Wiley). A color version of this figure can be found in Plate section 1.

These divisions join in the trigeminal ganglion outside the brain stem, and then enter the pons as a single nerve. A secondary relay then sends this facial somatosensory information to the ventral posterior medial (VPM) nucleus of the thalamus, where it undergoes further processing. The motor function of CN V is to supply the muscles of mastication (chewing).

The facial nerve (CN VII) is primarily motor in its function. This nerve originates from the facial nucleus in the pons and innervates the ipsilateral muscles of facial expression. Facial weakness related to dysfunction of this nerve or its connections is frequently seen in clinical neurology. CN VII also has one notable sensory function, which is to convey taste from the anterior two-thirds of the tongue via a branch

called the *chorda tympani* to the solitary tract in the pons and medulla.

The eighth CN is known as the *vestibulocochlear nerve* because it has two special sensory components called the *vestibular* and *cochlear* divisions. These two divisions mediate the vestibular (balance) system and the sense of audition (hearing), respectively. Each division of CN VIII makes use of mechanoreceptors found in the inner ear: Cells of the vestibular division are sensitive to positional head movements, and those of the cochlear division respond to sound stimuli. Complex mechanisms of transduction then permit the transmission of positional and auditory stimuli to the vestibular and cochlear nuclei in the pons. From there, vestibular input is extensively processed in the brain stem and cerebellum,

and auditory input is relayed rostrally up the brain stem to the medial geniculate nucleus of the thalamus and finally to the primary auditory cortex of the temporal lobe (Heschl's gyrus). Among the central functions of hearing in humans is that it serves as a necessary precursor to language.

The ninth CN, the glossopharyngeal nerve, participates in motor, sensory, and autonomic functions of the face. Motor fibers of CN IX innervate the pharynx; sensory fibers mediate somatic sensation of the tongue, nasopharynx, and middle and outer ear as well as taste from the posterior one-third of the tongue; and autonomic fibers supply parasympathetic input to the parotid gland. The tenth CN, the vagus nerve, is the most widely distributed of the CNs, providing parasympathetic input to many thoracic and abdominal organs, and contributing to the motor and sensory innervation of the larynx, pharynx, and outer ear. CN XI, the accessory nerve, is a pure motor nerve that arises from the lower medulla and upper spinal cord. CN XI supplies ipsilateral sternocleidomastoid and trapezius muscles. The 12th CN, the hypoglossal, is also purely motor in function. It arises from the medulla and enters the tongue ipsilaterally to supply its musculature.

### Brain Stem

The brain stem is the most caudal portion of the brain, serving structurally as a bridge between the spinal cord and the cerebrum and as an anchor for the cerebellum posterior to it. Its three divisions are the midbrain, lying just below the diencephalon and continuous with the thalamus; the pons, immediately caudal to the midbrain and anterior to the fourth ventricle; and the medulla, below the pons and continuous with the spinal cord. In addition to many CN nuclei, several ascending and descending tracts to and from higher structures are found within the brain stem, and also within this region is the important integrative structure known as the *reticular formation*.

An important point is that CNs III–XII have their central termini in the brain stem. This arrangement indicates that the brain stem serves as a general relay station conveying sensory, motor, and autonomic information between the CNS and the tissues and organs of the face and body. Damage to the brain stem can therefore have a major impact on CN function, and the diagnosis of many neurologic disorders is based on the localization of lesions causing CN deficits.

The long tracts in the brain stem are all continuations of fiber systems that originate at higher or lower levels of the nervous system. Four major tracts are most relevant clinically. First is the *corticospinal tract*, which begins in the precentral gyrus of the frontal lobe, descends to the spinal cord, and provides supraspinal input to motor neurons that directly innervate voluntary muscles. Within the brain stem, this tract occupies the ventral portion of the midbrain, pons, and medulla, and as it nears the most caudal portion of the medulla it crosses (decussates) so that most corticospinal

fibers travel to the opposite side of the spinal cord. As in the visual system, therefore, there is a crossing of motor fibers that renders one side of the cerebrum responsible for nervous activity on the other side of the body. The second major tract is the *corticobulbar tract*, which has a similar origin and role as the corticospinal tract, but which terminates on various brain stem motor nuclei. The remaining two brain stem tracts of note are sensory. The *medial lemniscus*, a continuation of the dorsal column system in the spinal cord, conveys information regarding vibratory and position sensation to the contralateral ventral posterior lateral (VPL) nucleus of the thalamus and then to the somatosensory cortex of the parietal lobe. The *spinothalamic tract* is a similar sensory tract that transmits pain and temperature sensation from the periphery to the contralateral VPL thalamic nucleus and then the parietal lobe.

The *reticular formation* is a diffusely organized collection of nuclei and tracts within the core of the brain stem that serves a vital integrative function. This area, defined more by its physiologic characteristics than by discrete anatomic boundaries, harbors the nuclei of several neurotransmitters that supply more rostral brain regions, among them norepinephrine from the locus ceruleus and serotonin from the dorsal raphe nuclei. Although the reticular formation participates in sensation, movement, and autonomic function, perhaps its most important role is in consciousness. In the upper pons and midbrain lies a portion of the reticular formation called the *ascending reticular activating system* (ARAS). The ARAS serves as a general activating system for the brain, sending fibers to the intralaminar nuclei of the thalamus, which in turn project to the entire cerebrum (Figure 6.7). The ARAS has a major role in wakefulness and sleep and is largely responsible for the normal circadian rhythm of humans, a schematic of which is also shown in Figure 6.7. Damage to the ARAS, as from a brain stem stroke or traumatic brain injury, may result in a loss of normal arousal and produce the dramatic state of coma. The ARAS therefore contributes to human consciousness in a fundamental way. By virtue of its capacity to enable the general arousal system of the brain, the ARAS underlies all the operations of higher function. Neurologists have long employed a useful distinction that brings some order to the neurobiology of consciousness: In this formulation, the ARAS can be regarded as responsible for the *level* of consciousness, in contrast to the *content* of consciousness that is elaborated by more rostral regions of the brain (Plum & Posner, 1982). These distinctions are further elaborated in Figure 6.7.

### Cerebellum

The cerebellum is a prominent structure of the brain lying posterior to the brain stem, to which it is extensively attached. Although it receives considerable sensory input, the cerebellum is considered part of the motor system because of its primary involvement with coordination, postural control,

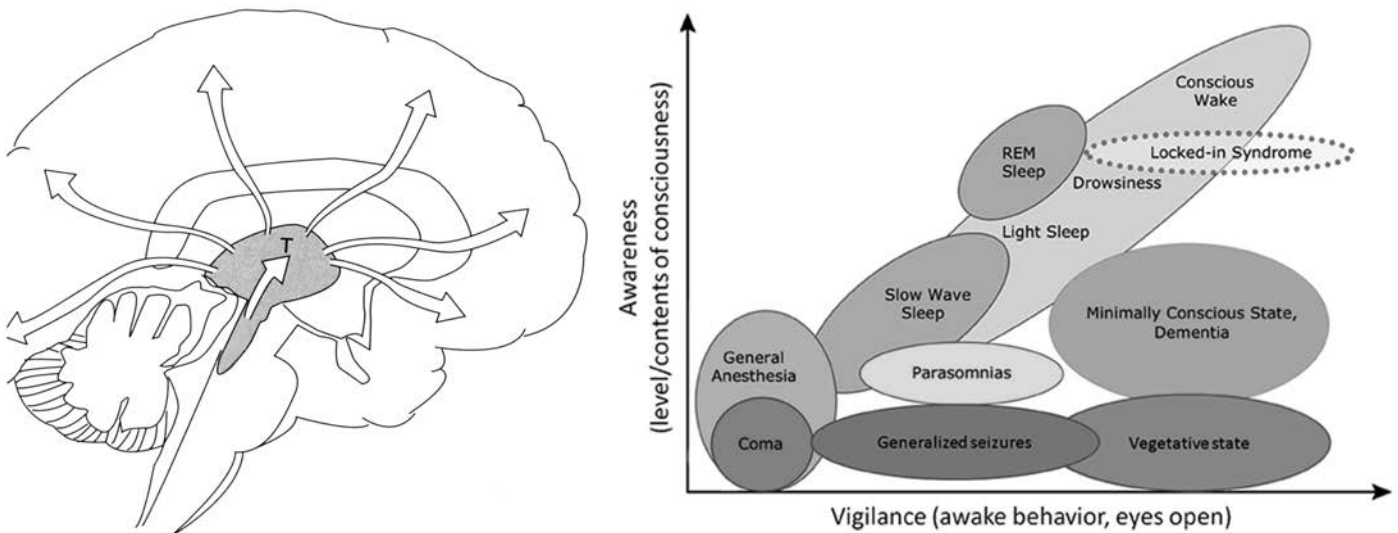

Figure 6.7 Left: midsagittal view of the brain showing structures responsible for arousal, including the ascending reticular activating system (ARAS) depicted as the upward projecting arrows and the thalamus (T). Right: The level of consciousness can be dissociated from behaviors that are traditionally regarded as signs of arousal (such as eye opening). Higher levels of consciousness are associated with an increased range of conscious contents (with permission from Boly et al., 2013).

equilibrium, and motor control. Recent information has suggested that the cerebellum also participates in neurobehavioral function.

Grossly, the cerebellum can be divided into the body of the cerebellum (*corpus cerebelli*) and the smaller *flocculonodular lobe*. In functional terms, however, a more useful distinction can be drawn between the two lateral cerebellar hemispheres and the centrally located *vermis* (Figure 6.8a). This division is important because the cerebellar hemispheres are devoted to coordination of the limbs whereas the vermis is involved with postural adjustment. Damage to these areas of the cerebellum thus causes, respectively, limb ataxia and postural instability (also known as *truncal ataxia*).

Like the cerebrum, the cerebellum contains both gray and white matter. The gray matter is found in the cerebellar cortex, where neuronal cell bodies are arranged in three layers—the superficial molecular cell layer, the intermediate Purkinje cell layer, and the deeper granular cell layer—and in four collections of cell bodies within the cerebellum called the *dentate*, *globose*, *fastigial*, and *emboliform* nuclei. The white matter consists of myelinated axons coursing to and from the cerebellar cortex, and three cerebellar peduncles—inferior, middle, and superior—that connect the cerebellum with the medulla, pons, and midbrain, respectively (Figure 6.8b).

The importance of the cerebellum in the motor system stems from its intermediate position between multiple sensory inputs and its connections with motor regions of the cerebral hemispheres. A variety of vestibular, spinal, and cerebral cortical inputs are received by the cerebellum through the inferior and middle cerebellar peduncles. After

extensive processing occurs, cerebellar output is sent via relays from the four deep nuclei through the superior cerebellar peduncle to the midbrain, and then to the contralateral ventral anterior (VA) and ventral lateral (VL) nuclei of the thalamus. These thalamic connections allow the cerebellum to influence the motor cortex, providing for the fine-tuning of limb and truncal movements. An important point for clinicians is that ataxia on one side of the body reflects damage on the same side as the cerebellar lesion: Unlike lesions of the cerebral hemispheres, cerebellar deficits are ipsilateral to the lesion because the cerebellar motor output crosses to the opposite thalamus, and then the corticospinal tract subserving voluntary movement crosses again to the side of the lesion.

Ataxia is the most characteristic feature of cerebellar damage, and may be most apparent in the limbs, the trunk, or in speech (as in a type of dysarthria called *scanning speech*). A wide-based gait and muscle hypotonia are also commonly encountered with cerebellar lesions. A contribution of the cerebellum to neurobehavioral function is being increasingly recognized. The acquisition of a skill such as playing a musical instrument (an example of procedural learning) appears to depend in part on the cerebellum, and mounting clinical evidence supports the notion the cognitive and emotional deficits can develop in individuals who have sustained cerebellar damage (Schmahmann & Sherman, 1998).

Figure 6.8b shows a sagittal MRI view off the midline showing the superior cerebellar peduncle and its attachment to the brain stem, with a coronal section cut somewhat obliquely that shows both cerebellar hemispheres (green lines

Figure 6.8a The cerebellum and functional lobes (© Hendelman 2006; reproduced with permission).

indicate the orientation and plane of each MR image). A close up of the cerebellar vermis is also shown with a midline MRI slice through the aqueduct of Sylvius and the fourth ventricle (upper right-hand image) depicting the ten lobules of the cerebellum. Lastly, sagittal DTI tractography shown in different colors depicts different trajectories of white matter pathways connecting the cerebellum and brain stem.

### **Diencephalon**

The diencephalon is a collection of four structures located deep in the cerebral hemispheres immediately rostral to the midbrain and surrounding the third ventricle: the thalamus, hypothalamus, subthalamus, and epithalamus. Although small in size, the diencephalon has many important roles in

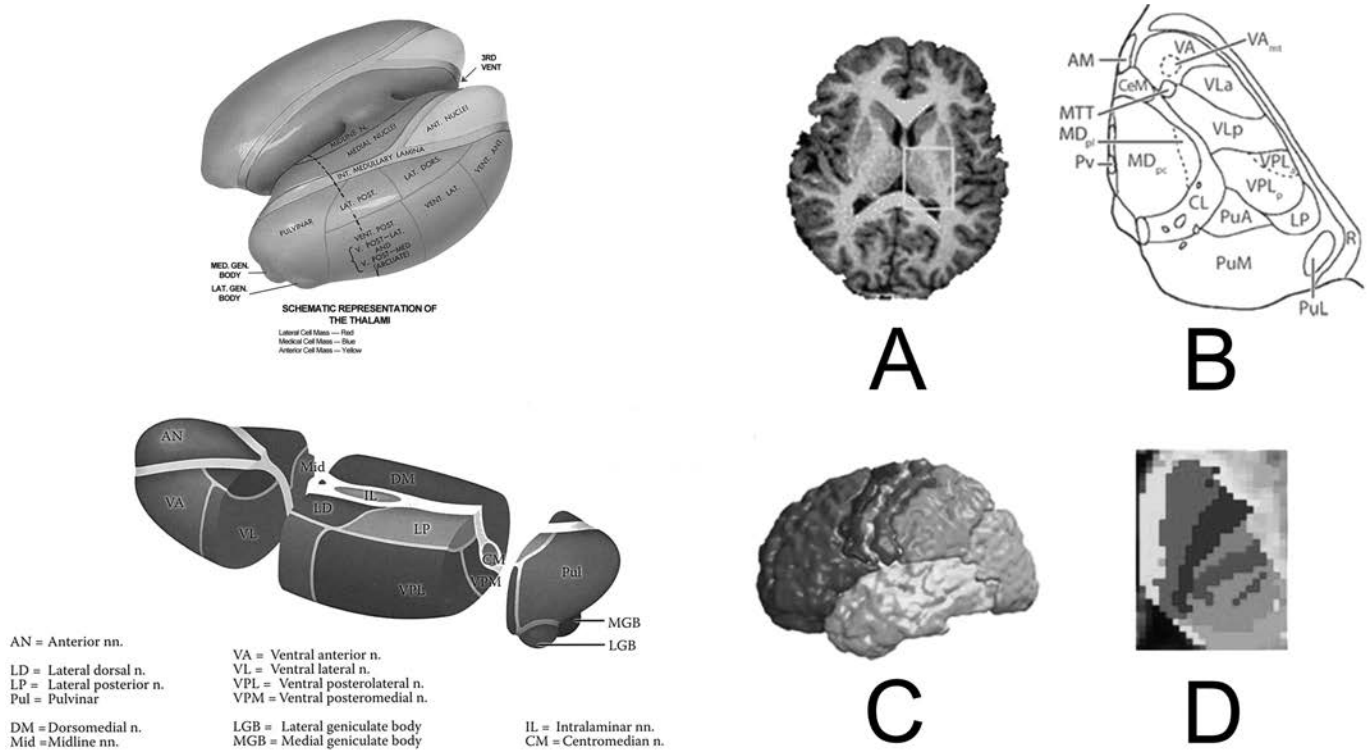

**Figure 6.8b** Upper left: a sagittal MR image cut off midline showing a section through the bulk of the cerebellum, with the coronal MRI demonstrating the appearance of the cerebellum in this plane. Lower left: a coronal image showing the level of cut (the vertical line) for the section shown in the upper image. Upper right: the traditional ten lobes of the cerebellar vermis as identified in the mid-sagittal cut. Bottom right: DTI tractography of the cerebellum and brain stem depicting the various major projections in this region. The left panel larger view of the cerebellum shows a lateral view, and the right larger panel shows a medial view where the smaller outside images depict the orientation of the superior (b), middle (c), inferior (d) cerebellar peduncles, and the corticospinal tract (a). Small insets show each pathway separately. The letters on each panel indicate the following: (A) anterior, (P) posterior, (D) dorsal, (V) ventral, (L) left, (R) right. (From Takahashi, Song, Folkerth, Grant, & Schmahmann, 2012; used with permission from Elsevier.) *A color version of this figure can be found in Plate section 1.*

nervous system function, particularly through the activities of the thalamus and hypothalamus.

The thalamus is an egg-shaped collection of nuclei that comprises about 80% of the diencephalon (Figure 6.9). Although primarily involved with sensation, the thalamic nuclei also participate in movement, arousal, cognition, and emotion. The most familiar thalamic function is to serve as a sensory relay station for stimuli that will eventually reach the cerebral cortex. All sensory systems with the exception of olfaction traverse the thalamus en route to their respective cortical areas. Accordingly, somatosensory information from the contralateral body and face reach the VPL and VPM nuclei, respectively, and taste fibers also project to the VPM nucleus. Similarly, visual projections from the optic nerve synapse in the lateral geniculate nucleus and auditory fibers in the medial geniculate nucleus. The VA and VL nuclei receive fibers from the cerebellum, and they also send fibers to the basal ganglia to enable their participation in the motor system. The intralaminar nuclei—the two largest of which are the centromedian and parafascicular nuclei—subserve the arousal system by

receiving input from the brain stem ARAS and then relaying this input rostrally to activate the cerebrum. The dorsal medial nucleus and the pulvinar are the major thalamic nuclei for association regions of the cerebral cortex, and they contribute to cognition by connecting with the frontal and parietal-temporal-occipital cortices, respectively. The anterior nucleus plays a role in emotion by virtue of its position within the limbic system. Contemporary neuroimaging methods permit the identification and parcellation of thalamic regions and their cortical projections, as shown in Figure 6.9.

The hypothalamus is much smaller than the thalamus but exerts a powerful influence on autonomic, endocrine, and emotional function. Situated inferior to the thalamus and superior to the pituitary gland, the hypothalamus contains many tiny nuclei that in general help maintain bodily homeostasis. As the control center of the autonomic nervous system, the hypothalamus regulates aspects of body temperature, digestion, circulation, water balance, and sexual function. The autonomic nervous system is divided into a parasympathetic branch, which is generally associated with anterior regions,

**Figure 6.9** Left: the thalamus and its many constituent nuclei. These nuclei function as relay stations for information traveling to and from the cerebral cortex. (© Hendelman 2006; reproduced with permission). Right: (A) standard T1-weighted axial MR image with the yellow box highlighting and outlining one half of the thalamus; (B) thalamic nuclei (this will be coordinated with the Handelman diagram), which provides seed regions to examine cortical projections from thalamic nuclei; (C) cortical projections; (D) the aforementioned seed regions. Note how thalamic regions have specialized areas of cortical projection. A color version of this figure can be found in Plate section 1.

and a sympathetic branch that is affiliated with posterior sites. Endocrine function is also governed by the hypothalamus via its extensive neural and vascular connections with the two lobes of the pituitary gland. Lastly, the hypothalamus is a key component of the limbic system, and thus contributes to emotional function. The “flight or fight” response to threat, for example, is an illustration of the dramatic emotional display that requires the activity of the hypothalamus.

The remaining diencephalic regions have more limited significance. The subthalamus is a small area inferior to the thalamus that contains the subthalamic nucleus and the zona incerta; these areas have connections to the basal ganglia and cerebral cortex, but their functions are largely obscure. The epithalamus lies superior and caudal to the thalamus, and consists of the pineal gland and the habenular nuclei. The pineal gland is an unpaired brain structure that was once considered by Rene Descartes to be the seat of the soul; today it is known to secrete a hormone called *melatonin* that is thought to contribute to sleep and gonadal function.

### Basal Ganglia

The basal ganglia include a number of gray matter structures located deep in the cerebral hemispheres. Their importance derives from their major role in motor function, and because

increasing evidence from clinical populations also relates these regions to cognitive and emotional functions.

No uniformity of opinion exists about which structures should be included within the basal ganglia. However, most authorities would agree that the caudate nucleus, globus pallidus, and putamen should be listed under this heading, and many also include the midbrain substantia nigra and the subthalamic nucleus of the thalamus. For purposes of this chapter, the caudate, putamen, globus pallidus, and substantia nigra will serve to focus the discussion (see Figures 6.1, 6.2, and 6.4b), as these nuclei are most frequently implicated in clinical disorders. Other terminology of these structures is also worth reviewing: the caudate and putamen are often called the *striatum*, and the putamen and globus pallidus are alternatively referred to as the *lenticular nucleus*.

The principal function of the basal ganglia is to serve as an integrated unit in the modulation of the cerebral cortical control of voluntary movement. In performing this role, the basal ganglia make use of a series of parallel loops that mediate their involvement in cortical motor output. The most prominent of these loops involves the following: a number of cortical inputs reach the striatum by means of white matter tracts called the *internal* and *external capsules*; from this point, connections proceed first to the globus pallidus

and then to the VA and VL thalamic nuclei; the final link involves connections returning from these nuclei back to the motor cortex, again via the internal capsule. The basal ganglia thus join the cerebellum as regions strongly connected to the voluntary motor system via specific thalamic relays. Whereas the cerebellum has a prominent role in coordination, the basal ganglia can be thought of as contributing to the initiation and timing of movements.

A final aspect of basal ganglia anatomy deserving attention is its neurochemical input, which arises from the midbrain substantia nigra (the general location of the midbrain is shown in Figures 6.4c and 6.6). Pigmented cells of the substantia nigra send axons rostrally to deliver the neurotransmitter dopamine to the striatum. Among the many functions of this important neurotransmitter, dopamine serves to activate the basal ganglia and the motor system in general, and its deficiency or absence within this system results in dramatic alterations in motor function. Parkinson's disease is the well-known neurologic disorder in which dopamine depletion in the substantia nigra causes classic clinical features of bradykinesia (slowness of movement), rigidity, and resting tremor. This is the most significant movement disorder because of its high prevalence, progressive course, and favorable response to dopaminergic drugs. Parkinson's disease has also served as a prototype disorder for the syndrome of subcortical dementia,

an important concept in behavioral neurology and neuropsychology (Cummings, 1990).

### Limbic System

The limbic system has long been a confusing but crucial concept in neuroanatomy and clinical neuroscience. The term *limbic* derives from the Latin *limbus*, meaning "border." The limbic system was identified by the French neurologist Paul Broca in 1878 as a collection of structures at the junction of the diencephalon and the cerebral hemispheres. Whereas some authors consider the limbic system to be a discrete lobe of the brain, its extensive thalamic, hypothalamic, and cortical connections justify its consideration as a transitional zone between the diencephalon and the hemispheres. Although opinions differ about what regions should be designated as the limbic system, there is little disagreement that the hippocampus, amygdala, cingulate gyrus, and parahippocampal gyrus deserve inclusion (Figure 6.10); other structures are variably listed in neuroanatomic accounts, but these details are less crucial than understanding the notion of the limbic system as a functional unit. It is now clear that the human limbic system, at one time thought to have a central role in olfaction, is actually much more devoted to memory and emotion. The two most important limbic components—the

Figure 6.11 The Papez circuit (reproduced and adapted with permission from Pliszka, 2005).

hippocampus and amygdala—serve as nodal points for these two critical limbic circuits. The location of these structures within the temporal lobe suggests a strong linkage of limbic and temporal systems, and the terms *temporal lobe-limbic* and *temporolimbic* are often used to signify their extensive neuroanatomic and functional overlap.

The role of the limbic system in emotion is firmly established. In 1937, James Papez published an influential paper proposing that an interconnected network of structures including the cingulate gyrus, the parahippocampal gyrus, the hippocampus, the fornix, the mammillary bodies, the mammillothalamic tract, and the anterior nucleus of the thalamus comprised the cerebral basis of emotion (Papez, 1937). After decades of study and debate, this network, known as the *Papez circuit* (Figures 6.10 and 6.11) endures as a central concept in the still poorly understood area of emotion. Studies in recent years have identified the amygdala, a dense collection of nuclei in the anterior temporal lobe, as centrally involved in emotional learning and response, and the amygdala has now assumed major status in the neuroanatomy of emotion (LeDoux, 1996). Sensory input to the brain is extensively funneled to the amygdala, where it undergoes processing that produces an assessment of emotional valence: This processing may involve powerful emotional experiences such as intense fear and influence an equally impressive response such as the “flight or fight” reaction that is mediated through autonomic and endocrine systems of the hypothalamus.

In parallel with this expanding knowledge of the representation of emotions in the brain, the prominence of the hippocampus in memory has become more apparent (Squire & Zola, 1996). *Hippocampus* serves as a shorthand term for a trio of regions called the *dentate gyrus*, *hippocampus proper*, and the *subiculum*. This curved sheet of three-layered (archi-)cortex is tucked into the medial temporal lobe (Figure 6.12a). Figure 12b shows a ventral schematic view of the base of the brain depicting the relative position of the hippocampus in relation to other temporal lobe structures. To the right of the schematic

is an actual post-mortem view of an intact ventral surface of the right temporal lobe compared to a dissected right temporal lobe revealing the different structures of the temporal lobe. The acquisition of declarative memory, which refers to the learning of facts and events as opposed to skills, is dependent in large part on the hippocampus, as it is well known that bilateral destruction of the hippocampus leads to severe and disabling dysfunction of recent declarative memory. Memory loss of this type may also follow damage to the dorsal medial nucleus of the thalamus and the basal forebrain (Figures 6.9 and 12a, b), implying that a network of interconnected structures subserves this domain. However, the centrality of the amygdala and hippocampus in the dual and tightly interconnected networks of emotion and memory is an intriguing neuroanatomic feature. The close proximity of these structures, and the systems they represent, likely accounts for the common experience that events with the greatest emotional significance are those most likely to be encoded in declarative memory.

### White Matter

White matter occupies nearly one half the volume of the brain, and it serves in general to link cortical and gray matter regions with each other. The white matter consists of collections of CNS axons ensheathed with myelin that are most commonly called *tracts*, but that may also be termed *fasciculi*, *bundles*, *lemnisci*, *funiculi*, and *peduncles*. In the brain, these tracts travel between often widely dispersed gray matter areas to integrate cortical and subcortical areas into functionally unified neural networks (Figure 6.13). These networks in turn subservise the many unique functions of the brain, from basic sensation and motor function to cognition and emotion. The dramatic increase in conduction velocity that is conferred by the myelin of white matter axons allows for the rapid transfer of information along white matter tracts, a feature that permits not only efficient communication in sensory and motor systems, but also the integration of higher functions mediated by networks involving neocortical systems. White matter is thus essential for the normal operations of all neural networks (Filley, 2012).

White matter tracts in the brain are generally classified into three major categories: projection fibers, commissural fibers, and association fibers. Projection fibers are solely involved with elemental sensory and motor function; thus they either ascend to the cerebral cortex from lower structures corticopetally, or descend from the cortex to lower regions corticofugally. Major corticopetal (afferent) tracts are the thalamic radiations, relaying somatosensory information from the thalamus to the parietal cortex, and the optic radiations, projecting from the lateral geniculate body to the occipital cortex. The most important corticofugal (efferent) tract is the corticospinal tract, which projects from the motor cortex to lower motor neurons in the spinal cord. The corticobulbar tract occupies a similar position but descends to lower motor neurons in the brain stem. Knowledge of the course of these motor tracts is regularly exploited in neurologic diagnosis. Both of these tracts first travel through the internal capsule, and then cross at different levels; corticospinal fibers decussate

in the lower medulla to reach the contralateral spinal cord, whereas corticobulbar fibers cross in the brain stem before synapsing on the motor neurons to which they project.

More critical in the mediation of higher functions are the commissural and association fibers (Figure 6.13). Commissural fibers are those that course between the hemispheres via the cerebral commissures. By far the largest of these commissures is the *corpus callosum*, a massive tract that connects the four lobes of the brain with homologous regions on the contralateral side; the anterior and hippocampal commissures are much smaller commissural fiber systems. The association tracts, in contrast, join gray matter regions within each hemisphere. Among these, neuroanatomists have distinguished two types: short and long association fibers. Short association

fibers, also called *arcuate* or *U fibers*, connect adjacent cortical gyri throughout the cerebrum. Long association fiber systems are longer and link ipsilateral cerebral lobes; these are the *superior occipitofrontal fasciculus*, the *inferior occipitofrontal fasciculus*, the *arcuate fasciculus*, the *uncinate fasciculus*, and the *cingulum*. An interesting neuroanatomic feature of these tracts is that they all have one terminus in frontal lobe, while the other terminus is variably in more posterior regions.

Many other white matter tracts can be identified, but two deserve special mention. The *fornix* is a prominent arched tract of the limbic system that connects the hippocampus and the mammillary bodies within the Papez circuit. The *medial forebrain bundle* joins the hypothalamus with both caudal and rostral brain regions and participates in the hypothalamic control of the autonomic nervous system.

Contemporary neuroimaging techniques, most impressively DTI, provide methods to extract aggregate images of white matter pathways from the brain, as shown in Figure 6.13. Beyond the capacity of DTI to show dramatic images of the brain and its major pathways, anisotropic measurements can also be made that actually reflect the microscopic integrity of the tissue. Thus not only can an image of a white matter pathway be generated in the living individual, but also quantification is possible regarding the condition of the pathway and its viability.

### Cerebral Cortex

The surface of the brain is grossly visible as the *cortex*, meaning “bark” in Latin. The cerebral cortex is the outermost layer of the cerebrum, and it consists of a thin sheet of neurons averaging 3 mm in thickness. The number of cerebral cortical neurons is estimated at 25 billion, and the number of synapses between these neurons may be an extraordinary 300 trillion. The computational power made possible by this remarkable number of contacts renders the cerebral cortex as the locus of the most advanced functions of the human brain. An understanding of cortical structure and function is a prerequisite for the neuroscientific study of the mind and all that this pursuit entails.

Microscopically, the cerebral cortex has a horizontally laminated structure. More than 90% of the cortex is classified as *neocortex*, a term that signifies the relatively recent arrival of this structure in the course of evolution. The neocortex consists of six layers: the outermost molecular layer, the external granular cell layer, the external pyramidal cell layer, the internal granular cell layer, the internal pyramidal cell layer, and the innermost multiform layer. A vertical organization to the neocortex can also be defined physiologically. Columns of cells, arranged perpendicular to the cortical surface, respond as a unit to a given stimulus. Hundreds of millions of these columns exist, connected with each other and many more caudal areas by the axons of pyramidal cells.

The remaining cortical regions are classified as *allocortex*, which is in turn made up of *paleocortex* and *archicortex*, ancient cortical types that are more prominent in lower animals than humans. The olfactory system is largely allocortical in composition, and one of the most important allocortical

zones is the hippocampus. As reviewed earlier, the hippocampus is a cortical area of the limbic system that is involved with the memory and emotional systems of the brain. The hippocampus has three layers: the outer molecular layer, the pyramidal cell layer, and the inner polymorphic layer.

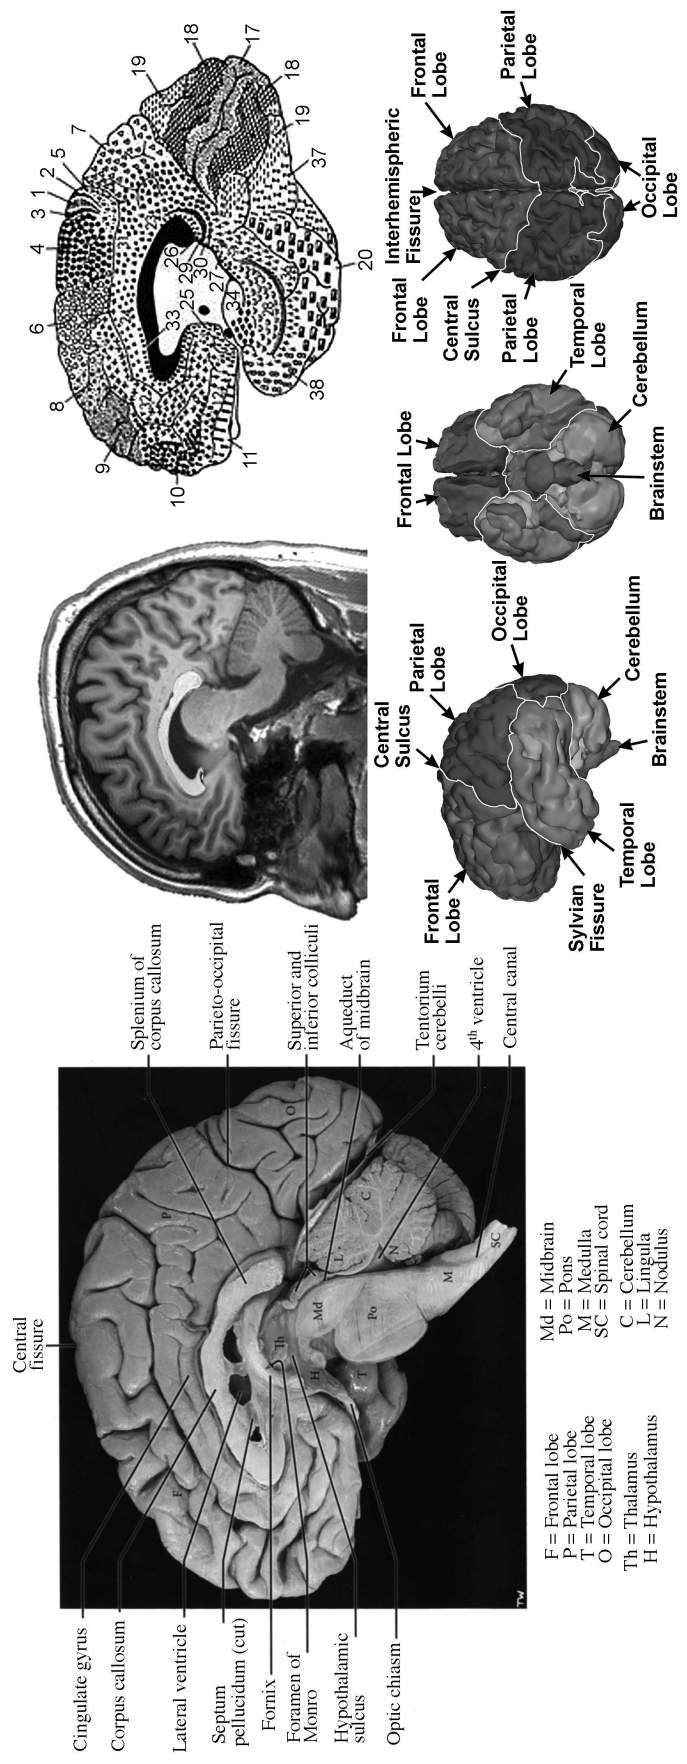

Neuroanatomists have often attempted to divide the cerebral cortex into discrete zones in an effort to understand its functional affiliations. The best known of these cortical parcellations is that of Korbinian Brodmann (Brodmann, 1994), who described about 50 areas of the cortex, based on distinct histological characteristics he found in each (Figure 6.14). Although some of these areas have been found to have clear functional roles, the significance of many still remains undetermined. Nevertheless, the cortical map of Brodmann has endured for almost a century, and reference to his carefully numbered zones is commonplace in accounts of neocortical anatomy and function.

The cortical surface serves as the basis for the definition of the four lobes of the cerebrum: the frontal, temporal, parietal, and occipital lobes (Figures 6.2, 6.4b, 6.9, and 6.14). These lobes are widely employed as convenient divisions of the cerebral hemispheres that facilitate conceptualizations of neurobehavioral functions in the brain. The frontal lobe is

the most rostral of the four, positioned anterior to the Rolandic fissure and superior to the Sylvian fissure. The temporal lobe lies inferior to the Sylvian fissure, and its posterior boundary is determined by the junction of two lines: one from the parietooccipital sulcus to the preoccipital notch and the other running posteriorly from the end of the Sylvian fissure (Figure 6.4b). The parietal lobe is found posterior to the Rolandic fissure, and its inferior margin is also defined by the two lines that form the posterior extent of the temporal lobe. The occipital lobe is located posterior to both the temporal and parietal lobes. Another small neocortical region, not visible on the brain surface, is the *insula*, or *island of Reil*, concealed under the Sylvian fissure by portions of the frontal, temporal, and parietal lobes.

### The Relationship of Brain and Behavior

The foregoing synopsis of neuroanatomy, however truncated, may appear overwhelming in its complexity. Moreover, the relevance of much neuroanatomic detail to neuropsychology may seem uncertain. In this section, an attempt will be made to develop a series of conceptual themes in neuroanatomy

**Figure 6.14** Left: medial illustration of the brain showing the position of the four lobes of the cerebral hemispheres (© Hendelman, 2006; reproduced with permission). Middle: MR image at a similar level (slightly off the midline, so as to reveal the gyral pattern of the medial surface unobscured by the falx cerebri, as it will most typically appear on a mid-sagittal cut with conventional MRI). A color version of this figure can be found in Plate section 1.

Filley & Bigler Neuroanatomy for the neuropsychologist

that are particularly useful to the clinical practice and research goals of neuropsychology. A working knowledge of neurobehavioral anatomy is clearly an essential prerequisite for the study of brain-behavior relationships (Cummings, 2003; Filley, 2012; Mesulam, 2001).

### General Principles

An initial grasp of the brain as the organ of human behavior can be gained by considering some general organizational principles. As a first step, brain function can be broadly considered by reference to a series of distinctions based on the vertical, longitudinal, and horizontal dimensions of the cerebral hemispheres.

**Vertical organization.** Seen in the context of its evolutionary development or phylogeny, the vertical organization of the brain becomes apparent (Cummings, 2003). The course of evolution has endowed human beings with a highly developed brain that enables unique behaviors permitting unprecedented mastery of the environment. This development mainly entails the progressive expansion of the cortical mantle seen in mammalian evolution, particularly the frontal lobes. However, many features of the human brain are shared in common with other animals, such as those concerned with basic needs such as feeding, defensive aggression, and reproduction. Humans have neuroanatomic residua of ancient neural systems common to many animals, but also harbor more recently evolved brain systems that confer a set of unique adaptive abilities. In this sense, the human brain can be seen as the most highly developed nervous structure in nature.

The hierarchical structure of the brain has been described by MacLean as the “triune” brain (MacLean, 1970). In his formulation, three levels of neural development can be identified: reptilian, paleomammalian, and neomammalian. The reptilian brain—including the brain stem, cerebellum, and thalamus—is a primitive inner core concerned with arousal, autonomic, cardiovascular, respiratory, and visceral functions. The paleomammalian brain, consisting of the limbic system, reflects early mammalian development and the advent of drives, child rearing, communal bonding, and territoriality. The neomammalian brain, essentially the cerebral cortex, harbors the most recent mammalian capacities that are generally referred to as cognition and emotional behavior.

Whereas the triune brain of MacLean has had considerable theoretical impact, a distinction based on the levels of neuroanatomic organization in the human cerebrum may have more direct applicability to clinicians and researchers in neuropsychology. In recent decades, much work has been devoted to contrasting the neuropsychological affiliations of the cerebral cortex with those of the subcortical gray matter (Cummings, 1990), and, more recently, the cerebral white matter (Filley, 2012). Although the disorders affecting these three broad regions are necessarily diffuse in their distribution, and thus these lines of inquiry do not assist in establishing specific brain-behavior relationships based on the study of focal lesions, the distinction between cortical, subcortical, and white matter dysfunction is relevant to the majority of patients seen

by neuropsychologists who have diffuse cognitive dysfunction from dementia or traumatic brain injury. Consideration of these categories therefore extends the classic lesion method of behavioral neurology to the study of diffuse brain disorders that are so common and challenging to medicine and society.

**Longitudinal organization.** Along its longitudinal axis, the brain can immediately be seen to have a clear division of functional specialization. In brief, this separation divides the anterior cerebrum, devoted to motor function, from the posterior cerebrum, dedicated to sensory function.

The frontal lobe is the most anterior lobe of the brain, and it harbors the neocortical basis of motor activity. The corticospinal and corticobulbar tracts originate in the precentral gyrus of the frontal lobe, enabling the cortical control of voluntary movement. In addition, the frontal lobes mediate motor aspects of language and emotional prosody by the operations of Broca’s area on the left and its analogous region on the right. The medial frontal regions also have a role in motor function in that they are thought to subserve the motivation to engage in voluntary action; damage to these regions may result in apathy or abulia, and, in extreme cases, akinetic mutism.

The posterior lobes of the cerebrum—temporal, parietal, and occipital—are primarily devoted to sensation. Audition and the comprehension of language and other sounds are functions of the temporal lobes. The parietal lobes are directly involved with the mediation of somatic sensation, and the right parietal lobe is selectively dedicated to the interpretation of visuospatial information. The occipital lobes are primarily dedicated to the sense of vision, which has assumed much greater importance in humans as the sense of olfaction has diminished in value with higher levels of adaptation.

**Horizontal organization.** A final dimensional distinction in the brain can be seen in the functional differences between the two sides of the cerebrum (Springer & Deutsch, 1989). Since the time of Broca, one of the best-recognized features of the human brain is its asymmetry with respect to function, an observation that led to the concept of *cerebral lateralization*. The most obvious of these functional asymmetries is the dominance of the left hemisphere for language in most individuals. The right hemisphere has also been recognized to possess dominant functions of its own. The reason for this arrangement is not known, as there appears to be no such lateralization of function in paired organs elsewhere in the body, such as the lungs and kidneys. Nevertheless, the neurobehavioral specializations of the cerebral hemispheres are increasingly well understood, and should always be considered in the assessment and care of neurologic patients.

The left hemisphere is dominant for language in most people. The great majority of right-handers and even most left-handers have their language skills primarily organized in the left hemisphere. It is commonly asserted that 99% of right-handers are left-dominant for language, and that 67% of left-handers are also left-dominant for this domain (Filley, 2012). While this generalization is adequate for routine clinical purposes, a more refined view is that 70% of the population is dextral and strongly left-dominant for language, 10% is sinistral and right-dominant for language, and 20%

is ambidextrous with anomalous (bilateral) language representation. These statistics find support in the asymmetry of the *planum temporale*, a structure of the superior temporal lobe concerned with language processing, in that about 70% of brains have a larger left side, 10% a larger right side, and 20% roughly equal sizes (Filley, 2012).

The right hemisphere, long considered the “nondominant” or “silent” hemisphere because of its relative inability to process linguistic information, has an impressive range of functions for which it can be regarded as dominant. The most uncontroversial domains that can be regarded as right-hemisphere dominant are constructional ability, spatial attention, and language prosody (Filley, 2012). Also attributed by many to the right hemisphere is music, although contributions from the left hemisphere also contribute to this highly complex capacity (Filley, 2012). In any case, the broad range of higher functions organized by both hemispheres, separately or in combination, clearly indicates that neither side is dominant in any absolute sense, that brain areas work together to produce optimal performance, and that, in neurobehavioral terms, there are no silent areas of the cerebrum.

### *Neural Networks*

As the preceding discussion suggests, the localization of higher function in the brain is a central goal of neuroscience. Whereas generalizations regarding the functional organization of the brain are useful, more specific localization of higher functions within the hemispheres remains an imperative of neuroscience research. The representation of cognitive and especially emotional function in the brain has long been vigorously debated because the precise determination of the locus of these skills has often proven elusive. It should be recalled that much of the history of neuropsychology and behavioral neurology took place during an era when the only means of determining brain-behavior relationships was through postmortem study, but even in the age of modern neuroimaging, uncertainty remains about the consistency with which a given function can be said to be represented in a specific brain region.

Traditionally, the debate about cerebral representation of higher function has had two major factions: *localizationists* and *equipotential theorists*. The former group begins with the time-honored practice of neurologists that emphasizes detailed understanding of nervous system structure and the localization of functions within it. This process permits the application of the lesion method to the study of higher functions, theoretically producing a secure map of brain-behavior relationships. Whereas this approach is highly effective in localizing elemental neurologic deficits such as CN deficits and hemiparesis, it has not proven as reliable in identifying the sites of higher functions. There is no simple correspondence, for example, between a given gyrus and a discrete cognitive domain, and this kind of localization of higher function has proven to be inadequate for capturing the complexity of brain-behavior relationships. In this regard, strict localization has been justifiably criticized for too closely resembling its intellectual predecessor, the phrenology of Franz Joseph Gall (Filley, 2012).

Equipotential theorists have contended that any specific localization of higher functions in the brain is impossible. Most closely associated with the early 20th century Karl Lashley, the equipotential theory held that all cerebral cortical areas are capable of supporting the operations of higher functions (Filley, 2012). The cortex was considered to be essentially undifferentiated with respect to mentation, and thus a lesion in any cortical zone could be expected to diminish neurobehavioral capacity in proportion to the amount of tissue damaged. Much clinical and experimental evidence—most obviously that supporting the lateralization of language function discussed earlier—contradicts this claim, and it is clear from numerous clinical and neuroimaging studies that considerable specialization of cerebral areas exists with regard to the higher functions. Thus, like strict localization, pure equipotentiality is insupportable in light of current knowledge.

The resolution of this debate appears to come from the concept of distributed neural networks (Mesulam, 2001). As a compromise position, the notion of neural networks postulates that integrated ensembles of interconnected cerebral structures subserve specific neurobehavioral domains. Thus there is no singular and exclusive relationship between a brain structure and a mental function, but neither is there a diffuse representation of functions in which no cerebral specialization exists. Rather, a given domain is represented within a neuroanatomically linked network that operates as a functional unit. Familiar examples of these networks include the left perisylvian language zone and the medial temporal lobe memory system. Other neural networks, such as those subserving executive function and visual perception, are being elucidated with the assistance of modern structural and functional neuroimaging. Increasingly supported by the emergence of new information, the notion of neural networks represents a satisfying resolution of an old debate, and points the way toward many research opportunities designed to explicate the workings of the human brain.

### *Functional Affiliations of the Cerebrum*

The clinical method used for the assessment of neurobehavioral disorders is based on the localization of higher functions in the brain (Filley, 2012; Mesulam, 2001; Cummings, 2003). Although the concept of neural networks increasingly influences thinking about brain-behavior relationships, an understanding of the basic functional affiliations of major brain regions is essential for clinical practice and research in neuropsychology. Individuals are typically referred for neuropsychological evaluation of a specific syndrome—a constellation of symptoms and signs that indicates the origin of clinical dysfunction. The neuropsychologist plays a crucial role in characterizing the nature and severity of the syndrome, defining the likely localization of the problem, helping to guide further diagnostic testing, assisting with providing the best possible medical care, and contributing to neuroscientific research on cerebral localization. Later chapters present detailed discussions of individual conditions that produce these syndromes; what follows here is a brief consideration

of the neurobehavioral functions of the four cerebral lobes, those brain areas most relevant to the neuropsychologist (see Table 6.2; Cummings, 2003; Filley, 2012; Mesulam, 2001).

The frontal lobe is the largest lobe of the human brain, occupying more than a third of the cortical surface, and it houses a variety of motor, cognitive, and emotional functions. However, because it has appeared most recently in phylogeny and its development seems to parallel that of human behavior, the frontal lobe is regarded as being particularly associated with the highest of human functions. Indeed, the lasting preoccupation of neuroscientists with this part of the brain stems from the enticing likelihood that singularly human capacities are most likely to be explained by reference to this lobe. Yet the essential role of the frontal lobe in human behavior remains elusive, even though much progress has been made in exploring its many contributions.

The most obvious role of the frontal lobe is in voluntary movement, which is based on the origin of corticospinal and corticobulbar tracts in the precentral gyrus (Brodmann area 4). Also important in movement is the supplementary motor area (area 6), which seems to have a special role in the initiation of voluntary movement and speech. In neurobehavioral terms, many other domains are securely associated with the frontal lobes, in particular those areas not concerned with motor function that are known as prefrontal cortex. Language fluency is clearly related to the function of Broca's area (areas 44 and 45) on the left side, and its counterpart in the right hemisphere is thought to subserve motor prosody. Working memory, a recently described domain that is related to both attention and memory, is likely affiliated with the dorsolateral prefrontal cortex (areas 9 and 46). The important concept of executive function, among the most critical

domains for effective human performance, is thought to be mediated by a larger area of prefrontal cortex that includes areas 8, 9, 10, 46, and 47. Comportment, the ability to inhibit limbic impulses and maintain an appropriate behavioral repertoire, largely depends on the integrity of orbitofrontal regions (areas 11, 12, and 25). Lastly, motivation is most closely associated with medial frontal structures including the anterior cingulate gyrus (areas 24, 32, and 33).

The temporal lobe has a primary role in audition, receiving sound stimuli in the primary auditory cortex (Heschl's gyrus, areas 41 and 42) that arise from the ear and ascend through CN VIII, the brain stem, and the thalamus. Further processing of these stimuli then occurs in the temporal lobe as well. On the left, speech sounds are decoded in Wernicke's area (the posterior part of area 22), allowing for the comprehension of language, while in a homologous region on the right, other aspects of sound are interpreted to permit the perception of prosody and related areas such as melody. In addition, the strong associations of the temporal lobe with the limbic system, reviewed earlier, provide the neuroanatomic substrate for the involvement of this lobe in the mediation of memory and emotion.

The parietal lobe has a primary somatosensory affiliation, and interpretation of tactile information occurs in the postcentral gyrus (areas 3, 1, and 2) of each hemisphere. Higher order sensory cortex in the parietal lobe (areas 5 and 7) subserves the perception of tactile stimuli to permit the appreciation of stereognosis and graphesthesia. On the right side, the parietal lobe in general is specialized for visuospatial function, without which the ability to negotiate three-dimensional space is compromised. The right parietal lobe is also specialized for the domain of spatial attention, a feature that explains the curious and often devastating phenomenon of left hemineglect in patients with right parietal damage. These specializations are among those that make the right hemisphere primarily responsible for a wealth of nonverbal skills that significantly enhance human existence. On the left side, in contrast, the predominantly verbal domains of reading and calculation are primarily organized in the angular gyrus (area 39) and the supramarginal gyrus (area 40).

The occipital lobe has the most unified functional affiliation of all the cerebral lobes. Located at the rear of the brain and dominated by the medially located calcarine cortex (area 17), the occipital lobe is devoted to vision. Of all the senses, vision requires the greatest amount of neural tissue, and the occipital cortices represent the neocortical destination of the visual information processed by the eyes. After the first order visual neurons from the retinae synapse in the lateral geniculate body of the thalamus, second order visual neurons project to the calcarine cortex and enable primary visual function at the cortical level. From there, further processing occurs in the visual association cortex (areas 18 and 19) adjacent to the primary occipital cortex, permitting the perception of visual stimuli. Still further visual processing occurs in temporal and parietal regions that are involved in visual recognition. Recent data have supported the existence of two parallel visual systems of visual processing, termed the "what" and "where" systems, involving ventral and dorsal streams, respectively,

of the visual association cortices. These streams begin in the visual association regions subserving visual perception, and then proceed anteriorly to inferior temporal cortices for the “what” system, and parietal cortices for the “where” system.

The affiliations of the four lobes of the brain serve as a useful introduction to the behavioral geography of the brain. In the succinct words of the influential behavioral neurologist Norman Geschwind: “Every behavior has an anatomy” (Geschwind, 1975). The anatomy of higher function is an amalgam of traditional neuroanatomic inquiry, the clinical study of neurologic patients, and the methods of modern neuroscience, all of which are expanding our insights into brain-behavior relationships as never before. Based on this knowledge, the neurobiologic basis of normal cognition, emotion, and consciousness becomes ever more clear. For those concerned with clinical assessment and treatment, this knowledge is a necessary precursor to the care of patients with disorders of the brain.

## Appendix: Structural Neuroimaging Basics for Understanding Neuroanatomy

Viewing neuroanatomy from brain imaging typically involves either CT or MRI, with MRI clearly superior for anatomical detail. In the same subject, Figure 6.15 compares CT with various MR pulse sequences that have different sensitivities to tissue type. In the mid-1990s MR DTI came on the scene, with the discovery that aggregate white matter tracts could be identified and extracted from the image because healthy axonal membranes constrain the direction of water diffusion perpendicular with the orientation of the fiber tract. By assessing directionality of water diffusion, fiber tract projections may be inferred. As shown in Figure 6.16, the diffusion scan from which DTI is derived has a rather fuzzy appearance in native space, but the actual diffusion color maps are rich in information about the directionality of water diffusion where green reflects anterior-to-posterior projecting

**Figure 6.15** Comparison of CT imaging in the axial plane with other standard MRI pulse sequences all from the same individual and all at approximately the same level and imaging plane. Note how each imaging sequence highlights differences in tissue type (see Table 6.3 for tissue characterization). FLAIR: fluid attenuated inversion recovery sequence. GRE: gradient recalled echo sequence. PD: proton density-weighted sequence.

**Figure 6.16** Diffusion imaging showing the diffusion scan in native space in the top center, compared to the T2- and T1-weighted images on either side, with the actual color map centered in the bottom row bordered by the apparent diffusion coefficient (ADC) map on the bottom left and the T2-weighted anatomical image. A color version of this figure can be found in Plate section 1.

tracts, warm colors (orange to red) side-to-side projections, and cool colors (blues) vertically oriented tracts. Figures 6.6, 6.8b and 6.12a and b all present white matter fiber tracts derived from DTI.

Understanding neuroanatomy from neuroimaging is facilitated by the sensitivity of both CT and MRI in detecting differences in white matter and gray matter. Because specific white matter and gray matter boundaries may be distinctly differentiated with high-field MRI, the actual gray matter cortical ribbon and subcortical nuclei can be readily identified, as shown in Figure 6.17. Also, CSF has very different signal intensity from brain parenchyma, meaning it too can be segmented as shown in Figure 6.17. Segmenting tissue also provides the basis for identifying classic brain regions, like the hippocampus as presented in Figure 6.17. By defining

**Figure 6.17** Standard T1-weighted coronal image that has been segmented to differentiate gray matter from white matter and CSF. The image is then classified into identifiable regions of interest or actual anatomical structures. *A color version of this figure can be found in Plate section 1.*

the boundaries of the hippocampus, that region of interest (ROI) may be extracted from the image and depicted in three-dimensional space, also demonstrated in Figure 6.17. Using similar techniques, any neuroanatomical ROI may be extracted from an image showing its anatomical position in relation to other structures as well as quantified in terms of volume, surface area, and shape, to name the most common quantitative measurements.

Figure 6.18 shows the same sagittal view of Figures 6.4c and 6.14 but this time with a vertical line showing the

**Figure 6.18** The mid-sagittal view shown at the top of this figure is the same as in Figures 6.4c and 6.14, with the downward arrow showing the coronal plane where the approximate cut occurred to generate the image in the lower left panel. The lower right panel shows a similar location in a formalin-fixed postmortem brain sectioned at approximately the same level. Note the similarity of the postmortem section to the MRI-derived coronal image as well as the general symmetry of the brain.

approximately level of a cut through the frontal and anterior temporal lobes (although at the mid sagittal level the anterior temporal lobe cannot be visualized in the mid-sagittal cut), with the resulting coronal image below (on the left). Adjacent to the coronal image from the MRI is a formalin-fixed coronal cut of a postmortem brain in approximately the same plane. Note the similarity of the MR image with that of the postmortem image, proof of the anatomical approximation of MRI findings to identify gross anatomy. From this image, the beautiful symmetry of the typical developed human brain also becomes apparent. Notice how the structures in one hemisphere mirror the other. This symmetry principle applies throughout the brain as depicted in a different coronal section more posterior to the position previously shown in Figure 6.19 or in the axial plane in Figure 6.20. Starting with

**Figure 6.19** This is a coronal image using a true inversion recovery sequence that provides exquisite anatomical detail. Note how each hemisphere is the mirror of the other in terms of the distribution and organization of major brain areas and ROIs: (1) interhemispheric fissure; (2) the number sits in the central white matter of the frontal lobe, with the arrow pointing to the caudate (gray matter) and lateral ventricle (dark space); (3) the lower part of the number sits in the corpus callosum, with the top of the number sits in the cingulum bundle within the cingulate gyrus, and the arrow points to the body of the fornix; (4) thalamus; (5) the number sits in the lenticular nucleus, which is formed by the lighter (meaning more white matter) globus pallidus (to the right of the number) and the putamen (darker gray, to the left of the number); (6) hippocampus; (7) superior temporal gyrus of the temporal lobe, which forms the top of the temporal lobe, with in descending order followed by the middle temporal gyrus, inferior temporal gyrus, fusiform, and parahippocampal gyrus; (8) Sylvian fissure to the left of the number, frontal lobe above, temporal lobe below and to the right of the number, insular cortex.

*Figure 6.20* This is also a true inversion recovery sequence but in the axial plane, showing the same symmetry than can be visualized in the coronal plane: (1) interhemispheric fissure; (2) the number sits within the posterior corpus callosum, with the bottom of the number within the posterior cingulum bundle within the cingulate gyrus and the right top of the number adjacent to the posterior aspect (atria) of the lateral ventricle; (3) dashed arrow points to the caudate, dotted arrow points to the internal capsule and the straight arrow to the claustrum, where to the left of the claustrum the external capsule may be visualized and to the right, the extreme capsule; (4) the number is within the thalamus, with the left arrow pointing to the third ventricle and the dashed arrow to the column of the fornix; (5) the insular cortex within the Sylvian fissure.

the interhemispheric fissure (see label Number 1, in either the coronal image of Figure 6.19 or the axial image of Figure 6.20), essentially one hemisphere duplicates the other. So as to not clutter the image, labelling numbers are given only in one hemisphere in these two figures, but it is readily apparent that the brain structures numbered in one hemisphere appear nearly identical to that of the other hemisphere.

For normal anatomical appearance the above description represents the symmetry principle of a typical, healthy brain (Bigler 2015). Typical brain development is dynamic, so understanding normal brain anatomy also means understanding changes that may be relevant to the age of the individual being scanned. However, in the “normal” aging process, purely age effects will be registered within this

normal symmetry, so that for a particular age ROIs appear symmetric across both hemispheres as reflected in Figures 6.18 to 6.20.

Combined with the principle of symmetry, also reflected throughout this chapter is the anatomical principle of normal “similarity” across healthy brains. In other words, in a very general sense, one brain appears similar to another. Returning to Figure 6.18, even though one image is based on an in vivo MRI section in a very much alive human adult and the other is postmortem, both are recognizable for their similar appearance at about the same point in the frontal and temporal regions of the brain in the coronal plane. Likewise the coronal image in Figure 6.17A is from a different pulse sequence than in Figure 6.19, yet there are obvious similarities. By applying the similarity and symmetry principles to understanding age-typical brain anatomy, in most cases a scan image may be straightforwardly identified as normal in appearance or not.

That last piece of a general overview to understand anatomy from imaging is understanding how the underlying physics of CT and MRI provide the basis for generating the resulting image. CT is based on x-ray beam technology where the physical density of tissue influences the speed of the x-ray beam as it passes through skin, the skull, and brain parenchyma. Reconstructing this information in two- or three-dimensional space provides an image as shown in the top left of Figure 6.15. By convention, on CT, bone is white, reflecting the greatest density encountered by the x-ray beam, whereas CSF and air pockets (as in a sinus area) provide the least density and are categorized as dark in a CT image. Because white matter is largely comprised of myelinated axons, it has a different density and water content compared to gray matter comprised of cell bodies. Accordingly, in viewing CT, white matter is darker gray, gray matter is lighter gray, CSF is dark gray to black, air is black, and bone bright white.

The MR signal is the result of a resonance interaction between hydrogen nuclei and externally applied magnetic fields spatially encoded to provide a mapping of the image area in two or three dimensions. The signal intensity depends on the density and the magnetic environment of the hydrogen nuclei (i.e., protons). Since white matter and gray matter differ in water content and have characteristically different MR signal properties, MR images of the brain with visible and distinguishable differences in gray and white matter may be shown as depicted in the various illustrations within this chapter, especially Figures 6.15 and 6.16. How distinct white and gray matter may be differentiated depends on the pulse sequence used, which will yield different findings as outlined in Table 6.3.

The use of innovative methods for varying the magnetic field strength, the delays between the sending and receiving of the radio waves, and the acquisition and display of the signal intensity allow a wide range of images to be produced.

Table 6.3 Neuroanatomy MRI appearance of commonly scanned tissues

Tissue	T1-Weighted	T2-Weighted	Proton Density-Weighted
Gray Matter	Gray	Light Gray	Light Gray
White Matter	White	Dark Gray	Gray
CSF or Water	Black	White	Dark Gray
Fat	White	Black	Black
Air	Black	Black	Black
Bone or Calcification	Black	Black	Black
Edema	Gray	White	White
Demyelination or Gliosis	Gray	White	White
Ferritin Deposits (e.g., in Basal Ganglia)	Dark Gray	Black	Black

Note: On fast spin echo (FSE) sequences (a faster variant of the SE sequence), fat appears bright in T2-weighted and proton density-weighted images.

For example, the behavior of the protons is characterized by two time constants, called T1 and T2. T1 reflects the rapidity with which protons become realigned with the magnetic field after a radio frequency (RF) pulse. Scans that are T1-weighted tend to show greater detail but less contrast between structures; these images are therefore optimum for showing anatomy. T2 reflects the decay of in-phase precession (desynchronization or “dephasing”) of protons after the pulse. Scans that are T2-weighted generally show normal structures as having an intermediate (gray) intensity, while fluid and many pathologic abnormalities appear with high intensity (white). These images provide excellent contrast between normal and abnormal structures and are, therefore, used for identifying both anatomy and pathology. Sequences that provide an average of T1 and T2 weighting are called *proton density sequences*. The appearance (brightness) on the various sequences can be used to characterize the tissue.

The true inversion recovery sequence shown in Figures 6.19 and 6.20 depicts the exquisite detail that can be achieved with MRI for portraying anatomy. For example, in Figure 6.19 the very thin band of gray matter that forms the claustrum may be visualized. Another sequence that uses subtle changes in magnetic field strength, called *gradient echo (GRE)*, allows excellent image detail in short imaging times and has the added advantage of being sensitive to the presence of blood as well as blood breakdown products (hemosiderin) as a result of hemorrhage. A *susceptibility-weighted imaging (SWI)* sequence (SWI) that uses a GRE pulse sequence is particularly sensitive in detecting venous blood as shown in Figure 6.21 and in pathological conditions, is sensitive in demonstrating presence of microhemorrhages. SWI impressively demonstrates the complex architecture of venous blood in a healthy individual as seen in Figure 6.21 (same as shown in Figures 6.18 and 20). The fluid attenuated inversion

Figure 6.21 Susceptibility weighted image at a level just below what was shown in Figure 6.20, from the same individual, showing venous distribution to the thalamus, posterior lateral ventricle, and basal ganglia as well as cortical surface-draining veins.

recovery (FLAIR) sequence is particularly sensitive to white matter pathology, but within a normal brain, as shown in Figure 6.15, signal in the parenchyma offers little distinction between white and gray matter.

# 7 The Central Nervous System and Cognitive Development

*Kathryn C. Russell*

## Introduction

Anyone who has met a child knows that children's abilities change over time—sometimes faster than seems natural. They make great gains in the major skills of cognition, from the most basic kinds of perceptual and learning skills to memory, attention, executive functions, and language. These changes over time are the essence of development. With cognitive development specifically, it may be useful to consider brain structural changes along with function, though the interplay between these two is only beginning to be addressed in the literature. You might imagine that a change in brain structure can bring about or facilitate a change in cognitive ability; but alternatively improvements in cognition might incite brain changes. To complicate matters, other factors such as experience and motivation are likely to influence this relationship (see Bates, Thal, Finlay, & Clancy, 2003). Finally, the changes that the brain undergoes, at least as we understand them now, tend to develop on a longer time scale than cognitive changes. If the state of affairs is truly that complex, what is to be done? There are certain periods of time when things are happening to the structure of the brain and there are contemporaneous enhancements in cognition. At this point, what we can do is describe these, which will be the focus of this chapter. While we often talk about “development” as shorthand for child development, both the brain and one's cognitive abilities continue to develop over the course of one's lifetime, with periods of greater and lesser noticeable change. Our discussion will thus extend through adulthood. Finally, when neurotypical development is prevented, interrupted, or somehow altered, there are consequences to cognitive ability; an example will also be briefly reviewed here.

## Prenatal Central Nervous System Development and Basic Principles

For a point of reference, the cortex of the brain is commonly divided into lobes, including the frontal, parietal, temporal, occipital, and limbic. They have a rough correspondence to functions, with somatosensory areas in the parietal lobe; visual processing falling largely under the occipital lobe's domain; auditory processing under the purview of the

temporal lobe; and motor and many aspects of language, planning, behavioral control, etc., being subsumed by the frontal lobe. Some cognitive processes, such as language, often draw on resources from multiple lobes. Smaller subdivisions are made possible by a pattern of ridges and grooves known as *gyri* and *sulci*. On the whole, our brains are largely like those of other mammals—what seems to be unique is the expansion and resulting convolution of the cortex that humans exhibit, which leads to the pattern of gyri and sulci we see, and allows greater connectivity between regions (Nolte, 1999, p. 50). The cortex itself is a folded sheet with a thickness of only a few millimeters and is composed of six layers of cells. Regional differences between areas of cortex are a topic of great interest to researchers, and these regions can show differences in their developmental timelines. For instance, changes are still being made to the prefrontal cortex (PFC; part of the frontal lobe) well into adolescence and early adulthood. Cortical regions are often thought to have default specialties/typical representation patterns, but it is well-established that there are circumstances under which some area of cortex can take on a function it is not known for—for example, in congenitally blind participants, the visual cortex can assume some tactile and auditory processing. One recent example reported increased brain activity in an area of visual cortex known for higher-level processing of visual motion (V5/MT+) in response to pure auditory tone presentation in blind participants (Watkins et al., 2013).

Formation of the basic structures of the brain happens in the prenatal period; however, once these are formed, the brain undergoes more fine-grained tuning processes, and it is these that are likely correspondent with the changes we see in cognition during postnatal development. These processes include both additive and subtractive events (Elman et al., 1996). The former, on the one hand, add new structure on the small scale, such as the birth and proliferation of neurons, the migration of neurons to their final destinations, production or extension of both long-range connections (axonal) and local (dendritic) branching, and additive synaptic changes (Elman et al., 1996), as well as increased myelination of existing neurons. (In myelination, a fatty coating is introduced around axons that speeds message transmission.) Subtractive events, on the other hand, change neural organization by way of reduction or elimination of existing structures through cell

death, axonal retraction, and synaptic pruning (Elman et al., 1996). These processes are also likely reflected in changes in brain metabolism over time. The general pattern that these processes follow is overproduction (of neurons, of synapses, etc.) followed by pruning, or selective reduction, with the former more rapid and the latter slower (Goldman-Rakic, 1987).

**Additive processes:** The birth of new neurons was originally thought to take place exclusively in the prenatal phase, though there is now evidence that there are exceptions to this limitation, including the olfactory bulb and the dentate gyrus of the hippocampus, in which new neurons have been found to be generated throughout the lifespan (see Lledo, Alonso, & Grubb, 2006, for a review). Most neurons, however, are generally thought to be born during the prenatal period and most are in place by the seventh month of gestation (Hoffelder & Hoffelder, 2007). Cell migration is the method by which neurons come to be “in place.” Brain cells are generally born in special zones known as *proliferative zones*. They migrate to their new destinations either passively (having been pushed out by newly emerging neurons) or actively, in most areas along a scaffold of glial cells (Nicholls, Martin, Wallace, & Fuchs, 2001 includes a good description). The former state of affairs is more common and produces an organization in which the older cells are nearer to the surface of the brain. When young cells move actively past the older cells, the gradient is reversed (Nowakowski, 1987). Sprouting and growth of new connections (*synaptogenesis*) takes place after the migration has occurred. There is evidence that these processes occur throughout life, and they have been observed even in aging animals as a result of experience in brain areas that were otherwise undergoing degradation (Greenough, Black, & Wallace, 1987). While the previous two additive methods seem to be more predetermined, the formation of new branches is likely highly experience-dependent, and related to learning (Elman et al., 1996). It also has been suggested that it is necessary for there to be a critical mass of synapses before a behavior will emerge, with fully mature levels of the behavior then being dependent on elimination of excess synapses (Goldman-Rakic, 1987). In studies with monkeys, Goldman-Rakic determined that the timing and rate of increase of synapses seems to be similar between cortical areas; beginning before birth, and continuing to increase until a peak at around 2–4 months, after which time is a longer elimination period of excess synapses (see Goldman-Rakic, 1987, for a review). Interestingly, it is around the time of synaptogenic peak in the dorsolateral prefrontal cortex (DLPFC) where monkeys started to be able to perform tasks dependent on DLPFC functions at longer delays (Goldman-Rakic, 1987). In humans, cortical areas are not thought to reach peak cortical thickness at the same rate, with areas such as DLPFC reaching peak thickness later than, for example, primary sensory areas (Shaw et al., 2008). As will be seen throughout the rest of this chapter, the differential

time course of these events has bearing on the course of cognitive development as well.

**Subtractive processes:** It may seem counterproductive that we should have neurons that were born only to die. While some cells that die have failed to make synapses or have innervated incorrect targets, it is thought that cell death is a way for the size of neuronal input to be matched to the size of the target (Nicholls et al., 2001). This feature is more easily illustrated in the motor realm: When looking at death in motor neurons innervating a limb, removal of the limb bud leads to more cell death than normal while adding a second limb bud yields less death (Hollyday & Hamburger, 1976). As compared to cell death, synaptic pruning is more of a refinement mechanism, and refers to a loss of some terminal branches and synapses through competition. It has been thought to play a role in helping functional organization and correcting mistakes, among other things (e.g., Nakamura & O’Leary, 1989). Activity can be involved in the rate and outcome of the competition that results in pruning (Nicholls et al., 2001), providing the possibility for learning to have influence on this process. Both axon degeneration as well as axon retraction help increase the precision of relationships between neuronal processions and target areas (see Luo & O’Leary, 2005, for a review).

**Plasticity:** Plasticity refers to changes that take place in the brain as a result of experience—it is part of the normal workings of the brain. It is not only called upon in response to some kind of insult, but also happens in response to learning. One commonly cited example involves reorganization of brain function in persons who are blind, such that cortex which generally contains visual representation can take on other functions (Kupers & Ptito, 2014), but can be as simple as the changes at a single synapse. The adult brain seems to be less plastic, which raises arguments about “sensitive” or “critical” periods during which some learning milestones must be reached if they are to be (fully) achieved. In humans, this argument often gets discussed in terms of language learning. There are a number of cases of children who were discovered late in life and who had not been exposed to typical language input (e.g., “Genie,” Fromkin, Krashen, Curtiss, Rigler, & Rigler, 1974, and see Curtiss, 1989 for a review). These cases are not without controversy, but it is generally reported that if the children are discovered after puberty, their speech tends to lack common features. In the second-language-learning realm, learners who begin later seem to show more difficulty in achieving fluency, and show differential representation for the language in neuroimaging studies (see Newport, 2002 for a brief review). Other researchers believe these outcomes arise because experience has shaped both the brain and what it can learn, producing effects that look like sensitive periods (see Bates et al., 2003). Numerous examples have also shown us that the adult brain does, in fact, retain some plastic abilities. For instance, persons taught to juggle were shown to have brain changes postlearning on MRI that receded to baseline levels with subsequent loss of

the skill (Draganski et al., 2004). Similar changes were also observed in elderly participants (Boyke, Driemeyer, Gaser, Büchel, & May, 2008). Overall, it seems that plasticity is an enduring feature of the brain, though there may be changes in the amount, location, or type of plasticity available over the life span.

### Time Periods

With the basic mechanisms reviewed, we now turn to the time periods with what may be the clearest examples of structural and functional concurrent change. In the developmental literature, a range is almost always given. This convention reflects the fact that not every person develops at the same rate, but also that a lot of our understanding of central nervous system (CNS) development relies upon animal models from species with slightly different trajectories, but similar patterns of development. The time periods we will be considering, which should not be considered an exhaustive set of examples, include: at birth, 2–3 months, 8–12 months, 16–24 months, 4 years through adolescence, and adulthood and normal aging, as these are periods where known changes are taking place in the brain that may be relevant to cognition (Elman et al., 1996; though see Bates et al., 2003 for reexamination of this evidence).

### Birth

Much of the general structure of the CNS is developed before birth, but many more studies of observed behavior have been done after birth, so this is the first time period to be discussed. By the time of birth, the neurons of the brain should have all been formed (save for the examples given on p. 92), and they should have finished migrating to their final positions. The brain as we know it is basically ready to learn, and although neonates have been described as experiencing the world as “a blooming, buzzing confusion” (James, 1890, p. 488), we now know that they actually come into the world with a set of tools to help them come to understand their surroundings, including basic reflexes and learning mechanisms. Predominant among those are reflexes that allow classical conditioning, the ability to learn by operant conditioning, and a preference for novelty. Imitation and statistical learning also play a role.

Examples of classical conditioning are easy to find in the newborn’s life—any parent who has kept a strict feeding schedule can tell you that a baby can learn to anticipate the timing of that schedule. The ability of newborns to learn by way of operant conditioning has also been demonstrated: for instance, newborns will suck faster to hear auditory stimuli (Floccia, Christophe, & Bertoncini, 1997). Babies are further born with a preference for novelty that helps guide their attention. Habituation is the process of becoming used to something—in the baby’s case, it means ceasing to prefer a given stimulus when it becomes familiar. When there is

a change in the stimulus, it again becomes attractive, with this process being known as *dishabituation*. Together, these processes exert a rudimentary kind of control on the infant’s attention without which it would be difficult for him or her to select a stimulus on which to focus. Researchers can use habituation and dishabituation to study basic perceptual, memory, and attentional processing in young babies. Newborns are also able to imitate observed behavior such as facial expressions like mouth opening and tongue protruding (see Meltzoff & Moore, 1983, for a review). Imitation, too, can be a powerful mechanism for learning. Statistical learning (the ability to extract and use patterns found in sensory input), was originally investigated in older babies as a method of learning how to segment a constant stream of speech (Saffran, Aslin, & Newport, 1996), but has recently been demonstrated in newborns in both language (Teinonen, Fellman, Näätänen, Alku, & Huotilainen, 2009) and visual (Bulf, Johnson, & Valenza, 2011) paradigms, suggesting this is a domain-general mechanism that is active from birth. Altogether, these findings would suggest that the newborn has a sophisticated bag of tricks for making sense of the environment, to the extent that his or her perceptual abilities are ready.

As far as perception is concerned, vision is the most discussed sense. It is quite poor at birth, as much as 20/600. Focus improves within the first couple of months, and acuity has progressed to 20/100 by 6–8 months (Courage & Adams, 1990). Newborns do show the ability to discriminate visual stimuli, as evidenced by habituation/dishabituation paradigms. As compared to vision, the sense of touch is more developed, and plays a role in many of the brain stem reflexes present at birth. Newborns can hear a variety of sounds, as discussed in more detail in the section on language at birth. What, then, about more common markers of “cognition” in the newborn? Glucose utilization as measured by positron emission tomography (PET) suggests the greatest functional activity is in primary sensory and motor cortex, as well as brain stem areas (Chugani, 1998). Cognitive activities, including memory, attention or executive functioning, and language tend to be heavily dependent upon these areas, and will now be considered in turn.

**Memory:** Most of us cannot recall instances from our very early life, thanks to a phenomenon known as *infantile amnesia*, which typically lasts until a child is between 3 to 5 years of age (Mullally & Maguire, 2014). The causes of this phenomenon are still under debate (see Rovee-Collier, 1999, for review). The use of the word “amnesia” does not mean that a newborn acts exactly as an adult with amnesia would, however; for instance by 3–4 days of age the newborn can recognize his or her mother’s face (Bushnell, Sai, & Mullin, 1989), suggesting that some retention of information is taking place.

**Attention and executive function:** During the newborn period, there are but short periods of alertness during the day. Ruff and Rothbart (1996) describe this initial state of

attention as being about orienting and investigating and driven by novelty. These periods are characterized by organized and selective looking—suggesting that rudimentary attention exists. Visual looking preferences have been noted for patterns with large features and high contrast (Fantz, 1963). Higher-level control is lacking, however, as newborns have been shown to have difficulty disengaging attention from a stimulus, even to the point of distress (see Ruff & Rothbart, 1996).

**Language:** It may be strange to talk about “language” in any real sense in the neonate, yet there are some communicative abilities and pre-language skills even at birth, such as the ability to imitate facial expressions. On the receptive side, newborns prefer “complex” sounds like noises and voices to pure tones (Bench, Collyer, Mentz, & Wilson, 1976), within a few days show sensitivity to word stress (Sansavini, Bertocini, & Giovanelli, 1997), and by at least 1 month of age can make basic discriminations between speech sounds (categorical perception; Eimas, Siqueland, Jusczyk, & Vigorito, 1971). These abilities set the stage for language learning. Social abilities such as gazing at the face of a caregiver and making smiling-type motions, which tend to be reinforced by the caregiver early on, are also developing and will bolster language learning.

### 2–3 Months

During this time period, increases in glucose utilization in parietal, temporal, and primary visual areas are seen (Chugani, 1998), suggesting that these areas are increasingly functionally active. Experience-dependent changes are focused in these areas as well (Casey, Tottenham, Liston, & Durston, 2005), and synaptic density in visual and auditory cortices are nearing peak values (Huttenlocher & Dabholkar, 1997). The ratio of symmetric to asymmetric synapses increases, suggesting a move from predominantly excitatory to more balanced activation, and more synapses are also seen on dendritic spines, which is thought to allow more specificity of information transfer (see Bates et al. 2003). Long connective pathways are forming, and myelination is of course continuing. Again, in this time period there are changes in memory, attention and executive functioning, and language.

**Memory:** Memory abilities are increasing during this time, though there is debate about the nature of memory processing being used. One interesting method of examining memory has been used by Rovee-Collier (reviewed in Rovee-Collier, 1999). Infants had ribbons tied to their legs that moved an interesting mobile when they kicked. (A version wherein an infant manipulates a train can be used for older infants.) She found that 2-month-olds could remember the information for a day or two, and 3-month-olds for about a week (Rovee-Collier, 1999). Memory ability was found to increase over time, such that older babies could retain information about the task for longer periods of time. Interestingly, changing

the training parameters or adding priming could make even younger babies show better performance (Rovee-Collier, 1999).

**Attention and executive function:** While executive functions are not evident at this time in development, there is reason to believe that attentional processes are developing. These gains in attention are bolstered by the infant’s tendency to spend longer periods of time awake and looking around, as well as increases in visual ability and maturation of pathways associated with vision (Lewis, Maurer, & Brent, 1989). During this period, the infant selects a pattern for attention on design features, not just salience; objects are more readily followed visually; and there is a greater ability to disengage attention (see Ruff & Rothbart, 1996, for a review). All of these features suggest that attention is becoming somewhat more mature and under at least rudimentary control of the infant.

**Language:** While it is still early for language to emerge, it is clear that the foundations are being laid as during this time babbling can begin. Between 2 and 6 months vowel sounds are produced in cooing or play-type activities (Bates et al., 2003), suggesting development in both the intentional production of speech sounds as well as interest in communication.

### 8–12 Months

During this period of time, long-range connections between major regions of cortex are being established (Elman et al., 1996), and prefrontal and association cortexes are starting to see more of the experience-dependent changes than is the sensorimotor cortex (Casey et al., 2005). The distribution of metabolic activity between regions becomes more adult-like, with an increase in glucose utilization in frontal areas (Chugani, 1998). Synaptogenesis has been taking place since before birth, and cortical areas are beginning to reach high points, with peaks happening some time between now and 2 years of age, differing by location (Huttenlocher, 1979). Myelination of these connections is continuing. Along with these processes there is a corresponding significant jump in various cognitive abilities. At this point, important brain networks are coming online and there is a watershed in cognitive abilities associated with this time period. Examples can again be seen in the areas of memory, attention and executive function, and language.

**Memory:** One of the most touted enhancements in cognition during this time is in the area of memory, even though some forms of memory can be difficult to measure in pre-linguistic children. There are many accounts of younger babies learning associations, and even using them flexibly, but around 9 months seems to be the time that babies begin to exhibit hippocampal-dependent memory processing (see Mullally & Maguire, 2014, for a review). This claim has evidence in that 9-month-olds who can complete a memory task show a different pattern of event-related potentials (ERPs) than do age-matched babies who cannot do the task

(Carver, Bauer, & Nelson, 2000). Interestingly, this pattern of results may represent a replacement of old, associative-heavy memory patterns, in that 12-month-old participants fail to perform on a memory task that younger babies can do and that relied upon an associative strategy (see Rovee-Collier & Giles, 2010). One focus of laboratory testing of memory in infants is how long events can be remembered. While 6-month-olds are rarely tested past 24 hours due to low success even at that time span, 9-month-olds show memory for testing events up to 1 month after presentation, and 10-month-olds for at least 3 months after presentation (Carver & Bauer, 2001).

**Attention and executive function:** Attention is another area of cognition that shows improvement around this time. In support of visual attention, acuity and binocular vision have been enhanced by this point (Aslin & Smith, 1988) and the infant is now able to manipulate objects. There is evidence that the posterior orienting network commonly believed to contribute to attentional processing is active by 6 months (e.g., Hood, 1993). Behavioral developments include longer durations of looking (e.g., at a toy during free play, see Ruff & Saltarelli, 1993), as well as an increase in shared attention (Bakeman & Adamson, 1984).

Working memory span also shows improvement during this period; Ross-Sheehy and colleagues (Ross-Sheehy, Oakes, & Luck, 2003) found that 10- and 13-month-olds showed signs of increased visual short-term memory spans as compared to 6.5-month-old infants. There is also an increase in the amount of delay after which an infant will still be able to succeed at the A-B Object Permanence task (Diamond, 1985), where a learned response must be inhibited. Animal models of this task show that use of the PFC is necessary for success (see discussion in Goldman-Rakic, 1987). An increase in working memory is also beneficial for gains in language, as both comprehension and production require keeping sequences of information (perceived sounds and vocal gestures, respectively) in mind.

**Language:** As such, language and communicative abilities are growing in leaps and bounds during this time as well. At the beginning of this period, the infant goes from babbling nonselectively to preferring sounds in his or her native language. Work by Werker and Tees (1984) has shown that while 6-month-olds show categorical perception for speech sounds in their own native language as well as an unfamiliar one (Hindi and Salish for English learners), fewer babies can do this by 8 months, with the ability to perceive the nonnative contrast dropping out for most babies by 10–12 months. These results hold whether a longitudinal or a cross-sectional design is employed. Also around this time period, utterances may begin to have language-like intonation. The learning of first words often occurs during this time period as well (Bloom & Markson, 1998), with the comprehension of words surging beyond production abilities (Benedict, 1979).

## 16–24 Months

This period is characterized by change at the level of the synapse such that there is a fast acceleration in the number of synapses within regions of cortex as well as between them. (Elman et al., 1996). At this point, these changes tend to be in association cortex areas as well as PFC (Casey et al., 2005). Myelination is continuing, and around 18 months, the corpus callosum reaches about 50% of full myelination (Rodier, 1994). Synaptic density in frontal areas is nearing peak levels at this point (Huttenlocher & Dabholkar, 1997). During the latter part of this period, the PFC and the dentate gyrus (part of the hippocampus) gain functional maturity and begin to take over their functions in memory (Bauer, 2007). While most of these changes are not unique to this period, there is cognitive growth in the areas we have been considering throughout.

**Memory:** Along with the changes in the hippocampus and frontal lobes, there is an increase in the length of time that events can be remembered during this period, going from around 1 month in duration of recall at 9 months of age up to one year in duration at 20 months of age (Bauer, 2007). Diamond, Towle, and Boyer (1994; Experiment 2) tested 1- to 2.5-year-olds on a delayed nonmatch-to-sample task, where reaching for a new object (and ignoring a remembered one) is rewarded. They found a major improvement on this task by 21 months of age.

**Attention and executive function:** Attention during this time is characterized by longer periods of sustained attention (Ruff & Lawson, 1990) and fully developed joint (shared) attention capabilities (Morales et al., 2000), including now following glances and points by others, as well as attempting to direct the gaze of another person. Eighteen-month-olds have been described as having greater executive abilities than younger children (see Posner, Rothbart, Thomas-Thrapp, & Gerardi, 1998). Indeed, as additional frontal cortex tracts develop, control of attention becomes the major attentional gain during this time period. In Diamond et al.'s 1994 study using the delayed nonmatch-to-sample task, it seems to be not only improvements in memory that allow better performance at 21 months, but also a complex relationship between the delay and the kind of reward used. These latter factors are suggestive that attentional control may be part of what generates the improvement.

**Language:** At this point, children are “proficient” at word learning, and there is the beginning of a rapid acceleration in vocabulary acquisition (Bloom & Markson, 1998). While the set of first words learned tends to include few verbs, there is now an increase in verbs and adjectives (Bates et al., 2003). With this increased vocabulary and increased knowledge of predicates, grammar begins in the form of two-word combinations around 18–20 months (Bates et al., 2003). The exact syntactic status of these combinations continues to be under debate, but these utterances seem to follow patterns. Also related to language is the skill of categorization. While

certain, largely perceptually based, categorization tasks can be completed before this time period, at around 18 months more active categorization becomes possible and seems to be related to vocabulary gains (Gopnik & Meltzoff, 1987). Overall, at this point language learning is beginning to rapidly increase.

#### *4 Years Through Adolescence*

While this is not a focused time period, there are long-developing processes that begin around 4 years of age and continue up to or through adolescence. Around this time there is a peak in the overall level of brain metabolism. Patterns of glucose metabolism have become qualitatively more adult-like, and overall rates of glucose utilization have been rising from birth until age 4. At this point they are twice the level of an adult (Chugani, 1998). They are maintained at this level between ages 4 and 10, and gradually decline to adult levels at around 16–18 years of age (Chugani, 1998). During this period, synaptic density is on the decline, starting with somatosensory areas and continuing with association areas and finally the PFC (Casey et al., 2005), a process that continues into adolescence. Experience-based growth in dendrites and synapses also continues throughout this period, as does myelination of the frontal lobes and connecting tracts. In one MRI study examining this myelination of tracts that connect to the frontal lobes, Paus et al. (1999) reported linear increases of left and right internal capsule and left arcuate fasciculus between ages 4 and 17. All of these processes contribute to the brain's efficiency in carrying out neural tasks. Processing time, as measured by various tasks, does decrease during this period (e.g., Kail, 1988). While we think of efficiency as purely a time- or energy-saving perk, there may also be cases where a certain amount of efficiency is necessary to perform a cognitive task. Neural efficiency also can help one to perform a task well, and given the coarse grain of most behavioral tasks, it may mean the difference between recording a success or a failure. Consequently, increases in cognitive abilities are seen during this time period even though there are not rapid changes in brain structure. This growth, however, is seen mainly in functions that rely on the brain areas undergoing the most tuning—i.e., attention and executive function, as well as the cognitive skills they support, like memory and language.

**Memory:** By age 4, recognition memory is often thought to be at adult-like levels (Brown & Campione, 1972; though see Sophian & Stigler, 1981), but there are improvements in other areas of episodic memory processing during middle childhood. While these gains partially rely upon the developments in the PFC and connecting white matter tracts (see Ghetti & Bunge, 2012, for a review), there are also other developments that are likely playing a role. During the period between age 4 and 25, the anterior hippocampus has been shown to lose mass while the posterior hippocampus gains mass (Gogtay et al., 2006). As the anterior hippocampus has

been associated with more flexibly bound memory representations, which in turn are associated with better performance, it has been hypothesized that the pruning of this area leads to specialization (see Ghetti & Bunge, 2012). In one study examining whether participants were able to use an episodic representation of an item versus simple recognition, 8-year-olds showed activation patterns consistent with the latter, 14-year olds and adults preferred an activation pattern more consistent with the former, and 10–11-year-olds seemed to be in transition between these, supporting the authors' hypothesis of increased selectivity over this time period (Ghetti, DeMaster, Yonelinas, & Bunge, 2010). Memory increases during this period also come about due to use of beneficial strategy: for example, Yim, Dennis, & Sloutsky (2013) show that the use of one type of complex memory structure emerged between 4 and 7 years of age and developed further between age 7 and adulthood, and Shing & Lindenberger (2011) review studies suggesting that strategy instruction and practice could boost memory performance in children up to adult levels.

**Attention and executive function:** An improvement in attention around this time period has been noted in the literature, though the timing of the change is still under debate, and seems to be task dependent. Some place it between ages 5 and 7 (see Bartgis, Thomas, Lefler, & Hartung, 2008, for a review), though others have found improvements past the age of 7 as well (Klimkeit, Mattingley, Sheppard, Farrow, & Bradshaw, 2004). Still others place it earlier, or show multiple stages of improvement (see Ruff & Rothbart, 1996, for a review). These studies all indicate a “spurt” of development that does not correspond to anything sudden we know about brain development happening at this point, although attention would be expected to improve gradually over time with the previously discussed ongoing brain changes. There are a few reasons why this might be the case. For example, many of the studies addressing this issue include children of only a couple of ages, while any gradual change would require a continuum of ages to be included. The effect of strategy development can also not be factored out; during this period strategies for focusing attention could be learned, especially since many of these children are attending school.

Multiple studies (see Tsujimoto, 2008, for a brief review) have pinpointed 4 years of age as a time after which more adult-like processing in PFC-reliant cognition—such as inhibition, executive control, and working memory—begins to emerge. For example, between ages 3 and 4, children become able to better perform a card-sorting task that involves inhibition (Carlson, 2005). This finding does seem to be tempered by complexity, however: When another sorting dimension is added in the previous study, older children can no longer complete the task (Carlson, 2005), but when the dimensions are separated, they can succeed at the task 6 months earlier (Diamond, Carlson, & Beck, 2005). Similar findings are reported in working memory and shifting executive processing as well, both for the initial emergence of the ability, as well as the continued improvements that

are often revealed through increasingly complex tasks (see Best & Miller, 2010, for a review). Short-term memory span, regardless of modality, shows linear increases throughout childhood and adolescence (Gathercole, 1999). Often, improvements in executive functions have been found even until early adulthood (Huizinga, Dolan, & van der Molen, 2006). These boosts in executive functions are also associated with differences in neuroimaging studies. In the original work on the topic, Casey and colleagues found that, while children and adults showed brain activation in the same areas using fMRI, children had larger volumes of activation in both working memory (Casey et al., 1995) and inhibition (Casey et al., 1997) tasks, again suggesting that the development of these skills is due to some tuning process or gains in efficiency. Further studies on the topic have found similar results (see Casey et al., 2005, for a review).

Overall, this literature is difficult to draw clear age-range conclusions from, due largely to difficulties in scaling a task to allow persons of a large range of ages to participate. What does seem fairly clear, however, is that during early childhood, the ability to use these processes emerges, and it shows improvement throughout childhood into adolescence, and in the cases of some tasks, up into adulthood—a trajectory that mirrors the changes taking place in the PFC.

**Language:** By 4 years of age, language is largely mature. Major syntactic features have been acquired (Bates et al., 2003; Bickerton, 1992). Communicative levels of vocabulary are in place, and improvements during this period seem more gradual. Vocabulary is still being acquired very rapidly, however—estimates place a 6-year-old's vocabulary at around 10,000 words and a high school graduate's at 60,000 (see Bloom & Markson, 1998). Grammatical development continues at least until the age of 9 (Bickerton, 1992) and some sentence constructions may not be fully ingrained until later. Discourse cohesion abilities are also continuing to develop.

### *Adulthood and Normal Aging*

When talking about developmental issues, a touchstone period is needed to compare performance—this is typically adulthood. During this time people have achieved what are generally considered to be mature cognitive abilities. Behaviorally, there appears to be a steady state for many years. Brain-based changes are continuing, however, with the previously discussed pruning continuing to the third decade of life (Petanjek et al., 2011), and eventually these changes lead to noticeable decrements in various cognitive skills. Other brain modifications begin as soon as one's mid-20s (such as the decline in gray matter volumes as noted by Good et al., 2001). Eventually these changes include a loss of white matter, the extent of which varies between studies (see Peters, 2007, for discussion), but that does seem to affect certain areas differently. It has been suggested that areas that myelinate last are first to be affected (Peters, 2007), with particular losses noted

in the frontal lobes and tracts that connect these to other brain areas (Hedden, 2007; Peters, 2007). There is further a reduction in microvascular plasticity in the aging brain that is often associated with changes in synaptic plasticity, though the relationship between these is still debated (see Sonntag, Eckman, Ingraham, & Riddle, 2007, for a review).

Cognitive changes are also noticed in the aging adult. Not surprisingly, these are most commonly seen in the areas of attention and various kinds of memory (Glisky, 2007), which are also the last to finish developing as frontal areas complete myelination. Working memory and episodic memory seem to be most affected while performance on semantic memory can be better than that of younger adults (Glisky, 2007). This time period is also characterized by much variability: Some older adults seem to retain complete control of cognition, while others noticeably suffer with everyday tasks. These patterns are also reflected in results from neuroimaging studies, where older adults often show a different pattern of brain activation to a task than do younger adults. For example, one study examining dual-tasking found older adults to activate areas not active in the younger adult group as a whole (Smith et al., 2001). Bilateral brain activation is also commonly seen wherein younger adults display unilateral activation. In one study examining verbal and spatial memory, younger adults show frontal activation in the left hemisphere for the former and the right for the latter, while older adults have bilateral activation for both types of stimuli (Reuter-Lorenz et al., 2000). Similar bilateral activation has been observed in posterior areas as well (Huang, Polk, Goh, & Park, 2012). In some studies (e.g., Huang et al., 2012; Rosen et al., 2002), persons in the group of older adults who show this kind of activation pattern have better performance than those who do not, perhaps pointing to a compensatory strategy.

Overall, this brief review suggests that the brain changes with aging are associated with cognitive declines, especially in memory and attention, but that there is variability within these, and that they may be ameliorated in some cases by the use of compensatory strategies.

### **Challenges to Development**

The course of events described in the previous section can be understood as being fairly typical. While the exact timing of events can differ from person to person, the general course tends to be accurate for most people, most of the time. What happens, then, when there are cases that do not follow this timeline? There are numerous things that can affect development; both congenital and acquired events can alter the course, and the outcome of such events is dependent upon the period of development during which they occur. An exhaustive categorization of such events is unfortunately beyond the scope of this chapter, but a brief example may help illustrate this point.

Spina bifida occurs very early during prenatal development, and subsequently affects much of cognitive

development to come. It comes about when a portion of the neural tube fails to close properly at the level of the spine (Juraneck & Salman, 2010). In the most common type of spina bifida, brain development is subsequently affected: Studies have noted incomplete generation of the corpus callosum, and some other white matter tracts also appear less well-organized or complete (see Juraneck & Salman, 2010, for a review). Although there are many physical sequelae associated with this condition, and they are sometimes thought of as comprising most of this disorder, cognitive complications are also quite common. Attention has been found to be affected from infancy (Dennis & Barnes, 2010), and skills like executive functioning do not seem to improve with age (Tarazi, Zabel, & Mahone, 2008). Deficits have been noted in areas such as timing, attention, movement, and perception (reviewed by Dennis & Barnes, 2010), and there is a high incidence of learning disabilities in this population, with one study reporting that 60% of their sample showed reading, math, or writing issues (Mayes & Calhoun, 2006). Without doubt, the early timing of the original insult plays a significant role in the widespread effects on cognition.

## Discussion

In this chapter, contemporaneous gains in cognitive functioning and changes in brain structure have been described. While it may seem as if brain structure and cognitive functions are the only things influencing each other, it should be reiterated that this is not the complete picture. Let us consider the role of experience. During the 8–12 month cognitive watershed period, there are often motoric leaps as well. This period is exactly when crawling tends to either emerge or become a highly practiced skill. With the ability to move around, babies gain new perceptual perspectives, and these perspectives undoubtedly influence the brain structure/function relationship. Take for example a study by Bell and Fox (1996) that examined the influence of crawling on intrahemispheric EEG coherence in 8-month-olds. They found that novice crawlers (1–4 weeks experience) had greater coherence than either prelocomotor infants or more experienced crawlers, a pattern they interpreted as showing that the onset of crawling was associated with changes in cortical organization (Bell & Fox, 1996). In the work by Rovee-Collier (1999) discussed on p. 94, memory in 2–6-month-old infants was effectively cued only by the original mobile they experienced, while 9–12-month-old infants could be cued by a novel item for shorter delays, suggesting that context is more flexible in the older infants who have some mobility and more experience with different contexts.

Another caveat to note is that, although the examples given in this chapter tended to relate changes in brain structure to *gains* in cognitive functioning, this is not always the case. In some cases, a change in brain structure can disrupt previous improvements in functioning. For example, babies become faster to dishabituate to previously viewed stimuli up

until 2 months or so, when there is growth in visual processing and dishabituation slows down dramatically (Hood et al., 1996). A similar disruption is seen in the strength of handedness preference during intense periods of language (Ramsay, 1985) and locomotor (Corbetta, Williams, & Snapp-Childs, 2006) learning. In these cases, gains are still being made in other areas, however.

Finally, learning and cognitive change is not static during the time periods that were not discussed here. While some highlights were chosen, it should not be believed that these are the only periods of interesting development. There are also smaller spurts and plateaus within some of the larger time periods. On the whole, there are many problems with the granularity of our knowledge of both brain changes as well as cognitive abilities. While a fascinating and worthwhile topic, the relationship between brain development and cognitive development is still only beginning to be investigated, and the variables are numerous—the interplay between them is likely to keep researchers busy for many decades to come.

# 8 Genomics and Phenomics

*Robert M. Bilder*

## Overview

This chapter aims to provide the clinical neuropsychologist with information about the genetic bases of cognitive functioning and disorders of cognition. The chapter begins by introducing basic principles of modern genomic research and review of some key genetic concepts. The next section surveys existing findings about genetic associations with cognitive phenotypes, including both normal function and dysfunction. The final section provides an overview of the complexities involved in formulating and testing hypotheses that span multiple levels of analysis from genome to neuropsychiatric syndrome.

## Basic Principles

### *The Central Dogma of Biology*

Before moving on to consider more complex associations between genotype and phenotype, it is important to review the central dogma of molecular biology. In brief, the central dogma of biology states that DNA is used to create RNA, which in turn is used to create proteins. The process through which DNA is “read out” to form messenger RNA (mRNA) is referred to as *transcription*. The process through which RNA is used for protein synthesis is referred to as *translation*. Additional features of central dogma that are important to understand are that DNA undergoes self-replication. The transcription of DNA to RNA relies on RNA polymerase. The translation of RNA and proteins relies on ribosomes, and tRNA is involved in assembly of amino acids into protein chains. These principles are reviewed in most elementary textbooks of molecular biology, and have been the subject of several videos (see for example, *Animation: The Central Dogma* at <http://youtu.be/J3HVVik2kNo>).

A few additional basics are important to appreciate much of what you will read in papers describing genetic studies. First, it should be recognized that the entire human DNA sequence of approximately 3 billion base pairs is the basis for coding approximately 20,000 genes. We may recall that these base pairs are formed from nucleotides: for DNA, adenine, guanine, cytosine, and thymine (A, G, C, T); for RNA, thymine is replaced by uracil). The “coding” in DNA is accomplished by triplets of these four nucleotides, with each triplet

coding for one of the 20 standard amino acids that are the basic structural units of proteins.

The classic use of the term *gene* in this context refers to the “chunk” of DNA (in more formal definitions, a *locatable region*) that is used to code for a single specific protein (or again, because there are now many exceptions to this “rule,” the region that is associated with functional outputs as manifest through regulation or transcription). If we were to divide the total number of base pairs by the total number of genes, we would estimate that each gene contains approximately 150,000 base pairs. But most human genes contain only about 1,000 to 30,000 base pairs (albeit certain genes are exceptionally large; e.g., dystrophin is 2.4 million base pairs). Thus large segments of the human genome sequence are not used specifically for encoding proteins. These sections of noncoding DNA were once thought to be “junk” DNA, but subsequently have been found to serve other functions. Among these functions, some noncoding DNA has been found to produce transfer RNA, regulatory RNA, and ribosomal RNA; other noncoding DNA sections may serve regulatory purposes by determining how the process of transcription unfolds.

Certain regions of the DNA sequence are known to have special purposes. For example, the “promoter” region of DNA is the location adjacent to where transcription starts. This is where RNA polymerase and other transcription factors bind to initiate transcription of mRNA. Other specialized regions of DNA include *enhancers* (which activates transcription when they bind *activator* proteins), and *silencers* (which antagonize enhancers by binding proteins that are referred to as *repressors*). The parts of the DNA in parenthesis and RNA) sequences that code for proteins are referred to as *exons*. In contrast, *introns* do not code for proteins and are “spliced” out of the pre-mRNA sequence to yield the final mRNA that is used for translation into proteins.

It should be recognized that the process of transcription from DNA to mRNA and translation of mRNA into a sequence of amino acids is only the first step to creation of a functioning protein. In brief, the sequence of amino acids comprising the protein undergoes a complex process of folding, which is under the influence of the local chemical environment, in order to form the ultimate three-dimensional protein structure.

### Classical Genetics Research Strategies

Before considering modern genetic research strategies, it is important to review some of the “classical” approaches that have provided the foundation of genetics research findings for biomedicine. In general, the idea of these studies has been to identify the “gene for” a specific phenotype: the set of observable characteristics of an individual resulting from the interaction of its genotype with the environment. In the case of biomedical research, the phenotype of interest is usually a disease state. The analytic process involves identifying a group of people with a specific phenotype or disease (“cases”) and then comparing them to a group of healthy people (“controls”). This is the basis of the *case-control* design. Before researchers had access to genotyping methods that now enable us to directly examine DNA differences between individuals, the structure of genes was often determined by inference from patterns of inheritance. Thus, we may recall the classical experiments of Gregor Mendel, who found through selective breeding of peas that certain characteristics would be passed down from one generation to the next (for example, that some genes coded for a round shape, while others coded for a wrinkled shape). Documenting these patterns led to the definition of *alleles*, which are alternative forms of a gene that may lead to different expressed phenotypes (e.g., round = R, and wrinkled = r; thus a single plant might have the RR, Rr or rr, and in this case given that “R” is dominant and “r” is recessive, both RR and Rr lead to the same round phenotype, while the rr genotype leads to the wrinkled phenotype).

Decades of genetic research have revealed that organisms may possess many alleles at a particular genetic region or locus, and that most phenotypes are the product of multiple allelic effects and their interactions. Indeed, these allelic effects may span multiple genes. For example, eye color reflects the interaction of allelic variation across multiple genes. Complex traits such as neuropsychiatric syndromes or cognitive functions are associated with variation across many genes. For example, recent studies suggest that the genetic risk for a disorder like schizophrenia (which is about 80% heritable), is accounted for by approximately 8,000 genes, or more than one-third of the entire human genome.

In most early genetic mapping studies, variation in the genome was identified using genetic “markers,” or identifiable sequences of DNA, and their proximity to each other was documented based on the likelihood that the markers would be inherited together (since closer segments of DNA are more likely to end up together during reproduction). With advances in the mapping of the human genome and high-throughput methods for testing DNA sequences, it is now routine to examine millions of locations across the entire human genome to conduct genome-wide association studies (GWAS), and it is becoming increasingly common to measure all 3 billion bases in the genome (whole genome sequencing). This has been technically feasible for almost

two decades, but in 2014 the cost fell below \$1,000, considered by some to be the “magic number” that will enable more widespread application.<sup>1</sup>

In brief, the methods for GWAS and whole genome sequencing involve examining specific genomic locations to determine exactly which nucleotides are present within a sequence of DNA. At some locations, there is not much variation across individuals, but some genetic loci are highly variable. These regions may have different forms or *polymorphisms*. If the difference occurs at a single nucleotide, that is referred to as a *single nucleotide polymorphism* (SNP). Most studies in the literature report on the frequencies of either specific “candidate” SNPs, or in the case of GWAS, enough SNPs that a picture of variation across the entire genome is possible (as provided by collecting hundreds of thousands to millions of SNPs). The primary reason for collecting a panel of SNPs rather than the entire genome, however, is cost. Now that the price for whole genome sequencing is dropping we can expect whole genome sequencing to become much more common, first in research reports, and ultimately in clinical databases.

### Evaluating the Quality of Genetic Association Results

It may be very confusing for anyone not familiar with genetic association studies to appreciate the results of these studies and distinguish those that are high quality from those that are not. It is useful for readers to familiarize themselves with recent guidelines. Following the development of standards for reporting results of epidemiology studies called “Strengthening the Reporting of Observational Studies in Epidemiology” (STROBE; see Gallo et al., 2011), a new statement was developed specifically for genetic studies: STrengthening the REporting of Genetic Association studies (STREGA; see Little et al., 2009). Many of these guidelines may seem obvious to neuropsychologists. For example, the guidelines indicate that authors should clearly report the study design, sample characteristics, all key variables to be analyzed, and the statistical analysis plan. There are two particularly important characteristics, however, that deserve some further explanation because these so frequently impact study quality and the conclusions that are reasonable to draw from a genetic association study: (a) control for false positive findings and (b) control for population stratification.

The greatest single challenge for genetic association studies is claiming that a statistically significant finding has emerged that adequately corrects for the number of statistical tests performed, when there may be hundreds of thousands or millions of tests. To help *control for reported false-positive findings*, one guideline in wide use is to claim “genome-wide significance” only for individual associations with probability values of less than  $5 \times 10^{-8}$  or  $1 \times 10^{-8}$  (to reflect approximate alpha levels of .05 and .01 respectively). This standard is derived from a Bonferroni correction, with the

assumption that there may be approximately 1 million independent variants in the human genome. There is a reasonable concern that the Bonferroni correction may be overly conservative, but even modified approaches that attempt to explicitly model the degree to which different genetic variants are not truly independent but instead correlated (in large part due to linkage disequilibrium, or the tendency of DNA segments to be inherited together), require P values of approximately  $1 \times 10^{-7}$ . It may seem somewhat alien to demand such stringent thresholds for claiming statistical significance, but there is now ample evidence that claims based on less rigorous thresholds have often turned out to be false positives.

The literature contains many reports of “candidate gene” associations, where usually a small number of SNPs is tested for association with one or more phenotypes. Authors sometimes claim that these studies do not require adjustments for multiple comparisons because they have only examined one SNP. But this strategy is unfortunately likely to yield an unacceptably high false positive rate, because there may be many SNPs in the genome that are associated with a complex trait (in some well-done studies, about one-third of the entire genome!), and if we consider the number of SNPs that may be in linkage disequilibrium with the selected SNP, it is clear why more stringent thresholds are needed to establish statistical significance. There are some methods that employ alternative methods for controlling false discovery rates (FDR) using “stepup,” “adaptive,” and “dependent” procedures; these may better control for Type I error without as much sacrifice of statistical power (van den Oord, 2005). But the thresholds remain far more stringent than we are accustomed to in neuropsychology research, usually by five or six orders of magnitude!

Regardless of the threshold selected for declaring a particular finding to be “significant,” readers should remain skeptical. Ioannidis (2005) has crafted criteria to grade the “credibility” of molecular evidence. This framework suggests that the following factors be evaluated.

- 1 Effect size: Large effects are more likely to be true than small effects.
- 2 Replication: Multiple, independent replications increase credibility.
- 3 Bias: Studies with bias are less credible; those with protection against bias are more credible.
- 4 Biological plausibility: The more functional/biological data, the more credible.
- 5 Relevance: The stronger the potential application in clinical practice or public health, the more credible.

One sobering message from this work is that many findings of interest to neuropsychologists that have very small effects (for example, most of the putative associations between cognitive function and genetic variants have relative risk less than 1.2) are unlikely to be credible. Ioannidis and colleagues estimate that even the extensively replicated effects of this

magnitude have credibility in the range of only 2% to 30% (Ioannidis, 2009).

Among the different kinds of bias (which also include bias in phenotype definition, bias in genotyping [lack of quality control], and selective reporting biases), the problem of *population stratification* deserves special attention. In brief, population stratification refers to the presence of differences in allele frequency associated with a particular subpopulation. If the subpopulation also differs in some phenotype of interest, then it is possible to observe a spurious association between genotype and phenotype due to this confound rather than a true association. There are several ways to handle this problem, including sampling within a specific subpopulation, using certain family based designs, and/or developing statistical representations of the population substructure (for example, using principal components analysis, or a “genomic control” strategy, which basically examines the hypothesis of association in subgroups defined specifically based on their genetic background (Devlin, Roeder, & Bacanu, 2001; Enoch, Shen, Xu, Hodgkinson, & Goldman, 2006; Kang et al., 2010).

It should be recognized that even when genetic studies reveal compelling associations that are considered significant at genome-wide levels and replicated, the identified variants may still account for only a small amount of the known heritability. Human height is a good example phenotype: Despite a heritability near 80%, only about 5% of phenotypic variance is explained by more than 40 known loci (Visscher, 2008). This has been referred to as the problem of “missing heritability” or the “dark matter” of heritability, and may be due to many reasons, including: (1) variants that the GWAS arrays are missing (i.e., the SNPs that have yielded association findings may not be the causative SNPs, and the true causative SNPs might have larger effects); (2) gene-gene interactions (epistasis) and/or gene-environment interaction effects too complicated to assess given current sample sizes and analytic strategies; (3) epigenetic effects; (4) much larger numbers of genetic variants with even smaller effects remaining to be found; and (5) inadequate accounting for shared environmental variance among relatives (Manolio et al., 2009).

Overall, those interested in surveying genetic associations with cognitive phenotypes of interest will be best served by large-scale meta-analyses that consider carefully the quality of studies based on all the factors noted in this section. Unfortunately, we still lack such evidence for the vast majority of cognitive or neuropsychological phenotypes. But given the increasing attention to harmonizing phenotype assessment, along with the increase in number of repositories for collecting genetic and phenotype data, the availability of high-quality association data should grow rapidly.

## Genetics of Cognitive Function and Dysfunction

A challenge faces those interested in understanding the genetic bases of cognitive impairment. Specifically, most

studies have focused on understanding the genetic bases of “disease” rather than the genetic bases of cognitive function or dysfunction, *per se*. Therefore, most of what is known about the genetics of cognition derives from studies about the genetic bases of cognitive syndromes.

Indeed, some of the most successful approaches have led to identification of very specific genetic associations with complex syndromes such as intellectual disabilities (formerly known as “mental retardation”) that are primarily characterized by cognitive deficits. Intellectual disabilities, while hardly representing a uniform or homogeneous set of cognitive dysfunction phenotypes, have been linked to more than 300 distinctive monogenic causes, albeit each of these specific conditions is relatively rare, so even this large number of genetic “causes” of cognitive deficit account for only about .01% of all cases (Butcher, Kennedy, & Plomin, 2006).

Despite the low frequency of these conditions, they may be informative about mechanisms important to brain development and cognition. For example, the study of Fragile X syndrome has led to multiple insights about the genetics of trinucleotide repeats, X-linked genetic disorders, and the enormous pleiotropy of single-gene deficits on neural and other systems (Heulens & Kooy, 2011). Similarly the study of neurofibromatosis, and the NF1 gene, has yielded major insights into the molecular basis of these syndromes, yielded novel transgenic rodent models in which mutants have superior abilities, and may stimulate novel treatment development (Lee & Silva, 2009; Silva, Zhou, Rogerson, Shobe, & Balaji, 2009).

Studies of dementia risk offer further clues to the genetic bases of cognitive deficit. Perhaps the most robust identified genetic associations for any neuropsychiatric syndrome is the association of apolipoprotein E, epsilon 4 allele (APOE\*E4) genotype with risk for dementia of the Alzheimer’s type or Alzheimer’s disease (AD; Corder et al., 1993; Saunders et al., 1993), with increased risk of clinical AD being large (with odds ratios ranging from twofold up to tenfold, depending on the population studied; see Online Mendelian Inheritance in Man or OMIM for reviews; Hamosh et al., 2005). While initial hypotheses centered on the possible role of this genotype in directly altering the formation of neurofibrillary plaques or tangles, subsequent hypotheses have focused attention on other cerebrovascular mechanisms or response to oxidative stress (Horsburgh, McCarron, White, & Nicoll, 2000; Wagle et al., 2009). Despite these efforts, the genetic basis of cognitive dysfunction associated with the APOE4 effect remains unknown.

A range of other associations between genetic variations and cognitive functions have been reported but, other than the association with APOE4 noted, none of these would satisfy the criteria for credibility of genetic findings as stipulated by Ioannidis and colleagues (see p. 104). Sabb and colleagues reviewed prior work on candidate genes for which investigators reported associations with cognitive phenotypes comprising “memory” (51 effects) and “intelligence” (42 effects)

(Sabb et al., 2009). They found generally modest associations of candidate genes with varying cognitive phenotypes, with most effect sizes (Cohen’s *d* for the effect distinguishing alleles) ranging from .09 to .23. An interesting result of this survey was that among genes investigated, two had relations specifically with intelligence (CHRM2 and DRD2), two had relations specifically with memory phenotypes (5-HTT and KIBRA), and four had reported links to both intelligence and memory phenotypes (DTNBP1, COMT, BDNF, and APOE). Other researchers have highlighted the replication of selected findings related to rare variants in key genetic regions (such as PDE10A, CYSIP1, KCNE1/KCNE2, CHRNA7) and their possible connection to both schizophrenia and cognitive impairment phenotypes (Tam et al., 2010). Finally, recent intriguing findings suggest that a variant of the KLOTHO gene (which increases klotho protein in serum) is associated with a beneficial effect on cognition in both humans and rodents, along with increasing longevity, possibly mediated by enhancement of long-term potentiation, via an NMDAR mechanism (Dubal et al., 2014). Notably, the effect size for KLOTHO on cognitive function was .34 (Cohen’s *d*), which is larger than the effect of the APOE genotype, and larger than the effects of any FDA-approved treatments for Alzheimer’s disease (Dubal et al., 2014).

I and my colleagues have made an effort to catalog genetic association studies pertinent to cognitive phenotypes in the development of a Web-based resource (CogGene) and enable automated meta-analysis (Bilder, Howe, Novak, Sabb, & Parker, 2011), in a way similar to the tools available for examining other phenotypes such as the diagnosis of Alzheimer’s disease (AlzGene) and schizophrenia (SczGene). Our analysis revealed only 12 associations that were nominally significant as reported in the original studies (that is, the 95% confidence intervals around the average effect size did not include zero). The “hits” included: APOE, CHRM2, DTNBP1, DRD2 (two SNPs), CHRM2/CHRNA4, IL1B, KIBRA, SNAP25 (two SNPs), IL1RAPL1, and CACNA1C. The only one of these putative candidates that has high credibility as a risk factor for cognitive impairment is the APOE\*E4 genotype.

Chabris and colleagues (Chabris et al., 2012) attempted to replicate published associations between 12 genetic variants and estimates of general intelligence (*g*) in three independent, relatively large samples (totaling nearly 10,000 individuals). They demonstrated that about half of the variance in *g* is accounted for by common genetic variation, but could not replicate any of the associations as being statistically significant. There was adequate power to detect even small effects. For example, in the first analysis they had 99% power to detect a joint effect of 12 variants of .52% (about half of 1% variance explained in phenotype by all 12 variants). Similarly, Lencz and colleagues in the Cognitive Genomics consortium (COGENT) (Lencz et al., 2014), looked for genetic associations to cognitive phenotypes in more than 5,000 people, and while they demonstrated shared polygenic risk

between schizophrenia and cognitive impairment, they could find no genome-wide significant loci for cognitive function.

It should further be noted that in the analysis of Chabris and colleagues (Chabris et al., 2012), APOE\*E4 was not significantly associated with *g*. This makes it clear that the effects of APOE\*E4 may be expressed primarily through pathological processes later in life. Indeed, the APOE effect may be seen as a special case of the general finding that the heritability of intelligence increases with age. Recent summaries suggest that  $H^2$  for IQ may increase from about .2 during infancy up to .80 in late adulthood (Haworth et al., 2010; Plomin & Deary, 2015). These authors highlight an alternate interpretation of this temporally increasing heritability or genetic amplification. They suggest that this may occur as “small genetic differences are magnified as children select, modify and create environments correlated with their genetic propensities” (Plomin & Deary, 2015; p. 100).

Research on the heritability of intelligence, other cognitive abilities, and academic skills and disabilities, further illustrates that so far we have not found more specific effects, and that we may be unlikely to find more specific genes for more specific neuropsychological domains. Meta-analysis suggests an average intercorrelation of about 0.3 among tests of different cognitive abilities, but the *genetic correlations* (that is, the amount of shared variance between tests due to shared genetic causes) tend to be greater than 0.6 (Plomin & Deary, 2015). These observations led to the formulation of the *Generalist Gene* hypothesis (Calvin et al., 2012; Plomin & Kovas, 2005), which suggests that common genetic factors are responsible for most cognitive abilities and skills, as well as for inherited dysfunctions affecting those abilities and skills.

It would be logical to reason that we could seek more specific associations between genetic variation and specific abilities by covarying for general abilities, and examining the residual variance in special abilities that may be associated with unique circuits or neural system-level functions. Unfortunately, given that traits like *g* are currently thought to reflect the operation of a very large number of very small genetic effects, extremely large samples may be needed to detect more subtle genetic effects that may only be apparent after “controlling for” the genetic backgrounds that govern general ability.

The perspective afforded by genetic studies may be very valuable to clinical neuropsychology, however, especially in helping to overcome “domain-specific” hypotheses that may not clearly reflect the true pathological processes suffered by our patients. For example, we frequently see neuropsychological reports organized in special sections with “domain” headings for “Language,” “Executive Functions,” and “Learning/Memory Functions” (to name only a few). But these “classic” domain headings were derived largely from the study of individuals with focal brain lesions following relatively normal development. In contrast, most genetic disorders are by definition “developmental,” regardless of whether the

genetic impacts are revealed early in life (as in Fragile X disorders) or later in life (as in those with APOE\*E4 genotype).

If we consider the ultimate mechanistic paths through which these genetic variants exert their effects, then it becomes clearer why specific gene effects do not usually translate into neuropsychologically specific variation. For example, even without detecting any of the specific genetic variants associated with cognitive function at a level that provides high credibility, it is possible to examine groups of genes and determine if there is statistical support for the involvement of one or more *gene networks* (i.e., a group of genes that may be clustered by the involvement of their gene products in a specific metabolic pathway or other biological process). Several studies using this approach have suggested that cognitive function/dysfunction may be linked to glutamatergic signaling and more specifically the NMDA receptor complex (Hill et al., 2014; Ohi, Kimura, & Haji, 2015); immunologic function (e.g., major histocompatibility complex class 1)(McAllister, 2014; Ohi et al., 2015); glial cell function, inflammatory response, and neurotransmission (Levine, Horvath, et al., 2013; Levine, Miller, et al., 2013); or other general processes including mitochondrial function, oxidative stress, posttranslational modifications, protein folding, and protein trafficking (Bhattacharya & Klann, 2012).

There is further promise that research on molecular and cellular processes in animal models will yield dramatic progress in understanding not only healthy cognitive function, but also disorders of cognitive function and possibly trigger development of new treatments. An excellent review of mechanisms that may *enhance* synaptic plasticity, long-term potentiation, and learning-memory functions in transgenic rodent models points to multiple potentially valuable molecular targets (Lee & Silva, 2009; Silva et al., 2009). Examples include multiple approaches to enhance NMDA receptor function, methods to regulate cyclic-AMP response-element-binding protein (CREB) function, manipulation of proto-oncogenes such as H-ras, and possibly enhancement of glial cell function. Through integration of these basic neuroscientific findings with emerging studies of molecular biomarkers in humans, which are enabling the assessment of genome-wide expression patterns and metabolic functions, there is hope that we will one day possess reliable roadmaps capable of explicating the final common paths for both disruption of systems that lead to cognitive impairment, and specifying the molecular targets that may correct deficits or even enhance healthy functions.

### **\*Omics Strategies for Understanding Brain Systems**

Following the advent of *genomics* to represent the systematic study of the entire genome (rather than selected genes), the last 15 years has seen a burgeoning list of “\*omics” strategies, including proteomics, metabolomics, and connectomics.

Early in these developments, Freimer and Sabatti (2003) argued that the ever-decreasing costs of genotyping would lead to the situation where the limiting step in discovery of molecular mechanisms would be found in characterizing the multitude of phenotypes, not genotypes. After all, the human genome contains only about 3 billion base pairs, comprising only four relatively simple nucleotides, in a linear sequence. In contrast, the collection of phenotypes is virtually infinite. Thus Freimer and Sabatti used the term *phenomics* to refer to the systematic investigation of phenotypes on a genome-wide scale. Implicit in this definition is the necessity to characterize multiple phenotypes simultaneously, thereby increasing the specificity of composite phenotype definition and presumably increasing the power to detect genetic association.

A fundamental distinction between the phenomics strategy and the more traditional strategy for GWAS is that the latter most often focuses on a “univariate” approach to seeking associations of an individual phenotype with a genome-wide assessment of variation. This is basically the equivalent of conducting a large number of statistical tests (as many as there are genetic variants in the assay, usually a million or more with current chips) and then correcting for multiplicity of testing to constrain the false-positive error rate. In contrast, the phenomics strategy implies assessment of multiple phenotypes both within a specific level of analysis (for example, multiple protein products) along with multiple phenotypes *across* levels of analysis (for example, not only proteins, but also cellular, neural system, and cognitive or behavioral phenotypes; see Bilder et al., 2009). Considering the complexity of establishing links across levels of analysis, and the number of levels that are interposed in any causal model linking structural genetic variation to a high-level behavioral phenotype, it can be demonstrated with simple calculations that most complex phenotypes would be likely to share only 0.01% up to 1.6% of variance with any specific genetic variant. A corollary of this calculation is that about 5,000 common variants may be necessary to explain the 50% heritability statistics reported for many cognitive traits such as *g* (Bilder & Howe, 2013; Plomin & Deary, 2015).

There is no consensus yet about how to navigate this vast search space, identify the most important variables, and prioritize the selection of paths that connect variables to each other most meaningfully. Development of novel informatics approaches holds promise. I and my colleagues have described an approach to visualization of variance (ViVA) and introduced graphical tools for visualization of the analysis of variance (VISOVA), to help navigate large data sets and detect patterns across large numbers of variables, and explore hypotheses about the correlates of neuropsychiatric phenotypes (Parker, Congdon, & Bilder, 2014). We have developed other approaches to represent specific multilevel hypotheses using graphical models (Bilder & Howe, 2013). For example, we assembled graphical representations of a few hypotheses about the cognitive construct *working memory* to include multiple levels of analysis including genes,

gene expression, proteomics, cellular systems and signaling pathways, neural systems/circuits, cognitive phenotypes, symptom phenotypes, and syndromal or diagnostic phenotypes (Bilder & Howe, 2013). At the more basic levels of analysis, there exist already good knowledge bases that can be queried (for example: Entrez Gene; Gene Ontologies; Gene Expression Omnibus; Entrez Protein, UniProt/SwissProt; NextProt; Ingenuity Pathways Analysis; KEGG Pathway). At the “highest” level of syndromes (as manifest for example in the *Diagnostic and Statistical Manual of Mental Disorders*) there is clear definition of each diagnostic class in terms of its constituent symptoms; this is straightforward to make explicit in graphical models. Similarly, formal definitions of cognitive or neuropsychological constructs can be articulated using structural equation models that make clear exactly what objective measurements are used to define each latent construct. The biggest gap exists at the level of neural systems, and while we have some outstanding frameworks for representing neural networks and neuroanatomic structure, there remains no widely accepted map of human neural circuits to serve as a scaffold for hypotheses about circuit functions. I and my colleagues established a neural circuit description framework in order to specify selected hypotheses about neural circuit functions (Bilder & Howe, 2013), but this was conceptual and lacked links to an explicit spatial map of the brain. We hope that future implementations of this approach to modeling may include direct mapping onto atlases of human connective anatomy that are emerging from the Human Connectome Project (Kocher et al., 2015).

If we can develop formal models about genetic hypotheses about cognitive phenotypes, this may enable fundamental advances. Much as drug discovery is now benefiting from *in silico* modeling of molecular species that can be designed to impact selected receptor targets, we hope that multilevel modeling may one day enable prediction of high-level cognitive consequences of genetic, proteomic, or metabolomic manipulations. These developments may have a profound impact on our understanding of the true dimensions of cognitive and other brain functions. For example, the current taxonomy of mental disorders specifies many classes of illness (diagnostic categories) for which there is sparse evidence of validity. For example, the current distinction between schizophrenia and bipolar disorder rests mostly on historical precedent—dating back to the time of Kraepelin—but more recent neurocognitive, neuroimaging, and neurogenetic data fail to support a clear distinction between these variants of psychotic illness, and may be better understood as reflecting a severity dimension (Bilder, 2015).

This effort to better carve nature “at its joints” is the desideratum of the National Institute of Mental Health (NIMH) Research Domains Criteria (RDoC) initiative, which also specifies the examination of key domains of function at multiple levels (or units) of analysis from genome to syndrome (see the NIMH’s RDoC web page at [www.nimh.nih.gov/research-priorities/rdoc/index.shtml](http://www.nimh.nih.gov/research-priorities/rdoc/index.shtml)). The goal of the RDoC

is to create new diagnostic systems that will use biologically based dimensions and categories to replace the current taxonomy, which is both atheoretical and based almost exclusively on clinical interviews and observation of symptoms. Within each of the research domains in the master RDoC “matrix,” there is a level to represent “genes”—albeit that level of the matrix remains lightly populated, given that we possess few well-validated candidate genes for these domains. We may note, however, that the domain of cognitive systems is relatively rich territory for neuropsychology, encompassing the following constructs and subconstructs (and associated genes where these were proposed):

- Attention (dopamine receptor genes (e.g., D4, D5); DAT1; serotonin receptor gene)
- Perception
  - Visual perception (Dysbindin/NRG1/Neuroigin/Neurexin)
  - Auditory perception (BDNF)
  - Olfactory, somatosensory, and multimodal perception
- Declarative memory (BDNF, KIBRA [hippocampal circuit]; FOXP2 [cortical, based on songbird model])
- Language behavior (FOXP2)
- Cognitive (effortful) control (COMT, BDNF, DISC1, 5HT2A, DRD4, DRD2, 5-HTTLPR, CHRM4, DAT1, MAO-A, 5-HTT)
  - Goal selection, updating, representation and maintenance
  - Response selection, inhibition or suppression
  - Performance monitoring
- Working memory (NRG1/Neuregulin, DISC1, DTNBP1/Dysbindin, BDNF, COMT, DRD2, DAT1)
  - Active maintenance
  - Flexible updating
  - Limited capacity
  - Interference control

It should be recognized, however, that most of the suggested candidate genes do not pass the threshold for credibility based on genome-wide significance, replication, and understanding of biological function. As data accumulate in RDoC projects, however, it is likely that more of the relevant evidence will be assembled, and new genetic targets and their biological correlates will be identified, ushering in a new era of *precision medicine* for neuropsychiatric disorders (Insel & Cuthbert, 2015). Insel and Cuthbert (2015) cite as an example recent work subtyping attention deficit/hyperactivity disorder (ADHD) into *mild*, *urgent*, and *irritable* subtypes, based on a combination of observations about temperamental characteristics, physiology, and neuroimaging measures (Karalunas et al., 2014). Whether these syndromal groups will prove to possess clearer genetic bases remains an open question, but at least by defining categories that have some biological validation, it seems

more likely that the links to underlying genetic differences will be found.

The ultimate promise of these strategies is to provide more complete pathophysiological explanations of neuropsychiatric syndromes that can serve as the basis for the design of rational interventions. In theory, complete knowledge of the genetic architecture for syndromal risk can lead to both highly specific preventative interventions, along with early detection and treatment of emergent dysfunction. The better we understand the mechanisms at a genetic level, along with the manifold expressions of gene action at proteomic, metabolomic, cellular and systems levels, the more clearly we can determine what is the optimal level to intervene in order to maximize benefits and minimize adverse effects. Paralleling this increase in understanding of biological processes and treatments, there is also a burgeoning knowledge of the biology, including *molecular* biology, nonsomatic treatments. Thus, for example, we are learning more about the patterns of gene induction accompanying cognitive training (Klingberg, 2010), epigenetic modification following meditation practice (Kaliman et al., 2014), and the possible mediating roles that certain genetic backgrounds may have for the efficacy of cognitive therapy (Bakker et al., 2014). Insel and Cuthbert (2015) noted the paradox that this new focus on basic biological processes may lead to a renaissance in the appreciation of psychotherapy as an intervention strategy capable of remodeling neural circuits, and leveraging the brain’s inherent neuroplastic capacities, in a highly personalized way.

## Introduction

In conjunction with traditional physical examination and, in the case of neuropsychology, formal psychometric evaluation, functional brain imaging continues to advance the literature on the neural substrates of human cognition. This has resulted in exponential growth of the neuroimaging literature, and for increasing enthusiasm in the pursuit of clinical applications of these technologies. As with any technology or test (including psychometric tests), it is important to always be mindful of what dependent variable is actually being measured, how reliably the dependent variable is being measured, and how valid any finding in an individual case might actually be in terms of clinical symptoms and functional outcome. This chapter will provide an overview of the major categories and types of functional imaging technologies that are likely to be encountered by clinical neuropsychologists in research and, to a more limited degree, clinical practice.

While the present authors recognize and acknowledge that virtually all of the imaging modalities to be discussed in this chapter are, rightly, classified as investigational for most clinical circumstances, it is also believed that having an appreciation of these technologies makes clinical neuropsychologists more informed consumers of research and the myriad (and, at times, speculative or even dubious) claims that are made for what various techniques add to clinical diagnosis and treatment.

## Resting Versus Activated Functional Imaging Paradigms

Historically, functional imaging procedures could be grossly divided into two types of studies: “resting” studies and “activated” studies (Ricker, 2014). Resting neuroimaging paradigms acquire functional images during periods of no overt activity, such as might occur in a baseline condition, or when acquiring images while participants are quietly in the scanner with their eyes closed. There is no explicit or experimental requirement or consideration beyond what may be technically necessary to acquire a reliable set of images (Kilts & Ely, 2012). While participants in a resting condition have been explicitly instructed to not engage in any overt or covert activity, this represents more of an ideal scenario rather than

what may be actually achieved. Indeed, it has been established through functional connectivity studies that the “resting” brain is actually quite “restless” (Raichle, 2015), in the sense that there are multiple brain networks that are active even when the brain is not task-engaged. There are numerous types of dependent variables that are examined in resting studies, such as cerebral blood flow (through single photon emission computed tomography, or SPECT; positron emission tomography, or PET; and certain magnetic resonance imaging, or MRI, applications); glucose uptake (using PET); or the detection of certain biomarkers, i.e., “molecular neuroimaging” (Price, 2012) using SPECT, PET or MRI-based techniques.

Activated imaging studies make use of explicit stimuli and/or activity in order to functionally “probe” regional brain activity during the processing of information or performance of a motor or cognitive task during a specified time period (Baribeau & Anagnostou, 2013). In a true experimental design, stimuli or tasks would be administered following a predetermined protocol. Such protocols will typically require some type of overt or objective response from the participant (Wilde, Hunter, & Bigler, 2012), although functional connectivity studies could be considered somewhat of an exception as these types of studies are evaluating networks of activation rather than specific focused areas of activation in response to overt stimuli.

In view of the biophysical properties of the dependent variables investigated (e.g., briefer half-lives of radioisotopes, or transient changes in hemodynamic response), activation studies have much briefer windows for time sampling than resting studies. Certain imaging technologies can delineate changes in a continuous manner (e.g., event related functional magnetic resonance imaging, or fMRI, and magnetoencephalography). With this degree of experimental control, investigators are in a better position to infer the specific cerebral regions subserving the cognitive process under examination (Hutzler, 2014).

## Radioisotope-Based Imaging

### *Single Photon Emission Computed Emission Tomography (SPECT)*

SPECT is a functional imaging technology that derives from the concept that regional changes in cerebral activity or brain chemistry may be indirectly measured through the use of

external gamma radiation detectors (“cameras”) that identify localized accumulation of tracer flow or receptor-binding isotopes (Hutton, 2014). While most of the application of SPECT technology has been used to study regional cerebral blood flow (rCBF), characterization of some neuroreceptors or neurotransmitter systems can be accomplished with certain SPECT tracers (Palumbo et al., 2014).

rCBF has historically been studied as a primary dependent variable given the fact that, in most circumstances, increased regional cerebral activity is correlated with an increase in blood flow. In other words, when the relative activity of the brain increases, related energy utilization is also increased (Ingvar & Risberg, 1965). Thus, while blood flow is being reflected, actual neural activity is not directly measured. Radioisotopes employed in SPECT (and, for that matter, PET) are actually incorporated into the glia that are proximal to the active neurons. The absorbed radioisotopes are not immediately excreted from glia, thus allowing the isotopes to remain in greater concentration in the more active regions of the brain (Kim & Mountz, 2011). There are two main blood flow tracers that are used in SPECT: Tc-99m Hexamethylpropylene Amine Oxime (HMPAO) and Tc-99m Ethyl Cysteinate Dimer (ECD), which is better for high flow rates, such as seen in ictal states (Heiss, 2014). As the isotopes undergo normal radioactive decay, they emit annihilated radioactive particles (i.e., photons) that are then detected by external gamma cameras. Computerized reconstruction allows for characterization of isotope concentration within a spatial array (Takaki et al., 2009). This reconstruction may then be depicted graphically, often in the depiction of a brain map.

SPECT has some practical advantages over other neuroimaging technologies (Palumbo et al., 2014). For example, because the technology and technical requirements are not as extensive as those of PET or fMRI, it is generally more widely available. In addition, most of the radiotracers used for SPECT are sufficiently stable enough to be shipped rather than needing to be made per use using a cyclotron and thus necessitating the involvement of a radiochemist. In fact, the radioisotopes most commonly used in SPECT may be taken into by the brain within two minutes, but might have half-lives of several hours to days, giving SPECT an additional advantage over PET (Rahmim & Zaidi, 2008; Lin et al., 2012).

While brain SPECT is used primarily to examine resting cerebral blood flow or static biomarkers, the technology has some limited use in evaluating temporally linked changes in brain physiology. For example, SPECT is routinely used in the examination of pre-ictal, and ictal states (Kim & Mountz, 2011). SPECT may, in some highly controlled circumstances, be used to characterize physiological changes associated with circumscribed behavioral engagement and related inferred cognitive events (Ludwig, Chicherio, Terraneo, Magistretti, de Ribaupierre, & Slosman, 2008). That stated, the previously mentioned long half-lives of SPECT ligands have functional significance for imaging, such that once the tracer has

been administered, the resulting images that are acquired will remain relatively static over the next several hours. As a result, SPECT would not be a good choice for the measurement of fluctuating changes such as those encountered in cognitive processes, where fMRI may be more advantageous (Ricker, Arenth, & Wagner 2013).

As is the case for any test (psychometric, physiological, or otherwise), measurement error is always present and must be seriously considered; SPECT is no different in this regard. In contrast to other technologies (for instance, PET), SPECT requires that regional counts be normalized to an anatomic area that is assumed to be free from injury and/or physiologic abnormality (Lin et al., 2012). While SPECT’s resolution does not yet approach that of PET imaging, this concern has been attenuated somewhat with the increased availability of combined SPECT and computed tomography (CT) technology (Maebatake et al., 2014). Color SPECT image reconstruction can produce striking images, particularly when spatially rendered into three-dimensional “maps,” but reliable and valid interpretation is best accomplished through quantitative approaches given the subjectivity and lack of standardization associated with interpreting three-dimensional images (Habert et al., 2011). It must be emphasized, however, that although SPECT can be used quantitatively, this is not the case in most settings. Visual inspection of SPECT maps is a qualitative process, and selection of regions of interest and interpretation may vary across clinicians or others viewing these images (Christen et al., 2013; Eo et al., 2014). In addition, image reconstruction is typically based on presumptions about which brain regions are “normal.” Relative flow values in SPECT are often based upon a region such as the thalamus or cerebellum. While such assumptions might be valid for some populations with focal lesions (e.g., stroke), they might not be valid for populations whose involvement is more diffuse (Hagerstrom et al., 2012). SPECT is quite sensitive to detecting regional differences in resting blood flow, but there is little specificity to the patterns that are obtained and the results depicted in series of SPECT images can be affected by many factors, including acute or chronic emotional disturbances, medications, or current substance use (Granacher, 2008; Ricker, 2012).

SPECT is also objectively less sensitive than PET, with PET being considered to be two to three times more sensitive (Rahmim & Zaidi, 2008). SPECT radioligands emit single photons, rather than two diametrically opposed photons as in PET. In addition, only photons that are essentially parallel to the holes in the lead collimators used in SPECT will reach the detectors, thus filtering out much of the potential source of data (Dougherty, Rauch, & Rosenbaum, 2004; Ogawa & Ichimura, 2014). SPECT image quality may also be impacted by many factors beyond its inherent biophysical limitations (Sohlberg, Watabe, & Iida, 2008). Obviously, patient motion can affect image acquisition (Kyme, Hutton, Hatton, Skerrett, & Barnden, 2003), but motion effects are by no means restricted to the head, as movement of the extremities may

result in changes in cerebral blood flow during SPECT scanning (Takekawa, Kakuda, Uchiyama, Ikegaya, & Abo, 2014). The patient's own biochemical status may also be a source of error. For example, caffeine and alcohol may impact cerebral blood flow, and sedating medications are known to impact SPECT tracer distribution (Juni et al., 2009).

### Positron Emission Tomography

PET is another imaging technology that utilizes radioisotopes. The dependent variable of interest is usually glucose utilization (indexed by fluorodeoxyglucose uptake), although blood flow may also be assessed, particularly for activated imaging studies (Kudomi et al., 2013). Nitrogen ( $^{13}\text{N}$ ) and carbon ( $^{11}\text{C}$ ) are additional radionuclides that are used in PET. Various tracers that are specific to certain transmitter systems are also available (Billard, Le Bars, & Zimmer, 2014; Fuchigami, Nakayama, & Yoshida, 2015), as well as for specific cell types or cellular components (e.g., glia and myelin (Matthews & Datta, 2015)). In resting PET studies, a radioisotope is injected peripherally into the bloodstream via a vehicle of intravenous saline. Brain regions of greater activity will take up proportionally greater amounts of glucose relative to less active brain regions, which leads to a greater concentration of protons relative to electrons (Nasrallah & Dubroff, 2013). This is depicted in Figure 9.1.

Unlike SPECT, the physics that underlie PET capitalize on the fact that the radioactive process involves results in the release of two diametrically opposed particles, known

as *photons* (Sossi, 2007). In PET, highly unstable radionuclides are injected into the participant. As the positrons from these radionuclides collide with electrons they annihilate each other, thus releasing radiation in the form of emitted photons, which are detected by a crystalline ring external to the head (Heiss, 2014). Both the location and level of photon release are subsequently calculated geometrically. Because there is a much larger array of crystalline detectors surrounding the head in PET (as contrasted with the holes within SPECT collimators), many more data points may be realized. Thus, PET provides a much richer data set for analysis and superior resolution than SPECT (Palumbo et al., 2014).

The half-life of the radioisotope used dictates the type of inferences that can be hypothesized regarding physiological activity during the scan. For example, the half-life of 18-FDG is several minutes, thus only very gross inferences can be made regarding an 18-FDG PET image and the underlying cognitive or motor activity. With oxygen-15, however, the half-life is two minutes, which permits briefer imaging periods and shorter wash-out periods between scans (Chugani, 2012). Thus, more reliable and valid inferences about cognitive or motor activity can be made, once, of course, one has introduced appropriate control conditions to account for general brain activation associated with task execution, such as button pressing, passive listening, ambient noise, and other factors that are controlled through cognitive subtraction analysis (Herrmann, Obleser, Kalberlah, Haynes, & Friederici, 2012).

A primary limitation of PET is that it remains a procedure with relatively limited availability, often only at academic medical centers or larger community hospitals. This is primarily because PET is a very expensive procedure, requiring an on-site chemist and, depending on the tracers needed, an on-site cyclotron (Wey, Desai, & Duong, 2013). Combined PET and CT systems (PET/CT) and magnetic resonance imaging (PET/MR) are now commercially available and are seeing use in nonacademic centers, but their use is typically more limited to very specific diagnostic questions, e.g., tumor characterization (Disselhorst, Bezrukov, Kolb, Parl, & Pichler, 2014; Shah et al., 2013).

### Molecular Imaging With SPECT and PET

Receptor-specific binding agents can be radioactively labeled or “tagged,” allowing for the characterization of regional concentrations of particular biochemicals—such as neuroreceptors, transporters, hormones, or enzymes—through the detection of the gamma particles that they emit (Kim & Mountz, 2011; Palumbo et al., 2014). Labeling neuroreceptors with radionuclides is by no means novel. The first approaches to molecular imaging actually developed in animal research through the process of receptor autoradiography, a process by which pharmacologic agents were radioactively tagged and introduced to the brains of animal subjects either in vivo through intravenous or direct

**Figure 9.1** Oxygen-15 PET blood flow image of a patient with a left frontal stroke. Note decreased blood flow in the compromised region (depicted in blue). Adapted with permission from M. Corbetta and L. T. Connor (2006). Neurological recovery after stroke (p. 140). In M. D’Esposito (Ed.), *Functional MRI: Applications in clinical neurology and psychiatry*. Abingdon: Informa Healthcare. A color version of this figure can be found in Plate section 1.

intracerebral injection, or in vitro through direct application to brain specimens (Cherry, 2004). The brains were then sectioned and exposed directly to photographic emulsions, and the emitted radiation from specific receptor sites or other relevant brain regions resulted in photographic exposure and highly accurate depictions of localized concentrations of ligands. Obviously, such an approach cannot be applied to the living human brain, but by using external gamma-detecting cameras, as well as computerized spatial reconstruction, areas in which radiopharmaceuticals bound to high-affinity receptors can be accurately depicted using SPECT (although still not with a precision afforded by autoradiography or PET). Molecular imaging using PET is similar to that for SPECT, but with a larger variety of potential ligands available (Hutton, 2014), and, of course, greater anatomic and temporal resolution (Heiss, 2014; Price, 2012). There are many markers available that are specific to receptors and neurotransmitters (e.g., dopamine, serotonin) and drug classes (e.g., benzodiazepines, opioids). PET and SPECT markers have been developed for specific types of neuropathology, such as beta amyloid and tau, which have been subjected to much research in Alzheimer's dementia and are now receiving attention in the context of traumatic brain injury (Cohen & Klunk, 2014; Watanabe, Ono, & Saji, 2015).

## Magnetic Resonance–Based Imaging

### Overview and Biophysics

All MRI techniques capitalize on the presence of hydrogen in all of the body's tissues. When hydrogen atoms are placed in a strong magnetic field, their nuclei align in parallel to the field's direction. In MRI, radio frequency (RF) pulses are presented at a 90° angle relative to the magnetic field. When this occurs, the hydrogen nuclei realign and begin spinning in a different direction (a phenomenon referred to as *excitation*). When the RF pulse is then stopped, these nuclei return to their original alignment and direction of spin. The physical process of resuming previous nuclei states results in the emission of a minute electrical signal that can be detected by the scanner (Plewes & Kucharczyk, 2012). Although only approximately 1% of the hydrogen atoms in the magnetic field emit a response, this results in enough signal change to permit the acquisition of images. Given that most of the atoms that are excited in this process are found within water molecules, water content (and thus tissue density) dictate the signal intensity that is detectable by the scanner and ultimately digitally reconstructed into an image (Kim & Ogawa, 2012).

### Functional Magnetic Resonance Imaging

In structural brain MRI, the primary goal is to generate high-resolution anatomic images of brain structure, but fMRI additionally allows the investigator to make inferences

Figure 9.2 fMRI demonstrating regions of increased blood flow during a verbal list-learning task in persons with TBI. Adapted from Arenth, Russell, Scanlon, Kessler, and Ricker (2012). A color version of this figure can be found in Plate section 1.

about regional changes in brain activity and to depict regions of activation or deactivation within the context of brain anatomy (see Figure 9.2).

As with other blood-flow related techniques, in fMRI specific tasks or stimuli are introduced to the individual while in the scanner in order to provoke a change in cerebral activity (Gaillard & Berl, 2012). When neural activity increases in a brain region, there is a related increase in blood flow to that region. While at rest, there is a tight correlation among rCBF) regional cerebral metabolic rate for glucose (rCMR<sub>glc</sub>) and regional cerebral metabolic rate for oxygen (rCMRO<sub>2</sub>). When a brain region becomes active, however, rCBF may increase by more than 50%, which greatly exceeds metabolic demands. The physiologic basis for this is not clear, however (Nagaoka et al., 2006). With an excess of blood flow to the region and only a minimal increase in oxygen extraction, there results a localized abundance of oxyhemoglobin relative to deoxyhemoglobin in the venous and capillary beds that perfuse active regions of cortex. Oxyhemoglobin is naturally diamagnetic, while deoxyhemoglobin is paramagnetic (i.e., becomes readily magnetized within a magnetic field). This results in an increase in signal intensity that can be detected externally, and is represented as higher signal intensity on T2\* (“T2-star”) weighted scans. This change in signal intensity referred to as the blood oxygen level dependent (BOLD) effect (Kim & Ogawa, 2012). The signal changes obtained are very small, on the order of 1% to 6%, and occur over approximately a 2 to 6 second time frame, depending on brain region, tasks being performed,

and the participant's age, among other factors (Simon & Buxton, 2015).

An additional technique known as arterial spin labeling (ASL) may be used in conjunction with fMRI. ASL is a noninvasive approach to characterizing cerebral blood flow by using biophysical "labeling" to provide an endogenous "contrast agent." Through ASL, a secondary pulse sequence is applied distal from the brain (e.g., at the level of the neck). This alters that area's blood's molecular spin and effectively "labels" that blood so that, upon reaching the brain, the difference in spin can be detected by the head coil and compared to the brain's own magnetic signal both before and after labeling, thus permitting direct inferences about brain perfusion (Aguirre & Detre, 2012).

Because fMRI utilizes the body's natural physical responses to high-strength magnetism, no exogenous tracers, radioisotopes, or contrast agents are necessary, and the anatomic resolution of fMRI is superior to that of SPECT or PET (Disselhorst et al., 2014). There are numerous activation paradigms that can be carried out in fMRI, and it allows for greater flexibility in paradigm with reference to repeatability and brevity of overall session (Kilts & Ely, 2012). In fMRI scanners of typical magnet strength (e.g., 1.5 Tesla), the signal changes that appear emanate from veins and large venules. In high-field magnets (e.g., 3 or 4 Tesla or higher), signal change in nonclinical populations is more likely obtained from microvessels, small venules, and capillaries (Buxton, 2013).

There are many technical considerations with regard to fMRI data acquisition and interpretation. Overt responses to tasks must be minimal at most. Movements of the jaw required for conversational speech are considered too excessive during fMRI, although some paradigms do allow for some degree of overt verbal responding (Gracco, Tremblay, & Pike, 2005), and the use of silent intervals within block designs allows for the use of fMRI to study the brain substrates of speech production (Berken et al., 2015). The normal high-frequency noise emitted by the scanner must be considered. The technician must also monitor the participant for idiosyncratic responses such as claustrophobia (Munn & Jordan, 2013). Most clinicians will know that any MRI-based technology presents safety issues in terms of obvious ferromagnetic objects and devices such as pacemakers, surgical clips, and other implanted devices, but image reconstruction artifacts and even misinterpretation may result from less obvious factors such as makeup, tattoos, or certain types of clothing (Krupa & Bekiesinska-Figatowska, 2015). Although virtually any contemporary MRI scanner can be adapted to functional imaging, fMRI is still investigational in most clinical populations with whom clinical neuropsychologists are likely to work (American College of Radiology, 2015), and is thus primarily a research tool at this time, mostly, though not exclusively, limited to academic medical centers, universities, and biomedical research centers.

A single fMRI session does not automatically generate clinically useable brain maps, although semi-automated

techniques have been developed (Karmonik et al., 2010). The resulting images must be carefully and skillfully reconstructed, and this reconstruction process could still be considered to be as much art as science. As with all imaging technologies, the approach that one takes (and the hypotheses that one holds) in reconstructing and displaying the data in the form of brain images data will impact the portrayal and interpretation of the end product.

fMRI has been used as a research tool in humans for well over 20 years, with the first studies appearing in 1992. Yet, there have been essentially no routine clinical applications of fMRI outside of its use in presurgical mapping for epilepsy surgeries and tumor resections (Greicius, 2008; Ricker, 2014). There are many technical limitations that contribute to this poor clinical representation (e.g., poor signal-to-noise ratio of fMRI, and difficulties when applying findings derived from group data to individual cases), but another major contributor is also the necessary engagement and reliable execution of the experimental cognitive or motor task being administered. This may prove to be challenging for some patient populations and essentially limits most clinical generalizations to higher functioning patients.

### *Functional Connectivity Magnetic Resonance Imaging*

While fMRI studies require an active administration of a stimulus or cognitive paradigm, with varying degrees of participant response or input, resting-state connectivity studies offer an opportunity to study the brain's functional connectivity without participants having to engage in prolonged, repetitive tasks during the scanning procedure. First, during "traditional" fMRI, the participant must be fully engaged in putting forth a good effort. As is the case with traditional psychometric testing, full effort during cognitive tasks in the scanner is imperative. Second, there is a relationship between task difficulty and cognitive activation. Greater levels of task difficulty usually result in more neural activation during cognitive task blocks, but if the task is too difficult a participant may become overwhelmed or simply disengage from the task, thus causing activation levels to return to a resting baseline level. These limitations can be partially mitigated through the use of fMRI during the resting state (Ricker, 2013).

Huettel and colleagues (Huettel, Song, & McCarthy, 2014) define functional connectivity as a "pattern of functional relationships among regions, inferred from common changes in activation over time, that may reflect direct or indirect links between those regions" (p. 293). The analyses used in functional connectivity studies are comprised of cross-correlations among activity concourses within separate brain regions, for which one assumes a priori functional relationships.

Resting-state studies are presently the most commonly used in functional connectivity MRI (fcMRI), but functional connectivity analyses may also be accomplished during cognitive tasks. There are two broad methodological approaches

for examining resting-state fMRI data (Peterson, Thome, Frewen, & Lanius, 2014). The first approach is to examine how resting-state configurations may affect functional connectivity. This involves comparing long periods of rest (rest blocks) with rest blocks that alternate with cognitive tasks. Event-related designs may also be applied in which activity is elicited through short but continuous events rather than in blocks. The second major fcMRI approach is voxel-based and emphasizes comparisons among the regions of interest. This requires a greater degree of a priori selection of brain regions to be studied during resting the fMRI periods. The first studies of functional connectivity often examined only functional interrelations, and did not really concern themselves with structural connectivity or anatomic explanations for the functional relationships (Medaglia, Lynall, & Bassett, 2015). At present, however, several reliable functionally connected cerebral networks have been identified through fcMRI, three of which are likely to be of greatest interest and relevance to clinical neuropsychologists.

The first, and most frequently studied to date, is the default mode network (DMN). The DMN represents a broad network of cerebral areas thought to result in an interrelated system of self-referential cognitive activities, such as self-monitoring, autobiographical processing, and social functions (Whitfield-Gabrieli & Ford, 2012). The DMN is comprised of the medial prefrontal cortex, retrosplenial neocortex (i.e., posterior cingulate and precuneus), and the inferior parietal lobes, bilaterally (Peeters et al., 2015). The DMN demonstrates its most prominent activity during passive rest (Hsu, Broyd, Helps, Benikos, & Sonuga-Barke, 2013), but it is active during some higher-level reflective tests that tap prospective thinking, accessing of autobiographical memory, and activities associated with making inferences about the mental states of others, in other words, the “theory of mind” (Dunbar, 2012).

Second, a specific central executive network has been characterized through use of functional connectivity investigations. The central executive network spans dorsolateral prefrontal cortex and the posterior parietal lobes (Chen et al., 2013). In general, it underlies externally driven and cognitive demanding mental activities, and its associated cognitive operations include executive control and working memory (Shaw, Schultz, Sperling, & Hedden, 2015).

Third, the salience network, comprised of the anterior insula and anterior cingulate, mediates dynamic switching between the DMN and the central executive network and thus functions to mediate attention between endogenous and exogenous events (Kiverstein & Miller, 2015).

While seemingly more straightforward and to a large degree, less demanding in terms of study design (i.e., investigators do not need to develop reliable cognitive paradigms that work within the constraints imposed by conventional fMRI, fcMRI is not without its own challenges and limitations. For example, even subtle motion during fcMRI may result in spurious signal perturbations that might be erroneously interpreted as having significance relative to the construct being studied (Power, Schlaggar, & Petersen, 2015).

## ***Molecular Imaging With MRI***

*Magnetic resonance spectroscopy* (MRS) is an MR-based technique that offers the capacity to localize and characterize brain-based biomarkers. As an MR-based technology, it is based on the same biophysics as MRI, fMRI, and fcMRI. It differs, however, in that it derives its signal not only from water-bound or lipid-bound hydrogen, but is also capable of localizing other endogenous biomaterials based on their own unique signal waveform properties (Cecil, 2013).

MRS is capable of differentiating the unique magnetic profiles of biomarkers markers such as glutamate (Glu), creatine or phosphocreatine (Cre), n-acetyl aspartate (NAA), and choline (Cho) related compounds (Bertholdo, Watcharakorn, & Castillo, 2013). Each biomarker possesses different numbers of electrons in its nuclei, and the greater the number of electrons, the greater the local reduction within the magnetic field, resulting in a reduced spectral peak (Dale, Brown & Semelka, 2015). This allows for the localization and quantification of biomarkers in space, although MRS data are usually represented as spectral waveforms rather than topographic brain maps commonly depicted in other neuroimaging modalities.

*Sodium MR imaging* is an MRI-based molecular imaging technique that reflects sodium homeostasis, and is therefore considered to be an index of cellular viability (Price, 2012). Sodium ion homeostasis is lost when cells die in the brain (Boada et al., 2005). Sodium MRI is similar to MR spectroscopy in the sense that it yields metabolic information, but because it focuses solely on the resonance of one biomarker (i.e., sodium), pulse sequences may be acquired at much higher resolution (Ouwkerk, 2011). Several critical processes at the cellular level depend on a balance of high extracellular and low intracellular sodium content, but many conditions (e.g., ischemia, injury, neoplasm) may lead to an increase in intracellular sodium, thus making sodium a potential biomarker for pathology or response to treatment (Madelin, Kline, Walvick, & Regatte, 2014).

## **Electrophysiological Brain Mapping Techniques**

### ***Quantitative Electroencephalography***

Electroencephalography (EEG) is electrophysiologically based technology that is used to monitor gross brain electrical activity, such as normal neuronal firing and seizure activity. Traditional EEG output does not, however, permit characterization of the wave frequency continua that occur in a human brain. But, when Fourier transformation analyses are applied to EEG, continuous monitoring and quantification across cerebral wave frequencies may be achieved. This approach to data transformation is referred to as *quantitative EEG* (QEEG; see Haneef, Levin, Frost, & Mizrahi, 2013).

QEEG is an general term applied to a group of interrelated technologies that derive from a mathematical approach referred to as spectral analysis (Billeci et al., 2013). Basically,

the EEG signal is digitally processed and the relative contributions of each frequency are identified and quantified. When digitized, the individual component frequencies of a complex waveform (i.e., the amounts of alpha, beta, delta, and theta activity contained within the signal) may be discerned in a manner superior to that of traditional visual analysis of EEG printed output (Trambaiolli et al., 2011).

There are various approaches for portraying spectral data from QEEG. In a compressed spectral array format, frequencies within specified time blocks (e.g., 30 seconds) are quantified. The output is then represented sequentially either in print or graphically, permitting interpretation of changes in the EEG signal over time (Williamson, Wahlster, Shafi, & Westover, 2014).

A common approach is to display QEEG spectra in the form of topographical maps. In this format, each electrode in the EEG montage is assigned a color or gray value representing each frequency range, with the shading or color intensity representing the frequency level that underlies the corresponding electrode. The shading or color gradient is subsequently superimposed on a head-shaped or brain-shaped oval. The resulting brain map thus resembles (somewhat) the topographical maps generated by a resting SPECT or PET scan. It needs to be understood, however, that a QEEG topographic map is really derived from a rather minimal number of solely cortical data points, and has numerous interpolated color values—specifically, all of the shades or colors between electrodes are actually interpolated (Kamarajan & Porjesz, 2015).

Another approach to depicting QEEG data is through probability mapping. This approach utilizes a topographic map as its basis, but then maps to a normative database (the “composite map”). An individual’s map may then be statistically compared to the normative map, and inferences are made based on deviation from the normal distribution (Trimble & George, 2010).

### **Magnetoencephalography (MEG)**

Neuronal activity generates minute magnetic fields, which may be detected through a technology referred to as *magnetoencephalography* (MEG). The physiological basis of MEG derives from normal neuronal membrane signal conduction. When a neuronal synapse becomes active, there is a current flow across the neural membrane. This current diffuses intracellularly, and subsequently emerges extracellularly at a consistent distance from where it began, i.e., from dendrite to synapse. This yields extracellular *sources* and *sinks*. In a neuron that is oriented asymmetrically in space, the sources and sinks create dipolar electromagnetic fields that cancel out one another and signals may be localized (Slater, Khan, Li, & Castillo, 2012). The intracellular current between the area of synapse activity and the area at where the current returns to extracellular space does not cancel out, which results in a change in the magnetic field that may be externally recorded (Owen, Sekihara, & Nagarajan, 2012).

MEG uses an array of electromagnetic conducting coils placed around a person’s head to detect changes in neuronal

activity. Each coil is cooled by liquid helium to a temperature of almost absolute zero. Such super-cooling greatly dampens the electrical resistance of the conductor, which allows very small magnetic field changes to be detected. The field changes are, however, still quite minute, and must be amplified through the use of what are known as superconducting quantum-interference devices (SQUIDS; see Schneiderman, 2014). A MEG scanner differs somewhat in configuration from other scanning devices such as those for SPECT and PET, allowing participants to be seated upright during scanned (as shown in Figure 9.3).

Although intuitively similar to EEG, MEG has several advantages. MEG frequencies are actually simpler to record than those from EEG, given that the detectors are placed in a helmet adjacent to the scalp and do not have to be individually applied and interconnected. Magnetic fields are also not affected by the variability in skull thickness over different regions of cortex. That said, however, there are some disadvantages to MEG. For example, it is not widely available and the physical facilities that must be specially constructed to support it are very expensive. In addition, MEG, similar to EEG, lacks the anatomic precision of other neuroimaging techniques and does not localize subcortical activity sources (Wilde et al., 2015).

**Figure 9.3** A MEG scanner. Note that the configuration allows for upright seating of the person being scanned. Reproduced with permission, from J. Ward (2015). *The student’s guide to cognitive neuroscience*, 3rd edition (p. 46). East Sussex: Taylor & Francis.

## Other Technologies

### *Optical (Near-Infrared) Imaging*

The category of optical imaging techniques includes those that derive from the biophysical principles of light absorption and reflectance. Of interest for human brain imaging is the application of near-infrared spectroscopy. The near-infrared light spectrum includes the range of nonionizing (and, thus, not harmful to living tissue) electromagnetic radiation with wavelengths between 700 and 1,000 nm. Similarly to fMRI, functional near-infrared spectroscopy (fNIRS) characterizes changes in the ratio of oxyhemoglobin to deoxyhemoglobin, which, in addition to having differing magnetic properties, also have differing light-absorption properties (Arenth, Ricker, & Schultheis, 2007)

When used as a neuroimaging modality, fNIRS requires the placement of light emitting diodes (LEDs) and detectors directly against a person's scalp. FNIRS measures many of the same physiological parameters as fMRI and O-15 PET, but also has possesses some unique advantages over these techniques (Amyot et al., 2015). FNIRS is noninvasive, has no ionizing radiation, and does not require the use of high-field magnetization, thus making it essentially risk-free. FNIRS has the unique advantage of being quite portable and mostly unaffected by subject movement.

### *Functional Transcranial Doppler Ultrasonography*

Transcranial Doppler (TCD) is used to depict blood flow within intracerebral arteries through the application of Doppler ultrasound technology. Ultrasound is capable of reflecting changes in blood flow through the placement of a sound source and receiver at the same location. The ultrasound beam that is projected into the skull is reflected back by blood cells that flow through the vessel that intersects the sound wave (Naqvi, Yap, Ahmad, & Ghosh, 2013).

Because sound does not travel well through bone, the ultrasound source must be placed against a thin or accessible skull region, referred to as an acoustic "window." The most common window for cognitive studies is the temporal window, which is located in the squamous region of the temporal bone. Additional windows include the transorbital, submandibular, and suboccipital windows (Kristiansson et al., 2013).

The data are initially represented as waveforms that reflect blood flow velocity, but are often subsequently portrayed using spectral analysis methods similar to those described above for QEEG. TCD has many positive features as an imaging modality. As is the case with near-infrared spectroscopy, TCD is noninvasive, emits no ionizing radiation, does not require a high-field magnet, is inexpensive, and is highly portable. Notably, however, TCD's spatial resolution is quite limited given that it is able to cover a very small number of cerebral regions (Purkayastha & Sorond, 2012).

## Methodological Considerations in Clinical Interpretation

For the most part, most functional imaging technologies remain tools of research as this volume goes to press. But, there is increasing clinical use of some of these technologies in limited forms of differential diagnosis (e.g., vascular cognitive impairment vs. a primary progressive dementia), and functional imaging appears as evidence in forensic cases with increasing frequency (often in the absence of any scientific support for its application in the injury, illness, or defense in question). It is therefore important that clinical neuropsychologists consider several general methodological issues that are relevant to essentially all functional neuroimaging modalities and clinical syndromes.

### *Injury and Illness Characteristics*

The impact of changes to brain morphology on image reconstruction must be considered. Functional imaging data from a brain that has been altered anatomically by surgery (e.g., resection of a tumor or lobe), injury (e.g., massive contusion), or disease process (e.g., progressive atrophy or an infarction) must be normalized, analyzed, and depicted carefully in order for regions of activation and deactivation to be represented in a reliable and valid manner (Ashburner & Friston, 2005).

Different image acquisition platforms (e.g., General Electric, Philips, Siemens) and image analysis and reconstruction software (e.g., AFNI, Brain Voyager, Statistical Parametric Mapping, or one of the numerous lab-specific specialized programs), may yield somewhat different findings across anatomic localization or activation intensity (Poldrack, Mumford, & Nichols, 2011).

Comorbid conditions, peripheral injuries, and pain can alter brain activation patterns independently of any relationship to actual brain status cognition, thus it is important to take into account a person's entire medical and physical status (which includes past and current medication and substance use) before making inferences and drawing conclusions from functional neuroimaging data. As just one example, sleep disorders—which are frequently encountered comorbidly (and premorbidly) in neuropsychological populations—are associated with differences in functional (De Havas, Parimal, Soon, & Chee, 2012) and even structural (Castronovo et al., 2014) neuroimaging findings, even in the absence of a primary neurological condition or injury.

There has been much debate in the functional imaging literature as to test-retest reliability and the nature of change (Aron, Gluck, & Poldrack, 2006) (Freyer et al., 2009), and functional imaging findings are often cited to support hypotheses about change in cognitive or brain status (e.g., as evidence of "decline," "improvement," "reorganization," etc.). Such inferences have no logical or empirical basis unless there have been are two or more sessions of imaging data

acquired, thus making the way one operationalizes “change” as critical if one is using functional imaging to support such hypotheses. Furthermore, signal changes that are observed in the population of interest in a single study may actually represent a more general response to neurological disruption rather than a change that is specific to one clinical population (Hillary et al., 2015).

## Conclusions and Future Directions

Functional neuroimaging has seen increased use in the study of cognitive and emotional functioning, and has changed many ways that brain-behavior relationships are conceptualized. While these technologies are intuitively appealing, it should be noted that virtually all of the types discussed in this chapter are classified as investigational for most clinical uses. Until much more benchmarking research is conducted, and numerous technical, methodological, and biophysical issues have been addressed, most functional neuroimaging technologies remain primarily research tools.

Interpretation of functional imaging examination results should vary in a reliable and predictable manner in relation to severity or degree of functional impairment. For example, it is counterintuitive—and scientifically unsupported—for imaging findings in a person, or sample of persons, with mild TBI to be interpreted as demonstrating greater pathology or dysfunction than would be expected using the same imaging procedure in a more severely injured person or sample. And, as scientifically trained psychologists first and foremost, clinical neuropsychologists should be able to readily appreciate that a “difference” or “change” cannot be not reflexively equated with pathology, dysfunction, or disability. The clinical utility of a given functional imaging tool may appear “self-evident” to some, but the evidence base has yet to be adequately established for the vast majority of populations likely to be evaluated and treated by clinical neuropsychologists (American College of Radiology Appropriateness Criteria, 2015; Ryan et al., 2014; Shetty et al., 2016). While often visually striking, functional imaging reconstructions must not be seen as literal “pictures” of brain status (Ward, 2015).

None of this should be misconstrued as taking a negative position; rather, it is a scientific and ultimately optimistic one. As existing approaches are deployed increasingly in clinical populations, and as even newer approaches such as optogenetic (Lu et al., 2015) and photoacoustic (Yao et al., 2015) imaging are eventually translated into humans, functional neuroimaging will eventually likely be a common adjunct to traditional assessment and intervention. For example, as reviewed recently (Ricker, DeLuca, & Frey, 2014), contemporary functional neuroimaging technologies have several potential applications to neurological populations. First, functional imaging could be used to evaluate the efficacy of behavioral or pharmacological interventions by potentially providing objective demonstration of long-term changes at

the cerebral level. Second, functional imaging might eventually be used as a primary assessment tool in and of itself. For example, once neurofunctional correlates (i.e., “markers”) of specific cognitive impairments have been established, it may be possible to compare an individual’s performance to that of large samples with a known disease or impairment. Finally, functional imaging may eventually be used as an additional clinical prognostic tool, either in isolation, or preferably, in conjunction with other biomarkers and objective neuropsychological data. For example, if after an intervention patients do not show any impact at the cerebral level, and this is corroborated by lack of change at a behavioral level, future strategies and planning might be directed toward compensating for permanent deficits. Ultimately, it appears likely that the future holds promise for the integration of functional neuroimaging as a complement to the practice of clinical neuropsychology.

# 10 Genetic and Neurodevelopmental Disorders

*E. Mark Mahone, Beth S. Slomine, and T. Andrew Zabel*

## Introduction

Neurodevelopmental disorders are conditions that involve early insult or abnormality in the developing brain or central nervous system and are associated with a wide spectrum of abilities and deficits in children. The behavioral and cognitive dysfunction associated with early neural damage can range from subtle (or absent) to diffuse and profound. Importantly, the functional disability observed in children with neurodevelopmental disorders is variable, and is rarely predicted by a child's IQ (or developmental quotient) scores alone.

In children with neurodevelopmental disorders, it can be assumed that there has been early interference to the developing nervous system, which can take place during prenatal, perinatal, or postnatal development. For the purposes of this chapter, we define "early" as occurring within the first three years of life. These early occurring insults set the stage for what is often a chronic course, beginning in early childhood, in which the "normal" development of the central nervous system has been altered. The result of this alteration is *reorganization* within the nervous system in an unexpected manner, and ultimately, *competition* among available brain structures to support the development of cognitive and behavioral function. In other words, early insults stimulate alternate neural pathways; subsequently, the functional effect occurs not only on the damaged brain region, but also the regions that support the new functions.

The timing of the reorganization is critical, and outcome is a function of *when* the change occurs relative to critical periods in brain development. Functional reorganization that affects a particular brain region during a critical period of growth may result in "crowding," in which outcome (i.e., performance of critical life skills) is often less efficient. This inefficiency in performance of life functioning is the hallmark trait of children with neurodevelopmental disorders. Performance on routine skills is often slower and more effortful than would be expected for the child's age, with new learning and skill development requiring more trials to master than in children without neurodevelopmental disorders.

*Sensitive periods* in development involve rapid periods of neural and functional growth and occur when specific regions and cells are also susceptible to insult at specific periods of brain development (i.e., selective vulnerability; Johnston,

2004). Given the importance of a sequential unfolding of multiple processes during these times, these sensitive periods represent great periods of vulnerability. The developmental neuropsychological framework necessarily considers how *timing* of central nervous system disruption can lead to different outcomes. For example, disruption in the first trimester can lead to major structural anomalies and often diffuse and pervasive neuropsychological deficits. Disruption in the second trimester affects neuronal migration. Disruption in the late second and early third trimester and postnatal is associated with more focal white and gray matter damage (Hoon & Melhem, 2000).

In neurodevelopmental disorders, the concept of the *time-referenced symptom* is critical. As a result of reorganization, functional impairments can be observed immediately; however, more often, the full range of functional deficits may not manifest until later in life, even though the neurobiological basis of the condition is present earlier (Rudel, 1981). The relationship between the biological vulnerability and psychological test performance may reside in the "take-a-test" demands with which assessment presents to the child, and the extent to which psychometric tests relate to functioning in the real-life (e.g., classroom) settings (Holmes-Bernstein & Waber, 1990).

Understanding brain-behavior relationships in children is challenging to the neuropsychologist for a variety of reasons. Frequently, no imaging studies will have been performed. Moreover, often there is no focal lesion as is the case in adults, and even when one is present, the neuropsychological deficits that manifest throughout the child's development are typically not consistent with a focal deficit.

In many instances, the early neural disruption occurs in multiple brain systems, leading to several types of functional reorganization. In typical development, functional skills develop along the same developmental timelines as nervous system development. In children with neurodevelopmental disorders, the development is often "off developmental track" behaviorally, and maturational timelines based on normal development become less applicable. Outcomes in children with neurodevelopmental disorders depend on the age of the child at the time of insult, the type of insult, whether the insult is chronic or acute, functional development prior to insult, and development that is not yet complete at the time

of the insult. Each of these factors should be considered when assessing children with neurodevelopmental disorders.

Functional outcomes in children with neurodevelopmental disorders are also considered in the context of the child's changing educational demands. As children mature, they are expected to work more independently. As a result of this expectation, classrooms progressively minimize and eventually withdraw the structures and supports that enable young students to accomplish their goals. For example, in first grade, a student's primary task is to learn how to be a student, i.e., to learn *how* to learn. First graders learn how to read and write, how to pay attention, and how to follow the rules. Teachers provide extensive structure and support developing executive control functions. By fourth grade, however, students are expected to have learned how to read and are required to use reading as the primary means of mastering other subjects. If reading capability is not in place at this time, new difficulties will emerge. By middle school, students are expected to organize themselves and, increasingly, to learn on their own. By high school, students are expected to be well organized and self-motivating.

### **Transition Into Adulthood**

Medical advances have sharply changed the life course of a number of genetic and developmentally involved conditions, making some conditions more survivable/compatible with life (e.g., very low birth weight preterm infants, hydrocephalus) and extending the expected life span for others (e.g., cystic fibrosis, sickle cell disease, and spina bifida). Due to higher survival rates and life spans extending into adulthood, increased attention has been given to the development of self-management and independence skills, and the transition into older adolescence and young adulthood. This transition is considerably different than transitions that have occurred earlier in development. For example, the academically based transitions of childhood (e.g., fourth grade, middle school, high school) have in many instances been scaffolded by parents, teachers, and entitlement-based accommodations and interventions. In contrast, the transition of youth with genetic and developmental conditions into young adulthood is often complicated by increased expectations of independence, a withdrawal of supports in general, and a transition into "eligibility"-based supports that may not be adequately available or funded.

During the period of "early adulthood," between the ages of 18 and 34 (Furstenberg, Rumbaut, & Settersten, 2005), individuals with genetic and developmental conditions are typically presented with a variety of opportunities and challenges, including employment, financial management, intimate relationships, parenting, etc. While early research suggests a more favorable adult outcome for some medically involved populations (e.g., prematurity; Saigal et al., 2006), adults with developmental disabilities in general still fall well behind age-matched peers in the attainment and performance

of these early adult milestones. For instance, the rate of employment of individuals diagnosed with intellectual disability is less than half that of nondisabled peers during late adolescence (Butterworth, Leach, McManus, & Stansfeld, 2013), and this gap widens in early adulthood (Sulewski, Zalewska, Butterworth, & Migliore, 2013). In addition to the more typical adult level expectations, the transition into adulthood for individuals with genetic and developmental conditions can be further complicated by the challenge of assuming responsibility from parents for the reliable completion of medical self-management tasks, ranging from less-complicated daily medication administration (e.g., sickle cell disease) to more-complicated bowel and bladder management procedures (i.e., spina bifida) and respiratory therapies (i.e., cystic fibrosis). Finally, many of these conditions are further complicated by cognitive changes experienced during adulthood, ranging from "early aging" processes (e.g., spina bifida; Dennis, Nelson, Jewell, & Fletcher, 2010) to more overt declines in memory, language, and cognitive functioning (Down syndrome; Zigman, 2013).

### **Classification of Neurodevelopmental Disorders**

There are two primary approaches to classification of neurodevelopmental disorders—one emphasizing *behavior*, and the other emphasizing *neurology* (see Table 10.1). Functional

*Table 10.1* Examples of behavioral and neurological diagnoses in neurodevelopmental disorders

##### *Multifactorial cause*

Spina bifida  
 Cerebral palsy  
 Prematurity

---

independence, as well as disability in children with neurodevelopmental disorders, should be considered through these frameworks. In general terms, a *disability* involves personal limitations that produce a disadvantage when attempting to function in one's society. The disability is necessarily considered within the context of the environment, personal factors, and individualized supports (Wehmeyer et al., 2008). Function is thus understood as the interaction between one's own biology and the environmental demands/supports. Disability occurs when there is a discrepancy between biological attributes and environmental demands. Given the ever-changing environment experienced by the child, the discrepancy (and thus the functional disability) can change over time.

### **Behaviorally Defined Neurodevelopmental Disorders in DSM-5**

Four of the *behaviorally* defined neurodevelopmental disorders outlined in the *Diagnostic and Statistical Manual for Mental Disorders*, fifth edition (DSM-5; American Psychiatric Association, 2013) that are most commonly encountered by neuropsychologists are described next. These include intellectual developmental disorder, specific learning disorders, attention deficit/hyperactivity disorder, and autism spectrum disorder.

#### ***Intellectual Disability (Intellectual Developmental Disorder)***

The prevalence of intellectual disability is estimated to be 1% of the population (Maulik, Mascarenhas, Mathers, Dua, & Saxena, 2011) with approximately 3 million people diagnosed with intellectual disability in the United States (Larson et al., 2011). Multiple etiologies occurring during various sensitive periods of development have been associated with intellectual disability, including a variety of genetic conditions, teratogen exposures, prenatal/perinatal traumatic events, and postnatal injuries and infections.

Although the name of the condition was changed from *mental retardation* to *intellectual disability* (coupled with the term *intellectual developmental disorder*) in the DSM-5, the general diagnostic criteria for intellectual disability that were previously contained in the DSM-IV-TR (American Psychiatric Association, 2000) were retained, including the requirement for deficits in both adaptive functioning and intellectual functioning (American Psychiatric Association, 2013). Intellectual deficits are defined as impairment in "general mental abilities such as reasoning, problem solving, planning, abstract thinking, judgment, academic learning, and learning from experience," with a guideline of an IQ score of  $\leq 70$  ( $\pm 5$  standard score points for error; American Psychiatric Association, 2013, p. 37). Adaptive deficits in at least one broad domain (i.e., conceptual, social, or practical) are determined by "both clinic evaluation and individualized, culturally appropriate, psychometrically sound

measures" (American Psychiatric Association, 2013, p. 37), and the DSM-5 provides a descriptive table to help determine the severity of adaptive impairment. In the DSM-5, deficits in adaptive functioning have become central in the determination of intellectual disability severity (compared to the DSM-IV-TR practice of setting intellectual disability severity based upon IQ score), as extent of adaptive dysfunction is considered more relevant than IQ score for the determination of level of support required. The quantification of adaptive deficits remains an area of ongoing discussion in the field of assessment, with criticism over current practices of assessing adaptive "skills" (e.g., activities of daily living) rather than "real-world" problem solving, gullibility, and vulnerability to exploitation (Greenspan, 2006).

The diagnostic formulation of intellectual disability is contingent upon a causal relationship between the intellectual and adaptive deficits, in that "the deficits in adaptive functioning must be directly related to the intellectual impairments described" (American Psychiatric Association, 2013, p. 37). This is an important clinical consideration of diagnosis, as adaptive dysfunction is commonly reported in individuals with a variety of developmental disorders, and may be attributable to physical limitations or cognitive variables other than intelligence (e.g., executive functioning; Culhane-Shelburne, Chapieski, Hiscock, & Glaze, 2002; Papazoglou, Jacobson, & Zabel, 2013).

#### ***Learning Disorders***

Learning disorders are neurodevelopmental disorders that affect the brain's ability to receive, process, store, and respond to information (Mahone & Mapou, 2013). Learning disorders typically have onset in early childhood, persist into adulthood, and are associated with academic underachievement problems that are otherwise unexpected, presumably related to underlying cognitive impairment. In this context, poor academic achievement is considered "unexpected" when it is not associated with low intelligence, sensory impairments, emotional disturbances, or limited opportunities to learn. Like most neurodevelopmental disorders, developmental learning disorders occur along a continuum, with significant variability in severity and characteristic features.

The diagnostic criteria in the American Psychiatric Association's DSM-5 for specific learning disorder reflect a hybrid model, in which diagnosis is made using synthesis of the individual's history (development, medical, family, education), psychoeducational reports of test scores and observations, and response to intervention. With learning disorders, there is a recognition that individuals may "grow into" their deficits (i.e., time-referenced symptoms), thus the full range of problems may not be fully manifest until a later age.

#### ***Attention Deficit/Hyperactivity Disorder***

Attention deficit/hyperactivity disorder (ADHD) is the second most common behaviorally defined neurodevelopmental

disorder (behind learning disorders). Affecting as many as 9%–11% of school age children, the onset of behaviors occurs most often in the preschool years and can persist into adulthood (Akinbami, Liu, Pastor, & Reuben, 2011). The primary symptom complex (inattention, hyperactivity, impulsivity) emerges and changes over time, and is associated with a wide range of comorbid behavioral conditions (Larson et al., 2011). Despite often having “normal” intelligence, children with ADHD manifest considerable functional difficulties, including higher rates of learning problems, missed school, troublesome relationships, and mental and physical conditions that result in 33% reduced earning as adults (Fletcher, 2013).

The DSM-5 retained most of the diagnostic criteria for ADHD that were previously contained in the DSM-IV-TR (American Psychiatric Association, 2000). Several important changes were introduced and may ultimately lead to an increase in the rates of diagnosis. First, the DSM-5 age of onset criterion was changed to require that symptoms are present prior to age 12, compared to the DSM-IV criterion of before age 7. Second, in DSM-5, the symptoms of inattention and/or hyperactivity-impulsivity are only required to be present, whereas in DSM-IV, the symptoms were required to cause impairment. Third, unlike the DSM-IV, the DSM-5 includes a provision for adult diagnosis (ages 17 and older), for which the symptom criterion is met with five (rather than six) symptoms of inattention and/or hyperactivity-impulsivity.

As a group, children with ADHD demonstrate widespread reductions in cortical volume, as well as disruption to the development of subcortical structures, including basal ganglia and cerebellum (Mahone et al., 2011). Moreover, recent research has suggested that these ADHD-related anomalies can be detected in preschool children as young as age 4 years (Mahone et al., 2011). Nevertheless, at the individual level, MRI scans of children with ADHD are routinely read as normal, without individually identifiable lesions. The scan of a 4-year old boy with ADHD, which was read as entirely normal, is shown in Figure 10.1.

### Autism Spectrum Disorder

Autism spectrum disorder also represents a behaviorally defined phenotype. The Centers for Disease Control and

Figure 10.1 MRI scan of a 4-year old boy with ADHD

Prevention estimates that in the United States, one in 68 8-year-old children have been diagnosed with autism spectrum disorder (Centers for Disease Control and Prevention, 2014). According to the DSM-5, autism spectrum disorder represents a continuum of impairment from mild to severe and includes all four diagnoses that were previously separated in the DSM-IV, including autism, Asperger’s disorder, childhood disintegrative disorder, and pervasive developmental disorder—not otherwise specified. Autism spectrum disorder is characterized by a selective impairment in social interaction as well as restricted and repetitive patterns of behavior (American Psychiatric Association, 2013). Within the DSM-5, difficulties with language and communication were deemphasized as a core feature of autism spectrum disorder because communication ability can vary greatly in individuals with autism spectrum disorder. While the risk factors are heterogeneous and complex (Willsey & State, 2015), over the last two decades several diagnosable genetic conditions commonly seen by neuropsychologists have been associated with this autism spectrum disorder, including Fragile X (Budimirovic & Kaufmann, 2011), tuberous sclerosis (Muzykewic, Newberry, Danforth, Halpern, E. F., & Thiele, 2007), and 22q13.3 deletion (Cusmano-Ozog, Manning, & Hoyme, 2007).

### Neurodevelopmental Disorders Associated With Neurological Conditions

The *neurological* approach to classification of neurodevelopmental disorders provides for an understanding of the neurological development as well as the associated physical abnormalities. Children with neurological diagnoses can display many of the behaviorally defined disorders outlined in DSM-5. The behavioral diagnosis, however, provides little insight into the etiology of the condition, and the DSM framework is often agnostic with regard to etiology. More likely, children with known medical or neurological conditions manifest symptoms of several behaviorally defined conditions, including ADHD, intellectual disability, learning disorders, communication disorders, motor disorders, and/or autism spectrum disorder. This observation highlights the limitations of relying only on the behavioral definitions outlined in DSM-5 when working with children with neurodevelopmental disorders.

Professionally, neuropsychologists work within these two schema in two ways. They search for neurological correlates of behaviorally defined conditions (ADHD, dyslexia, autism). At the same time, they search for behavioral phenotypes of genetic or neurologically defined disorders (e.g., Williams syndrome, Neurofibromatosis Type 1, Down syndrome). In clinical care, understanding the evidence-based research is needed when interpreting data, formulating clinical impressions, and providing recommendations.

## Common Neurodevelopmental and Genetic Disorders

### Down Syndrome

Down syndrome, also called *trisomy 21*, is a chromosomal disorder that typically results in an extra chromosome 21 (i.e., instead of 23 pairs of chromosomes, children are born with 22 pairs and one set of three chromosomes). Down syndrome is the most common known *genetic* cause of intellectual disability. It occurs in one out of every 732 live-births in the United States with advanced maternal age as the most significant risk factor (Sherman, Allen, Bean, & Freeman, 2007). Down syndrome has a high prevalence of many medical conditions including cardiac, neurological, gastrointestinal, immunological, respiratory, sensory, and orthopedic abnormalities, although medical advances have resulted in increased longevity (Bittles, Bower, Hussain, & Glasson, 2006).

Cognitive deficits are also prominent among individuals with Down syndrome. While cognitive assessment can be challenging due to associated difficulties with communication, vision, and hearing, Down syndrome is commonly associated with intellectual disability, ranging from mild to profound intellectual disability (Lott & Dierssen, 2010). Additionally, while the pattern of impairment is variable, the behavioral phenotype of Down syndrome is usually associated with impairments in verbal short-term memory and long-term memory, with relative strengths in visuospatial short-term memory, associative learning, and implicit long-term memory functions (Lott & Dierssen, 2010). A variety of age-related changes occur earlier in individuals with Down syndrome (Bittles et al., 2006). Several physical, neurological, and psychiatric conditions develop early in individual with Down syndrome (Trotter Ross & Olsen, 2014). With age, individuals with Down syndrome often develop neuropathology and declines in memory, language, and cognitive functioning consistent with dementia of the Alzheimer's type (Zigman, 2013).

### Fragile X Syndrome

Fragile X syndrome is the most common known *inherited genetic* cause of intellectual disability. Fragile X is a genetic condition resulting from mutations to the Fragile X mental retardation 1 (FMR1) gene on the X chromosome. The full mutation of the gene, defined as having > 200 CGG repeats, occurs in 1 in 4,000–7,000; however, permutation carriers are more common, and are estimated to include one in 130–250 females and one in 250–810 males ((Lozano, Rosero, & Hagerman, 2014). Given the significant overlap between the mutation and permutations, the term *Fragile X spectrum disorder* has been proposed to include the range of FMR1 mutations (Lozano et al., 2014).

Since the full mutation of FMR1 leads to absence or severe deficiency of FMR1 protein, a critical protein for synaptic

plasticity, the lack of protein often leads to intellectual disability in males with Fragile X. In females with the full mutation, due to their other normal X chromosome, some FMR1 protein is produced, which results in IQ scores ranging from intellectual disability to normal. Deficits in executive functions, including response inhibition and working memory as well as visuospatial processing and visuomotor skills, are also associated with Fragile X (Fung, Quintin, Haas, & Reiss, 2012). Additionally, Fragile X is the most common known cause of autism spectrum disorder and accounts for 5% of cases (Budimirovic & Kaufmann, 2011). Premutations in both males and females are also associated with developmental problems including learning disabilities, autism spectrum disorder, ADHD, and prominent anxiety, although these difficulties are more pronounced in males (Lozano et al., 2014).

### Cerebral Palsy

Cerebral palsy affects approximately two in 1,000 children, and is the most common motor disorder of early childhood (Menkes & Sarnat, 2000). While most commonly diagnosed in the early developmental period (i.e., by age 3 years), in less-severe cases, it can also be diagnosed later in the childhood years. Cerebral palsy refers to a group of motor impairment syndromes in which a static and nonprogressive cerebral lesion produces abnormal motor control—resulting in problems with muscle tone, strength, and fluidity of movement—as well as a variety of cognitive and behavioral deficits (Johnston & Hoon, 2006). The term *cerebral palsy* describes a syndrome, not an etiology, and diagnosis is made based upon a pattern of motor symptoms.

There are numerous genetic and acquired etiologies of cerebral palsy, including prematurity, neonatal encephalopathy, and various postnatal insults (Fennell & Dikel, 2001; Korzeniewski, Birbeck, DeLano, Potchen, & Paneth., 2008). The concept of selective vulnerability (Johnston, 2004) is particularly important when considering etiology, as the varieties of etiology in cerebral palsy are associated with susceptibility to injury of specific cells and brain regions at different sensitive periods of prenatal and neonatal development. Disruptions of neuron migration during the first trimester can result in brain malformations (i.e., lissencephaly, heterotopia, schizencephaly, etc.; Barkovich, Kuzniecky, Jackson, Guerrini, & Dobyns, 2001) and subsequent cerebral palsy. During the late second and early third trimesters of pregnancy, immature oligodendroglia are particularly vulnerable to injury secondary to hypoxia-ischemia or infection, which can in turn lead to another etiology of cerebral palsy, i.e., periventricular white matter injury (Johnston, Hoon, & Kaufmann, 2008). Finally, developing neuronal circuits are sensitive to injury in the weeks leading up to and following a term pregnancy, and are vulnerable to various disruptions that underline cerebral palsy, such as perinatal stroke (Johnston & Hoon, 2006). Given the different mechanisms of injury presenting at different sensitive periods of development, it is not surprising that

the concept of cerebral palsy includes a broad range of phenotypic and neurologic presentations, with broad divisions (i.e., spastic vs. extrapyramidal), topographical distinctions (e.g., limb involvement), and specific motor subtypes (e.g., dystonia, dyskinesia, ataxia, hypotonia, etc.).

The diversity of etiologies of cerebral palsy has slowed the development of a cognitive phenotype. In general, severity of motor impairment is associated with intellectual functioning in individuals with cerebral palsy, and co-occurring seizure disorder increases the likelihood of intellectual disability (Fennell & Dikel, 2001). A variety of other neuropsychological findings have been reported, including nonverbal reasoning deficits (Pirila et al., 2004; Sigurdardottir et al., 2008), attention problems (Christ, White, Brunstrom, & Abrams, 2003), and visuospatial/visuoperceptual deficits (Kozeis et al., 2007). Of note, significant motor impairments (e.g., fine motor, oromotor, etc.) associated with cerebral palsy can complicate neuropsychological assessment. To help manage these threats to validity, a combination of targeted assessment with accommodations, process observations, and informal assessment techniques are suggested for the neuropsychological assessment of individuals with cerebral palsy (Zabel & Schmidt, 2011).

### Prematurity

*Prematurity* is a broad term used for neonates born less than 37 weeks gestation. Due to advances in obstetric and neonatal care, there has been decreased mortality rates as well as increased age of viability among preterm infants since the 1970s. With these advances, there has been increased morbidity among preterm children, especially at the lower limits of viability (Allen, 2008). The literature in the area is complicated by the multitude of terms used to describe premature gestational age and low birth weight as well as the decreasing threshold of viability. At this time, the American College of Obstetricians and Gynecologists uses the term “threshold of viability” for preterm newborns born less than 25 weeks gestation or who weigh less than 1,000 grams, although extremely low birth weight has been commonly used to describe children less than 1,000 grams (American College of Obstetricians and Gynecologists, 2002, reaffirmed 2010).

Children with higher gestational age and more recent year of birth have lower rates of neurodevelopmental impairment; however, outcome studies with adolescents and young adults are needed to better understand the long-term outcome of extremely preterm birth (Vohr, 2014). Extremely preterm and extremely low birth weight children are at greatest risk for severe neurodevelopmental disabilities. At the threshold of viability, children have a high rate of cerebral palsy, intellectual disability, blindness, and sensorimotor hearing loss (Jarjour, 2014). In school-aged children and adolescents who were born very preterm (<32 weeks of gestation), neuropsychological deficits have been identified in many areas, including processing speed, attention, visuoperceptual and

Figure 10.2 MRI scan of former preterm infant (courtesy of Thangamadhan Bosemani, Andrea Poretti, and Thierry A.G.M. Huisman)

motor skills, memory, executive functioning, and language (Anderson, 2014). Importantly, until recently late preterm births (34–36 weeks gestation) were thought to be associated with low risk for neuropsychological impairment; however, recent research suggests that while these children function better than very preterm children, they display significantly more subtle neuropsychological deficits relative to full term children (Baron, Litman, Ahronovich, & Baker, 2012). Figure 10.2 shows the MRI of a 2-year-old former preterm infant with a history of posthemorrhagic hydrocephalus. Axial T2-weighted images of the brain (A and B) show loss of white matter volume predominantly in the bilateral parietal and occipital lobes (arrows) with moderate dilatation of the lateral ventricles and third ventricle, consistent with periventricular leukomalacia.

### Spina Bifida

Spina bifida is the second most common birth defect after cerebral palsy, and had an overall prevalence of 3.39 cases per 10,000 live births in 2003–2004 (Boulet et al., 2008). This represents a decline in cases relative to the prevalence of spina bifida prior to 1998, at which time the U.S. Food and Drug Administration began requiring folic acid fortification of cereal grain products (Centers for Disease Control and Prevention, 2004). Folate deficiency has been established as a risk factor for spina bifida, as have maternal factors such as diabetes mellitus, obesity, exposure to high heat during pregnancy, and certain anti-convulsant medications. A gene-environment interaction is suspected as a cause, but has not yet been specifically identified.

Spina bifida is a neural tube defect occurring in the sensitive period of the third and fourth weeks of pregnancy. It is caused by an incomplete closure of the spinal canal, and can include protrusion of the meninges (meningocele) or spinal cord (myelomeningocele) outside of the spinal column. While

typically corrected surgically shortly after birth, emerging evidence suggests that prenatal surgical repair of spina bifida results in improved neurologic functioning (Adzick et al., 2011). Associated neurological complications frequently include Chiari II malformation (Treble-Barna, Kulesz, Dennis, & Fletcher, 2014), partial agenesis of the corpus callosum (Hannay, Kramer, Blaser, & Fletcher, 2009), increased (abnormal) cortical thickness of the frontal lobes (Juranek et al., 2008), and neurogenic bowel and bladder (Charney, 1992). Obstructive hydrocephalus is also a commonly associated condition with spina bifida, and shunt placement has been the conventional treatment for hydrocephalus since the 1960s. Approximately 50% of shunts in children fail within the first two years of placement, and alternative treatment approaches are being explored, including a “wait and see” monitoring of infants with hydrocephalus as well as consideration of minimally invasive procedures such as endoscopic third ventriculostomy (Warf & Campbell, 2008).

Intellectual functioning of individuals with spina bifida is typically grossly intact. Neuropsychological functioning was originally described within a nonverbal learning disability model, but has more recently been conceptualized within the “cognitive phenotype of spina bifida” model (Dennis & Barnes, 2010). This model proposes core deficits in motor, timing, and attentional processes. Within this context, persons with spina bifida frequently have strengths in associative processing (e.g., in the case of language, associating words with word meanings) and weaknesses in assembled processing (e.g., constructing text understanding). Time-referenced symptom presentation is noteworthy, as youngsters with spina bifida frequently experience functional academic issues when the demands for assembled processing increase (i.e., in fourth grade). Learning disability in math is particularly problematic for individuals with spina bifida, extended well into young adulthood (Hetherington, Dennis, Barnes, Drake, & Gentili, 2006). Executive dysfunction is also commonly reported by parents and teachers (Tarazi, Zabel, & Mahone, 2008; Zabel et al., 2011).

### *Fetal Alcohol Syndrome*

While genetic factors may be responsible for many neurodevelopmental conditions, other common neurodevelopmental conditions may be due to external factors, such as fetal exposure to neurotoxins. Fetal alcohol syndrome (FAS) is the most common and significant condition resulting from exposure to an external agent. *Fetal alcohol spectrum disorder* is an umbrella term used to describe the entire continuum of clinical deficits related to prenatal alcohol exposure. In addition to a likely history of prenatal alcohol exposure, at the one end of the continuum, fetal alcohol spectrum disorder is characterized by a specific pattern of minor facial dysmorphic features (flattened philtrum, thin upper lip, short palpebral fissures), growth deficiency at any point in the child’s life (height and weight <10th percentile), and structural and/

or functional central nervous system features (microcephaly, intellectual disability, psychiatric conditions; Hoyme et al., 2005), although specific diagnostic criteria are still debated (Dorrie, Focker, Freunsch, & Hebebrand, 2014). Additionally, this narrow set of criteria is most commonly used to identify children with FAS. Children with other types of fetal alcohol spectrum disorder—including those with partial fetal alcohol syndrome, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects—do not exhibit all criteria. Prevalence estimates vary, but when all disorders falling under the umbrella of fetal alcohol spectrum disorder are included in population-based studies, prevalence rates may be as high as 2%–5% in elementary school-aged children (May et al., 2009). While not included in the DSM-IV, the DSM-5 mentions fetal alcohol spectrum disorder as an example of a condition that may be used for the code Other Specified Neurodevelopmental Disorder. In addition, “Neurobehavioral Disorder associated with Prenatal Alcohol Exposure” has been included in the conditions for further study section (American Psychiatric Association, 2013).

Fetal alcohol spectrum disorder has been associated with a range of neurobehavioral abnormalities. While intellectual functioning ranges from intellectual disability to high average functioning, many individuals with fetal alcohol spectrum disorder have significant deficits with attention, executive functioning, and adaptive skill development (Dorrie et al., 2014). Population based studies of school-aged children, however, suggest that many children with fetal alcohol spectrum disorder do not display significant neurobehavioral deficits (May et al., 2009).

### *22q11.2 Deletion Syndrome*

22q11.2 deletion is in most cases a sporadic, de novo mutation occurring in parental sperm or ovum, with an estimated minimal prevalence of one in 4,417 to one in 8,224 births (Botto et al., 2003). Originally named after constellations of symptoms (i.e., velocardiofacial syndrome) and/or the researchers who first described them (Kirkpatrick & DiGeorge, 1968; Shprintzen et al., 1978), the syndrome was eventually linked to a microdeletion in the long arm of chromosome 22 in the 1990s (Carey et al., 1992; Driscoll, Budarf, & Emanuel, 1992) and was later unified under the term *22q11.2 deletion syndrome*. For diagnosis, identification of small interstitial 22q11.2 deletions is verified by fluorescence in situ hybridization (FISH). The physical phenotype is highly heterogeneous, with various combinations of “midline abnormalities” arising from impaired migration of neural crest cells, including cardiac abnormalities (e.g., interrupted aortic arch, Tetralogy of Fallot, ventricular septal defect, persistent truncus arteriosus), abnormal facies (e.g., small cup-shaped ears, narrow eye opening, long narrow face/flat cheeks), and palatal insufficiency (Gothelf, 2007).

Within the context of presentation heterogeneity, the possibility of a cognitive/neuropsychological phenotype

has been explored. Moss and colleagues identified relative and significant deficits in areas such as nonverbal reasoning, attention, visual memory, and arithmetic performance (Wang, Woodin, Kreps-Falk, & Moss, 2000; Woodin et al., 2001). ADHD is the most common behavioral diagnosis made in individuals with 22q11.2 deletion syndrome (35% to 46%; Arnold, Siegel-Bartelt, Cytrynbaum, Teshima, & Schachar, 2001; Feinstein, Eliez, Blasey, & Reiss, 2002), but anxiety and mood disorders are also commonly identified during childhood (Baker & Skuse, 2005). Perhaps of most concern, however, is a prolonged and gradual evolution of subthreshold psychotic and neuropsychiatric features occurring in approximately one-third of individuals with 22q11.2 syndrome (Gothelf, 2007). The combination of psychiatric concerns and cognitive deficits is particularly problematic for the transition of youth with 22q11.2 into adulthood, as many of these symptoms manifest during adolescence and contribute to a decline in adaptive functioning and autonomy.

### **Framework for Conceptualization of Neurodevelopmental Disorders**

The primary role for the neuropsychologist when working with children with genetic and/or neurodevelopmental disorders is to help better understand the current fit between the child's unique biology and the ever-changing demands (and supports) in the environment. Developmental neuropsychologists focus not only on understanding the child's current needs, but also—and just as importantly—on helping to predict and plan for future needs.

A *family practice* model of developmental neuropsychology is most effective when working with children with neurodevelopmental disorders and their families. In this model, the neuropsychologist frequently works with the child and family over multiple years—often from preschool through young adulthood. Assessments are completed within a framework of changing developmental needs and supports. The goal of the neuropsychologist is not to simply provide diagnosis and recommendations on a one-time basis, but rather to assess the developing child–environment interaction in developmental context, not only uncovering current needs, but also helping the family plan for changing needs throughout the child's lifetime. Psychological care is often comprehensive and continuing, and emphasizes the critical role of the child's family, schools, friends, and leisure activities. Importantly, the goal of neuropsychological interventions with children with neurodevelopmental disorders is prevention, reduction, and amelioration of disability, and promotion of healthy and adaptive neuropsychological functioning throughout childhood and into adulthood. Multiple types of assessments are used over the lifetime within this model, and are described in the next section. In this family practice model, the neuropsychologist is an active treating provider for the child, rather than simply a consultant, and commonly works collaboratively with the child's school to provide translation of

how medical and neurological dysfunction affects behavior and learning in the classroom.

### **Assessment of Neurodevelopmental Disorders**

Our approach to assessment draws information from three primary sources—history, observations, and formal testing (Bernstein & Waber, 1990)—but takes into account the unique life circumstances and the chronicity of illness seen in children with neurodevelopmental disorders. Additionally, neuropsychologists are now called upon to draw information from a fourth source—the relevant research literature—in order to increase the evidence-based validity to their conclusions, and to apply assessment principles in light of research findings applicable to their patient's unique characteristics.

In applying these methods, review of the child's neurologic history is crucial to determine whether the “lesion” is *static* or *unstable*. The neuropsychologist also needs to consider current testing needs or adaptations, based on known deficits in communication skills and stamina, as well as motor or sensory needs. It is also critical to carefully review prior assessments, not only from psychologists, but also from other service providers (occupational therapists, speech/language pathologists, physical therapists, teachers). The *interdisciplinary model* is frequently used in hospitals or large centers working with children with neurodevelopmental disorders. In this model, the neuropsychologist's role may be more circumscribed and can defer to other members for focused assessment of other domains (e.g., language, motor skills).

Before assessing a child with a genetic or neurodevelopmental disorder, it is critical to determine what type of neuropsychological assessment is most appropriate. There are at least four common types of neuropsychological assessments used in children with neurodevelopmental disorders, and the clinician's approach should be different for each:

- 1 *Baseline assessment*, which is typically completed early in a child's life, is necessarily broad-based and comprehensive. Baseline evaluations have the purpose of setting the stage for planned, future follow-up, and are most effective when initially completed in the preschool years. Often, baseline assessments can help medical teams by mapping out the phenotype in order to assist with genetic diagnosis. As part of the baseline assessment, the neuropsychologist works with the family to understand and predict future life transitions and stress points for the child, based on the biological risk and early identified needs, with the goal of preparing the family for the changing (and often increasing) challenges the child faces as he or she “grows into” additional deficits.
- 2 *Planned follow-up assessments* may be broad-based or focused, and allow the clinician to compare both raw score data (to assess for loss or development of skills) as well as standard score data (to assess rate

of progress relative to peers). Among young children with neurodevelopmental disorders, planned follow-up assessments are most effective when implemented just before known transition points in the child's life (Mahone & Slomine, 2008)—for example, just before the child enters first grade, fourth grade, middle school, and high school.

- 3 *Neuropsychological screening* is used to determine if there is a need for a more comprehensive neuropsychological assessment (i.e., either a baseline or follow-up assessment). By definition, a screening should rapidly (e.g., 15–20 minutes) assess several neurobehavioral domains in order to answer the questions: “Is this skill generally intact? Are the child's needs being met in the current setting? Is more diagnostic information needed?” In certain contexts, this screening can take the form of a brief, focused “check in,” which is not as comprehensive as a planned follow-up, but more extensive than the screening done in busy clinic settings. These check-in sessions are often completed between regular full assessments. The information collected in a brief check-in can be used to tailor recommendations in the moment. One recommendation may be to return for a full evaluation, but other recommendations may be related to more subtle changes in the child's treatment plan.
- 4 *Problem-focused assessment* typically involves focused follow-up to assess decline or improvement in a specific problem area following some treatment (e.g., reassessing attention skills following introduction of stimulant medication; reassessment of memory following an introduction or change in anticonvulsant medication). This type of assessment is also crucial to assess for pre-post treatment change among children who require surgery. For example, children with congenital hydrocephalus who require shunt revision may have planned neuropsychological assessment pre- and post-surgery to document change.

#### ***Developmental Neuropsychological Formulation for Neurodevelopmental Disorders***

When working with children with genetic and/or neurodevelopmental disorders, the neuropsychologist is challenged to consider results in the context of child's condition, life situation, and current interventions. Often brain imaging or mapping has not been completed, and the clinician is required to make interpretations based on the clinical presentation. Developmental formulation is based on the timing of follow-up, relative to the onset of the brain anomaly. In formulating the developmental neuropsychological diagnosis, the child's full history should be clearly reviewed, with reference to the known or expected sequelae of the particular type of disorder. Assessment (considering history, observations,

and testing) is synthesized in light of the available research. Optimally, the neuropsychologist is able to tell the family what the literature says about difficulties and outcomes with their child's disorder, and how what is known (generally) fits with their particular child's own neuropsychological profile.

Neuropsychological evaluation of individuals with genetic and developmental conditions should take into consideration the extent of typical and atypical demands placed upon the individual. Tarazi, Mahone, and Zabel (2007) describe a model that differentiates typical and atypical adaptive demands placed upon individuals with developmental and medical conditions, and the extent to which atypical demands may increase the burden of executive functioning. Most typically developing individuals are faced with the challenge of meeting typical adaptive demands over their developmental course. Individuals with developmental and genetic conditions are faced with these same challenges, but are often presented with additional atypical self-care requirements associated with their conditions. For example, an individual with spina bifida is expected to master typical adaptive skills such as personal hygiene, housekeeping, food preparation, etc., but may also be presented with atypical adaptive demands such as clean intermittent self-catheterization, bowel management programs, skin inspection, and other self-management requirements. These atypical self-management requirements may increase the demands placed upon the individual's prospective memory, initiation, organization, planning, and other executive functions. Tarazi et al. (2007) contend that the context of these atypical adaptive requirements may make the individual appear “more dysexecutive,” and/or legitimately increase the need for executive functioning accommodations/supports. In this model, it is those individuals with both atypical adaptive skill requirements *and* impaired executive functioning who are considered the most vulnerable, and require the greatest degree of intervention/accommodation.

#### ***Challenges to Conceptualization and Service Provision for Children With Neurodevelopmental Disorders***

There are a variety of challenges to understanding brain-behavior relationships in children with genetic and/or neurodevelopmental disorders. For example, many theories employed in child neuropsychology were developed on adults. Children, in contrast, have developing brains, which represent moving targets when attempting to understand function in relation to an early neurological insult. In children, these early insults change the child's course of learning and behavior, and disrupt the availability of brain systems to perform the developmental tasks intended. The result can be a disability in which the child's own neurology leads to interfering behaviors, which ultimately impede new learning opportunities, which serve to further impact the child's

overall functional outcomes. In other words, children have a wide range of variability with respect to timetables of development. Children with neurological compromise are more vulnerable to problems with regulation of behavior, attention, and stamina—affecting integrity of test data (Mahone & Zabel, 2001).

### *Terminology*

Some of the challenge to conceptualization involves clarity in *terminology*. For example, the term *delay* is often confusing to families. Use of the term *delay* simply implies that the child has slower than expected development in one or more domains of learning or behavior. When hearing this term, parents often assume that their child will catch up to peers following a period of intervention, remediation, or extra practice. In some situations (especially when opportunities to learn skills have been limited) this expectation may be realistic. In other cases, however (as in a child with intellectual disability), the use of the term *developmental delay* interchangeably with the more specific diagnosis can be misleading.

The term *deficit* can also be troublesome to families because it is not time-referenced (Mahone, 2007). In this context, the term *deficit* simply suggests absence of a behavior or skill; however, it is also used to indicate significantly impaired performance. Without clear reference to expected levels of functioning for a child's age, the term *deficit* can also be misleading. For example, a behavioral or cognitive deficit (i.e., absence of a skill) at one age may be abnormal, whereas while at another age it may represent age-appropriate functioning.

In children with neurodevelopmental disabilities, parents and clinicians often express concerns regarding behavioral or cognitive *regression*. The challenge for the neuropsychologist in these instances is to determine (often with objective performance-based tests) whether there is a true loss of skill in an absolute sense, or (as is more commonly the case), decline in *relative standing* to peers. Using objective, performance-based assessment, the psychologist can often clarify the nature of the regression by comparing a child's raw score performance on one or more standardized tests to his or her raw score performance on the same tests at a later point in time. True regression occurs when a child manifests an actual loss of skill from one time to the next. Conversely, *failure to keep pace* in skill acquisition may be present in children with neurodevelopmental disabilities when the environmental demands increase at a faster rate than skill development, and the child's rate of improvement is more protracted than that of peers (resulting in decreases in standard scores over time).

### *High-Stakes Educational Testing*

An additional challenge to service provision comes in the form of the politics of high-stakes testing. Developmental

neuropsychologists often assess children who have been simultaneously assessed within the school system. This scenario leads to three specific areas of difficulty. First, the focus of assessments within schools is to determine whether the child meets criteria for one or more of the 14 federally defined educational disabilities, and if so, what functional needs are present that would need to be addressed within an individual education plan (IEP). Unfortunately, the 14 federal educational disability definitions do not map directly onto the DSM-5 behavioral criteria. The result is that the school assessment is focused on the educational requirements of the school district. In contrast, the neuropsychologist functioning outside a school is more interested in identifying all potential areas of dysfunction, and recommending evidence-based interventions that can ameliorate the functional deficits. While the goals of the school and the neuropsychologist are often in harmony, at times (often as a result of limited resources), school systems feel pressure to provide only “appropriate” interventions, while outside neuropsychologists seek to implement “optimal” levels of service.

Second, the fact that most children with neurodevelopmental disorders receive some type of psychological assessment within the school system leads third-party insurers to be more reluctant to pay for assessment of diagnostic conditions that are considered “educational.” Examples of the diagnostic categories typically rejected by third-party payers include autism spectrum disorders, communication disorders, learning disorders, intellectual disabilities, and (increasingly) ADHD. Given that these conditions are present in the vast majority of children with neurodevelopmental disorders, it becomes a challenge to the neuropsychologist working outside the school setting to receive third-party payment for neuropsychological assessment services, unless the child otherwise has a qualifying medical condition that can serve as the primary billing diagnosis.

Third, given the increasingly limited resources within educational systems, frontline school psychologists are often instructed by their administrators not to make certain diagnoses (e.g., intellectual disability), despite having the training, expertise, and evidence to do so. At the same time, neuropsychologists find themselves having to provide diagnostic formulations for these types of conditions later in life, when the evidence within the school records indicates that the diagnosis could have been made earlier.

### *Multiple Assessments*

Because children with neurodevelopmental disabilities often require multiple neuropsychological assessments it is imperative to understand the challenges involved in interpreting repeat assessments. There are several ways in which to compare age-corrected standard scores across multiple assessments, including regression-based approaches and reliable change indices (RCI) (Duff, 2012; Heilbronner et al., 2010).

These types of statistical procedures account for the reliability of the test measures used, and are helpful in determining if a statistically rare change in a test score has occurred. If a statistically rare decline in a score has occurred, additional raw score analysis is necessary. Because standardized scores are typically corrected for age, a child with a declining standardized score over time may appear as if he or she is losing skills when he or she is actually gaining skills, but not acquiring skills at the same rate as same-aged peers. In these situations, it is helpful to examine changes in raw scores as a way to assess ongoing development or identify a true decline in skills. Making these raw comparisons, however, is possible only if the same exact measure is used on each occasion.

### *Flynn Effect*

While using the same measure on multiple occasions can be helpful in the individual level, when comparing the individual to him- or herself, it may be problematic when comparing the child to same-aged peers. Flynn and others have documented an upward drift in normative performances on intelligence tests (Carlton & Sapp, 1997; Flynn, 1984, 1985, 1987; Truscott & Frank, 2001). Known as the *Flynn effect*, these score increases in the United States amount to approximately three IQ points per decade. Correspondingly, as time passes, normative samples used to develop new measures of intelligence can represent a higher-functioning group than their cohorts who acted as the normative sample for previous versions of the same test. As a result, when an IQ test is renormed, which occurs every 15–20 years, the mean is reset to 100, and children may have to become “smarter” or otherwise show improvement in performance in order to maintain a constant performance level (Kanaya, Scullin, & Ceci, 2003).

### *Practice Effects*

In addition to thinking about comparing raw score changes using the same test, and considering the Flynn effect in interpretation, it is important to consider practice effects. While practice effects are typically considered when testing occurs close in time (a few months apart), repeat assessment for longer intervals can result in practice effects especially if the same test is given several times. Unfortunately, there is little literature to guide our interpretation in these situations.

### **Conclusions**

Neuropsychologists who practice in a developmental and/or life span context will undoubtedly encounter individuals with neurodevelopmental and/or genetic conditions. These individuals represent a diverse population, requiring an understanding of both neuropsychological principles and child development. The neuropsychologist should be fluent in both the behavioral and neurological approaches to classification, and should be prepared to work alongside

colleagues in the school system. It is, in fact, necessary for the neuropsychologist to access school observations, records, and assessments when considering the “history” of a child with a neurodevelopmental condition. The DSM-5 even references this requirement in the revised diagnostic criteria for ADHD, by noting, “confirmation of substantial symptoms across settings typically cannot be done accurately without consulting informants who have seen the individual in those settings” (American Psychiatric Association, 2013: 61). Given these considerations, ecologically valid neuropsychological assessment of children with neurodevelopmental disorders is necessarily a collaborative effort between the referred patient, parents, schools, and (often) multiple treating clinicians.

The developmental course of genetic and neurodevelopmental disorders is often chronic, necessitating a “family practice” approach to neuropsychological assessment and consultation, in which the clinician provides care in different contexts and in different formats throughout the life of the individual with the condition. This approach requires flexibility in assessment methodology and a willingness to understand diagnostic formulations as dynamic, rather than static, regardless of the level of stability of the neurological condition itself. In this context, it is essential for the clinician to recognize how changing environmental demands interact with the individual’s neurobiology, and how these interactions may change over the child’s lifetime.

Despite the complex and often diffuse nature of the neurological conditions in children with neurodevelopmental and genetic disorders, thoughtful neuropsychological assessment can be extremely helpful in elucidating strengths and weaknesses and planning appropriate interventions, especially considering the many challenging life transitions. When considering these transitions, clinicians working with children with neurodevelopmental disorders and their families are challenged to understand the unique way that services are provided in the community, and the difficulties associated with accessing such services upon transition into adulthood. As such, the developmental framework is essential, and the neuropsychologist is often in the unique position to provide the life span approach to assessment and intervention, throughout childhood, and (often) well into adulthood.

# 11 Traumatic Brain Injury in Children and Adolescents

*Keith Owen Yeates and Brian L. Brooks*

Traumatic brain injuries (TBIs) arising from closed-head trauma in children are the most common source of acquired brain injury among children and adolescents, and represent a major public health problem, with total annual health care costs exceeding \$1 billion in the United States (Schneider, Shields, Hostetler, Xiang, & Smith, 2006). Our understanding of the neuropsychological outcomes of pediatric TBI has increased significantly over the last two decades, as reflected in multiple recent reviews (Anderson & Yeates, 2014; Bodin & Yeates, 2010; Kirkwood, Peterson, & Yeates, 2013; Taylor, 2010; Yeates, 2010). Nevertheless, much remains to be learned (Anderson & Yeates, 2010; Kochanek, 2006). In the present chapter, we summarize current knowledge regarding pediatric TBI. We then critique existing research, and highlight recent conceptual and methodological advances. We next provide a clinical case illustration. Finally, we conclude by discussing new directions for future investigation.

## **Epidemiology**

### *Incidence and Prevalence*

Epidemiological studies of pediatric TBI vary widely in their methodologies (Kraus, 1995). The most recent and complete data for the United States comes from the Centers for Disease Control (CDC; Faul, Xu, Wald, & Coronado, 2010), which estimated nearly 700,000 TBIs annually for children ages 0–19, based on deaths, hospitalizations, and emergency department visits, with an overall incidence of 857 per 100,000.

Incidence varies as a function of injury severity. Using data from a 14-state surveillance system, the CDC estimated that 71%–77% of hospital discharges for TBI across youth ages 0–19 years were classified as mild, 7%–11% as moderate, and 8%–12% as severe (Langlois et al., 2003). This is consistent with estimates based on international statistics indicating that 80%–90% of all pediatric TBI fall in the mild range (Cassidy et al., 2004). Both the incidence of pediatric TBI and the proportion that are mild in severity are almost certainly underestimated, because many injuries are treated in outpatient settings and do not result in hospital visits, or go unreported entirely (Sosin, Sniezek, & Thurman, 1996).

### *Cause of Injury*

The most common causes of TBI involve transportation, falls, and blunt trauma (i.e., unintentionally being struck by or against another object, such as colliding with another player during sport). Together, those three causes account for approximately 80% of all pediatric TBI (Faul et al., 2010). The distribution of causes varies significantly as a function of age (Keenan & Bratton, 2006). Infants are especially likely to sustain TBI through falls. School-age children are most likely to be injured through falls or blunt trauma. Adolescents are increasingly likely to be injured in motor vehicle collisions, although falls and blunt trauma remain significant causes among youth.

### *Demographic Variation*

Boys are more likely to sustain TBI than girls, although the ratio is lower in infants and young children than during older childhood and adolescence (Faul et al., 2010). Children ages 0–4 years are most likely to visit emergency departments for evaluation of TBI, with an annual incidence of about 1,256 per 100,000, suggesting that milder injuries may be especially common among younger children. In contrast, older adolescents ages 15–19 show the highest rates of hospitalizations and deaths, with a combined annual incidence of about 139 per 100,000, likely reflecting the increasing severity of TBI in that age group as a function of transportation-related injuries.

Incidence rates also appear to vary as a function of race and socioeconomic status. According to the CDC, Blacks demonstrate higher rates of emergency department visits for TBI than Whites among children 0–14 years of age and higher rates of hospitalization and death for motor vehicle-related TBI among children 0–9 years of age (Faul et al., 2010; Langlois, Rutland-Brown, & Thomas, 2005). The risk of TBI, particularly those linked to motor vehicles, is also substantially higher for children of lower socioeconomic status (Brown, 2010; Howard, Joseph, & Natale, 2005).

### *Mortality*

Unintentional injuries are the leading cause of death among children and adolescents in the United States, and about

40%–50% of the deaths resulting from trauma are associated with TBI (Kraus, 1995). Mortality rates are higher among adolescents and adults than among children, likely because of the increasing rates of transportation-related injuries at later ages. The CDC estimates an annual mortality rate around 3.6 per 100,000 for children 0–14 years of age, but a rate of about 19 per 100,000 for 15–19 year olds (Faul et al., 2010). The mortality rate is highest among children with severe TBI, and very low among children with mild to moderate injuries (Kraus, 1995).

### Neuropathology and Pathophysiology

TBI involves multiple forms of neuropathology, ranging from overt damage to brain tissue to disruptions in brain function at a cellular level (see Table 11.1). The pathophysiology of TBI involves interwoven processes that begin at the time of impact but continue for an extended period of time (Farkas & Povlishock, 2007; Giza & Hovda, 2001; Povlishock & Katz, 2005). Thus, TBI can result in protracted neurodegenerative changes in children (Keightley et al., 2014), and is best understood as a disease process and chronic health condition rather than an isolated event (Corrigan & Hammond, 2013; Masel & DeWitt, 2010).

Children's brains respond differently to trauma than do adult brains (Giza, Mink, & Madikians, 2007). For example, children are more likely than adults to display posttraumatic brain swelling, hypoxic-ischemic insult, and other diffuse injuries, but less likely to have focal mass lesions. The biomechanical properties of the young brain may explain at least some of these differences. Compared to adults, children have a larger head-to-body ratio, less myelination, and higher relative proportion of water content and cerebral blood volume. During adolescence, TBI-related pathology begins to more closely resemble that seen in adults.

Table 11.1 Neuropathology of TBI

Type of Insult	Neuropathology
Primary	Skull fracture Focal contusions and lacerations Shear/strain injury
Secondary	Brain swelling Cerebral edema Elevated intracranial pressure Hypoxia-ischemia Mass lesions (e.g., epidural hematoma)
Neurochemical and Neurometabolic	Excessive production of free radicals Excessive release of excitatory neurotransmitters Alterations in glucose metabolism Traumatic axonal injury
Late/Delayed	Cerebral atrophy Posttraumatic hydrocephalus Posttraumatic epilepsy

### Primary and Secondary Injuries

Observable injuries resulting from closed-head trauma can be classified into two broad categories: *primary* and *secondary*. Primary injuries result directly from the impact to the head itself. They include skull fractures, contusions and lacerations, and mechanical injuries to nerve fibers and blood vessels. Secondary injuries arise indirectly from the trauma and include brain swelling and edema, hypoxia and hypotension, increased intracranial pressure, and mass lesions.

The biomechanics of TBI are not fully understood in children (Margulies & Coats, 2010). TBI often involve acceleration/deceleration forces that can result in both translational and rotational trauma. Translational trauma can result in deformation of the skull or skull fractures, as well as contusions at the site of impact. Rotational trauma results in the tearing or bruising of blood vessels that gives rise to focal contusions or hemorrhage, as well as in shearing or straining of nerve fibers associated with traumatic axonal injury. Focal lesions are especially likely to occur in the frontal and temporal cortex, because of its proximity to the bony prominences in the anterior and middle fossa of the skull (Bigler, 2007; Wilde et al., 2005). Traumatic axonal injury is most common at the boundaries between gray and white matter.

Medical management of TBI tends to focus less on primary injuries than on the secondary injuries that can arise indirectly following the initial trauma (Kochanek, Carney, Adelson, & Warden, 2012). Brain swelling and cerebral edema are two major secondary complications of TBI and are especially common in children (Kochanek, 2006). They can result in decreased cerebral blood flow, increased cerebral blood volume, and increased intracranial pressure (i.e., intracranial hypertension), which combined can give rise to hypoxic-ischemic injury, as well as to brain herniation and death.

### Neurochemical and Neurometabolic Mechanisms

The mechanical forces involved in TBI do not account for the majority of traumatic axonal injury. Instead, traumatic axonal injury likely results from a cascade of biochemical and metabolic reactions that occur after the initial trauma, including the overproduction of free radicals and excitatory neurotransmitters, the disruption of normal calcium homeostasis, and changes in glucose metabolism (Farkas & Povlishock, 2007; Giza & Hovda, 2001; Novack, Dillon, & Jackson, 1996). Despite considerable promise in animal research, clinical trials designed to reduce brain injury by altering neurochemical and neurometabolic mechanisms have been uniformly disappointing in humans (Narayan & Michel, 2002).

### Late Effects

TBI can be associated with a variety of late effects. Neurodegenerative processes can result in cerebral atrophy and

ventricular enlargement (Ghosh et al., 2009; Keightley et al., 2014). Ventricular dilatation may also be the result of post-traumatic hydrocephalus, although this typically develops only after severe injuries associated with certain predisposing factors, such as subarachnoid hemorrhage (McLean et al., 1995). Early posttraumatic seizures, defined as occurring within the first week after TBI, occur frequently and can involve focal status epilepticus (Statler, 2006). Early post-traumatic seizures do not clearly place children at risk for later epilepsy, which occurs in about 10%–20% of children with severe TBI. Posttraumatic epilepsy is more common in children with penetrating or inflicted injuries, or injuries associated with depressed skull fractures.

## Outcomes

### *Cognitive Abilities*

The cognitive consequences of pediatric TBI have been the subject of several reviews and meta-analyses (Babikian & Asarnow, 2009; Taylor, 2010; Yeates, 2010). Overall, research indicates that TBI, especially when severe, can produce deficits across a variety of cognitive domains. In comparison, mild TBI is unlikely to result in long-term cognitive deficits (Belanger, Spiegel, & Vanderploeg, 2010).

Orientation and alertness are often disturbed following TBI, particularly during the initial phase of recovery. Most children with TBI, especially those that are moderate or severe, experience acute fluctuations in arousal, as well as disorientation, confusion, and memory loss after the injury, a constellation typically referred to as posttraumatic amnesia (Ewing-Cobbs, Levin, Fletcher, Miner, & Eisenberg, 1990).

Children with TBI often demonstrate deficits in sensory and motor skills. Approximately 25% of children with severe TBI display deficits in stereognosis, finger localization, and graphesthesia (Levin & Eisenberg, 1979). Deficits are also common in fine-motor skills, especially on timed tasks (Bawden, Knights, & Winogron, 1985). Disturbances in gait and gross motor skills are also common (Kuhtz-Buschbeck et al., 2003).

Children with TBI tend to display both verbal and nonverbal intellectual deficits, as measured by traditional IQ tests, and the magnitude of the deficits is related to injury severity (Anderson, Morse, Catroppa, Haritou, & Rosenfeld, 2004, 2005b; Taylor et al., 1999). IQ scores tend to increase over time following TBI, with the most rapid increases occurring immediately after injury and among children with more severe injuries (Yeates et al., 2002). Persistent deficits in IQ are more likely among children with severe TBI and those injured early in life (Anderson et al., 2004, 2005a).

Spontaneous mutism and expressive language deficits are common immediately after TBI (Levin et al., 1983), but overt aphasic disorders rarely persist. Language deficits typically improve over time, with the greatest gains seen following severe TBI (Catroppa & Anderson, 2004), although

long-term deficits have been identified in a variety of basic linguistic skills (Ewing-Cobbs & Barnes, 2002). The most pronounced difficulties, though, occur in the pragmatic aspects of language, particularly narrative discourse (Chapman et al., 2004; Dennis & Barnes, 1990).

Long-term deficits in nonverbal skills are a relatively frequent consequence of pediatric TBI. Deficits have been reported on a variety of constructional tasks (Thompson et al., 1994; Yeates et al., 2002). Deficits also occur on measures of perceptual or spatial skills that do not involve motor output (Lehning et al., 2001), although they tend to be less pronounced than those in other domains (Babikian & Asarnow, 2009).

Complaints about attention problems are very common following childhood TBI (Yeates et al., 2005), as are deficits on formal tests of attention. On continuous performance tests, children with TBI display poorer response modulation, especially in the presence of distraction, as well as slower reaction times (Dennis, Wilkinson, Koski, & Humphreys, 1995). Children with TBI also show deficits on measures of sustained, selective, shifting, and divided attention, particularly on more complex and timed measures (Catroppa & Anderson, 2005; Catroppa, Anderson, Morse, Haritou, & Rosenfeld, 2007; Ewing-Cobbs et al., 1998b).

Childhood TBI frequently results in concerns about memory deficits (Ward, Shum, Dick, McKinaly, & Baker-Tweney, 2004). Deficits also have been reported on a wide variety of tasks assessing explicit memory, particularly in children with severe TBI (Catroppa & Anderson, 2002, 2007; Yeates, Blumenstein, Patterson, & Deils, 1995). Children with TBI may be less likely to display deficits in implicit memory, which involves demonstrations of learning or facilitation of performance in the absence of conscious recollection (Ward, Shum, Wallace, & Boon, 2002; Yeates & Enrile, 2005). In contrast, children with TBI do display deficits in prospective memory (McCauley & Levin, 2004; Ward, Shum, McKinaly, Baker, & Wallace, 2007).

Deficits in executive functions occur frequently after childhood TBI (Levin & Hanten, 2005) and can persist for years after injury (Nadebaum, Anderson, & Catroppa, 2007). Young children and those with severe injuries are particularly vulnerable to executive deficits following TBI (Anderson & Catroppa, 2005; Ewing-Cobbs, Prasad, Landry, Kramer, & DeLeon, 2004b). Children with TBI also display executive deficits in everyday settings (Mangeot, Armstrong, Colvin, Yeates, & Taylor, 2002; Sesma, Slomine, Ding, & McCarthy, 2008) that have been linked to broader difficulties with social and behavioral adjustment (Ganesalingam, Sanson, Anderson, & Yeates, 2007).

### *Functional Outcomes*

Childhood TBI is frequently associated with declines in school classroom performance (Ewing-Cobbs et al., 2004a; Taylor et al., 2002) and other academic difficulties (Ewing-Cobbs,

Fletcher, Levin, Iovino, & Miner, 1998a; Taylor et al., 2003). Deficits on formal achievement testing are more likely in children injured at a young age (Ewing-Cobbs et al., 2004a, 2006). Academic difficulties are predicted by factors such as premorbid classroom performance (Catroppa & Anderson, 2007), postinjury neuropsychological functioning (Kinsella et al., 1997; Miller & Donders, 2003), and postinjury behavioral adjustment (Yeates & Taylor, 2006). The family environment also moderates academic performance, such that more supportive and functional homes lessen the impact of TBI (Taylor et al., 2002). Surprisingly, standardized achievement testing is not always a strong predictor of academic outcomes after TBI (Yeates & Taylor, 2006).

Childhood TBI also often results in problems with social functioning (Rosema, Crowe, & Anderson, 2012; Yeates et al., 2007). Following TBI, children display deficits in theory of mind (Dennis et al., 2013), as well as in social problem solving (Hanten et al., 2008; Janusz, Kirkwood, Yeates, & Taylor, 2002). Deficits in executive functions and social information processing are linked to poor social outcomes after TBI (Yeates et al., 2004; Robinson et al., 2014). Although frontal lobe injury in association with TBI has been linked in some studies to poor social outcomes (Dennis, Guger, Roncadin, Barnes, & Schachar, 2001a; Hanten et al., 2008; Levin et al., 2004), the relationship of regional brain injury to social functioning after TBI is quite variable (Bigler et al., 2013; Yeates et al., 2014).

TBI in children increases the risk for a wide range of emotional and behavioral problems (Li & Liu, 2013; Taylor et al., 2002). In contrast to cognitive deficits, behavioral problems are more likely to show a stable or even worsening pattern over time (Fay et al., 2009). Indeed, behavioral functioning does not appear to be closely related to cognitive outcomes of TBI (Fletcher, Ewing-Cobbs, Miner, Levin, & Eisenberg, 1990). The determinants of cognitive and behavioral outcomes also may be somewhat independent. Cognitive outcomes are related more strongly to injury-related variables, whereas behavioral outcomes are related more strongly to measures of preinjury family functioning (Yeates et al., 1997).

Childhood TBI is associated with an increased risk of formal psychiatric disorder (Bloom et al., 2001). The most common diagnoses following childhood TBI are oppositional defiant disorder (ODD; Max et al., 1998a), attention deficit/hyperactivity disorder (ADHD; Levin et al., 2007; Max et al., 2005b; Yeates et al., 2005), and personality change due to TBI (Max et al., 2000, 2005a). Internalizing disorders also occur, including obsessive-compulsive symptoms, generalized anxiety, separation anxiety, and depression (Grados et al. 2008; Luis & Mittenberg, 2002; Vasa et al., 2002). Symptoms of posttraumatic stress disorder (PTSD) are also elevated following childhood TBI, although relatively few children meet full diagnostic criteria for PTSD (Gerring et al., 2002; Levi et al., 1999).

Moderate or severe TBI is followed by persistent deficits in adaptive behavior, including poorer communication,

socialization, and daily living skills (Fay et al., 2009; Max et al., 1998c). Children with TBI also demonstrate significant declines in their overall quality of life, although differences are more pronounced based on parent reports than when based on children's self-reports (DiBattista, Soo, Catroppa, & Anderson, 2012; Stancin et al., 2002).

Although few studies of long-term adult outcomes following childhood TBI have been conducted, the existing research clearly documents an increased risk of persistent functional deficits. As adults, children with severe TBI are likely to demonstrate less educational attainment, reduced employment and occupational status, poorer socialization, increased psychiatric disorder, and reductions in functional independence and perceived quality of life (Anderson, Brown, Newitt, & Holie, 2009, 2011; Beauchamp, Dooley, & Anderson, 2010).

### **Predictors of Outcomes**

Most research on the outcomes of pediatric TBI has focused on group comparisons (e.g., severe TBI versus orthopedic injuries). Although such comparisons are informative, they fail to capture the substantial heterogeneity that characterizes the outcomes of TBI, even when stratified by injury severity. These individual differences in outcomes reflect a complex interplay among injury characteristics, non-injury related influences, and developmental factors. Research nowadays more often focuses on factors that predict individual differences in outcome, partly in hope of identifying fruitful avenues for intervention.

### ***Injury Characteristics***

Injury severity is a major determinant of the consequences of TBI, with more severe injuries resulting in poorer outcomes. Injury severity can be assessed using a variety of clinical metrics, including level of consciousness, duration of impaired consciousness, and length of posttraumatic amnesia. Other specific medical indicators of severity include brain stem abnormalities (e.g., pupillary reactivity) and elevated intracranial pressure. The Glasgow Coma Scale (GCS; Teasdale & Jennett, 1974) is probably the most frequent metric of injury severity.

The motor scale on the GCS can be used to assess duration of impaired consciousness, often defined as the number of days from an injury until a child is able to follow commands consistently (i.e., the number of days that the score on the GCS motor scale falls below 6). Duration of impaired consciousness is an indirect indicator of rate of recovery, because it reflects the speed with which a child's mental status improves post injury. The length of posttraumatic amnesia also reflects the child's rate of recovery. In comparative studies, duration of coma (i.e., GCS score < 9), impaired consciousness, and posttraumatic amnesia have generally been better predictors of outcome than static measures such as the

lowest postresuscitation GCS score (Ewing-Cobbs, Fletcher, Levin, Hastings, & Francis, 1996; McDonald et al., 1994).

The classification of injury severity using the GCS and other clinical metrics has begun to give way to more sophisticated indices that are linked more directly to the pathophysiology of TBI (Saatman et al., 2008). Neuroimaging allows much better characterization of underlying neuropathology. Computed tomography (CT) is preferred acutely after TBI because it is widely available and relatively inexpensive, and also sensitive to lesions that may necessitate neurosurgical intervention (Poussaint & Moeller, 2002). However, magnetic resonance imaging (MRI) is superior to CT in documenting most pathology associated with TBI (Sigmund et al., 2007).

A variety of advanced imaging procedures have been developed to assess both structural and functional brain abnormalities in childhood TBI (see Ashwal, Holshouser, & Tong, 2006b, 2010; Munson, Schroth, & Ernst, 2006). Newer MRI sequences that show increased sensitivity to the structural effects of pediatric TBI include susceptibility-weighted MR imaging (Ashwal et al., 2006a; Beauchamp et al., 2011) and diffusion tensor imaging (Yuan et al., 2007). Brain function can be assessed directly using techniques such as functional MRI (Kramer et al., 2008), proton magnetic resonance spectroscopy (Ashwal et al., 2006a; Babikian et al., 2006), positron emission tomography, and single-photon emission CT (Munson et al., 2006).

Neuroimaging studies in children with TBI generally indicate that the greater the structural or functional abnormalities, the greater the morbidity (Brenner, Freier, Holshouser, Burley, & Ashwal, 2003). In some cases, studies have shown predictable brain-behavior relationships in children with TBI (e.g., Levin et al., 2004; Newsome et al., 2008), although expectations based on adult models are not necessarily applicable after childhood TBI. For instance, frontal lesion volume does not consistently predict attention or executive function (Power, Catroppa, Coleman, Ditchfield, & Anderson, 2007; Slomine et al., 2002), and fronto-temporal lesions do not predict memory performance better than lesions outside those regions (Salorio et al., 2005). A major challenge for neuroimaging studies is that the lesions associated with pediatric TBI are extremely heterogeneous, with relatively little overlap in lesion location from one child to the next (Bigler et al., 2013).

### *Non-Injury-Related Influences*

Because injury severity fails to account for most of the variance in postinjury outcomes after TBI, research has begun to focus on non-injury-related influences. For instance, children's premorbid functioning appears to be an important determinant of the outcomes of childhood TBI (Fay et al., 2010; Yeates et al., 2005), consistent with theories of cognitive and brain reserve capacity suggesting that vulnerability to neurological insults varies as a function of preinjury

cognitive abilities and brain integrity (Dennis, Yeates, Taylor, & Fletcher, 2007).

Environmental influences also help to account for outcomes following TBI. General measures of socioeconomic status and family demographics predict outcomes, as do more specific aspects of family status and parenting. Indeed, the family environment actually moderates the impact of TBI, by buffering or exacerbating its adverse consequences (Taylor et al., 2002; Yeates et al., 1997, 2004). Thus, the effects of TBI are more pronounced for children from dysfunctional families.

The treatments and interventions that children with TBI receive are also likely to be critical environmental influences on recovery. Unfortunately, treatment research is very sparse. Guidelines for acute medical management of childhood TBI lack a firm evidence base (Adelson, 2010; Kochanek et al., 2012). Comprehensive reviews of inpatient and outpatient rehabilitation also highlight the relative paucity of research in that domain (Anderson & Catroppa, 2006; Slomine & Locascio, 2009; Tal & Tirosh, 2013; Ylvisaker et al., 2005), and even less is known about the effectiveness of educational interventions (Ylvisaker et al., 2001). Cognitive remediation programs have been developed for pediatric TBI, but research provides little evidence that their effects generalize to everyday environments (Catroppa & Anderson, 2006; Laatsch et al., 2007; Robinson, Kaizar, Catroppa, Godfrey, & Yeates, 2014).

Research regarding treatment for the psychosocial sequelae of pediatric TBI is also relatively limited (Donders, 2007; Ross, Dorris, & McMillan, 2011), although some support exists for certain treatments of behavioral and social problems (Warschawsky, Kewman, & Kay, 1999; Ylvisaker, Turkstra, & Coelho, 2005; Ylvisaker et al., 2007). Family based interventions that promote better communication and problem solving, and that incorporate parent training, have shown particular promise in promoting better psychosocial outcomes for children with TBI and their families (Brown, Whittingham, Boyd, & Sofronoff, 2013; Wade, 2010).

### *Developmental Considerations*

The outcomes of childhood TBI vary as a function of three distinct but interrelated developmental dimensions: age at the time of injury, the amount of time that has passed since the injury, and age at the time of outcome assessment (Taylor & Alden, 1997). Injuries sustained during infancy or early childhood are associated with more persistent deficits than those occurring during later childhood and adolescence (Anderson et al., 2005a; Ewing-Cobbs et al., 2006). Younger children demonstrate a slower rate of change over time and more significant residual deficits than do older children, particularly after more severe injuries (Catroppa, Anderson, Morse, Haritou, & Rosenfeld, 2008; Koskiniemi, Kyyka, Nybo, & Jarho, 1995).

Children with TBI generally display a gradual recovery after injury, with the most rapid improvement occurring soon

after the injury (Yeates et al., 2002). The initial rate of recovery is most rapid among children with severe TBI, although severe injuries are more likely to be associated with persistent deficits after recovery slows (Fay et al., 2009). Studies of long-term outcomes show little evidence that children with TBI show progressive deterioration in cognitive functioning after their initial recovery (Jonsson, Horneman, & Emanuelson, 2004; Klonoff, Clark, & Klonoff, 1995), although deterioration can occur in behavioral functioning (Fay et al., 2009).

The influence of age at testing has not been a major focus of research. The effects of age at testing would be reflected in latent or delayed sequelae resulting from children's failure to meet new developmental demands following a TBI. Although such sequelae are sometimes suspected in individual cases (Baron, 2008), they are difficult to detect in research because the effects of age at testing are difficult to disentangle from those of age at injury and time since injury (Taylor & Alden, 1997).

## Methodological Critique

### *Sample Selection, Recruitment, and Attrition*

Shortcomings in the selection and recruitment of participants characterize many studies of TBI. Children with TBI are sometimes selected retrospectively, based on admission to a rehabilitation facility or referral for neuropsychological evaluation (e.g., Yeates et al., 1995). Samples selected in this way are likely to be less representative than those that are recruited prospectively from consecutive admissions to a hospital or trauma center.

Even when samples are recruited prospectively, they may not be representative of the larger population from which they are drawn or they may become unrepresentative because of selective attrition. The agreement to participate in scientific research is not a random decision, nor is the decision to discontinue participation. Unfortunately, few studies report participation rates or compare participants and nonparticipants in terms of demographics or clinical characteristics, to determine if study participation has introduced bias into sample selection. Similarly, few studies compare children who complete follow-up to those who drop out, to determine if attrition biases their results (Blaha et al., 2015). Statistical procedures such as pattern-mixture analysis can be used to determine whether attrition has biased study results (Hedeker & Gibbons, 1997).

The selection of comparison groups in research on TBI also can be problematic. Children with mild TBI have sometimes been used as a comparison group, despite ongoing controversy regarding the outcomes associated with mild TBI (Satz, 2001; Yeates et al., 2009). In other cases, noninjured children matched for age, gender, and other demographic variables have been used as a comparison group (Jaffe, Polissar, Fay, & Liao, 1995). However, noninjured children are not equated to children with TBI in terms of the experience of a traumatic injury or ensuing medical treatment. Moreover, they may also differ from children with TBI in a variety of premorbid characteristics that are not controlled

by matching on demographic factors alone. Children who sustain injuries frequently display more preexisting behavioral, developmental, and learning problems than children who are not injured (Asarnow et al., 1995; Bijur & Haslum, 1995), and also are more likely to come from families that are socially disadvantaged and dysfunctional (Christoffel, Donovan, Schofer, Wills, & Lavigne, 1996; Howard et al., 2005; Parslow, Morris, Tasker, Forsyth, & Hawley, 2005). Although background differences are not reported between children with TBI and noninjured controls or between children with TBI of varying severity in all studies (Catroppa et al., 2015), comparison groups consisting of children who have sustained injuries not involving the head and who have undergone comparable medical treatment are often desirable.

## Measurement

### *Injury characteristics*

The literature on TBI suffers from a lack of consistency in the characterization of injury severity. Greater uniformity in the assessment of severity would allow more meaningful cross-study comparisons (Saatman et al., 2008). Future studies are likely to need to incorporate multidimensional approaches to classifying severity that incorporate clinical indicators, neuroimaging, and other biomarkers.

Specific criticisms can be raised about traditional clinical indices of injury severity. The GCS is problematic when used with infants and young children, despite attempts to make suitable modifications (Durham et al., 2000). The duration of impaired consciousness can be difficult to assess reliably, because it is often measured retrospectively, based on clinical assessments by nursing staff or physicians. Similarly, post-traumatic amnesia is often assessed based on retrospective reports from caretakers, despite the availability of standardized instruments such as the Children's Orientation and Amnesia Test (COAT; Ewing-Cobbs et al., 1990) that can provide more reliable and objective measurement.

As noted earlier, neuroimaging allows characterization of injury severity based on underlying neuropathology. The advent of more advanced neuroimaging techniques, such as susceptibility-weighted imaging, diffusion tensor imaging, functional MRI, and proton magnetic resonance spectroscopy, will provide more precise measures of both the diffuse and focal neuropathology associated with TBI, which can in turn be used to predict neurobehavioral outcomes (Levin et al., 2004; Newsome et al., 2008).

Research suggests that serum biomarkers may also provide a more precise characterization of injury severity by assessing biochemical and protein indicators of the neurochemical cascade that occurs in TBI (Berger, Adelson, Richichi, & Kochanek, 2006, 2010; Papa et al., 2013). Biomarkers may be particularly important for diagnosing TBI in young children, for whom conventional indices such as the GCS are often invalid, and for children with inflicted TBI, who may suffer head trauma that is not disclosed (Berger, Ta'Asan, Rand, Lokshin, & Kochanek, 2009; Shore et al., 2007).

### *Non-injury-related influences*

Measures of children's premorbid status are likely to moderate the effects of TBI (Catroppa et al., 2015), and hence should be incorporated into future research. In this regard, a substantial opportunity exists to explore the association of genetics with outcomes. Aside from a small literature on the apolipoprotein (APOE) gene, little is known about genetic influences on recovery from TBI, despite their critical role in neural plasticity and inflammatory responses (Kurowski, Martin, & Wade, 2012).

Research also needs to incorporate more precise measures of children's environments to determine the mechanisms by which the environment moderates the outcomes of childhood TBI. A recent study of parenting skills in preschool children with TBI provides an example of such an approach (Wade et al., 2008).

Future research is also badly needed on the effectiveness of the interventions used to manage TBI. Clinical trials in children with TBI are challenging (Adelson, 2010; Natale et al., 2005), but are badly needed to evaluate the efficacy and effectiveness of potential medical treatments such as hypothermia. The benefits of postacute medical interventions such as psychotropic or anticonvulsant medications, rehabilitative and educational programs, and psychological and behavioral interventions targeted to children and their families also require further investigation.

In recent years, concerns have been raised about relying on randomized clinical trials for assessing treatment effectiveness in TBI, partly because of the difficulties inherent in conducting such trials, but also because of their repeated failures to advance treatment of TBI (Adelson, 2010). These concerns have led to calls for comparative effectiveness studies, which rely on natural variations in care across multiple sites and large numbers of patients to detect the effectiveness of specific interventions (Maas & Menon, 2012; Maas et al., 2012; Powell, Temkin, Machamer, & Dikmen, 2002). Several studies based on this approach are under way in the United States and internationally.

### *Outcomes*

Limitations characterize many of the outcome measures used in studies of pediatric TBI. Clinical judgments, such as those reflected in the Glasgow Outcome Scale (Jennett & Bond, 1975), often lack sensitivity to subtle differences in outcomes. Psychometric tests generally provide more sensitive outcome measures, but their interpretation is complicated by the multifactorial nature of test performance. Tests designed to assess specific skill deficits or that employ experimental manipulations of task demands may yield more precise information about the cognitive sequelae of TBI (Taylor, 2010).

Psychometric testing is not always feasible for measuring critical functional outcomes following TBI, including social competence, behavioral adjustment, and adaptive functioning. The latter outcomes are typically assessed using rating

scales and interviews, although many commonly used rating scales were not developed for use with children with TBI and may prove insensitive in that population (Drotar, Stein, & Perrin, 1995; Perrin, Stein, & Drotar, 1991). The use of rating scales that are specifically targeted to children with TBI may be more informative (Yeates et al., 2001).

The range of outcomes assessed in previous research has also been limited, although more attention is beginning to be paid to important outcomes such as social functioning (Yeates et al., 2007), family functioning (Wade et al., 2006), school performance (Taylor et al., 2003), or quality of life (Di Battista et al., 2012). Notably, these functional outcomes are more likely to be moderated by environmental factors than are children's cognitive abilities.

A lack of consistency in outcome measures across studies is also a problem, because it hampers the comparison of results and pooling of data for the purpose of systematic reviews and meta-analyses. The lack of standards or guidelines in this regard has been problematic, but researchers are now being encouraged to use common outcome measures, such as those recommended by the National Institutes of Health (NIH) Common Data Elements Project (McCauley, Wilde, Anderson, Bedell, & Yeates, 2012).

### *Mechanisms Underlying Recovery*

Few studies have attempted to explain the mechanisms that underlie the sequelae of TBI in children (Taylor, 2010). The causal mechanisms that underlie recovery from brain injury may be especially amenable to research in nonhuman animals (Kamper et al., 2013). For instance, although we do not know why younger children display less recovery from TBI than older children, research on nonhuman animals suggests important differences in neural plasticity may play a role (Bittigau et al., 1999; Giza & Prins, 2006). Research on nonhuman animals is not limited to understanding the neural mechanisms that affect recovery from brain injury, but also provides a platform for understanding non-injury-related mechanisms, such as the rearing environment (Bondi, Klitsch, Leary, & Kline, 2014).

### *Analysis of Change*

Cross-sectional designs have been used in many studies of childhood TBI, but they preclude investigation of the process of postinjury recovery. Longitudinal studies are needed to determine the relative importance of injury characteristics, non-injury-related influences, and developmental factors as predictors of outcomes across time (Taylor & Alden, 1997). Most previous longitudinal studies have followed children for relatively brief periods; investigations of much longer duration are needed to document the long-term, adult outcomes of childhood TBI (Anderson et al., 2009, 2011; Beauchamp et al., 2010).

Existing longitudinal studies also have not consistently adopted a developmental approach to modeling

recovery. Traditional approaches to data analysis in longitudinal designs, such as repeated-measures analysis of variance, treat individual differences in change as error variance. However, recovery from TBI inherently involves change that is heterogeneous in nature, and individual differences in developmental change should represent a major focus in studies of childhood TBI. Growth curve modeling and related statistical approaches permit the investigation of change at an individual level (Francis, Fletcher, Stuebing, Davidson, & Thompson, 1991). Mixture modeling is another approach that can be used to examine intraindividual change. It empirically identifies latent classes of individuals based on different developmental trajectories (Nagin, 1999). In a study using that technique (Yeates et al., 2009), children with mild TBI were more likely than those with orthopedic injuries to demonstrate trajectories involving high acute levels of symptoms, especially if their acute clinical presentation reflected more severe injury.

### *Prediction of Individual Outcomes*

Clinicians involved in the care of children with TBI want to know whether a given child is likely to recovery fully or demonstrate persistent difficulties. Research can help to address this question by focusing more on individual outcomes. For instance, children with TBI can be divided into subgroups based on injury characteristics or environmental factors to determine if outcomes are different for the different subgroups. Alternatively, individuals with a given outcome can be identified, and then the risk factors linked to this outcome can be determined. The latter method has the advantage of permitting the study of combinations of risk factors associated with the outcome. Analyses of reliable change provide one means of identifying individual children who display

unusual decrements in functioning compared to pre-injury estimates and examining the risk factors associated with such increases (McCrea et al., 2005; Yeates et al., 2012).

In the long run, prognostic models and decision rules are needed that can predict which children with TBI will demonstrate poor versus good outcomes. Research along these lines has been very successful at identifying children with mild TBI who are at risk of clinically significant lesions on neuroimaging (Kuppermann et al., 2009; Osmond, Klassen, Wells, Correll, & Stiell, 2010). To be clinically useful, research on outcome prediction must meet a variety of methodological prerequisites, such as large sample sizes, that are likely to necessitate multisite cooperative studies (Mushkudiani et al., 2008). A study along these lines, examining the prediction of postconcussive symptoms in children with mild TBI from acute clinical characteristics in the emergency department setting, was recently completed in Canada (Zemek, Osmond, & Barrowman, 2013).

### **Case Illustration**

To illustrate a fairly typical clinical case of childhood TBI, we have chosen to present Jane, an 11-year-old girl who was struck by a motor vehicle. Her premorbid birth, developmental, school, and psychosocial histories were unremarkable. She sustained multiple internal and orthopedic injuries, and required surgery for a depressed skull fracture. At the scene, her GCS score was 5 out of 15; it increased to 11 en route to the hospital, but dropped to 5 upon arrival, at which time she was intubated and sedated.

MRI of the brain eight days postinjury revealed multiple focal lesions in the right parietal region, inferior portion of the left frontal lobe, bilateral anterior temporal lobe, and left posterior temporal lobe (see Figure 11.1). Multifocal hemorrhages also were apparent, along with traumatic axonal

*Figure 11.1* MRI of TBI case illustration 12 contiguous axial images obtained on a 1.5T magnetic resonance scanner at eight days postinjury using a fluid attenuated inversion recovery (FLAIR) sequence

injury. Based on formal assessments using the Children's Orientation and Amnesia Test (Ewing-Cobbs et al., 1990), Jane demonstrated posttraumatic amnesia for 21 days postinjury. Her mother reported a period of retrograde amnesia of at least eight hours.

Jane completed a brief neuropsychological evaluation 24 days postinjury. Her performance on a measure of word reading, which provided an indicator of premorbid functioning, was average. She demonstrated clear deficits in reaction time and psychomotor speed, cognitive flexibility, and memory. Jane was subsequently referred for a follow-up neuropsychological evaluation six months postinjury.

On interview, Jane's mother reported gradual improvements in Jane's cognition, personality, mood, and behavior, which were characterized as largely back to baseline. However, she described ongoing concerns regarding poor concentration, forgetfulness, hyperactivity and fidgetiness, reduced speed of mental processing, and increased fatigue. She also reported difficulties remembering multistep directions, comprehending new or complex concepts, making simple decisions of everyday life, independently initiating activities, and

transitioning between activities. She denied sleep problems, pain, mood problems, social difficulties, or psychological adjustment problems.

Jane was polite and cooperative during the assessment. She did not display overt hyperactivity or inattention, and her expressive language, motor, hearing, and vision skills appeared intact. Her mood was flat, and she appeared indifferent to success or failure on the tests. She did not initiate conversations or other forms of social interactions with the examiner. Over time, she displayed increasing fatigue.

Jane understood very simple test instructions, but was visibly confused by multistep or complex instructions. Despite multiple repetitions, simplification of test instructions, extended practice, and demonstrations, she was not able to follow some instructions. Her comprehension difficulties may have affected her performance on some tests. However, she displayed adequate performance on a formal measure of performance validity.

On formal testing (see Table 11.2), Jane's overall intellectual functioning was somewhat below average. She showed a moderate difference, found in less than 16% of her peers,

Table 11.2 Summary of assessment results

<i>Test Domain/Measures</i>	<i>Standard Score</i>	<i>Percentile</i>
<b>Intellectual Abilities</b>		
WISC-IV General Ability Index	Index = 76	5
WISC-IV Verbal Comprehension Index	Index = 87	19
WISC-IV Perceptual Reasoning Index	Index = 72	3
<b>Language Skills</b>		
NEPSY-II Comprehension of Instructions	SS = 4	2
WISC-IV Vocabulary	SS = 6	9
<b>Visuospatial Abilities</b>		
WISC-IV Block Design	SS = 5	5
<b>Learning and Memory</b>		
CVLT-C Trials 1–5 Total Recall	T = 47	38
CVLT-C Long Delay Free Recall	Z = -1.0	16
CVLT-C Recognition Discriminability	Z = -1.5	7
Continuous Visual Memory Test Total	Raw = 54	<3
Continuous Visual Memory Test Delayed Recognition	Raw = 2	<10
<b>Information Processing Speed</b>		
WISC-IV Processing Speed Index	Index = 78	7
NEPSY-II Inhibition-Naming Combined	SS = 4	2
CNS Vital Signs Reaction Time	Index = 87	19
TOVA Response Time	Index = 58	0.3
<b>Attention and Concentration</b>		
TOVA Omission Errors	Index = 40	<1
TOVA Commission Errors	Index = 113	81
<b>Executive Functioning</b>		
CNS Vital Signs Stroop Commission Errors	Index = 78	7
NEPSY-II Inhibition-Inhibition Combined	SS = 5	5
<b>Motor Abilities</b>		
CNS Vital Signs Finger Tapping, Right Hand	Index = 88	21
CNS Vital Signs Finger Tapping, Left Hand	Index = 86	18

Table note: Index = index score, which has a mean = 100 and standard deviation = 15. SS = scaled score, which has a mean = 10 and standard deviation = 3. T = t score, which has a mean = 50 and standard deviation = 10. Z = z score, which has a mean = 0 and standard deviation = 1.0.

favoring her verbal comprehension over her perceptual organization. Reasoning and concept formation were below average on a visual task, but average on a verbal test.

In the language domain, Jane's ability to follow simple instructions was well below average. She also performed below average when defining words. Her visuospatial skills, as reflected in block construction, were also below average. Verbal learning and memory were largely intact, but non-verbal memory fell below average. Ratings by Jane's mother suggested significant deficits in daily memory skills.

Jane's processing speed was below average, although her reaction time was average on a relatively brief measure. Jane's sustained attention was below average, and declined over time. Ratings of her day-to-day attention reflected significant deficits. Inhibitory control was variable, ranging from below average to average. Jane's cognitive flexibility was below average. Ratings of her everyday executive skills suggest significant problems in initiation, working memory, and planning and organization.

Parent ratings of Jane's psychological adjustment were largely within normal limits, although they suggested limited emotional resiliency and ability to cope with emotional problems. She was reported to show mild to moderate postconcussive symptoms. Her mother rated Jane's adaptive skills from below average to average. Jane perceived her adaptive functioning as similar to before her injury, but reported clinically significant symptoms of depression and anxiety.

In summary, despite improvements in reaction time and memory compared to the postacute assessment, Jane displayed persistent and widespread deficits that encompassed language and nonverbal skills, memory, processing speed, attention, and executive functions. She was described as displaying many features of ADHD, presumably secondary to her TBI (i.e., school records and parent report did not suggest that this was a preinjury problem). She also reported significant mood problems. Her neuropsychological profile was consistent with the severity of her injury and with the widespread neuropathology documented on neuroimaging.

Jane was recommended for ongoing special education services, especially to address her difficulties with response speed, attention, and executive functions. She also was referred for ongoing behavioral health services, including psychotherapy and psychiatric consultation to consider psychotropic medication. She was fortunate to have a supportive, well-functioning family, and an unremarkable premorbid history. Both of the latter features increased her chances of ongoing recovery.

### Future Directions

Future research on the outcomes of childhood TBI will be shaped by a number of conceptual advances. Our understanding of the underlying biological mechanisms associated with recovery will be enhanced by research on genetic influences, as well as by the search for serum and neuroimaging

biomarkers of injury. Biological research also may suggest treatment approaches that minimize the secondary injuries that occur after TBI. At the same time, a growing appreciation that the environment affects recovery should lead to closer study of the ways in which family functioning and parenting affect outcomes, as well as to the translation of such research into psychosocial interventions designed to promote recovery. Ultimately, research is needed that examines the interplay of both biological and environmental influences on recovery.

Methodological improvements will also characterize future research. These will include the study of a broader range of outcomes, moving beyond cognitive abilities to broader aspects of children's functioning, such as friendships and peer relationships, health care utilization, and overall quality of life. Shared outcome measures, based on common data elements, will facilitate the comparison of studies and the pooling of data across studies. Additionally, prospective, longitudinal research designs will provide a better understanding of individual recovery and the variability in outcomes that characterize children with TBI. Combined with statistical techniques that focus on the prediction of individual outcomes, such studies will also promote more accurate prognostic judgments in clinical settings. The advent of comparative effectiveness studies may provide us with more insights into treatment effectiveness than have resulted from randomized clinical trials to date.

In the long run, to truly understand the outcomes of pediatric TBI, research will need to occur outside of traditional academic silos. Research is needed that is integrative, cutting across domains or disciplines, as well as translational, promoting the application of knowledge to clinical care. Scientific advances within specific domains are not likely to yield significant progress in the clinical management of children with TBI until they become the topic of collaborative research that cuts across multiple levels of analysis. The time is ripe for interdisciplinary efforts that promote translational research aimed at improving the lives of children with TBI and their families (Anderson & Yeates, 2010).

# 12 Pediatric Cancer

*Celiane Rey-Casserly and Brenda J. Spiegler*

Pediatric oncology has been a productive and rewarding field for neuropsychologists, both because of the remarkable successes in medical care and survival achieved over the past generation and because of the important contributions made by our profession to scientific advances and clinical care. As survival rates for childhood cancer have improved, pediatric neuropsychologists have become increasingly involved in efforts to foster optimal outcomes through participation in interdisciplinary care teams, assessment, and intervention. Childhood cancer was a fatal diagnosis in the 1950s; today more than 80% of children with some forms of cancer (e.g., acute lymphoblastic leukemia, or ALL) will survive (Pui, Carroll, Meshinchi, & Arceci, 2011). Ten-year survival for children with malignant brain tumors has improved from 46% (1973–1976) to 69% (2002–2006) (Ostrom et al., 2015). This remarkable increase in survival is true for many pediatric cancer diagnoses and was achieved with increased intensity of treatment and multimodality therapy (surgery, if warranted; multiagent and multiroute chemotherapy; radiation therapy). Figure 12.1

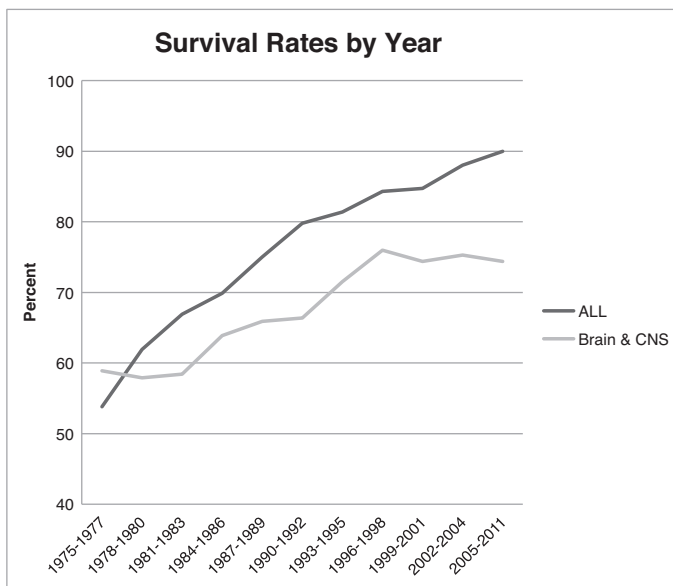

Figure 12.1 Five-year survival rates by year for ALL and brain tumors (Howlader et al., 2015; these data are based on November 2014 SEER data submission, posted to the SEER web site, April 2015)

plots five-year survival rates for brain tumors and ALL from the mid-1970s when central nervous system directed treatment was introduced for ALL. Intense treatment and the resulting increase in survival have come at a cost: Late effects on various organs (heart, lung, kidney, bone, brain), early aging, and second malignant neoplasms affect nearly two-thirds of survivors, with up to one quarter reporting severe or life-threatening conditions (Oeffinger et al., 2006). Many of these adverse late effects are more prevalent in survivors of childhood leukemia treated with cranial radiation therapy (CRT) (Hudson et al., 2013) and survivors of central nervous system (CNS) tumors (Armstrong et al., 2009). As a result, quality of survival has become central to the cost-benefit analysis—and here both health psychologists and neuropsychologists have played a prominent role. In fact, it was early neuropsychological research that first documented the fact that CRT administered to the developing brain was associated with cognitive impairments affecting IQ and academic achievement (Eiser, 1978; Eiser & Lansdown, 1977; Meadows, Massari, Fergusson, Gordon, & Moss, 1981; Waber & Tarbell, 1997; Waber et al., 1995). Later studies began to focus more narrowly on core neuropsychological processes underlying these cognitive impairments. With increasingly effective techniques to image white matter in the brain and advances in the understanding of genetic factors, the study of brain-behavior relations in pediatric oncology has taken on new energy and is an exciting, dynamic area of study with new implications for changes in treatment and care of the child with cancer.

In this chapter, we will present the historical perspective on incidence, treatments, and survival in childhood cancer, and then focus on the neuropsychological complications and late effects associated with leukemia and brain tumors. These two most common forms of childhood cancer account for approximately 50% of cases and have differing incidence through childhood (Figure 12.2). We will discuss some of the rarer, but particularly interesting, populations (e.g., infants and adolescents/young adults), forms of cancer, and developmental/neuropsychological complications. Finally, we will outline future directions for research and clinical care in this dynamic medical specialty.

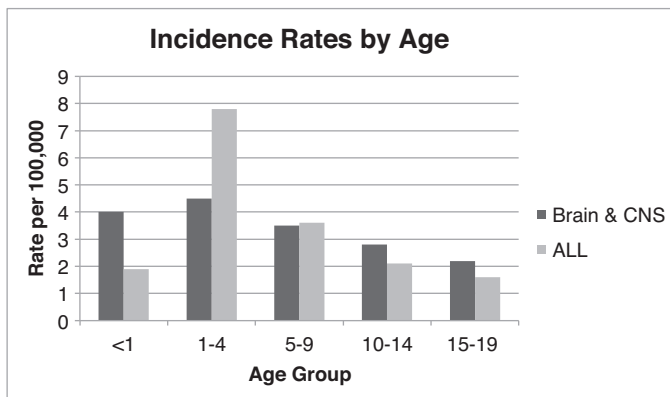

Figure 12.2 Incidence rates by age group for ALL and brain tumor (U.S. Cancer Statistics Working Group, 2014)

### Acute Lymphoblastic Leukemia

Leukemia is the most common form of cancer in childhood, with one form, ALL, comprising nearly 25% of all new cancer diagnoses in children under the age of 15 (Kaatsch, 2010). ALL develops when the precursors of white blood cells in the bone marrow proliferate, crowding out healthy and functional cells, impairing formation of normal white blood cells, and causing infiltration of leukemic cells into the bloodstream. ALL is most commonly diagnosed during the preschool years, with peak incidence between 2 and 5 years of age (Inaba, Greaves, & Mullighan, 2013). Boys are 20% more likely to be diagnosed with ALL than girls (Pizzo & Poplack, 2006).

Before the advent of modern multimodal treatments and multiagent chemotherapy, children with ALL survived only a few months (Simone, 2006). The increase in survival from this previously fatal disease is one of the great medical success stories of the past 50 years (Hudson, Link, & Simone, 2014). Even after early chemotherapy regimens allowed short periods of survival, patients invariably relapsed, with disease invading the CNS. This realization led to the recognition that leukemia cells cross the blood-brain barrier and are present in the meninges early in the course of the disease. Subsequently, the addition of craniospinal radiation and CNS-directed chemotherapy dramatically improved long-term survival.

Once high survival rates were achieved, the problem of neuropsychological morbidity and other adverse late effects began to take on greater importance. As the cohort of childhood ALL survivors began to expand in the late 1970s, the significant associated neuropsychological deficits were documented (Eiser, 1978; Eiser & Lansdown, 1977; Meadows & Evans, 1976; Meadows et al., 1981). Neuropsychology as a discipline has been central in identifying the role of CRT and, more recently, high-dose methotrexate and steroids on the neurodevelopmental trajectories of ALL survivors. Documenting the relations among host, treatment factors,

and neurocognitive outcome has helped shape modifications in treatment, which highlights the central role of neuropsychology in the specialty of pediatric oncology.

### Treatment Protocols

Early protocols utilized 24 Gy of CRT as CNS-directed therapy; while this was effective in eradicating leukemic cells that infiltrated the CNS, neuropsychological studies documented that intellectual level and academic skills declined after treatment, particularly in arithmetic (Eiser, 1978; Meadows et al., 1981; Moss, Nannis, & Poplack, 1981). An early meta-analysis documented an IQ loss of 9 to 10 points relative to controls and population norms (Cousens, Waters, Said, & Stevens, 1988). Beyond IQ, Dowell and colleagues reported effects on tests of memory and attention that were negatively correlated with radiation dose (Dowell, Copeland, Francis, Fletcher, & Stovall, 1991).

In the 1990s, CRT doses were reduced from 24 Gy to 18 Gy in an effort to mitigate neuropsychological late effects. This was achieved without affecting survival by increasing the intensity of chemotherapy. A dose effect was demonstrated in that intellectual outcomes were generally better after 18 Gy than 24 Gy (Halberg et al., 1992; Moore, Kramer, Wara, Halberg, & Ablin, 1991; Smibert, Anderson, Godber, & Ekert, 1996) although this was not a consistent finding (Mulhern, Ochs, & Kun, 1991; Rodgers, Britton, Kernahan, & Craft, 1991; Waber et al., 1995). But even at 18 Gy, CRT was associated with intellectual and academic declines in survivors (Rubenstein, Varni, & Katz, 1990). Declines in neuropsychological functions, including visual-motor integration, processing speed, attention, and short-term memory are most often reported in children treated with 18–24 Gy (Brouwers & Poplack, 1990; Reddick et al., 2006a; Schatz, Kramer, Ablin, & Matthay, 2000; Taylor, Albo, Phebus, Sachs, & Bierl, 1987) while verbal and language abilities are less frequently affected (Ciesielski et al., 1994). In the past decade, the customary dose of CRT, when necessary at all, has been reduced to 12 Gy, but long-term neuropsychological outcomes have yet to be reported.

With contemporary chemotherapy protocols, well over 80% of children with standard risk ALL can expect to survive for the long-term (Pui, Carroll, Meshinchi, & Arceci, 2011; Pui & Evans, 2006; Pui, Relling, & Downing, 2004). Current ALL treatment is designed to minimize adverse late effects while maintaining high survival rates. Late effects are less global and less severe in children treated with chemotherapy-only protocols (Buizer, de Sonnevill, & Veerman, 2009; Harila, Winqvist, Lanning, Bloigu, & Harila-Saari, 2009; Janzen & Spiegler, 2008; Spiegler et al., 2006). For this reason, current protocols omit CRT whenever possible. Patients are stratified according to risk of relapse: Low- and standard-risk patients typically receive chemotherapy-only regimens, while CRT is reserved for the 2%–20% of patients considered at high risk for CNS relapse on the basis of presentation or

genetic factors (Pui & Howard, 2008). Still, many patients treated with chemotherapy show some degree of neuropsychological impairment (Anderson & Kunin-Batson, 2009; Cheung & Krull, 2015; Conklin et al., 2012; Moleski, 2000). The literature on neuropsychological outcomes after treatment for childhood leukemia with chemotherapy suffers from small sample sizes and variations in sample characteristics, comparison groups, outcome measures, and length of follow-up. In a recent systematic review, Cheung and Krull (2015) confirmed that outcomes are better among this population compared to historical cohorts treated with CRT. But they also showed that cognitive impairments remain measurable, clustering in the domains of attention, executive function, memory, and motor function. In some cases, even when group mean differences do not attain statistical significance, the proportion of ALL survivors with scores below a predetermined cutoff (e.g., 2 SD below the mean) is significantly higher than expected in the normal population, indicating that the rate of significant impairment in the treatment group is increased.

Attention and working memory impairments are most commonly documented among children treated for ALL with chemotherapy only (Ashford et al., 2010; Conklin et al., 2012; Krull, Bhojwani et al., 2013). For example, when tested 120 weeks after completion of consolidation therapy, patients treated with chemotherapy only did not differ from general population means in the domains of cognitive development, academic abilities, learning, and memory. However, sustained attention was impaired, with a full 40% of the sample scoring below the predefined cutoff of 1 SD below the mean (Conklin et al., 2012). Executive function and processing speed (both motor and cognitive processing speed) are other commonly documented areas of impairment (Jansen et al., 2008; Kahalley et al., 2013; Mennes et al., 2005; Winter et al., 2014). Measures of general cognitive development (IQ) are often in the average range and not significantly different from population norms (Conklin et al., 2012; Jansen et al., 2006; Schatz et al., 2000). Several studies have shown that the intensity of chemotherapy, as reflected by the number and cumulative dose of methotrexate (MTX), is related to particular aspects of attention (Conklin et al., 2012; Krull, Bhojwani, et al., 2013). Further study of the factors and mechanisms associated with neuropsychological impairment in survivors treated with chemotherapy for ALL may lead to additional adjustments to treatment protocols and concomitant improvements in outcome.

### ***Risk Factors in Neuropsychological Outcomes***

In addition to treatment factors, such as history and dose of CRT, a number of host factors have been shown to moderate outcomes. Girls (Bleyer, 1990; Iuvone et al., 2002; Waber, Tarbell, Kahn, Gelber, & Sallan, 1992; Waber et al., 1990) and children radiated at a younger age are at greater risk for poor outcome (Bleyer, 1990; Cousens et al., 1988; Edelstein,

D'Agostino, et al., 2011; Jankovic et al., 1994; Jannoun, 1983; Kingma, Mooyaart, Kamps, Nieuwenhuizen, & Wilmink, 1993; Moss et al., 1981). Longer time since treatment is also associated with lower scores on intelligence and neuropsychological tests of speed and accuracy for survivors treated with CRT (Edelstein, D'Agostino, et al., 2011; Moore et al., 1991; Rubenstein et al., 1990). Some of the same moderators appear to be related to outcome for children treated with chemotherapy only. When an effect is found, it is usually in the same direction: Poorer outcomes are noted for girls and children who are younger at diagnosis and treatment (Buizer et al., 2009; Conklin et al., 2012). Time since diagnosis/treatment does not appear to moderate chemotherapy only treatment effects as it does for CRT (see Janzen & Spiegler, 2008 for review).

Because of the considerable variability in outcome for children treated with chemotherapy only, even after considering the known host and treatment factors, recent studies have investigated genetic polymorphisms and concepts such as brain and cognitive reserve as factors related to neuropsychological outcome. Genetic susceptibility to folate cycle dysfunction, which may be exaggerated by the antifolate MTX, has been suggested as a risk factor for chemotherapy-related neuropsychological deficits. That is, specific genetic polymorphisms may put children at more or less risk for poor neurocognitive outcome if it makes them more or less sensitive to the effects of particular chemotherapeutic agents. Krull and colleagues documented a relationship between folate pathway genetic polymorphisms and the development of attention and processing speed deficits after treatment for ALL in childhood (Kamdar et al., 2011; Krull et al., 2008). Children with specific 5,10-methylenetetrahydrofolate reductase (MTHFR) and methionine synthase (MS) polymorphisms scored more poorly on tests of attention and processing speed and the risk was greater in children who had more risk alleles in the folate pathway. This pattern was confirmed and extended in a more recent study in which children with a specific polymorphism in MS were more likely to show performance deficits in attention and response speed, while parent-reported attention problems were more common in children with a specific polymorphism in apolipoprotein E4 (Krull, Bhojwani, et al., 2013). As more is learned about genetic and epigenetic patterns in relation to neuropsychological outcomes in survivors of ALL, risk stratification may begin to incorporate individualized risk of neuropsychological and other late effects into personalized approaches to treatment.

### ***Methotrexate-Related Neurotoxicity***

Methotrexate is a core agent in the successful treatment of childhood leukemia. Intravenous and intrathecal routes of administration can be associated, in a minority of patients, with clinical neurological toxicities that are usually transient and reversible, but can be severe, and more rarely lead to

coma and/or death (Tufekci et al., 2011). Toxicities can be acute (hours after administration), subacute (days to weeks after administration), or chronic (months to years after administration). Acute toxicity may present with symptoms such as headache, nausea, vomiting, dizziness, confusion, and somnolence. Seizures may also occur. Subacute toxicity may be characterized by a stroke-like syndrome (SLS) including aphasia, dysarthria, dysphagia, diplopia, hemiparesis, and hemisensory deficits. In one series, the clearest risk factor for SLS was concomitant administration of IV cyclophosphamide and cytarabine (ara-C) (Bond et al., 2013). Chronic toxicity is usually characterized by leukoencephalopathy and disturbances of higher cognitive function (Mahadeo, Dhall, Panigrahy, Lastra, & Ettinger, 2010).

Case reports have described acute chorea (Necioglu Orken et al., 2009) delirium, agitation and encephalopathy (Summers, Abramowsky, & Cooper, 2014), SLS with hemiparesis, dysarthria, and emotional lability (Brugnoletti et al., 2009), generalized tonic-clonic seizures followed by right hemiparesis, aphasia, altered mental status, persistent seizures, and progressive neurological deterioration (Mahadeo et al., 2010). Most patients recover completely and the clinical deficits most often do not recur after further administration of MTX (Bhojwani et al., 2014; Bond et al., 2013).

A characteristic imaging pattern, reflecting leukoencephalopathy (LE), consists of white matter hyperintensities on diffusion weighted and T2 weighted MR images (Figure 12.3). The longitudinal prevalence of LE is related to dose and number of MTX exposures (Bhojwani et al., 2014; Reddick, Glass, Helton, et al., 2005), and can reach up to 85% after seven courses of MTX (Reddick, Glass, Helton, et al., 2005). The prevalence of LE declined by about half when the patients were scanned at week 120 of therapy, about 1.5 years after the last MTX treatment (Reddick, Glass, Helton, et al., 2005). Although this constitutes a significant reduction over

*Figure 12.3* A 12-year-old male diagnosed age 2 years with ALL and treated with chemotherapy and radiation (18Gy); periventricular deep white matter changes

time, about 40% of patients continued to show LE at this time point and it is unknown whether further normalization occurs over time.

Posterior reversible encephalopathy syndrome (PRES) is an uncommon MTX-associated toxicity (Dicuonzo et al., 2009) characterized by headaches, seizures, and focal neurological signs. Altered mental status and visual disturbances are also reported (de Laat et al., 2011). High blood pressure precedes symptom onset and the syndrome is thought to be associated with dysregulation of the cerebral vasculature, endothelial damage, capillary leakage and vasogenic edema (Figure 12.4). Some studies find that clinical and radiological recovery is the norm (de Laat et al., 2011), although this is not universal (Lucchini et al., 2008; Morris, Laningham, Sandlund, & Khan, 2007). Morris et al. (2007) found the majority of their 11 patients with PRES had irreversible sequelae in the form of abnormal electroencephalogram (EEG) with or without clinical seizures or radiographic abnormalities. Neurological evaluation was normal in all cases. Long-term

*Figure 12.4* Posterior reversible encephalopathy syndrome in a 4-year-old female being treated for ALL with intrathecal chemotherapy and developed seizures. MRI shows scattered areas of signal abnormality in the subcortical white matter at the posterior temporal lobes bilaterally, inferior right frontal lobe and both cerebellar hemispheres (cerebellum not shown in these images).

neuropsychological, cognitive, or developmental outcomes have not been described.

### ***Steroid Treatment***

Corticosteroids are a mainstay of treatment for ALL; either dexamethasone or prednisone is incorporated into every modern chemotherapy protocol. During the weeks of active steroid treatment, behavioral and emotional changes are frequently reported by families. Children are described as more emotional and harder to control, and significant sleep problems are noted. In a prospective design, Pound and colleagues (2012) demonstrated higher rates of externalizing disorders as described by parents of children older than 5 who were receiving steroids during maintenance therapy for ALL. Treatment with dexamethasone was associated with greater behavioral impairment than treatment with prednisone (Pound et al., 2012).

With respect to neuropsychological outcomes, Kadan-Lottick et al. (2009) found no significant differences between survivors who had been randomized to receive dexamethasone versus prednisone. However, another research group found that adult survivors of ALL who had been treated with dexamethasone exhibited weaker memory performance on multiple tests, than those treated with prednisone (Edelmann et al., 2013).

### **Brain Tumors**

Brain tumors are the second most common malignancy in childhood and the most common solid tumor. Survival rates have increased substantially over the past 20 years, although brain tumors continue to have the highest mortality of all childhood cancers (Ostrom et al., 2015). Overall five-year survival rates are 73.3% for children diagnosed between birth and 19 years; survival rates vary by tumor type and location: 95% for pilocytic astrocytoma, 65% for medulloblastoma and primitive neuroectodermal tumors, and 28.4% for high-grade glioma (Ostrom et al., 2015). Survival rates also vary by age group, with infants (< 1 year) having the lowest survival rates.

Risk factors for developing brain tumors in childhood include some genetic predisposition syndromes (e.g., Li-Fraumeni, Gorlin's syndrome, neurofibromatosis) and exposure to ionizing radiation (Hottinger & Khakoo, 2009; Preston-Martin, 1996). Other environmental risk factors (e.g., parental exposure to pesticides, advanced parental age, maternal intake of nitrosamines, maternal medications) have been investigated but research findings in these areas have been only suggestive or inconclusive (Grill & Owens, 2013; Johnson et al., 2014).

Brain tumors in children differ from adult onset disease in many respects. The brain is the primary site for intracranial malignancies in childhood, whereas for adults, brain tumors are more likely to be metastatic (originating in other primary

sites in the context of melanoma, or cancer of lung, breast, colon, etc.). The same histological type of tumor can carry a very different prognosis and respond to a different treatment depending on whether it occurs in the child or adult setting. Overall, survival rates for pediatric brain tumors are much more favorable than for adult-onset tumors. These findings support the notion that the childhood brain functions very differently with respect to brain tumor biology due to factors affecting the unique microcellular environment of the developing brain. It may be that in the near future, childhood brain tumors will be classified in a different manner than adult neoplasms, incorporating biologic, molecular genetic, and brain maturation factors, not just histology and location. Advances in developmental neuroscience and in the understanding of brain development in childhood are contributing to a more nuanced appreciation of why certain brain tumors emerge at different periods in development and how factors that regulate the sculpting of the brain contribute to tumorigenesis. Furthermore, concepts of selective vulnerability and plasticity are critical in evaluating the emergence and impact of brain insult at different epochs in development and in predicting late effects.

### ***Treatment Protocols***

Treatment for pediatric brain tumors varies by age, type of tumor, and location. Surgery is the first-line intervention in most cases if the tumor is in a resectable location; in general, extent of resection is a valuable prognostic indicator for event-free survival. Childhood brain tumors are often associated with hydrocephalus due to blockage of circulation of cerebral spinal fluid at the level of the third ventricle for sellar/suprasellar tumors and the fourth ventricle for posterior fossa tumors. Resection of the tumor can often treat the hydrocephalus but in some instances other procedures are needed such as placement of an external ventricular drain before surgery, ventriculostomy, or ventricular-peritoneal shunt.

Radiation therapy is required in the context of malignant tumors, incomplete resection, or progression. Radiation is avoided in very young children and in tumors associated with neurofibromatosis-1 as this is associated with unacceptable neuropsychological compromise in the former and with increased risk of second tumors or cerebrovascular abnormalities in the latter. Advances in radiation therapy include proton beam therapy that avoids the exit dose to normal brain tissue, thus sparing or lowering the dose to vital structures such as the medial temporal lobe, cochlea, and hypothalamus (Greenberger et al., 2014; MacDonald et al., 2008).

Chemotherapy has become an important tool in the management of childhood brain tumors, allowing for reduction of radiation dose and for targeting unique aspects of certain tumors. Chemotherapy regimens vary as a function of type of tumor. Cytotoxic chemotherapy was incorporated into treatment protocols and found to

be effective for medulloblastoma and low-grade gliomas. Currently, innovative and targeted therapies are being studied in clinical trials and used in treatment protocols; these include agents targeting angiogenesis (Kieran, 2005), immune response (Pollack, Jakacki, Butterfield, & Okada, 2013), and tumor-signaling pathways (Gerber et al., 2014; Nageswara Rao & Packer, 2012). The long-term effects of these therapies is as yet unknown and the basis of these treatments center on interrupting biologic mechanisms that may also support essential brain developmental processes. Consequently, monitoring of neuropsychological outcomes and late effects will need to be included in the ongoing study of these therapies.

### **Risk Factors in Neuropsychological Outcomes**

Children treated for brain tumors are at substantial risk for developing cognitive, academic, adaptive, and psychosocial impairments. For children treated with craniospinal radiation, particularly at a younger age, progressive decline in abilities occurs (Palmer et al., 2003; Palmer et al., 2001; Ris, Packer, Goldwein, Jones-Wallace, & Boyett, 2001). Contributing factors are multiple and interrelated, and have ongoing impact across development (Reimers et al., 2003). These factors include tissue damage related to location, brain response to injury, radiation field and intensity, surgical complications, hydrocephalus, and chemotherapy treatments. Direct impact of endocrine and motor/sensory deficits related to the tumor and its treatment can also compromise neuropsychological function. Host factors—such as age at diagnosis, time since treatment, psychosocial and family circumstances, socioeconomic status, and specific genetic vulnerabilities—are also critical variables. An individualized approach to understanding the role and relationships among these factors is needed in the long-term management of these children.

Advances in surgical techniques have the potential to improve long-term neuropsychological outcomes; MRI-guided surgery allows for more complete resections and can limit possible neurological injury (Choudhri, Klimo, Auschwitz, Whitehead, & Boop, 2014). Surgical sequelae remain challenging and these include perioperative stroke, neurological deficits, changes in physical appearance, and damage to pituitary/hypothalamic structures. Posterior fossa syndrome (PFS), also referred to as *cerebellar mutism*, is a complication of posterior fossa surgery that occurs more commonly in children than adults. The incidence reported in the literature varies, but clusters in the range of 25% following resection of posterior fossa tumors in children (Pollack, 1997; Robertson et al., 2006). Symptoms develop 12 to 48 hours after surgery and can include mutism or limited speech, dysarthria, ataxia, emotional lability, and personality changes. Cranial nerve deficits are also commonly seen. Treatment in a rehabilitation hospital is often needed to address speech/language, motor, and emotional dysfunction. PFS used to be referred

to as a “transient” complication since symptoms improve over time; however, long-term neurobehavioral sequelae persist. Impact on speech fluency and processing speed tends to be long lasting (Huber, Bradley, Spiegler, & Dennis, 2006). With respect to etiology, PFS appears to have increased in frequency over recent years and has been associated with more extensive tumor resection (Pitsika & Tsitouras, 2013). Various theories have been proposed related to the etiology of PFS: disruption of cerebellar (dentate nuclei)-thalamocortical pathways, incision/splitting of cerebellar vermis, and brain stem involvement are implicated as risk factors (Law et al., 2012; Pitsika & Tsitouras, 2013; Reed-Berendt et al., 2014). From a neuropsychological perspective, children who have PFS require ongoing follow-up and intervention. Persistent difficulties in speed of processing and production compromise functioning in academic, social, and emotional domains. In neuropsychological outcome studies of children treated for medulloblastoma, those who had PFS consistently demonstrate poorer performance (Knight et al., 2014; Palmer et al., 2010).

Hydrocephalus is a significant risk factor for compromise in neuropsychological functioning. Many brain tumors are associated with symptoms of increased intracranial pressure related to obstruction of cerebral spinal fluid flow. Cognitive and motor/sensory complications can ensue, often secondary to damage to periventricular white matter pathways. In a group of children with ependymoma, hydrocephalus at diagnosis was associated with increased risk of neuropsychological deficits, even after the effects of the tumor and treatment were accounted for (von Hoff et al., 2008). In a study of medical complications in children treated for posterior fossa tumors (cerebellar astrocytoma and medulloblastoma), Roncadin et al. (2008) noted that medical complications, such as increased intracranial pressure, affect long-term outcome, even in children who do not require additional tumor-directed treatment after surgery.

Radiation therapy is an essential modality of treatment for many pediatric brain tumors and doses are much higher in this context than for prophylactic treatment in ALL. For malignant embryonal tumors such as medulloblastoma, standard protocols include 24.3 Gy craniospinal to control disease across the neuroaxis, with a focal boost to the posterior fossa up to 54 Gy. Younger age at treatment is a critical risk factor for more severe neuropsychological late effects that can manifest years after treatment. Other important factors include dose, field, and critical brain structures involved. Radiation dose above the range of 20 Gy is likely to cause late effects in children (Thorp & Taylor, 2014): These include neuropsychological deficits, endocrine dysfunction including compromised fertility, hearing loss (particularly in the context of platinum-based chemotherapy agents), vision problems (cataracts), bone growth issues, vasculopathies, and increased risk of second malignancies (Fossati, Ricardi, & Orecchia, 2009; Shih, Loeffler, & Tarbell, 2009).

The pathophysiology of neuropsychological late effects after CRT in children treated for brain tumors is related to the increased vulnerability of rapidly developing brain processes to toxicity. CRT can disrupt the blood-brain barrier through damage to cerebral vascular endothelium, selectively injure oligodendrocyte progenitor cells critical for myelination, and affect the microcellular environment that supports neurogenesis in the hippocampal region (Dietrich, Monje, Wefel, & Meyers, 2008; Gibson & Monje, 2012). Consequently, psychological processes such as working memory, processing speed, and attention, are commonly affected in children treated with CRT for brain tumors and contribute to declines in ability over time (Mabbott, Penkman, Witol, Strother, & Bouffet, 2008). Decline in intellectual ability is related to failure to acquire new skills at the expected rate for age, rather than loss of skills or developmental regression (Palmer, 2008). Studies have documented decreased volume of white matter in survivors of childhood brain tumors that is correlated with reduced neuropsychological function (Merchant, Kiehna, Li, Xiong, & Mulhern, 2005; Reddick, Glass, Palmer, et al., 2005; Reddick et al., 2006b; Reddick et al., 2003a; Reddick et al., 2003b). Processing speed is particularly vulnerable in children treated for brain tumors. In a prospective study that examined change in these processes over time, scores on processing speed tests declined following treatment for medulloblastoma with surgery, CRT, and chemotherapy (Palmer et al., 2013). Younger age at diagnosis, more intensive treatment and higher radiation dose due to high-risk disease, and higher baseline scores contributed to a steeper decline in processing speed. Similar findings were found for working memory and broad attention, but processing speed scores were the lowest. These same factors (younger age at diagnosis and higher intensity treatment) are associated with reduced white matter volume relative to peers; the discrepancy in white matter volume as compared to peers increases over time (Reddick et al., 2014).

Chemotherapy has become increasingly useful in the treatment of childhood brain tumors. It is an important component of protocols for malignant embryonal tumors, for young children, and for low-grade glioma. The late effects of chemotherapy in the treatment of brain tumors need to be considered in the context of other factors such as type and location of tumor, complications, and combination with other therapies. Various types of chemotherapy agents are used in the treatment of brain tumors that have different side-effect and long-term risk profiles (Gururangan, 2009). As described on p. 160, antimetabolites such as MTX affect white matter integrity. Vinca alkaloids (vincristine) can cause peripheral neuropathy that can persist after treatment. Sensorineural hearing loss is associated with the use of platinum-based agents such as carboplatin and cisplatin. CRT exacerbates the risk of hearing loss, which needs to be monitored periodically over time as the loss can be progressive and does not necessarily emerge during or immediately

after treatment. The late effects of newer chemotherapy treatments on the developing child are as yet unknown.

### ***Types of Brain Tumors and Neuropsychological Outcomes***

#### ***Low-grade glioma***

Low-grade gliomas are common brain tumors in childhood; they vary in histology and location. Pilocytic astrocytoma is the most frequently diagnosed pediatric low-grade glioma, often occurring in the cerebellum (Figure 12.5) (Bergthold et al., 2014). Survival rates are very high: A recent review of outcomes from 1973 to 2008 demonstrated a long-term (20 year) survival rate of 87% (Bandopadhyay et al., 2014). Surgery, if possible, is the primary treatment and often the only treatment needed. For tumors in the optic pathway, hypothalamus, or brain stem, surgery may not be an option or be incomplete due to risk of neurological complications. Chemotherapy is often used to treat progression seen on imaging or exacerbation of symptoms. Despite excellent survival and more limited use of CRT in this population, neurobehavioral outcomes can be compromised due to effects of the tumor and treatment. In a study of survivors of low-grade gliomas treated with surgery only, medical late effects were common. Overall intellectual ability for this cohort is generally in the average range, though investigators find that a larger proportion of the group performs in the below average range on measures of intelligence, executive function,

**Figure 12.5** Juvenile pilocytic astrocytoma in the cerebellum: T2-weighted MRI shows astrocytoma in cerebellum with cystic and solid components

and adaptive skills (Beebe & Ris, 2001; Ris et al., 2008; Turner et al., 2009). In this group with normal intelligence, compromise in executive function had a greater impact on overall adaptive skills and level of independence than intellectual ability.

### *Craniopharyngioma*

Craniopharyngioma is a relatively rare tumor of the sellar/suprasellar region that accounts for 4% of brain tumors in children less than 14 years of age (Ostrom et al., 2015). It arises from remnants of Rathke's pouch, from which the pituitary develops in embryological development. Though technically a benign tumor, it often recurs and its location near to and invasion of critical brain structures such as the optic nerves and chiasm, hypothalamus, pituitary, and vascular structures of the circle of Willis contribute to its significant morbidity (Figure 12.6). Although survival rates are high, neuropsychological, psychosocial, and medical late effects significantly compromise quality of life (Lo et al., 2014). There is considerable controversy regarding treatment strategies for craniopharyngioma; extent of surgical resection is associated with risk of recurrence, though more aggressive surgery is believed to cause more extensive damage to the hypothalamic-pituitary-axis (Müller, 2014; Zygourakis et al., 2014). Radiation therapy is used in the context of incomplete resection and progression. Studies from St. Jude Children's Research Hospital note more favorable outcomes with respect to intellectual ability in those treated with more limited surgery plus radiation as compared to gross total resection (Merchant et al., 2002). Children diagnosed with craniopharyngioma often present with headaches as well as evidence of neuroendocrine dysfunction and vision changes (Müller, 2014; Ullrich, Scott, & Pomeroy, 2005). Endocrine dysfunction continues postsurgery and most survivors have pituitary hormone deficiencies (diabetes insipidus, hypothyroidism,

adrenal insufficiency, growth hormone deficiency, and sex hormone deficiency). Hypothalamic dysfunction causes obesity, daytime sleepiness, sleep disturbance, circadian rhythm irregularities, and problems regulating body temperature. Visual acuity as well as visual fields can be affected due to the pressure effects of the tumor and hydrocephalus, or surgical damage to the optic pathway or vascular supply (Ullrich et al., 2005). Specific neurobehavioral sequelae are seen in memory, executive function (initiation, inhibitory control, organization), and emotional regulation (Carpentieri et al., 2001; Ullrich et al., 2005; Waber et al., 2006). Memory problems affect the child's ability to encode and retrieve material as well as to track everyday activities and are likely a consequence of disturbance in limbic pathways secondary to the tumor and surgery. The combination of complex medical issues and neuropsychological dysfunction contributes to adverse quality of life despite generally average intellectual ability. Hypothalamic obesity is a significant health and psychosocial problem. Survivors of craniopharyngioma can have symptoms similar to Prader-Willi syndrome, with unremitting food-seeking behaviors and limited regulation of affect and aggression. In severe cases, specialized residential programming can be required. A recent systematic review of psychological and social outcomes found a high incidence of school problems, emotional and behavioral difficulties, and social isolation in survivors of pediatric craniopharyngioma (Zada, Kintz, Pulido, & Amezcua, 2013).

### *Medulloblastoma*

Medulloblastoma is a malignant embryonal tumor that occurs in the cerebellum (Figure 12.7). It can occur at all ages in childhood and is rarely seen in adults; the incidence is highest between the ages of 4 and 7 years. Since it has the propensity to disseminate across the neuroaxis, multimodality treatment including surgery, CRT, and chemotherapy is

**Figure 12.6** Craniopharyngioma: MRI shows tumor in region of third ventricle and evidence of transependymal flow secondary to obstructive hydrocephalus (image 1); dilated ventricles (image 2)

*Figure 12.7* Medulloblastoma: MRI shows large, enhancing midline cerebellar tumor (image 1) and tumor obstructing fourth ventricle and associated obstructive hydrocephalus (image 2)

given in most cases. Presenting symptoms often are related to increased intracranial pressure due to hydrocephalus or signs of cerebellar dysfunction. Surgical resection and management of hydrocephalus are the first steps in treatment. Children with medulloblastoma have been traditionally classified into standard or high risk based on clinical factors such as age at diagnosis, degree of dissemination/metastasis, and extent of residual disease postsurgery. Advances in molecular biology now demonstrate that medulloblastoma is a much more heterogeneous disease than previously thought. Gene expression patterns are now used to distinguish four different subgroups, each having different profiles of incidence in specific groups, neurodevelopmental origin, response to treatment, and clinical implications (Gibson et al., 2010; Northcott, Korshunov, Pfister, & Taylor, 2012; Northcott et al., 2011; Taylor et al., 2012). Based on these stratification variables, future treatment protocols will be able to treat specific subgroups with less intense regimens that will reduce toxicity and late effects. In addition, targeted therapies can be developed based on gene expression and signaling pathways.

Survival rates for standard-risk medulloblastoma are now quite high but late effects compromising health status and neuropsychological and adaptive function are common. Tumor location in the cerebellum is an important factor given the now-accepted notion that the cerebellum is critically involved in cognitive as well as motor function in the brain. Associated hydrocephalus and other complications as well as high-dose CRT are associated with adverse neuropsychological outcomes. Studies consistently demonstrate a decline in IQ over time, and this decline is more pronounced in survivors who were younger at diagnosis and who had higher functioning at baseline; decline in IQ is estimated at 2 to 4 points per year (Palmer et al., 2001; Ris et al., 2001; Spiegel et al., 2006). This pattern of decline in intellectual and academic abilities is seen even when CRT dose is reduced (Ris et al., 2013).

Working memory, attention, and processing speed are believed to be core deficits in children treated for medulloblastoma that in turn compromise neuropsychological and academic progress over time (Mabbott et al., 2008; Palmer et al., 2013). In our clinical experience, children, adolescents, and young adults treated for medulloblastoma often encounter difficulties with higher-order integrative skills that emerge over time, even in the context of normal intellectual ability. Progressive decline in abilities is presumed to be related to volume reductions in white matter (Palmer, 2008) and in the hippocampus (Nagel et al., 2004). Recent studies using diffusion tensor imaging reveal damage to cerebro-cerebellar pathways in children treated for medulloblastoma (Law et al., 2015), as well as reductions in fractional anisotropy associated with decreased intellectual ability (Khong et al., 2006; Mabbott, Noseworthy, Bouffet, Rockel, & Laughlin, 2006; Rueckriegel et al., 2010). These findings support the notion that children treated for medulloblastoma have an evolving brain injury that affects development in a dynamic and interactive way throughout development.

### **Adult Outcomes, Cognitive Reserve, and Early Aging in Childhood Cancer Survivors**

There were 388,501 survivors of childhood cancer alive in the United States as of 2011 and this number is expected to increase in coming years (Phillips et al., 2015). Survival into adulthood is now the expectation. In 2011 there were more than twice as many adult survivors of childhood CNS cancer than ALL in the over-40 age group; however, the number of ALL survivors is expected to increase substantially as current childhood/young adult survivors move into later adulthood. The quality of adult survivorship is an area of active research efforts with findings that are relevant for adult and pediatric neuropsychology practice. The Childhood Cancer Survivor Study (CCSS) is an important resource for understanding

adult outcomes of childhood cancers. The study uses periodic surveys to track the outcomes of approximately 14,000 participants treated for childhood cancer between 1970 and 1986, comparing findings to sibling controls (Robison et al., 2005; Robison et al., 2002). Participants were recruited from cancer centers across North America and represent a geographically and socioeconomically diverse cohort. The CCSS is a rich source of information regarding the long-term quality of life, health, and social outcomes of survivors. In general, adult survivors of childhood cancer are more likely to have chronic health-related problems and the prevalence of these problems increases with age (Hudson et al., 2015; Oeffinger et al., 2006). Adverse health outcomes experienced by childhood cancer survivors include increased risk of infertility (Barton et al., 2013), physical performance limitations (Rueegg et al., 2012), endocrine and cardiovascular problems (Gurney et al., 2003), higher hospitalization rates (Kurt et al., 2011), and pulmonary complications (Huang et al., 2014). Additionally, the risk of second neoplasms is substantially higher in survivors of childhood cancer compared to siblings; those treated with radiation, treated in an earlier era, of female sex, and with diagnosis of Hodgkin lymphoma were more likely to develop a subsequent malignancy (Friedman et al., 2010).

In most of these adult outcome studies, survivors treated with CRT were more likely to experience adverse health and quality of life outcomes (Armstrong, Stovall, & Robison, 2010), including stroke and sensory-motor impairments (Bowers et al., 2006; Packer et al., 2003). A dose-dependent relationship exists between risk of stroke in adulthood and prior treatment with CRT (Mueller et al., 2013).

Psychosocial and adaptive outcomes are notable for increased likelihood of special education, lower employment status, and decreased rate of marriage and college attendance; these outcomes were more common in survivors with cancers or treatment affecting the CNS (Gurney et al., 2009). Employment limitations (likelihood of lower-skill occupations) were more likely in survivors who were Black, of younger age at diagnosis, or treated with high-dose CRT (Kirchhoff et al., 2011).

The CCSS provides valuable insights into the life span outcomes of childhood cancer survivors. The outcomes of children currently undergoing treatment for ALL and CNS tumors may be moderated somewhat given the marked changes and refinements in treatment protocols that are now being used. Nevertheless, the combined impact of CNS-directed treatment and chronic health conditions will continue to affect long-term adult outcomes and we need to be increasingly concerned with how survivors navigate the developmental challenges of later adulthood (Ris & Hisock, 2013).

*Cognitive reserve* represents the idea that an individual's ability to cope with brain injury of any type is related to genetic, environmental, and/or experiential factors that can mediate brain or cognitive resources. A person with higher

cognitive reserve can theoretically maintain better cognitive function than a person with lower cognitive reserve, after sustaining a comparable degree of brain injury (Stern, 2009). Kesler et al. (2010) explored the concept of cognitive reserve, as indexed by maternal education, as a moderator of outcome in children treated for ALL with chemotherapy only. Their index of cognitive reserve was directly related to cognitive performance on tests of verbal learning and working memory for ALL survivors. Furthermore, as predicted, cognitive reserve was inversely related to brain white matter volume of ALL survivors, suggesting that children with higher cognitive reserve could withstand more WM damage before exhibiting cognitive changes.

Another way to think about the contribution of cognitive reserve in this population is to study outcome in children treated for ALL who come into their diagnosis with premorbid developmental vulnerabilities, another expression of reduced cognitive reserve. Children with preexisting developmental vulnerabilities comprise up to 25% of new ALL diagnoses (Janzen et al., 2015) yet are systematically excluded from neuropsychological outcome studies. A recent study of children with Down syndrome (DS) who were also survivors of ALL documented a pattern of deficits in multiple neuropsychological domains and in overall adaptive function, in comparison to children with DS who had not been treated for cancer (Roncadin et al., 2014).

Recently, several studies of 20–25 year outcomes have been published, comparing adult survivors treated for ALL in childhood with CRT to those treated with chemotherapy only. Without exception, adults treated with CRT in childhood fare more poorly on a variety of measures than those treated with chemotherapy. Among nearly 2,000 adult survivors of ALL in the CCSS, self-reported neurocognitive function was worse than sibling controls on measures of task efficiency, memory, and emotional regulation for the subgroup that had been treated with CRT. Higher dose of CRT (>18 Gy) was associated with greater risk of impairment than lower dose (Kadan-Lottick et al., 2010).

Similar findings are seen for the 2,000 survivors of CNS tumors in the CCSS cohort who consistently reported more problems in neurocognitive function than survivors of other types of childhood cancer. Impairments in neurocognitive functioning were correlated with CRT dose; impairments in memory were associated with higher CRT dose to the temporal brain regions, with CRT to the frontal regions associated with more health problems and physical disabilities (Armstrong et al., 2010). The types of neuropsychological problems noted in adult survivors that affect working memory and information processing (Ellenberg et al., 2009) mirror the cognitive difficulties associated with aging.

The concept of accelerated aging was framed in the context of biological and cognitive reserve by Dennis, Spiegler, and Hetherington (2000). This concept is now being discussed in the context of adult survivors of childhood cancer (Armstrong, 2013). Data supporting accelerated aging

have been reported for adult survivors of ALL treated with CRT in childhood who have now reached middle adulthood (Schuitema et al., 2013). Changes in spectral power on MEG imaging that are characteristic of the aging brain were demonstrated in adult survivors of ALL treated with CRT in childhood, but not in survivors treated with chemotherapy only (Daams et al., 2012). The documented pattern of change in white matter integrity (decreased fractional anisotropy-FA) with increasing age in ALL survivors 25 years after treatment with CRT mimics aging in its pattern and progression. However, the rate of decline was accelerated when compared to healthy controls. Lower FA was correlated with both cumulative radiation dose and younger age at treatment. Lower FA was also correlated with performance on tests of visual-motor function on a computerized test battery. In contrast, survivors treated with chemotherapy only did not show the pattern of white matter changes characteristic of accelerated aging.

Early aging was also suggested by the high rate of impairment in a range of neuropsychological outcome measures in another group of ALL survivors a mean of 25 years post-diagnosis. Increasing risk of impaired executive function was associated with longer time from diagnosis. Compared to a group of survivors treated with chemotherapy only, patients treated with 24 Gy CRT were at six times the risk for impaired executive function after 45 years (Krull, Brinkman, et al., 2013).

Perhaps of most concern is the finding that adult survivors of ALL who were treated with 24 Gy CRT and tested in their early 40s, with a median time since treatment of 30 years, demonstrated very high rates of immediate and delayed memory impairment. The mean performance on a test of delayed story memory was comparable to population expectations for adults over the age of 69! On tests of word pair recall and visual reproduction, performance was comparable to expectations for the 55–64 year old group in the general population. Early onset of delayed memory impairment but without functional impairment (employment rates did not differ among the groups) is suggestive of mild cognitive impairment and may reflect the reduced cognitive reserve induced by CRT in childhood. In support of this argument is the finding that the group of survivors with memory impairment also showed changes on structural and functional imaging in patterns similar to that seen in older adults with mild cognitive impairment (Armstrong et al., 2013).

Adult survivors of childhood brain tumors are at increased risk of a number of late effects, many of which compromise neurological and neuropsychological function. Long-term follow-up studies continue to clarify the quality of survival for these patients. Similar to research with the CCSS, findings from European studies of survivors of childhood brain tumors reveal lower educational achievement, more restricted employment opportunities, lower income, and lower likelihood of living independently (Boman, Lindblad, & Hjern, 2010; Koch et al., 2006; Kuehni et al., 2012).

Marriage, employment, income level, participation in physical activities, and social engagement are all protective factors relative to quality of life and decline in older adults; survivors of childhood brain tumors may be at increased risk of early aging due to multiple sources of reduced brain and cognitive reserve.

Signs of early aging are seen in adult survivors of medulloblastoma in declining working memory performance over time (Edelstein, Spiegel, et al., 2011). Ris and colleagues (Ris, 2014) are currently studying adult outcomes of survivors of childhood low-grade gliomas in a multisite study using the CCSS cohort (NIH/NCI R01 CA132899–01). Preliminary findings reveal more survivors relative to controls with more limited education and at the lower extremes of income, particularly for those treated with surgery and CRT. Motor, sensory, and neurological impairments were more common in the brain tumor survivor group as compared to a sibling control group. With respect to neuropsychological outcomes, the proportion of survivors scoring below the expected range was much higher than expected on measures sensitive to the effects of aging and in attention. The goal of this study is to identify factors that contribute to accelerated cognitive aging in this population and the role of cognitive reserve in mitigating cognitive decline.

A proportion of emerging adult survivors of brain tumors may have significant compromise of cognitive, physical, and social skills. Consequently, degree of independence with respect to major financial, social, and medical decision making needs to be assessed in order to provide optimal care and guidance to patients and their families and health care providers. Neuropsychologists play a unique role in the care team at this time of developmental transition.

## Special Issues

### *Adolescence/Young Adulthood*

When an adolescent or young adult (AYA) is diagnosed with cancer, an entirely different set of treatment, adaptive, and psychosocial challenges require individualized management that recognizes the unique needs of this population as they transition to adulthood. During this phase of “emerging adulthood,” promoting a sense of normalcy is crucial to health-related quality of life. Developmental challenges at this stage involve enhancing and increasing social and financial autonomy, increasing independence from parents, developing personal and unique values and identity, focusing on peer relationships—including intimate and sexual relationships—and preparing to join the workforce. Optimal care requires flexibility on the part of the care team, because dealing with illness and following through with treatment regimens can be challenging (Windebank & Spinetta, 2008). The team must develop sensitivity to the unique developmental needs of the AYA population; they must learn to provide information in a respectful and open manner, openly address

issues of sexuality and fertility, and address academic, vocational, and financial concerns (D'Agostino, Penney, & Zebrack, 2011).

The survival rates for the AYA population continue to lag behind younger children for several reasons. The psychosocial and biological changes that are characteristic of the AYA population contribute to delays in diagnosis and also relate to the types of cancer seen and treatment outcomes. Presenting symptoms may be difficult to distinguish from normal maturational changes at this time. Once diagnosed, patients in this age group are less likely to participate in clinical trials, which can limit advances in knowledge and treatment outcomes (Ferrari, Montello, Budd, & Bleyer, 2008). Treatment compliance can suffer when the AYA patient is not under the full-time care of a parent; managing issues of independence and complex treatment protocols can be challenging. Longer-term longitudinal studies are often not undertaken and lack of coordination from pediatric to adult health care can contribute to poor continuity in follow-up and management. Because the types of cancer most commonly diagnosed in the AYA population differ from both the pediatric and the older adult population, different treatments and clinical trial recruitment strategies are required if survival rates are to improve (Burke, Albritton, & Marina, 2007).

For the AYA patient diagnosed with ALL, poorer outcomes are likely due to a combination of biological factors (higher incidence of Philadelphia chromosome, higher incidence of high risk (T-cell) ALL), treatment with adult rather than pediatric-like regimens, and poorer compliance with treatment (Figure 12.8) (Pui et al., 2011; Pui & Howard, 2008).

In the AYA age group, both brain tumor location and histology differ from younger children: Embryonal tumors become much less common, and pituitary and germ cell tumors increase in frequency, suggesting that processes associated with puberty have an impact on the brain environment and tumorigenesis such that different biological mechanisms are involved (Bleyer et al., 2008). Outcomes for the same tumor type can vary whether it is diagnosed in

adolescence or early adulthood; for example, prognosis for low-grade gliomas varies by age, and adolescents are more likely to respond to chemotherapy regimens that may not be as effective in adulthood.

### *Opsoclonus Myoclonus Ataxia Syndrome*

Opsoclonus myoclonus ataxia syndrome (OMA) is a rare autoimmune disorder that occurs as a paraneoplastic phenomenon in a small proportion (2%–3%) of children diagnosed with neuroblastoma (Hayward et al., 2001; Mitchell et al., 2002; Rudnick et al., 2001). The mechanism is thought to be cross-reactive autoimmunity between neuroblastoma cells and nervous system cells, particularly affecting cells in the cerebellum. Children with neuroblastoma and OMA generally have lower-stage disease and excellent outcomes of their cancer diagnosis (Russo, Cohn, Petruzzi, & de Alarcon, 1997). This may be explained by the hypothesis that higher autoimmune response limits tumor growth, and thus is associated with lower-stage disease. This higher autoimmune response then also attacks healthy neurons, leading to OMA.

### *Presentation*

Children often present with symptoms of OMA before the diagnosis of neuroblastoma is made. Presentation is characterized by a unique constellation of neurological, cognitive, and behavioral features. Neurological symptoms include involuntary conjugate eye movements (opsoclonus), ataxia, and involuntary jerking of limbs and trunk (myoclonus). Sleep disturbance is common, with more than 90% of parents reporting sleep disturbance in their children with OMA (Pranzatelli et al., 2005). Cognitive or neuropsychological features include regression and impairments in speech and language, attention, and fine and gross motor skills. Behavior often becomes highly disruptive, with irritability, aggression, and rage attacks quite unlike the child's premorbid personality (Pranzatelli et al., 2005; Turkel, Brumm, Mitchell, & Tavare, 2006). Children are described as inconsolable, aggressive (biting, kicking, hair pulling, head banging) and set off by minor frustrations, not getting their way, trivial provocations, or no apparent reason. These episodes are easily distinguished from normal tantrums by severity and duration, with rage attacks lasting from 20 minutes to several hours. They are more frequent in children with disrupted sleep. These marked changes in sleep and behavior can be especially distressing and difficult to manage. Treatment with trazodone improved sleep and behavior in 95% of those treated, with a 72% increase in total sleep time and a 33% reduction in rage attacks (Pranzatelli et al., 2005).

### *Treatment*

Treatment is aimed at reducing autoimmune reactivity, and commonly involves oral corticosteroids, adrenocorticotropic

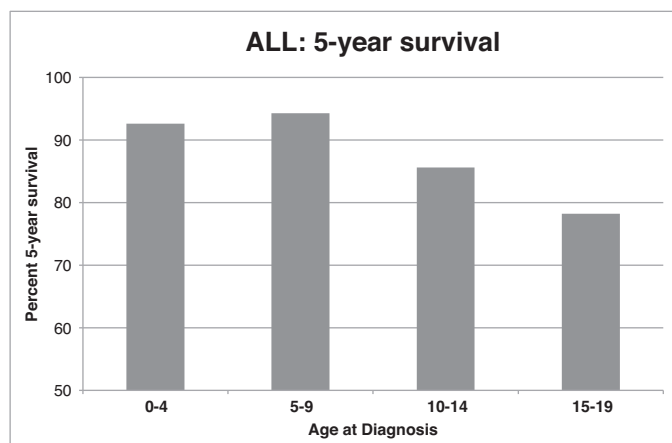

Figure 12.8 5 Year survival Rates for ALL and age at diagnosis

hormone, intravenous immunoglobulin, chemotherapy, or some combination of these. More recently, rituximab (anti-CD20 monoclonal antibody) has shown promising preliminary efficacy (Brunklaus, Pohl, Zuberi, & de Sousa, 2011). Children often require treatment for months to years as most tend to relapse with attempts to wean treatment or as a function of intercurrent infection.

#### *Long-term outcome*

Unlike the neuropsychological late effects associated with treatment for pediatric cancers, OMA is associated with long-term speech and language impairment and behavioral disorders, as well as significant cognitive deficits (Mitchell et al., 2002). The neurological symptoms of OMA (opsoclonus, myoclonus, and ataxia) tend to respond to treatment and improve slowly over time, but other symptoms are long-lasting, even if small improvements are achieved (Catsman-Berrevoets et al., 2009; Mitchell et al., 2005; Russo et al., 1997). General cognitive development can remain well below average, often in the borderline range (Brunklaus et al., 2011; Catsman-Berrevoets et al., 2009; Mitchell et al., 2002; Papero, 1995; Turkel, 2006). Speech impairment is characterized by low intelligibility associated with motor features of oral, phonatory, and respiratory incoordination (Brunklaus et al., 2011; Catsman-Berrevoets et al., 2009; Mitchell et al., 2002; Papero et al., 1995). Expressive language is generally more impaired than receptive language (De Grandis et al., 2009; Papero et al., 1995). Psychiatric and behavioral features persist in about 70% of cases (De Grandis et al., 2009) with attention deficit, irritability, dysphoric mood, and poor affective regulation (Brunklaus et al., 2011; Catsman-Berrevoets et al., 2009; Mitchell et al., 2002; Turkel et al., 2006). Quality of life estimates from parents reveal impairments in autonomy, and cognitive and social function. This pattern of neurobehavioral symptoms may represent an extreme example of cerebellar cognitive affective syndrome (Schmahmann & Sherman, 1998).

#### *Prognosis*

The most consistent prognostic feature is course of illness. A minority of patients have a monophasic course (they can be tapered from treatment without relapse) and these children tend to have a better cognitive outcome than those who have multiple relapses (Brunklaus et al., 2011; De Grandis et al., 2009; Klein, Schmitt, & Boltshauser, 2007). Although numbers are small, Mitchell et al. (2005) showed that the majority of children with a monophasic course can achieve normal range performance on cognitive, behavioral, and adaptive measures.

Children with initially more severe OMA symptoms tended to have a chronic relapsing course more often than those with mild initial symptoms which, in turn, predict cognitive problems in the long term (Brunklaus et al., 2011). Treatment

type or length was not associated with differences in cognitive, adaptive, or motor outcome (Catsman-Berrevoets et al., 2009; Mitchell et al., 2002). When followed over a period of years, it appears that small improvements can be documented (Brunklaus et al., 2011; Mitchell et al., 2005); in any event, the prognosis is not one of progressive deterioration. Longer length of follow-up has been associated with better outcomes (Hayward et al., 2001), another piece of evidence that the condition tends to slowly improve over time. One study suggested that younger children improve more than older children (Mitchell et al., 2005) while another showed that children who were younger at diagnosis and had more severe initial symptoms were more likely to have cognitive problems in the long run (Brunklaus et al., 2011). Russo et al. (1997) did not find an association between age at diagnosis and outcome or persistence of symptoms.

Time between symptom onset and diagnosis/treatment, or *diagnostic delay*, has been explored as a prognostic factor. In one study, longer diagnostic delay was associated with worse outcome on measures of memory, motor function, and behavior (De Grandis et al., 2009). More often, however, no differences in cognitive, adaptive, or motor outcome were documented as a function of diagnostic delay (Catsman-Berrevoets et al., 2009; Hayward et al., 2001; Koh et al., 1994; Mitchell et al., 2002; Russo et al., 1997). Degree of response to initial treatment did not consistently predict outcome (Brunklaus et al., 2011; Russo et al., 1997).

Paradoxically, Rudnick and colleagues (2001) showed that patients with more advanced stage neuroblastoma and OMA had better neurological outcomes, perhaps due to a diminished immune response to tumor in these patients (leading to more aggressive tumor growth/spread) and also sparing normal neurons. The effect of steroid treatment on the development of the young brain has not been directly addressed in these studies.

#### ***Infant ALL and Brain Tumors***

Survival rates for infants (defined as under 1 year of age at diagnosis) with ALL have historically been far lower than for older children, and even in a recent trial, the 4-year event-free survival (EFS) for infant ALL was only 47%. This is due in part to a more aggressive biology in a vulnerable host (Brown, 2013). This rare condition often presents with high white blood cell counts, CNS involvement, hepatosplenomegaly, and skin infiltration.

MLL gene rearrangements (MLL-r) occur in 5% of childhood ALL cases overall, but in 70% to 80% of infant ALL. The presence of this genetic signature is associated with poorer outcomes. In CCG-1953, the five-year EFS for MLL-r infants was 34% compared with 60% with germline MLL (MLL-g) (Brown, 2013). Younger age and higher white blood count at diagnosis were independent predictors of poor outcome. A common pattern of response to chemotherapy is to achieve rapid complete remission, but then to relapse in

the first year, suggesting the emergence of chemo-resistant cell populations. Another risk for these young patients is that infants are more vulnerable to complications and toxicities than are older children. They are particularly vulnerable to infection, and early mortality from treatment-related complications is much more common among infants.

For those infants who do survive, cognitive outcomes are poor, especially for survivors of CRT at such a young age. Babies under the age of 2 treated with 18–24 Gy displayed significant deficits in overall intellectual ability, math, and memory when tested five to ten years after diagnosis and compared to cancer controls (Mulhern et al., 1992). Longer time since treatment was correlated with lower IQ and poorer performance on tests of auditory long-term memory and math achievement. Therefore, all efforts are made to avoid CRT in infants with ALL. When chemotherapy-only regimens are used, neurodevelopmental outcomes improve dramatically. Infants treated with an intense chemotherapy protocol and without CRT had mean developmental estimates in the average range at four to five years postdiagnosis (Kaleita, Reaman, MacLean, Sather, & Whitt, 1999). At a median of 13 years postdiagnosis, specialized tutoring or special education placement was reported for 10% of infant ALL survivors treated with chemotherapy only; 59% of those treated with chemotherapy and CRT; and 86% of those treated with chemotherapy, CRT, and bone marrow transplant. For every month younger a child was at CRT, the estimated odds of academic problems increased by 18% (Leung et al., 2000).

Brain tumors that present in infancy are also particularly challenging to treat. Similar to ALL, tumors in this age group tend to be more aggressive and these children are more vulnerable to brain injury. Given the unacceptable side effects of radiotherapy at this young age, treatment options are limited. Delay in diagnosis, as well as increased vulnerability to surgical complications in this age group, also present challenges for management (Bishop, McDonald, Chang, & Esiashvili, 2010; Van Poppel et al., 2011).

New treatment protocols for young children with malignant brain tumors are showing some promise of improved survival and disease control (Rutkowski et al., 2005). Use of CRT in young children has declined and is typically deferred to the extent possible (Bishop et al., 2010). Innovative strategies include use of high-dose chemotherapy that can be followed by autologous stem cell transplant (Dhall et al., 2008). In European protocols for malignant brain tumors in infants, intraventricular methotrexate is used during induction and high-dose chemotherapy treatment (Friedrich et al., 2013; Rutkowski et al., 2010). Overall survival has been favorable for children with medulloblastoma (93%) and less favorable for children with other malignant tumor types (Friedrich et al., 2013). In children who do not respond to induction or who have progressive disease, radiation therapy is then used as a salvage treatment.

Studies of neuropsychological outcomes in this group are limited due to small numbers, changes in treatment (some

children go on to receive CRT), use of historical controls for comparison, and lack of longer-term follow-up. Imaging studies show evidence of leukoencephalopathy during and after treatment that improves in some patients over time; the long-term implications of these findings are unclear (Rutkowski et al., 2010). In a study of children treated with high-dose myeloablative therapy and autologous stem cell transplantation, neuropsychological outcomes remained fairly stable over a 12-year follow up period (Guerry, Finlay, & Sands, 2014). This is in marked contrast to the findings of decline in neuropsychological function seen in children treated with CRT for medulloblastoma.

## Intervention and Treatment

Even after decades of studying and documenting neuropsychological late effects in survivors of childhood cancer, and relating them to host and treatment factors, much still remains to be understood. As reviewed in this chapter, efforts to reduce late effects of ALL treatment have taken the form of reducing dose and field of radiation or eliminating CRT entirely, especially in young children, and by replacing CRT with more intense and multimodal chemotherapy. For children with brain tumors, reduction of radiation dose or field, or elimination of CRT, has been achieved through refinements in risk stratification strategies and the addition of chemotherapy. These efforts have been successful in reducing the frequency and severity of neuropsychological deficits. Nonetheless, many are now turning to the study of interventions to prevent or ameliorate neuropsychological late effects when they do occur (Askins & Moore, 2008). Intervention efforts take several forms: pharmacological, behavioral, cognitive, educational, and social (Castellino, Ullrich, Whelen, & Lange, 2014).

### Pharmacological

Pharmacological interventions are used to address specific cognitive or emotional symptoms. Because the attention deficits exhibited by survivors of pediatric cancers treated with CNS-direct chemotherapy and CRT are reminiscent of children with ADHD, methylphenidate (MPH) has been used in an attempt to treat those symptoms. Early reports were observational in nature and variable in outcome (DeLong, Friedman, Friedman, Gustafson, & Oakes, 1992): Eight of 12 patients with ALL or brain tumor showed a “good” response; two a “fair” response and two a “poor” response to treatment with MPH. In another early study, treatment did not have an effect on attention and memory deficits in children with malignant brain tumors (Torres et al., 1996). Acute efficacy was documented in randomized, double-blind, placebo-controlled trials (Thompson et al., 2001) and patients showed a significant improvement on a test of sustained attention after 90 minutes, but not on tests of verbal memory or learning ( $N = 32$ ). Longer term effects

were documented in a randomized, double-blind, three-week crossover trial of low versus moderate dose MPH compared to a placebo control group. While there was no difference between the low and medium dose treatment groups, they were both rated as improved compared to the placebo group on parent and teacher ratings of attention, and teacher ratings of social skills. No direct measures of performance or achievement were included in this trial (Mulhern et al., 2004). A third study in this series ( $N = 122$ ) added measures of attention, memory and academic achievement in a two-day double-blind crossover trial -comparing moderate dose MPH with placebo (Conklin et al., 2007). Results documented significant improvement on a test of cognitive flexibility and processing speed (Stroop), but no effect on tests of academic achievement, verbal learning, or attention. The authors point out that study participants with lower IQs ( $<70$ ) were less likely to show a positive response to the MPH than did participants with average IQs and this factor should be considered in clinical settings. Furthermore, use of performance versus parent/teacher report measures may also affect the ability to document positive responses to MPH as an intervention for neuropsychological late effects in survivors of childhood cancer.

Because fewer children who have been treated for cancer have a positive response to MPH than do children with developmental ADHD, Conklin et al. (2010) studied factors that predicted a positive response to MPH in this population ( $N = 106$ ). Teacher report of changes in the ADHD Index of the Conners Teacher Rating Scale was used as the definition of positive clinical response, and this outcome was documented for nearly half the subjects in the moderate-dose group (45%). This is significantly lower than the reported response rate in developmental ADHD populations (75%). Unlike in their 2007 study, Conklin and her colleagues did *not* find that higher global cognitive level was associated with a positive response. Rather, only parent and teacher reports of attention and behavior problems at screening were predictive of a positive medication response.

Conklin and her colleagues studied longer-term efficacy of MPH treatment in a group of brain tumor and ALL survivors (Conklin, Reddick, et al., 2010). Over the course of one year, treatment benefits were documented by performance and observational measures, at home and at school, affecting both attention and behavioral variables. No effects were observed on measures of cognitive function or academic skills. Similar findings were noted in a systematic review of controlled trials of stimulant medication to address cognitive late effects in children treated for brain tumors; attention processes appear to improve but impact on academic progress is not evident (Smithson, Phillips, Harvey, & Morrall, 2013).

Researchers have also investigated medications used to treat dementia symptoms in adults. Donepezil, an acetylcholinesterase inhibitor, was used in a small pilot study with survivors of childhood brain tumors. Some improvements in

executive functions on the D-KEFS Tower and on the Plan/Organize scale of the Behavior Rating Inventory of Executive Function (BRIEF) were documented. A large multisite trial has been undertaken but no findings have been released to date. Modafanil, a stimulant medication, is used to treat fatigue and daytime sleepiness in children treated for brain tumors. A multicenter clinical trial sponsored by Children's Oncology Group (ACCL0922) is under way to evaluate if a six-week course of modafanil can improve neuropsychological function (attention, working memory, processing speed) in children treated for brain tumors. The study will also evaluate the medication's effect on fatigue and domains of executive function.

Psychopharmacological treatment is used clinically to address emotional adjustment issues seen in children treated for cancer. These problems can include anxiety and depression, as well as significant behavioral/emotional regulation deficits. In these instances, traditional psychopharmacological and psychotherapeutic interventions are indicated.

### **Behavioral**

The role of exercise and physical fitness in promoting health as well as mood and cognitive function is being elucidated in a number of populations. In animal and human studies, physical activity has been associated with neurogenesis in the hippocampus (Pereira et al., 2007). Exercise as a form of intervention for survivors of childhood cancer has been found to be feasible (Keats & Culos-Reed, 2008) and safe (Baumann, Bloch, & Beulertz, 2013). Positive outcomes have been demonstrated on level of fatigue (Chang, Mu, Jou, Wong, & Chen, 2013) and quality of life (Baumann et al., 2013; Rodgers, Trevino, Zawaski, Gaber, & Leasure, 2013). Exercise represents a potential treatment that may help mitigate the adverse effects of radiation therapy on brain plasticity. Preliminary evidence suggests that cognitive late effects can be traced to CRT induced suppression of hippocampal cell proliferation and that exercise may be effective as an independent or adjuvant therapy (Rodgers et al., 2013). Mabbott and colleagues have shown that an aerobic exercise intervention may be effective for repairing neural damage following CRT in survivors of brain tumors (Riggs et al., 2014). Results suggest that aerobic exercise may not only promote white matter repair and hippocampal growth, but also improve reaction time in these patients.

### **Cognitive**

Cognitive interventions, based on rehabilitation strategies developed for patients with traumatic brain injury, are being increasingly applied to survivors of childhood cancer. Butler and colleagues (2008), developed and evaluated a cognitive rehabilitation intervention program that draws upon techniques from three disciplines: brain injury rehabilitation, educational psychology, and clinical psychology. The

intervention, delivered individually by a trained therapist, was programmatic but individualized as necessary to meet the child's needs. Twenty two-hour weekly sessions were conducted over a four- to five-month period and incorporated techniques to improve attention, concentration, and processing speed; metacognitive strategies to improve study skills; and cognitive behavioral strategies to address executive function. In a randomized, multicenter clinical trial, changes in attention, memory/learning, academic achievement and parent and self-reports of attention, self-esteem, and quality of life were assessed and compared to a wait list control group. Although significant improvements were documented for several variables (academic achievement, metacognitive strategy use, parent report of attention) there were no significant changes in neuropsychological function and effect sizes were small.

Because the time, effort, and cost of the Butler approach was large in comparison to demonstrated outcomes, home-based computerized intervention programs have been explored for feasibility and efficacy. Hardy and colleagues (Hardy, Willard, & Bonner, 2011) demonstrated good acceptability and variable compliance with a home-based computerized cognitive training program in a small group of brain tumor and ALL survivors ( $N = 9$ ) with documented attention and working memory problems. Preliminary evidence suggested some degree of efficacy, with significant improvements at posttest for digit span forward and parent reported attention problems, but not for digit span backward or number letter sequencing. In this pilot study, there was no control group, and so the authors could not rule out parent reporting bias or practice effects on performance measures.

Kesler and colleagues tested the feasibility and efficacy of an internet-based cognitive rehabilitation program with 23 survivors of childhood posterior fossa brain tumors or ALL (Kesler, Lacayo, & Jo, 2011). The intervention was aimed at ameliorating deficits in executive function, including cognitive flexibility, attention, and working memory, and was designed as an eight-week course with five sessions per week, 20 minutes per session. They assessed neuropsychological function and conducted fMRI studies before and after the intervention. Results were encouraging and demonstrated excellent compliance with 83% of the group completing the course. Significant improvements were documented on tests of processing speed, cognitive flexibility and memory, but not on direct measures of working memory or attention. fMRI showed significant increases in dorsolateral prefrontal cortex activation following the intervention compared to baseline.

In an effort to specifically target working memory deficits, Hardy and colleagues (2011) tested the feasibility and preliminary efficacy of Cogmed Working Memory Training (Cogmed) as an at-home rehabilitation program for 20 survivors of childhood brain tumor and ALL. Two-thirds of the sample was assigned to the intervention arm, which consisted of 25 sessions over five to eight weeks in which

difficulty was adapted to performance. The remaining one-third of the sample was assigned to an active "control" condition wherein the same exercises were presented but the difficulty level remained static. Feasibility was good with 85% of subjects completing at least 80% of training sessions. Participants' ratings of ease of use and acceptability were also good. When the groups were compared with respect to efficacy of treatment, significant post active intervention increases were noted on performance measures of visual working memory and parent-rated learning problems. No effects were documented on tests of verbal working memory or attention; children with higher baseline IQ demonstrated greater improvements after training.

### **Educational**

Educational interventions are delivered at various levels. School consultation and reintegration programs support survivors of childhood cancer in the school setting and provide a valuable educational component, helping teachers and school personnel understand cognitive and psychological late effects. Pediatric neuropsychologists work with schools to help implement interventions needed to address the impact of cancer and its treatment on learning and adjustment. An intervention specifically aimed at ameliorating the common deficits in math performance was tested by Moore et al. (Moore et al., 2000). Using a two-group longitudinal design, eight children treated for ALL received an active math intervention; seven children comparably treated for ALL received no intervention. The intervention group received 40–50 hours of math tutoring, which was skill and concept-based and was individualized to student needs. At follow-up, the treatment group showed improvement in math achievement compared to their baseline, while the control group did not.

The investigators then asked whether it was possible to prevent declines in math skills by intervening early, during active treatment (Moore, Hockenberry, Anhalt, McCarthy, & Krull, 2012). Fifty-seven children treated for ALL with chemotherapy only were enrolled at diagnosis and 60% (32 subjects) completed all assessments. The baseline assessment was conducted 12 months after completion of induction therapy. Post intervention assessment was conducted one year later, soon after completion of the one-year math intervention. The final assessment was conducted one year thereafter. Patients were randomized to math intervention or standard care. After completion of the intervention, the intervention group showed significant improvement on tests of calculation and applied math. One year later, visual working memory was significantly better than at baseline in the intervention group only. Improvements were specific to math and visual working memory, as they were not apparent on test of reading or spelling. The standard care group did not improve over time on any measure; however, neither did that group decline as predicted.

## **Social**

Social competence is significantly affected, particularly in survivors of brain tumors. Reviews of the literature on social development in this group found that both social adjustment and competence are compromised (Hocking et al., 2015; Schulte & Barrera, 2010). Research findings and our clinical experience reveal that the social problems experienced by survivors of childhood brain tumors are characterized by social isolation, lack of sustaining peer friendships, and lack of peer acceptance. Studies of friendship quality in children treated for brain tumors note lack of integration and involvement in activities by peers (Vannatta et al., 2008; Vannatta, Gartstein, Short, & Noll, 1998; Vannatta, Gerhardt, Wells, & Noll, 2007). Compromise in executive functions may underlie these problems as well as limited opportunities to expand and refine social skills across development (Wolfe et al., 2012). Interventions to address social problems include support groups and structured events for adolescent and young adult survivors. Schulte and colleagues have developed a group social skills program consisting of eight weekly sessions focused on friendship making, cooperation, managing social cruelty, conflict resolution, empathy, and assertiveness (Schulte, Bartels, & Barrera, 2014; Schulte, Vannatta, & Barrera, 2014). Sessions use cognitive behavioral problem-solving strategies, role modeling, and cooperative activities. Following the intervention, improvements were noted in teacher and parent ratings of social skills, as well as in observed social performance, but there was no effect noted on a measure of social problem solving. These pilot studies are helpful in identifying targets for guiding social skill intervention programs.

## **Future Directions**

The field of oncology is moving toward individualized and targeted therapies. Advances in understanding molecular genetics, disease processes in patients, and types of neoplasms foster refinements in treatment protocols that are adapted to the unique combination of specific disease within a particular host or context. Risk stratification strategies are much more sophisticated. In ALL, protocols now incorporate information regarding the individual's specific vulnerability to toxicity of treatment agents and chemotherapy doses are adjusted accordingly (Cheek & Evans, 2006). Similarly, now that we understand specific subgroups of medulloblastoma, less-intensive treatment can be considered for some patients to reduce neurotoxicity. These techniques have the potential to reduce the neurobehavioral impact of cancer therapies on the developing child.

Efforts to mitigate or prevent late effects may be advanced through the study of neuroprotective factors (Albers, Cavaletti, & Donehower, 2014; Avan et al., 2015). This area of investigation is still in its early stages but the focus of this research is to identify ways of protecting healthy cells, sparing cells in stages of active neurodevelopment, or replacing

damaged cells to preserve cognitive development and function (Gibson & Monje, 2012).

Ongoing research in childhood cancer must continue to incorporate long-term follow-up of neuropsychological outcomes. In neuropsychology, the focus is on understanding how specific cognitive processes are affected and the related downstream effects of disruptions in brain development in childhood. A more nuanced understanding of plasticity, injury, and dynamic developmental processes will contribute to these approaches (Dennis et al., 2013; Johnston, 2009). Plasticity has been described as a double-edged sword: Less developed systems have more capacity for growth and development, yet the same developmental processes that support brain development also contribute to the developing brain's exquisite vulnerability to injury or insult and carry lifelong consequences.

Neuropsychologists working in childhood cancer have incorporated lessons learned from the study of traumatic brain injury in children in research and clinical care. Although the pathophysiology of the insult to the brain is different, similar neuropsychological processes are affected in both conditions. Intervention efforts in childhood cancer are based on cognitive rehabilitation techniques used to treat brain injury. In addition, studies of risk and resilience can assist with identifying targets for intervention. The field needs to move toward addressing modifiable risk factors over the short and long term. For example, we know that family and psychosocial factors have a significant impact on response to and outcome of any type of brain injury. Intervention efforts need to be individualized as well as comprehensive, addressing family functioning in subgroups at increased risk of adverse outcomes (Ach et al., 2013). As the transition to adulthood is considered, addressing health behaviors, social integration, and independence needs to be included in the scope of neuropsychological care.

Future research into intervention strategies will need to identify the active elements of effective interventions and their impact at different stages in development. As we learn more about how brain systems and neuropsychological processes of attention, working memory, and information processing speed are affected by childhood cancer and treatment, preventive educational or training strategies may be incorporated early in the treatment course, before these issues are manifest and compromise functioning; a similar strategy is proposed for addressing emerging working memory problems in children born very prematurely (Pascoe et al., 2013).

Clinical care and research endeavors need to be comprehensive and interdisciplinary, with active interchange of ideas that integrate physiological, developmental, and psychological systems. In order to truly advance the field, research methodologies will need to incorporate all of these factors, yet retain an individualized focus. Identifying the factors that contribute to resilience in some children as well as those involved in the selective vulnerability of others is of critical importance.

# 13 Autism Spectrum Disorder

Gerry A. Stefanatos and Deborah Fein

## Introduction and Definition

Although the behaviors associated with autism have been noted for centuries (Houston & Frith, 2002; Wolff, 2004), its recognition as a discrete disorder occurred only decades ago, based on Leo Kanner's (1943) seminal description of 11 children evaluated at Johns Hopkins University clinics. Kanner meticulously outlined a behavioral symptom-complex shared by these children that he felt differentiated their condition from other recognized forms of childhood psychopathology. The predominant characteristic was *marked difficulties in relating to other people and situations in a normal manner*. This was reflected in striking limitations of social awareness and a relative disregard for the people around them. The children often acted "as if people weren't there," (p. 223) seemed "happiest when left alone," (p. 218) or displayed an inordinate interest in objects and pictures that seemed to eclipse their interest in people. Indeed, Kanner remarked that one 5-year-old "did not pay even the slightest attention to Santa Claus in full regalia." (p. 218) Secondly, the children demonstrated an *anxiously obsessive desire for the maintenance of sameness*, manifested in repetitive and stereotyped behaviors, and negative reactions to changes in routines or their environment. A third core feature, *unusual or impaired use of language for interpersonal communication*, was reflected in verbal communications that were marked by echolalic utterances, stereotyped language, and a tendency to reverse personal pronouns ("I" for "you"). By parent history, behavioral anomalies had been evident in infancy and toddlerhood and had persisted through subsequent stages of development. Kanner recognized that the extreme aloneness, obsessiveness, stereotyped behaviors and echolalia resembled childhood-onset schizophrenia. However, he reasoned that his cohort did not fit this diagnosis because their symptoms were evident "from the very beginning of life" (p. 248). He therefore conjectured that their symptom-complex represented a separate disorder which he subsequently dubbed *early infantile autism* (Kanner, 1944).

Characterizations of the core features of autism have varied considerably since its initial description, and establishing reliable diagnostic criteria has proven difficult. The development of an acceptable diagnostic algorithm and classification scheme has entailed a reiterative process of formulation,

evaluation, and revision that has continued to the present day (Wing, Gould, & Gillberg, 2011). Accordingly, the nomenclature and diagnostic criteria outlined in the current American Psychiatric Association's *Diagnostic and Statistical Manual*, fifth edition (DSM-5; APA, 2013) differs in substantive ways from previous iterations. Autism is no longer presented as a categorical designation diagnosis with defined boundaries to separate it from similar diagnostic entities such as Asperger's disorder, childhood disintegrative disorder, and pervasive developmental disorder—not otherwise specified. Instead, DSM-5 has merged these subtypes into a single category called *autism spectrum disorder (ASD)*. This somewhat controversial reframing reflects an ongoing "revolution" (Rutter, 2013) in conceptualizing autism, its diverse manifestations, and its diagnosis. Explicit in this integrated view is the notion that ASD is not a single, unified disorder but is instead a collection of disorders that reflect the diverse consequences of functional compromise of neural networks involved in the development of social communication, and appropriately flexible and diverse thinking and behavior.

A prodigious amount of research has been directed towards ASD in recent years. The search for a simple etiology has been abandoned in the face of overwhelming evidence of multiple pathogenetic pathways, with many or most involving a complex interplay of several genetic and environmental risk factors. Neurodevelopmental anomalies have been identified at numerous levels of neural structure and function, from cytoarchitecture and neurochemistry to gross neuroanatomy, electrophysiology, and regional cerebral metabolism. Efforts to understand these alterations and their association to potential etiopathogenetic mechanisms now span numerous scientific disciplines, from molecular genetics to immunology and gastroenterology. The extant literature on ASD is enormous, remarkably diverse and expanding at a formidable and somewhat daunting rate.

In this chapter, we constrain our discussion of ASD to a selective review of topics of greatest relevance to theory and practice in neuropsychology. We begin with a brief review of the changes in the diagnostic criteria set forth in DSM-5 and their implications for clinical practice. This is followed by a cursory overview of the epidemiology of ASD in which we survey evidence suggesting an alarming increase in prevalence. Sections on etiology summarize some of the complex

and diverse factors thought to increase risk for the diagnosis. We then consider the latest advances in our understanding of the neurobiological basis and neuropsychological correlates of the disorder. More comprehensive coverage of ASD is available to the interested reader in edited volumes by Amaral, Geschwind, and Dawson (2011); Volkmar (2013); Patel, Preedy, and Martin (2014), each more than 1,400 pages in length. Alternatively, Reber (2012) provides a concise discussion of the biological foundations of the disorder and practical discussions regarding its treatment. In addition, excellent reviews of the neuroscience and neuropsychology of autism are available in volumes edited by Fein (2011) and Buxbaum and Hof (2012).

### **Comparative Nosology—Refining the Diagnosis of ASD**

Autism has proven to be one of the most complex and enigmatic forms of developmental psychopathology to define, in part because of the substantial diversity in its expression. Given that it emerges in infancy or early childhood and is a lifelong disorder, the symptoms vary considerably in their manifestations, severity, specificity, and developmental course, resulting in marked variation across individuals and within individuals over time. Furthermore, the diversity in early clinical presentation does not map in any straightforward way onto the heterogeneity in genetic findings, family history, outcome, or neuroimaging results. Even the heterogeneity in one area of function, such as language, does not seem to map easily onto heterogeneity in other areas, such as social functioning (Rapin, 2014; Waterhouse, 2013).

This diversity has greatly complicated the development of a widely accepted and broadly applicable classification scheme and diagnostic algorithm to identify the disorder and differentiate it from other similar disorders (Wing et al., 2011). Kanner waited more than a decade after his original description before he delineated the facets of the disorder that he believed all patients had in common and could be used for diagnostic purposes. He settled on “extreme self-isolation” and “obsessive insistence on the preservation of sameness” as the two key features of the disorder (Eisenberg & Kanner, 1956, p. 557). However, from a diagnostic standpoint, these characteristics failed to define a unique or homogeneous population, and disagreements regarding the definition and validity of infantile autism as a distinct clinical entity ensued for over two decades.

Rutter (1978) and Wing and Gould (1979) conceptualized three core areas of deficit in autism often referred to as the *autism triad*: (a) social interaction, (b) communication, and (c) rigid and repetitive activities and interests. These formulations guided the delineation of the diagnostic criteria for *infantile autism* when it was first incorporated as a distinct diagnosis in the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders, Third Edition* (DSM-III; APA, 1980). The Diagnostic Statistical Manual-III criteria were associated with

high sensitivity but low specificity, while revisions implemented in DSM-III-R (APA, 1987) resulted in the opposite pattern.

Modifications incorporated in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV; APA, 1994) and carried over to the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR; APA, 2000) marked a substantial change over previous iterations. Autistic disorder (AD) was conceived as one of five diagnoses in a broader category entitled *Pervasive Developmental Disorder* (PDD). The inception of the PDD category was intended to provide a supraordinate framework within which the heterogeneous clinical presentations of AD and closely related disorders could be parsed into distinguishable, clinically meaningful diagnostic entities on the basis of differences in patterns of behavioral symptoms, their severity, and age of presentation. Besides AD, the category included Asperger’s Disorder (AspD), Childhood Disintegrative Disorder (CDD), Rett’s Disorder (RD), and a nonspecific diagnosis entitled *Pervasive Developmental Disorder—Not Otherwise Specified* (PDD-NOS).

The diagnostic criteria for AD were based on 12 separate symptoms spanning the three domains of the autism triad. To meet criteria for the disorder, a child needed to exhibit six or more of these symptoms, with at least two symptoms involving impairments in the *social interaction* domain and at least one symptom from each of the remaining two domains (*communication, restrictive/stereotyped behaviors and interests*). The onset of symptoms had to occur before 3 years of age in at least one of these three areas. This schema resulted in good sensitivity (.91) and specificity (.53) for the AD diagnosis. However, it was criticized as being too static, of questionable help in diagnosing infants, young children, and adults, and difficult to apply consistently across different clinical practices and treatment centers (Leekam, Libby, Wing, Gould, & Gillberg, 2000; Wing et al., 2011). These shortcomings were largely related to the failure of the scheme to adequately accommodate differences in the clinical picture that occurred as a function of age, gender, or different environments.

In addition, problems surrounded the definition and criteria used for the other disorders comprising the PDD category. Specifically, RD (a progressive disorder) did not seem to fit the category, while others such as AspD and PDD-NOS had relatively poor specificity (0.34 and 0.24, respectively). Moreover, the boundaries differentiating the disorders sometimes seemed arbitrary with no clear guidelines on how to operationalize them. Miller and Ozonoff (1997), for example, pointed out that none of the original cases described by Asperger (1944) met DSM-IV criteria for AspD, but instead would be diagnosed with AD. Similarly, questions arose as to whether the proposed criteria could reliably distinguish CDD from AD because of issues concerning the age of onset (Hendry, 2000). In view of clinician dissatisfaction with the DSM-IV scheme and a perceived lack of robust, replicated evidence to support some of the diagnostic distinctions, the term *autistic spectrum disorder* (Allen, 1988) came into

increasingly common usage to refer collectively to AD and the closely related disorders such as AspD and PDD-NOS.

### **Current Criteria for Diagnosis and Classification**

The diagnostic framework recently outlined in DSM-5 (APA, 2013) differs from previous iterations in several important respects. In order to avert some of the diagnostic boundary issues discussed in the last section, DSM-5 eliminated the supraordinate category of (PDD) and its associated subtypes (AD, AspD, CDD, PDD-NOS), and instead, defined a single category: ASD. RD has been excluded entirely from this new category due to recognition of its clear genetic basis (Amir et al., 1999).

This reorganization has been accompanied by a restructuring of the domains of behavior covered by the symptom checklist. While DSM-IV-TR treated social and communication impairments as separate domains, DSM-5 has combined them into a single domain entitled *social communication*. Accordingly, children must demonstrate persistent impairment from early childhood in two domains: (a) social communication (SC) and (b) restricted, repetitive patterns of behaviors and interests or activities (RRBIA). Factor analytic studies have shown that these domains emerge as separable factors (Frazier et al., 2012; Mandy, Charman, & Skuse, 2012).

An important aspect of this reorganization is that disorders of language development are treated as separate from ASD. Correspondingly, an individual can have ASD with or without a coexisting language disorder. If present, the language disorder is coded separately. Deficiencies in particular aspects of language use that have long been strongly associated with AD continue to be reflected in the new diagnostic criteria, but have been reallocated to the most appropriate SC or RRBIA symptom category. For example, the inability to have a normal conversation, which reflect problems with the pragmatic or social use of language, is included under SC. By contrast, stereotyped language, such as pedantic speech and echolalia, is now found under RRBIA. Other common comorbid disorders where separate coding is now permitted include Attention Deficit/Hyperactivity Disorder (ADHD) and Intellectual Disability (ID).

The symptom list has also been consolidated so that the number of symptoms required to meet the diagnostic criteria has been reduced from the twelve in DSM-IV-TR to seven in DSM-5. Some of these describe more general principles and behaviors. In addition, the age of onset criteria have been relaxed. While symptoms should be present early in childhood, it is recognized that they may not fully manifest until demand characteristics increase later in development. Endorsement of symptoms on the diagnostic checklist can be made on the basis of current presentation or by history so that symptoms are scored on the basis of lifetime occurrence.

Symptoms must be present across multiple contexts and be clearly atypical from a developmental perspective. Hand

flapping, for example, would not necessarily be considered atypical if seen only between 6 to 9 months of age or within a somewhat later temporal window in a child with general developmental delays. In general, the same behavior should not be utilized as an exemplar to satisfy two criteria. In order to mitigate overly strict application, the DSM-5 manual explicitly states that the given examples are illustrative and not exhaustive, and that some symptoms may be masked by strategies learned later in life. Finally, and importantly, in recognition of the dimensional nature of ASD, the diagnostic criteria are accompanied by a severity scale in order to capture the substantial variation in the degree of impairment that characterizes this population. This is operationalized in a three-point classification system according to the level of support a child requires: “support,” “substantial support,” or “very substantial support.” As these indicators are new and were not evaluated prior to their inclusion in DSM-5, it remains unclear how well they will function in clinical practice (Lord & Bishop, 2015).

Interestingly, there is less flexibility allowed in scoring the diagnostic checklist in DSM-5. Within each behavioral domain, the symptom checklist is divided into subdomains: there are three subdomains of SC and four subdomains of RRBIA. In order to meet criteria for the diagnosis, a child must demonstrate symptoms in all three of the SC subdomains and in at least two of the four subdomains of RRBIA. An outline of the key domains of impairment, subdomain symptoms, and criteria is provided in the left-hand column of Table 13.1; the right column lists some of the corresponding early behavioral markers that have been identified in infancy and childhood. A narrative description relevant to the contents of the table is provided in next section.

### *Social Communication*

SC has long been recognized as a cardinal area of impairment in ASD. The DSM-5 criteria pertaining to SC require that individuals demonstrate impairment in social-emotional reciprocity that is persistent and apparent across multiple contexts. Impairment must be evident in *each* of the following three subdomains: (a) deficits in social approach, (b) deficits in nonverbal communicative behaviors used for social interaction, and (b) deficits in developing and maintaining relationships (see Table 13.1, section A, subsections 1, 2, and 3 respectively in the left column).

Deficits in the first subdomain, social approach, can include abnormal social initiation, approach, and responsiveness. Children may fail to approach other individuals to engage them socially or may be inappropriately disinhibited or indiscriminative in approach (e.g., with strangers). Similarly, they may fail to respond appropriately to social overtures. Deficits may also be apparent in an inability to maintain normal back-and-forth conversation (poor pragmatics), reduced or absent social interest, or a lack in sharing thoughts, interests, and emotions/affect.

Table 13.1 DSM-5 diagnostic criteria for ASD with extension to infants and toddlers

Must meet DSM-5 diagnostic criteria A, B, C, and D

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive, see text).

DSM-5 criteria (SC)  
(must include problems in all three areas)

Behaviors at 2 Years or Earlier

Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).</li> <li>2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns or verbal nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat food every day).</li> <li>3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).</li> <li>4. Hyper or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).</li> </ol> | <ul style="list-style-type: none"> <li>• Excess of repetitive play (e.g., lining up cars, spinning wheels)</li> <li>• Excessive adverse reaction to changes in routines or environment (e.g., resists changing clothing as weather changes, insists on particular foods, seating arrangements, wearing certain clothing)</li> <li>• Motor mannerisms or stereotyped behavior (e.g., hand flapping, unusual finger movements, toe walking, rocking)</li> <li>• Unusual interests, interest in nonfunctional elements of play material (e.g., spinning tires on a toy car)</li> <li>• Unusual sensory interests (e.g., excessive interest in spinning objects or particular textures, explores objects from the corner of eyes rather than central vision, constantly sniffs objects, seeks out deep pressure stimulation)</li> <li>• Produces unusual complex mannerisms</li> <li>• Immediate echolalia</li> <li>• Stereotyped language</li> <li>• Hypersensitivity to certain forms of visual, auditory, tactile, olfactory input (e.g., bright lighting, sound of vacuum cleaner, blender, certain food textures, clothing fabrics, seams, tags, noxious reactions to certain smells)</li> <li>• Hyposensitivity to sensory input (e.g., at times appears deaf, unconcerned by extreme temperatures or painful events such as ear infection)</li> </ul> |
|--|--|

C. Symptoms must be present in early childhood (but may not become fully manifest until social demands exceed limited capacities).

D. Symptoms together limit and impair everyday functioning.

The left column presents the DSM-5 criteria for ASD. The diagnosis requires that a child demonstrate a minimum of seven symptoms of impaired function across two domains. A child must demonstrate symptoms in all three of the SC subdomains and in at least two of the four subdomains of RRBIA. The right column lists some of the corresponding early behavioral markers that have been identified in infancy and childhood.

Deficits in the second subdomain, nonverbal communicative behaviors, involve a lack of integration of verbal and nonverbal communication that is normally intrinsic to social interaction. Problems can include anomalies in eye contact and body language, and deficits in understanding and using nonverbal communications. Problems with gesture and nonverbal communication may be evident in simple failures to utilize head or hand gestures such as pointing, waving, or nodding, and a lack of facial expression. Correspondingly, impairment may also be reflected in difficulties reading and responding appropriately to gestural communications. Symptoms affecting particular language-related behaviors may be included in this category if they are fundamentally related to underlying problems with social communication and interaction.

The third subdomain involves deficits in developing and maintaining relationships appropriate to the child's developmental level. This may be evident in difficulties adjusting behavior so that it is appropriate and in keeping with different social contexts. Children may demonstrate a lack of imaginative play with peers, interest in developing peer relationships (friendships) or social imitation (e.g., during social games). If severe, these difficulties may entail an absence of interest in others, significant withdrawal and aloofness, and a strong preference for solitary activity.

#### *Restricted and Repetitive Patterns of Behavior Interests and Activities*

The second broad domain in which impairment must be evident to be diagnosed with ASD relates to RRBIAs. These behaviors are also diverse in their manifestations and have been divided into the following four subdomains: (a) stereotyped or repetitive speech, motor movements, or use of objects; (b) excessive adherence to routines and rituals and resistance to change; (c) highly restricted interests and preoccupations; and (d) hyper- or hyporeactivity to sensory input. An individual must demonstrate impairment in at least two of these four RRBIA areas (see Table 13.1, section B, subsections 1, 2, 3 and 4 respectively in the left column). The manifestations of these behaviors can vary over the course of development. For example, "lower-order" hand and finger mannerisms or unusual sensory interests are fairly common (~87.5%) by age 2, while "higher-order" behaviors such as compulsions and unusual preoccupations are less common at this age but evolve over time (Lord et al., 2006; Richler, Huerta, Bishop, & Lord, 2010).

The first subdomain includes a variety of complex stereotyped behaviors such as lining up objects and intricate mannerisms (e.g., tapping the teeth before ingesting food). It also encompasses a number of "lower-order" behaviors including simple sensory-motor stereotypies (e.g., facial grimacing, finger flicking, hand flapping, toe walking) and unusual sensory interests (e.g., watching ceiling fans). In addition, it incorporates utilization of stereotyped or ritualized forms

of language such as echolalia, idiosyncratic speech, and pronoun reversal (e.g., using "you" when referring to self), repetitive questioning, and pedantic speech.

The second subdomain concerns insistence on sameness, resistance to change, and inflexible adherence to routines or ritualistic behaviors. These "higher-order" RRBIAs encompass compulsions and rituals such as having unusual attachments to particular objects or a needing to perform certain activities in a rigid or heavily prescribed manner. The subdomain also subsumes inordinate reactions to small changes in the environment, an insistence on strict adherence to rules, greeting rituals, difficulties transitioning from one activity to another, and rigid or perseverative thinking patterns (e.g., failure to understand idioms, irony, humor). Behaviors comprising this subdomain load as a separate factor from the repetitive sensorimotor behaviors described in the previous subdomain and appear to become more salient with increasing age (Cuccaro et al., 2003; Leekam, Tandos, et al., 2007).

The third subdomain concerns manifestations of highly restricted or circumscribed interests that are fixated or of unusual intensity. This can include preoccupation with unusual objects, excessive, perseverative areas of circumscribed interests (e.g., intense interest in train schedules, lawn mowers), and perfectionism. It can also consist of preoccupations or obsessions, and may entail the development of unusual fears (e.g., fear of bananas). These behaviors may also become more evident with increasing age.

Sensory hypersensitivities and hyposensitivities comprise the fourth subdomain. Long recognized in ASD, these symptoms were excluded from the diagnostic criteria in earlier versions of DSM, presumably because they can occur in a variety of neurodevelopmental disorders (e.g., ADHD, Fragile X, schizophrenia) (Reynolds & Lane, 2008). Their inclusion in DSM-5 therefore marks a significant addition to the new criteria. In the context of ASD, hypersensitivity refers to either increased sensory acumen (e.g., lowered sensory thresholds) or to exaggerated or inappropriate responses to sensory stimuli that, in a typical person, would yield unremarkable sensory responses.

Hypersensitivity in the auditory domain is often referred to as "hyperacusis" (Klein, Armstrong, Greer, & Brown, 1990). In children with ASD, everyday sounds (e.g., vacuum cleaner or food blender) that are neither threatening nor uncomfortably loud to a typical person may cause children with hyperacusis to cover their ears, undertake avoidant measures, and demonstrate considerable distress and dysphoria. These same children may tolerate other similar noises without difficulty. Often, the oversensitivity cannot be simply attributed to sound levels or the presence of particular frequencies.

In the somatosensory realm, tactile hypersensitivities may be reflected in "tactile defensiveness," in which children respond negatively to being touched or held, or display an aversion to social touch as may occur when in crowded situations. These hypersensitivities can cause a dislike to particular articles of clothing or fabrics (e.g., tags), certain

foods because of their texture (e.g., creamy liquids), or specific activities (e.g., having their hair cut, brushing teeth). It may influence toy preferences (e.g., hard objects) or unusual attachments to particular objects or situations. Alternatively, children may seek out particular forms of somatosensory stimulation (e.g., deep pressure) that they may find calming, or perform self-stimulatory activities (e.g., rubbing certain textured objects), which may be reinforcing.

In the visual domain, children can show a particular fascination with reflections and brightly colored objects or alternatively demonstrate avoidant responses to them. Children may prefer to look at objects only out of the corner of their eyes, from unusual angles, or when squinting. Hypersensitivity can also be evident to particular smells or tastes and may therefore influence food preferences and aversions. Unusual or idiosyncratic exploratory behavior can occur in any of these modalities as part of this propensity to demonstrate RRBIAs.

As with hypersensitivity, hyposensitivity may also be evident in any of the five senses. In the auditory domain, for example, hypoacusis may be evident in diminished or inconsistent responses to sounds in the environment. This may occur to an extent that it raises concerns of possible hearing impairment. Children with ASD may demonstrate diminished or absent startle reflex to loud sounds in the environment, such as a loud clap produced behind them. Examples of hyposensitivity in the somatosensory domain include reduced sensitivity to cold temperatures (e.g., walking barefoot in snow) or high pain thresholds. Sensory regulatory anomalies can emerge as early as the first year (Baranek, 1999; DeGangi, Breinbauer, Roosevelt, Porges, & Greenspan, 2000).

### *Implications of Changes in DSM-5*

Several preliminary studies revealed that the merging of the subgroups of PDD into a single diagnosis of ASD in the DSM-5 has resulted in significant improvements in several psychometric indices. Field trials using criteria close to those adopted in the final DSM-5 version have shown good test-retest reliability ( $\kappa = 0.69$ ) and improved specificity (0.74), indicating a reduced number of false-positive diagnoses (Regier et al., 2013). However, the higher degree of specificity may have come at a cost of lowered sensitivity. Although some studies have found no substantial change in sensitivity (0.89 to 0.93; see Huerta, Bishop, Duncan, Hus, & Lord, 2013) others claim a reduction in diagnosis as high as 88% in selected subgroups (Barton, Robins, Jashar, Brennan, & Fein, 2013; Mayes et al., 2014; McPartland, Reichow, & Volkmar, 2012; Taheri & Perry, 2012). The reduced sensitivity appears to particularly affect the diagnosis of older children, adolescents, adults, individuals without intellectual impairment, and individuals who previously met criteria for AspD and PDD-NOS. In addition, the new criteria may also have reduced sensitivity when diagnosing low-functioning

adults (Matson, Belva, Horovitz, Kozlowski, & Bamburg, 2012) and at-risk toddlers (Matson, Kozlowski, Hattier, Horovitz, & Sipes, 2012).

Questions have arisen as to whether the observations of lower sensitivity of the DSM-5 criteria could be an artifact of the methodology used in these preliminary studies. In most, the data used were collected using DSM-IV-TR criteria and then mapped onto the DSM-5 descriptions, so these data may not provide sufficient information to adequately assess the full range of behaviors delineated in the DSM-5 criteria (Swedo et al., 2012). However, a prospective study by Gibbs, Aldridge, Chandler, Witzlsperger, and Smith (2012) provided evidence supporting the view that the new criteria may be overly stringent. Clearly, more experience is needed with the new criteria to address these questions.

One of the primary reasons that children diagnosed with a PDD using DSM-IV-TR criteria failed to meet the DSM-5 diagnosis for ASD is that they did not demonstrate sufficient evidence of deficits in nonverbal social communication. It has therefore been suggested that “relaxing” the number of social communication subdomain symptoms required to meet criteria from three to two might increase sensitivity (Frazier et al., 2012; Matson, Hattier, & Williams, 2012; Mayes et al., 2014). Empirical evaluation has confirmed that this approach results in an increase in sensitivity. However, the relaxation also caused a decrease in specificity relative to the original criteria (Taheri & Perry, 2012), although in many cases this was minimal (Mayes et al., 2014).

An additional concern with toddlers is that repetitive behaviors and resistance to change may not appear until age 3–4 years or even later for some children, while the social communication impairments of ASD appear as early as the first or second year of life (Garon et al., 2009; Osterling, Dawson, & Munson, 2002; Stone et al., 1999). Therefore, Barton et al. (2013) suggested that, at least as applied to toddlers, reducing the required number of repetitive behaviors to one would prevent unduly lowered sensitivity.

One of the more sensitive and heated criticisms of the changes in DSM-5 is that the new criteria will threaten delivery of services to some individuals. Since the inception of the Individuals with Disability Act in 1990, individuals receiving the diagnosis of autism have been eligible for special education services. Given changes in the sensitivity of the DSM-5 criteria, it is likely that a proportion of individuals (estimated from 10% to 47%) diagnosed with a PDD such as AspD or PDD-NOS according to DSM-IV-TR may no longer meet criteria for ASD using the new criteria (Huerta, Bishop, Duncan, Hus, & Lord, 2012; Matson, Kozlowski, et al., 2012; McPartland et al., 2012).

### *Epidemiology*

Data from developed countries have shown consistent increases in ASD prevalence over the past 20 to 30 years (Davidovitch, Hemo, Manning-Courtney, & Fombonne,

2013; Elsabbagh et al., 2012; Kogan et al., 2009; Parner et al., 2011; Russell, Rodgers, Ukoumunne, & Ford, 2014). Numerous social and methodological issues have complicated the interpretation of this trend. Factors thought to contribute to the higher estimates include: (a) increased public and professional awareness of AD; (b) improvements in case-finding methods (e.g., higher estimates from studies that utilize repeated developmental checks); (c) heightened awareness of the full spectrum of the disorder; (d) increased recognition that AD can be associated with other developmental, physical, or psychiatric disorders; (e) earlier age of recognition; (f) better diagnostic tools; (g) diagnostic substitution (e.g., with intellectual deficiency); (h) rise of advocacy and disability rights; (i) better access to services and surveillance mechanisms (e.g., state-wide screening programs and national screening mandates (Plauché Johnson & Myers, 2007)); and (j) broadened criteria and greater sensitivity of more recent diagnostic criteria (DSM-IV/DSM-IV-TR) in comparison to earlier formulations (DSM-III-R) (Elsabbagh et al., 2012; Fombonne, Quirke, & Hagen, 2009; Wing & Potter, 2002). However, prevalence rates have continued to show increases despite use of the same diagnostic criteria (Keyes et al., 2012).

The magnitude of the increase has been cause for serious concern. Based on studies published from 1966 to 2008, Fombonne (2009) suggested that prevalence rates for children diagnosed with an ASD were in the range of 60–70 per 10,000, corresponding to approximately one child in about 150 children. By contrast, recent large-scale surveys have yielded substantially higher prevalence estimates, in the range of 1%–2% (Baron-Cohen et al., 2009; Blumberg et al., 2013; Russell et al., 2014). Figures recently released by the Centers for Disease Control and Prevention (CDC) in the United States suggested that one in 88 children (11.3 per 1,000 8-year-olds) sampled in 2008 from multiple communities across the United States were identified with ASD (Baio, 2014). Overall, these recent figures mark an apparent continuation of a significant increase in prevalence estimates in the United States with approximately 36,500 cases added each year (Wingate et al., 2014). Increases have also been noted in Asia (Chien, Lin, Chou, & Chou, 2011; Kim et al., 2011), Europe (Baron-Cohen et al., 2009), and Australia (Williams, MacDermott, Ridley, Glasson, & Wray, 2008). Some data from the United Kingdom suggests that these incremental changes may be reaching a plateau (Taylor, Jick, & MacLaughlin, 2013).

One finding to possibly temper the alarming increase in prevalence observed worldwide is a study of autism prevalence in adults of different ages in the United Kingdom (Brugha et al., 2011). This study found no difference in prevalence for adults in different age bands, and adult prevalence was similar to that reported recently for children. These findings suggest that apparent increases may relate, at least in part, to case definitions and ascertainment methods. Nevertheless, ASD currently ranks as one of the most common

forms of developmental disability. It is also one of the most costly disabilities, with an estimated lifetime cost of \$3.2 million for an individual and family, resulting in approximately \$34.8 billion in societal costs (Ganz, 2006).

Adopting the DSM-5 diagnostic criteria may complicate the continued monitoring of prevalence over time (Maenner et al., 2014; Mattila et al., 2011). The decreased sensitivity of the DSM-5 criteria would result in exclusion of some individuals classified with an ASD according to DSM-IV-TR or the International Classification of Diseases – 10th Edition (ICD-10) diagnostic criteria (Gibbs et al., 2012; Wing et al., 2011). This shift in diagnostic bias could potentially result in stasis or a lowering of future prevalence estimates.

### *Gender*

ASD is four to five times more common in males compared to females (Brugha et al., 2011; Fombonne, 2009). This gender difference increases to approximately 6:1 in individuals with normal-range intelligence (Fombonne, 1999) and decreases to approximately 2:1 in individuals with severe ID (Mattila et al., 2011). The gender difference may increase to 11:1 when individuals with milder variants (e.g., Asperger's disorder) are included (Gillberg, Cederlund, Lamberg, & Zeijlon, 2006). Variability in male/female ratios may, in part, reflect gender differences in expression. Males are more likely to come to attention because they demonstrate externalizing behaviors such as aggression, hyperactivity, and stereotypies. Females are more likely to demonstrate internalizing symptoms such as anxiety, depression, or other mood disorder (Solomon, Miller, Taylor, Hinshaw, & Carter, 2012; Szatmari et al., 2012). In addition, females tend to exhibit better adaptive strategies or behaviors that “camouflage” behaviors associated with the diagnosis (Attwood, 2007; Dworzynski, Ronald, Bolton, & Happe, 2012; Kopp & Gillberg, 2011). Because of these differences in presentation, girls may need to have more cognitive or behavioral difficulties than males to be clinically diagnosed with ASD. Indeed, empirical studies have suggested that girls who receive the diagnosis are likely to be more severely affected. When the severity of autistic traits is held constant, boys remain more likely to get an ASD diagnosis, but the gender disparity is substantially reduced (Giarelli et al., 2010; Russell, Steer, & Golding, 2011).

Several lines of evidence have suggested that gender differences may also reflect the influence of protective factors in females that may mitigate, to some extent, the effects of genetic influences on the expression of ASD (Robinson, Lichtenstein, Anckarsater, Happe, & Ronald, 2013). In the circumstances of comparable genetic risk, males are more likely to exhibit symptoms of ASD, such as repetitive behaviors (Szatmari et al., 2012), and are more likely to receive a diagnosis of ASD than are females (Sato et al., 2012). It is unclear whether this effect is related to genetic factors (i.e., sex chromosomes), hormonal influences, or both. Given that

individuals at the high end of the spectrum have a reduced likelihood of meeting the DSM-5 criteria for ASD, it is possible that fewer girls will be given the diagnosis.

### **Social Class**

Kanner's (1943) original cohort came mainly from highly intelligent families with upper socioeconomic status. Parents and grandparents included physicians, lawyers, scientists, and writers. While subsequent studies have described an excess of college-educated professionals in parents of children with ASD, the findings have not been consistent. It has been hypothesized that the "systematizing" tendencies that are believed to form a latent trait of individuals within the broader autism spectrum may be advantageous in certain professional activities. Systematizing, according to Baron-Cohen, Richler, Bisarya, Guranathan, and Wheelwright (2003), refers to the drive to analyze how systems work, how they can be built, and how they can be controlled. In support of this hypothesis, several studies have observed that relatives of children with ASD are overrepresented in a number of technically-oriented occupations in which systematizing tendencies would be particularly advantageous (Windham, Fessel, & Grether, 2009). This includes engineering (Baron-Cohen, Wheelwright, Stott, Bolton, & Goodyer, 1997; Turner, Stone, Pozdol, & Coonrod, 2006), mathematics (Baron-Cohen, Wheelwright, Burtenshaw, & Hobson, 2007), and computer or information technology sciences (Roelfsema et al., 2012).

### **Race**

ASDs have similar prevalence in many countries around the world and different cultures or ethnicities (Fombonne, 2009). However, several recent reports have suggested that Caucasian children were more likely than African American or Hispanic children to be identified with ASD. In recent estimates from the CDC, ASD was identified in 1 of 63 White children, one in 81 African American children, and one in 93 Hispanic children. Furthermore, children with ASD from minority, low socioeconomic status, or rural families are likely to be screened and diagnosed later than others (Mandell, Listerud, Levy, & Pinto-Martin, 2002; Mandell & Novak, 2005).

### **Parental Age**

Recent epidemiological studies have disclosed a possible association between advancing parental age and risk of autism (Croen, Najjar, Fireman, & Grether, 2007; Grether, Anderson, Croen, Smith, & Windham, 2009; Parner et al., 2012). However, the nature of this effect has been somewhat inconsistent across studies. Some reports have found modest independent effects of both maternal and paternal age, while others have observed that the age of only one

(Reichenberg et al., 2006) or neither parent (Lauritsen, Pedersen, & Mortensen, 2005) was associated with risk of ASD in offspring (Lauritsen et al., 2005; Reichenberg et al., 2006).

A meta-analysis conducted by Hultman, Sandin, Levine, Lichtenstein, and Reichenberg (2011) in an attempt to resolve these disparities revealed a strong monotonic relationship between paternal age and risk of autism. The underlying mechanisms, however, remain unclear. One possible explanation is deferred paternity; paternal traits related to the broader ASD phenotype, such as shyness and aloofness, may delay success when searching for prospective mates and thus result in older paternal age (Puleo et al., 2012). This deferred paternity may increase risk of spontaneous genetic mutations due to either biological or environmental factors. Spermatogonial stem cell divisions, for example, are prone to higher mutation rates and cytogenetic abnormalities with advancing age (Buwe, Guttenbach, & Schmid, 2005; Crow, 2000). In addition, the longer the timeframe to conception, the greater the risk of exposure to potentially harmful environmental events (Yauk et al., 2008). This increased risk for spontaneous genetic mutations may combine with heritable genetic factors to increase the probability of penetrance of the ASD phenotype. This explanation is of considerable interest given growing evidence of the contribution of *de novo* mutations to the disorder (discussed in the next section). These possibilities are depicted schematically in Figure 13.1 (upper left) among a variety of other potential genetic, epigenetic, and environmental contributions to the risk of ASD, which will also be discussed in more detail in the following section.

## **Etiology**

### **Genetic Influences**

#### *Dysmorphogenesis in ASD*

Gross and minor physical anomalies can provide clues to identifying genetic factors contributing to abnormalities in embryonic or postnatal development. Although Kanner (1943) remarked on the absence of gross dysmorphic features in his original cohort of 11 children, he noted in passing that five of the children had "relatively large heads." (p. 248) In the absence of correlated signs or symptoms (e.g., other physical stigmata, raised intracranial pressure, hyperostosis), this physical feature was likely of uncertain significance. While it was recognized at that time that an unusually large head or *macrocephaly* was potentially indicative of excessive growth (hypertrophy) of the brain (Wilson, 1934), it was also well-established that benign forms of macrocephaly existed. Outcome was known to be quite diverse, from supranormal intelligence (e.g., Lord Byron, Oliver Cromwell, see Lawson, 1875) to severe developmental retardation and seizures (Campbell, 1895; Fletcher, 1900; Middlemass, 1895).

Subsequent investigations have revealed that children with ASD do indeed exhibit more dysmorphic features than the general population (Dufour-Rainfray et al., 2011; Miles &

Hillman, 2000; Ozgen, Hop, Hox, Beemer, & van Engeland, 2010). These anomalies tend to be minor and manifest in four body areas: the head, ears, mouth, and hands (Tripi et al., 2008). They include low-settled ears, adherent ear lobes, posteriorly rotated ears, hypertelorism, macrocephaly, furrowed tongue, large hands, two-to-three toe syndactyly, and small feet (Rodier, Bryson, & Welch, 1997; Walker, 1977). Some of these slight morphological deviations have been taken as evidence of genetic contributions to the development of ASD (Miles et al., 2005). A recent meta-analysis confirmed a robust effect of increased minor physical anomalies in ASD and suggested that this resulted from shared genetic vulnerability involving genes that play a role in shaping body morphology (Ozgen et al., 2010).

Macrocephaly and its association with ASD has received considerable attention in recent years. Macrocephaly may occur for a variety of nongenetic reasons such as hydrocephalus, neonatal intraventricular hemorrhage, or infection. From a genetic viewpoint, a large number of syndromes have been associated with macrocephaly, some with identified genetic determinants (e.g., neurofibromatosis, PTEN hamartoma syndromes, Soto's syndrome, Fragile X syndrome, Alexander disease). Macrocephaly occurs in about 15%–35% of children with ASD. Family studies have suggested that 35%–45% of children with ASD who have macrocephaly have a parent with a similarly elevated head size (Lainhart et al., 2006; Miles, Hadden, Takahashi, & Hillman, 2000). Younger siblings of children with ASD also appear to demonstrate this trait with higher than expected frequency (Elder, Dawson, Toth, Fein, & Munson, 2008), although this finding has not been consistently found. Familial forms of macrocephaly are generally benign and asymptomatic. In these cases, increased head size is attributable to increased cerebrospinal fluid (CSF) space (in early development) and not increased brain volume. In ASD, macrocephaly appears to be correlated with increased brain volume in early development and therefore meets criteria for *megencephaly*. Megencephaly is discussed at some length in the “Neuroscience of ASD” section.

### *Heritability*

Initial descriptions of ASD noted the presence of behavioral peculiarities or idiosyncrasies in many of the parents of affected children (Asperger, 1944; Kanner, 1943). Kanner commented, “For the most part, the parents, grandparents, and collaterals are persons strongly preoccupied with abstractions of a scientific, literary, or artistic nature, and limited in genuine interest in people” (p. 250). However, in the absence of major mental illness in parents, it was generally concluded that genetic factors were not a relevant feature of the clinical picture (Judd & Mandell, 1968). This seemed to be supported by family pedigree data that suggested that the recurrence rate in families

was fairly low, in the order of ~3% (Hanson & Gottesman, 1976; Smalley, Asarnow, & Spence, 1988). However, beginning in the late 1950s, case reports pointed to a high concordance in monozygotic (Campbell, Dominijanni, & Schneider, 1977; Chapman, 1957; McQuaid, 1975) and dizygotic twins (Kotsopoulos, 1976). A subsequent multifamily study showed a significantly higher concordance rate in monozygotic (36%) compared to dizygotic (0%) twins (Folstein & Rutter, 1977). Given that monozygotic (MZ) twins share ~100% of their DNA while dizygotic (DZ) twins share ~50%, it was concluded that genetic factors may indeed play an important role in increasing risk for the disorder.

Subsequent studies have generally confirmed higher concordance estimates in monozygotic (43%–95%) relative to dizygotic (0%–25%) twins (Nordenbaek, Jorgensen, Kyvik, & Bilenberg, 2014; Ritvo, Freeman, Mason-Brothers, Mo, & et al., 1986). On the basis of such differences, heritability was estimated to be as high as 80%–90% (Bailey, Le Couteur, Gottesman, & Bolton, 1995; Farley et al., 2009; Folstein & Rutter, 1988), placing ASD among the most heritable of child psychiatric disorders (Lichtenstein, Carlstrom, Rastam, Gillberg, & Anckarsater, 2010). However, some investigators have expressed caution regarding these estimates and their interpretation. The basic underlying premise that the quality of the pre- and postnatal environment in the two types of twin is comparable has been called into question (Carrier & Spitz, 1999). Greenberg, Hodge, Sowinski, and Nicoll (2001), for example, pointed out that complications arising from the twinning process itself (e.g., restriction of growth, risk of placental dysfunction) may be an important factor in increasing risk and inflating concordance for ASD in twins. Other problems with twin studies of ASD include low sample size and limitations or inconsistencies in case definition (Anderson, 2012). While some recent twin studies have supported a high heritability rate (Nordenbaek et al., 2014), others have yielded substantially lower estimates, ranging from 38% (Hallmayer et al., 2011) to 50% (Sandin et al., 2014), suggesting an equally important role for shared environmental influences in the expression of the disorder (Deth, Muratore, Benzecry, Power-Charnitsky, & Waly, 2008). Methodologically, the lower recent estimates may be due, in part, to the stricter cutoffs used for autism. Relatedly, while ASD may show high heritability in childhood, estimates drop in adulthood due to different assessment strategies or to complex gene-environment interactions (Posthuma & Polderman, 2013).

### *Broader Autism Phenotype*

The heritable contribution to risk for ASD is also evidenced to some degree by observations of recurrence within families. If a family has a child with ASD, the likelihood that an

additional child will also receive the diagnosis is significantly increased. Recent estimates of this recurrence risk range from 10%–20% (Constantino, Zhang, Frazier, Abbacchi, & Law, 2010; Ozonoff et al., 2011), substantially higher than previously thought. This represents as much as a 20-fold increase in risk compared to the general population (~1%) (Baird, Simonoff, et al., 2006). These high recurrence rates may underestimate the true risk of recurrence due to “reproductive stoppage rules,” whereby parents of a child with a severe disability choose not have further children.

Heritability may also contribute to observations that similar but milder behavioral anomalies occur in 10%–20% of the nontwin siblings of children with ASD (Bolton, Macdonald, Pickles, Rios, & et al., 1994; Piven, Palmer, Jacobi, Childress, & Arndt, 1997). These irregularities in social communication and RRBIAs are mild or subtle, generally do not warrant clinical concern (subclinical), and tend to aggregate more often in male relatives compared to female relatives (Wheelwright, Auyeung, Allison, & Baron-Cohen, 2010). Similar if less pronounced anomalies may also be evident in grandparents, uncles/aunts, and first cousins (Pickles et al., 2000; Szatmari et al., 2000). These observations have argued for the existence of a “broader autism phenotype” (BAP) comprised of relatives (parents, siblings and to a lesser degree more distant relatives) who share some of the traits of autism present in the family member diagnosed with ASD (Piven, Palmer, et al., 1997). When twins meeting criteria for ASD are pooled with twins possessing traits of BAP, then concordance among monozygotic twins rises to 82% compared with approximately 10% in dizygotic twins.

Recent twin and BAP studies have suggested that the inherited liability for ASD is associated with some trait specificity (Ronald, Larsson, Anckarsater, & Lichtenstein, 2010). For example, children with ASD who show a high frequency of repetitive behaviors are nine times more likely to have parents with obsessive-compulsive disorder compared to children with ASD who demonstrate lesser repetitive behaviors (Hollander, King, Delaney, Smith, & Silverman, 2003). Comparable effects have also been observed for communicative abilities (Alarcon, Cantor, Liu, Gilliam, & Geschwind, 2002; Chen, Kono, Geschwind, & Cantor, 2006) and social aspects of ASD (Liu et al., 2011; Sasson, Nowlin, & Pinkham, 2013). Similarly, a recent study has also implicated specific genetic influences on sensory atypicalities such as tactile sensitivity (*GABRB3*, which influences GABA metabolism) (Tavassoli, Auyeung, Murphy, Baron-Cohen, & Chakrabarti, 2012). A few studies have suggested that the BAP may also share cognitive difficulties (e.g., executive function) (Hughes, Plumet, & Leboyer, 1999) and dysmorphic features (e.g., megencephaly) (Elder et al., 2008). Together, the twin and BAP findings could potentially be due to family genetic influences or shared genetic and environmental influences but is unlikely to be

accounted for by environmental influences alone. Some have inferred from this body of evidence that ASD may result from anomalies of multiple genes where each contributes to specific traits that form part of the larger constellation of symptoms comprising ASD.

The schematic shown in Figure 13.1 is a hypothetical representation of the variety of genetic, epigenetic, and environmental factors implicated in the etiopathogenesis of ASD. The influence of these factors on neurodevelopment is complex and often dynamic. They have the potential, usually when occurring in combination, to cause alterations in neurodevelopment that lead to neuropsychological impairments and neurobehavioral anomalies. The resulting constellation of behavioral symptoms, if sufficient in number, breadth and severity, can lead to a diagnosis of ASD. For example, *TSC1* and *TSC2* are genes that encode for Hamartin and Tuberin respectively and are believed to be involved in tumor suppression. Mutations of these genes can lead to tuberous sclerosis complex (TSC) which can sometimes result in a co-diagnosis of ASD. Mutations of these and other genes (e.g., *NF1*, *FMR1*) account for a number of the syndromic forms of ASD. Lesser genetic anomalies such as single nucleotide polymorphisms (SNPs) and copy number variations (CNVs) can also result in perturbations of neurodevelopment, affecting processes such as cell differentiation, proliferation, adhesion, migration and apoptosis. As conceptualized in Figure 13.1, when these anomalies are sufficient in number and/or their impact on neurodevelopment, they can contribute to behavioral differences and delays that can increase risk for a diagnosis of ASD. While a comprehensive discussion of the genetic contributions to ASD is well beyond the scope of this chapter, we attempt to summarize some of this extremely complex and rapidly expanding literature in the sections that follow. Table 13.2 (p. 198) lists a number of the genes that have been tentatively linked to ASD in recent years along with their impact on neurodevelopment.

### *Syndromic Forms of ASD*

Despite compelling evidence for genetic contributions to ASD, early cytogenetic studies failed to identify consistent and specific anomalies associated with the full spectrum of the disorder. These studies were able only to detect anomalies large enough to be resolved through microscopic cytogenetic analysis. Analyses of the karyotypes of children with ASD established that only a small, albeit significant, number of children diagnosed with an ASD demonstrated visible cytological abnormalities (Gillberg, Winnergard, & Wahlstroem, 1984; Mariner et al., 1986). Anomalies included assorted sex chromosome abnormalities such as 45X (Turner syndrome), 47XYY, and 47XXY. Other rare chromosomal disorders associated with ASD include trisomy 21 and abnormalities of chromosome 15 (Wassink, Piven, & Patil, 2001). A

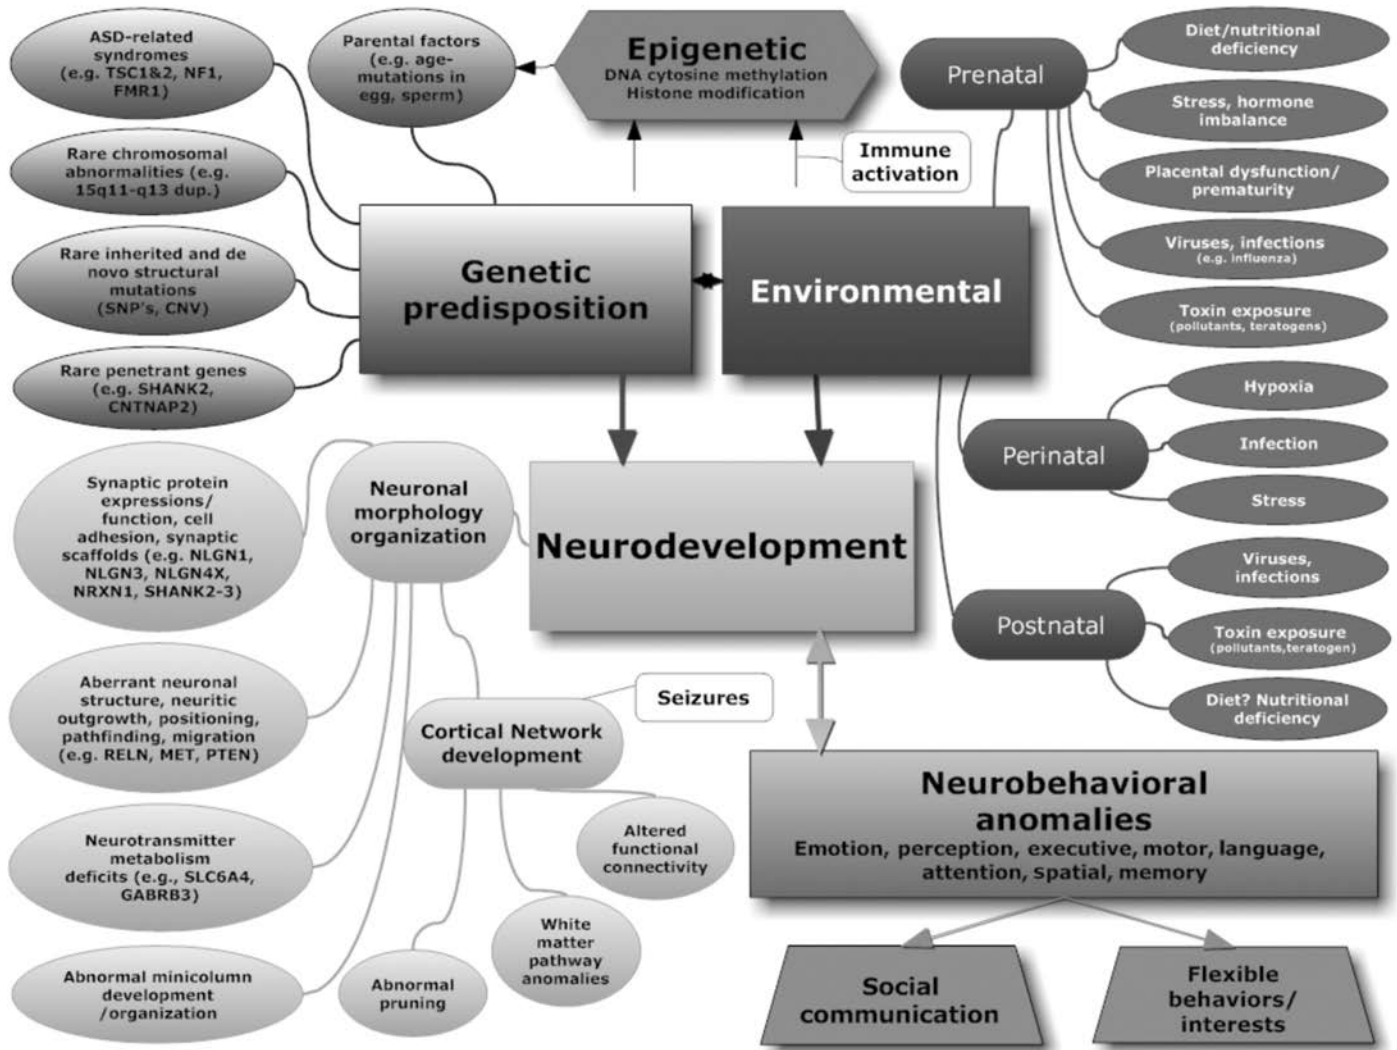

Figure 13.1 Etiopathogenic pathways in ASD

number of anomalies associated with Mendelian modes of inheritance were also identified, including Fragile X (~1%–2%), tuberous sclerosis (~1%), neurofibromatosis (<1%) and Rett syndrome (~0.5%). Overall, rare chromosomal abnormalities were found in approximately 5% of ASD samples. One of the most common cytogenetic anomalies, identified in 1%–3% of individuals diagnosed with ASD, has been a 15q11-q13 duplication of the maternal allele associated with Prader-Willi/Angelman syndrome (Muhle, Trentacoste, & Rapin, 2004).

Subsequently, a number of other uncommon single gene defects and rare marker deletions associated with genetic syndromes have been found in populations of children with ASD. This includes but is not limited to Williams-Beuren, Sotos, Moebius, Smith-Lemli-Opitz, Cowden, Potocki-Lupski and Timothy syndromes (Johansson, Gillberg, & Rastam, 2010). Taken as a whole, approximately 1%–20% of cases of ASD are associated with medical and genetic conditions

(Barton & Volkmar, 1998; Bauman, 2010). Individuals with these so-called syndromic forms of ASD are commonly but not uniformly excluded from genetic studies, which typically focus on exploring the genetic correlates of idiopathic forms of ASD. Systematic cytogenetically-visible anomalies in idiopathic ASD have been observed in 2.2% (Xu, Zwaigenbaum, Szatmari, & Scherer, 2004) to 5.8% (Marshall et al., 2008) of cases.

#### *Genomic Perspectives on ASD: From Microscopic to Molecular*

Advances in molecular genetics in the last 15 years have enabled in-depth examination of the molecular structure of the genome. While this has significantly enhanced efforts to identify the genetic factors that confer increased susceptibility for the disorder, this area of investigation is extremely complicated and fraught with methodological issues and

challenges in interpreting the data. It is beyond the scope of this chapter to comprehensively review this complex and rapidly changing literature, but we offer here an abbreviated discussion of this material to provide the reader with a sense of the state-of-the-art. For the sake of brevity, this treatment assumes some basic knowledge of genetic principles and provides only a cursory coverage of those essential aspects of molecular genetics required for understanding terminology and concepts relevant to the literature on ASD. To provide a foundation for the material to follow, we first discuss some fundamental concepts.

#### FUNDAMENTALS CONCEPTS OF MOLECULAR GENETICS

DNA is a nucleic acid present in the nucleus of every cell. The DNA molecule is a polymer made up of (monomer) units referred to as *nucleotides*. Each nucleotide consists of a nitrogenous base—adenine (A) thymine (T), cytosine (C) or guanine (G)—connected to a sugar (deoxyribose) and a phosphate group. The sugar and phosphate of each nucleotide is linked to the sugar-phosphate molecules of adjacent nucleotides, forming a linear chain referred to as the *backbone*. The nitrogenous bases extend from the backbone like the teeth of a zipper. The DNA molecule consists of two long parallel strands of these nucleotides held together in the middle by weak bonds linking specific nitrogenous bases into pairs (A with T and G with C). Because these pairings are specific, knowing the order of nucleotides in one strand allows precise knowledge of the order in the opposing strand. These strands wind around together to form a spiral staircase-like double-helix structure. Approximately 6 billion nucleotides make up each DNA molecule. Genetic information—the genetic blueprint used to assemble the entire body—is coded in the sequence of the bases along either strand.

Genes are the basic physical and functional unit of heredity. Genes consist of a specific sequence of nucleotide bases at a given position on the DNA molecule. They vary in size from just a few thousand pairs of nucleotides to more than 2 million base pairs. Genes are packaged into 46 chromosomes, which are divided into two sets of 23 chromosomes, one set inherited from each parent. Approximately 20–25 thousand genes collectively comprise the human genome. Chromosomes vary enormously in size and are numbered from largest to smallest (1–22). While chromosome 22 was originally thought to be the smallest, it was subsequently discovered that chromosome (21) was actually smaller, containing 447 to 635 genes, which corresponds to approximately 48 million nucleotide base pairs. The numbering was not changed because mutations of chromosome 21 had become known to possibly lead to Down syndrome. The largest chromosome (1) contains approximately 2,000 to 2,100 genes, spanning about 249 million base pairs. The sex chromosomes make up the 23rd chromosome pair (XX or XY). Only about a third of genes are expressed (active) primarily in the brain.

Genes consist of three types of nucleotide sequences: coding regions, noncoding regions, and regulatory sequences. The genetic code present in DNA instructs the cell how to assemble amino acids in order to make different proteins. Proteins are involved in virtually every aspect of cell growth and function, from the physical structure of the cell to the enzymes involved in neurotransmission. Each gene provides the code for the synthesis of specific proteins. The actual synthesis of proteins takes place outside of the nucleus of the cell. Code present in the DNA must therefore be transcribed and conveyed by messenger RNA (mRNA) to ribosomes, where it is translated to create amino acid chains that will be folded to create a protein.

Genes are biologically programmed to turn on and off in a prescribed manner over the course of development. Their expression can function as catalysts in the timing of important chemical and physiological events. However, the results of gene activity in the brain are incorporated into the dynamic and ever-changing molecular and cellular physiology of the brain, which is heavily influenced by experience. As a consequence, experience plays a large part in determining the extent to which genetic influences are expressed. Environmental events can result in molecular interactions that can impede the transcription of information stored in DNA. Epigenetic mechanisms such as DNA methylation, RNA-associated silencing, and histone modification can inhibit and even prevent the implementation of genetic instructions. Alterations in development can therefore result from anomalies of genetic structure, environmental influences, gene-environment interactions, gene-gene interactions and epigenetic factors. (These issues are discussed at length in the sections on genetic factors that follow.)

Comparing any two unrelated individuals reveals that 99.9% of the genome is identical, although the DNA sequence comprising the same chromosome may vary between the two versions. Numerous studies have now shown that significant variations in the sequencing structure of the genome occur in ASD. One type of genetic variation, termed *single nucleotide polymorphisms* (SNP), involves an alteration in DNA sequence in which there is a substitution of one nucleotide for another in the base pairs comprising the molecule (e.g., substitution of C with T so that DNA fragments differ between individuals (e.g., AAGCCTA vs. AAGCTTA). SNPs are not an uncommon feature of normal variation: from the approximately 3 billion base pairs comprising the human genome, roughly 10 million SNPs may occur in coding or noncoding areas. Variations can be transmitted or acquired through de novo mutations. While most of these alterations have no effect on health or brain development, it is believed that some of the SNPs that occur in individuals with ASD may play a direct or indirect role in risk for the disorder.

While SNPs affect a single nucleotide base, *copy number variation* is an anomaly affecting relatively large regions of the genome in which sections have been deleted or duplicated

more than the usual number of times. Normally, an individual inherits two copies of every gene, one from each parent. However, in some regions in the genome, there are deviations from the two-copy rule, resulting in copy number variants (CNV). In these regions, the number of copies may vary from 0 to more than 14 copies of a gene. CNVs may range in size from about 1 kilobase (1,000 nucleotide bases) to as many as several megabases. They can be limited to a single gene and have implications similar to a SNP, or they can involve several genes (Lee & Scherer, 2010).

These structural variations contribute to our uniqueness, influencing traits that include susceptibility to diseases and disorders. CNVs, for example, account for some of the differences distinguishing so-called identical twins. They also account for some of the phenotypic variability associated within a disorder (due to differences in gene dosage). It is thought that rare de novo and inherited CNVs contribute to genetic vulnerability for ASD in as many as 10% of cases (Abrahams & Geschwind, 2008).

#### CANDIDATE GENE AND LINKAGE STUDIES

CNV screening and direct sequencing have provided rapid and useful methods to identify both large and small genetic variations that merit further characterization in relation to ASD. Given the large number of base pairs comprising the human genome and the fact that SNPs are not an uncommon feature of normal variation, discriminating those SNPs and CNVs that are specifically related to ASD from random variants or anomalies related to other traits poses a daunting task. Traditionally, efforts to identify genes related to a specific disorder begin with studies that attempt to identify the rough location of a candidate gene. These studies often try to localize the search to a region of the genome that is deemed etiologically relevant by virtue of its association with a specific syndrome or disorder. A number of early initiatives focused on linkages between the diagnosis of ASD and anomalies at loci in regions that had been implicated in prior cytogenetic studies as related to particular phenotypes, deficits, or diseases. Additionally, the search for candidate loci also guided by hypotheses regarding the biological origins of ASD. Once a locus has been identified, linkage and association studies can then attempt to identify which genes in that region may have a specific association to ASD. For example, given that duplications in chromosome 15 had been identified in previous cytological studies (Wassink et al., 2001), molecular studies have explored associations between ASD and anomalies in the region of chromosome 15, which spans more than 102 million base pairs. These efforts ultimately resulted in the identification of anomalies involving a gene in chromosome 15 that influences glutamate metabolism (GABRG3; Martin et al., 2000; Menold et al., 2001; Yang & Pan, 2013). In a similar vein, motivated by numerous studies demonstrating anomalies of serotonin metabolism in ASD, early molecular genetic studies identified polymorphisms in

genes involved in 5-HT metabolism (e.g., SLC6A4, which codes for a serotonin transporter protein; see Betancur et al., 2002; Cook et al., 1997; Huang & Santangelo, 2008; Sutcliffe et al., 2005).

#### GENOME-WIDE ASSOCIATION STUDIES (GWAS)

Advances in molecular genetics in the last decade have made it possible for researchers interested in ASD to perform scans of the entire genome in search of the SNPs that contribute to risk for developing the disorder. In genome-wide association studies (GWAS), large numbers of individuals with ASD are assayed (i.e., genotyped) to obtain a comprehensive catalog of genetic markers distributed across the coding regions of the genome. Using techniques such as *logistic regression analysis*, control family members who have never met criteria for the disorder are compared to members of families with at least two affected relatives (typically siblings). Ideally, dense pedigrees (3+) are optimal, but these are often difficult to recruit in the ASD population given the reduced fecundity of individuals with ASD (Power et al., 2013) and the tendency for reproductive stoppage after parents have given birth to an affected child (Jones & Szatmari, 1988). The aim of the analysis is to identify those structural DNA variations or markers that may predispose individuals to develop ASD. From these analyses, it is possible to distinguish multiple genetic risk factors and discern inherited from de novo structural variations.

Overall, however, complications (i.e., heterogeneity, reproductive stoppage, insufficient sample size) have contributed to slow progress in showing definitive correspondences between specific genetic anomalies and risk for idiopathic ASD. A recent review of the literature catalogued 103 disease genes and 44 genomic loci that may potentially be associated with AD or autistic behavior (Betancur, 2010). This underscores the substantial heterogeneity of the genetic determinants of ASD. In their review, Abrahams and Geschwind (2010) nicely conveyed the greater complexities of this area of investigation, suggesting that 20% of autism cases may be attributable to a mutation involving a known risk gene, but no single region within the genome can account for more than 1%–2% of cases. This has led to a discussion of the “missing heritability problem,” which relates to the observation that loci detected by GWAS explain such a small amount of the inferred genetic variants associated with ASD.

#### RARE AND COMMON VARIANTS

Both rare and common genetic variants underlie risk for most complex disorders. The twin studies of ASD prompted speculation that the genetic liability for ASD may be conferred by anomalies in a small number of genes that had large effects. A number of rare SNPs and CNVs have been identified in ASD, each with a frequency of occurrence of less than 1%. These rare variants include NLGN3, NLGN4, NRXN1, SHANK2, SHANK3, PTCHD1, 1q21.1,

maternally inherited duplication of 15q11-q13, 16p11.2, CDH8, ASTN2, and CNTNAP2 among others. A number of these anomalies can have significant influences on neurodevelopment, sufficient enough to be monogenic causes of ASD. (For more details, see the “Genetic Influences on Neurodevelopment in ASD” section). However, these rare variants account for only a small proportion of individuals diagnosed with ASD.

More recent reconsideration of the available evidence has suggested that liability for ASD may more generally arise from the influence of many genes with small to modest effects on the traits associated with ASD. A recent population-based study from Sweden used statistical models to partition the heritable risk of ASD from rare and common variants (Gaugler et al., 2014). Gaugler and colleagues estimated that more than 90% of the heritable risk was likely to be due to common variants. While several hundred structural variants have been identified in families of individuals with ASDs (Marshall et al., 2008), GWASs have largely failed to identify common CNVs and SNPs that can account for the expected degree of transmitted variation (Cook & Scherer, 2008; Devlin & Scherer, 2012; Freitag, Staal, Klauck, Duketis, & Waltes, 2010). Some of the difficulty is that, given the large number of statistical comparisons (~1 million) and the small effect sizes, many of the studies have relatively low power, resulting in a paucity of consistently replicated results (Lee et al., 2013). For example, a meta-analysis by Anney et al. (2010) of three previously identified SNPs (on 5p14.1, 5p15, and 20p12.1) failed to support consistent effects on any of the identified loci. Due in part to power issues, associations identified in GWAS may represent the “low-hanging fruit” that reached statistical significance for a variety of reasons and are thus not consistent between studies (Anney, 2013).

#### DE NOVO MUTATIONS

In view of the inconsistency in the genes identified in association studies, a number of recent studies have underscored the potential contribution of de novo (not inherited) genetic variations in the risk for ASD (Ronemus, Iossifov, Levy, & Wigler, 2014). It has been suggested that between 10% and 30% of the genetic liability for ASD can be traced to de novo CNVs, point mutations, insertions, or deletions (Devlin & Scherer, 2012; Iossifov et al., 2014; Neale et al., 2012). New mutations are fairly common (~100 per child) but very few (~1%) fall within coding regions of the genome (Awadalla et al., 2010). De novo mutations have been observed in approximately 7% of families with ASD and are more likely to account for ASD in singleton families (since one family member is affected, the child is compared to his or her parents). There is a two- to fourfold increase in de novo mutations among ASD individuals (Neale et al., 2012; Sanders et al., 2012). While some of these mutations can potentially have large effects (Gilman et al., 2011; Iossifov et al., 2012; Sebat et al., 2007), affected individuals more often have

multiple sequence variants and CNVs with presumed small-to-medium effects. These findings suggest that the high incidence of autism in some families could best be explained by structural variants at multiple loci. Factors that may contribute to risk for de novo mutations are multifold, including a variety of potential environmental and biological (e.g., aging) risk factors. The effects of advancing parental age, for example, may be related to either or both, insofar as aging both increases the risk for spontaneous mutations as well as provides more opportunity for exposure to possible mutagenic environmental influences (Lee & McGrath, 2015).

A number of the genes that have been identified in studies examining de novo mutations have been previously implicated as candidate genes. Some of the identified de novo variants include FMRP, CNTNAP2, SHANK 2, PTEN, CHD2, CHD8, SYNGAP1, DYRK1A, GRI, SCN2A, and TBR1. Among these, CHD8, SCN2A, and DYRK1A, have been most consistently implicated (Neale et al., 2012, p. 6; O’Roak et al., 2012; Sanders et al., 2012). Many of these genes play a significant role in signaling and synaptic function during neurodevelopment, some by influencing the action of other genes that have been implicated directly or indirectly in ASD (e.g., PTEN; see Devlin & Scherer, 2012; Krumm, O’Roak, Shendure, & Eichler, 2014). A full appreciation of the genetic determinants of ASD requires an understanding of gene networks and how anomalies of particular genes may affect the expression of other genes. Some examples of this are illustrated in the following discussion on “Genetic Influences on Neurodevelopment in ASD.” Such considerations also relate to the important role that epigenetic factors play in the risk for ASD. Epigenetic factors refer to those influences that affect gene expression that are not due to structural alterations in DNA. This is briefly discussed in a separate section on “Epigenetics.”

#### *Genetic Influences on Neurodevelopment in ASD*

The genes that have been implicated in ASD impact a variety of physiological processes including chromatin remodeling, transcription and translation, and metabolic function. A significant number of them have an impact on synaptic function. A selection of these genes and their function are illustrated in Table 13.2.

Several of the more penetrant genes fall within the neurexin and cadherin (calcium-dependent adhesion) superfamilies of genes (Pardo & Eberhart, 2007; Redies, Hertel, & Hubner, 2012; Sudhof, 2008). The neurexin genes (e.g., NRXN1, NRXN2, NRXN4) code for proteins that facilitate the formation of neuronal trans-synaptic cell adhesion complexes (Lise & El-Husseini, 2006; Varoqueaux et al., 2006). The activity of these genes can influence axonal and dendritic growth, synaptic formation, and neural plasticity. Anomalies have the potential to result in broad effects on brain development and function, influencing neurotransmission, particularly glutamatergic and GABAergic synapses, as

Table 13.2 Genes implicated in risk for ASD

<i>Gene Family</i>	<i>Gene Name</i>	<i>Locus</i>	<i>Function</i>	<i>Comorbidities</i>
SYN (Synapsin)	SYN1 SYN2	Xp11.23 3p25	Synaptic vesicle cycling	ASD, epilepsy
RIM (Regulating synaptic membrane exocytosis)	RIMS3	1p34.2	Synaptic vesicle cycling	ASD
CACN (Calcium channels, voltage-dependent)	CACNA1E CACNB2	1q25.3 10p12	Neurotransmission	ASD
SCN (Sodium channels voltage-gated)	SCN1A SCN2A SCN3A	2q24.3 2q24.3 2q24	Neuronal excitability	Dravet syndrome, ASD, epilepsy
KCNM (Potassium channels, calcium activated)	KCNMA1 KCNMB4	10q22.3 12q	Neuronal excitability	ASD
KCN (Potassium channels)	KCNQ3 KCNQ5 KCND2	8q24 6q14 7q31	Neuronal excitability	ASD, epilepsy
NRXN (Neurexin)	NRXN1 NRXN2	2p16.3 11q13	Cell adhesion	ASD, schizophrenia
NLGN (Neuroigin)	NLGN3 NLGN4X	Xq13.1 Xp22.32-p22.31	Cell adhesion	ASD, ID
CNTNAP (Contactin-associated protein-like 2)	CNTNAP2 (aka NRXN4) CNTNAP4	7q35 16q23.1	Cell adhesion	ASD, ID, language impairment, schizophrenia, epilepsy
CDH (Cadherin)	CDH5 CDH8 CDH9 CDH10 CDH11 CDH13 CDH15	16q22.1 16q22.1 5p14 5p14.2 16q21 16q23.3 16q24.3	Cell adhesion	ASD, ID
PCDH (Protocadherin)	PCDHB4 PCDH10 PCDH19	5q31 4q28.3 Xq22.1	Cell adhesion	ASD, ID
CNTN (Contactin)	CNTN4 CNTN5 CNTN6	3p26.3 11q22.1 3p26-p25	Cell adhesion	ASD, ID
IL1RAPL (Interleukin 1 receptor accessory protein-like 1)	IL1RAPL1	Xp22.121.3	Cell adhesion	ASD, ID
SHANK (SH3 and multiple ankyrin repeat domains)	SHANK1 SHANK2 SHANK3	19q13.3 11q13.3 22q13.3	Glutamate receptor signaling	ASD
SYNGAP (Synaptic Ras GTPase activating protein)	SYNGAP1	6p21.3	Glutamate receptor signaling	ASD
GABRG (Gamma subunits of GABA-A receptor)	GABRB3	15q12	Neurotransmission	ASD
FMR1 (Fragile X mental retardation 1)	FMRP	Xq27.3	Synaptic Plasticity	Fragile X syndrome, ASD, Fragile X-associated tremor/ataxia syndrome
RELN (Reelin)	Reelin	7q22	Neuronal migration	ASD, schizophrenia, bipolar disorder, major depression, temporal lobe epilepsy, lissencephaly with cerebellar hyperplasia
PTEN (Phosphatase and tensin homolog)	PTEN	10q23	Neuron, positioning, dendritic development, synapse formation	ASD
CHRNA7 (Cholinergic receptor, nicotinic, alpha 7)	CHRNA7	15q13.3	Signal transmission	ASD, schizophrenia
UBE3A (Ubiquitin protein ligase E3A)	UBE3A	15q11.2	Protein degradation targeting	Angelman's syndrome
MECP2 (Methyl CpG binding protein 2)	MECP2	Xq28	DNA methylation, transcription repressor	Rett's syndrome, ID

This table provides information regarding some of the genes implicated in risk for ASD, their known or suspected role in neurodevelopment, and the clinical conditions that have been associated with mutations. (Adapted and expanded from Giovedi et al. 2014)

well as resulting in neuronal migration abnormalities. They have been implicated in a variety of other neuropsychiatric disorders, including epilepsy. Genes that code for neuroligands (NLGN3, NLGN4X) have also been implicated in ASD (Freitag et al., 2010; Volaki et al., 2013), although the evidence has been mixed (Gauthier et al., 2005).

Relatedly, both common and rare variants of the contactin associated protein-like 2 gene (CNTNAP2, CNTNAP4 also known as Caspr2 and Caspr4 respectively) have been implicated in ASD (Bakkaloglu et al., 2008; Burbach & van der Zwaag, 2009; Penagarikano & Geschwind, 2012). CNTNAP2 is located on chromosome 7 (7q35) and was first connected to ASD as a recessive mutation associated to a syndromic form of ASD known as *cortical dysplasia-focal epilepsy syndrome* (CDFE; see Strauss et al., 2006). CNTNAP2 codes for a cell adhesion protein that mediates neuron-glia interactions and the clustering of potassium channels in myelinated axons (Poliak et al., 2003). Nearly two-thirds of individuals with this anomaly demonstrate epileptic seizures, language regression, intellectual impairment, and ADHD symptoms. CNTNAP2 has since been linked to increased risk of ASD and ASD-like endophenotypes comprised of four key features: ID, seizures, autistic characteristics, and language problems (Scott-Van Zeeland et al., 2010). The associated language impairments range from dysarthric speech and language delay to the absence of speech. Nearly half of affected individuals demonstrate evidence of a neuro migrational disorder on structural neuroimaging.

Other disorders associated with CNTNAP2 include schizophrenia, developmental delay, and ADHD. In addition, SNPs and CNVs in the CNTNAP2 region have also been linked to specific language impairment (SLI) and dyslexia (Newbury et al., 2011; Simpson et al., 2015). CNTNAP2's location on the chromosome is near the FOXP2 gene (7q31), which has also been implicated in developmental disorders affecting speech and language. Interestingly, FOXP2, a gene associated with verbal dyspraxia and impaired linguistic processing (Vargha-Khadem, Gadian, Copp, & Mishkin, 2005), has not been implicated in ASD.

A number of genes in the cadherin family (e.g., CDH9, CDH10, CDH13, CDH15, PCDH19) have also been implicated in ASD (Chapman et al., 2010; Pagnamenta et al., 2011; Sanders et al., 2012; Wang et al., 2009). These genes code for cadherins, which are proteins that play an important role in cell adhesion, forming and remodeling of synaptic junctions, and mediating aspects of intracellular signaling (Giagtzoglou, Ly, & Bellen, 2009; Hirano, Suzuki, & Redies, 2003). They also play an important role in neural tube regionalization, neural migration, and gray matter differentiation (Hirano & Takeichi, 2012; Redies et al., 2012).

Other genes implicated in risk for ASD include the SHANK family (e.g., SHANK2 and SHANK3) of genes (Berkel et al., 2010; Boccuto et al., 2013; Moessner et al., 2007). The SHANK genes code for proteins that are involved in the process of synaptic development by scaffolding and

connecting neurotransmitter receptors, ion channels, and other membrane proteins to the neuronal cytoskeleton. They therefore play an important role in the formation, maturation, and maintenance of synapses and dendritic spines (Blundell et al., 2009; Guilmatre, Hugué, Delorme, & Bourgeron, 2014; Uchino & Waga, 2013). SHANK3, located on chromosome 22, seems to be associated with more common, milder variants of ASD (Boccuto et al., 2013). While some genes may begin to be expressed during fetal brain development, the SHANK genes may have the greatest impact on changes that occur in the postnatal period during critical periods of proliferation of neural processes (axons and dendrites) and the formation of synapses (Gutierrez et al., 2009; Yamakawa et al., 2007). They are thought to play an important role in specifying synaptic functions and interactions with other proteins to localize neurotransmitter receptors on postsynaptic neurons as they mature. Other genes thought to potentially influence neurotransmission include SYNGAP1 (which codes for a protein largely localized to dendritic spines and neocortical pyramidal neurons, where it suppresses NMDA receptor mediated synaptic plasticity), GABRG1 (which codes a protein that plays a role in GABAergic neurotransmission), and CHRNA7 (which codes for a protein involved in acetylcholinergic signal transmission).

RELN is a gene that encodes an extracellular protein, reelin, that is involved in cell-to-cell interactions critical for cell positioning and neuronal migration during brain development (Fatemi et al., 2005). Decreased levels of reelin have been identified in cerebellar tissue obtained from post-mortem examination of individuals with autism (Persico & Bourgeron, 2006). Interestingly, findings in mice have linked reelin pathway anomalies to prenatal infection with influenza virus or other causes of activation of the immune system during pregnancy (Fatemi, Emamian, et al., 2002). These findings form part of a larger literature connecting ASD to both genetic and environmental influences on immune system function (see "Immunological Factors" in the following section for more information).

The synapsin family of genes (SYN1, SYN2) has also been implicated in ASD. These comprise a family of genes that act as regulators in synaptic development and plasticity (Giovedi, Corradi, Fassio, and Benfenati et al., 2014). Interestingly, these genes are expressed at low levels at birth but their expression increases progressively in the course of early development, reaching a plateau at about 2 months coinciding with the beginning of a period of increasing synaptogenesis. This window also coincides with one of the peak periods of epileptogenesis in ASD. Mutations in SYN1 have been identified in individuals with both epilepsy and ASD while SYN2 mutations have been observed in ASD without epilepsy.

When considered individually, the contribution of these genes to ASD appears relatively small (Hugué, Ey, & Bourgeron, 2013). Overall, the genetic anomalies that have been associated with ASD do not appear to be specific

to the ASD phenotype, but rather are associated with a range of phenotypes, many of which are characterized by symptoms that are often comorbid in ASD. This includes epilepsy (Mefford et al., 2010; Penagarikano et al., 2011), ADHD (Rommelse, Franke, Geurts, Hartman, & Buitelaar, 2010; Ronald, Simonoff, Kuntsi, Asherson, & Plomin, 2008; Semrud-Clikeman, Fine, Bledsoe, & Zhu, 2014), developmental language disorders (Bartlett et al., 2014; Nudel et al., 2014; Stefanatos & Postman-Caucheteaux, 2010), and schizophrenia (Stefansson et al., 2014; Sullivan et al., 2012). It has therefore been argued that, like schizophrenia, ASD liability arises from the cumulative effect of genetic variation involving multiple mutations. Individual mutations, whether inherited or *de novo*, may exert a small effect, but collectively they can exert a major influence on ASD risk (Klei et al., 2012; Pinto et al., 2010).

### *Epigenetics*

A variety of factors influence how the genotype is transformed into the phenotype in the course of development of ASD. These include interactions between genes and the environment, interactions between genes themselves, or from unknown events or influences. Through diverse mechanisms, “epigenetic” factors result in alterations in gene expression through mechanisms other than changes in DNA sequence (Elia, Laracy, Allen, Nissley-Tsiopinis, & Borgmann-Winter, 2012). Epigenetic mechanisms include chromosome organization, DNA methylation, and effects of transcriptional factors. For example, animal models have demonstrated that environmental insults such as prenatal stress or maternal deprivation can influence DNA methylation. This can result in sustained hypersensitivity to stress, which in turn can affect mood, cognition, and reactivity later in life. Environmental influences that have been specifically implicated in ASD include exposure to environmental toxins, parental age, and teratogenic effects such as the maternal use of valproic acid during pregnancy. Epigenetic pathways are varied, and in many cases are not very well understood. However, in the case of valproic acid, it appears that maternal use can inhibit histone deacetylase, which has downstream effects on the production of GABAergic inhibitory neurons (Stodgell, Gnall, & Rodier, 2001) and glutamate metabolism (Kim et al., 2013).

Several genes implicated in autism may be influenced by epigenetic factors, including *GABRB3*, *UBE3A*, and *MECP2*. These genes have decreased expression in the brain of individuals with ASD, and are known to have a significant impact on neurodevelopment. As mentioned earlier, *GABRB3* is a gene located on 15q11–13 and is important to the development of GABA<sub>A</sub> receptors, which are known to be underexpressed in the brains of individuals with ASD. Animal models have shown that when this gene is no longer able to exert its effects, it results in seizures and autistic-like behaviors, including impaired social ability and anxiety (DeLorey, 2005). *UBE3A* has been implicated in Angelman’s

syndrome and appears to play a role in maintaining synaptic plasticity and experience-dependent changes in the brain (Yashiro et al., 2009). *MECP2* is a gene on the X chromosome that is important in a number of epigenetic processes critical to synaptogenesis and long-term synaptic plasticity (Kavalali, Nelson, & Monteggia, 2011). While anomalies of a gene that codes for protein called *MECP2* is highly associated with Rett syndrome, recent studies have shown significant reductions in *MECP2* protein expression also occurs in a substantial proportion of individuals with ASD (Gonzales & LaSalle, 2010). In individuals without Rett syndrome, *MECP2* gene mutations appear to be associated with global developmental delay with obsessive-compulsive disorder and ADHD (Suter, Treadwell-Deering, Zoghbi, Glaze, & Neul, 2014).

Some of the other genes implicated in ASD may also have an epigenetic role in the expression of the disorder. This includes *RELN* (discussed on p. 193), the *FMR1* gene related to Fragile X syndrome and the oxytocin receptor gene (*OXTR*). Oxytocin is a hormone produced in the hypothalamus that acts as a neuromodulator in the brain. It has effects on affiliative behavior and has been implicated in deficits in social relatedness and repetitive behavior in ASD (Bakermans-Kranenburg & van Ijzendoorn, 2014; LoParo & Waldman, 2015).

### *Endophenotypes*

It appears that structural genetic variants associated with ASD may play a role in determining risk for particular symptoms or symptom clusters rather than exerting influences that are specific to the disorder itself. As noted in the previous section on heritability, it appears that different behavioral characteristics associated with ASD may have distinctive underlying genetic determinants (Happé & Ronald, 2008). Familiarity effects have been observed for repetitive behaviors (Hollander et al., 2003), communicative abilities (Alarcón et al., 2002; Chen et al., 2006), and social aspects of ASD (Liu et al., 2011; Sasson et al., 2013). These observations have prompted a strategic shift in genetic research on ASD that emphasizes the importance of delineating endophenotypes. Endophenotypes are defined by key or fundamental deficits that underlie a disorder and contribute to its expression in a significant way (Gottesman & Gould, 2003). An underlying assumption of this approach is that these fundamental problems may more directly reflect or index the influence of genetic factors than does symptomatic behavior. Interest has recently grown in identifying cognitive endophenotypes of ASD—patterns of cognitive ability or disability that may provide a more direct expression of genetic variation in ASD (Charman, Jones, et al., 2011; Happé, Briskman, & Frith, 2001; Hughes et al., 1999; Tager-Flusberg & Joseph, 2003). Recent studies have utilized language endophenotypes or levels of impairment, for example, to help strengthen signal and reduce variability in genome-wide studies (Bartlett et al., 2014; Spence et al., 2006). A visual endophenotype has

been defined, characterized by deficits in sensitivity to visual stimuli that are low in spatial frequency and high in temporal frequency (Goodbourn et al., 2014). An endophenotype based on executive function deficits has also been proposed (Delorme et al., 2007).

### *Summary and Broader Implications*

Overall, studies of SNPs, CNVs, sequence-level changes, and other variants in seemingly noncoding regions of the genome have implicated potentially hundreds of genes in the expression of the ASD phenotype (Neale et al., 2012; Persico & Napolioni, 2013; Stein, Parikshak, & Geschwind, 2013). The genetic contribution to ASD is likely to be polygenic, possibly involving as few to as many as 15 genes in various combinations. The mechanisms appear to include both inherited genetic influences and de novo mutations. An X-linked genetic or epigenetic contribution has been suggested given that males are more likely to be diagnosed with the disorder (Jiang et al., 2013; Piton et al., 2010). Some of the anomalies have fairly direct influences on brain development because they code for the expression of structures involved in cellular development, positioning, or migration. Other genetic influences may act on neurodevelopment indirectly through their influence on immune or hormonal function or through epigenetic pathways.

Given the diversity of the genetic anomalies that have been associated with ASD, and given their often broad impact on neurodevelopment, it is perhaps not surprising that some of the genes that confer risk for ASD also confer risk for conditions that are often comorbid in ASD. Among these, ADHD ranks among the most common comorbid conditions, with approximately 50% of children with ASD also meeting criteria for ADHD (Rommelse et al., 2010). Indeed, there is growing evidence to suggest that individuals diagnosed with ADHD also demonstrate some characteristics commonly associated with ASD (Demopoulos, Hopkins, & Davis, 2013). This relationship suggests that the two disorders may share some common neurobiological risk factors, possibly because the same gene or genes may contribute to different phenotypes. Such pleiotropic relationships are often mediated by gene effects on a metabolic pathway that contributes to different behavioral phenotypes. Pathways implicated in both ASD and ADHD include both the dopamine (Swanson et al., 2007) and GABA neurotransmitter systems (Fatemi et al., 2012). A few studies that have examined the shared genetic risk between the two conditions found that it is modest and that there are also some common environmental influences explaining their covariation (Polderman, Hoekstra, Posthuma, & Larsson, 2014; Ronald, Edelson, Asherson, & Saudino, 2010). Interestingly, Polderman et al. found that stronger genetic correlations (from .22 to .64) occurred when symptoms associated with restricted repetitive and stereotyped behaviors and interests were compared to dimensions of ADHD. Other conditions

commonly comorbid in ASD, possibly through pleiotropic effects, include epilepsy, language impairment, depression, and anxiety disorders. More comprehensive discussions of comorbidity in ASD are provided by Mannion and Leader (2013) and (Bauman, 2010).

### **Environmental Influences**

Given the high estimates of heritability for ASD by twin studies, environmental factors were until fairly recently thought to play a relatively minor causative role in ASD (Burd, Severud, Kerbeshian, & Klug, 1999). However, as mentioned on p. 192, some recent genetic studies have suggested that the heritability of autism may not be as great as previously believed (Hallmayer et al., 2011; Ronald & Hoekstra, 2011). Moreover, recent increases in ASD prevalence cannot readily be explained on the basis of heritability. Individuals with autism and their siblings demonstrate reduced fecundity (Power et al., 2013). The lower probability of reproducing in these individuals seems incompatible with the rise in prevalence due to heritable genetic factors alone. In addition, growing recognition of the importance of de novo genetic mutations in determining risk for ASD has necessitated a closer look at identifying potential environmental determinants of these mutations. These factors have led to increased interest in elucidating potential gene–environment interactions that could have implications for neurodevelopment and thereby increase risk for autism (Herbert, 2010; Stamou, Streifel, Goines, & Lein, 2013).

### *Adverse Pre-and Perinatal Events*

Numerous studies have established an association between adverse pre- and perinatal events and risk for ASD (Juil-Dam, Townsend, & Courchesne, 2001; Piven, Simon, Chase, Wzorek, & et al., 1993; Wilkerson, Volpe, Dean, & Titus, 2002). Some of the more commonly implicated factors include low birth weight, multiple gestation, prematurity, vaginal bleeding, threatened abortion, poor fetal growth, prolonged labor, hypoxia, a need for resuscitation at birth, and a five-minute Apgar score below 7 (Hultman, Sparen, & Cnattingius, 2002). A review by Kolevzon, Gross, and Reichenberg (2007) identified low birth weight and intra-partum hypoxia as two of the more consistent obstetric risk factors for autism.

Schieve et al. (2011) examined multiple perinatal factors associated with obstetric risk (e.g., preterm, very preterm, low and very low birth weight, multiple birth, cesarean delivery, breech presentation, and assisted reproductive technology use) and evaluated their contribution to increases in prevalence of ASD identified in recent population studies. Their analysis suggested that these factors alone or in combination accounted for a very small proportion (less than 1%) of the observed increase in ASD prevalence. Given that most children born under conditions of obstetric risk do not

develop ASD, it has been suggested that decreased obstetric optimality may be an epiphenomenon of ASD that derives from preexisting abnormality of the fetus, rather than being a causative agent at delivery (Zwaigenbaum et al., 2002).

Others have pointed to a variety of pre-and perinatal environmental exposures as potentially increasing risk for ASD. This includes maternal cigarette smoking during early pregnancy (Hultman et al., 2002), exposure to certain drugs (e.g., sodium valproate, thalidomide, cocaine), and psychological stress during pregnancy (Dawson, Ashman, & Carver, 2000) as potential risk factors for adverse outcomes. The data supporting some of these assertions has been mixed.

Events such as hypoxia result in a cascade of immune responses, including neuroinflammation. In prenatal development, the fetus is highly vulnerable to a broad range of events or environmental exposures that can potentially elicit an innate or adaptive immune response (Onore, Careaga, & Ashwood, 2012; Rossignol & Frye, 2012; Stigler, Sweeten, Posey, & McDougle, 2009). Numerous studies have identified abnormalities of immune function in individuals with ASD (Depino, 2013; Noriega & Savelkoul, 2014). Some have suggested anomalies of the blood-brain barrier (Noriega & Savelkoul, 2014), while others have proposed that some of the genetic contributions to ASD may involve genes that influence immune system activation and regulation (Campbell, Li, Sutcliffe, Persico, & Levitt, 2008; Torres, Westover, & Rosenspire, 2012).

### ***Immunological Factors***

One obvious mechanism by which immune system dysfunction can increase risk for ASD involves prenatal susceptibility or inadequate protection against viruses or other pathogens. It has long been recognized that direct viral infection (e.g., herpes encephalitis, congenital rubella) of the developing brain can have devastating neurodevelopmental consequences that increase risk for ASD (Chess, 1971; Ghaziuddin, Al-Khoury, & Ghaziuddin, 2002; Gillberg, 1986).

Recent interest has turned to the possibility that milder infectious episodes may also increase risk for ASD. Approximately one in every six brains of individuals with ASD demonstrates some evidence of immune-mediated reactions (lymphocytic infiltrates) in postmortem brain tissue samples (Bailey, Luthert, et al., 1998; Guerin et al., 1996). Some of the findings have implicated anomalies occurring during fetal development. The presence of lymphocytes in brain tissue is indicative of an adaptive immune response to infection. While maternal infection with mild common infectious diseases or febrile episodes is not associated with ASD, Atladottir, Henriksen, Schendel, and Parner (2012) have suggested that maternal influenza infection during pregnancy may double the risk for autism, and episodes causing prolonged fever can triple the risk. Although these results are preliminary and require replication, there is compelling data from animal studies associating both maternal fever (Edwards,

2006) and maternal influenza infection (Fatemi, Earle, et al., 2002; Fatemi, Folsom, Reutiman, Huang, et al., 2009) with alterations in fetal and postnatal development.

The underlying mechanisms for the anomalies in brain development in offspring remain unclear, but potential mediators include increased placental cytokines and oxidative stress. Animal models of the effects of influenza have shown that maternal immune activation results in elevations of pro-inflammatory cytokines and activation of astrocytes and microglia that may especially affect particular areas of the fetus's developing brain. Cytokines are proteins that regulate the nature, duration, and intensity of immune reactions and are involved in multiple aspects of neurodevelopment. Immune cytokines can influence neurodevelopment, specifically impacting progenitor cell differentiation, neural migration, and synaptic network formation (Deverman & Patterson, 2009).

Cytokine dysregulation can potentially have widespread effects on neurodevelopment (Goines & Ashwood, 2013). Animal studies have shown that areas of the brain showing evidence of cytokine activation include frontal and cingulate cortices, the hippocampus (Garay, Hsiao, Patterson, & McAllister, 2013), the cerebellum (Fatemi, Folsom, Reutiman, Abu-Odeh, et al., 2009) and the brain stem (Miller et al., 2013). Fatemi et al. (2008) found that prenatal exposure to influenza in mice resulted in reduced brain volumes at birth, but macrocephaly in later development. Fatemi and colleagues have suggested that maternal infection leads to abnormal gene regulation with consequent effects on brain development. These findings are of particular interest given evidence of a higher than expected incidence of macrocephaly in ASD (Barnard-Brak, Sulak, & Hatz, 2011; Davidovitch, Patterson, & Gartside, 1996; Deutsch, Folstein, Tager-Flusberg, & Gordon-Vaughn, 1999; Lainhart et al., 2006; Woodhouse et al., 1996). (See the section on "Head Circumference, Macrocephaly, and Megalencephaly.") Anti-neuronal antibodies can be found in the sera of children with ASD and as well as their mothers (Zimmerman et al., 2007) and are correlated with the autism severity (Piras et al., 2014). These findings appear to dovetail with several population-based cohort studies in humans which have identified maternal immune activation (MIA) as a risk factor in ASD (Atladottir et al., 2012; Zerbo et al., 2013).

Several studies have found abnormal immunoglobulin profiles in children with autism, although the evidence for this has been variable. Serum IgG, for example, has been described as increased, decreased, or both (Stigler et al., 2009). A recent animal study has also demonstrated some of the effects that immunoglobulins can have on brain development. When macaque mothers were administered immunoglobulins (IgG), and then isolated from mothers of children with ASD, their offspring not only showed abnormal social behavior during development but also demonstrated structural differences in brain development, particularly involving white matter in the frontal lobe (Bauman et al., 2013). Relatedly,

studying humans has shown that parenteral autoimmune disease status was significantly associated with autism in offspring (Keil et al., 2010; Lyall, Ashwood, Van de Water, & Hertz-Picciotto, 2014).

Evidence of another type of immune response, one involving the production of microglia and astroglia, has also been observed in postmortem studies of ASD brains. Microglia are indigenous macrophages of the brain and are activated as part of the innate immune system's response in order to scavenge the brain for damaged neurons and infectious agents, which are then removed. They play a particularly important role in protecting the brain due to the unavailability of antibodies from other parts of the body that are too big to cross the blood-brain barrier. Microglia must therefore be sensitive to extremely small pathological changes in order to prevent fatal damage. Their activation is typically followed by the activation of pro-inflammatory and anti-inflammatory cytokines. Microglia and astroglia are also involved in repair and restoration following neuronal loss and produce growth factors to help maintain normal function within the CNS. Vargas, Nascimbene, Krishnan, Zimmerman, and Pardo (2005) examined postmortem brain tissue samples from individuals with ASD and observed evidence of widespread microglial and astroglial activation that was most common in cerebellum (present in 9 out of 10 brains). Laurence and Fatemi (2005) found increased levels of a protein marker of astroglial activation in the cerebellum, cingulate cortex and frontal lobe in postmortem samples from ten individuals with ASD. Morgan et al. (2010) examined postmortem tissue samples from dorsolateral frontal cortex (Brodmann area 9/46) of 13 individuals with autism and found evidence of microglial activation and increased microglial density in 38% of their sample. Zimmerman and colleagues have also demonstrated the presence of neuroglia and innate immune system activation in brain tissue of individuals with autism, supporting the view that neuroimmune abnormalities may contribute to the autism phenotype (Pardo, Vargas, & Zimmerman, 2006).

The circumstances prompting microglia and astroglia activation in the brains of autistic individuals remain unclear. Given that microglia activation is the main cellular response to CNS dysfunction, it could potentially reflect an innate autoimmune response to synaptic or neural network disturbances. Similar responses are evident in a number of neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. This contrasts with the findings of an adaptive immune response (e.g., lymphocyte and/or antibody-mediated reactions) observed in other neuropathological studies of the brain in ASD (Bailey, Luthert, et al., 1998; Guerin et al., 1996), which signify a response to infection.

Numerous reports have speculated on possible autoimmune factors that may prompt the production of autoantibodies that attack the brain (Braunschweig et al., 2013; Connolly, Streif, & Chez, 2003; Singer et al., 2008; see Stefanatos, Kinsbourne, & Wasserstein, 2002b for discussion).

Data from diverse samples have suggested that anti-brain autoantibodies have been identified in about 30% to 70% of autistic children (Singh & Rivas, 2004; Singh, Warren, Averett, & Ghaziuddin, 1997; Todd, Hickok, Anderson, & Cohen, 1988). This includes but is not limited to autoantibodies to serotonin receptors, alpha-2 adrenergic binding sites, brain endothelial cells, myelin basic protein, and nerve growth factor (Ashwood & Van de Water, 2004; Hsiao, 2013; Krause, He, Gershwin, & Shoenfeld, 2002). In addition, there have been scattered reports of elevated anti-brain antibodies in the serum of mothers of children diagnosed with ASD (Zimmerman et al., 2007), suggesting that maternal antibodies might cross the placenta and affect prenatal brain development of their offspring. To further complicate interpretation, some of the observed cytokine elevations are similar to those associated with inflammation caused by epileptic spikes and may perhaps be suggestive of excessive glutamate excitotoxic effects (Pickering, Cumiskey, & O'Connor, 2005). Alternatively, the increased cytokines may represent a heightened immune response possibly associated with chronic brain inflammation and tissue necrosis (Li et al., 2009). The production of cytokines can have a significant impact on gene expression and neurodevelopment related to ASD (Cohly & Panja, 2005; Crespi & Thiselton, 2011; Gesundheit et al., 2013).

One of the first suggestions that autoimmune dysfunction may play a role in etiology of ASD emanated from a case report describing a child with ASD and a strong family history of autoimmune disorder (Money, Bobrow, & Clarke, 1971). This has since been followed by several studies indicating that autoimmune disorders cluster in the families of ASD children. Comi, Zimmerman, Frye, Law, and Peeden (1999) found that 46% of families with an autistic child had two or more members with autoimmune disorders. Common conditions were Type 1 diabetes, adult rheumatoid arthritis, hypothyroidism, and systemic lupus erythematosus. It is noteworthy that immune function is mediated by similar genes to those implicated in brain development (Warren et al., 1996).

Together, these findings suggest that different immune-mediated mechanisms may be operative in ASD. In some cases, the activation could possibly represent an abnormal neuroimmune response to some unspecified infection, while in others it could reflect an innate reaction to CNS dysfunction (Morgan et al., 2010; Vargas et al., 2005).

### *Genetic/Environmental Interactions*

It has been suggested that some variants of ASD may occur as a result of genetically-related susceptibility to environmental stressors and exposures such as air pollution, heavy metals, insecticides, ethyl alcohol, food contaminants, and maternal smoking early in pregnancy (Geier & Geier, 2007; Kalia, 2008; Roberts et al., 2013; Roberts & English, 2013; Volk, Lurmann, Penfold, Hertz-Picciotto, & McConnell,

2013). In addition, a number of teratogenic influences have been implicated (e.g., thimerosal, thalidomide, valproic acid, ultrasound) (Landrigan, 2010; Williams & Casanova, 2010; Young, Geier, & Geier, 2008).

Some forms of exposure can potentially result in *de novo* genetic mutations that could potentially lead to deleterious phenotypes in the next generation. Others may result in oxidative stress, neuroinflammation, or mitochondrial dysfunction that could increase risk of consequences related to obstetric suboptimality (Rose et al., 2012; Zerbo et al., 2014). To date, there have been no large-population, cohort, or case-control studies that have definitely identified a specific toxic agent as a specific risk factor.

### **Stress**

It has been argued that stressful life events and hardships should also be included among the pre- and perinatal risk events, since these events can potentially have biological effects on the pregnancy, delivery, and the neonatal phase (Dawson et al., 2000; Kinney, Barch, Chayka, Napoleon, & Munir, 2010). Ward (1990) previously reported that mothers of children with ASD described significantly higher family discord and psychiatric problems during pregnancy than mothers of children without ASD. The causal mechanisms underlying this association are ambiguous. However, Kinney, Miller, Crowley, Huang, and Gerber (2008) noted an increase in prevalence of ASD in Louisiana that was related, in a dose-response fashion, to the severity of storm exposure in the prenatal period, especially with exposures near the middle or end of gestation. Further exploration of this hypothesis in a large study examining the impact of multiple stressful life events failed to find an association between prenatal exposure and risk for ASD (Rai et al., 2012). This may relate to difficulties in operationalizing stress effects at the individual level.

### **Summary**

Overall, there is reasonably compelling evidence connecting immune dysfunction to autism, but much of it remains indirect and fragmented. The mechanisms by which immune mechanism may alter brain anatomy and physiology of the specific pathways that are involved in autism are complex and remain to be fully elucidated. Further explorations in this area holds the promise of potentially leading to new avenues to treat or prevent the disorder (Chez, Memon, & Hung, 2004; Zerbo et al., 2014).

To date, evidence that immune-based therapy is beneficial in autism remains sparse. Groundbreaking reports by Buitelaar et al. (1992) and Stefanatos, Grover, and Geller (1995) described isolated successes of this approach in specific cases. These have been followed by additional case studies (Matarazzo, 2002; Mordekar, Prendergast, Chattopadhyay, & Baxter, 2009; Shenoy, Arnold, & Chatila, 2000) and small

group studies (Plioplys, 1998; Stefanatos, Kollros, & Rabinovich, 1996). A recent retrospective study by Duffy et al. (2014) compared 20 children with regressive autism spectrum disorder (RASD) treated with corticosteroids to 24 children with ASD not treated with steroids (NSA). They described significant improvements in both clinical function as well as in the steady-state auditory evoked responses as described by Stefanatos (1993) and (Stefanatos, Foley, Grover, & Doherty, 1997). This research provides a rationale for a randomized trial with steroid therapy to determine the longer-term benefits and complications of steroids in this population (Golla & Sweeney, 2014).

### **Neuroscience of ASD**

Diverse anomalies involving neural structure and function (cytoarchitecture, gross neuroanatomy, electrophysiology, regional cerebral metabolism, and neurochemistry) have been identified in children with autism. Here, we selectively review this literature with a view to providing sufficient background to understand current neuropsychological conceptualizations of ASD and its biological basis.

#### ***Head Circumference, Macrocephaly, and Megalencephaly***

As noted earlier, Kanner's observation of "relatively large heads" in five of the children in his original cohort was likely of uncertain significance given the diverse developmental sequelae of macrocephaly. In order to differentiate the benign from the more neurologically-involved cases, Fletcher (1900) adopted the term *megalencephaly* to specifically denote head-size enlargement associated with pathological brain growth that resulted in impairment of function. In his defining post-mortem investigation of megalencephaly, Fletcher described an overtly well-formed brain of increased volume and weight that on microscopic inspection revealed a variety of cyto-architectural anomalies, the main one being excess density and number of glial cells. Kinnier Wilson (1934), one of the preeminent neurologists of the 1920s and 1930s, described diverse abnormalities of neural structure and organization in megalencephaly, including irregularities in cellular shape and size, heterotopias, perturbations in the laminar composition of the cortex and "disharmonic" distribution of gray and white matter (e.g., small corpus callosum, "packed" appearance of cerebral gyri). A case presented by McGrath (1935) is of particular interest given Kanner's observations. McGrath described a 32-year-old gentleman who, like many previously-reported cases of megalencephaly, was extremely low-functioning (mental age of 5 years, 11 months) and had a seizure disorder. The case is noteworthy because this gentleman displayed an unusual talent for remembering dates—a savant skill. He could correctly name the day of the week of any given date and could remember the precise date of significant events that occurred to himself or others on his ward

(e.g., deaths, promotions, job start dates, blood draws, spinal taps, etc). While Kanner (1943) recognized special talents in his original 11 cases of infantile autism, he regarded them as “unquestionably endowed with good cognitive potentialities,” and only one (Case 10) had a childhood history of seizures.

Kanner’s observation regarding head size was overlooked for a half a century until Bailey et al. (1993) reported heavier than normal brain weight in a handful of cases of ASD who had come to postmortem investigation. These findings extended an earlier postmortem report of increased brain weight in one of two individuals with ASD (Williams, Hauser, Purpura, DeLong, & Swisher, 1980). Though the number of cases was small, Bailey et al. (1993) underscored the significance of this observation by pointing to findings from an epidemiological twin study showing a curiously high percentage of boys (42%) with autistic disorder (> 16 years) with unusually large occipital-frontal head circumference (OFHC) measurements (> 97th percentile) (Bailey et al., 1995). As evidence that this increased rate of macrocephaly was unrelated to twinning, Bailey et al. (1995) noted that a separate family genetic study showed a very similar elevation (37%) of macrocephaly in singletons with ASD (Bolton, Macdonald, Pickles, Rios, & et al., 1994). Given the established high correlation between OFHC and both brain weight (Lemons, Schreiner, & Gresham, 1981) and volume (Bray, Shields, Wolcott, & Madsen, 1969), Bailey et al. (1993) conjectured that a substantial proportion of cases of ASD were related to megalencephaly.

Numerous reports subsequently confirmed a significantly higher frequency of macrocephaly (9.5%–31.1%) in children and adults with ASD (Courchesne & Pierce, 2005a; Davidovitch et al., 1996; Fidler, Bailey, & Smalley, 2000; Fombonne, Roge, Claverie, Courty, & Fremolle, 1999; Gillberg & de Souza, 2002; Lainhart et al., 1997; Sacco et al., 2007a) compared to the general population (~3%). Indeed, this was, for a time, one of the most replicated anatomical findings concerning ASD (Lainhart, 2003). However, estimates of the proportion of affected individuals varied considerably from one study to the next, with relatively few studies matching the high rates observed by Bailey and colleagues (Bailey et al., 1993; Bailey et al., 1995; Bolton, Macdonald, Pickles, Rios, & et al., 1994; Woodhouse et al., 1996). Pooling data from several sources, Fombonne et al. (1999) estimated that approximately 20% of individuals with ASD met criteria for frank macrocephaly. However, many subsequent studies have reported somewhat lower prevalence estimates (Deutsch et al., 1999; Lainhart et al., 1997; Torrey, Dhavale, Lawlor, & Yolken, 2004), and a few have failed to find that the frequency of macrocephaly in ASD was significantly different from reference populations (Cederlund, Miniscalco, & Gillberg, 2014; Constantino, Majmudar, et al., 2010; Davidovitch, Golan, Vardi, Lev, & Lerman-Sagie, 2011).

The age at which head circumference measurements are taken was identified as an important factor influencing the

frequency of observations of macrocephaly in ASD. Mason-Brothers et al. (1987) examined birth records of children with ASD and found that the rate of macrocephaly (2%) was unremarkable. Subsequent studies have yielded similarly low estimates (typically 1%–6%), and most have concluded that the rate of macrocephaly at birth in ASD is not significantly different from that seen in the general population (Courchesne et al., 2001; Dementieva et al., 2005; Dissanayake, Bui, Huggins, & Loesch, 2006; Lainhart et al., 1997; Mraz, Green, Dumont-Mathieu, Makin, & Fein, 2007; Stevenson, Schroer, Skinner, Fender, & Simensen, 1997; Torrey et al., 2004; Whitehouse, Hickey, Stanley, Newnham, & Pennell, 2011). Interestingly, a couple of studies retrospectively examined prenatal ultrasound images and found a low frequency of macrocephaly in the fetal brain of children later diagnosed with ASD (Hobbs et al., 2007; Whitehouse et al., 2011). When observed, it was usually transient and normalized by birth. Indeed, anomalies in head size at birth in children with ASD may as likely be reflected in unusually small head circumference or *microcephaly* (defined as an OFHC < 3rd percentile) (Courchesne, Carper, & Akshoomoff, 2003; Fombonne et al., 1999; Grandgeorge, Lemonnier, & Jalil, 2013; Mason-Brothers et al., 1990; Miles et al., 2000; Torrey et al., 2004). Given these findings, it was reasoned that the higher rates of macrocephaly observed in young children and adults must be associated with developmental changes that occur some time after birth.

Although the number of children with ASD meeting criteria for macrocephaly is relatively small, it has been argued that this finding may have broader significance in understanding the neurobiological basis of ASD insofar as this subgroup may represent the extreme of a more general positive shift in the distribution of head size in children with ASD (Davidovitch et al., 2011; Dementieva et al., 2005; Fombonne et al., 1999). Considerable effort has therefore been devoted to gaining a better understanding of the mechanisms and time course associated with the emergence of macrocephaly in ASD. Given that neurogenesis is mostly complete by the end of the second trimester (Bystron, Blakemore, & Rakic, 2008), excess neurogenesis during fetal development seems an unlikely direct cause of subsequent observations of brain enlargement in ASD. Rather, the postnatal onset of macrocephaly more likely implicates a period of exuberant growth that occurs in the first few years of life (Huttenlocher, 1999; Koenderink & Uylings, 1995), although proliferative events in utero could possibly predispose children to exhibit anomalies at this later point in neurodevelopment. The first few years are a remarkably important period of brain development during which there is rapid growth of axons and apical dendrites, expansion of cortical synaptogenesis and interneuronal connectivity, and significant local proliferation and differentiation of glial cells (Ge, Miyawaki, Gage, Jan, & Jan, 2012). While all major sulci and gyri are established by the end of the third trimester of gestation (Chi, Dooling, & Gilles, 1977), brain volume and cortical surface at birth are only one-third of the adult brain (Hill et al., 2010; Thompson

et al., 2007). In the first year alone, growth results in a near doubling (1.8x) of the cortical surface (Li et al., 2013) and is associated with an increase in head circumference at rates of approximately 0.4 cm per week (Lorber & Priestley, 1981). By 24 months of life, head size has grown to two-thirds of its eventual adult size.

Development of the cortex is a highly dynamic process, unfolding according to genetic code but influenced by experiential and epigenetic factors. The growth of connections between neighboring aggregations of cortical neurons located in different layers of cortex gives rise to the formation of *minicolumns*, the basic processing units of the cerebral cortex (Casanova, Buxhoeveden, Switala, & Roy, 2002; Mountcastle, 1997). This process begins at about the 20th gestational week and continues until about the second year of postnatal life. A spurt of growth at around 7 to 10 months involves lengthening of dendritic terminal segments and bifurcations, particularly in layers III and V (Koenderink, Uylings, & Mrzljak, 1994), which are the source of associational and projectional connections, respectively (Mrzljak, Uylings, Vaneden, & Judas, 1990). While cortical synaptogenesis begins at about 25 weeks gestation (Zecevic, 1998), peak periods occur in the first few years of postnatal life (Bianchi et al., 2013; Huttenlocher, 1999). Periods of proliferation are typically followed by subtractive phases during which there is pruning of superfluous axons, dendrites and synapses as well as programmed cell death (apoptosis). This pruning occurs in order to fine-tune and increase the efficiency of developing neural networks and is a particularly protracted process continuing into the third decade of life (Petanjek et al., 2011). As a consequence of these subtractive influences, the adult brain possesses approximately half the number of synapses as an average 2-year-old brain.

Given this extended postnatal timetable for neurodevelopment, numerous studies have attempted to identify when in childhood macrocephaly emerges. Early studies of macrocephaly in ASD defined a window for onset between 2 and 12 years (Aylward, Minshew, Field, Sparks, & Singh, 2002; Lainhart et al., 1997), during which there appeared to be a linear increase in the rate of macrocephaly with age (Fombonne et al., 1999). However, more than a dozen systematic retrospective and prospective studies subsequently demonstrated that most children with ASD show unusual enlargement in head size in the first two to three years of postnatal life (Courchesne et al., 2003; Courchesne et al., 2001; Dawson, Munson, et al., 2007; Dementieva et al., 2005; Mraz et al., 2007; Torrey et al., 2004; Webb et al., 2007). These studies have characterized an atypical head growth trajectory in ASD marked by an accelerated rate of increase in head circumference beginning around the fourth through sixth months (Courchesne & Pierce, 2005a; Dawson, Munson, et al., 2007; Gillberg & de Souza, 2002) that continues until just after the first year and then plateaus or decelerates (Courchesne et al., 2003; Dawson, Munson, et al., 2007; Sacco et al., 2007b). The accelerated rate of growth occurs

independently of increases in body weight or length. While some studies report normalization of brain volume by adolescence (Aylward et al., 2002; Courchesne et al., 2001) and a lower frequency of macrocephaly (Bailey et al., 1995), others have reported that macrocephaly was more common in adolescents and adults with ASD than in younger children (Fombonne et al., 1999; Lainhart et al., 1997).

According to Courchesne et al. (2001), accelerated brain growth can be observed in the majority (~70%) of 2- to 3-year-old children with ASD, whether or not they eventually meet criteria for macrocephaly. It has been suggested that this accelerated early head growth trajectory may be a more important risk factor than macrocephaly for the later development of ASD (Dementieva et al., 2005; Elder et al., 2008). Others have suggested that the abnormal brain growth trajectories may be present in only a subpopulation of individuals with ASD. Suren, Stoltenberg, et al. (2013), for example, reported that accelerated head growth was not evident in girls with ASD and suggested that it may be a gender-specific phenomena. A few recent studies reported that accelerated head growth was limited to children with ASD who had a history of developmental regression (Chaste et al., 2013; Nordahl et al., 2011), although other studies have failed to find any such association (Webb et al., 2007) (see extended discussion of regression phenomena in the "Clinical Features and Developmental Course" section). Some investigators have suggested that macrocephaly may be a marker of more severe involvement, evidenced by significant correlations between macrocephaly and psychological characteristics such as low intelligence (Deutsch & Joseph, 2003; Miles et al., 2000), and greater severity of some of the core diagnostic features of autism (Lainhart et al., 2006). Others have reported that individuals with macrocephaly have higher levels of adaptive and social functioning (Dementieva et al., 2005).

It also remains unclear to what extent this pattern of early accelerated growth is specific to autism. Several studies have noted that it cuts across the autism spectrum to include Asperger syndrome and PDD-NOS (Dissanayake et al., 2006; Gillberg & de Souza, 2002). A few studies have observed that the prevalence of macrocephaly was also higher in relatives of macrocephalic children with ASD (Biran-Gol et al., 2010; Constantino, Majmudar, et al., 2010; Fidler et al., 2000; Miles et al., 2000), suggesting that it may be related to familial or endophenotypic factors. Elder et al. (2008) found that siblings of children with ASD who exhibited larger head circumference at 12 months with a subsequent deceleration of head growth between 12 and 24 months were more likely to demonstrate symptoms of autism than those siblings with more typical head growth trajectories. Rommelse et al. (2011) have argued that abnormal head growth may actually occur in other psychiatric disorders such as ADHD, oppositional defiant disorder, and communication disorders. Others have also noted a connection to ADHD symptomology (Ghaziuddin, Zaccagnini, Tsai, & Elardo, 1999; Gillberg & de Souza, 2002; Shinawi et al., 2010).

Genetic investigations have observed an association between macrocephaly and the gene PTEN (Buxbaum et al., 2007; Herman et al., 2007; Klein, Sharifi-Hannauer, & Martinez-Agosto, 2013; Marchese et al., 2014; McBride et al., 2010), which regulates a signaling pathway involved in controlling cellular growth, proliferation, and survival (Zhou & Parada, 2012). As a consequence of this relationship, screening PTEN has become a standard part of genetic screening in patients who present with autism and macrocephaly. In addition, mutations in the GLIALCAM gene can also result in megalencephaly and developmental delays and are sometimes associated with ASD and seizures (van der Knaap et al., 2010). Polymorphisms in the HOXA1 gene (Conciatori et al., 2004) and CNVs in the 16p interval (Luo et al., 2012) have also been associated with risk for an abnormally large head. These genes, like many others that have been implicated in ASD, may confer susceptibility to ASD by their role in multiple aspects of gene expression affecting morphogenesis and differentiation, influencing neuronal growth, migration, and the formation of neural connections. Behavioral anomalies associated with these mutations can span the autism spectrum and are certainly not specific to it.

The study of macrocephaly in ASD has remained an intense area of interest, in part because the measurement of OFHC offers an inexpensive, effective, and widely available means of monitoring brain growth early in development. The inconsistency in the findings may stem in part from relatively small sample size in many of the studies. Other factors potentially contributing to the variability in results include differences in recruitment methods (e.g., clinic, community, epidemiological), sample demographic characteristics (e.g., gender distribution, age), diagnostic criteria (e.g., strictly autistic disorder vs. ASD), and variations in the definition of macrocephaly. While most studies have defined macrocephaly as an OFHC of more than two standard deviations above the mean (Fishman, 1990), this has been interpreted slightly differently (e.g.,  $\geq 97$ th percentile vs.  $> 97$ th percentile vs.  $\geq 98$ th vs.  $> 98$ th percentile). A related procedural difference concerns the choice of normative databases used to determine the empirical cutoff for classification of macrocephaly. Studies completed in the United States have utilized norms from Roche, Guo, Wholihan, and Casey (1997); Nellhaus (1968); or the CDC (Kuczumski et al., 2002; Rollins, Collins, & Holden, 2010). Studies from the United Kingdom have often utilized norms compiled by Tanner (1978) or the World Health Organization (WHO, 2007), while Scandinavian studies (e.g., Cederlund et al., 2014; Gillberg & de Souza, 2002) have utilized national and local population norms. The choice of normative database has become a critical issue given recent observations that different norm sources describe substantially different distributions especially at the upper percentiles (Daymont, Hwang, Feudtner, & Rubin, 2010). Indeed, Raznahan et al. (2013) have argued that many of the observations of accelerated head growth in ASD reflect biases in the head circumference

norms used. Specifically, they cite several recent studies suggesting that utilization of norms from the CDC (Kuczumski et al., 2002) can lead to observations of abnormal growth trajectories in the first year in samples of healthy neurotypical children. Relatedly, given secular increases in population head circumference measurements that have apparently occurred over time (Ounsted, Moar, & Scott, 1985), it has been argued that norms widely used in the United Kingdom (Tanner, Gairdner-Pearson, 1978) are obsolete. While new norm sources are available, problems also exist with these alternatives at least beyond the age of 2 years (Rollins et al., 2010; Wright et al., 2002).

A recent study by Muratori et al. (2012) is illustrative of some of the procedural issues and problems inherent in a number of these investigations. These investigators retrospectively analyzed serial head circumference measurements from birth to 12 months in 50 preschoolers who had been diagnosed with ASD following assessment at a second-level autism center. These measurements were then compared to measurements obtained from 100 healthy typically developing children seen in pediatric practices in the same metropolitan area (Pisa, Italy). Measurements were collected at four time points for each child: birth, 1–2 months, 3–5 months, and 6–12 months of age. Consistent with some previous reports, there were no group differences in head circumference at birth, but by the third to fifth months, mean head size was significantly larger in the ASD group. When referenced to the CDC norms at the 6–12 month interval, 18% of the children with ASD had macrocephaly compared to 9% of the controls. These results were interpreted as demonstrating that the accelerated growth in head circumference in children with ASD begins in the first few months of life, a conclusion that is consistent with some other reports (e.g., Dementieva et al., 2005). However, it is noteworthy that the rate of macrocephaly reported in the neurotypical controls in this study matched or exceeded the rate found in ASD in some other studies (e.g., 4%, see Cederlund et al., 2014; 4.4%, see Davidovitch et al., 2011; 6%, see Grandgeorge et al., 2013; 9%, see Suren, Bakken, et al., 2013). In light of the lower prevalence of macrocephaly observed in these studies and the methodological concerns discussed on p. 206, questions have arisen as to whether there is a special connection between head size or macrocephaly and ASD (Cederlund et al., 2014; Davidovitch et al., 2011).

### *Neuropathological Studies*

Several early studies attempted to identify neuroanatomic substrates underlying ASD through histological analysis of postmortem brain specimens (Schain & Yannet, 1960; Williams et al., 1980) or biopsy material (Aarkrog, 1968). Although Schain and Yannet alluded to the “dropping out of cells in the hippocampal formation” (1960, p. 565), due to the subtle nature of the underlying pathophysiology and

given technological limitations of the time, these studies had limited yield. However, the emergence of rigorous computer-facilitated stereological analytic methods to examine the cytoarchitecture of the brain in the 1970s proved to be a significant technical advance for comparing brain development in neurotypical individuals to individuals with ASD.

### *Limbic and Paralimbic Structures*

In a pioneering study, Bauman and Kemper (1985) compared postmortem specimens obtained of a 29-year-old man with autism to that of an age- and sex-matched control. While they observed no differences in myelination or in the cellular architecture of several subcortical structures (basal forebrain, thalamus, hypothalamus, and basal ganglia), anomalies were apparent in the cerebellum, limbic, and paralimbic structures. Neurons in the hippocampus and amygdala were smaller in size and showed higher cell-packing density (increased number of neurons per-unit volume). Similar findings were evident in samples taken from the subiculum, entorhinal cortex, mammillary bodies, and medial septal nucleus. Further analysis revealed that hippocampal neurons from layers CA1 and CA4 showed evidence of limitations in intercellular connectivity and communication, which were apparent in diminished complexity and extent of dendritic arbors. They did not find evidence of substantial gliosis and overall regarded the observed changes as characteristic of neural architecture at an early stage of brain maturation rather than brain damage. While the results from this case were potentially confounded by a premorbid history of epilepsy (Amaral, Bauman, & Schumann, 2003), similar anomalies were evident in five additional cases by the same investigators (reviewed in Kemper & Bauman, 1993) and in an independent sample of two subjects (Raymond, Bauman, & Kemper, 1996). However, others have suggested that this is not a consistent finding (Bailey, Luthert, et al., 1998). Amaral, Schumann, and Nordahl (2008), for example, failed to observe anomalies in neuronal size in amygdala, but did find significant overall reductions in neuron counts.

Wegiel et al. (2010) recently reported the presence of heterotopias in hippocampus as well as in periventricular areas in 4 of 13 individuals (31%) with ASD. Irregular organization of neurons has also been identified in posterior cingulate gyrus (Kemper & Bauman, 1993; Oblak, Rosene, Kemper, Bauman, & Blatt, 2011). These findings are suggestive of problems in neural migration.

### *Cerebellum*

A more consistent finding, initially observed by Bauman and Kemper (1985) and subsequently replicated by several other investigators (Bailey, Luthert, et al., 1998; Fatemi, Emamian, et al., 2002; Kemper & Bauman, 1998; Lee et al., 2002; Ritvo & et al., 1986; Wegiel et al., 2010), concerns a decrease in the number and size of Purkinje cells and, to a

lesser degree, granule cells in the neocerebellar cortex and the inferior olivary nucleus of the brain stem. Kemper and Bauman (1998) commented that, in their experience, these anomalies occurred in the absence of glial cell hyperplasia and therefore likely emerged early in the prenatal period (prior to 30 weeks gestation) when glial cells are unable to proliferate. The cerebellum and the inferior olivary nucleus develop reciprocal connections during fetal development that are fairly well established by 28–30 weeks gestation. Loss of Purkinje cells after this period generally results in retrograde degeneration of neurons in the inferior olive. Given that neurons in the inferior olivary nucleus appeared small, but not diminished in number, Bauman and Kemper (2005) argued that it is likely that the Purkinje cells loss in ASD occurs early in neurodevelopment before the functional coupling with the inferior olive. Others, however (e.g., Bailey, Luthert, et al., 1998), have observed that Purkinje cell loss may sometimes be accompanied by gliosis, allowing the possibility that postmortem anomalies in some cases reflect peri- or postnatal factors. Purkinje cells have an exceptionally high metabolic demand and are susceptible to multiple pathogenic influences. Some of these influences may be associated with birth trauma (ischemia, hypoxia, excitotoxicity), while others may be related to adverse events during fetal development such as viral infections, thiamine deficiency, and exposure to heavy metals and toxins (Kern, 2003). While loss of Purkinje cells has been reported in nearly three-quarters of known autopsy cases (Palmen, van Engeland, Hof, & Schmitz, 2004), the neurodevelopmental significance of this finding remains to be fully elucidated.

### *Cortex*

Although early studies reported no anomalies of the cerebral neocortex (Bauman & Kemper, 2005; Coleman, Romano, Lapham, & Simon, 1985; Guerin et al., 1996), more recent studies have identified subtle disturbances of cortical development in a proportion of cases (Bailey, Luthert, et al., 1998; Casanova, 2007; Hof, Knabe, Bovier, & Bouras, 1991). Anomalies include cortical thickening, increased neuronal density, irregular patterns of cortical lamination, small and unusually-oriented pyramidal cells, and heterotopias (Bailey, Luthert, et al., 1998; Coleman et al., 1985; Kemper & Bauman, 1998). However, the number of subjects in these studies was often small, and there is typically considerable interindividual variability. These issues continue to be evident in more recent studies. Jacot-Descombes et al. (2012) studied eight postmortem brains of individuals with ASD and identified decreased size of pyramidal neurons in areas 44 and 45 (Broca's area), although there was no difference in neuron number or layer volumes. By contrast, Courchesne et al. (2012) examined seven postmortem brains and found 67% more neurons in the prefrontal cortex (PFC) and 75% more neurons in dorsolateral prefrontal cortex compared to controls. This was accompanied by an increase

in brain weight. Given the atypical developmental trajectories of brain growth in ASD, the difference in findings may be attributable to the younger age at which the specimens became available for study in the Courchesne study (6–16 years vs. 4–48 years). However, (Stoner et al., 2014) recently reported that the brains of individuals with ASD demonstrated focal patches of cytoarchitectural abnormalities, which showed some degree of regional variation across individuals. Specifically, they observed abnormal laminar cytoarchitecture and cortical disorganization of neurons in most patches of tissue from prefrontal and temporal cortex, but not in tissue from occipital cortex. Glial cells were unaffected. Anomalies were most clearly evident in layers 4 and 5, although no layer was spared. These findings point to disturbances of cortical layer formation and neuronal differentiation that typically occurs during prenatal brain development. While these findings may reflect a migrational defect, they could also possibly arise from early anomalies of genetic transcriptional changes that sequentially specify distinct cell fates of progenitor cells.

Additional anomalies in corticogenesis have been identified by Casanova et al. (2002), who reported that cortical minicolumns were unusually configured in the brains of individuals with ASD in at least three areas of cortex: (a) Brodmann area 9 (BA 9) of prefrontal cortex, (b) BA 21 in the temporal lobe, and (c) BA 22 in posterior temporal cortex. Columns were smaller and there was less of the space between cells that normally contains dendrites, axons, and synapses (neuropil). Minicolumns were abnormally narrow in frontal and temporal cortex but not in occipital cortex. It was suggested that the resulting circuitry may lack the inhibitory influences that minicolumns typically exert on adjacent columns. This lack of lateral inhibition may potentially result in diminished ability to discriminate sensory information due to an increase in “neural noise,” which may account for the hypersensitivity seen in many children with ASD. In addition, islands of excessive excitatory activity could potentially develop into seizure foci (Casanova, 2006). The factors underlying the emergence of this atypical architecture remain unclear. Since the number of minicolumns in developing cortex is related to the number of cells produced in the subventricular proliferative zone (Kornack & Rakic, 1998), the apparent migrational disturbances may indirectly relate to excessive proliferation of neurons earlier in development.

A few studies have provided evidence indicating that individuals with ASD also demonstrate an excess of dendritic spines on apical dendrites of pyramidal cells in cortical layer 2 of frontal, temporal, and parietal cortex (Hutsler & Zhang, 2010; Phillips & Pozzo-Miller, 2015). This excess potentially implicates problems during embryogenesis, or alternatively, these observations may reflect a failure of pruning processes that normally follow exuberant growth. In contrast to these excesses, significant reductions in neuronal density (van Kooten et al., 2008) and decreases in GABA<sub>A</sub> and GABA<sub>B</sub>

receptor density have been observed in the fusiform gyrus (FG), an area thought to play a special role in face perception. Similarly, significant reductions in GABA<sub>A</sub> receptor density have been observed in anterior and posterior cingulate cortex (PCC; see Oblak, Gibbs, & Blatt, 2009; Oblak, Gibbs, & Blatt, 2010), structures involved in cognitive control that have been implicated in restricted or repetitive behaviors in ASD. Fatemi, Reutiman, Folsom, and Thuras (2009) observed reductions in GABA<sub>A</sub> receptor subunits in the cerebellum, superior frontal cortex (BA9), and parietal cortex. These areas have often been implicated in ASD utilizing a variety of methods of investigation. Several studies have recently confirmed anomalies in GABA concentration in vivo utilizing <sup>1</sup>H magnetic resonance spectroscopy (<sup>1</sup>H MRS). These are discussed in a later section, “Magnetic Resonance Spectroscopy and Positron Emission Tomography.”

### Summary

The interpretation of histopathological studies in ASD is complicated by a large number of potential confounding variables. The very small number of cases comprising each of these studies is a serious problem that is exacerbated by inconsistencies in the quantitative histopathological techniques used and the tremendous heterogeneity of the disorder itself. Most of the studies have involved the examination of human pathological material obtained from deceased older children and adults, so the results are inevitably also confounded by an enormous number of potential epigenetic and environmental effects. Given the manner in which specimens come under study, important variables such as the presence of intellectual disability, seizure disorders, medical complications, and use of medications have remained uncontrolled. It could therefore be argued that the findings described in these reports reflect the effects of having autism as much as the neurobiological circumstances that increase risk for developing the disorder.

Other findings such as increased neuronal density and number, variations in cortical thickness, disturbances of laminar structure, the presence of ectopic neurons, and the anomalies of minicolumn formation implicate anomalies in neural proliferation and migration probably occurring in the first six months of gestation (Bailey, Palferman, Heavey, & Le Couteur, 1998; Gillberg, 1999; Piven, Berthier, Starkstein, Nehme, et al., 1990). Other anomalies implicate disturbances of program cell death (apoptosis), cell fate specification, pruning, and neuronal connectivity that could reflect anomalies in the postnatal neurodevelopment. As already discussed, recent advances in genetics have implicated the possible role of a number of genes that have a direct impact on neurodevelopment after birth, towards the second half of the first year. These anomalies can lead to a number of disturbances identifiable at the macrostructural level such as atypical formation of the cortex (e.g., polymicrogyria or macrogyria) and cortical heterotopias.

### **Structural Neuroimaging**

Head circumference has provided an easy and important window to study early brain growth in ASD. However, approximately 90% of adult total brain volume occurs by 5 years of age, so that an increasing proportion of variance in subsequent head growth is accounted for by growth of non-neural tissue (Tate, Bigler, McMahon, & Lainhart, 2007). As a result, the strong correlation (.88–.93) that exists between head circumference and total brain volume in young children (Bartholomeusz, Courchesne, & Karns, 2002; Hazlett et al., 2005) decreases with age to about .67 (Piven, Arndt, Bailey, & Andreasen, 1996). Recognizing these limitations, an increasing number of investigators have undertaken a more direct approach to examining brain growth using high-resolution structural neuroimaging. This approach offers an opportunity to examine brain development in vivo with exquisite anatomic resolution and independently of other aspects of physical growth. On the assumption that symptoms of ASD must arise from anomalies of neural function that arise prior to the end of toddlerhood, a growing number of these studies have been directed to examining brain growth in the first few years of life at a time when symptoms of autism are unfolding.

Overall, structural MRI studies have generally confirmed that young children with ASD (2–4 years) demonstrate larger whole-brain volumes of gray and white matter than controls (Aylward et al., 2002; Piven et al., 1995; Sparks et al., 2002) than controls. Differences were identified in the first 6 to 12 months after birth, and by 2 to 4 years of age, whole-brain volumes in ASD were approximately 10% larger than neurotypical controls (Hazlett et al., 2005; Redcay & Courchesne, 2005). By 4 to 5 years of age, brain size in individuals with ASD approached maximum volume, which was comparable to the volume of typically developing adolescents (Courchesne et al., 2001). Some studies have suggested the total brain volume in adolescents are within normal limits (Courchesne et al., 2001; Stanfield et al., 2008), while others have reported that elevated total brain volume can persist into adolescence and adulthood (Freitag et al., 2009; Hazlett, Poe, Gerig, Smith, & Piven, 2006).

While differences in brain size in ASD have been most reliably indexed by total volume measures, a number of studies have suggested differential involvement of various regions of cortex (Piven et al., 1996). Several reports have described an anterior-to-posterior gradient, with most enlargement in frontal lobes and temporal lobes (Courchesne et al., 2007), followed by parietal areas (Amaral et al., 2008), and least enlargement in the occipital lobes (Brun et al., 2009; Carper & Courchesne, 2005; Hazlett et al., 2006). A number of studies have explored this further, utilizing methods to parcellate whole-brain images into smaller reliably-defined regions of interest. Several studies have identified enlargement in dorsolateral prefrontal and medial frontal cortex and noted that these volumetric increases were apparent

in the first couple of years and changed less over time compared to typically-developing children. (Carper & Courchesne, 2005; Carper, Moses, Tigue, & Courchesne, 2002).

Other areas of enlargement noted in the first 2 to 4 years includes the temporal and parietal lobes (Hazlett et al., 2011; Schumann et al., 2010), the cingulate (Schumann et al., 2010), cerebellum (Bloss & Courchesne, 2007; Courchesne et al., 2001), and the amygdala (Mosconi et al., 2009; Schumann, Barnes, Lord, & Courchesne, 2009; Sparks et al., 2002). Relatively few studies have examined differences in subcortical structures in young children with ASD. A few studies have reported decreased volumes in the brain stem (Hashimoto et al., 1995) and cerebellar vermis relative to controls (Bloss & Courchesne, 2007; Hashimoto et al., 1995; Webb et al., 2009). However, conclusions derived from the results of these studies must be tempered with recognition of the often small sample sizes. Other studies have found no evidence of early abnormalities in brain structure in ASD (Zeegers et al., 2009).

A meta-analysis by Stanfield et al. (2008) of 43 structural imaging studies largely involving children greater than 7 years of age, adolescents, and adults, confirmed that the total brain volume in individuals with ASD was larger than controls. In addition, the analysis revealed increased volume of both left and right cerebral hemispheres, the cerebellum and the caudate. By contrast, decreased volumes were evident in midbrain, cerebellar vermis, and parts of the corpus callosum. Overall, the results reveal a complex pattern of regional overdevelopment and underdevelopment within more general effects related to overall brain volume. Because of the continual changes that occur in brain development from infancy through adulthood, longitudinal studies are required to assess the reliability of obtained and cross-sectional studies. Some preliminary longitudinal studies recently described increased volume in amygdala and hippocampus in children with ASD between 2 and 4 years (Mosconi et al., 2009; Nordahl et al., 2012) and also in 8–12 year olds (Barnea-Goraly et al., 2014). One of the largest longitudinal studies followed 41 children diagnosed with ASD examining multiple scans that had been collected from 1.5 years up to 5 years of age. Significant enlargement in both cerebral gray and white matter were evident by 2.5 years of age, with the most severe enlargement occurring in frontal, temporal, and cingulate cortices (Schumann et al., 2010).

### *Gray Matter Versus White Matter*

Questions arose as to whether this excess growth primarily affected gray or white matter, or both. A meta-analysis by Via, Radua, Cardoner, Happe, and Mataix-Cols (2011) focused on a small number of studies utilizing voxel-based morphometry (VBM), a method that is well-suited to detecting regional differences in gray and white matter throughout

the brain. The analysis failed to find differences in global gray matter volumes between individuals with ASD and controls, although small increases in gray matter volume were evident in left middle inferior frontal gyrus (BA 46 and BA 10). These areas in rostral and adjacent dorsolateral prefrontal cortex are thought to be involved in executive function. By contrast, robust gray matter reductions in the ASD group were evident in the amygdala/hippocampus (particularly on the right side) and medial parietal areas (precuneus-BA 7). A meta-analysis by Cauda et al. (2011) revealed rather more extensive gray matter increases involving the cerebellum, middle temporal gyrus, cingulate cortex, regions around the junction of the occipital, temporal and parietal lobes, and several subcortical structures including the caudate head and the insula. Decreases in gray matter were evident bilaterally in the cerebellar tonsils, inferior parietal lobule, right amygdala, insula, and middle temporal gyrus, as well as the caudate tail and precuneus. Together, these analyses revealed a very mixed pattern of over- and underdevelopment in highly-distributed areas of frontal, temporal, and parietal cortex, as well as in several subcortical structures including the cerebellum, amygdala, and parts of the basal ganglia.

A few studies have shown an accelerated decrease in cortical thickness in temporal, parietal, and occipital cortex during late childhood and early adolescence (Hardan, Libove, Keshavan, Melhem, & Minshew, 2009; Raznahan et al., 2010; Scheel et al., 2011; Wallace, Dankner, Kenworthy, Giedd, & Martin, 2010). These changes then appear to abate in adulthood (Zielinski et al., 2014). Cortical thinning has been noted in several studies of adults with ASD (Hadjikhani, Joseph, Snyder, & Tager-Flusberg, 2006; Hardan, Muddasani, Vemulapalli, Keshavan, & Minshew, 2006) involving areas critical to both communication and social function (inferior frontal cortex, superior temporal sulcus) as well as regions that may be more specifically involved in social perception and interaction (FG, cingulate gyrus, inferior parietal lobule). By contrast, gray matter increases have been noted in primary and associative auditory and visual cortex, providing a potential structural correlate to observations of enhanced auditory and visual processing skills (Hyde, Samson, Evans, & Mottron, 2010).

Analysis of white matter differences also revealed a complex pattern of anomalies. Some studies have reported increased whole-brain white matter volume (Bigler et al., 2010; Hazlett et al., 2005), while others have observed no difference. Reports of increased volume in specific regions, particularly areas underlying frontal and temporal cortex, have been inconsistent (Ke et al., 2009). There has been greater agreement regarding areas of diminished white matter volume. One of the more consistently reported structural neuroimaging findings in individuals with ASD is decreased volume of segments of the corpus callosum (CC), although there is inconsistency as to which sections (genu, body, or splenium) are mainly affected (Hardan, Pabalan, et al., 2009;

Piven, Bailey, Ranson, & Arndt, 1997; Uddin et al., 2011; Waiter et al., 2005). Both anterior and posterior connections may potentially have a major influence on neuropsychological functions that require integration of information between the hemispheres and may have a particular impact on social development and social communication (Rosema, Crowe, & Anderson, 2012).

Several studies have suggested that long-range fibers comprising cortico-cortical pathways may also be compromised in ASD. While short U-shaped association fibers provide connections between adjacent gyri, these long association fibers mediate the communication of information between widely distributed areas of cortex. Several studies have identified anomalies of fibers linking frontal cortex to other areas in the brain (Courchesne & Pierce, 2005b; Just, Cherkassky, Keller, Kana, & Minshew, 2007; Just, Cherkassky, Keller, & Minshew, 2004). Herbert et al. (2004) suggested that the timing of myelination is a primary contributor to regional variations in white matter enlargement. Consistent with this, Carper and Courchesne (2005) observed a rapid increase in white matter volume in dorsolateral and medial frontal cortex in children with ASD between 2 and 5 years of age. Dorsolateral prefrontal cortex subsequently showed decreased development with increasing age from 2 to 11 years. Overall, the results add to growing evidence of patterns of local overconnectivity and long-distance underconnectivity in ASD (Belmonte et al., 2004; Wass, 2011).

Decreased white matter volume has also been identified in the cerebellum (Brun et al., 2009; Lotspeich et al., 2004; McAlonan et al., 2005). Given that the results that many of these studies are based on a small number of subjects, Radua, Via, Catani, and Mataix-Cols (2011) performed a meta-analysis combining information from 13 data sets. This analysis failed to find global volumetric differences in white matter. However, increased white matter volumes were evident in the right arcuate fasciculus, and left uncinate and inferior fronto-occipital fasciculi. The left external and extreme capsule were also moderately enlarged. Small decreases in white matter volume were evident in right anterior cingulate and corpus callosum.

### *Summary*

The reliability of a number of the identified differences in brain structure and function remains uncertain given the relatively small number of studies incorporated into the analyses and the broad age range of the combined sample. Since brain development is a dynamic and nonlinear process, it is possible that changes in ASD that are particular to early childhood are not currently appreciated. Importantly, a number of recent longitudinal studies have been completed focusing on young children with ASD (<4 years). These have generally found significant enlargement in gray and, to a lesser extent, white matter volumes compared with other

clinical samples and typical controls (Carper et al., 2002; Hazlett et al., 2005; Hoefl et al., 2011; Schumann et al., 2010; Sparks et al., 2002). Schumann et al. (2010) found enlargement in frontal, temporal, and cingulate cortices starting by age 2.5 years. Hazlett et al. (2011) noted generalized cortical enlargement that was particularly evident in temporal white matter. There was no significant increase in the rate of cerebral growth across multiple brain regions from 2 to 4 years of age, suggesting that volumetric differences had emerged earlier in life. No between-group differences were found for cortical thickness, but there were significant increases in estimates of cortical surface area. Overall, they concluded that the overgrowth was most likely related to increased cortical surface area. Overgrowth tends to be observed in association areas more consistently than in primary sensory or motor cortex (Carper & Courchesne, 2005).

### *Diffusion Tensor Imaging*

The significance of anomalies of white matter development in ASD also been examined utilizing diffusion tensor imaging (DTI). By tracking local water molecule displacement patterns, DTI provides measures of the integrity of axons: fractional anisotropy (FA); mean diffusivity (MD); and the degree of myelination, which is inversely related to radial diffusion (RD). Several recent DTI studies have disclosed anomalies in the microintegrity of subsections of the corpus callosum (Brito et al., 2009; Noriuchi et al., 2010; Shukla, Keehn, Lincoln, & Muller, 2010; Thomas, Humphreys, Jung, Minshew, & Behrmann, 2011; Weinstein et al., 2011). In addition, a number of studies have fairly consistently implicated anomalies of the internal capsule (Brito et al., 2009; Ingalhalikar, Parker, Bloy, Roberts, & Verma, 2011; Keller, Kana, & Just, 2007; Shukla, Keehn, & Muller, 2011) and cerebellar white matter pathways, particularly the middle cerebellar peduncle (Brito et al., 2009; Cheng et al., 2010; Shukla et al., 2010; Sivaswamy et al., 2010). There are also numerous reports of abnormal diffusivities involving long tracts that mediate cortico-cortical connectivity including the cingulum (Bloemen et al., 2010; Noriuchi et al., 2010), arcuate and superior longitudinal fasciculus (Fletcher et al., 2010; Ingalhalikar et al., 2011; Knaus et al., 2010; Kumar et al., 2009), uncinate fasciculus (Poustka et al., 2012), occipital-frontal fasciculus, and inferior longitudinal fasciculus (in the region of the right FG) (Jou et al., 2011; Mills et al., 2013).

Overall, these studies suggest widespread microstructural anomalies of the axonal membranes and/or myelin in multiple long white matter tracts involved in cortical-subcortical connectivity and both intrahemispheric and interhemispheric transmission of information (Vissers, Cohen, & Geurts, 2012). Given the plasticity of the nervous system, and the important role of use-dependent connectivity, it is perhaps not surprising that anomalies of white matter would follow from perturbations of cellular structure and function.

A study by Wolff et al. (2012) suggests that these anomalies are present early in life. They measured FA starting at 6 months until 2 years of age in high-risk siblings of children with ASD. Out of 15 fiber pathway trajectories, 12 showed significant differences between children who eventually demonstrated ASD at 2 years relative to those that did not. FA was higher at 6 months, but changed over time and was lower by age 2 years in those children with ASD. Low FA remains low across development into adolescence with ASD. These findings are of interest since they suggest that altered neural circuitry antedates the clinical onset of ASD. The significance of the higher than typical FA early in the first year of development may represent dampened axonal elimination during the pruning that occurs during this period (Cascio et al., 2013; de Graaf-Peters & Hadders-Algra, 2006).

Given particular involvement of multiple long pathways, some have suggested that ASD should be conceptualized as a disconnection syndrome (Frith, 2004; Geschwind & Levitt, 2007; Melillo & Leisman, 2009). According to this viewpoint, many symptoms of ASD may reflect dysfunction of distributed functional networks resulting from anomalies of white matter affecting association and commissural fibers rather than from localized impairment. Due to the widespread distribution of identified white matter anomalies, the functional implications may be many and diverse. Abnormalities of the corpus callosum would suggest inefficiencies in the interhemispheric transfer of information between homologous areas of cortex. These anomalies can potentially impact many aspects of higher-order cognition requiring bihemisphere integration of information and may affect patterns of cerebral organization and modes of processing (Conturo et al., 2008; Fletcher et al., 2010; Travers et al., 2012). Widespread involvement of association fibers may pose problems both in intrahemispheric communication and in cortical-subcortical transfer of information, potentially compromising the function of neural networks distributed in frontal, temporal, and parietal cortex that mediate language, social perception, and behavioral regulation (Langen et al., 2012). Sensory and perceptual processing may also be affected. For example, anomalies of the microstructure (low FA) of inferior longitudinal fasciculus and the splenium of the corpus callosum have been implicated in atypical sensory processing in ASD, including "tactile defensiveness" (Pryweller et al., 2014). Subcortical tracts that appear to be compromised include cortico-subcortical connections between the prefrontal cortex and the thalamus, cingulate, and cerebrotocerebellar circuits. Compromise of these white matter tracts can potentially impede memory and motor function (Shukla et al., 2010). They may also affect communication with subcortical structures involved in emotional regulation and attentional divestment such as the amygdala, basal ganglia, and cingulate cortex (Mike et al., 2013; Zikopoulos & Barbas, 2010). Although some studies have also shown compromise of short-distance tracts (Shukla, Keehn, Smylie, & Muller,

2011), local white matter fibers appear to be less affected and some studies have suggested that they may be overdeveloped (Courchesne & Pierce, 2005b).

### **Metabolic neuroimaging**

#### *Magnetic Resonance Spectroscopy*

Proton magnetic resonance spectroscopy (MRS) is a very useful neuroimaging method for examining cerebral metabolism in autism. Early studies utilized MRS to inspect metabolic markers of neuronal integrity. Contrary to some expectations based on ana observations of excessive proliferation, concentrations of metabolites of neural activity derived from MRS (NAA, Cr, Cho, mI, and Glx) have been noted to widespread reductions rather than an increase in neuronal or synaptic activity. Metabolite levels have been noted to fluctuate in an age-dependent manner across the whole brain, and in some areas, increases were evident. Overall, these studies have implicated reductions of gray matter integrity in cortex, amygdala, hippocampus, cerebellum, thalamus, cingulate gyrus, and in subregions of the frontal, temporal, and parietal lobes (DeVito et al., 2007; Endo et al., 2007; Hardan et al., 2008; Suzuki et al., 2009). Recent meta-analyses have shown that the metabolic abnormalities tend to decrease and normalize with age (Baruth, Wall, Patterson, & Port, 2013; Ipser et al., 2012). More recently, emphasis has turned to measurement of glutamate metabolism due to postmortem studies that have disclosed evidence of glutamate dysfunction in ASD (Purcell, Jeon, Zimmerman, & Pevsner, 2001). MRS is the only tool available for noninvasive nonradioactive in vivo assessments of glutamate neurotransmission. These studies have revealed alterations of glutamate metabolism in the frontal and temporal lobes and the cingulate gyrus, but not in the cerebellum (Brown, Singel, Hepburn, & Rojas, 2013; Harada et al., 2011; Joshi et al., 2013; Tebartz van Elst et al., 2014). Significant reductions have also been noted in GABA in motor and auditory areas of frontal and temporal lobes, respectively (Gaetz et al., 2014; Harada et al., 2010; Rojas, Singel, Steinmetz, Hepburn, & Brown, 2014). Since GABA is the major inhibitory neurotransmitter in the central nervous system, these findings are compatible with the notion that an imbalance between excitatory and inhibitory influences on neurotransmission is a fundamental aspect of the problems in brain function associated with ASD (Rubenstein, 2010).

#### *Positron Emission Tomography*

Positron emission tomography (PET) has allowed the examination of serotonergic metabolism in ASD. The serotonergic system has long been implicated in autism due to observations that approximately 25%–30% of individuals with ASD demonstrate whole blood serotonin levels that are 25% higher than average. Given that serotonin is involved in regulating mood, sleep, and a form of behavioral inhibition,

these findings were considered to have etiologic significance. In addition, serotonin is known to play an important role in neurodevelopment, having important neurotrophic properties during neural migration as well as influencing aspects of neuronal differentiation, myelination, dendritic maturation, and synaptogenesis (Vitalis, Ansorge, & Dayer, 2013; Whitaker-Azmitia, 2001). Several PET studies have found evidence of deficient serotonin metabolism in the brain, specifically in frontal cortex, thalamus, and dentate nucleus (Beverdort et al., 2012; Chugani et al., 1997). Given cytoarchitectonic evidence of anomalous dendritic development in ASD, it is noteworthy that serotonin influences overall dendritic length, spine formation, and arborization in the hippocampus and cerebral cortex (Sikich, Hickok, & Todd, 1990).

### **Functional Neuroimaging and Connectivity**

While DTI discloses information regarding the microstructural integrity of white matter pathways, these data do not necessarily speak to the functional and effective connectivity of distributed neural networks (Damoiseaux & Greicius, 2009). Examination of functional and effective connectivity is generally addressed in investigations of temporal synchrony or coherence in electrophysiological signals (e.g., Electroencephalogram, Magnetoencephalogram, Event-Related Potentials) or through the analysis of coactivation patterns in blood oxygenation level dependent responses (BOLD) as measured with functional magnetic resonance imaging. This area of investigation is one of the most rapidly growing areas of functional neuroimaging (Friston, 2011) and arguably has particular relevance to the study of ASD given the identified anomalies of white matter development discussed in the previous section. We now briefly review studies of functional and effective connectivity in ASD, leaving discussion of more traditional functional neuroimaging findings to later sections of this chapter where it is interwoven into discussions of neuropsychological and cognitive neuroscience aspects of ASD.

Contemporary models of human brain function posit that the brain is organized into multiple large-scale neural networks distributed in anatomically segregated areas of the cortex, each having distinctive roles in mediating perceptual, motor, and cognitive processing. The function, distribution, and interaction of these networks can be inferred from the analysis of correlated patterns of neural activation either during performance of behavioral tasks or during the resting state. *Functional connectivity* is inferred from statistical dependencies among physiological responses measured from different regions of cortex. Since this method does not account for the direction of information flow, it cannot be used to infer causality. By contrast, *effective connectivity* applies methods such as dynamic causal modeling and independent component analysis to the same kind of data to evaluate the influence that one neural system may exert or cause in another.

Based on these methods, several large-scale intrinsic brain networks have been identified with specialized roles

in processing information (Menon, 2011; Seeley et al., 2007; Yeo et al., 2011). These networks demonstrate consistent spatial and temporal patterns of coactivation across markedly different tasks. They include a sensory-motor network, a visual cortex network, a limbic network, dorsal and ventral attention networks, a frontal-parietal network involved in executive control, and a default mode network (DMN). With the exception of the DMN, the existence of each of these networks had been recognized previously through multiple areas of investigation. By contrast, the DMN was discovered through observations in functional imaging studies that certain brain regions became active when an individual was not performing a task, but was in a state of wakeful rest, unfocused on the outside world. Key nodes of the network are located in medial prefrontal cortex, anterior and PCC, middle temporal gyrus, and precuneus (Buckner, Andrews-Hanna, & Schacter, 2008). These nodes become active during mind wandering but also during self-referential thinking. They are fairly consistently deactivated in normal controls during cognitive and attention-demanding tasks (Greicius, Supekar, Menon, & Dougherty, 2009). Various subnetworks exist within the DMN, including one for memory (e.g., autobiographical memories of places or experiences) centered in the medial temporal lobe and one for social cognition (e.g., theory of mind – ToM) in prefrontal cortex.

Task-based functional and effective connectivity studies of ASD have identified anomalies in interregional connectivity during performance of tasks examining language (Jones et al., 2010; Just et al., 2004), visual motor coordination (Villalobos, Mizuno, Dahl, Kemmotsu, & Muller, 2005), working memory (Koshino et al., 2008), executive function and cognitive control (Agam, Joseph, Barton, & Manoach, 2010; Just et al., 2007), and social cognition (Di Martino et al., 2009; Kleinmans et al., 2008), among others (see Schipul, Keller, & Just, 2011 for a review). The patterns of coactivation observed in ASD have suggested underconnectivity of long-range connections (Hughes, 2007; Muller, 2007) while short-range connections are either within normal limits or show overconnectivity (Keown et al., 2013; Rippon, Brock, Brown, & Boucher, 2007). It has been argued that this pattern reflects a failure in the fine-tuning of neural networks during development. Some have suggested that underconnectivity is global (Just et al., 2007; Just et al., 2004), although the evidence for this has not been entirely consistent. For example, several studies have shown hyper-connectivity of some long-range thalamocortical connections (Mizuno, Villalobos, Davies, Dahl, & Muller, 2006) and cortico-cortical connections (Noonan, Haist, & Muller, 2009; Shih et al., 2011). Inconsistencies may reflect inherent complexities of brain connectivity, although a variety of other factors can also influence the pattern of results in these studies. This includes variations in task demands, analytic methods, and whether or not movement artifact was adequately addressed (Maximo, Cadena, & Kana, 2014; Muller et al., 2011; Nair et al., 2014). Most of these studies were completed on higher-functioning

adolescents and adults because of the need to comply with task demands. For this and other reasons, the results are not readily generalizable to the broader ASD population.

In order to circumvent some of these issues, a number of investigators have turned to utilization of resting-state functional MRI (rs-fMRI). In this paradigm, participants are instructed to rest for 5 to 8 minutes, during which BOLD signals are collected. Strong correlations in spontaneous low-frequencies (< 0.1 Hz) in the BOLD signal in distinct but functionally-related regions of cortex disclose the shared spontaneous neural activity of intrinsically connected networks (Biswal, Yetkin, Haughton, & Hyde, 1995). In the normal course of development, correlations between distant brain regions increase with age, presumably reflecting the strengthening of connections between nodes of distributed networks (integration) (Fair et al., 2007). Simultaneously, there is an increase in segregation from other networks, although short-range functional connections may also increase reflecting improvements in local communication. The results from rs-fMRI have been shown to correlate with neuropsychological performance on measures of higher cortical function such as language (Waites, Briellmann, Saling, Abbott, & Jackson, 2006) and memory (Bettus et al., 2008) in conditions where neural network function has been compromised. The relative merits of utilizing rs-fMRI to examine brain connectivity are that data can be acquired in a shorter space of time than task-based BOLD studies and it requires minimal cooperation (e.g., lying still, stay awake), thus reducing or eliminating some state-related and task-related sources of variability that can be difficult to control without introducing other potential confounds (e.g., cooperation, performance levels, strategies, etc). In addition, the data derived from this paradigm show good test-retest reliability (Shehzad et al., 2009) and are reportedly sufficiently stable that the results can be collected and compared across different imaging facilities (Fair et al., 2012). These attributes make it possible to assess a broader range of individuals (in both age and level of function) (Yerys, Jankowski, et al., 2009), potentially increasing the generalizability of obtained results.

Many studies of functional connectivity in ASD have focused on the DMN, in part because of its role in mediating self-directed thinking and aspects of social cognition. In keeping with task-related studies of connectivity, rs-fMRI studies of adults with ASD demonstrate hypoconnectivity between nodes of the DMN (Assaf et al., 2010; Kennedy & Courchesne, 2008; Weng et al., 2010), particularly between anterior and posterior components (Cherkassky, Kana, Keller, & Just, 2006; Monk et al., 2009; Starck et al., 2013), while overconnectivity is apparent within local DMN nodes (Washington et al., 2014). These *in vivo* findings are consistent with postmortem brain tissue studies that have demonstrated decreased long-distance and increased short-distance axonal connections in frontal cortex of adults with ASD (Zikopoulos & Barbas, 2013). Observations of decreased long-range connectivity between the precuneus and medial

prefrontal cortex/anterior cingulate have suggested anomalies in circuitry involved in self-reflective thinking and ToM, and were inversely correlated with the severity of social and communication deficits (Assaf et al., 2010). Weak long-range connections have also been identified in interhemispheric pathways, specifically the corpus callosum (Anderson et al., 2010; Hahamy, Behrmann, & Malach, 2015). Anomalies of the corpus callosum, including agenesis, have been noted for some time in ASD (Piven, Bailey, et al., 1997). More recently, it has been argued that these disturbances potentially increase risk for the development of ASD (Paul, Corsello, Kennedy, & Adolphs, 2014). These anomalies may be associated with perturbations in the development of hemispheric asymmetries of function in ASD (Floris et al., 2013).

Overall, the findings from functional and effective connectivity studies have been taken as evidence in support of developmental disconnection models of ASD (Belmonte et al., 2004; Just et al., 2004). Related speculations have suggested that these patterns of abnormal connectivity may be a consequence of widespread anomalies of synaptic elimination or formation (Sporns, Tononi, & Edelman, 2000). However, a number of recent studies have complicated the picture, prompting caution against simplistic interpretation regarding general patterns of functional under- or overconnectivity, their behavioral significance, and broader implications. Some studies, for example, have suggested that anomalies of connectivity are not evident in young children (6–9 years) but become apparent in older children and adolescents (Washington et al., 2014). This potentially casts doubt on the primacy of the observed underconnectivity problems and seems inconsistent with some of the structural white matter studies suggesting that problems arise earlier in development. Some have suggested that the connectivity differences in ASD may reflect a maturational lag. However, patterns of functional connectivity are highly idiosyncratic in children and adolescents with ASD, and this may also be true of adults (Hahamy et al., 2015; Uddin, 2015). Age-related changes in connectivity of the DMN are evident in both neurotypical controls and individuals with ASD, but the developmental trajectories and regional expression of the changes differ substantially between groups and show particular variability in the ASD group (Doyle-Thomas et al., 2015; Nomi & Uddin, 2015). The current literature highlights inconsistencies that make generalizations difficult to draw at this point. Nevertheless, it does seem that functional connectivity measures are sensitive to differences in brain function between normal controls and individuals with ASD.

Other intrinsic large-scale networks with particular relevance to the study of ASD include the salience network (SN) and the central executive network (CEN). The SN responds when individuals evaluate the degree of subjective salience of a stimulus, which depends on many factors, including past experience, stimulus attributes, top-down attention, cognitive control processes, and visceral/autonomic responses, among others. This network is likely involved in determinations

of the emotional and social significance of environmental stimuli and is thought to play a role in regulating and switching between endogenous and exogenous attention to relevant stimuli that guide our behavior. It may accordingly also function like a switch between the DMN and the CEN (Goulden et al., 2014). Key nodes of this network are distributed in the anterior cingulate cortex (ACC) and anterior insula. Some recent studies have suggested that in ASD this network is overconnected within itself and spatially occupies a more restricted distribution (Zielinski et al., 2012). Uddin et al. (2013) also identified hyperconnectivity of the SN in ASD and indicated that this was the best discriminator of ASD among all the large-scale networks they examined. They and others have suggested that dysfunction of this network is associated with the severity of socioemotional impairment as well as RRBIAs (Ebisch et al., 2010; Nielsen et al., 2013; Uddin et al., 2013).

In summary, examination of the functional connectivity of these large-scale neural networks provides a useful complement to other areas of investigation of the neural correlates of ASD. Poor connectivity can potentially introduce disruptive levels of imprecision into the complex neural computations underlying both simple sensory and higher-order information processing, as well as in organizing appropriate behavioral responses (Pajevic, Basser, & Fields, 2014). The repeated coactivation between regions of the brain that underlie development of network relationships is also important for experiential learning. Problems at this level can thus contribute to anomalous or atypical development of social and communicative behavior. The determinants of the problems observed at a functional connectivity level are unclear but may possibly relate to structural differences such as the degree of myelination (Deoni et al., 2015; Nair, Treiber, Shukla, Shih, & Mueller, 2013) or anomalies at the cellular or molecular level. A possible genetic contribution to the underconnectivity picture was recently raised by Scott-Van Zeeland et al. (2010), who identified reduced functional connectivity in medial prefrontal cortex in carriers of the CNTNAP2 gene. In addition, frontal lobe connectivity is also compromised in individuals with 16p11.2 deletion (Ottet et al., 2013). However, there has been growing recognition that white matter pathways exhibit experience-dependent plasticity (Lovden et al., 2010; Yogarajah et al., 2010), so it also seems possible that underconnectivity may be subject to experiential factors. A better understanding of functional and effective connectivity in ASD has the potential to greatly deepen our understanding of individuals with ASD and to advance progress in other areas of investigation.

### *Implications and Limitations*

Variability has become a hallmark of neuroimaging findings in ASD. Brain volumes can vary according to a number of subject-related variables, such as the age of the child, gender, clinical characteristics (e.g., severity of social impairment,

IQ), and genetic dispositions (Lenroot & Yeung, 2013; Stanfield et al., 2008). Without closer control over these variables, caution is warranted in interpreting the results of the volumetric imaging studies to elucidate the neurobiological basis of ASD. Overall, however, the findings suggest that there are multiple facets and phases to the abnormal cortical development that occurs in individuals with ASD. Accelerated expansion of brain volume of multiple regions involving both gray and white matter occurs in early childhood. These changes do not appear to be regionally-specific, although they appear evident in some areas more than others and follow a different developmental course in various areas of the brain. This is followed by accelerated thinning of cortex in later childhood and adolescence. Finally, there is a deceleration of cortical thinning that occurs in adulthood (Zielinski et al., 2014). These findings are suggestive of anomalies in the normal course of subtractive processes (i.e., dendritic pruning) during postnatal neurodevelopment.

Despite initial overgrowth of white matter in the first two years of life, individuals with ASD later show widespread but idiosyncratic patterns of hypoconnectivity and hyperconnectivity, particularly with regions of the frontal and the fusiform face area (Abrams et al., 2013; Courchesne, Redcay, Morgan, & Kennedy, 2005; Just et al., 2007). Questions remain unanswered as to what is driving the idiosyncratic patterns in ASD and what their significance is in understanding behaviors associated with ASD. Longitudinal studies and better-controlled large-scale replications of cross-sectional data are needed to confirm and extend existing results.

Many of the studies suffer from small numbers of subjects. Researchers are often faced with difficult choices in designing appropriate controls, particularly when functional tasks are used. The vast majority of the functional studies in ASD have recruited high-functioning individuals with ASD (IQ greater than 70) (Stanfield et al., 2008), a selection bias motivated by the need to optimize the probability that participants will be sufficiently cooperative and adaptive to the high constraints of imaging protocols. While this makes pragmatic sense, observed differences may not be generalizable to the broader ASD population. When lower-functioning groups of children with ASD have been studied, their data have often been compared to higher-functioning normal controls. Riva et al. (2011) for example, examined brain volumes in a low-functioning group of ASD children (aged 3–10 years) with a mean IQ of 52 and contrasted the data from this group against neurotypical controls with normal range IQ. Given this design, the pattern of observed gray matter volumetric difference may simply be related to IQ rather than the diagnosis of ASD (Rutter, 2013). It is clear that future neuroimaging studies need to better specify and control for various neuropsychological variables, including age, handedness, gender, general cognitive level, language ability, nature and severity of social impairment, and the presence and severity of RRBIA.

## Clinical Features and Developmental Course

Kanner's contention that autism was an "inborn" or congenital condition was based on his interpretation of retrospective reports by parents who recounted various atypical behaviors they had observed in their child's interpersonal interactions in the first year. It has become apparent that most parents (~80%) become aware of developmental anomalies or delays in their children with AD by two years of age (De Giacomo & Fombonne, 1998) and nearly 50% harbor concerns in the first year (Young, Brewer, & Pattison, 2003); parents with an older affected child tend to have earlier concerns than those with an older unaffected child or no older children (Herlihy, Knoch, Vibert, & Fein, 2013). Despite these suspicions, a definitive diagnosis of AD is often not made until children are 3–4 years of age, due to the difficulties in ruling out developmental delays or other similar conditions such as cognitive deficiency in very young children (Howlin & Moore, 1997; Mandell, Novak, & Zubritsky, 2005).

Given the importance of early intervention (Webb, Jones, Kelly, & Dawson, 2014; Wong & Kwan, 2010; Zachor, Ben-Itzhak, Rabinovich, & Lahat, 2007), considerable effort has been devoted to identifying the earliest behavioral signs that are predictive of a later diagnosis of ASD. Given the delays in recognition during ontogeny, initial investigations of the developmental precursors or early manifestations relied on retrospective analyses and were largely limited to parental reports. Detailed and accurate information is difficult to abstract from retrospective parental reports, given that it relies upon recollection of behaviors their child exhibited at an earlier age of development. Bias in memory recall can greatly influence responses to structured interviews and questionnaires (Zwaigenbaum et al., 2007). However, the rise in availability of home video recording and playback equipment that occurred in the 1980s (from 1% of U.S. American households in 1980 to more than 75% in 1992) afforded an opportunity to supplement parental histories with systematic examination of the child's behavior as captured on home videos taken by parents at family events (e.g., birthday parties) before the recognition of their child's ASD. The coding of behaviors such as eye contact, attention to communications, motor abilities, emotional reactivity, and expression, provided a remarkably useful window to explore the extent to which children demonstrated anomalies in the first couple of years of life (Adrien, Faure, et al., 1991; Werner & Dawson, 2005). While this approach has inherent methodological limitations (Saint Georges et al., 2010), it has yielded substantial insights into the early development of children with ASD.

The task of delineating those behaviors that can reliably predict later development of ASD is complex and requires very careful analysis of the dynamics of behaviors and an appreciation of the developmental and social context. Given the limitations of these retrospective methods, a number of studies have adopted prospective designs that involve

screening and developmental surveillance methods. These studies attempt to identify children as early as 12–18 months through systematic screening and then follow their development over the next few years to ascertain their eventual diagnosis (e.g., Barbaro & Dissanayake, 2010; Bryson et al., 2007; Landa & Garrett-Mayer, 2006; Ozonoff et al., 2010). In addition, some prospective studies have explored even earlier developmental precursors by systematically monitoring from infancy the development of siblings of children with ASD who are at elevated risk for the development of autism due to the shared genetic liability.

In the following sections, we provide a brief overview of the key symptoms associated with ASD from infancy to adolescence, with particular emphasis on recent advances in understanding the early markers and identifying ASD in the first couple of years of life. To contextualize this discussion, we begin with a brief synopsis of our current understanding of typical development of the “social brain.” We then provide a cursory overview of changes that may occur over the life span with particular emphasis on the early years. This overview is divided into “Social Communication” and “Restricted and Repetitive Patterns of Behavior Interests and Activities” subsections, which correspond to the “autistic dyad” outlined in the DSM-5 framework for defining ASD (see Table 13.1). The correspondence between the early signs and the behaviors considered diagnostic of ASD is a loose one, given that some developmental precursors or predictors may have broad developmental impact and relate to several later emerging problems that may span more than one domain. Table 13.1 represents an effort to map these early signs with the corresponding behavioral domain as identified in DSM-5.

### ***Social Communication***

Impairments in social relatedness and communication are the hallmark features of autism. Parent reports have long suggested that critical social behaviors are often slow or limited in their development in children with ASD. Eye gaze has received considerable attention as a potential early behavioral marker of ASD. Eye contact is regarded as a foundation for early social interaction and communication, and humans demonstrate a preference for direct eye gaze very early in life (Csibra & Gergely, 2006; Itier & Batty, 2009). Kanner (1943) noted anomalies of eye contact in his original description of ASD, and deficient “eye-to-eye gaze” is a specific example of impaired use of nonverbal behaviors to regulate social interaction and communication in the DSM-5. A variety of anomalies of gaze have been described in infants and toddlers, including so-called empty gaze (Dahlgren & Gillberg, 1989), abnormal intensity of eye contact (Wimpory, Hobson, Williams, & Nash, 2000), and unpredictable eye gaze such as inconsistently following another person’s eye gaze. A recent paper by Jones and Klin (2013) found that infants at risk for ASD who later received

the diagnosis showed an overall decline in eye fixation from normal levels at 2 months of age to lower than normal levels at 6 months of age. These findings suggested that that eye tracking measures as early as 6 months might be useful in detecting children at particular risk for autism.

Additionally, impairments are evident in other early emerging social behaviors seen in typical infants, such as social smiling, interest in faces and facial expressions, strong motivation to have caregivers pay attention to their activities, directing facial affect toward caregivers, and responding to their own name when called. Studies combining the retrospective analysis of videotape with interviews revealed that children diagnosed with ASD tended to show lower frequency of looking at others, diminished orienting to being called by name, a lack of interest in sharing interests or showing objects to others, and a lack of pointing (Mars, Mauk, & Dowrick, 1998; Osterling & Dawson, 1994). Some behavioral differences were identifiable as early as the first 12 months of life (Adrien, Perrot, Hameury, Martineau, & et al., 1991; Baranek, 1999; Clifford & Dissanayake, 2008; Goldberg, Thorsen, Osann, & Spence, 2008; Werner, Dawson, Osterling, & Dinno, 2000). A number of these behaviors seemed useful in distinguishing the behavior of infants with ASD from infants later diagnosed with ID without ASD. While both ID and ASD groups demonstrated more repetitive and stereotyped behaviors compared to typically-developing infants, infants who later developed an ASD looked at other individuals less and failed to orient to their names as often (Osterling et al., 2002).

Overall, these findings underscore the importance of examining social attention and communication in identifying the best early indicators of ASD. A very important feature in early childhood, perhaps the most discriminating feature between autism and other developmental disabilities, is the delayed or absent development of joint attention. Joint attention is reflected in a child’s motivation to coordinate his or her attention to an object with that of another person. It can be seen in acts the child initiates (e.g., pointing to show, holding up an object to show) or in responding to the parents’ initiation (e.g., following the parent’s gaze, following the parent’s pointing). Parents often report such behaviors, but when questioned closely, the objects the child brings to them are ones with which he or she needs help (e.g., read me this book, open this box of cookies), not ones being shown for the simple joy of shared attention. Other early signs of ASD are not noticing others’ emotions unless they are very obvious, and showing inappropriate reactions, such as laughing if another child is crying.

By the second year of life, typical children show substantial interest in other children. They generally have no cooperative play skills, but are very interested in watching other children or playing near them. Children developing ASD are often minimally interested in other children and are happy when left to play alone. In general, the social interactions of the young child developing ASD are more need-oriented

(e.g., they may come to mom for food, tickles, help with a toy, or when distressed) and they show much less than typical interest in simple social play or social contact (e.g., babbling back and forth, sharing facial expressions). Since facial expressions are less meaningful to them, they usually show less than typical social referencing—that is, looking to a caregiver when confronted with an unfamiliar stimulus to see if they look calm and reassuring or worried. Emergence of simple motor imitation is usually delayed in emerging autism. Delays in the simplest forms of ToM can be seen in the fact that some children with emerging autism will make some communicative efforts with parents but without making sure they have the adult's attention or gaze first.

In the later preschool period (ages 2–4), some children continue to have severe delays in all of these areas. Others will develop simple imitation and pretend play but generally remain delayed or impaired in interest in peers and in joint attention. In a preschool, they may be able to join a social group with adult facilitation, but otherwise tend to remain on the margins of the group. If pretend play develops, it tends to be quite simplified and repetitive, unless guided by a peer or sibling. Pretend play scenarios, instead of being a complex series of actions around a theme, tend to remain simple one- or two-act schemas, or acting out of perseverative themes often taken from favorite games or movies.

As the child moves into later childhood and adolescence, a great deal depends on the child's cognitive level and degree of language impairment. With functional language, conversational ability is usually quite impaired, with conversation possible only on preferred topics or reliant on the conversational partner to keep it going. Children with autism are often strongly motivated to ask questions perseveratively to which they already know the answers. Immediate echolalia (repeating what they just heard) and delayed echolalia (quoting extensively from familiar scripts) are very common, although they tend to abate as functional language develops. Pronoun reversals are common; this used to be interpreted as indicating poor sense of self and other, but is now regarded as cognitive difficulty with relational terms. In later childhood and adolescence, a key feature of autism is poor ToM, in which the individual has a poor grasp on what others are thinking, feeling, expecting, or remembering, or on what different information people are able to access.

### ***Restricted and Repetitive Patterns of Behavior Interests and Activities***

These features fall into two broad categories: repetitive activities and resistance to change. A third category, that of sensory over- and underreactivity, has been added to this group in DSM-5. Except for this third category (to which we will return shortly), many very young children with emerging autism have few of these behaviors; it may not be until the third or fourth birthday that clear repetitive behaviors and resistance to change emerge (Barton et al., 2013;

Turner et al., 2006). Many very young children, especially with cognitive delays, are insufficiently aware of routines to be distressed when they are violated, and may not have the cognitive ability to develop their own routines or their own preoccupying interests. When symptoms in this domain are present in very early childhood, they are usually repetitive motor behaviors such as rocking, toe walking, or hand flapping (although hand flapping with excitement is often seen in normal toddlers as well).

However, sensory symptoms are often seen in toddlers with ASD. On one hand, they may be oblivious to verbal input from others and may ignore auditory, visual, tactile, or even painful stimuli. On the other hand, they may be overreactive, showing distress by crying or covering their ears in response to certain noises, such as vacuum cleaners, washing machines, and the hum of fluorescent lights. They may find it hard to tolerate tactile input such as haircuts, cuffs, or tags—and especially light touch—and prefer deeper input such as being squeezed or being under a heavy blanket. Visual fascinations are very common, especially after age 2. Some of the most common of these are squinting; looking at things out of the corner of the eye; staring at shadows, mirrors, or credits going by on a TV; creating or finding lines (lining up toys or trains, or staring at the junction of two walls) and staring at them at eye level; or moving objects back and forth in the periphery of vision.

In later childhood, repetitive activities extend to verbal and play routines, where they prefer to reenact the same scenes over and over or repeat phrases. Frank obsessions and compulsions may appear, with a drive to complete activities and great distress if routines are violated, environments are changed, or expectations are violated (e.g., even to taking a different route to get somewhere). Older children and adolescents tend to develop very strong preoccupying interests; the nature of these will depend on the cognitive level of the child. At the lowest level, they may be demonstrated by such activities as carrying around things of a certain color, or unusual objects (e.g., paper clips). At higher cognitive levels, such if the child is verbal, he or she may want to talk about a certain topic to the exclusion of most others (e.g., *National Geographic* collection, favorite video game), and they may be fascinated by unusual stimuli such as toilets flushing. Older children and adolescents may have large collections of favorite objects. In the best cases, these interests can actually lead to constructive interests (e.g., dinosaurs, astronomy), although the depth of social disability often prevents these interests from developing into useful activities or pastimes.

### ***Patterns of Onset***

In his original description, Kanner (1943) contended that children with autism demonstrated symptoms from the “very beginning of life.” (Kanner, 1943, p. 242) While Kanner conveyed that this pattern of early onset was seen uniformly across the group, one child may have demonstrated a somewhat different developmental trajectory—one

associated with a loss of previously acquired skills. By parent report, Richard (Case 3) had exhibited some proficiency in imitating words and sounds early in his development but subsequently lost this ability. When seen at age 3 years, 3 months, his mother stated that, "It seems that he has gone backward mentally gradually for the last two years" (Kanner, 1943, p. 225). Kanner did not comment on the significance of this parent's observation beyond mentioning it. However, over a decade later, and after having diagnosed more than 120 children with autism, he noted that some cases developed normally until 18 to 20 months and then demonstrated a "loss of language function, failure to progress socially, and the gradual giving up of interest in normal activities" (Eisenberg & Kanner, 1956, p. 558).

As experience with early infantile autism increased, reports of developmental regression or setbacks became more commonplace. In the first epidemiological study of ASD, Lotter (1966) reported that 31.3% of children with autism had a history of developmental setback comprised either a "loss of some ability" or "a failure to progress after a satisfactory beginning." (Lotter, 1996, p. 130) Rutter and Lockyer (1967) noted that 15% of their cohort of children with ASD regressed after a period of "reasonably definite normal development" (p. 1172). However, the phenomena received scant attention for almost two decades. Kurita (1985) then reported on a cohort of 261 children with ASD, of which more than one-third (37.2%) had demonstrated speech loss. Similar observations were made in a subsequent study in a Japanese cohort (Hoshino et al., 1987). Despite the significant number of affected individuals, the phenomena continued to receive little mention until Rogers and DiLalla (1990) underscored regression as one of a few possible developmental trajectories in ASD, and reports by Deonna, Ziegler, Moura-Serra, and Innocenti (1993); Rapin (1995) and Stefanatos et al. (1995) highlighted that regression may imply distinctive etiologic pathways that differed from nonregressive forms of autism.

Parental reports and clinical observations suggest at least three distinguishable patterns of onset in ASD (Rogers & DiLalla, 1990). In the most common "congenital" or "early onset" pattern of onset, behavioral manifestations of ASD emerge generally in the first year of life. Both retrospective studies of children with ASD and prospective studies of children at high risk for the disorder suggest that symptoms tend to become evident in the latter half first year, although sometimes problems may manifest in the first six months (Jones, Gliga, Bedford, Charman, & Johnson, 2014; Ozonoff, Heung, Byrd, Hansen, & Hertz-Picciotto, 2008; Zwaigenbaum, Bryson, & Garon, 2013). Developmental differences gradually become apparent in impairments of joint attention, eye contact, anticipatory behavior, motility, communication, social interest/responsiveness, and emotional modulation (Maestro et al., 2005; Osterling & Dawson, 1994; Werner et al., 2000). The saliency of these developmental delays or deviations increases with time due to the increasing divergence from a normal trajectory (Dawson, Munson,

et al., 2007) to the point where they trigger parental concerns. While 36% (Short & Schopler, 1988) to 55% (Volkmar, Stier, & Cohen, 1985) of parents report noticing problems in the first year, the nature and potential significance of the difficulties are often not appreciated until the second or third year, resulting in a mean age of recognition of 18–19 months (De Giacomo & Fombonne, 1998; Stone et al., 1999).

In a second scenario, children may show normal or near normal early growth and then demonstrate a developmental arrest or "stasis" that is unexpected given the preceding developmental trajectory (Siperstein & Volkmar, 2004). Many of the children fitting this picture may show timely onset of early language milestones and progress normally from babbling to production of proto-words, but then fail to show the usual rapid expansion in their inventory of speech sounds (e.g., consonants) or progress to the production of words, word combinations, phrases and sentences. Recent prospective studies of children with ASD suggest that individuals in this subgroup are later diagnosed because their "plateau" in development tends to occur in the second year of life (Landa & Garrett-Mayer, 2006; Landa, Holman, & Garrett-Mayer, 2007).

### *Regression*

The third pattern of onset entails a developmental regression or setback characterized by loss of skills in one or more domains of behavior. The onset of regression usually occurs between 14 and 30 months (Barger, Campbell, & McDonough, 2013; Fombonne & Chakrabarti, 2001) and is generally characterized by a conspicuous loss of previously-acquired language abilities. Children cease to use words that were previously part of their vocabulary, produce fewer verbal communications, and may manifest a deterioration in their articulation of speech (Kurita, 1985; Lord, Shulman, & DiLavore, 2004; Rogers & DiLalla, 1990). These changes can eventuate in a child who is non-verbal at least for a period of time. The loss of speech is often, but not invariably, accompanied by noteworthy decrements in receptive language (Stefanatos et al., 1995). Children may fail to respond to their name being called or have trouble following directions they were previously able to understand. A concomitant deterioration in social behavior is frequently observed, manifested in reductions in eye contact, social engagement, and play skills (Bernabei, Cerquiglioni, Cortesi, & D'Ardia, 2007; Goldberg et al., 2003; Meilleur & Fombonne, 2009; Ozonoff, Williams, & Landa, 2005). Restricted, repetitive or stereotyped behaviors may also emerge, but are often overshadowed by the deterioration in communicative and social domains at this stage of development. Some loss of adaptive skills (e.g., feeding, dressing, toileting) and motor abilities (fine or gross motor) can occur around this time, although these areas of function are typically relatively preserved in comparison to the loss of communication and social skills.

In the majority of cases, both language and social skills are affected, although the loss of language is often more salient and is usually one of the primary cues prompting parental concerns. Some children appear to demonstrate more selective loss that seems to disproportionately affect language or social skills (Goldberg et al., 2003; Hansen et al., 2008; Luyster et al., 2005). The selective deterioration of social function may be difficult to recognize due to problems differentiating the alterations in behavior from changes in behavior resulting from events such as minor illnesses, trauma, adversity in the family, sibling rivalry, and other stresses. Changes in behavior may also be misinterpreted as reflecting the moodiness, negativity, and temperament changes associated with the characteristically difficult stage of social development referred to as the “terrible twos.” Consideration of the complexities surrounding the identification of regression prompted Volkmar et al. (1985) to question the existence of regression in ASD. However, the phenomenon has been validated, in part by comparison of pre- and post-regression videotaped material (Goldberg, Thorsen, et al., 2008; Werner & Dawson, 2005).

Alterations in behavior can manifest over the course of a few days to months. Regression can occur in children who were demonstrating seemingly normal or near-normal development or in children with preexisting problems or developmental delays (Kurita, 1985; Ozonoff, Williams, et al., 2005; Richler et al., 2006). The proportion of children showing some preexisting problems varies between studies (Hoshino et al., 1987; Kurita, 1985; Ozonoff, Williams, et al., 2005). Loss of skills may be apparent in a variety of other behaviors in addition to those that define ASD. Changes can include onset of sleep problems (Giannotti, Cortesi, Cerquiglini, Vagnoni, & Valente, 2011), gastrointestinal symptoms (Valicenti-McDermott, McVicar, Cohen, Wershil, & Shinnar, 2008), increases in behavioral disturbances, tantrums, aggressive behavior, and sensory disturbances (Stefanatos, 2008; Thurm, Manwaring, Luckenbaugh, Lord, & Swedo, 2014a).

A recent meta-analysis of 85 studies reported the overall prevalence rate of regressive ASD (RASD) as 32.1%, although estimates have ranged from 12.5% to 50% (Barger et al., 2013). This wide variance has been attributed, in part, to inconsistencies over the operational definition of regression (Hansen et al., 2008; Stefanatos, 2008). Defining regression is problematic as it can occur in disparate domains, to varying degrees, and over different temporal courses. Language regression has traditionally been considered to be a defining feature of RASD but definitions have varied in terms how much language needs to be acquired before regression occurs, the extent of delays that can exist before regression, the magnitude of the loss, the duration of the loss, and whether a loss of babbling and/or nonverbal communication is considered language regression (Ozonoff, Williams, et al., 2005).

It is noteworthy that regression with speech loss is relatively uncommon in children with forms of developmental

disability other than ASD. It is comparatively rare both in specific developmental language disorders (Pickles et al., 2009) and in children with general intellectual disabilities (1%–3%) or other developmental problems (Baird, Charman, et al., 2008; Kurita, 1996; Wilson, Djukic, Shinnar, Dharmani, & Rapin, 2003). Like ASD, RASD appears to cut across all socioeconomic strata (Christopher, Sears, Williams, Oliver, & Hersh, 2004). Unlike ASD, there appear to be no significant gender differences in the prevalence of RASD (Lord et al., 2004; Luyster et al., 2005).

Since the late 1990s, there has been a considerable increase in interest in understanding the context and potential etiological basis of regression in ASD. Preliminary studies of possible genetic contributions have provided some evidence of familiarity. Lainhart et al. (2002) reported that features of the BAP were equally present in ASD and RASD, raising the possibility of shared genetic liability. Parr et al. (2011) found that only 14 out of 74 affected pairs of ASD siblings were concordant for regression. This concordance rate for regression (18.9%) is not significantly different from the base-rate for regression (estimated to be 23.9%) in ASD. They therefore concluded that there was no separate familial influence on regression other than that related to ASD. However, a linkage study by Molloy, Keddache, and Martin (2005) identified genetic loci that they speculated conferred susceptibility to autism, but possibly with a modified presentation in the group with regression. In particular, the strongest linkage was evident at candidate regions on chromosomes 21 and chromosome 7. Several of the genes mapping to these locations are involved in various aspects of fetal development such as cell differentiation, adhesion, and apoptosis.

The genetic analysis of RASD is especially intriguing given that, as a group, children with RASD show normal or near normal development and attainment of developmental milestones. They produce their first words earlier than children with nonregressive ASD (Baird, Charman, et al., 2008), and at 24 months they show greater skill attainment than children in a nonregressive group (Luyster et al., 2005). Despite the more promising early course, it has been suggested that children with RASD are more likely to demonstrate in long-term severe speech difficulties (Hoshino et al., 1987; Kurita, Uchiyama, & Takesada, 1985), difficulties in initiating conversation, asking or answering questions, or conveying information verbally (Brown & Prelock, 1995), and intelligence estimates in the cognitively deficient range (Hoshino et al., 1987; Kurita et al., 1985; Meilleur & Fombonne, 2009). Thus, notwithstanding evidence of higher levels of cognitive development prior to the regression, these children may have poorer long-term developmental trajectories, particularly in the area of communication (Bernabei et al., 2007; Goin-Kochel, Esler, Kanne, & Hus, 2014; Hansen et al., 2008; Rogers, 2004). In addition, they also demonstrate a higher frequency of comorbid psychiatric conditions and challenging behaviors (Matson, Wilkins, & Fodstad, 2010).

These findings may possibly be explained by postulating either additional or differential genetic liability in RASD compared to nonregressive ASD. Alternatively, individuals with RASD may experience a second biological “hit” or predisposition that is stimulated by environmental or developmental factors and that causes derailment of language and social function (Lainhart et al., 2002; Stefanatos et al., 2002b). Proposed associations with vaccination (Baird, Pickles, et al., 2008), gastrointestinal problems (Baird, Charman, et al., 2008), mitochondrial disease (Shoffner et al., 2010), and low birthweight (Christopher et al., 2004; Lampi et al., 2012; Mann, McDermott, Bao, Hardin, & Gregg, 2010) have not been substantial enough to differentiate this group from children with nonregressive ASD. In addition, traditional risk factors in ASD—such as pre-, peri- or postnatal complications or intrauterine exposure to viruses or other immune challenges—have not been causally linked to the emergence of RASD (Christopher et al., 2004).

The emergence of epilepsy and epileptiform disorders has been considered as related to a potential “second hit” mechanism. Numerous studies have noted that the prevalence of epilepsy is higher in both ASD and RASD (~5% to 38%) compared to population estimates in children (2%–3%) (Danielsson, Gillberg, Billstedt, Gillberg, & Olsson, 2005; Spence & Schneider, 2009). The prevalence of epileptiform abnormalities with or without seizures is also substantially higher in children with ASD (6%–60%) compared to healthy children (1%–4%). The evidence overall does not appear to disclose consistent differences between RASD and ASD in either the prevalence or form of epilepsy or epileptiform abnormalities (Hansen et al., 2008; Luyster et al., 2005). However, a couple of studies have found a twofold increase in epileptiform EEG abnormalities in RASD compared to ASD (Baird, Robinson, Boyd, & Charman, 2006; Tuchman & Rapin, 1997). Such observations have prompted continuing conjecture on a potential causal relationship between these symptoms.

While regression is rare in developmental disorders other than ASD, it is a hallmark of a newly defined category of disorders termed *epileptic encephalopathies* (Nabbout & Dulac, 2003) in which epileptiform activity is thought to be responsible for cognitive and behavioral deterioration. The exemplar for this group of disorders is epileptic aphasia, commonly referred to as Landau-Kleffner syndrome (LKS) (Landau & Kleffner, 1957). In its classic form, children with LKS develop language normally until 2 and 10 years of age and then demonstrate an acute or insidious loss of language accompanied by epileptiform EEG abnormalities. Overt seizures may not be evident, but if they occur, they are only loosely related to the onset of regression and are typically infrequent and easily managed. The regression results in a profound aphasia, affecting both the production and comprehension of language. This language loss is considered to result from “functional ablation” of eloquent cortex caused by the seizures or persistent epileptiform discharges (Landau & Kleffner, 1957). Severe forms of the disorder tend to

be associated with near continuous spike-and-wave activity during sleep (CSWS) (Dulac, 2001; Van Hirtum-Das et al., 2006). Behavioral disturbances commonly co-occur, ranging from ADHD symptomology to behaviors associated with ASD (Deonna & Roulet-Perez, 2010; Stefanatos & DeMarco, 2010). Though rare, this disorder has become the most frequently described form of acquired aphasia in children (Stefanatos, 2011). Given some similarities in the natural history and symptomology of RASD and LKS, it has been speculated that similar mechanisms of action may underlie both disorders (Nass, Gross, & Devinsky, 1998; Nass & Petrucha, 1990).

The relationship between LKS and RASD has long been discussed (Deonna & Roulet-Perez, 2010; Stefanatos et al., 2002b; Tuchman, 2006) and continues to attract interest and debate, particularly given recent studies suggesting that the prevalence of regression in autism may be considerably higher than previously thought (Ozonoff et al., 2010; Thurm, Manwaring, Luckenbaugh, Lord, & Swedo, 2014b). The epileptic encephalopathy explanation has some superficial appeal, in view of the high rates of both epilepsy and epileptiform activity in ASD (Parmeggiani et al., 2010) and the twofold increase in epileptiform abnormalities in children with RASD. However, given that cognitive outcome is poorer in children with regression (Hoshino et al., 1987), these increases may, in part, reflect a more general relationship between epilepsy/epileptiform activity and lower cognitive ability (Viscidi et al., 2013). Canitano, Luchetti, and Zappella (2005) found no evidence to support a causal relationship between regression rate in children with RASD and the presence or absence of epilepsy/epileptiform abnormalities. Relatedly, while CSWS can be observed in RASD, it is relatively uncommon (Tuchman, 2009). At best, epileptiform abnormalities may play a minor role in the emergence of RASD, perhaps exerting an effect in a small number of special cases like CSWS or when particular neurologic circumstances exist (Deonna, Roulet-Perez, Chappuis, & Ziegler, 2007). Overall then, the weight of evidence does not support a general causal relationship between epilepsy or epileptiform abnormalities and regression in ASD (Deonna & Roulet, 2006; Rapin, 1995).

Early in this line of inquiry, Stefanatos et al. (1995) suggested that alternative mechanisms would be needed to account for regression in ASD, possibly involving immunologic/inflammatory mechanisms. Implied in this view is that epileptiform activity can largely be considered an epiphenomenon of the pathophysiological anomalies that underlie RASD. A variety of intriguing correspondences related to evidence of immunologic dysfunction shared by these conditions has since come to light (Braunschweig et al., 2013; Connolly et al., 2003; Singer et al., 2008; see Stefanatos et al., 2002b for discussion). Links between RASD and abnormal immune or autoimmune function have been observed in a variety of reports (Jyonouchi, Sun, & Le, 2001; Molloy et al., 2006; Shenoy et al., 2000; Stefanatos et al., 1995), including

rare conditions such as NMDA receptor encephalitis (Gonzalez-Toro et al., 2013; Scott et al., 2014). Regression has been shown to be significantly associated with a family history of autoimmune disorders (Molloy et al., 2006; Valicenti-McDermott et al., 2008). One gene implicated by Molloy et al. (2005) is a member of the immunoglobulin superfamily, which may possibly relate to speculations that regression is associated with abnormal immune responses to viruses. Relatedly, a couple of recent studies have implicated immunoglobulin imbalances, particularly in children with regressive forms of ASD (Braunschweig et al., 2013; Wasilewska, Kaczmarek, Stasiak-Barmuta, Tobolczyk, & Kowalewska, 2012).

Interestingly, associations have been noted between large head size and a positive history of allergic/immune disorders in parents of affected offspring (Sacco et al., 2007a). A number of investigations have suggested that increased head circumference is more likely to occur in RASD (Chaste et al., 2013; Nordahl et al., 2011) and that the timing of regression coincides with a period in development when macrocephaly is most likely to emerge in ASD (Courchesne & Pierce, 2005a). Animal models have shown that maternal immune challenge during pregnancy can result a cascade of events that can influence the expression of genes in offspring and cause alterations in brain function and development, including larger brain size and regression (Fatemi, Earle, et al., 2002).

Correspondences between LKS and RASD have also prompted the recent discovery of similarities at the genetic level (Lesca et al., 2012). Comparative genomic assays revealed that individuals with LKS demonstrate a large number of anomalies involving genomic regions that have also been associated with ASD. Implicated genes include CDH9, CDH13, CNTNAP2, and SHANK3. The investigators suggested that CNVs encoding cell adhesion proteins (cadherins, protocadherins, contactins, and catenins) were particularly evident. The effect of these anomalies may be particularly important during periods of rapid synaptic development. Rapid brain growth is typically followed by a period of subtractive changes that refine circuitry by pruning inefficient neural elements. A related hypothesis derived from computational modelling has suggested that regression may be the result of overly aggressive synaptic pruning (Thomas, Knowland, & Karmiloff-Smith, 2011).

In summary, there are no a priori reasons to suspect that a common causal agent can account for all or most cases of RASD. There is emerging evidence that multiple phenotypes of RASD exist and may relate to diverse pathways of etiopathogenesis (Ozonoff et al., 2010; Rapin, 2006; Stefanatos & Baron, 2011). These pathways may entail the combined influence of genetic susceptibility and abnormal immune responses during pre- or postnatal life (Fatemi et al., 2008; Needleman & McAllister, 2012; Wei, Alberts, & Li, 2013). At present, our knowledge of the diverse manner in which immune function can influence brain development remains rudimentary, so how exactly these factors may play a role in risk for RASD needs to be explored.

## Assessment

It is now appreciated that most parents (~80%) recognize developmental anomalies or delays in their children with ASD by 2 years of age (De Giacomo & Fombonne, 1998), and 30%–50% harbor concerns as early as the first year of life (Harrington, Rosen, & Garnecho, 2006; Young et al., 2003). Despite this, a definitive diagnosis of ASD is often not made until children are 3–4 years of age (Howlin & Moore, 1997; Mandell et al., 2005; Yeargin-Allsopp et al., 2003). Recognizing and validating the critical earliest behaviors that are predictive of a later diagnosis of ASD has been a major concentration of recent research, motivated in part by recognition that availability of reliable tools for early identification would permit more timely initiation of intervention (Bryson, Rogers, & Fombonne, 2003). In addition, more precise specification of the earliest signs and subsequent evolution of the disorder would also potentially facilitate a better understanding of the diverse underlying pathogenic mechanisms, guide the identification of endophenotypes, and possibly inform subtyping of the disorder (e.g., early vs. late onset vs. regressive; Shumway et al., 2011; Stefanatos, Kinsbourne, & Wasserstein, 2002a). Given evidence that the risk of having a second child with autism is considerably increased (>25 times) over that of the general population (Abrahams & Geschwind, 2008; Smalley, 1991), early detection and diagnosis can also have a substantial impact on family planning.

## Screening, Early Identification, and Diagnosis

Baron-Cohen, Cox, Baird, Sweetenham, and Nightingale (1996) conducted one of the first prospective studies of ASD in order to assess the validity of an observational tool called the Checklist for Autism and Toddlers (CHAT), which can be used in primary health care settings to identify 18-month-old children at risk for an ASD (Baron-Cohen et al., 2000). The CHAT, while highly specific, has limited sensitivity (Baird et al., 2000). A modified version of the CHAT, the Modified Checklist for Autism in Toddlers (M-CHAT; Robins, Fein, Barton, & Green, 2001), is now the most widely used instrument for early ASD screening; a recent revision (Robins et al., 2014) detects more cases and has better psychometric properties. These instruments are for children 16–30 months and have been endorsed by the American Academy of Pediatrics. Preliminary data suggest the utility of screening for autism as early as 12 months for some children (Pierce et al., 2011; Turner-Brown, Baranek, Reznick, Watson, & Crais, 2013), although some symptoms are clearly not prevalent until after 12 months (Ozonoff et al., 2010). It is recommended that all children be screened specifically for ASD during well-child doctor visits at 18 and 24 months. Some children do not show frank symptoms until the second or even occasionally the third year, so additional screening in the second year and later is also needed. A summary of measures designed to assist in the early identification of at risk children is presented in Table 13.3.

When screening measures suggest significant risk for the development of ASD, a second, more detailed level of evaluation may be indicated. These “Level 2” evaluations are typically multidisciplinary, involving pediatricians and pediatric specialists in psychology, psychiatry, developmental pediatrics, or neurology, as well as a variety of other medical (e.g., genetics) and allied health specialties (e.g., speech-language pathology, audiology, occupational therapists). Pediatric psychologists and neuropsychologists are integral members of this team, often taking charge of assessing the cognitive and behavioral functioning of children with a known or suspected ASD. Information obtained from these evaluations assist in the diagnostic assessment but are also instrumental in formulating the team’s treatment recommendations.

The structure of such an evaluation is often tailored to address the referral issues, the presentation of the child, and the goals of the assessment. The form of the evaluations may vary substantially depending on the age and level

of functioning of the child. Primary efforts are directed to gathering information relevant to behaviors included in the DSM-5 diagnostic criteria. This is usually accomplished by a thorough and comprehensive interview, in addition to observing and interacting with the child in both structured and unstructured interactions. A number of instruments have been specifically developed in order to assist the diagnostic process. A summary of selected measures is briefly presented in Tables 13.3 and 13.4. Unfortunately, at present, there are relatively few unbiased sources to guide clinicians in the choice of these instruments (Norris & Lecavalier, 2010).

Neuropsychologists may also perform more comprehensive assessments of children with ASD. They are particularly well-suited for this due to their training and expertise in assessing and integrating information across multiple cognitive and behavioral domains relevant to ASD. Neuropsychological evaluations can provide useful information

Table 13.3 Diagnostic screening measures for ASD during infancy and toddlerhood

<i>Screening Measures for ASD</i>			
<i>Measure</i>	<i>Parent</i>	<i>Clinician</i>	<i>Comments</i>
Autism Observation Scale for Infants (Bryson, Zwaigenbaum, McDermott, Rombough, & Brian, 2008)		X	Developed to detect and monitor early signs of autism as they emerge in high-risk infants at 6, 12, and 18 months. Uses structured activities to elicit 18 behaviors including visual tracking, disengaging attention, orienting to name, reciprocal smiling, differential response to facial emotion, imitation and social anticipation. Early data suggested potential to distinguish high- from low-risk infants as early as 12 months (Zwaigenbaum et al., 2005).
Infant-Toddler Checklist (ITC) (Wetherby & Prizant, 2002)	X		Comprised of 25 questions from the Communication and Symbolic Behavior Scales and Developmental Profile (Wetherby & Prizant, 2002) that can be used as a broadband screener for ASD (2008). Positive predictive values above 70% for children age 9–24 months for communication delays, and 93.3% sensitivity for ASD in particular, but does not discriminate ASD from other communication delays unless social competence score is less than the 10th percentile.
First Year Inventory (FYI) (Reznick, Baranek, Reavis, Watson, & Crais, 2007)	X		Developed to assess behaviors in 12-month-olds suggestive of an eventual diagnosis of AD. Large-scale longitudinal study has not yet been reported to evaluate predictive validity.
Modified Checklist for Autism in Toddlers (M-CHAT) (Robins et al., 2001):	X	X	A 23-item parent questionnaire completed at 18 months. Good estimates of specificity and sensitivity when follow-up interview with clinician is added to review failed items. Positive predictive value reported as .68–.74 after interview (Kleinman et al., 2008). Does not allow good differentiation of ASD, language delays and global delays.
Pervasive Developmental Disorders Screening Test-II (PDDST-II) (Siegel, 2004)	X		A three-stage screening questionnaire completed by parent. Stage 1 completed by pediatricians has high sensitivity (.92) and specificity (.91). Useful as a Stage 2 screener with children in developmental clinics (but see McQuistin & Zieren, 2006).
Parent Observation of Early Markers Scale (Feldman et al., 2011)	X		Developed to allow parents to prospectively monitor 61 possible early behavioral manifestations of ASD in 1- to 24-month-old infants. Overall specificity and sensitivity were .74 and .73, respectively.
Screening Tool for Autism in Two-year-olds (STAT) (Stone, Coonrod, & Ousley, 2000)		X	A 12-item, 20-minute interactive test administered by trained professionals measuring play, requesting behavior, directing attention and motor imitation. Good sensitivity (.93) and specificity (.83). Designed to differentiate toddlers with autism from those with other developmental disabilities.

Instruments used to screen for signs of ASD in the first two years of life. These measures are broadly aimed at identifying atypical development of social communication, social orienting, imitation, use of gestures, joint attention, repetitive behaviors, anomalies of play and reciprocal affective behavior. (Adapted and expanded from Stefanatos, 2012.)

Table 13.4 Diagnostic screening measures for ASD in older children and adolescents

<i>Diagnostic Assessment Measures for ASD</i>	
<i>Measure</i>	<i>Comments</i>
Autism Diagnostic Interview-Revised (ADI-R; Rutter, LeCouteur, & Lord, 2003)	Semi-structured interview that elicits information from a parent or caregiver regarding behaviors required to make an ICD-10 or DSM-IV-TR diagnosis of autism (social interaction, communication skills, repetitive activities, stereotyped interests). Designed to distinguish developmental delays, qualitative impairments, and behaviors that would be regarded as deviant at any age. Interrater reliability is excellent. Gold standard measure for research because of high interrater reliability. Not advised for use for children with IQs below 20 or mental age below 20 months (Cox et al., 1999).
Autism Diagnostic Observation Schedule Second Edition (ADOS-2; Lord et al., 2012) c	A semi-structured, interactive observation widely accepted as a “gold standard” diagnostic instrument developed for children from 2 to 9 years of age. It is a Level C measure that should be administered and interpreted only by appropriately-credentialed professionals from psychology, medicine, or a related discipline. It can be administered in approximately 40 to 60 minutes. The revisions have expanded diagnostic algorithms in Modules 1 to 4 (Hus & Lord, 2014) and added a Toddler Module for children 12 to 30 months.
Autism Spectrum Screening Questionnaire (ASSQ; Ehlers, Gillberg, & Wing, 1999; Luyster et al., 2009)	Designed as a screening tool for older children (6–17 years of age) with mild to no intellectual impairment. Comprised of 27 yes/no questions addressing social interaction (11 items), communication (6 items), restricted behavior and interest (6 items), and associated symptoms (5 items). Psychometric properties vary depending on the sample and the respondent (parent or teacher). A cutoff score of 19 for parent respondents in a clinical setting yielded a sensitivity of .62 and specificity of .91. Their scores can be used to help differentiate high-functioning ASD from other behavior and learning disorders.
Autism Spectrum Rating Scale (ASRS; Goldstein & Naglieri, 2012)	Comprised of questionnaires to be completed in about 20 minutes by parents and teachers to rate ASD behaviors. Separate forms for ages 2–5 and 6–18 for both parent and teacher ratings. Short screening forms (five minutes) are available. The normative and clinical samples for the ASRS are large. Recent updates are available to score protocols according to DSM-5 criteria. In addition, a scoring updates is available for scoring nonverbal individuals or individuals who speak infrequently.
Child Autism Rating Scale–Second Edition (CARS-2; Schopler & Van Bourgondien, 2010)	This update of the CARS remains the single most widely used standardized instrument specifically designed for the diagnosis of autism. CARS-2 retains the original CARS form for use with younger or lower functioning individuals (renamed the CARS2-ST for “Standard Form”). Has a new separate rating scale for use with higher-functioning individuals (named the CARS2-HF for “High-Functioning”). Designed as a clinician rating scale to be completed after a direct observation of the child by a trained professional familiar with autism. Information from parents can be obtained with the CARS2-QPC (Questionnaire of Parent Concerns).
Gilliam Autism Rating Scale–third Edition (GARS-3; Gilliam, 2013)	GARS-3 consists of 56 items based on the DSM-5 diagnostic criteria for ASD. Items are grouped into six subscales: Restrictive, Repetitive Behaviors, Social Interaction, Social Communication, Emotional Responses, Cognitive Style, and Maladaptive Speech. Yields standard scores, percentile ranks, severity level, and probability of autism.
Parent Interview for Autism–Clinical Version (PIA-CV; Stone, Coonrod, Pozdol, & Turner, 2003)	A 118-item semi-structured interview provides information about the presence and severity of autistic symptomology across several behavioral domains. Good psychometric properties and sensitive to symptomology present in younger samples. Good sensitivity to behavioral change in 2-year-olds.
PDD Behavior Inventory (PDDBI; Cohen, Schmidt-Lackner, Romanczyk, & Sudhalter, 2003)	Comprised of rating scales completed by caregivers or teachers assessing both adaptive and nonadaptive behaviors. Sensitive to change in maladaptive behaviors. Assesses joint attention skills, pretend play, and referential gesture. Good internal consistency and test-retest reliability.
Social Communication Questionnaire (SCQ; Rutter, Bailey, & Lord, 2003)	Utilizes 40 critical questions from the ADI-R and the same diagnostic algorithm. Items are arranged in four subscales: Social Interaction, Communication, Abnormal Language, and Stereotyped Behaviors. Applicable in children from 4 years (or mental age of 2 years) to adulthood. Not advised for use with profound ID.
Social Responsiveness Scale (SRS; Constantino et al., 2003)	Comprised of 65 items using a 4-point Likert response scale measuring reciprocal social behavior. Yields a single score that indexes the severity of impairment in reciprocal social behaviors. Psychometric properties are acceptable (sensitivity of .78 and a specificity of .77). The SRS is a highly focused measure of social impairment that may not be appropriate for children with moderate to profound intellectual disability.

A selection of instruments developed for use in diagnostic assessments of children to support the diagnosis of ASD. Some measures such as the ADI-R, ADOS and the CARS are intended to be administered by experienced clinicians with expertise in the diagnosis of ASD and who have undergone training on the use of these instruments. The other measures are questionnaires to be completed by parents and teachers and are designed to solicit observations regarding the presence of behaviors indicative of impairments of social communication and manifestations of restricted and repetitive behaviors, interests and activities. (Adapted and expanded from Stefanatos, 2012)

regarding areas of strength or weakness that can guide the provision of services and facilitate the task of educators and therapists in designing and implementing appropriate interventions. A comprehensive discussion of the role of the neuropsychologist in the evaluation of ASD is beyond the scope of this chapter. For more extensive discussions the reader is referred to Black and Stefanatos (2000); Ozonoff, Goodlin-Jones, and Solomon (2005) and Kanne, Randolph, and Farmer (2008). In the next section, we provide a brief summary of the neuropsychological correlates of ASD.

### *Neuropsychological correlates*

#### *Intelligence*

Intelligence estimates span an enormous range in ASD, from severe ID to the very superior range of intelligence. Decades ago, several studies suggested that about 25% of children with ASD had IQs of 70 or above and were thus classified as high-functioning. Correspondingly, approximately 75% were considered to function in a range indicative of intellectual handicap (<70). These proportions have become outdated due to changes in diagnostic criteria in DSM-IV and DSM-IV TR, such that less than half (~45%) of children with ASD were considered to fall within the range of ID (Chakrabarti & Fombonne, 2005; Charman, Pickles, et al., 2011; Fombonne, Quirke, & Hagen, 2011). It remains to be seen how these proportions will change with the new diagnostic criteria in DSM-5. However, as mentioned earlier in this chapter, preliminary studies suggest that high-functioning individuals are less likely to receive the diagnosis. As a result, a higher proportion of individuals who receive the diagnosis may function in the range indicative of intellectual handicap.

Several investigators have attempted to identify patterns of performance on IQ measures to index the etiological heterogeneity of ASD and provide a basis for subtyping (Bolton, Macdonald, Pickles, Rios, Goode, et al., 1994; Fein et al., 1999; Zwaigenbaum et al., 2000). Performance on the Comprehension and Vocabulary subtests are often relatively weak, reflecting difficulties with language skills and a poor appreciation of social norms and expectations (Dawson, Soulieres, Gernsbacher, & Mottron, 2007). By contrast, individuals with ASD tend to score significantly better on some nonverbal subtests, specifically Block Design (BD) (Dawson, Estes, et al., 2007). A peak on BD, while not uniformly found (Charman, Jones, et al., 2011), is present in the subtest profile of almost half (47%) of individuals with ASD compared to only 2% of the typical population (Caron, Mottron, Berthiaume, & Dawson, 2006). The strong performance on BD is thought to be related to relatively enhanced ability to perceive figure-ground relationships (Dawson, Estes, et al., 2007). This forms part of a larger pattern whereby individuals with ASD tend to struggle with verbal tasks and do better on

visuospatial tasks (Bolte, Dziobek, & Poustka, 2009). Strong performance is also frequently evident on Matrix Reasoning and Picture Concepts (Mayes & Calhoun, 2008), in part because of relatively preserved or even enhanced visual perceptual functioning (see reviews by Mottron, Dawson, Soulieres, Hubert, & Burack, 2006; Simmons et al., 2009) and visual imagery (Soulieres, Zeffiro, Girard, & Mottron, 2011). However, low scores are often apparent on Symbol Search and Coding, in part because of relative deficiencies in visual motor skills (Green et al., 2009). Dawson, Estes, et al. (2007) suggested intelligence in ASD is often underestimated, and the low estimate should be regarded to reflect atypical rather than dysfunctional cognition.

While IQ appears to be as steady and predictable in ASD as it is in other clinical populations, the temporal stability of specific patterns of subtest or index scores is generally poor (Borsuk, Watkins, & Canivez, 2006). This may be related to interactions between the child's stage of development and the demand characteristics of tasks. Subtests requiring verbal information processing tend to produce lower estimates of intelligence than those dependent on spatial reasoning and this may be especially true early in development. Mayes and Calhoun (2003) observed that 67% of a cohort of children with ASD demonstrated relatively depressed Verbal IQ estimates (compared to Performance IQ) throughout their preschool years, reflecting delayed language development. As language improved with increasing age, this gap diminished, resulting in higher overall IQ estimates. Given the intersubtest variability, it has been argued that the use of short-form IQ tests or abridged administration may be associated with some reductions in the predictive validity. However, these declines do not seem disproportionate to those seen in neurotypical individuals, according to Minshew, Turner, and Goldstein (2005). Nevertheless, it is important to bear in mind that the specific content of the short form used can have a significant impact on an individual's score.

Some have argued that the use of IQ tests in the ASD population is of questionable utility, since the results do not reveal diagnostically-relevant traits (Zander & Dahlgren, 2010). The measure is not a sensitive marker of genetic risk factors associated with ASD (LeCouteur et al., 1996), in as much as autistic traits appear to be genetically independent of intellectual functioning (Hoekstra, Happé, Baron-Cohen, & Ronald, 2010). Others highlight the utility of IQ as a stable measure of general cognitive function that is also a reasonably good predictor of long-term outcome (Bolte et al., 2009; Gillberg & Steffenburg, 1987; Howlin, Goode, Hutton, & Rutter, 2004) and academic achievement (Mayes & Calhoun, 2008). A Performance IQ of less than 70 appears to be associated with much poorer prognosis in adulthood (Howlin et al., 2004). Overall, independent living is a possibility for individuals with ASD who have an IQ in the normal range (> 70), although outcome can still be variable at this level (Howlin et al., 2004).

*Motor*

Among the neurological comorbidities of ASD, motor impairment is among the most common. Indeed, Kanner (1943) noted that several of the children in his initial cohort were “somewhat clumsy in gait and gross motor performance.” Impairments may become apparent early in life in delays in attaining motor milestones such as righting, sitting, crawling, and walking, as well as a failure to demonstrate protective motor responses when falling (Baranek, 1999; Teitelbaum, Teitelbaum, Nye, Fryman, & Maurer, 1998). In toddlerhood, sensory motor deficits such as hypotonia are common (~50%), although this may dissipate over time (Ming, Brimacombe, & Wagner, 2007). Children with ASD tend to walk 1.6 months later than their age peers (Sheat-Klein, Shinnar, & Rapin, 2014) and often demonstrate gait abnormalities. Periods of toe walking may also be observed in a smaller number of children with ASD (Ming et al., 2007). Disturbances in both fine and gross motor coordination, gait (Jansiewicz et al., 2006; Rinehart et al., 2006), balance (Jansiewicz et al., 2006; Whyatt & Craig, 2012), motor planning (Dowd, McGinley, Taffe, & Rinehart, 2012; Hughes, 1996), and spontaneous imitation of actions (Rogers, Young, Cook, Giolzetti, & Ozonoff, 2008; Stephens, 2008) become apparent in the course of development and cannot be attributed to motor weakness, sensory loss, or general intellectual deficiency (Vivanti, Trembath, & Dissanayake, 2014). Some of these early problems are predictive of future diagnosis of autism (Teitelbaum et al., 1998), the presence of coexisting communication difficulties (Bhat, Galloway, & Landa, 2012; Gernsbacher, Sauer, Geye, Schweigert, & Hill Goldsmith, 2008), and pragmatic language skills (Miniscalco, Rudling, Rastam, Gillberg, & Johnels, 2014), and whether or not the child will retain the diagnosis of ASD later in life (Sutera et al., 2007). On standardized assessment batteries, individuals with ASD between 7 and 32 years of age demonstrate poor upper limb coordination during tasks requiring manual dexterity and visual motor coordination. In addition, they exhibit poor performance on tasks requiring balance, agility, speed, and coordination of the lower limbs (Dewey, Cantell, & Crawford, 2007; Ghaziuddin & Butler, 1998). These difficulties were initially thought to be limited to children with lower IQ scores, but in more recent studies, it has become evident that impairment exists in children with normal range intelligence as well. Deficits may even be evident in specific fairly common tasks such as reaching to grasp (Mari, Castiello, Marks, Marraffa, & Prior, 2003). Motor issues persisting into adulthood can also include features of an ataxic gait characterized by constrained range of motion of the ankle, increased variability in stride distance, and instability (Hallett et al., 1993).

One of the most consistent findings is that individuals with autism are impaired in their ability to imitate skilled gestures. Early theories postulated that these difficulties were related to disturbances in the perceptual organization

of movements that limit their ability to develop representations of the sequence of movements to be imitated (Smith & Bryson, 1994). Numerous studies have suggested that children with ASD may be limited in their capacity to build internal representations of actions and use them to organize, plan, and execute movements (Dowd et al., 2012; Dowell, Mahone, & Mostofsky, 2009; Haswell, Izawa, Dowell, Mostofsky, & Shadmehr, 2009). According to this view, the ability to perform skilled actions is contingent upon the formation of internal models of the complex movement sequences required to execute actions. This process is thought to entail a system of correlating executed motor programs with proprioceptive and visual feedback obtained during self-generated attempts to perform and evaluate the success of a given action. Learning involves generalization based on both proprioceptive and visual feedback as well as watching others perform the same or similar actions. Building upon knowledge gained from the discovery of mirror neurons (Rizzolatti & Fabbri-Destro, 2008), some have speculated that these difficulties may be rooted, at least in part, in failure of the mirror neuron system. According to some recent findings, individuals with ASD may discount visual cues during the process of performing motor actions and build stronger than normal associations between self-generated motor commands and proprioceptive feedback (Haswell et al., 2009). This would place them at a significant disadvantage in imitating movements and understanding other people's actions.

Given evidence of difficulties with movement sequencing, gestural imitation, production of gesture to command, and disturbances in the use of objects and tools (Mostofsky et al., 2006; Williams, Whiten, & Singh, 2004), it has been proposed that individuals with ASD may have a generalized praxis deficit (Dewey et al., 2007; Miller, Chukoskie, Zinni, Townsend, & Trauner, 2014; Mostofsky et al., 2006). It has been suggested that a variety of dyspraxic forms may exist in ASD, including ideational, limb kinetic and buccal-facial forms (Dewey et al., 2007; Miller et al., 2014). While some studies have found an association between impairment of basic motor skills and dyspraxic difficulties (Dowell et al., 2009; Dziuk et al., 2007), the problems with dyspraxia cannot simply be attributed to the more basic problems (Miller et al., 2014). Potential underlying difficulties range from problems with motor pre-programming to deficient meta-knowledge regarding the properties and motor execution of complex actions. Explanations invoking general deficiencies of the mirror neuron system seem incompatible with the prevalence of echopraxia and echolalia in this population as well as the results of a recent neuroimaging study (Spengler, Bird, & Brass, 2010). Conceptually, the findings broadly implicate deficiencies in top-down control of motor actions that are contingent upon integrating proprioceptive, visual, and motor information with conceptual representations of action and the intent of actions (e.g., mental state considerations). The level(s) and precise nature of the underlying

processing impairment(s) remain to be more fully explored in future research.

### Attention

Attention functioning in ASD has been a topic of clinical and research interest since the publication of Rimland's landmark book (1964) in which he pointed out many of the attentional abnormalities commonly seen in this population. Abnormally prolonged attention for preferred activities along with great distractibility and difficulty engaging mental effort for nonpreferred activities is a common clinical observation. Starting in Britain in the 1960s and 70s and accelerating in the 1980s, experimental studies of various aspects of attention have attempted to pinpoint the underlying sources of these clinical observations. A recent source of interest in attention in ASD is studies of the emergence of symptoms in infant siblings of affected children, in which difficulty disengaging social inattention can be seen as early as 6 months of age in some children (Bhat, Galloway, & Landa, 2010), and problems disengaging visual attention become evident by 12–14 months or even earlier (Elsabbagh et al., 2013; Zwaigenbaum et al., 2005). Whether attentional findings in ASD reflect primary abnormalities in attention system(s) or stem from a different motivational structure from whatever comparison group is being used is unclear, since most studies do not manipulate or attempt to maximize motivation (for informative exceptions, see Garretson, Fein, & Waterhouse, 1990; Ozonoff, 1995). There is a large literature on ASD and the many components of attention; the reader is referred to recent reviews (Ames & Fletcher-Watson, 2010; Sanders, Johnson, Garavan, Gill, & Gallagher, 2008) for a more comprehensive discussion.

### EXOGENOUS AND ENDOGENOUS ORIENTING

Exogenous orienting refers to involuntary orienting in which attention is pulled to an external stimulus, often in the periphery; this system develops within the first few months of life (Johnson, Posner, & Rothbart, 1991). Using a Posner-type orienting task, several studies have found relative deficiency in exogenous orienting in individuals with ASD (Greenaway & Plaisted, 2005; but see Minshew, Luna, & Sweeney, 1999; Renner, Grofer Klinger, & Klinger, 2006; Townsend et al., 1999). Furthermore, the components of exogenous orienting have been identified as *disengaging* from the current focus of attention, *moving* attention to the new location, and *re-engaging attention* on the new stimulus, each of which have been correlated with activity of relatively distinct brain systems (Posner & Fan, 2004). Several studies suggest that individuals with high-functioning ASD have relative impairment in the *disengaging* component of exogenous orienting (Landry & Bryson, 2004; Pascualvaca, Fantie, Papageorgiou, & Mirsky, 1998; Wainwright-Sharp & Bryson, 1993), which has been suggested to rely heavily on

parietal functioning (Posner & Fan, 2004). In contrast, the later-developing endogenous orienting system, in which attention is voluntarily and intentionally moved to a new location (e.g., in response to a task instruction such as an arrow appearing at central fixation pointing to where attention should be reallocated), is found to be relatively intact in ASD (Landry, Mitchell, & Burack, 2009). However, when the time between the cue and target is very short, results are more mixed (Landry et al., 2009; Senju, Tojo, Dairoku, & Hasegawa, 2004).

Townsend et al. (1999) suggest that attentional shifting in ASD is generally slowed and is similar to performance of patients with cerebellar lesions (Courchesne et al., 1994), while Renner et al. (2006) propose that attentional shifting in ASD requires more effortful, endogenous processing, which is slower than normal exogenous shifting. Minshew et al. (1999) demonstrated that oculomotor functioning in automatic shifts of attention is normal while volitional eye movements (e.g., antisaccades) are inefficient, and argue that this implicates frontal-parietal circuitry and not cerebellar circuitry.

Furthermore, even when performance on selective visuospatial attention tasks is normal, activation of neural systems is not. Belmonte and Yurgelun-Todd (2003) found abnormal patterns of activation in a small group of autistic individuals, including more activation in occipital and subcortical areas and less activation in frontal, parietal, and temporal areas than typically-developing controls. Haist, Adamo, Westfield, Courchesne, and Townsend (2005) also found reduced activation in a spatial cuing task in parietal and especially in frontal regions and occipital regions, and a virtual lack of activation in the cerebellar vermis.

### FOCUS OF ATTENTION

Literature going back to the early 1970s has demonstrated overselective attention to specific details in ASD (Fein, Tinder, & Waterhouse, 1979; Lovaas & Schreibman, 1971). In fact, a detail-oriented perceptual style in which elements are not integrated into more holistic percepts and concepts was originally suggested in Rimland's (1964) groundbreaking book on autism. Enhanced perceptual analysis of elementary aspects of stimuli has been demonstrated in a series of studies by Mottron and colleagues (Mottron et al., 2006) and confirmed by others (Eigsti & Fein, 2013); findings are generally consistent in showing a local over global perceptual bias in ASD (Wang, Mottron, Peng, Berthiaume, & Dawson, 2007). Manjaly et al. (2007), in looking at activation during a local visual search task, confirmed behavioral superiority in autism in local processing and found not only enhanced occipital activation in adolescents with ASD, but more right-lateralized activation compared to controls.

Various theoretical models have been proposed in which this enhanced local processing and orientation to detail form a central explanatory concept of autism referred to as

*central coherence*. According to this conception, individuals with ASD suffer from weak central coherence in which a detail-oriented bias prevails, with mixed evidence on whether global processing is impaired or simply not preferred. Weak central coherence has been evoked to explain perceptual performance as well as social deficits (Happé & Frith, 2006). This conception is somewhat similar to Rimland's (1964) proposal. Other theoretical models of autism have related attention deficits, including the overfocused and perseverative interest in details, to both overarousal (Dawson & Lewy, 1989; Hutt, Hutt, Lee, & Ounsted, 1964) and to unstable arousal (Hiscock & Kinsbourne, 2011).

Some attentional abnormalities seen in ASD are core diagnostic features of the diagnosis in both DSM-IV and DSM-5. This includes the repetitive and unusual sensory—rather-than-meaning-oriented visual examination of objects, especially visual displays with straight lines, shadows, lights, or objects that can be moved in the visual periphery. There is some inconsistency in reports about when these behaviors tend to emerge, with some arguing that they generally emerge later than social deficits (Stone et al., 1999), while others have found them in infant siblings, who later received an ASD diagnosis, as early as 12 months (Ozonoff, Heung, et al., 2008).

In addition to detail orientation, and on more elementary perceptual elements, the content of attentional focus has been repeatedly shown to be abnormal in autism. In particular, there is avoidance of social stimuli, starting at an early age (Bhat et al., 2010), and in particular, avoidance of the eye region of others' faces, which starts to decline in the initial half of the first year and continues to decline over the first two years or so (Jones & Klin, 2013). Children with autism show selective deficits in orienting to social information, such as a parent calling their name (Dawson, Meltzoff, Osterling, Rinaldi, & Brown, 1998). A study of source memory showed that memory for origins of information was impaired only in aspects of the source related to the face of the speaker (O'Shea, Fein, Cillessen, Klin, & Schultz, 2005), and Goldberg, Mostow, et al. (2008) showed that direction of eye gaze was difficult for individuals with ASD to use as an endogenous orienting cue. One striking example of this avoidance of the face can be seen in a fascinating set of drawings by a 3-year-old girl with autism, in which there are some beautifully done drawings of human figures up to the neck, with the head represented by a tiny circle (Selfe, 1995).

#### INHIBITION

Individuals with ASD, both high-functioning and with ID, appear to be relatively intact in their capacity to inhibit prepotent responses, when compared to typical individuals or those with mild intellectual disability and no autism (Happé, Booth, Charlton, & Hughes, 2006; Ozonoff & Jensen, 1999; Ozonoff & Strayer, 1997; Raymaekers, Antrop, van der Meere, Wiersema, & Roeyers, 2007; Russell, Jarrold, &

Hood, 1999). However, at least two studies suggest that while children with ASD may perform similarly to mental-age-matched peers, adolescents and adults with ASD may be deficient relative to typical controls (Raymaekers, Van der Meere, & Roeyers, 2004; Solomon, Ozonoff, Cummings, & Carter, 2008). Despite good behavioral performance, neuroimaging suggests that individuals with ASD may need to employ different levels of activation in inhibitory areas to achieve the same behaviors (Kana, Keller, Minshew, & Just, 2007; Schmitz et al., 2006).

#### SUSTAINED ATTENTION

The ability of individuals with ASD to *sustain attention* has been examined with variations on the Continuous Performance Task. Garretson et al. (1990) found that children with ASD sustained attention comparably to mental-age-matched typical children, as long as motivation was maximized with tangible reinforcers, and the task difficulty was kept to a moderate level (slow rather than fast stimulus presentation). Several other studies using a variety of paradigms and test batteries have also found relatively strong ability to sustain attention (Goldstein, Johnson, & Minshew, 2001; Johnson et al., 2007; Pascualvaca et al., 1998) although, as with other aspects of attention, functioning neuroimaging reveals different patterns of activation underlying normal behavioral performance. Christakou et al. (2013) examined neural activation in groups of typically-developing boys with ADHD and ASD in a sustained attention task with varying cognitive loads, and reported shared abnormalities in fronto-striato-parietal activation and suppression of the default mode network, but an autism-specific fronto-striato-cerebellar dysregulation. Kennedy and Courchesne (2008), however, present evidence that resting state functional connectivity is abnormal in the large-scale neural networks responsible for social-emotional processing, but essentially normal on the large-scale network underlying sustained attention and goal-directed activity.

Therefore, overall, evidence is fairly consistent that sustained attention seems to be an area of spared functioning in autism, as long as the exertion of mental effort required is moderate and motivation is present, although different neural activation patterns probably underlie this performance.

#### SET-SHIFTING

Set-shifting differs from endogenous and exogenous shifts in that the former is a general change in cognitive strategy, which may be spatial or along some other dimension, while the latter has most often been studied in the context of shifts of spatial attention. In addition, set-shifting is usually initiated by the subject in response to changes in some environmental condition, rather than being specifically instructed or elicited by the stimulus material, and is taken as an index of cognitive flexibility. Set-shifting has most often been examined with the

Wisconsin Card Sorting Test or a similar task. Most studies show deficits in set-shifting in autism (Goldstein et al., 2001; Tsuchiya, Oki, Yahara, & Fujieda, 2005), with particular tendencies to perseveration, and, as with exogenous shifts of attention, a particular problem with disengaging from a previously reinforced strategy (Pascualvaca et al., 1998), although the deficits are sometimes mild (Kaland, Smith, & Mortensen, 2008). Although the majority of studies do find tendencies to perseveration and poorer set-shifting in ASD, Ozonoff (1995) and Pascualvaca et al. (1998) demonstrated that a computer version of a set-shifting task showed attenuated deficits in set-shifting over standard administration with social feedback, implicating a motivational component to the deficit.

#### SUMMARY

In general, inhibition, sustained attention, and endogenous shifts of attention are relatively spared in individuals with ASD, while exogenous shifts, set-shifting, and focus of attention are abnormal. However, there are many individual exceptions to these generalizations and much inconsistency among studies, depending on specific tasks and subject characteristics. In fact, it is a significant shortcoming in most studies that they report group-level performance rather than focusing on variability within clinical groups or correlations between attention measures and clinical phenomena. Functional imaging studies are much more recent and less numerous, and show, if anything, more variability and inconsistency in results than behavioral studies. Variability is undoubtedly driven not only by differences in samples and in task parameters, but in imaging and analysis methods.

#### *Memory*

As with other neuropsychological functions, the study of memory in high-functioning individuals with autism has to be considered separately from that of memory in low-functioning individuals, in whom separating memory deficits from their general ID is very difficult. Most of what we know about selective memory impairments in autism, therefore, comes from the study of high-functioning groups. The literature on memory impairment also overlaps with the literature on attention, executive functions, and material-specific processes such as verbal memory. We will focus here on studies that specifically identify themselves as memory research. For more detailed reviews, see Boucher, Mayes, and Bigham (2012) and Shalom et al. (2003).

One conclusion that can be drawn about memory research in autism is that mixed and contradictory findings abound, more so than in some other areas of cognitive research. For example, despite some contradictions in the literature on language, there is a general body of consistent research on basic functions (e.g., phonology, syntax). This may be due in part to the fact that language impairments form part of

the definition of autism in some diagnostic and descriptive systems, while memory impairment does not. The further one gets from definitional features, the more inconsistency is found in the body of research, and this is certainly true for memory. This is probably due in part to sensitivity of findings to method variation among studies of recall and recognition, and perhaps even more to the heterogeneity of relatively small samples in these studies. For these reasons, there are few general conclusions about memory functioning in autism, but there are several areas that show some fairly consistent findings.

#### MEMORY PROCESSES

Profiles of ability on the Wechsler Memory Scale-III (WMS-III) in high-functioning autism (HFA) were characterized by Williams, Goldstein, Carpenter, and Minshew (2005). Performance was unimpaired on immediate and delayed memory for paired associates and stories, and on a verbal working memory task. Autistic performance was impaired on immediate and delayed recall of faces and of family scenes as well as spatial working memory; the latter was attributed to the computational demands of this particular task, and the former to a deficit in memory for social material, which directly impacts functioning in daily life (Williams, Goldstein, Carpenter, et al., 2005; Williams, Goldstein, & Minshew, 2005, 2006).

Working memory has been confirmed as impaired by some groups (Williams, Goldstein, et al., 2006), while others have found intact verbal working memory in HFA (Ozonoff & Strayer, 2001); as with other areas, it is likely that differences among studies rest on heterogeneity of samples and subtle or not-so-subtle differences in task procedures and motivational conditions. Rather surprisingly, given the general superiority of visuospatial over linguistic processes in autism, verbal working memory has been found to be more intact in autism than visuospatial working memory (Steele, Minshew, Luna, & Sweeney, 2007). Luna et al. (2002) examined neural activation during a spatial working memory task and reported that individuals with autism showed less task-related activation in dorsolateral prefrontal cortex and PCC but not in other regions related to spatial working memory, including the cortical eye fields, ACC, insula, basal ganglia, thalamus, and lateral cerebellum.

Renner, Klinger, and Klinger (2000) directly addressed the idea that autism might involve an amnesia comparable to that of medial temporal lobe patients, in which explicit but not implicit memory would be expected to be deficient. Their findings did not support this idea: They showed, instead, that both explicit and implicit memory functions were intact, but that the strategy for explicit recall was different in participants with autism. These participants did not show the usual pattern developing of primacy and recency effects, but recalled words mainly from the end of the recall list, a finding that can be interpreted as suggesting a passive rather than an active encoding approach,

or shallow encoding. Reduced primacy effects were also reported by Toichi and Kamio (2003). Other studies have confirmed the generalized sparing of implicit learning. For example, implicit learning of spatial context (Barnes et al., 2008), perceptual priming (Gardiner, Bowler, & Grice, 2003), and implicit category formation (Molesworth, Bowler, & Hampton, 2005) were all found to be unimpaired in HFA. (Brown, Aczel, Jimenez, Kaufman, & Grant, 2010) examined autistic performance on four implicit learning tasks (contextual cueing, serial reaction time, artificial grammar learning, and probabilistic classification learning) and found them all to be unimpaired in individuals with autism.

Within the explicit memory domain, recognition memory for a variety of types of material has generally been found to be normal or even superior in autism, while various forms of free and cued recall produce much more mixed findings. Recognition memory for shapes, words, and objects (but not faces) has been consistently comparable to controls or even superior (e.g., Barth, Fein, & Waterhouse, 1995; Brian & Bryson, 1996; Hillier, Campbell, Keillor, Phillips, & Beversdorf, 2007; Renner et al., 2000; Toichi & Kamio, 2002).

Free recall is generally reported as less intact in autism than cued recall, although this varies to some extent with stimulus materials, and is often interpreted as a strategic deficit in activating appropriate recall strategies without a degree of “task support” (Bowler, Gardiner, & Berthollier, 2004). For example, Gaigg, Gardiner, and Bowler (2008) tested the hypothesis that memory for relational information rather than item-specific information is impaired in autism and concluded that while the former is impaired in spontaneous memory, it can be deployed when environmental support is provided. In general, free recall of unrelated items is less impaired than recall of related items, presumably because the individuals with autism essentially treat the semantically related items as unrelated; this seems to hold for both immediate (Smith & Gardiner, 2008) and delayed recall (Renner et al., 2000). For example, Fein et al., 1996, reported that performance in HFA was comparable to that of matched individuals with specific language impairment for memory for sentences, but superior for digit memory and inferior for story memory. Minshew and Goldstein (2001) also found impaired autistic performance on the California Verbal Learning Test (CVLT) and on a story memory task. Bennetto, Pennington, and Rogers (1996) presented a detailed analysis of performance of individuals with ASD on the CVLT. The ASD group showed less free recall of the word list on Trials 3–5, but did not forget more words than controls over short or long delay periods. However, overall, they showed increased intrusions. Additionally, while they correctly endorsed an equivalent numbers of words on a recognition trial, they demonstrated increased false positives that were from the interfering list or other words that were semantically related to the target words. Phelan, Filliter, and Johnson (2010), in contrast, found unimpaired overall list learning ability on the CVLT in HFA, but reported that cued

recall was superior to free recall (relative to norms). (Bowler, Gaigg, & Gardiner, 2009) also showed that although autistic participants did use semantic clustering to aid recall, the categories they formed were idiosyncratic, in contrast to the word groupings of typical controls.

With regard to episodic and autobiographical memory, Bowler, Gaigg, & Gardiner, 2008, reported that the experiences of remembering events by individuals with autism are qualitatively similar to those of controls, although they report fewer such memories. Reduced recall of autobiographical episodes in the context of normal recall of autobiographical and other facts (Crane & Goddard, 2008; Klein, Chan, & Loftus, 1999; Minshew et al., 2005) confirms this impaired retention or reporting of meaningful personal episodes. This impairment is difficult to reconcile with the often-reported extremely detailed memory of some autistic individuals for specific, distant episodes, complete with details that are not viewed as central or memorable by others, and suggests that only certain episodes capture the attention of these individuals sufficiently for these details to be retained. For interesting discussions of the relationship between episodic memory and the concept of the self in autism, see Toichi and Kamio (2002); Lind and Bowler (2010) and Lombardo and Baron-Cohen (2010).

A few studies have examined various aspects of source memory (memory for time, place, or other aspects of situation in which the event occurred) in autism, including source monitoring (attributing a remembered event to one’s own thoughts, words, or actions [internal source] or to another’s actions or words [external source]). Generally intact identification of the source of memories has been found in HFA, especially when recognition tasks are used (Bowler et al., 2004; Gaigg et al., 2008; Williams, Goldstein, & Minshew, 2005). Bowler, Gardiner, and Grice (2000) showed intact recognition of words in autism, but recognition was more often present when subjects reported “knowing” that they had seen the word rather than “remembering” the actual event; Bowler et al. interpret this finding as indicating deficit in self-aware (autonoetic), episodic memories. O’Shea et al. (2005) reported intact recognition of impersonal contextual information (e.g., the color of the wall behind the speaker), but impaired recognition of social contextual information (e.g., the face of the speaker). Hala, Rasmussen, and Henderson (2005) also found source monitoring to be less efficient in autism than in controls, although the pattern of difficulty of different types of source monitoring (e.g., self vs. other, real vs. imagined) was the same in both groups.

#### MATERIAL-SPECIFIC DEFICITS

A series of studies by Gaigg and Bowler (Gaigg & Bowler, 2008; Gaigg et al., 2008) examined the effect of emotionally arousing stimuli on conditioning and found that fear conditioning was impaired in autism, and although emotionally arousing words were learned more readily than neutral

words, as in typical controls, such words were not as resistant to forgetting in the autism group as they were in the controls. Gaigg and Bowler argue that these and other results support the idea that amygdala–cortical connections are underrepresented in autism, leading to abnormal conditioning of arousing stimuli. Illusory memories are less likely in controls when stimuli are emotionally charged than when they are neutral, while subjects with ASD are less affected by the emotionality of the stimuli (Gaigg & Bowler, 2009).

As mentioned on p. 230, incidental source memory was found to be normal on all aspects of the context in which stories were heard, except for a specifically social aspect of the learning context (e.g., the face of the speaker; see O’Shea et al., 2005), confirming a memory deficit for social information, possibly secondary to reduced attention to this aspect of the environment. A material-specific deficit in memory for faces has been confirmed in direct tests of face memory (Dawson et al., 2002; Hauck, Fein, Maltby, Waterhouse, & Feinstein, 1998; Klin et al., 1999; Williams, Goldstein, & Minshew, 2005). Howard et al. (2000) also found poor recognition memory for faces, and found it to be associated with enlarged amygdala volume and abnormal processing of fear expressions. Koshino et al. (2008) examined brain activation and functional connectivity in a working memory task involving faces. There was reduced activation in the autism group in the left inferior prefrontal and right posterior temporal areas and a slightly different location for fusiform activation. The results were interpreted as reflecting impacted working memory, ToM processing, and a tendency to analyze faces as nonsocial stimuli.

#### MEMORY AS SECONDARY TO OTHER COGNITIVE PROCESSES

Some theorists have argued that memory deficits in autism are secondary to other cognitive deficits. In particular, Minshew and Goldstein (2001) have maintained that apparent memory impairments are not amnesic deficits per se, nor are they material-specific, but rather are secondary to impaired deployment of organizing strategies to improve memory efficiency. They administered a battery of memory tests to a group of high-functioning adolescents and young adults with autism; memory deficits were directly related to the complexity of the material being remembered (e.g., complex vs. simple mazes, paired-associates vs. list and story recall). Williams, Goldstein, et al. (2006) confirmed this complexity effect and also found deficits in working memory, which depends on strategy utilization. In addition, they established that memory factor structure was different in autistic and control groups.

Similarly, Bennetto et al. (1996) found specific impairment in an HFA group in temporal order memory, source memory, supraspan free recall, and working memory, but not on short- and long-term recognition, cued recall, or new learning. They interpreted this pattern of findings as consistent with a primary executive dysfunction, which contributed to the memory impairments.

Compensation for poor semantic encoding with the use of rote memory strategies or phonological encoding has also been suggested. For most populations, semantic strategies assist memory more than phonological ones, but Toichi and Kamio (2002) found a lack of superiority of semantic cuing over phonological cuing in HFA. Mottron, Morasse, and Belleville (2001) suggest that in autism, phonological processing of language cues is enhanced (rather than suggesting semantic deficits).

#### SUMMARY

Memory findings in autism are extremely mixed and contradictory. The most consistent findings are probably the material-specific abnormality in memory for social stimuli, especially faces, and the lack of differential memory for emotionally arousing versus neutral stimuli. Free recall is often reported as abnormal, both in total amount of material recalled and in strategies spontaneously deployed to aid recall (reduced or idiosyncratic semantic encoding and clustering, reduced primacy but reliance on recency effects). Cued recall seems to boost memory in participants with autism more than in controls. Just as cued recall is better than free recall, recognition memory is better yet, but there is a tendency towards endorsing related false positives. Once learned, forgetting over immediate and longer-term retention intervals is not generally reported. Findings on source memory and source monitoring is mixed, but there is some evidence that episodic memory, and particularly autobiographical remembering, is impoverished in HFA, despite clinical accounts of some remarkable event memory. When functional imaging is performed during memory tasks, areas of activation are often abnormal, even in the context of normal-level behavioral performance.

#### *Perceptual abilities*

Sensory and perceptual abnormalities in autism have been in the literature since Kanner’s original paper in 1943, where he described such classic sensory autistic behaviors as a child looking at objects while shaking or spinning them, and showing pleasure at watching spinning items. Early researchers such as Ornitz, Rimland, and the Hutts wrote extensively about sensory phenomena and theories in the 1960s and 70s (Ornitz, 1973). Following these descriptions and simple experiments, sensory phenomena rather fell out of favor among mainstream autism researchers, who were focusing on language, other cognitive processes, and initial attempts at biological research, followed by an upsurge in interest in social behavior and social cognition. In the last 10–15 years, however, there has been a resurgence of interest in sensory and perceptual processing in autism, perhaps best indicated by the inclusion of sensory abnormalities as a diagnostic criterion in the recently published DSM-5. For more extensive reviews of sensory and perceptual research, see Rogers and Ozonoff

(2005); Leekam, Nieto, Libby, Wing, and Gould (2007), and Fine, Musielak, and Semrud-Clikeman (2014), which also has an interesting historical perspective. The piecemeal perceptual style of most individuals with autism (Happé & Frith, 2006) has been variously viewed as a deficit in integrative processes leading to poor gestalt perception and intact perception of detail, or as a processing style or preference in which the inclination is to process detail, but in which integrative processing of gestalts is not impaired when the motivation for it exists (see discussion by Bolte et al., 2012).

#### CLINICAL PHENOMENA AND DIAGNOSTIC CRITERIA

Rogers and Ozonoff (2005) include in their review of sensory features of autism over- or underresponsiveness, preoccupations with sensory features of objects, and unusual reactions to sensory stimuli. Overresponsiveness might include such behaviors as covering the ears in response to loud sounds, oversensitivity to smells that other don't notice, overly picky food choices based on texture or temperature, or resistance to being touched. Underresponsiveness might include ignoring loud sounds, ignoring others' voices, insensitivity to painful experiences (such as minor injuries or blood draws), and insensitivity to being hot or cold. Preoccupations with sensory features of objects might include visual fascinations with things like shadows, water dripping, objects spinning, movie or TV credits scrolling, and straight lines. Unusual reactions could encompass all of the above, and usually refer to specific isolated sensitivities or fascinations, like being fearful of vacuum cleaners. It could also include sensory-seeking behavior, where the individual engages in behaviors that appear to be intended to provide to provide unusual sensory input, like wiggling fingers in the visual periphery or looking at things upside down.

Although DSM-IV does not mention sensory abnormalities per se, it includes two criteria under "restricted and repetitive behaviors" that can include abnormal responses to sensory input: first, "encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus," and second, "persistent preoccupation with parts of objects" (APA, 2000, p. 71). Although the first of these is often applied mainly to objects that the individual with autism wants to talk about, collect, or play with, it can also apply to fixations on sensory qualities, such as wanting to carry around yellow things. The second relates more directly to sensory abnormalities, an example being a child who persistently stares at or spins the wheels on a toy rather than playing with the toy functionally. Since the DSM-IV is polythetic, allowing for a selection among symptoms, it permits a diagnosis of PDD-NOS with *no* repetitive behaviors, including the two types just mentioned. A diagnosis of autistic disorder can be made with just one of these types of restricted and repetitive behavior. DSM-5 is more nomothetic, that is, it requires all three of the social-communication symptoms to be present, although it allows more flexibility in the domain of repetitive behaviors, requiring

two of the four such symptoms. One of these is explicitly sensory: "Hyper- or hypo-reactivity to sensory input or unusual interests in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement)" (APA, 2013).

The inclusion of explicitly sensory symptoms in the DSM-5 has not drawn a lot of criticism, since the presence of these symptoms in many affected individuals has been well-established for so long, but the requirement of at least two repetitive behaviors has raised concerns about individuals who met DSM-IV-TR criteria for an ASD losing the diagnosis. Leekam, Nieto, et al. (2007), using the Diagnostic Interview for Social and Communication Disorders (DISCO; Leekam, Libby, Wing, Gould, & Taylor, 2002) found that more than 90% of children with autism had sensory abnormalities. Furthermore, sensory symptoms were shown in multiple domains (including atypical responses to auditory, visual, tactile and olfactory stimuli, and insensitivity to pain), with the biggest differences between children with autism and those with other clinical conditions being in the specific domains of smell/taste and vision. They also found that symptoms persist across time, but can manifest differently at various ages, and with different levels of cognitive functioning.

Despite this high prevalence of abnormal responsiveness to sensory stimuli in autism, some empirical data have suggested that a not-insubstantial number of individuals with autism may not meet the DSM-5 requirement of two RRBIA symptoms. McPartland et al. (2012) found reduced sensitivity of DSM-5 relative to DSM-IV-TR, with a significant number of cases failing to meet two of the four RRBIA criteria. Barton et al. (2013) investigated the sensitivity and specificity of the DSM-5 criteria with specific reference to toddlers, raising the concern that although sensory over- and underresponsiveness and fascinations may be present in many toddlers, other repetitive behaviors such as obsessive interests, repetitive movements and speech, and resistance to change in routines and environments may not appear until later. Therefore a significant number of toddlers may lose the diagnosis. In fact, they found that sensitivity of DSM-5 for toddlers previously diagnosed was inadequate unless the criteria were relaxed to two-thirds of the social symptoms and one-fourth of the repetitive symptoms.

Methodological issues abound in the domain of sensory and perceptual research. First is the problem that plagues autism research in general: the heterogeneity of subject samples, in terms of age, cognitive functioning, social relationships, biological features, and sensory abnormalities themselves. As Waterhouse (2013) repeatedly points out, grouping together a set of individuals who meet some criteria for autism and investigating their sensory functioning, when they vary tremendously on multiple dimensions, presents many problems and uninterpretable results. Second is the measurement issue. Many studies rely on parent report,

some by interview using instruments like the ADI or the DISCO, and some with questionnaires such as the various version of Dunn's Sensory Profile. Valuable as parent report is, especially since it can encompass behavior across time and in multiple situations, it needs validation with more objective measures and cannot reveal anything about underlying mechanisms. In recent years, EEG, ERP, functional imaging, and psychophysical experiments have greatly supplemented the reliance on clinical observation and parent report. However, these suffer from the problem of taking a (usually) one-time measurement in a group in which attention and motivation can greatly impact performance on sensory tasks.

#### PARENT REPORTS

Much of the literature to the present day has relied on various versions of Winnie Dunn's Sensory Profile (Dunn & Westman, 1997). Ninety-five percent of the sample of children with ASD demonstrated some degree of sensory processing dysfunction on the Short Sensory Profile Total Score, showing differences from controls on 92% of items and across all domains (Tomchek & Dunn, 2007). The greatest differences from controls were found on the Underresponsive/Seeks Sensation, Auditory Filtering, and Tactile Sensitivity sections. Rogers, Hepburn, and Wehner (2003) also used the Sensory Profile in comparing three clinical groups and controls. The group with autism had poor auditory filtering and showed elevated scores on the Seeks Stimulation/Underresponsive sections (that is, seeking stimulation with such activities as wiggling objects and fingers in front of eyes but failing to respond to caregiver-presented stimuli). While they were comparable in overall abnormality to children with Fragile X, the autistic group had the highest rates of irregularity in taste and smell specifically. This and other studies conclude that sensory deficits are not specific to autism, but that certain behaviors—particularly involving taste, smell, and tactile input—may be more specific to autism than more general categories like underresponsiveness.

Similar results were reported by Wiggins, Robins, Bakeman, and Adamson (2009), who explored the sensory functioning of very young children with autism at the time of diagnosis. They found that these young children with ASD had more tactile and taste/smell sensitivities and difficulties with auditory filtering than age-matched children with other developmental disorders. In addition, sensory abnormalities were associated with stereotyped interests and behaviors. These findings were taken as supportive of the inclusion of sensory abnormalities in diagnostic criteria for autism. The relationship of sensory abnormalities—in particular tactile defensiveness—was also reported by Baranek, Foster, and Berkson (1997), who showed that individuals with higher levels of tactile defensiveness were more likely to display rigid or repetitive behaviors in other domains, such as stereotyped speech.

Also using the Sensory Profile, Kern and Jones (2006) confirmed that a wide age range of individuals with autism were

abnormal across all domains. Their results suggest that sensory abnormalities in autism are global in nature (involving several modalities) but have the potential to improve with age, except for low threshold for tactile input, which was consistent across age and could lead to tactile defensiveness.

Liss, Saulnier, Fein, and Kinsbourne (2006) looked at a large group of individuals with ASDs to examine the relationship of sensory reactions to Kinsbourne's hypothesized "overfocused attention" style (Kinsbourne, 1991). They assessed whether children with unstable arousal systems who might overreact to sensations would overfocus on preferred topics and develop extraordinary memory for selected material. They added items to the Sensory Profile to cover some specific autistic behaviors, resulting in a 103-item expanded Sensory Profile. Parents of children with ASD rated items in the areas of "sensory overreactivity," "sensory underreactivity," "sensory seeking behaviors," "overselective attention" and "exceptional memory," and completed the Vineland Adaptive Behavior Scales. On one hand, overreactivity in the whole group was significantly associated with social symptoms and delays, perseveration and overfocusing, and with reports of exceptional memory. Underreactivity, on the other hand, was strongly related to all domains of autism symptomatology and to lower cognitive and adaptive functioning, but not to exceptional memory. Sensory seeking was also found to be related to all domains of autism symptomatology and lower adaptive skills, and sensory seeking and underreactivity were the most strongly intercorrelated of the three reaction patterns. Cluster analysis showed one large group of children with the predicted overfocused pattern of attention who demonstrated overreactivity, perseverative behaviors and interests, and exceptional memory. A second clear cluster was underreactive and sensory seeking, with prominent autism symptoms and low adaptive skills. The conclusion, therefore, was that overreactivity was associated with unstable arousal with consequent defensive overfocusing on selected interests, resulting in exceptional memory for this material. In contrast, underreactivity and sensory seeking were more strongly associated with severe autism and low adaptive skills.

#### LABORATORY STUDIES

A very useful review of controlled laboratory studies was conducted by Rogers and Ozonoff (2005). They conclude, unlike some of the studies cited earlier, that although sensory symptoms are commonplace in children with autism and more frequent than in typical children, they also appear with equal or greater frequency in other developmentally challenged groups, such as those with Fragile X and deaf-blind children. They also considered the overarousal and underarousal theories to explain abnormal sensory responses and concluded that the overarousal theory had little support. Children with autism, in their view, are more likely to be underaroused and underresponsive, but the methodological

limitations, lack of replications, different subject samples, different sensory modalities, and different assessment methods leave this matter unresolved.

A number of studies have attempted to shed light on the social deficits characteristic of ASD by examining basic sensory and perceptual abilities that may come into play when processing social stimuli. Perception of nonbiological motion (such as randomly moving dots) triggers activity in an area of extrastriate cortex known as visual area MT (V5). One class of studies examined the percentage of dots that must move in the same direction for perceived motion to occur. Studies are consistent in finding that in autism, as in dyslexia, the threshold for perceiving motion is higher than in controls (Pellicano, Gibson, Maybery, Durkin, & Badcock, 2005). This finding has been interpreted as suggesting an impairment in dorsal visual stream processing in ASD. Furthermore, the deficit appears to lie primarily in later parts of the dorsal stream. Kenet et al. (2012), however, reviewed other evidence suggesting that these findings do not reflect a difficulty in the dorsal stream processing *per se*, but rather a more general deficit in perception of motion *or* complex stationary stimuli, possibly based in a broad signal-to-noise problem. For example, a variant on the movement paradigm, where dot coherence is needed to perceive a shape (rather than motion), also showed that individuals in the HFA group were impaired (needing higher dot coherence), while individuals with dyslexia or Asperger syndrome were not impaired (Tsermentseli, O'Brien, & Spencer, 2008). Bertone, Mottron, Jelenic, and Faubert (2003) found deficits in specific motion perception paradigms but not others and concluded that these results support a deficit in perception of complex stimuli rather than a deficit in the motion-detection magnocellular pathway *per se*. Similar conclusions were reached by Sanchez-Marin and Padilla-Medina (2008), who found impaired perception of a vertical line embedded in visual noise, whether moving or stationary. Vandenbroucke, Scholte, van Engeland, Lamme, and Kemner (2008) suggest that deficits are found in studies using high spatial frequency, whether they involved motion or not (see Kenet, 2011, for more discussion and interpretation of these studies).

Perception of biological motion has been localized to a small area in the superior temporal sulcus, with more activity generally on the right side (Grossman, Klin, Carter, & Volkmar, 2000). In the last ten years, a number of studies have examined both behavioral and neurological responses to biological motion perception tasks in autism. Blake, Turner, Smoski, Pozdol, and Stone (2003) compared performance on a biological motion task (point-light animated figures) to a static visual perception task (perception of a gestalt from fragments) and found specific deficits on perception of biological motion. Freitag (2008) found that a group of adolescents and adults with autism showed abnormal neural activation and slowed reaction time in response to a biological motion detection task. However, they unexpectedly showed deficits in perception and recognition of spatially-moving

point lights even in nonbiological motion. They also found a correlation of the biological motion task with difficulties in hand/finger imitation; these combined results suggest the possibility that difficulties with perception of biological motion may be part of a larger class of visual-perceptual deficits but specifically impact social development.

In an effort to identify more precisely where in the processing stream of biological motion the autistic impairment is found, Kroger et al. (2014) studied ERPs in children and adolescents watching human motion stimuli. Like Freitag (2008), they unexpectedly found diminished amplitude of early response components; specifically, the P100 amplitude was decreased in response to both random and biological motion, suggesting deficits in visual processing that were not specific to biological motion stimuli. Furthermore, the N200 component showed abnormal lateralization, and a later human-motion-specific activation also appeared reduced and more diffuse in autism. Results of this study were taken to support the idea that abnormal early sensory processing abnormalities contribute to higher-order, later components specific to perception of biological motion.

Finally, Klin, Lin, Gorrindo, Ramsay, and Jones (2009) examined the preferential-looking behaviors of 2-year-olds with diagnosed autism to point-light displays of adults playing children's games such as peek-a-boo, with a control condition where the display was played upside down and backwards, out of sync with the audio of the actor. Comparison groups were typically-developing and developmentally delayed toddlers. The group with autism showed no preference for either stimulus type, while both comparison groups preferred the (upright) biological motion with synced voice. Further analysis showed that the group with autism was strongly influenced by concordance of audio change in amplitude with velocity change in each light point, attending preferentially to the more synchronized display, while the control groups were not influenced by the audio-visual synchrony but consistently preferred the upright moving figures. Klin et al. interpreted this as indicating that the attention of toddlers with ASD was captured by the coincidence of physical audio and visual stimuli, rather than the social input associated with the true biological motion. They also suggested that this could explain the child's preference for looking at the mouth rather than the eyes of a speaker, because the mouth has more synchrony with the sound produced than the eyes.

#### SUPERIOR PERCEPTUAL ABILITY

Both in the visual and auditory domains, it has been suggested that perceptual acuity is actually superior in autism and might drive the attention-to-detail processing style that impairs perception of gestalts and extraction of meaning. A recent study by Ashwin, Ashwin, Rhydderch, Howells, and Baron-Cohen (2009) showed that individuals with ASD have superior visual acuity, extending even into the acuity range of birds of prey. However, Bolte et al. (2012) and others have

questioned this finding and have not replicated it. Keita, Mottron, and Bertone (2010) failed to find better visual acuity in individuals with autism but did observe a lack of visual crowding effect, suggestive of altered local lateral connectivity in early perceptual processing streams underlying spatial information processing, which might lead to downstream processing abnormalities.

However, in the auditory domain, there is replicated evidence of normal or even superior performance in ASD for pitch discrimination and musical ability (Bonnell et al., 2003; Lepisto et al., 2005; Mottron et al., 2006). The Lepisto et al. study documented enhanced ERP response to small differences in pitch to nonspeech stimuli, but this response was attenuated to differences in speech sounds.

Eigsti and Fein (2013) studied individuals diagnosed with ASD before age 5, who later have no autism symptoms (e.g., having optimal outcomes). As in previous studies, the non-optimal ASD comparison group showed heightened pitch discrimination. By contrast, the optimal outcome group's abilities did not differ from those of typical controls. Furthermore, enhanced pitch discrimination was associated with current autism symptomatology and with delayed early language onset. They suggest that exceptional pitch discrimination may lead to overdevelopment of low-level perceptual processes in general (Bonnell et al., 2003), consistent with local neural overconnectivity (Belmonte et al., 2004), which in turn may impede the formation of phonological categories and lead to inability to extract words from acoustic signals.

Mismatch negativity response on EEG to a deviant frequency or duration sound reflects behavioral discrimination ability and is a preattentive process. This is important to study in autism, since poor attention to language may cause (rather than result from) poor auditory discrimination of language sounds. Kenet (2011) reviewed studies of preattentive auditory discrimination using mismatch negativity and concluded that the findings are extremely heterogeneous among studies. Response latency has been variously described as shortened, lengthened, or normal, while one study found no mismatch negativity response at all.

The tactile modality is the least studied of the major sensory systems, but clinical observations of tactile oversensitivity and defensiveness abound. One tactile perception study (Cascio et al., 2008) showed that adults with ASD were more sensitive than controls to vibrations on their forearm, and to thermal pain on both the forearm and the palm. In contrast, there were no differences between groups in detection of light touch or innocuous thermal stimuli. Cascio et al. (2012) examined psychophysical ratings and fMRI responses to tactile stimuli in adults with autism and controls. They found that while ratings were fairly similar, the autism group gave more extreme ratings. In addition, the BOLD responses were quite different, with the autism group showing more extreme responses to unpleasant textures in PCC and the insula. This suggested that an exaggerated limbic response to unpleasant touch might mediate some of the social avoidance.

Taste/smell sensitivity, resulting in picky eating and aversion to certain people and environments, is very commonly reported. Taste/smell sensitivity seems to be more specific to autism than abnormalities in other modalities, as mentioned on p. 233. Very little laboratory investigation has occurred in this domain, but behavioral reports are thoroughly reviewed by Cermak, Curtin, and Bandini (2010).

#### THEORETICAL ACCOUNTS AND RELATIONSHIP TO CORE AUTISM CRITERIA

Rogers and Ozonoff (2005) reviewed the leading theories that attempt to account for abnormal responses to sensory stimuli. Most of these are variants of theories that go back into the 1960s, 1970s, and 1980s and comprise ideas of overarousal, underarousal, unstable arousal, and poor cross-modal integration. Waterhouse, Fein, and Modahl (1996) and Brock, Brown, Boucher, and Rippon (2002) suggest that failure to bind sensory elements together into cross-modal percepts or to perceive events in association with their context lead to focus on individual perceptual elements of a stimulus, with a consequent impairment in perception of meaning, similar to the lack of central coherence theory. The focus on individual elements leads to emphasis on parts of objects rather than wholes, in addition to a focus on the physical characteristics of stimuli. Hiscock and Kinsbourne (2011) suggests that unstable arousal leads to a defensive focus on narrow and perseverative aspects of stimuli, as well as avoidance of social stimuli and engagement in repetitive movements. This linking of putative unstable arousal with a focus on unusual aspects of stimuli also posits avoidance of social stimuli because they are unpredictable and thus potentially arousing. This idea is also presented by Dawson and Lewy (1989), who described social stimuli as more novel and complex and therefore more arousing. Kenet (2011) suggested that imbalance in overall excitatory-inhibitory control over early cortical activity could be produced by abnormalities in GABA or glutamate. This could lead to abnormal signal-to-noise ratio, which in turn may lead to heightened perceptual response to sensory input. It might also relate to other aspects of autism, such as vulnerability to seizures. Kenet elaborated on how these "hypersensitivities, distortions, and altered pathways for responding to sensory stimuli" (p. 216) can have downstream effects on higher cognitive functions.

#### SUMMARY

As with other areas of neuropsychological function, there are inconsistencies and contradictions in this literature. However, a few sensory/perceptual findings have been replicated: in the auditory domain, hyperacusis and increased discriminability are often found and are related to impaired language development. In visual and tactile domains, there are abundant reports of behavioral abnormalities, but no consistent electrophysiological findings. There are sufficient

findings of EEG and ERP abnormalities at early cortical levels to suggest that preattentive processes in early sensory processing are abnormal for most individuals with autism, and cannot be attributed to different states of attention or motivation. The weight of the evidence is that the attention-to-detail processing style is just that, a processing preference, rather than a deficiency in the ability to form *gestalts*, once motivation is maximized and task demands are clear. It seems plausible that early processing abnormality and an overfocus on physical characteristics of stimuli could lead to many of the downstream cognitive style attributes of autism, as well as deficiency in language comprehension and social interaction. Biological suggestions related to arousal differences, signal-to-noise ratio differences, poor processing related to complexity or spatial frequency of stimuli, or differences in cortical under- and overconnectivity, are just beginning to be seriously investigated. The extent to which the nature of social interaction and social input leads to avoidance of social stimuli, costing proficiency in social learning, is not yet known.

### *Language*

While many individuals with ASD have little-to-no speech, a significant proportion have no delay in language development (Wilkinson, 1998). Language difficulties were one of the three defining categories of autism symptoms in DSM-IV-TR. Within this category, the three symptoms were delayed language (no words by 18 months, no phrases by 24 months), difficulty having a reciprocal conversation (when sufficient language was present), and repetitive or echolalic language. A fourth symptom placed in this category was absent, delayed, or repetitive pretend play. With the advent of DSM-V, language symptoms have been folded into the other two categories: poor conversational ability is covered in the social communication category, and repetitive speech and play are covered in the repetitive behavior category. Language delay per se is no longer present as a symptom, but the presence of language impairment is coded as a separate dimension. Some autism researchers, especially those who deal with young children, regret the deletion of language delay as a defining symptom since this is consistently shown to be the most common first concern of parents of children with autism (Herlihy et al., 2013). Furthermore, the age of first words is a powerful predictor not only of later language, but also of cognitive and adaptive skills (Mayo, Chlebowski, Fein, & Eigsti, 2013).

Language impairments are virtually universal in autism, but vary tremendously among individuals, ranging from subtle pragmatic difficulties to essentially no language, either receptive or expressive. The prior estimate of as many as 50% of children with autism being totally mute has given way to a less pessimistic estimate, although language impairments are often severe (Lord & Paul, 1997). This decrease in nonverbal children is probably due to more effective and

successful early intervention, as well as increasing numbers of high-functioning, verbal individuals being diagnosed with some form of autism (Kelley, 2011). In general, pragmatics and prosody tend to be consistent areas of difficulty (Lord & Paul, 1997), while syntax, phonology, and semantics tend to be spared relative to overall verbal level, with many individual exceptions (Condouris, Meyer, & Tager-Flusberg, 2003; Kjelgaard & Tager-Flusberg, 2001; Swensen, Kelley, Fein, & Naigles, 2007).

### PHONOLOGY

Phonological ability, that is, the ability to discriminate and produce basic speech sounds, has been generally thought not to be an area of a specific deficit in autism (Bartolucci, Pierce, Streiner, & Eppel, 1976; Kjelgaard & Tager-Flusberg, 2001; Tager-Flusberg, 1981), although low-functioning children with significant intellectual deficiency often do have significant difficulties with both receptive and expressive phonology, consistent with their overall impairment in language and cognitive functioning. In addition, some individuals with HFA or Asperger syndrome show distortions of articulation (Shriberg et al., 2001). It has been argued that phonological impairments, when they exist, are secondary to a more general motor disability (Gernsbacher et al., 2008). However, a fascinating glimpse into the social nature of phonological functioning was provided by Baron-Cohen and Staunton (1994), who showed that the majority of children with autism raised in England by non-native-speaking mothers acquired their mothers' accents, while typical children in the same situation acquired the accent of their English peers. Furthermore, relatives of individuals with autism often share the social communication difficulties in milder form (BAP), but do not share the phonological difficulties, suggesting that these difficulties are characteristic only of those with the full-blown syndrome and not the prodromic form (Bishop et al., 2004).

### PROSODY

Prosody is another acoustic characteristic of speech. The term refers to the melody of speech that conveys both grammatical and emotional information. Prosodic abnormality, both expressive and receptive, has often been noted as one of the most pervasive areas of autistic language impairment, but is also very difficult to characterize (Kelley, 2011; McCann & Peppe, 2003). Adults with ASD tend to place stress in the wrong place in a sentence or display unusual melodic contour (Shriberg et al., 2001). Not only do they produce abnormal prosody, but they have difficulty in using it to disambiguate meaning from a speaker; for example, Diehl, Bennetto, Watson, Gunlogson, and McDonough (2008) showed that individuals with ASD did not use prosody to decide between different possible meanings of a sentence, and individuals with ASD have particular difficulty

with producing and understanding stressed words (Paul, Augustyn, Klin, & Volkmar, 2005). Peppe, McCann, Gibbon, O'Hare, and Rutherford (2007) also showed that receptive and expressive prosody were highly correlated to verbal mental age, and were both delayed and deviant in autism. In an fMRI study of comprehension of prosody in autism, Eigsti, Schuh, Mencl, Schultz, and Paul (2012) found several more brain areas recruited in the group with autism; this widespread activation was taken as evidence of multiple cognitive strategies being employed to comprehend what is a relatively simple and automatic task in typical individuals. A study of irony comprehension in high-functioning children with autism (Wang, Lee, Sigman, & Dapretto, 2006, 2007), using both contextual and prosodic cues, showed similar results: the autistic group's neural activation included areas recruited by typical controls, but was much more widespread, indicating greater effortful processing needed. Overall, it is clear that prosodic information is difficult for individuals with autism to both produce and comprehend, although the deficient components of this complex set of processes remains to be identified and quantified.

#### GRAMMAR

Grammar is usually defined to include syntax (word order to convey meaning) and morphology (combining basic units of meaning, such as a noun plus "s" to convey plural or possessive). Until fairly recently, syntax was considered to be an aspect of speech and language, like phonology, that was relatively preserved in autism and consistent with overall language level (Kelley, 2011; Swensen et al., 2007). Some recent findings, however, suggest that syntax in HFA may be somewhat repetitive and simplified, and use forms that place less load on working memory (Eigsti, Bennetto, & Dadlani, 2007). Despite a roughly normal progression of emergence of grammatical morphemes (Waterhouse & Fein, 1982), children with ASD do show some specific difficulty with relational terms, including pronouns, prepositions, and tense (Bartolucci, Pierce, & Streiner, 1980; Lord & Paul, 1997). In a study that received a good deal of attention, Kjelgaard and Tager-Flusberg (2001) described a subset of verbal autistic children whose language was quite similar to that of children with specific language impairment (SLI), including difficulties with syntax. They were also found to have delays or abnormalities in morphology (Roberts, Rice, & Tager-Flusberg, 2004). Tager-Flusberg has argued that specific impairments in structural aspects of language, such as syntax and morphology, is not a characteristic of all individuals with autism, but of a subset of affected children who may share genetic risk with individuals with SLI. Kelley (2011) discussed the performance-competence distinction in relation to grammar in ASD; for many children, they may have mastered syntax and morphology, but because their language is used more for need fulfillment than social communication, language samples may fail to capture their competence. In addition, the

tendency to produce perseverative and repetitive language, which is a defining characteristic of ASD in DSM-IV, may lead to perseveration of simple language forms, even if complex ones are within their repertoire.

#### SEMANTICS

Semantics, or word meanings, has been well studied in autism over the last 40 years. In general, semantics is another area of language that is considered to be relatively preserved in autism, especially when tested as single-word receptive and expressive vocabulary (Kjelgaard & Tager-Flusberg, 2001; Swensen et al., 2007). However, there are a few exceptions to this generalization. First, despite scores on standardized tests of vocabulary that tend to be a high point in their language profiles, children with ASD may show somewhat reduced fluency when asked to quickly produce words in response to semantic or phonemic cues (Turner, 1999b), and the words they produce may be less paradigmatic of the category than words produced by controls (Dunn, Gomes, & Sebastian, 1996). Klinger and Dawson (2001) found that children with ASD as well as those with Down syndrome had relative difficulty in categorizing new information by forming prototypes, but performed normally when given explicit rules about a category. Kamio and colleagues (Kamio, Robins, Kelley, Swainson, & Fein, 2007; Kamio & Toichi, 2000) documented impaired semantic priming in a lexical decision task in individuals with ASD and normal verbal IQ. Though children with ASD and typical speakers have difficulty in using semantic categories, individuals with ASD seem to have particular difficulty with mental state words, words that convey specific information about processes such as knowing, guessing, expecting, and estimating (Akechi, Kikuchi, Tojo, Osanai, & Hasegawa, 2014; Baron-Cohen et al., 1994b; Dennis, Lazenby, & Lockyer, 2001; Kelley, Paul, Fein, & Naigles, 2006; Tager-Flusberg, 1992). As with studies of other aspects of language, beginning research on neural activation with semantic processing suggests that even when behavior performance is spared, activation patterns are different. In one case, semantic processing shifted activation from Broca's to Wernicke's area (Brodmann Area 22) in children with autism relative to controls, with less sensitivity to concrete versus abstract word differences (Harris et al., 2006). Overall, therefore, semantics is a spared area of function in autism, depending on overall language and cognitive level, but with some abnormality in specific semantic classes, in fluency and in semantic priming.

Verbal memory has also been examined in ASD; in general, verbal memory is worse than visuospatial memory and suffers from less automatic processing for meaning than in typical development. Compared to children with other language impairments, Fein et al. (1996) found that children with autism were superior in remembering digits, showed equivalent performance with sentences, and were inferior in recalling stories. They interpreted these findings

as supporting the idea that children with autism relied on rote memory and did not tend to automatically encode the material for meaning or use that meaning to aid recall. These findings were consistent with those of Gabig (2008), who also found difficulty in autism with recalling material of greater complexity or semantic structure. This interpretation has been generally supported by tests of list learning, such as the CVLT, where children with ASD may have difficulty using semantic information to recall lists of words (Bennetto et al., 1996; Minshew & Goldstein, 1993; but see Phelan et al., 2010 who found no difference between TD and ASD children and adolescents). A recent study by Tyson et al. (2014) confirmed the poorer use of semantic cues to aid recall, as well as more perseverations and intrusions, in a group with HFA, although their scores were still mostly within the average range. Furthermore, Tyson et al. (2014) examined the performance of a group of optimal outcome children on this task and found no differences from the typical group on any learning characteristics.

#### PRAGMATICS

Pragmatics, or the social use of language, is abnormal in autism, almost by definition. As summarized by Kelley (2011), pragmatics includes taking the perspective of the listener; maintaining the topic of interest; giving enough (but not too much) information to the listener; using humour, sarcasm, metaphor, and idiom; and using nonverbal communication (e.g., facial expressions and gesture). In addition, constructing narratives is often included in discussions of pragmatics. If all aspects of pragmatic function are normal, then autism is unlikely. Degree of pragmatic difficulties are correlated to severity of autism symptoms (Volden, Coolican, Garon, White, & Bryson, 2009), and subtle pragmatic difficulties are often found in the BAP that are sometimes apparent in unaffected relatives (Landa, Folstein, & Isaacs, 1991; Whitehouse, Barry, & Bishop, 2008). Expressive pragmatic language impairments cause a great deal of stigmatization of individuals with ASD, and receptive difficulties impair their ability to understand the conversational intent of others (Landa, 2000). High-functioning adolescents and young adults with ASD have particular difficulty during conversation in maintaining eye contact with their partner, intonation, and appropriately staying on topic (Paul, Orlovski, Marcinko, & Volkmar, 2009). In fact, inability to hold a reciprocal conversation, insensitivity to cues from the listener, and the improper word selection for the social context (e.g., not being overly formal) is so pervasive that difficulty with conversation is a symptom of autism in the DSM-IV. Individuals with ASD have difficulty with nonliteral language, especially figures of speech and idioms (Dennis et al., 2001; MacKay & Shaw, 2004), and also with making inferences about incomplete verbal information (Dennis et al., 2001; Norbury & Bishop, 2002). Although comprehension and recall of stories was good in high-functioning individuals with autism, their retelling

was less coherent, and they tended to neglect causal connections among events as well as the psychological states of the main characters (Capps, Losh, & Thurber, 2000; Diehl, Bennetto, & Young, 2006; Ge & Han, 2008). Kelley et al. (2006) found some persisting similar deficits in constructing narratives in a group of optimal outcome (OO) children with a history of autism (i.e., those who no longer met diagnostic criteria), despite normal scores in semantic and grammatical language measures. Suh et al. (2013) confirmed the presence of multiple deficits in story-constructing in high-functioning adolescents with autism (including fewer “gist” elements, more ambiguous pronouns, speech dysfluency, and not naming characters). Although their OO adolescents did not show most of these features and were average or above on almost all measures of language (Tyson et al., 2014), they demonstrated subtle persisting signs of dysfluency and idiosyncratic language. Overall, therefore, pragmatic deficits in the social use of language as well as in constructing or retelling narratives are ubiquitous in autism, present in relatives without autism, and persist in subtle form even when almost all other language abnormalities and delays have resolved.

#### SUMMARY

Language was one of the first areas of autism functioning to be studied, and the literature on this topic is enormous. By and large, the generalizations made in the 1980s and 1990s that individuals with autism show almost universal abnormality in prosody and pragmatics has been supported. Language development in other domains such as phonology and syntax are more variably impaired, and for the most part, semantics is often relatively spared. However, many exceptions both in individual children and in components of these “spared” processes have been found. More sophisticated theory and methodology—such as correlations with genetic subtypes, studies of language deficits in unaffected relatives, use of preferential looking to test comprehension without the necessity of test responses (Naigles, Kelty, Jaffery, & Fein, 2011), and functional activation on language tasks—will no doubt further our understanding of this very complex set of questions, and help the design of more effective therapies.

#### *Executive Function*

One of the more long-standing neuropsychological theories of autism proposes that key aspects of the disorder are based in disturbances of executive function. Propounding this viewpoint, Damasio and Maurer (1978) remarked that the disturbances of attention, repetitive/stereotyped behaviors, and cognitive flexibility seen in autism were remarkably similar to problems typical of patients with acquired frontal lesions. Restricted and repetitive patterns of behavior, interests, and activities are cardinal features of ASD and thus are seen with regularity in school-aged children through to adults

(Hughes & Ensor, 2007; Sachse et al., 2013). Speculations that these symptoms may reflect a breakdown in executive function is compatible with observations that, throughout this age range, a positive association exists between rigidity/stereotyped behavior and executive function deficits (Bramham et al., 2009; Yerys, Wallace, et al., 2009). Also in keeping with this notion are claims by some investigators that executive function is profoundly and pervasively impaired in ASD (Corbett, Constantine, Hendren, Rocke, & Ozonoff, 2009; Verte, Geurts, Roeyers, Oosterlaan, & Sergeant, 2006). However, there is also sufficient contradictory evidence to call into question the strength of this association: first, numerous studies have shown that many aspects of executive function are relatively intact or only mildly impaired in ASD (Goldberg et al., 2005; Happé et al., 2006; Losh et al., 2009). Second, it has been reported that significant deficiencies in executive function occur in only a minority of children with ASD (Geurts, Sinzig, Booth, & Happe, 2014).

The inconsistencies between studies may, in part, relate to inherent difficulties in defining and operationalizing elements of executive function and in devising appropriate measures to assess these aspects of cognitive function in this population. Pennington and Ozonoff (1996) outlined six domains of executive function, including working memory, contextual memory, inhibition, planning, generativity (or fluency), and cognitive flexibility or set-shifting. Of these, the most commonly implicated problems in ASD include inhibitory and inference control (Adams & Jarrold, 2009; Christ, Kester, Bodner, & Miles, 2011; Happé et al., 2006), and set-shifting/cognitive flexibility (Corbett, Constantine, et al., 2009; Van Eylen et al., 2011). The findings related to these specific aspects of executive ability are again inconsistent, with some studies demonstrating intact function in many aspects of inhibitory control (Brian, Tipper, Weaver, & Bryson, 2003; Christ et al., 2011) and relatively unimpaired performance on measures of set shifting and cognitive flexibility (for reviews, see Pellicano, 2012; Russo et al., 2007).

It has become apparent through these investigations that relatively minor variations in task demands or administration can have a significant influence on whether or not performance in individuals with ASD is impaired (Kaland et al., 2008; Ozonoff, 1995; Rinehart, Bradshaw, Moss, Brereton, & Tonge, 2000). Other neuropsychological measures (e.g., Trail Making), hybrid neuropsychological/experimental measures (e.g., CANTAB), and experimental test-switching paradigms have also yielded somewhat inconsistent findings. Many of the formal measures of executive function are highly contrived and structured, yet deficits in ASD may be more likely to be evident in everyday situations that are unstructured, unpredictable or uncontrolled, or when open-ended questions are used (Mackinlay, Charman, & Karmiloff-Smith, 2006; Van Eylen, Boets, Steyaert, Wagemans, & Noens, 2015). Investigations have been further complicated by the fact that different aspects of executive function emerge at various points in development and unfold at different rates.

Preschoolers are relatively unimpaired on measures of executive function appropriate to that age group (Yerys, Hepburn, Pennington, & Rogers, 2007), while greater divergence from normative levels of performance may occur in ASD with increasing age. Differences may therefore be particularly evident for metacognitive executive abilities (Rosenthal et al., 2013). Overall, a clear understanding of the relationship between RRBIAs and executive function requires more precise and ecologically valid measurement tools (Geurts, Corbett, & Solomon, 2009; Van Eylen et al., 2015).

There has long been a debate over the relationship of executive function to ToM (Ozonoff, Pennington, & Rogers, 1991; Pellicano, 2010). ToM refers to the cognitive capacity to make inferences regarding the mental states of others, their feelings, beliefs, and intents (Baron-Cohen, 2001; Premack & Woodruff, 1978). This ability to successfully and accurately “mentalize” or “mind read” another person and respond appropriately is thought to play an important role in multiple aspects of social communication, including the establishment of a common ground or frame of reference for the exchange of information and the sharing of interests (Sperber & Wilson, 2002). Deficits in ToM have been advanced to account for many of the core problems associated with ASD, including but not limited to deficiencies in joint attention, social relatedness, and empathy. The neural substrate mediating the development of ToM, and relatedly empathy, appears to involve medial PFC, superior temporal sulcus (STS), and the temporal parietal junction (TPJ), along with the precuneus (Dodell-Feder, Koster-Hale, Bedny, & Saxe, 2011).

Some have argued that poor ToM can be understood in terms of problems with executive function or language processing (de Villiers, 2000; Fine, Lumsden, & Blair, 2001; Russell, Saltmarsh, & Hill, 1999). It has become apparent that difficulties with ToM are not unique to ASD—similar if less severe problems in performing ToM tasks have been observed in children with hearing impairment, language disorder, and intellectual handicap (Harris et al., 2008; Lecciso, Petrocchi, & Marchetti, 2013; Li et al., 2014; Peterson, Wellman, & Liu, 2005). Given this, it has been suggested that linguistic and executive abilities may be important precursors to the development of ToM (Dahlgren, Sandberg, & Hjelmquist, 2003; Fisher, Happe, & Dunn, 2005) or are at least moderating factors in the performance on ToM tasks. In order to address this question and gain a clearer perspective on the relationship between ToM and executive function, Iao and Leekam (2014) recently reported a study that utilized a non-verbal ToM task that was specifically devised to circumvent the language and executive function confounds of more traditional ToM tasks (e.g., false belief). As predicted, children with ASD performed worse than typically-developing children on this task. While Iao and Leekam (2014) contended that this performance deficit could not be explained by problems with executive functioning or language problems, they further concluded it may not be adequately accounted

for by a specific ToM deficit either. They instead related the poor performance to representational demands inherent in performance of ToM tasks.

### **ASD: A Developmental Cognitive Neuroscience Perspective**

A fundamental assumption in neuropsychology is that developmental and learning disorders reflect functional compromise of domain-specific neural systems that mediate various aspects of cognition and behavior (e.g., attention, memory, perceptual skills, motor abilities, language, executive function). Each system is conceptualized as having specialized processing components (modules, nodes), interconnected in distributed networks in the brain, resulting in localization or regional specialization of cerebral functions. These networks are thought to be sufficiently independent in their organization that the development of a particular system or subsystem may be arrested, delayed, or otherwise impaired in a fairly selective manner, causing delays or differences in development in the respective domain of behavior. The possible sources of such disruptions are diverse since alterations can occur at various levels (structural, metabolic, electrophysiological, neurochemical) that are often interrelated.

As reviewed in this chapter, there is now overwhelming evidence that ASD represents a collection of disorders that are fundamentally rooted in alterations in neural structure and function. Anomalies have been identified at multiple levels of analysis, from neuronal morphology and organization to neural pathway development and functional connectivity. A primary manifestation of these differences in neurodevelopment is compromised ontogeny of one of the most important aspects of human behavior: social communication (see Stefanatos & Baron, 2011 for a review).

There has been much discussion in recent years in the fields of social and communication neuroscience suggesting that specialized neural networks evolved in the human brain to mediate the highly complex and specialized computational demands underlying our capacity to communicate with each other (Berwick, Friederici, Chomsky, & Bolhuis, 2013; Tomasello, 2008). Given that communication is intrinsically a social act, related and overlapping systems evolved in tandem, one to process language and the other to mediate intersubjectivity which is existing between conscious minds, and the ability to make inferences about the intentions, feelings, and thoughts of another person (Baron-Cohen & Ring, 1994; Brothers, 1990; Frith & Frith, 2010). From an evolutionary viewpoint, the requisite neural architecture likely emerged both through exaptation (exploiting, redeploying existing neural circuits without necessarily compromising their original functions) and through substantial expansion of neural substrate, including but not limited to areas of frontal and temporal neocortex (Dunbar, 2012; Schoenemann, 2009). This circuitry is necessarily intimately connected with other cortical systems normally engaged in social

communication (e.g., motor control, hearing, vision) as well as with subcortical structures involved in processing socially relevant information and interactions, particularly the amygdala, thalamus, basal ganglia, and cerebellum.

The resulting neural circuitry involves a collection of parallel, highly-distributed, sometimes overlapping neural networks with critical components distributed cortically in the frontal, temporal, and, to a lesser degree, parietal lobes. Components involved in communication are mainly distributed in perisylvian cortex of the left cerebral hemisphere, including inferior frontal lobe, middle and superior temporal gyrus, STS, anterior temporal lobe, supramarginal gyrus, and insula (Aboitiz et al., 1995; Catani, Jones, & ffytche, 2005; Friederici, 2011). Recent reconceptions of ASD have placed greater emphasis on the system sometimes referred to as the “social brain” (Adolphs, 2009; Brothers, 1990), which evolved to mediate social awareness, intersubjectivity, social attunement, and mentalizing another person’s mental or emotional state. This system involves components in ventromedial prefrontal cortex (BA10), intraparietal sulcus, medial parietal cortex (precuneous), posterior superior STS, and TPJ, ACC, anterior temporal cortex, and the amygdala (Adolphs, 2009; Brothers, 1990; Lewis, Rezaie, Brown, Roberts, & Dunbar, 2011; Mills, Lalonde, Clasen, Giedd, & Blakemore, 2014). In the following sections, we provide a brief synopsis of how this conceptual understanding of these networks, their function and evolution, bear on and enrich our conceptualizations of the neural basis for the chief problems associated with ASD.

### ***Social Communication***

Social communication is such an important aspect of human behavior that infants appear to be born with native biases and predispositions to attend to, observe, and process socially-relevant information. Within hours of birth, newborns demonstrate preferential responses to the voice of their mother and face-like visual configurations (Johnson, Dziurawiec, Ellis, & Morton, 1991). Within days of birth, infants prefer direct eye gaze (Farroni, Menon, Rigato, & Johnson, 2007) and show sensitivity to facial geometry and expressions (Leppanen & Nelson, 2009; Parr, Modi, Siebert, & Young, 2013) and patterns of biological motion (Bardi, Regolin, & Simion, 2011). These nascent capacities likely reflect genetic predispositions, and form the foundations for the development of the highly complex system that will unfold across the course of development to mediate social cognition. Evidence from diverse sources suggests that some of these early dispositions are mediated via subcortical mechanisms (e.g., Johnson, 2005), and that cerebral specialization for processing the human voice, faces, and emotion begins to emerge in the first days of life and continues to evolve in the following months as new components of the system come “online” (Cheng, Lee, Chen, Wang, & Decety, 2012; Johnson, Grossmann, & Farroni, 2008; Simion, Leo, Turati, Valenza, & Dalla Barba, 2007)

A large body of research has linked face recognition problems with ASD (Sasson, 2006), and it has been proposed that face processing difficulties are an essential aspect of the disorder (Dawson, Webb, & McPartland, 2005; Schultz, 2005; Weigelt, Koldewyn, & Kanwisher, 2013). It has long been recognized that individuals with ASD often avoid direct eye contact, have poor eye-to-eye gaze (Itier & Batty, 2009), and are poor at judging direction of eye gaze. Reduced attention to the eyes contributes to and is often accompanied by deficiencies in face processing in children and adults with ASD (Dalton et al., 2005; Spezio, Adolphs, Hurley, & Piven, 2007; Sterling et al., 2008). Early face recognition problems, evident at 7 months of age, have recently been observed to be predictive of an ASD diagnosis at 3 years (Gliga, Jones, Bedford, Charman, & Johnson, 2014). Similar, if milder, difficulties can also be observed in unaffected family members, suggesting that problems with face recognition may represent a cognitive endophenotype of the disorder (Dawson, Webb, Wijsman, et al., 2005; Wallace, Sebastian, Pellicano, Parr, & Bailey, 2010).

The FG, located in the ventral temporal lobe, has received wide attention for its seemingly special role in processing faces (Corbett, Carmean, et al., 2009; Critchley et al., 2000; Schultz, 2005). Functional neuroimaging studies of face processing have revealed that older children and adults with ASD do not show the usual pattern of activation of the amygdala and the FG that is seen in neurotypical individuals. Some have suggested that these anomalies may relate, at least in part, to a lack of the attentional bias for faces that is generally evident from an early age in typically-developing infants (Chawarska, Volkmar, & Klin, 2010). Others have contended that the difficulties with face recognition are neither related to the perceptual nor attentional issues but are contingent upon the memory demands of the task (Weigelt et al., 2014). Interestingly, normal patterns of activation of FG have been observed when participants with ASD were explicitly directed to fixate on the eye region (Hadjikhani et al., 2004; Hadjikhani, Joseph, Snyder, & Tager-Flusberg, 2007) or when pictures of personally familiar individuals were presented (Pierce, Haist, Sedaghat, & Courchesne, 2004; Pierce & Redcay, 2008). Given these findings, it has been suggested that anomalous activations may be related to social motivational deficiencies (Dawson, Webb, & McPartland, 2005) or the allocation of visual attention (Hadjikhani et al., 2004). It may be that evaluative and interpretive processes mediated by the amygdala (e.g., emotional significance, unfamiliarity) determine deployment of visual attention to stimuli, and this in turn influences the likelihood of anomalous patterns of activation in FG (Adolphs, 2010). Despite ongoing disagreements regarding the nature of the underlying processing difficulties and the significance of the anomalous activations of FG (Gauthier, Curran, Curby, & Collins, 2003), there seems to be compelling evidence from behavioral, event-related potential, and functional neuroimaging studies suggesting that individuals with ASD, from a very early age, spend less

time and therefore have less experience processing faces. This may impede social interactions by the effect it has on their ability to utilize information derived from the face in social interactions (Pelphrey, Shultz, Hudac, & Wyk, 2011).

Areas in posterior STS also play a critical and varied role in social cognition (Zilbovicius et al., 2006 for a review). Like the amygdala, the STS is commonly activated during the processing of facial expressions (Hadjikhani et al., 2007; Humphreys, Hasson, Avidan, Minshew, & Behrmann, 2008) and the perception of eye gaze (Materna, Dicke, & Thier, 2008; Pelphrey, Morris, & McCarthy, 2005). Direct eye gaze improves facial recognition of another individual (Itier & Batty, 2009). The STS also plays a special role in processing biologically-based motion (Castelli, Happe, Frith, & Frith, 2000; Freitag et al., 2008; Pelphrey & Carter, 2008) and has been implicated as part of a network involved in the perception of action, the analysis of gesture, and the ability to understand and attribute the intentions of others (Vollm et al., 2006). The STS often fails to show normal patterns of activation in individuals with ASD during performance of these tasks (Grezes, Wicker, Berthoz, & de Gelder, 2009; Hirai & Hiraki, 2005; Klin & Jones, 2008; Klin et al., 2009; Pelphrey, Morris, McCarthy, & Labar, 2007). Interestingly, STS is also an area that normally becomes active during voice recognition, and studies have shown that individuals with ASD fail to show this activation, despite their having normal activation of STS in response to nonvocal sounds (Gervais et al., 2004).

Evidence from structural and functional imaging studies have confirmed long-held beliefs that ASD is associated with alterations of functioning of the amygdala (Nordahl et al., 2012; Paul, Corsello, Tranel, & Adolphs, 2010). These findings provide anatomical and functional correlates to the cytoarchitectural anomalies (e.g., reduced neuron counts, smaller size) identified in clinicopathological studies (Amaral & Schumann, 2003; Bauman & Kemper, 2005). From an evolutionary standpoint, the amygdala has long been a hub in neural systems mediating communication. Its volume increased greatly in size (especially the lateral portion) in conjunction with the rapid expansion of the human cortex that occurred approximately 100,000 years ago. Wired to rapidly process social information, it has intimate connections with neighboring structures involved in memory (hippocampus) and more remote structures involved in processing socially-relevant information including the FG, both auditory and somatosensory systems, and prefrontal cortex. The amygdala emerges as a key component in the development of the social brain in the first several months of life. It is widely known for its involvement in fear processing and emotional regulation, but it has also been implicated in later emerging problems of social interaction in ASD, particularly in deficits in the development of empathy and systematizing (Baron-Cohen, 2009). As previously discussed in this chapter, these capacities are mediated by a complex and distributed neural network involving the amygdala, cingulate gyrus, medial

frontal cortex, orbital frontal cortex, inferior frontal gyrus, and the superior temporal sulcus (Baron-Cohen et al., 1994a; Happé et al., 1996; Schulte-Ruether et al., 2011; Vollm et al., 2006). Individuals with ASD perform poorly on ToM tasks, and on functional imaging, they do not demonstrate typical patterns of activation during tasks requiring mentalizing and ToM (Kana, Keller, Cherkassky, Minshew, & Just, 2009; Schulte-Ruether et al., 2011; Williams, Waiter, et al., 2006). The distribution of this network overlaps substantially with the mirror neuron system, and it has been suggested that dysfunction of the mirror neuron system may contribute to problems with empathy and some other social deficits experienced by individuals with ASD (Dapretto et al., 2006; Iacoboni & Dapretto, 2006). Others have suggested that these systems are dissociable (Marsh & Hamilton, 2011).

Over the course of development, the amygdala comes under the increasing control of orbital and medial prefrontal cortex, which are also essential components of the social brain. The relationship between these structures is such that it is difficult to consider the function of one without reference to the other. Areas in the PFC are responsible for conscious deliberation and rational decision-making. These structures work dynamically with the amygdala to evaluate the significance of environmental events and to formulate an appropriate response. Serving a regulatory role over the amygdala, the PFC incorporates and integrates information from internal bodily sensations, external information, and past experience and knowledge, and incorporates this information to temper responses of the rapidly reactive amygdala. Pathological changes have been identified in the PFC of individuals with ASD, including increased neuron numbers (Courchesne et al., 2011), increased glial cell numbers (Edmonson, Ziats, & Rennert, 2014), and abnormalities of minicolumn development (Casanova, 2008). At a macrostructural level, documented differences include frontal lobe overgrowth in childhood evident in increased brain volume and cortical thickness (Carper & Courchesne, 2005; Ecker et al., 2013; Keller et al., 2007; Mundy, Sullivan, & Mastergeorge, 2009).

The frontal cortex also interacts closely with the cingulate gyrus, which seems to play an intermediary role in evaluating information and organizing appropriate responses. The exact functions of the cingulate are incompletely understood but appear to be diverse. Circuitry in the frontal cortex and ACC form part of a larger fronto-striato-thalamo-parietal network involved in inhibitory controls and conflict detection (Solomon et al., 2014). This will be discussed in the next section. The PCC, on the other hand, seems to be involved in supporting internally-directed cognition, forming part of the default mode network, but also in directing attention (Leech & Sharp, 2014). In addition, the PCC forms part of a circuit including the medial frontal cortex and lateral temporal cortex that is involved in mentalizing. Damage to the PCC affects the function of this system and decreases empathy, emotional expressiveness, and motivation (Dennis

et al., 2013; Kiehl, 2006). Relatedly, a recent study has identified cytoarchitectural abnormalities in the PCC, evident in irregularly-distributed neurons, poor laminar organization in layers IV and V, and increased presence of neurons in white matter (Oblak et al., 2011).

Perhaps the most discussed subcortical structure implicated in autism is the cerebellum. The cerebellum has long been known to play a major role in motor planning and control, but in recent years, there has been growing recognition of its involvement in various cognitive and language processes, including procedural and working memory, attentional control, speech production, aspects of language acquisition, and behavioral planning (O'Halloran, Kinsella, & Storey, 2011; Schmahmann, 2010; Strick, Dum, & Fiez, 2009). Emerging evidence suggests that early cerebellar injury may influence remote cortical development causing functional compromise of a fronto-cerebellar pathway extending from lateral regions of each cerebellar hemisphere (crus I and II) to contralateral areas of neocortex including dorsolateral prefrontal cortex (PFC), premotor and sensorimotor cortex, and mid-temporal region (Limperopoulos et al., 2014). This was correlated with scores on measures of gross motor skill and expressive language. Relatedly, Skefos et al. (2014) reported decreases in Purkinje cell density in crus I and II in ASD and suggested that this may cause dysfunction of a prefrontal cortical network involved in modulating aspects of social behavior and behavioral planning (Schmahmann, 2010). Other studies have also implicated fronto-cerebellar networks in impaired expressive language, working memory, attention, and aspects of gross motor function (Hodge et al., 2010; Rogers et al., 2011; Townsend et al., 2001). Loss of vermis volume has been tentatively associated with more global impairments of development (Bolduc et al., 2011). Overall, this body of literature is theoretically of importance, particularly in highlighting that early damage or dysfunction to a particular node in a distributed network can have substantial remote effects on other parts of the network.

### ***Restricted and Repetitive Patterns of Behavior Interests and Activities***

Restricted and repetitive patterns of behavior, interests, and activities are among the earliest signs of ASD (Wolff et al., 2014). They can be seen in infants and toddlers (Kim & Lord, 2010; Morgan, Wetherby, & Barber, 2008), supporting their status as a core diagnostic feature. However, some have questioned their diagnostic utility in children younger than 3 years, in part because repetitive behaviors are also seen in other disorders and indeed in the normal course of early development (Moore & Goodson, 2003). In infants with ASD, these behaviors include atypical patterns of object exploration (Ozonoff, Macari, et al., 2008), sensory self-stimulation (Zwaigenbaum et al., 2005), preferential attending to nonsocial stimuli (Bhat et al., 2010), and difficulty shifting attention away from objects (Zwaigenbaum et al., 2005).

Despite their considerable clinical importance, these behaviors have received less research attention, and as a consequence less is known about their nature and basis. In recent years, interest has focused on the possibility that restricted interests and stereotyped behaviors may reflect underlying deficits in aspects of executive function, particularly cognitive flexibility (Lopez, Lincoln, Ozonoff, & Lai, 2005). Cognitive flexibility refers to the ability to shift thoughts or actions depending on situational demands and contingencies (Monsell, 2003). While a relationship between impaired cognitive flexibility and RRBIAs seems to have face validity, it has proven difficult to prove or disprove. Confusions stem both from inherent difficulties in operationalizing and quantifying problems in cognitive flexibility, as well as in the diversity of the ASD population. For example, one of the more frequently cited findings pointing to deficits in cognitive flexibility in ASD is impaired set-shifting (often indexed as perseverative errors on the Wisconsin Card Sorting Test). While several studies have shown that individuals with ASD are impaired in set-shifting (Corbett, Constantine, et al., 2009; South, Ozonoff, & McMahon, 2007), others using the same or similar measures have found that set-shifting is relatively spared (Goldberg et al., 2005; Kaland et al., 2008; Minshew, Goldstein, & Siegel, 1997; Rinehart, Bradshaw, Moss, Brereton, & Tonge, 2001). Some of the discrepancies in results may relate to participant characteristics (e.g., IQ, age, severity of ASD symptomology, comorbid conditions).

In this context, rigidity and stereotyped behavior in ASD have been shown to be positively associated with set-shifting deficits in school-aged children and adults (Bramham et al., 2009; Yerys, Wallace, et al., 2009). In addition, increased severity of repetitive and stereotyped behaviors have been related to difficulties in maintaining set (Miller, Ragozzino, Cook, Sweeney, & Mosconi, 2015). Given the variability that characterizes such investigations, the strength of these associations and their basis remains to be firmly established through further studies. Progress in this area will depend upon development of more finely tuned paradigms (Geurts et al., 2009; Van Eylen et al., 2015).

Recently, a number of neuroimaging studies have provided evidence supporting the notion that restricted and repetitive behaviors may be related to pathophysiology of neural networks subserving executive function. As already discussed, it is well-established from both structural and functional neuroimaging and postmortem studies that frontal lobe development proceeds in an atypical fashion in ASD. In addition, frontal lobe connectivity is abnormal, with overconnectivity via short fiber connections but poor connectivity through long fibers, such as those connecting it to striatal structures (Courchesne & Pierce, 2005b; Lee et al., 2009). A number of studies have linked dysfunction of this circuitry to stereotypic and repetitive behaviors in ASD changes in activation patterns that involve frontal lobe and the frontal-striatal system (Philip et al., 2012). Shafritz, Dichter, Baranek, and Belger (2008), for example, noted that individuals with ASD

showed reduced activation in frontal, striatal, and parietal regions during performance on a task requiring shifts in cognitive set. The severity of repetitive or restricted behaviors in ASD was associated with decreased activation of anterior cingulate and posterior parietal regions. Anomalies of cingulate cortex have also been implicated in studies of response inhibition (Agam et al., 2010) and cognitive control (Solomon et al., 2014) in individuals with ASD. The connectivity between ACC and other components of the fronto-striatal network also appears to be compromised. Thakkar et al. (2008) found reduced integrity of white matter (indexed by fractional anisotropy on DTI) in the region of the anterior cingulate was associated with higher ratings of repetitive behavior.

Structures in the basal ganglia, particularly the caudate, have also been implicated in ASD. In a recent longitudinal study, Langen et al. (2014) observed that the volume of caudate nucleus in children (~9–12 years of age) with ASD increased at double the rate seen in the normal controls. The faster growth rate was correlated with more severe repetitive behaviors seen during their preschool years. Interestingly, Langen et al. (2014) speculated that this increased growth rate was a secondary consequence of the presence of repetitive and restricted behaviors, rather than related to some underlying causal factor.

Overall, these lines of evidence implicate dysfunction of the fronto-striato-thalamo-parietal network that is thought to be involved in aspects of self-regulatory behavior such as response monitoring, cognitive flexibility, inhibitory controls, and conflict detection (Solomon et al., 2014; Turner, 1999a; Verte, Geurts, Roeyers, Oosterlaan, & Sergeant, 2005). The central role that the cingulate and caudate appear to play in RRBIA remains to be more clearly specified. Both structures play key roles in attention, response selection, inhibition, and cognitive control, and both have also been consistently implicated in ADHD. Additionally, the anterior cingulate plays a special role in error detection. It forms part of a cortical limbic component to fronto-striatal circuitry, having connections to both lateral prefrontal and parietal cortex as well as the amygdala nucleus, accumbens, thalamus, and insula. It is therefore well-positioned to coordinate response monitoring and error detection with structures involved with in emotional responses and reward.

## Summary

Despite substantial research effort, the etiological basis and precise mechanisms that lead to autism remain incompletely understood. Risk factors appear to be multifactorial, involving complex interactions between environmental factors, genetic predispositions, epigenetic mechanisms, and other biological variables (Abrahams & Geschwind, 2008; Grafodatskaya, Chung, Szatmari, & Weksberg, 2010; Herbert, 2010). Figure 13.1 presents in schematic form the enormous complexities involved in teasing these various factors apart.

While many of the genes implicated in ASD may have fairly direct effects on neurodevelopment, others may influence risk for ASD through their role in increasing risk for disease states or conditions or through epigenetic pathways that can have neurodevelopmental implications.

As depicted in Figure 13.1, the final common pathway of the diverse risk factors—whether genetic, environmental, or epigenetic—is that they directly or indirectly affect neurodevelopment. Happé and Ronald (2008) have cogently argued that the symptom complex defining ASD is fractionable and that deficits in each domain (social communication, restricted activities and interests) are likely related to largely independent genetic influences. While some evidence supports this notion (Gotts et al., 2012), the majority of the genes currently implicated in risk for ASD have rather broad effects on neurodevelopment. It is possible that by virtue of their specific functional implications and timeline for expression, some may influence the behaviors associated with ASD more than others. However, none has effects that are specific to the manifestation of the cardinal features of the disorder, and it is likely that multiple variations of mutations can result in the complex behavioral constellations associated with ASD.

Genetic propensities may lay out biological constraints on behavioral potentialities, but it is through experience—through attending, perceiving, remembering and responding to sensory inputs—that infants ultimately learn to read emotions, decipher intentions, and understand and share interests with others. Impairments in the development of neuropsychological systems can be viewed as intermediary influences in the causal links between brain dysfunction and the overt behaviors that comprise the manifest disorder of ASD. How neuropsychological systems are affected and how this relates to the broader symptom complex associated with ASD remains to be fully detailed.

Evidence from a variety of sources has suggested that the developing brain may not possess the same degree of functional localization as the adult brain. Specifically, the immature brain is thought to be anatomically less differentiated and more interconnected (Neville, 2006), but becomes progressively modularized in its organization over the course of development (Johnson, 2001; Karmiloff-Smith, 2010). Given the highly dynamic and interactive processes underlying these changes, dysfunction emerging early in neurodevelopment can interfere with this modularization and differentiation process, with the result that additional brain regions may be recruited to subserve developing cognitive or behavioral processes. Early dysfunction can result in a cascading influence on subsequent growth and function. Disturbances of lower level structures and functions can impede the function of upstream structures and later developing processes. However, it is also plausible, given the interconnectivity and functional dependence of each component on exposure to appropriate experience, that dysfunction at higher level systems can also result in faulty development of downstream processes. Supporting the position cogently outlined by Brothers (1997) Franks (2010)

reinforces the assertion that “The functioning brain is social in the sense that any given brain is completely dependent on other brains for its development” (p. 39). A potential functional consequence of the less optimal organization stemming from early damage or dysfunction is that it can result in more generalized patterns of cognitive and behavioral impairment.

Overall, there is compelling evidence to suggest that several aspects of social and self-regulatory functions that normally emerge early in development are derailed in individuals with ASD. Our understanding of the development of these systems is currently rudimentary, and available data is often inconsistent, so the determination of precise causal pathways remains open for speculation. Such considerations provide a strong and continuing rationale to examine ASD from a neuropsychological standpoint and attempt to tease apart the various processing deficits that may underlie the problems observed in social communication and behavioral flexibility. A major area for future expansion of the field, both from a neuropsychological and neuroimaging viewpoint, will be to understand factors influencing brain development in the first two years of life and to further explore genetic-environmental interactions and their relation to identified anomalies in brain structure and function.

### Acknowledgements

We would like to thank Harry Zobel, Rachel Taormina, Ben Sargent, Maura Lunney, and Meredith Benner for their assistance in tracking down references and editing previous drafts. Harry Zobel also created the tables and flow chart, and Arianna K. Stefanatos proofread the entire manuscript and provided helpful suggestions. In addition, we are grateful to Temple University and the University of Connecticut for their support during its preparation.

# 14 Neurodevelopmental Disorders of Attention and Learning

## ADHD and LD Across the Life Span

*Jeanette Wasserstein, Gerry A. Stefanatos, Robert L. Mapou, Yitzchak Frank, and Josephine Elia*

### Introduction

Although learning disability (LD) and attention deficit/hyperactivity disorder (ADHD) are commonly intertwined in clinical presentation, their recognition as separate clinical entities followed rather distinctive historical paths. On one hand, the origins of the concept of LD are closely tied to notions of localization of cognitive function in the human brain that emerged in the late 19th century. Broca's (1861) association of circumscribed deficits in speech production to acquired damage of inferior frontal gyrus prompted speculation that specific language impairments in children may have a similar anatomic basis (Vaisse, 1866). While this was soon dispelled by Cotard (1868), the notion remained that some children demonstrated fairly specific cognitive impairments that may be based in dysfunction or maldevelopment of particular areas of the brain. On the other hand, problems related to ADHD, have a rather different and more varied conceptual history, originally having been considered a defect of moral control (Still, 1902), and then a disorder of excessive movement (hyperkinesis) (Laufer, Denhoff, & Solomons, 1957), before eventually being conceptualized as a neurodevelopmental disorder (ADHD) that particularly affected neural systems mediating attention (Douglas, 1972, Cantwell, 1983).

From a public health perspective, both LD and ADHD are among the most common neurobehavioral disorders of childhood (DHHS, 2003, Wallman, 2008). Educators have reported a rise in the number of children diagnosed with these disorders (Education, 2007) with concomitant increases in the number of children requiring special education services (Wagner, Kutash, Duchnowski, Epstein, & Sumi, 2005). Both disorders are associated with increased risk for a range of emotional, behavioral, and psychosocial issues (Murphy, Barkley, & Bush, 2002; Daniel, Walsh, et al., 2006; Goldston, Walsh, et al., 2007) and pediatricians have recorded increases in outpatient visits to address these related problems (Keller, McInerney, Gardner, Childs, & Wasserman, 2000). While the disorders emerge in childhood, associated difficulties often persist in some form into adulthood, resulting in occupational concerns ranging from performance issues and underemployment (Halmoy, Fasmer, et al., 2009; Barkley & Fischer, 2011) to increased injury risk (Breslin & Pole, 2009).

Long-term outcome can be significantly improved with continuing treatment and support, resulting in significant public health costs that often persist beyond childhood and adolescence (Schnoes, Reid, et al., 2006).

The high rate of comorbidity of these disorders has long been recognized both in clinical samples (Semrud-Clikeman et al., 1992) and in nonreferred samples recruited from the community (Fergusson & Horwood, 1992; Pastor & Reuben, 2008). The actual observed degree of overlap has varied broadly across studies. For example, the prevalence of LD in the ADHD population has reportedly ranged from a quarter or less (Pliszka, 1998), to two-thirds (e.g., Mayes, et al., 2000) or more (Semrud-Clikeman et al., 1992). According to a recent report by the Centers for Disease Control (Pastor & Reuben, 2008), approximately 5% of school-aged children in the United States are diagnosed with ADHD without LDs and approximately 5% have LDs without ADHD. An additional 4% are diagnosed with both conditions (i.e., roughly 30% comorbidity in this sample). All three groups require special education services, and are likely to have other health conditions and neurobehavioral dysfunction of varying degrees through much of the life span.

Numerous factors have been proposed to explain the comorbidity between these disorders, ranging from shared genetic and environmental risk factors (Fisher & DeFries, 2002, Gayan et al., 2005) and shared underlying processing deficits (e.g., Denckla, 1993, Seidman, Biederman, Monuteaux, Doyle, & Faraone, 2001) to interactions between the disorders whereby the existence of one disorder influences the diagnosis and course of the other (see Boada, Willcutt, & Pennington, 2012 for a review). Given the complex interweaving of these disorders, they are presented together in this chapter. We review the historical roots of conceptualization and nosological classifications of each disorder, their clinical presentations over the life span, current neuroscientific understanding, assessment highlights and emerging or controversial issues.

### *Historical Roots of LD and ADHD*

One of the first recognized accounts of LD was a description of a specific reading disorder published, in 1896, by the English pediatrician W. P. Morgan. He described a bright and intelligent 14-year-old boy who was quick with games

and intellectually no weaker than any of his peers (Morgan, 1896). His singular great difficulty was his inability to learn to read despite the utmost effort. Morgan referred to the disorder as “congenital word-blindness” because, in his view, the pattern of impairment resembled adult acquired cases of “word-blindness” or alexia that had been previously described by Kussmaul (1877) and others. Word blindness referred to loss of the ability to interpret written or printed language despite normal vision and the ability to see words and letters distinctly. It was thought to occur from acquired damage to the left angular gyrus, which functionally compromised a center for the processing of a construct termed *optic images of letters* (Dejerine, 1892).

Morgan’s report represented an attempt to utilize these concepts to explain congenital forms of reading impairment that he ascribed to defective development of that same region of the brain. Due to confusions arising from the term *word-blindness* (Broadbent, 1895), it was slowly replaced by *dyslexia* (Hinshelwood, 1896), which had been coined a decade earlier by the German ophthalmologist Rudolph Berlin (1887). Dyslexia came to refer to an inability to learn to read despite adequate vision, intelligence, motivation, and instruction. For many years, it was considered related to difficulty in the visual analysis and representation of written or printed symbols (Hinshelwood, 1917, Orton, 1925), although later research implicated subtle language-processing abnormalities as the major determinant (Myklebust & Johnson, 1962).

Over several decades, additional forms of LD affecting the acquisition of other academic and even social skills were eventually delineated. This includes dyscalculia (math LD) (Cohn, 1968; Kosci, 1974), dysgraphia (writing LD) (Ohare, Brown, & Aitken, 1991), and nonverbal LD (NVLD, primarily social LD) (Johnson, 1987; Rourke, 1989). More recently, clinicians have posited an LD based upon executive dysfunction, although this has not yet been recognized as a separate entity (see Wasserstein & Denckla, 2009 for review). Dyslexia remains the most common and best understood LD (see Frank, 2014 for review). Over time, the acronym *LD* has been transmuted to meaning *learning disorder* and/or *learning difference*. These terms are essentially synonymous, although the latter sometimes implies lesser degree of challenge or deficit.

The delineation of ADHD started earlier and followed a rather different history. Sir Alexander Crichton alluded to children with attention problems in a chapter entitled “On Attention and Its Diseases” (Crichton, 1798), in which he noted that such problems likely resulted from “an unnatural morbid sensibility of the nerves” that may be either “born with the person, or may be the effect of accidental diseases.” Heinrich Hoffman, a German physician, later depicted two characters—Zappel-Philipp (i.e., Fidgety Philip) and Hans Kuck-in-die-Luft (i.e., Hans Look-in-the-Air)—who demonstrated characteristics of ADHD in an illustrated children’s book of short moral fables entitled *Der Struwwelpeter* (1845).

Fidgety Philip demonstrated behaviors consistent with the impulsive/hyperkinetic subtype or presentation, while Hans demonstrated behaviors consistent with the inattentive presentation. The first scientific discussion of the disorder is often credited to Sir George Still, a British pediatrician who discussed similar children that he described as having “defect of moral control . . . without general impairment of intellect” (Still, 1902, p. 1079). While his portrayals spanned many types of disruptive behavior disorders, he placed particular emphasis on impulsivity and poor capacity for sustained attention, which he linked to possible brain damage. This correlation between early brain damage and subsequent behavior problems and/or learning difficulties was reified on a global scale by the encephalitis lethargica epidemic from 1917 to 1928 (Lange, et al., 2010)—surviving children often became hyperactive, distractible, and unmanageable in school (Hohman, 1922; Ebaugh, 1923).

In 1932 two German physicians, Franz Kramer and Hans Pollnow, coined the term *hyperkinetic disease* to denote children with probable brain damage who showed marked motor restlessness and many other currently recognized symptoms of ADHD. Subsequently, theoreticians like Strauss and Lehtinen (1947) collapsed the multiple cognitive and behavioral disorders seen in childhood into one entity, “minimal brain dysfunction” (MBD). The term carried the implication that brain damage existed in children who demonstrated these behaviors, even though it may not be detectable because of the fallibility of neurological examinations. However, the moderating role of environmental factors became apparent in observations that postencephalitic children who were successfully treated in special residential treatment centers commonly relapsed when they returned to maladjusted parents (Bond & Smith, 1935). As evidence accrued, it became apparent that the full spectrum of causality in cognitive and behavior disorders needed to consider multiple factors, including genetic influences, gestational and perinatal experiences, and the stresses and trauma of later life (Clements & Peters, 1962).

Such observations, along with recognition that brain dysfunction was in fact only being inferred (Kessler, 1980), shifted the emphasis away from a focus on structural brain damage (i.e., MBD) toward a focus on symptoms or behavior, such as excessive activity and inattention. The terms *hyperactivity* and/or *hyperkinesis* gained popularity in the 1960s when excess motor activity was emphasized (Chess, 1960; Laufer, Denhoff, & Solomons, 2011). Subsequently, the role of attention deficits was highlighted based on observations that these children performed poorly on laboratory measures of attention (Douglas, 1972; Douglas, 1976), and *attention deficit disorder (ADD)*, with or without hyperactivity emerged in the 1980s. Finally ADHD was adopted (Sommers, Fragapane, & Schmock, 1994), an acknowledgment of the diverse manifestations of disordered behavior (i.e., activity level vs. attention). Three possible subtypes were delineated: predominantly inattentive, predominantly hyperactive/impulsive,

and a combined subtype. These changes completed the segregation of this disorder from specific disorders of learning (i.e., LDs).

### *Changing Concepts and Nosology*

#### *ADHD*

The American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders* (DSM) initiated the first systematic effort to categorize and define the full gamut of behavioral disorders now associated with ADHD. In its second edition, DSM-II (APA, 1968), the disorder was termed *Hyperkinetic Reaction of Childhood* with the clear focus on the high levels of motor activity as the primary deficit. The third edition of the DSM, the DSM-III (APA, 1968) marked a turning point when it explicitly incorporated into the disorder's symptomology deficits of attention and impulse control, as well as the long-observed hyperactivity. Accordingly, the disorder was renamed *attention deficit disorder*, with two subtypes (with and without hyperactivity). The DSM-III also introduced the category of ADD-Residual Type, recognizing that some adolescents and adults outgrew hyperactivity yet still exhibited other symptoms of inattention and impulsivity without remission. While this category acknowledged that the condition could persist, in a partial form, into an older age group, there was still no recognized adult version of the full disorder. By regrouping symptoms into subtypes with and without hyperactivity, DSM-III (APA, 1980) made motor activity a secondary symptom of the disorder. DSM-III R (APA, 1987) then shifted to a global conception that unified the three core symptoms into a single entity (with one symptom list). The DSM-IV (APA, 2000) returned to a dichotomous conception of ADHD, and reframed it as a multidimensional spectrum disorder based on the primary symptom clusters of inattention and/or hyperactivity/impulsivity (i.e., predominantly hyperactive/impulsive type, predominantly inattentive type, and combined type). Interestingly, while acknowledging in the text that ADHD may be diagnosed in adults (e.g., "In . . . adults, symptoms of hyperactivity take the form of feelings of restlessness" (APA, 2000, p. 79) and "a minority experience the full complement of symptoms . . . into mid-adulthood" (p. 82), no formal anchors were established. Thus, the description and criteria remained oriented towards children and adolescents (ages 4–17 years) and offered few practical guidelines for diagnosing adults.

Criteria for ADHD in the most recent fifth edition of the DSM (APA, 2013) are very similar to those in the DSM-IV, except that ADHD in adults is now formally acknowledged and requires a lower number of symptoms (i.e., five symptoms from either the Inattention cluster or the Hyperactivity and Impulsivity cluster). While this new symptom threshold is less than the six symptoms required for children, it is still higher than the four symptoms suggested by the only two existing empirical studies of diagnostic thresholds for adults

(Barkley, 2010; Solanto, Wasserstein, Marks, & Mitchell, 2012). Another change is the use of "presentation" as opposed to "type" when referring to the predominant symptom cluster(s). This semantic shift recognizes the empirical reality that the primary areas of problem behaviors often change in the same individual over time. That is, the child who shows excessive hyperactive/impulsive or combined type symptoms can, and often does, become mainly inattentive as an adult.

#### *LD*

Samuel A. Kirk (1963), a clinical psychologist who is often regarded as the father of special education, introduced the term "learning disabilities" at a conference devoted to the problems of perceptually handicapped children. His statement captures the essence of a diagnosis by exclusion:

I have used the term 'learning disabilities' to describe a group of children who have disorders in development in language, speech, reading, and associated communication skills needed for social interaction. In this group I do not include children who have sensory handicaps such as blindness or deafness, because we have methods of managing and training the deaf and the blind. I also exclude from this group children who have generalized mental retardation.

(Kirk, 1963, p. 6)

His conceptualization had a significant impact on the field and on social policy. Subsequently a number of legal definitions of LD were created. The first federal definition was established in the late 1960s, and was later included in special education law in the well-known 1975 Education for All Handicapped Children Act (Public Law 94–142). Despite advancing research, this federal definition has remained essentially unchanged in the 1990 Individuals with Disabilities Education Act (IDEA, Public Law 101–476), and its 1997 and 2004 revisions. This definition is also widely used when developing individual education plans (IEPs) and 504 plans for children in public schools. It states:

Specific learning disability means a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, that may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations. The term includes such conditions as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. The term does not include children who have learning problems that are primarily the result of visual, hearing, or motor handicaps; of mental retardation; of emotional disturbance; or of environmental, cultural, or economic disadvantage.

(IDEA, 1990)

Unfortunately, this definition is not well operationalized, is not neuropsychologically based, and does not recognize the

persistence of LD into adulthood. The definition also lumps acquired neurological disorders (i.e., brain injury) together with developmental disorders, reflecting the initial focus of special education law on identification and service delivery for children with all types of cognitive disabilities. However, learning in adolescents and adults who developed normally but subsequently experience brain damage is likely different from that of those born with LD. Consequently, a number of other organizations took on the challenge of defining the disorder (disorders).

Following several revisions, the National Joint Committee on Learning Disabilities (1990) proposed another definition:

*Learning Disabilities* is a general term that refers to a heterogeneous group of disorders manifested by significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or mathematical abilities. These disorders are intrinsic to the individual and presumed to be due to central nervous system dysfunction, and may occur across the life span. Problems in self-regulatory behaviors, social perception, and social interaction may exist with the learning disabilities, but do not, by themselves, constitute a learning disability. Although learning disabilities may occur concomitantly with other disabilities (e.g., sensory impairment, mental retardation, serious emotional disturbance), or with extrinsic influences (such as cultural differences, insufficient or inappropriate instruction), they are not the result of those conditions or influences.

While recognizing that LDs persist across the life span and are brain-based, this definition excludes problems with self-regulatory behaviors, social perception, and social interaction. This is problematic for individuals with NVLDs, for whom difficulties with social perception and social interaction often define the disorder and lead to its initial identification (Tsatsanis & Rourke, 2008; Wasserstein, Vadhan, Barboza, & Stefanatos, 2008, but see and subsequent sections in this chapter for contrary views). It is also problematic for individuals who have disorders of executive functioning and self-regulatory behavior, but who do not meet strict diagnostic criteria for attention-deficit/hyperactivity disorder (Cutting & Denckla, 2003).

A third definition, oriented toward rehabilitation of adults with LDs, was established by the Rehabilitation Services Administration (RSA) in 1985, following their acceptance of learning disabilities as a medically recognized disability (Katz, Goldstein, & Beers, 2001):

A specific learning disability is a disorder in one or more of the central nervous system processes involved in perceiving, understanding, and/or using concepts through verbal (spoken or written) language or nonverbal means. This disorder manifests itself with a deficit in one or more of the following areas: attention, reasoning, processing, memory,

communication, reading, writing, spelling, calculation, coordination, social competence, and emotional maturity.

(Rehabilitation Services Administration, 1985, January 24)

From a neuropsychological standpoint, this definition is the best of the three. It is also better suited for adults. However, the definition is not widely known to many working in the LD field or used very often. The first two definitions, via IDEA and NJC, have been disseminated far more broadly.<sup>1</sup> Although definitions of specific LDs that are based on empirical research using specific criteria, i.e., evidence-based, would be desirable, there is just one close approximation, for dyslexia. It states:

Dyslexia is a specific learning disability that is neurobiological in origin. It is characterized by difficulties with accurate and/or fluent word recognition and by poor spelling and decoding abilities. These difficulties typically result from a deficit in the phonological component of language that is often unexpected in relation to other cognitive abilities and the provision of effective classroom instruction. Secondary consequences may include problems in reading comprehension and reduced reading experience that can impede growth of vocabulary and background knowledge.

(Lyon, Shaywitz, & Shaywitz, 2003)

Unfortunately, there are no evidence-based definitions of specific LDs in mathematics or written expression. Nonetheless, research has identified some core skills affected by these disorders (Fletcher, Lyon, Fuchs, & Barnes, 2007). These have been incorporated into the new DSM-5, wherein LDs are now classified as neurodevelopmental disorders. Key characteristics include the following (APA, 2013: 67):

- Symptoms must persist for six months, despite intervention.
- Academic skills are “substantially and quantifiably below those expected for the individual’s chronological age” and cause “significant interference” with academic, occupational, or everyday functioning.
- Difficulties are confirmed by “individually administered standardized achievement measures and comprehensive clinical assessment.”
- For individuals 17 or older, a documented history of impairing learning difficulties may be substituted for the standardized assessment.
- Onset is during school years, but effects may not become fully obvious until learning demands increase.
- Difficulties are not better accounted for by another disorder, lack of language proficiency, or inadequate instruction.

In contrast to the DSM-IV, there is only a single category for LD in DSM-5, specific learning disorder, with specifiers for the types of academic domains affected: reading, written expression, and/or mathematics. For each academic skill domain

there are subdomains that have been supported by research, although these subdomains are best established for reading disorders. Specific skill areas and their subdomains are shown below. Full diagnosis includes the level of severity of the specific LD (i.e., mild, moderate, and severe) and the subdomains affected.

**315.00 (F81.0) with impairment in reading:**

- Word reading accuracy
- Reading rate or fluency
- Reading comprehension

**315.2 (F81.81) with impairment in written expression:**

- Spelling accuracy
- Grammar and punctuation accuracy
- Clarity or organization of written expression

**315.1 (F81.2) with impairment in mathematics:**

- Number sense
- Memorization of arithmetic facts
- Accurate or fluent calculation
- Accurate math reasoning

Thus, the DSM-5 recognizes considerable differences in the presentation of the LDs. This allows identification and research in even more subcategories, with potentially different underlying neuropsychological deficits. For example, poor oral word reading may reflect the well-established phonemic processing deficit, or an oral dyspraxia, and/or even a subset of visual agnosia. However, in contrast to the DSM-IV, which included a category for unspecified LD, the DSM-5 restricts the Specific LD category to only academic skill deficits. As a result, people with what was called nonverbal/social/visual-perceptual LD (i.e., NVLD or NLD) may no longer meet criteria for any specific form of LD, despite having executive and other deficits that globally impede their academic and social learning (Wasserstein et al., 2008; Wasserstein & Denckla, 2009). Historically, the actual existence of LD had been operationalized by using defined statistical discrepancies between aptitude and achievement test scores, e.g.,  $-1.5$  SD or greater in DSM-IV (APA, 1994). More recently, however, some researchers argue the approach is not empirically supported (Fletcher et al., 2007; see Siegel and Smythe, 2008 for review). There is ongoing controversy on this issue, especially in identification of LD in the high-IQ individual. In such cases, most or all of the achievement scores may fall within normal ranges but well below expectations for aptitude. Arguably, reliance on the DSM V criteria of “a documented history of impairing learning difficulties” could be used.

### Clinical Profiles

Clinical profiles of ADHD and LD are complex and change over time, in part as a function of developmental demands (Mapou, 2009a) and successful remediation and/or learning. It is also emphasized that both ADHD and LDs are “continuum disorders,” that is, disorders that exist at the extremes

of the normal distribution (e.g., (Shaywitz, Escobar, et al., 1992). Thus many qualitative descriptions apply to most people to varying degrees. However, there is no consensus regarding where to draw the line regarding where “normal” ends and disorder begins. Opinions differ greatly (e.g., psychometrically defined 95th or 98th percentiles for age-cohorts, arbitrary symptom cutoffs applied across all most ages). Finally, while ADHD and LD clearly coexist, they are separate conditions that are often mistaken for each other and can be difficult to disentangle, both conceptually and clinically.

### *ADHD: Presentations and Possible Underlying Deficits*

ADHD is characterized by a pattern of persistent problems related to inattention and/or hyperactivity-impulsivity, which are more frequent and severe than typically seen in individuals at similar levels of development (i.e., age inappropriate). The behavioral manifestations are diverse and can include excessive motor activity (Kinsbourne, 1977; Halperin, Matier, Bedi, Sharma, & Newcorn, 1992); poor inhibitory control over behavior (Chelune, Ferguson, Koon, & Dickey, 1986; Barkley, 1997a, 1997b; Nigg, 2001); and difficulties focusing, sustaining, and shifting attention (Douglas, 1972; Levine et al., 1982; Seidel & Joschko, 1990; Epstein, Conners, Ehrhardt, March, & Swanson, 1997; Cepeda et al., 2000). The performance of individuals with ADHD is notoriously inconsistent and context dependent, suggesting that motivational factors and reinforcement contingencies are also important considerations in neuropsychological conceptualizations of the disorder (Sonuga-Barke & Coghill, 2014).

Symptoms of the disorder commonly emerge in the preschool years (Campbell, 1995; Connor, 2002) and often persist in altered form into adolescence and adulthood (Faraone, Biederman, & Friedman, 2000; Barkley, Fischer, Smallish, & Fletcher, 2002). The changes in the manifestations reflect mixed influences related to biological maturational changes, as well as successful application of self-applied or formal treatment interventions (Hechtman & Weiss, 1983; Wender, 1998). Hyperkinesis decreases most consistently while problems with inattention and executive function may persist or even become more apparent (e.g., Wolf & Wasserstein, 2001).

The exact prevalence of ADHD is difficult to specify. Depending on the criteria used for “abnormal” (e.g., above 95th to 98th percentile for same-age peers), ADHD would be expected to exist in about 2%–5% of the population. However, a recent (2011) Centers for Disease Control (CDC) survey found that roughly one in five male high school students and one in ten females had ever been given this diagnosis. These data argue that base rates during childhood range from 10% to 20%, depending on the child’s sex (i.e., boys twice as high as girls). Even allowing for the uncertainty regarding diagnostic criteria used, ADHD is clearly extremely common in children. Similarly, the exact prevalence of ADHD in adults is also unknown.

There is a continuing controversy around the persistence of ADHD into adulthood. It is estimated that 50%–75% of ADHD children will have significant symptoms by adolescence (Barkley, Fischer, et al., 2002) while anywhere from 4%–60% will still have significant symptoms during adulthood (Weiss, Hechtman, Milroy, & Perlman, 1985; Barkley, Fischer, et al., 2002). Conservative estimates now converge at around 50% persistence in clinical samples (Pary et al., 2002). From a different perspective, community studies place the adult prevalence rate between 4% and 5% (Murphy & Barkley, 1996; Heiligenstein, Conyers, Berns, & Miller, 1998). Combining clinical outcome data and epidemiological studies, the prevalence estimate would be between 2% and 4% of the general adult population (Pary et al., 2002). Notably, however, the standards used to define excessive levels of residual symptoms in these studies relied on criteria set for children aged 7–17. Since adults should be compared with adults, and not with children or teenagers, utilization of the existing child-oriented criteria may result in underestimation of base rates for adults.<sup>2</sup>

The gender ratio in children is approximately 4:1 in favor of males (Wolraich, Hannah, Pinnock, Baumgaertel, & Brown, 1996) but appears to be a more balanced 3:2 in adults (Biederman et al., 1994; Murphy & Tsuang, 1995). Thus, ADHD females may be underidentified during childhood, and/or the later higher ratio may indicate adult ADHD females are more inclined to pursue services (Wilens et al., 2002). Overall, gender differences in prevalence are confounded by gender biases in diagnostic criteria. Gender differences also vary according to ADHD type (see Stefanatos and Baron, 2007, for a fuller discussion of gender issues in the diagnosis of ADHD).

Disruptive behavior and poor school performance are the most typical referral reasons for children with ADHD. By contrast, many ADHD adults refer themselves for evaluation due to difficulties in day-to-day functioning, at home and/or at work, many of whom have not been diagnosed (Faraone, Spencer, Montano, & Biederman, 2004). Time management (e.g., not paying bills or filing taxes) and organizational problems (e.g., not finishing or tracking long-term projects, running a household) become especially more apparent during the teen years and adulthood. Many adults also self-refer after the diagnosis of a child or other family member triggers their own recognition of the symptoms (Faraone et al., 2004). In addition, they seek consultation after learning about the condition through the media, or when seeking accommodations in school or work settings (Wolf & Wasserstein, 2001). Some are referred by spouses or other medical professionals (Faraone et al., 2004). Irrespective of the referral source, adults with ADHD fall into two broad categories: those who were originally diagnosed as children and those who were never diagnosed. The first group often includes those who were hyperactive and/or oppositional as children. The second group may be more difficult to recognize and frequently show an inattentive presentation and/or variable levels of compensation skills.

ADHD is diagnosed when one or more of the three core symptoms lead to significant functional deficits at home, school, and/or work. Children with ADHD may be unable to sit through, or to focus on, classes or reading material. They may touch objects compulsively, make excessive noise while playing or studying, and otherwise be “disruptive.” Adults with ADHD may be unable to sit through a meeting or persevere on projects, and/or may be disorganized at work or in their homes. Sources of distraction for either age group can be external, like ambient noises or visual data, or internal, like thoughts. Although no one person shows all problems, individuals with ADHD, irrespective of age, often perform inconsistently or below expectations. It is emphasized that ADHD is seen at all intellectual and professional levels. Contrary to lay conceptions, having a JD, MD or PhD does not rule it out. The distinguishing feature is significant underperformance and/or underachievement relative to apparent aptitude and/or education. Such aptitude/achievement discrepancies can create a diagnostic quagmire around ADHD and the specific LDs, which contributes to the frequent conflation of these different and sometimes-discrete neurodevelopmental conditions. This ambiguity also sometimes makes it difficult to disentangle the two—ADHD or LD—in a given individual.

Approximately two-thirds (50%–70%) of ADHD individuals demonstrate academic learning difficulties (Barry, Lyman, & Klinger, 2002; Mayes et al., 2000). These problems reflect comorbid specific LD (e.g., dyslexia, dyscalculia, dysgraphia), the disruptive impact of core ADHD symptoms on learning, or both. Learning problems can appear as early as the preschool years when acquisition of preacademic skills can become disrupted by poor impulse control, motor overactivity, and difficulties attending to instruction (DuPaul, McGoey, Eckert, & VanBrakle, 2001; Barkley, Shelton, et al., 2002). Over time, deficiencies in attention (Aaron, Joshi, Palmer, Smith, & Kirby, 2002), working memory (Martinussen & Tannock, 2006), and executive function (Samuelsson et al., 2004; Miranda et al., 2006) play a greater role in academic performance and productivity, and detract from the child’s ability to benefit from explicit learning experiences. These factors ultimately can also have a subtle impact on general intellectual development and acquisition of early reading and listening comprehension skills. In fact, difficulty with basic prereading and arithmetic skills are often evident during the first school year (Mariani & Barkley, 1997). By late childhood (~11 years), as many as 80% of children with ADHD have fallen behind grade level in one or several of these areas (Baker & Cantwell, 1992). Dysgraphia is also common, particularly among children with ADHD combined presentation (Marcotte & Stern, 1997).

Compared to controls, adults with ADHD are more likely to have dropped out of school, received below average grades, and/or performed below their potential. Such academic deficits certainly explain the well-documented lower occupational status of probands compared to controls

(Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1993). Retrospective studies of scholastic dysfunction are consistent with the prospective studies discussed earlier. These show that adults with ADHD have a greater lifetime prevalence of academic remediation, grade repetition, and special education placement (Biederman et al., 1993). Murphy and Barkley (1996) and others (Crozier et al., 1999) also found that, relative to controls, clinic-referred adults with ADHD had more academic underachievement with higher rates of subsequent occupational impairment.

A number of different etiological models have been proposed regarding the core deficits underlying ADHD (see Swanson et al., 2007). Most frequently emphasized are various aspects of executive dysfunction, including impaired inhibitory control (Barkley, 1997a, 1997b) and impaired executive working memory (Rappaport, VanVoorhis, Tzelepis, Friedman, 2001). Somewhat paradoxically, Halperin and Schulz (2006) focus on the role of intact executive functioning in compensating for a proposed core subcortical dysfunction in arousal. See Table 14.1 for a summary of the principal current models and their associated seminal papers. As can be seen, there is as yet no clear consensus, and details of the debates are beyond the scope of this chapter. This literature is extensive and interested readers may want to consult relevant books and review articles (e.g., Solanto, 2011; Barkley, 2012).

### *Common Types of Comorbidity in ADHD*

#### PSYCHIATRIC DISORDERS

While the symptoms of ADHD decline with increasing age, the probability of having a comorbid psychiatric diagnosis increases (Biederman, Mick, & Faraone, 2000). By adulthood, only 13% of individuals with ADHD are free of comorbid diagnosis (McGough et al., 2005). Moreover, ADHD adults and children differ in their comorbidity patterns. Children more consistently show acting-out behaviors and learning issues, while adults more commonly show mood and anxiety disorders, in addition to well-known tendencies for substance use and antisocial behavior. Considerable variability has also been reported with regard to psychiatric comorbidity rates in adults, likely reflecting use of prospective versus retrospective/cross-sectional designs, as well as other methodological differences between studies. That is, retrospective and cross-sectional studies typically report higher rates of diagnostic overlap, because participants are on average ten years older than those in longitudinal studies and have had greater opportunity to receive a psychiatric diagnosis. Their elevated rates of reported psychiatric comorbidity may further reflect a referral bias whereby patients who sought psychiatric services may distort (typically inflate) their level of impairment.

There are a number of explanations for the high rates of psychiatric comorbidity among ADHD individuals (Marks, Newcorn, & Halperin, 2001). Some researchers suggest that comorbidities reflect similar genetic and/or environmental

underpinnings. For example, Biederman and colleagues have repeatedly shown elevated rates for psychiatric diagnoses in the first-degree relatives of ADHD probands, including antisocial behavior (Faraone & Biederman, 1997), mood (Biederman, Newcorn, & Sprich, 1991; Faraone & Biederman, 1997), and anxiety (Biederman et al., 1992) disorders. Others argue that comorbid disorders might constitute the psychiatric sequelae of living with ADHD (see discussion in Marks et al., 2001). Still others have intimated that the syndromes might be linked such that ADHD might be seen as a risk factor or developmental precursor for subsequent externalizing behaviors (e.g., Faraone & Biederman, 1997; Caron & Rutter, 1991).

Taken together, such findings are consistent with both the psychological impact of lifelong struggles, as well as structural or genetic overlap with other psychiatric disorders. Biological and environmental factors during development also play a role (see reviews by Swanson et al., 2007). Relative to their childhood counterparts, adults with ADHD have more mature brains, but also have endured a longer period of psychosocial stressors (e.g., protracted academic underachievement, increased rates of divorce, occupational instability, etc.). Behaviors that were viewed as developmentally appropriate during childhood may have become increasingly maladaptive over time (e.g., task avoidance, dependence on others to provide structure). Accordingly, when considering comorbidities in ADHD across the life span, one must consider the developmental and environmental context. Wasserstein and Stefanatos (2016) have posited that the high frequency of comorbidities, as well as their variability, may reflect structural or functional abnormalities (or disruptions) in different regions (and levels) of frontal corticostriatal pathways. This perspective builds on the work of Cummings (1993) who argued for a pivotal role of these pathways in many forms of psychopathology. While reductionist, this perspective may be worth keeping in mind. The following sections review the more common comorbidities.

#### ANTISOCIAL BEHAVIOR AND SUBSTANCE USE

In their 15-year prospective investigation of hyperactive children, Weiss and colleagues (1985) found that antisocial personality disorder was approximately ten times more common among young ADHD adults (23%) relative to controls (2.4%). In two independent longitudinal investigations, Mannuzza et al. (1993, 1998), also found elevated rates of adult antisocial behavior in formerly ADHD children without comorbid conduct disorder. One study (Mannuzza et al., 1993) closely approximated the elevated (i.e., nearly ten-times higher risk profile) found by Weiss et al. (1985), and the second (Mannuzza et al., 1998) documented a fourfold increase in antisocial behavior relative to age-matched controls. Among adult probands, Satterfield and Schell (1997) observed a 21-fold increase in rates of felony offenses and a significantly higher rate of incarceration (12% of probands vs. 0% of controls). Murphy and Barkley (Crozier et al.,

Table 14.1 ADHD etiological models with testable predictions regarding neurocognitive training

<i>Model</i>	<i>Model description of ADHD</i>	<i>Probable Neurocognitive Intervention Targets</i>	<i>Representative publications</i>
Attentional Lapse Models	Models vary from DSM-5 Clinical Model (core attention deficit in ADHD) to attention deficits attributable to alternate processes/mechanisms.	One or more attention processes	Leth-Steensen, Elbaz, and Douglas (2000)
Behavioral Inhibition Model	A core deficit model wherein deficits in behavioral inhibition (stopping pre-potent/ongoing responses and interference control) result in four areas of executive dysfunction that collectively result in ADHD behavioral symptoms.	Behavioral inhibition	Barkley (1997a, 1997b)
Cognitive Neuroenergetic/State Regulation Deficit Model	Decreased ATP production and inadequate lactate supply from deficient astrocyte functioning cause depletions in energetic resources associated with activation and effort. These depletions result in performance variability, which in turn impacts performance on executive functioning tasks. Executive functions interact with primary impairments in effort and activation via both top-down and bottom-up processes to result in the behavioral features of ADHD.	Response variability; information processing efficiency; attention; inhibition, due to association with energetic dysfunction; activation and/or effort	Russell et al. (2006, 2014); Sergeant (2005)
Default Mode Network Model	A multiple pathway model that hypothesizes that disruptions in cortico-striato-thalamo-cortical neuroanatomical circuitry—consisting of “hot” and “cool” regions—contribute to functional behavioral and cognitive differences in ADHD. Rhythmic, periodic interruption of resting state (“default mode”) brain waves into task-positive networks during task engagement result in ADHD inattentive behavior.	Unclear; response variability?	Castellanos et al. (2005); Castellanos and Tannock (2002); Sonuga-Barke and Castellanos (2007)
Dynamic Developmental Model	A core deficit model that hypothesizes that reduced dopaminergic functioning causes narrower reinforcement gradients and altered extinction processes in normal behavior-consequence relationships. These deficient dual processes contribute to core ADHD symptoms and behavioral variability, which vary based on context, task, and function. Executive dysfunction, particularly disinhibition, is viewed as an outcome of these altered reinforcement and extinction processes.	Unclear; training to widen reinforcement gradients?	Sagvolden, Johansen, Aase, and Russell (2005)
Subcortical Deficit Model	A developmental model that hypothesizes that ADHD is caused by subcortical neural dysfunction that manifests early in ontogeny, remains relatively static throughout life, and is not associated with the remission of symptomatology. Executive dysfunction does not cause ADHD symptoms, but developmental growth in executive functions facilitates recovery.	Working memory manipulation. Note: Expected to benefit only patients with major allele homozygosity in two DRD1 polymorphisms; may be more beneficial later in development.	Halperin and Schulz (2006)
Tripartite Pathway Model	A multiple pathway/equifinality model in which ADHD symptoms are caused by deficits in one or more dissociable cognitive (behavioral inhibition, temporal processing) and/or motivational (delay aversion) processes.	Behavioral inhibition, temporal processing, and/or delay aversion dependent on patient’s particular pattern of impairments	Sonuga-Barke et al. (2010)
Working Memory Model	A core deficit model that views inattention, hyperactivity, and impulsivity as phenotypic/behavioral expressions of the interaction between neurobiological vulnerability and environmental demands that overwhelm these children’s impaired working memory. Associated features of ADHD arise through direct effects of impaired working memory, or indirect effects of impaired working memory through its impact on core behavioral symptoms.	Central executive (CE) and working memory (WM; i.e., updating, dual-task/ manipulation, serial reordering). Note: Expected to benefit ~80% of children with ADHD with CE WM deficits.	Rapport, Chung, Shore, and Isaacs (2001); Rapport et al., 2008) Rapport, Orban, Kofler, and Friedman (2013)

Reprinted from Chacko, Kofler, and Jarrett (2014).

1999) found that adults with ADHD were 17 times more likely than controls to have received a lifetime diagnosis of conduct disorder (CD), and five times more likely to have received a diagnosis of oppositional defiant disorder (ODD). Nevertheless, from a clinical perspective, in our experience as practitioners, most ADHD adults seen in outpatient practice do not share this outcome.

It is unclear how much the persistence of ADHD symptoms into adolescence or adulthood is a risk factor for substance abuse. Results of scientific studies have varied with methodological technique. A retrospective study reported alcohol abuse to be two to three times greater among ADHD adults than among controls (Shekim et al., 1990). By contrast, neither of the longitudinal studies conducted thus far has found differences in rate of alcohol abuse between probands and controls (Hechtman & Weiss, 1986; Mannuzza et al., 1993; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1998). However, studies consistently find that ADHD adults are more than twice as likely to meet criteria for tobacco dependence (Lambert & Hartsough, 1998), and two to four times as likely to have a lifetime history of non-alcohol-related substance use (Mannuzza et al., 1993; Biederman et al., 1995; Mannuzza et al., 1998). Encouraging data suggest that effective psychopharmacological treatment of ADHD may mitigate this increased risk for substance-use disorders (Wilens, Faraone, et al., 2003).

#### MOOD AND ANXIETY DISORDERS

In all age groups, the overlap between many symptoms of ADHD and affective disorders complicates differential diagnosis for both conditions (Marks et al., 2001). For example, unrecognized (and thus untreated) ADHD was associated with "treatment failure" in adults originally diagnosed with depression (Ratey, Greenberg, Bemporad, & Lindem, 1992). Yet empirical findings are inconsistent. Prospective investigations of ADHD have not found group differences in lifetime rates of mood disorders (Mannuzza et al., 1998; Weiss et al., 1985), while cross-sectional and retrospective studies have found higher rates of comorbidity. For example, Biederman and colleagues reported that 31% of probands versus 5% of adult controls met criteria for major depression (Biederman et al., 1993). These differences in rates of mood disorders may reflect sampling differences. That is, the longitudinal studies disproportionately included children with acting out behaviors, while the cross sectional studies disproportionately included adults seeking help because of a lifetime of struggles.

Murphy et al. (2002) found that, relative to controls, young adults with ADHD had significantly higher rates of dysthymia. Thus, as noted previously, ADHD can be both difficult to differentiate from mood disorder and/or they may coexist.

#### PERSONALITY DISORDERS

Enduring ADHD symptoms, and their psychosocial impact, are associated with maladaptive personality traits. Fisher and

colleagues (2002) measured the prevalence of DSM-IV Axis II disorders as part of their prospective follow-up of hyperactive children. Compared to community controls, more ADHD adult probands met criteria for passive-aggressive (18%), borderline (14%), and histrionic (12%) personality disorders. Notably, however, these elevations in risk are explained mostly by the presence of child conduct problems and adolescent conduct disorder rather than ADHD per se. Addressing this confound, May and Bos (2000) compared the prevalence of Axis II personality disorders in a cohort of adults classified by the persistence of ODD or other (unspecified) comorbid diagnoses. According to these investigators, ADHD-only adults evinced mild histrionic traits, while ADHD-comorbid participants displayed predominantly avoidant and dependent characteristics. In particular, ADHD-ODD adults exhibited histrionic, narcissistic, aggressive-sadistic, and negativistic qualities, while the ADHD-ODD-comorbid group demonstrated avoidant, narcissistic, antisocial, aggressive-sadistic, negativistic, and self-defeating personality features. It may therefore be the case that comorbid psychiatric phenomena may aggregate in an additive fashion to increase the risk of maladaptive characterological features in ADHD.

From a psychodynamic perspective, Bemporad (2001, p 306) proposed that core symptoms of ADHD lead to development of "characteristic defensive operations" that are built upon neurologically based tendencies. Thus, for example, hyperactive impulsive traits may predispose to "apparent neglect of feelings or intensions of others," and both "their tendency to escape into action" and inattention enable "systematic denial . . . by diverting their attention to less threatening subjects or activities." By extension, such "characteristic defensive operations" could be argued to underlie narcissism and hysteria, respectively. While not fully developed, this approach provides interesting alternative formulations for personality disorder in ADHD. That is, some neurological tendencies due to ADHD may predispose to the development of certain personality pathologies.

#### LANGUAGE DISORDERS AND AUTISM

ADHD co-occurs with numerous other neurodevelopmental disorders in addition to the specific LDs (see Stefanatos & Baron, 2007). Of these, speech and language disorders are particularly common in children diagnosed with ADHD (Baker & Cantwell, 1992; Baird et al., 2000; Cohen, Vallance, et al., 2000; Bruce, Thernlund, & Nettelbladt, 2006). Some clinical samples find that 40%–64% have speech and language difficulties of sufficient magnitude to require evaluation and/or therapeutic intervention (Taylor, Sandberg, Thorley, & Giles, 1991; Humphries, Koltun, Malone, & Roberts, 1994). Since children with speech and language disorders also have higher-than-expected prevalence of ADHD (30%–58%) some regard this as a two-way comorbidity (e.g., Tannock & Brown, 2000).

A percentage of children with or without concomitant language problems demonstrate particular difficulty

understanding what they hear despite normal hearing sensitivity. Problems may be particularly apparent when material is unfamiliar or if it is presented in a noisy or distracting environment, such as a classroom. If comprehension problems become apparent during school, children may be referred to an audiologist to determine if they have a hearing problem or central auditory processing disorder (CAPD; see Riccio, Hynd, Cohen, Hall, & Molt, 1994; Gomez & Condon, 1999; Breier, Gray, Klaas, Fletcher, & Foorman, 2002). CAPD is thought to arise when central neural processes underlying the analysis of auditory information by the brain are functionally compromised. The disorder encompasses deficits in one or more of the following auditory behaviors: sound localization and lateralization, auditory discrimination, auditory pattern recognition, and auditory temporal processing (e.g., resolution, integration). Although recognized for more than 50 years, there is poor agreement on when a CAPD diagnosis should be made and on its significance. The clinical presentation of CAPD includes a variety of symptoms that overlap with ADHD, including poor concentration, distractibility, fidgetiness, and poor academic achievement (Stefanatos & DeMarco, 2012). Consequently, a child diagnosed with ADHD by a physician or mental health provider may possibly have received a diagnosis of CAPD if first seen by an audiologist or speech/language pathologist. The relative presence of ADHD and/or CAPD is not clear, in part because each exists in different nosology systems. In short, ADHD and CAPD may be different conditions that are sometimes comorbid, or the same condition assessed by different disciplines.

ADHD is also very common in children with autism spectrum disorder (ASD). While DSM-IV did not permit comorbid diagnosis of ADHD and ASD, 30%–50% of children diagnosed with ASD demonstrated symptoms consistent with ADHD (Lee & Ousley, 2006; Leyfer et al., 2006; Simonoff et al., 2013; Mannion & Leader, 2014). In addition, studies have shown that as much as 20% with a diagnosis of ADHD demonstrate symptomology associated with ASD (e.g., Clark, Feehan, et al., 1999). A more recent study examining this relationship found that when mothers had a diagnosis of ADHD, their first-born offspring were at increased risk of ADHD alone (sixfold increase) or ASD alone (2.5-fold increase). Given the high rate of comorbidity and the fact that both disorders are highly heritable, it has been suggested that both disorders may share some familial transmission and including genetic risk factors (van der Meer et al., 2012) and partially overlapping diathesis (Musser et al., 2014). Both disorders are highly represented in populations of institutionalized children, perhaps pointing to a contribution of experience (Nelson, 2015). Regardless of these complex issues, the DSM-5 now recognizes that the two conditions can coexist.

#### GENETIC DISORDERS

ADHD is commonly diagnosed in several genetic disorders, including Klinefelter syndrome (Ross et al., 2008),

Turner syndrome (Zinn et al., 2007), neurofibromatosis, tuberous sclerosis, Fragile X, and Williams syndrome (Lo-Castro, D'Agati, & Curatolo, 2011; Cederlof et al., 2014). A recent study indicated that ADHD was the most frequent disorder in children (37.10%) with chromosome 22q11.2 deletion syndrome (Schneider et al., 2014), a neurogenetic disorder that occurs in one of 2,000–4,000 live births and is commonly also referred to as *DiGeorge syndrome* or *velocardiofacial syndrome*. The neurocognitive profile in these children generally includes low average to deficient intelligence, learning difficulties, motor delay, and attention/executive problems. This syndrome has emerged as a genetic model for the development of schizophrenia, given that 23%–43% of individuals with a schizophrenia spectrum disorder demonstrate the deletion (Monks et al., 2014). However, the study of this condition also has implications for understanding the ADHD behavioral phenotype. The deletion in chromosome 22 leaves only one copy of about 60 genes, among them COMT, a gene that codes an enzyme that participates in the inactivation of catecholamines such as dopamine. Interestingly, this enzyme particularly affects dopamine metabolism in prefrontal cortex and has significant effects on executive function and working memory (Magalona et al., 2013). Individuals with 22q11.2 deletion syndrome have only a single allele (Val or Met) whereas normal individuals have two alleles (Val/Val, Met/Met, or Val/Met). The Met variant has significantly lower COMT activity, presumably resulting in slower degradation of dopamine in the synapse. Carriers of a single Val allele perform worse on measures of intelligence and executive control (Carmel et al., 2014).

#### MOTOR DISORDERS

Among the neurodevelopmental disorders, motor and tic disorders have among the highest rates of comorbidity with ADHD. Approximately half of children diagnosed with a tic disorder also meet criteria for ADHD (Kurlan et al., 2002). Conversely, approximately 20% of children with ADHD are also diagnosed with a tic disorder (Kadesjo & Gillberg, 2001; Robertson, 2006). Both disorders appear to be related to diminished dopaminergic function that fails to modulate amino acid-based signal transmission (primarily glutamate in GABA). This particularly affects the nigrostriatal dopamine branch, which is involved in modulating motor function and also plays a role in mediating aspects of impulse control, procedural learning, and working memory (Sagvolden et al., 2005). While these conditions appear to share some common neurobiological correlates such as reduced volume of caudate nuclei and corpus callosum (Hynd et al., 1991; Giedd et al., 1996; Plessen et al., 2006), there also appear to be neuroimaging findings that differ between these entities. For example, children who demonstrate ADHD show reduced volumes in prefrontal cortex only (Castellanos, Giedd, et al., 2001), while children with Tourette Syndrome and Tourette

Syndrome+ADHD show larger dorsal prefrontal volume (Peterson et al., 2001).

Motor problems and neurological soft signs have long been associated with ADHD. Several studies have reported that as many as 50% of children diagnosed with developmental coordination disorder (DCD) demonstrate comorbid ADHD (Gillberg, 2003; Watenberg, Waiserberg, Zuk, & Lerman-Sagie, 2007). Aside from sharing some motor symptoms, there is significant overlap in cognitive symptoms. Children with DCD have difficulties performing a variety of visuospatial processing tasks that do not have a motor component (Wilson & McKenzie, 1998), suggesting that visuospatial processing deficits are closely associated with DCD and exist independent of the contribution of motor deficits. Similar visuospatial difficulties can be observed in a subgroup of children with ADHD (Voeller & Heilman, 1988; Stefanatos & Wasserstein, 2001; Dobler et al., 2005; Kalanthroff, Naparstek, & Henik, 2013; Jung, Woo, Kang, Choi, & Kim, 2014). These findings have implicated right-hemisphere pathophysiology in ADHD and this has been supported by numerous structural (Semrud-Clikeman et al., 2000) and functional neuroimaging studies (Overmeyer et al., 2001; Courvoisie, Hooper, Fine, Kwok, & Castillo, 2004; Rubia, Halari, et al., 2009). Very few neuroimaging investigations have been conducted in children with DCD independent of a comorbid ADHD. However, a recent study examining functional connectivity in a small group of children with DCD found similar neurophysiological anomalies to those observed in children with ADHD in children with both DCD and ADHD (McLeod, Langevin, Goodyear, & Dewey, 2014). Some studies have suggested that they may share genetic etiology (Martin, Piek, & Hay, 2006).

#### SEIZURE DISORDERS

Children with epilepsy have increased risk of comorbid ADHD, with approximately 12%–17% receiving the diagnosis (Davies, Heyman, & Goodman, 2003; Reilly, 2011). In tertiary care centers, however, ADHD is even more common, affecting approximately one-third of preschoolers and almost two-thirds of school-aged children with epilepsy (Thome-Souza et al., 2004). Although in most cases the diagnosis of epilepsy precedes the diagnosis of ADHD, in some cases ADHD symptoms predate the onset of epilepsy. Children with epilepsy are most likely to receive a diagnosis of the predominantly inattentive subtype of ADHD, followed by the hyperactive impulsive subtype (McDermott, Mani, & Krishnaswami, 1995; Williams, Griebel, Dykman, 1998). Attentional problems have often been attributed to the seizure disorder or to its treatment. However, a history of attention problems is twice as common in children seen after their first seizure compared to controls (Austin et al., 2001; Hesdorffer et al., 2004), suggesting that a common antecedent may exist for both conditions.

#### LD: Presentations and Possible Underlying Deficits

Presentations of the specific LDs vary with the type of LD, stage in life, and level of remediation. Each type of LD can occur alone or in combination with other types, or with comorbidities, especially ADHD (e.g., Greven, Kovas, et al., 2014).

Delays in meeting early developmental milestones can be risk signs for future LD. Language delays are particularly noteworthy indicators for potential dyslexia (Chilosi et al., 2009; Nash et al., 2013), while difficulty with visual-motor tasks such as scribbling and puzzle assembly may indicate risk for nonverbal/spatial deficits seen in dyscalculia and/or NVLD (Rourke, 1993). By definition, school-age children with LD have difficulty learning basic skills out of proportion to their age-peers and/or intellectual endowment. For dyslexic children this may be seen in slow acquisition of letter names and/or letter sounds, look-say vocabulary, and later in spelling. For children with dyscalculia this may be seen in slow acquisition of number facts, such as automatic recall of single-digit addition or memorizing the times tables. Later, children with dyscalculia may have struggles learning/recalling math operations and/or appreciation of quantity and spatial relations. Difficulties with word problems can be seen with either dyslexia and/or dyscalculia. School-age children with LD may also show behavioral signs of underlying academic distress in the form of avoidance, withdrawal, and/or disruptive behavior. In addition, they tend to be less well liked by peers, because of frank deficits in social processing (as seen in NVLD) and/or because of linguistic processing deficits (i.e., pragmatic dysfunction), either of which make it difficult for the child to participate in reciprocal relationships. All of these problems translate into high likelihood of low self-esteem, as well as many other forms of psychological comorbidity (both internalizing and externalizing). Similar to children with ADHD, the later presumably reflects reactions to their struggles as well as to underlying structural overlap between syndromes.

Having LD can have negative impact throughout adulthood. For example, Witte, Philips, and Kakelaet al. (1998) reported that college graduates with LD reported less satisfaction with pay, promotional opportunities, and their job overall, in addition to educational impact, such as taking longer to graduate and lower college GPA. Many other studies have found that adults with LD are at increased risk for psychosocial difficulties (e.g., Gregg, Hoy, King, Moreland, & Jagota, 1992; Hooper & Olley, 1996; Hoy & Manglitz, 1996; Vogel & Forness, 1992; Katz et al., 2001). This was the case for both those with NVLD, which is commonly associated with difficulty processing emotional information (Ahmad, Rourke, & Drummond, 2002; Cleaver & Whitman, 1998), as well as for those with other types of LD. Notably, while NVLD has been associated with pronounced psychosocial dysfunction, a more recent naturalistic study reported wide and varied outcomes (Wasserstein et al., 2008).

Anecdotally, the authors of this chapter have found that once LD children reach adulthood, many will have reached a functional level in basic academic skills. Most can learn, albeit laboriously and to varying levels of proficiency: i.e., they have “disabilities,” not inabilities. Nevertheless, qualitative (e.g., slow fluency) and even quantitative (i.e., both normative and ipsative) deficits can remain. Thus, LDs in adults may be subtle and implied, rather than overt and obvious.

### *Dyslexia and/or Reading Disorders*

Dyslexia is the prototypical form of LD and is the most common type. It usually manifests in slow and inaccurate single word recognition, despite adequate intelligence and instruction, and the absence of gross sensory or motor problems. While characterized by inordinate difficulties with accurate or fluent word decoding, spelling is commonly also affected and often to a similar degree. Different types of dyslexia have been proposed, including dysphonetic, dyseidetic, neglect, and semantic forms (i.e., phonological, visual, attentional, and comprehension basis, respectively). Hulme and Snowling (2013) provide a review of current thinking about dyslexia and its underlying cognitive deficits, which can subsume most types. Briefly, reading is argued to develop via a “triangle model” composed of interactions between orthography, phonology, and semantics. *Orthography* refers to writing systems and their codes (i.e., spelling and other rules of written language). *Phonology* refers to the fundamental elements of the linguistic system or smallest units of sound, phonemes. *Semantics* refers to meaning in whatever form. In alphabetic orthography systems, such as English, auditory phonemes are represented by visual graphemes (i.e., the smallest units in written language, or letters). In learning to decode words, a reader has to initially segment the word into its underlying auditory elements, the phonemes (i.e., units of sound), or fundamental elements of the linguistic system. In written material the phonemes have been translated into graphemes, reflecting direct connections between phonological and orthographic codes (Plaut, McClelland, Seidenberg, & Patterson, 1996). Semantic representations, the third leg of the triangle model of reading, are thought to activate a word’s meaning and pronunciation, and ultimately contribute to understanding as well as to decoding in context.

Given the diversity of deficits found in the neuropsychological profiles of reading impaired patients, the implications of the triangle model of reading are compelling. Logically, disturbances in any of the three legs could lead to a reading disorder that is not necessarily based on deficits in phonetic processing. For example, visual and attention dysfunction could disrupt the orthography unit of reading skill acquisition, while receptive language disorders could disrupt the semantic leg. Notably, early classification of reading disorders separated children into those who could not read due to difficulties with word sounds (dysphonetic) and those who

had difficulties with visual processing of words (dyseidetic) (see Greenblatt & Greenblatt, 1997 for discussion). Thus, dysfunction in processing of orthographic information (due to visual-perceptual, attentional, and/or nonverbal memory dysfunction) could also lead to dysfluent single-word decoding, as was originally described for dyseidetic dyslexia. Dysfunction in the semantic leg of the triangle model could lead to deficits in reading comprehension rather than word decoding. The latter would create a type of reading disability comprised of individuals who show accurate phonological decoding, but poor understanding of material that is read. Some researchers reserve the term *dyslexia* solely for individuals with phonological reading disorders. Thus poor readers who do not have phonetic processing deficits may not be regarded as having dyslexia, but may still be diagnosed with a “reading disability.” Others use the terms *dyslexia* and *reading disability* interchangeably, thereby implicitly accepting a more complicated model of reading and component abilities.

Despite such ambiguity, abnormal phonetic awareness and processing has been found in the majority of studies of reading disabled children (e.g., de Gelder & Vrooman, 1996; Elbro, 1998; Katz et al., 2001; Birch & Chase, 2004), in line with the emphasis on phonology in the triangle model. Such deficits have also been found cross-culturally (e.g., Paulesu et al., 2001). For example, Birch and Chase (2004) found that adults with stronger phonological skills were better readers, while better orthographic skills did not predict better reading. There also does not appear to be a pure orthographic deficit group in adults (e.g., Osmon, Braun, & Plambeck, 2005). Consequently, a reading disorder is currently thought to usually reflect inadequate processing/representation of phonemic units, resulting in a difficulty with single word decoding in reading, writing, and spelling. To the extent that word recognition in dyslexia is slow and labored, comprehension can also be affected, although typically this is more intact. Nevertheless, multiple neuropsychological deficits have been associated with reading dysfunction; a review of these follows.

One of the first neuropsychological deficits found to be predictive of dyslexia was a weak ability to rapidly name objects, colors, letters, and/or numbers, which is referred to as rapid automatic naming (RAN). Originally developed and reported by Denckla and Rudel (1976), they characterized RAN as a “deficit in the automatization of verbal responses to visual stimuli, not restricted to symbols.” Subsequently RAN was found to be one of the best predictors of later reading achievement in children with and without reading disabilities, independent of their level of phonemic awareness (e.g., Blachman, 1984; Scarborough, 1998; Manis, Seidenberg, & Doi, 1999) and dissociated from ADHD (e.g., Semrud-Clikeman, Guy, et al., 2000). The basis for this predictive ability for reading skill acquisition is not yet understood, although it has been suggested that RAN tasks assess speed of linguistic processing rather than

general processing speed (Neuhaus, Foorman, Francis, & Carlson, 2001). The possibility of a double-deficit in RAN, as well as in phonological awareness, has been proposed, and is supported to some degree (Birch & Chase, 2004; Vukovic, Wilson, & Nash, 2004; Cirino, Israelian, Morris, & Morris, 2005). For example, Laasonen and colleagues (Laasonen, Lehtinen, Leppämäki, Tani, & Hokkanen, 2010), in a study of Finnish dyslexic adults, reported deficits in phonological awareness and phonological memory, as well as deficits in rapid naming. They also had deficits in arithmetic accuracy, showing the co-occurrence of math and reading problems often found in children with dyslexia. In any case, RAN clearly taps into a key component of fluent reading, which deserves further understanding and research.

Broader problems in auditory-verbal attention, working memory, vocabulary, spoken language comprehension, and general knowledge are also frequent in people with reading disabilities (Isaki & Plante, 1997; Katz et al., 2001; Ransby & Swanson, 2003; Birch & Chase, 2004; Braze, Tabor, Shankweiler, & Mencl, 2007). Furthermore, phonological awareness may be more important for reading acquisition than for reading comprehension, where language skills and general knowledge may make a more important contribution. For example, in the Laasonen et al. (2010) study, controlling for IQ enhanced the findings on the phonological measures, but attenuated the findings on the reading measures. The latter result suggests that brighter adults with dyslexia compensate more effectively for reading difficulties, a theme that is common in studies of LD. Thus, when their language and metalinguistic skills are stronger, those with dyslexia can compensate more effectively for underlying difficulties with phonological awareness. Similarly, Stothers and Klein (2010) found that phonological deficits, which persist in adults with reading disabilities, can affect reading speed, but not necessarily comprehension. With relevance to compensation, they also found that stronger vocabulary and nonverbal processes (i.e., Perceptual Organization Index) were associated with stronger comprehension.

Berninger et al. (2006), who studied families of children and adults with dyslexia, found a complex picture of contributing deficits in three working memory components (phonological and orthographic word-form storage), a time-sensitive phonological loop that involves naming orthographic stimuli, and executive functions (focusing and shifting attention) involving phonology. They found that phonologic, orthographic, morphologic, rapid naming and switching, verbal fluency, and inhibition acted in combination to determine reading and writing skills in adults. A second study from this group showed how impairment in executive functioning can also affect strategic coordination of the phonologic, orthographic, and morphologic demands of reading, even when the individual skills are not impaired (Amtmann, Abbott, & Berninger, 2007). The inability of

individuals with LDs to apply skills strategically is echoed by the dysexecutive type of LD discussed by Wasserstein and Denckla (2009). These studies illustrate how broad assessment of spoken language, attention, executive functions, and general knowledge are all-important when evaluating reading problems.

Some dyslexic individuals have weaknesses in visual perceptual skills (Graves, Frerichs, & Cook, 1999; Iles, Walsh, Richardson, 2000; Ben-Yehudah, Sackett, Malchi-Ginzberg, & Ahissar, 2001; Mano & Osmon, 2008) and orthographic skills (Osmon et al., 2005), and have visual hemi-attention (Gabay et al., 2013). Nevertheless, studies have not found clear evidence that deficits in visual skills are causal in reading disorder (Vellutino, Fletcher, Snowling, & Scanlon, 2004), or that remediation of visual skills improves reading (Handler et al., 2011). Nevertheless, Stothers and Klein (2010) found that stronger visuospatial skills are associated with better reading comprehension. Similarly, Bacon and Handley (2010), using a reasoning measure that required transitive inference, found that college students with dyslexia were more likely than controls to use a visual rather than an abstract verbal strategy. Unlike subjects without dyslexia, they also did not show interference from visual information and visual memory predicted reasoning accuracy. Bacon and Handley (2010) concluded that rather than cause dyslexia, visual processes could help offset weaknesses in phonological awareness and verbal memory.

More recently, Swanson (2012) attempted to parse out the relative contributions of various neuropsychological functions through a meta-analysis of 52 studies. His overall sample consisted of 1,793 adults with reading disabilities and 1,893 adults without reading disabilities. They ranged in age from 18 to 44, and 55% were male. The overall effect size on all measures was 0.72, most with nonreading impaired adults performing better. As expected, for the reading-impaired group, effect sizes were largest for word attack, reading recognition, reading comprehension, and spelling. Effect sizes also were large for writing and math, reflecting the frequent co-occurrence of written expression and math disabilities with reading disabilities. Regarding the component skills needed for reading, effect sizes were largest for phonological processing, processing speed (including rapid naming), vocabulary, verbal intelligence, general information, and verbal memory. Unlike the studies by Berninger and colleagues, effect sizes for executive functioning skills (problem solving and reasoning, cognitive monitoring) were small. The effect size for social and personal skills also was small, as was the effect size for overall intelligence. Interestingly, effect sizes for perceptual motor skills and visuospatial memory were moderate and favored adults with reading disabilities. This intriguing finding again suggests strength in visual memory can be used to compensate. It is not clear why the small effect size for auditory-perceptual skills favored the adults with reading disabilities, but most likely reflects basic auditory-perceptual skills separate from phonological awareness.

These observations likely apply to children as well, although replication is needed.

### *Dyscalculia and/or Math Disorders*

Developmental dyscalculia (DD) is a specific LD affecting mathematical skills and numerical competence that is found in children and adults with normal intelligence and without acquired neurological injuries (American Psychiatric Association, 1987). People with DD have mixed combinations of problems in mathematics, including difficulty with learning and retrieving number facts (e.g., times tables), executing calculation procedures/operations (e.g., long division, adding mixed numbers), understanding mathematical concepts (e.g., fractions, percents, or negative numbers) (Geary & Hoard, 2001), and developing problem-solving strategies (Shalev & Gross-Tsur, 2001). They also have long solution times and high error rates (Geary, 1993), presumably due to all of the previously listed challenges.

The prevalence of DD across countries is relatively uniform, with estimates of 3%–7% (range 1.3%–10.3%) in the normal population, similar to that of dyslexia and ADHD (Kucian et al., 2006). Girls and boys seem to be affected equally (Devine, Soltesz, Nobes, Goswami, & Szucs, 2013), and like other LDs, DD has a significant familial aggregation, suggesting a role for genetics (Alarcon, Pennington, et al., 2000). While DD may in some cases occur as a stand-alone LD (Rourke, 1993), it is frequently (but not always) present in association with other learning impediments, especially a reading/spelling disability or ADHD (Gross-Tsur, Manor, & Shalev, 1996; Shalev & Gross-Tsur, 2001).

Early references to DD were by Henschen (1920); Berger (1926); and Gerstmann (1940). Later, Kinsbourne and Warington (1963) noted that dyscalculia existed in children without acquired brain damage, but Cohn (1968) was the first to employ the term *developmental dyscalculia*. Regarding the neural basis of arithmetic skills and disorders, Henschen (1920) wrote, “the calculation ability is a highly composite cerebral function that results from the collaboration of various posterior areas of the left hemisphere.” Twenty years later, Gerstmann (1940) described the Gerstmann syndrome, which consists of dyscalculia, finger agnosia, left-right confusion and dysgraphia, and was attributed to damage to the left angular gyrus region. Around that same time, Luria (1946) noted that dyscalculia was common in diffuse high cortical impairment. However, after years of additional study of brain-damaged individuals, he later subdivided dyscalculia into three types: spatial, verbal, and operational, reflecting at least three corresponding regions of brain dysfunction (i.e., posterior right hemisphere, posterior left hemisphere, and frontal, respectively; see Luria, 1966). Over the years there have been other attempts to classify the neurocognitive abnormalities that underlie dyscalculia, in addition to the three-system typology of Luria. Kosci (1974) distinguished six types: verbal, apractognostic, lexical, graphic,

ideognostic, and operational. Later Rourke (1993) proposed two types, either due to visuospatial or verbal/auditory perceptual dysfunction.

The education literature noted that mathematics is particularly complex, involving language and other symbols, understanding of space and quantity, and recall and use of operations. An important conceptual distinction was made between “primary dyscalculia,” where the deficit reflects abnormality in underlying numerical cognition (i.e., domain specific), as well as cases wherein the dyscalculia is “secondary” to other more general cognitive impairments, such as deficits in memory, attention or visual-perceptual and spatial understanding (i.e., domain-general impairments) (Rosenberger, 1989; Henik, Rubinsten, & Ashkenazi, 2011). Domain general research has examined the association of DD/dyscalculia with other nonnumeric deficits, such as poor working memory (Luculano, Moro, et al., 2011; Geary, 1993; David, 2012), inattention (Ashkenazi & Henik, 2012), disorders of visual-spatial functioning (Venneri et al., 2003), impaired memory retrieval, and executive function deficits (Szucs et al., 2013). Domain-specific research has examined abilities more specifically related to numerical understanding and abilities.

Overall, the weight of evidence has revealed involvement of combinations of general cognitive capacities (i.e., domain general). For example, in two studies of college students referred for assessment of LDs, Cirino, Morris, and Morris (2002, 2007) found that written calculation and math problem-solving skills were predicted by retrieval of semantic knowledge, executive functioning, and visuospatial skills. Osmon and colleagues (Osmon, Smerz, et al., 2006), using academic and cognitive measures from the Woodcock-Johnson tests and standard neuropsychological tests, also found that college students with DD showed impairment in visuospatial skills and executive functioning. Those who were impaired in both areas (i.e., double deficit) had the most impaired skills. More recently, and also using the Woodcock-Johnson tests in DD college students, Proctor (2012) found that the Math Calculation score was predicted by the Processing Speed and Working Memory scores, and the Math Reasoning score was predicted by the Comprehension-Knowledge, Fluid Reasoning, and Working Memory scores. This, too, showed the importance of attention, working memory, processing speed, and reasoning and acquired knowledge for math skills.

Another strand of education research has focused on more domain-specific abilities, such as the role of lower-level “building blocks of numerical cognition” (Ansari & Karmiloff-Smith, 2002) or “foundational numerical capacities” (Butterworth, 2010), which may underlie DD. *Numerical cognition* is one of such domain-specific ability categories, which include subitizing and counting, comparative judgments and distance effect, and automaticity of numerical processing (see Henik, Rubinsten, et al., 2011, for review). Subitizing refers to the number of objects the mind can simultaneously process

without counting and averages around four to five in adults (e.g., immediate recognition of dice). A number of studies have reported slower processing speed and smaller subitizing ranges among those with DD (e.g., (Landerl, Bevan, & Butterworth, 2004). For example, Koontz and Berch (1996) asked DD children to decide whether two stimuli (using mixtures of dots and/or digits) were the same or not, and found slower times. Such findings are not universal among those with DD. For example, Desoete and Gregoire (2007) found that only 33% of school-aged DD children had subitizing deficits. *Comparative judgment* refers to tasks wherein subjects are asked to decide which of two numbers is larger, and is thought to utilize an internalized number line. Most variations on this approach have found that DD children show a “distance effect.” That is, it takes them longer than controls to decide relative differences between two numbers, which is thought to reflect less well-differentiated representations of numbers on their mental number line (see Henik, Rubinsten, et al., 2011, for review)

There are a number of other proposed domain specific abilities that may be compromised in DD. Children with DD also show deficits in their *automaticity of numerical processing*, which refers to the rapid subjective understanding of the numerical symbol system, e.g., the meaning of digits. Multiple group studies, using various procedures, have found automaticity deficits in both children and adults with DD (see Henik, Rubinsten et al., 2011, for review). This is thought to reflect a deficiency in the association of symbols with quantities and sizes.

According to recent conceptualizations, elementary numerical processing is dependent upon fundamental numerical systems. A Small Number System mediates the exact representations for numbers under 4, while larger numbers require an Approximate Number System (ANS) that enables children to develop representations and make comparisons approximate magnitudes/amounts of objects, events, and time (Dehaene, Molko, Cohen, & Wilson, 2004; Feigenson, Dehaene, & Spelke, 2004). Some research has found correlation between ANS deficits and mathematical ability in DD children (Piazza, Facoetti, et al., 2010). However, Butterworth (2010) has argued that a deficit in numerosity coding (i.e., capacity to quantify sets and operations upon them), rather than the ANS, was central to DD.

A number of studies have suggested that numerical sense deficits and weakness in particular domain-general abilities may combine in particular constellations to impede mathematical skill development (Fuchs, Geary, et al., 2010). For example, problems in basic aspects of number sense representation were found to exist in combination with deficits in working memory and visual spatial processing (Geary, Hoard, Nugent, & Bailey, 2012). Another research group (Rubinsten & Henik, 2005) examined both domain general (i.e., attention) and domain specific numerical processing in DD college students. First, using a Stroop task in which digits of differing numerical value were presented in different

physical sizes, Rubinsten and Henik found a smaller interference effect in the DD students. They interpreted this finding as showing a lack of automaticity in activation of numerical value, both thought to be domain-specific skills. In a second study they found that DD students had difficulty recruiting attention to numerical information (Ashkenazi, Rubinsten, & Henik, 2009), thereby replicating and extending their initial study. In a third study, using a Posner-type task, they found broader deficits in the alertness and executive functioning networks in DD college students (Ashkenazi & Henik, 2010a). Finally, they found that attention training improved attention in college students with DD, but had no effect on numerical processing (Ashkenazi & Henik, 2012). Examining attention in a different way, Ashkenazi and Henik (2010b) administered standard line and number line bisection tasks to college students with DD. Those with DD did not show the usual leftward bias on the line bisection task, but showed a more pronounced leftward bias on the number bisection task, implying that they had an internal logarithmic representation of numerical value that is more typical of younger children. Performance on the two tasks was unrelated. These studies showed deficits in both attention and numerical processing, reflecting underlying dysfunctions in both domain general and domain specific skills. Consequently, these authors argued that DD is a heterogeneous disorder with both domain general and domain specific determinants.

A final consideration is the role of anxiety in math dysfunction (Katz, Goldstein, et al., 2001), as it can either worsen and/or even simulate DD. Although early difficulties in math may dissipate over time, adults may remain highly anxious and thus dysfunctional when attempting computations. For example, Buelow and Frakey (2013) found that math anxiety affected performance on the Arithmetic subtest of the Wechsler Adult Intelligence Scale-Fourth Edition but did not affect performance on other Working Memory subtests that did not require arithmetic.

### *Dysgraphia*

Dysgraphia denotes a failure in the normal development of writing skills despite adequate intelligence, motivation, and instruction (Gubbay & Deklerk, 1995). Writing is a complex task requiring the mastery and integration of a number of subskills, including fine motor control, visual and tactile perception, language, memory, and executive functioning. The term itself is derived from conjoining the Greek words *dys* meaning “impaired” with *graphia* meaning “making letterforms by hand” (De Ajuriaguerra et al., 1979). Some children or adults have difficulties in one aspect of the process, such as producing legible handwriting or spelling, whereas others have difficulty organizing and sequencing their ideas. Difficulties in one area can delay skill development in the other areas. Some regard dysgraphia to include problems with spelling and other writing mechanics (such as punctuation and grammar), while others maintain the more narrow

view that regards the disorder as an abnormality of complex motor skill or handwriting (Berninger & May, 2011). Thus the scope and limits of this disorder are not well-defined and there is considerable confusion regarding what is being described with this diagnosis.

Due to the extreme differences in definition, and the lack of a “gold standard” measurement instrument, prevalence estimates vary greatly, ranging from 5% to 27% of school-aged children (van Hartingsveldt, de Groot, Aarts, & Nijhuis-van der Sanden, 2011). Future studies will be further complicated by the trend to deemphasize handwriting in favor of keyboarding skills. As a consequence, increasing numbers of students are not receiving formal instruction in cursive handwriting, despite its continuing importance in many academic endeavors (Christensen, 2009). Handwriting difficulties usually manifest during early schooling. By contrast, problems with spelling and other writing mechanics, and/or with composition, become more apparent during middle school. Absent intervention, both can persist throughout life.

Similar to the other academic skills, handwriting is a complex task that engages a variety of cognitive processes including attention, memory, proprioception, and linguistic processing (Graham & Weintraub, 1996; Bara & Gentaz, 2011), as well as the more obvious fine-motor skills. It requires access to both mental representations of letters and words, as well as access to the motor programs for executing selected letters and letter sequences. In addition, execution must be constrained by the spatial arrangement of the page. Letter shape, size, spacing, sequencing, slant, direction, trajectory, and allographic considerations must all be taken into account, while implementing the motor program, which must be accomplished with the potential for online correction in order to maintain consistency with previously written letters. Thus, the task also engages multiple executive processes (Graham, Struck, Santoro, & Berninger, 2006).

Problems with written expression denote difficulties with writing, writing mechanics (like spelling and/or grammar and punctuation), and/or with execution of text (like organization, initiation, and completion). Given the broad clinical profile, it is no surprise that dysgraphia is often seen with other neurodevelopmental disorders. Poor writing mechanics, especially spelling, are among the more common comorbid problems of dyslexia. For example, Connelly, Campbell, MacLean, and Barnes (2006) found that college students with dyslexia wrote poorer-quality essays, with the best predictors of essay quality being handwriting speed and spelling errors, similar to conclusions drawn by Peverly (2006) in a review. Dyslexic college students also made more spelling errors in their essays than expected based on a separate spelling test, suggesting that the dual demands for spelling and writing may have overloaded their processing systems. Berninger, Nielsen, Abbott, Wijsman and Raskind (2008), in their family study of dyslexia, found that male adults with dyslexia were more impaired in handwriting, spelling, orthographic, and composing skills than female adults with dyslexia. They

also reported that the males were more impaired in reading rate and accuracy. They concluded that reading and writing difficulties were confounded by gender differences, and that over time, men with dyslexia may fall behind women with dyslexia in the development of their writing skills. Finally, while spelling dysgraphia is most frequently associated with dyslexia, clinically we have found that poor handwriting and/or poor composition are often seen in the context of ADHD. Nevertheless, dysgraphia can also exist alone.

### *Nonverbal Learning Disability*

First described in the latter half of the 20th century by Johnson and Myklebust (1967), NVLD is one of the most recently recognized forms of LD. Originally it was described as a social learning disorder that grew out of poor “reading” of nonverbal social and emotional cues (due to poor spatial and perceptual processing). Only later did Johnson and Myklebust (1971) report that this social LD often, but not always, was associated with dyscalculia. Myklebust eventually coined the term “nonverbal learning disabilities” and attributed it to dysfunction of the right cerebral hemisphere (1975). Rourke, through studying neuropsychological deficits in dyslexic and dyscalculic children, subsequently popularized awareness of this LD and more tightly intertwined dyscalculia and social processing LD, along with deficits in visuospatial skills, motor skills, and complex problem solving (e.g., Rourke, Young, Strang, & Russell, 1986; Tsatsanis & Rourke, 2008). Similar to Myklebust, he attributed this deficit profile to right-hemisphere dysfunction, but primarily of white matter. The suggestion of almost universal co-occurrence between dyscalculia and NVLD may be an overgeneralization from the LD samples Rourke originally studied, which consisted of children with either dyslexia, dyscalculia, or both. Different comorbidity patterns were seen in a retrospective chart review study by two coauthors of this chapter and other colleagues (Wasserstein et al., 2008). Consistent with Rourke’s model, most of these people had deficits in visuospatial-constructional skills, visual memory, and fine motor skills. As expected, 80% also reported impairment in social functioning. However, while 50% had (or reported) math disorder, another 50% showed (or reported) reading disability, with and without dyscalculia. Interestingly, 85% showed inattention and executive dysfunction, and were diagnosed with ADHD. Thus, NVLD often occurred with reading disorder, was not universally associated with dyscalculia, and was most commonly associated with executive dysfunction and/or ADHD.

Not surprisingly, there is controversy over whether NVLD is a specific LD separate from other disorders, such as math disabilities, ADHD, developmental coordination disorders, and ASDs (Pennington, 2008). Fletcher, Lyon, Fuchs, and Barnes (2007) do not include NVLD in their model of specific LDs, because there is not always impact on a specific academic skill. More damaging to the concept is Spreen’s

(2011) critical review of the extant research on NVLD. He made the following arguments:

- NVLD has been accepted as a viable diagnosis without sufficient support.
- Studies of NVLD have not sufficiently researched and demonstrated reliability and validity of the diagnosis.
- The characteristics of subjects defined as having NVLD vary from study to study.
- NVLD occurs rarely, despite unsupported prevalence estimates of 10%–29%.
- Support for associated socioemotional disorders has been mixed.
- Unlike dyslexia, for which there is neuroimaging support, there is no neuroimaging support showing that NVLD is due to white matter dysfunction or focal right hemisphere dysfunction, as hypothesized.
- The NVLD profile is not found universally in childhood disorders with which it has been proposed to be associated.

In summarizing the literature, Spreen (2011) concluded that:

The concept of NVLD has been discussed and investigated for more than 30 years. Yet, no firm data are available on the frequency of occurrence of NLD, its socioemotional features, or its hypothetical neurological basis. At this point, it must be concluded that NVLD remains a hypothesis, but that it should not be used in clinical practice unless it is supported by solid research findings.

(p. 435)

Thus while each of the specific LDs appear to be multifaceted and likely represent a number of subtypes, NVLD may be the most so. Until there is more definitive research, the NVLD category has to be considered tentative and evolving. With appropriate caveats, however, it can be helpful in conceptualization of some neuropsychological profiles, and as an explanatory vehicle for both patient/parent.

## Neuroscience of ADHD and LD

Neurobiological theories of ADHD and LD have been developed in addition to the clinical and psychological descriptions reviewed previously. Such theories were originally based on similarities between problems resulting from various forms of acquired brain damage and the problems seen in children with either disorder. However, neurobiological theories were historically met with skepticism, which persists in some circles to this day (e.g., Timimi & Taylor, 2004; Visser & Jehan, 2009). Advances in genetics, and structural and functional neuroimaging, have provided unprecedented perspectives on the neural correlates of ADHD and LD. For example, structural magnetic resonance imaging (MRI) can differentiate, in exquisite anatomic detail, the spatial location, extent, and

boundaries of different forms of tissue (gray matter, white matter), enabling quantification of the physical characteristics of various brain structures such as the volume, thickness, or surface area. This capacity has allowed investigators to examine rates and patterns of growth of various brain structures in individuals with ADHD or LD, and compare them to typically developing individuals. In addition, functional neuroimaging and electrophysiological methods, such as quantitative EEG and event-related potentials (ERP), have provided useful methods to evaluate the functional implications of structural differences.

There is more research regarding the genetics of ADHD versus LD, and the following reviews are weighted accordingly. There is also more research with children than with adults, and some findings likely change with development. Where possible such distinctions are made. Finally, disorders of reading represent the LD for which there is the most research and are consequently the emphasis of the LD section. Dyscalculia, dysgraphia, and NVLD are considered but not as extensively discussed.

## Neurobiology of ADHD

### Genetics of ADHD

ADHD is strongly familial, with higher rates reported in siblings of ADHD probands (20.8% vs. 5.6% in controls) (Biederman et al., 1992), first-degree family members of ADHD males (Lombroso, Pauls, & Leckman, 1994) and females (Faraone et al., 1991; Faraone et al., 1995), second-degree relatives (Faraone et al., 1994), and biological parents (18% ADHD in biological vs. 6% in adoptive parents) (Sprich, Biederman, Crawford, Mundy, & Faraone, 2000). In a recent study of adopted children and their adoptive and biologically related mothers, the biological mothers' ADHD symptoms significantly predicted the child's ADHD symptoms at age 6 (Harold et al., 2013), further supporting the existence of shared genes responsible for the increased familial aggregation. There are a number of different approaches to researching the genetics of any condition including studies of heritability, candidate genes, genome-wide association studies, epigenetic modulators, and animal models.

### HERITABILITY STUDIES

Twin studies attempt to distinguish genetic and environmental risk factors by comparing phenotypes of monozygotic (100% genetically identical) and dizygotic (sharing about 50% of genes) twins. These have reported heritability rates in the 70% range in childhood ADHD (Nikolas & Burt, 2010) for both severe and subthreshold levels (Larsson, Anckarsater, Rastam, Chang, & Lichtenstein, 2012). Lower heritability estimates, in the range of 30%–40%, have been reported in ADHD adults (Posthuma & Polderman, 2013).

Data from the few ongoing longitudinal studies provide greater understanding of heritability estimates across the life

span. Results from the Twins Early Development Study in the United Kingdom suggest that some of the same genes may confer risk for hyperactive-impulsive symptoms, while a different set of genes may confer risk for the inattentive symptoms (McLoughlin, Rijdsdijk, Asherson, & Kuntsi, 2011). Similarly, a Swedish longitudinal study of ADHD twin pairs, followed from childhood to adolescence, noted a decrease in hyperactivity-impulsivity and increase in inattentive symptoms across development, with both trajectories being highly heritable (Larsson, Dilshad, Lichtenstein, & Barker, 2011). In this sample attention problems were investigated from childhood to young adulthood using multiple informants rather than just self-report. Results showed that the genetic effects operating at ages 8–9 continued to explain 41%, 34%, and 24% of the total variance at ages 13–14, 16–17 and 19–20 years, respectively. Rater variance was considered to be playing a role in another longitudinal study, the Netherland Twin Registry, where heritability of ADHD was estimated to be 70%–74% during childhood based on maternal ratings, followed by lower estimates (i.e., 51%–56% in adolescence and 40%–54% in adulthood) based on self-ratings (Kan et al., 2013). Importantly, new sets of genetic risk factors have been noted to emerge in adolescence and young adulthood (Chang, Lichtenstein, Asherson, & Larsson, 2013), suggesting that different genes may be relevant at different developmental stages. For example, in adolescence there is accelerated development of dorsolateral prefrontal and temporal brain regions, areas with the highest DRD4 expression. Thus this gene may confer greater risk during this time period (Meador-Woodruff et al., 1996). Epigenetics may also be contributing as seen by decreased DAT mRNA expression reported with age (Bannon & Whitty, 1997).

#### CANDIDATE GENE STUDIES

The high heritability reported in the twin studies prompted the search for genes involved in neurotransmission. The initial approach had been to focus on genetic variation within *prespecified genes* (i.e., candidates) and phenotypes or diseases. This approach assumed that variations in these candidate genes, which were involved in neurotransmission, would occur at greater frequencies in individuals with ADHD versus those without ADHD. Observed differences would lead to the identification of the common genes conferring a higher level of risk for the disorder. Numerous studies were performed, but the predicted variants were not consistently found in most ADHD subjects and also occurred at high frequencies in controls. As reviewed by Chiyoko and colleagues (Akutagawa-Martins, Salatino-Oliveira, Kieling, Rohde, & Hutz, 2013) and Gizer and colleagues (Gizer, Ficks, & Waldman, 2009), the strongest support emerged for gene variants in dopaminergic genes (e.g., DAT1(SLC6A3), DRD4, DRD5, DBH, DDC), noradrenergic (NET1(SLC6A2), ADRA2A, ADRA2c), serotonergic (5-HTT(SLC6A4), HTR1B, HTR2A, TPH2) and others (SNAP-25, CHRNA4,

NMDA, BDNF, NGF). However, in humans, variations in these genes were found to confer minimal risk (Gizer et al., 2009).

Numerous methodological issues further confounded candidate gene studies, including sample size and complex phenotypes derived from various age ranges. An example is the seven-repeat (7R) allele of DRD4, one of ADHD candidate genes thought to confer decreasing sensitivity to dopamine (Asghari et al., 1995, Schoots & Van Tol, 2003). A longitudinal study of ADHD subjects and their nonaffected siblings (from childhood through adolescence) (Altink et al., 2012) indicated that the proposed effect may differ across the developmental trajectory. In this study, non-ADHD adolescents who were DRD4 7R carriers performed worse than noncarriers on neurocognitive function. However, the effect was not observed in the younger children, suggesting there was varying brain susceptibility during the different developmental stages. Such developmental differences may reflect increased sensitivity in the adolescent brain due to global changes that occur during this period, such as decrease in gray matter and increase in white matter density (Krain & Castellanos, 2006), shifts in cortical thickness (Polderman et al., 2007) and, as noted previously, accelerated development of dorsolateral prefrontal and temporal brain regions (i.e., areas with the highest DRD4 expression; see Meador-Woodruff et al., 1996). Increased vulnerability during adolescence may also be conferred by the decreasing dopamine receptor density (Thompson, Pogue-Geile, & Grace, 2004), rendering carriers of DRD4 7R, known to produce fewer or less responsive D4 receptors to dopamine stimulation (Asghari et al., 1995), even more vulnerable. By contrast, the state of brain development in younger children may render them less vulnerable to DRD4 variants.

Despite such considerations, data from current genetic studies have not usually taken into account developmental stages, making it difficult to associate the phenotypic data with genetic data. Developmental variations in gene expression may also be especially important in ongoing discussions about the possibility of later onset ADHD.

#### GENOME-WIDE ASSOCIATION STUDIES

Advances in bioinformatics (i.e., an interdisciplinary field that develops methods and software for understanding biological data) and genotyping technology (i.e., determining the genetic make-up of an individual) allow extensive exploration across the whole genome. Unlike the candidate gene method, these methods provided the opportunity to discover variants not otherwise considered since genes were not chosen with any a priori hypothesis. At this time no “common variant” has been identified (Neale et al., 2010; Hinney et al., 2011; Williams et al. 2012; Yang et al., 2013). This refers to a similar genetic variation that confers risk in many individuals (Casals & Bertranpetit, 2012). However the technology has led to the discovery of “structural variants” in ADHD

cohorts. What are structural genetic variants? Human DNA consists of more than 3 billion base pairs, which are not always arranged in the same order. In contrast to single nucleotide variations (referred to as single-nucleotide polymorphisms, or SNPs), more than 13% of the DNA consists of large sections (ranging from 1,000 to 1 million nucleotides) that are repeated (once or a number of times) or that may be deleted (Stankiewicz & Lupski, 2010). These are called *structural variations*, and are thought to play a significant role in: (a) phenotypic variability (i.e., by changing gene dosage), (b) complex behavioral characteristics such as those seen in ADHD, as well as in (c) disease susceptibility (Zhang, Gu, Hurles, & Lupski, 2009).

Inherited rare structural variations conferring risk in ADHD were fairly recently reported by Elia and colleagues (Elia et al., 2010), discovered in genes known to be important in learning, behavior, and synaptic transmission. Additional inherited and de novo variants have been reported by other groups (Williams et al., 2010; Lesch et al., 2011; Lionel et al., 2011; Elia, Glessner, et al., 2012; Stergiakouli et al., 2012; Williams et al., 2012; Jacob et al., 2013; Yang et al., 2013). Rare variants, by definition, are identified in only a few individuals and therefore are not usually replicable. However, as would be expected, different rare variants impacting on similar genes in ADHD samples are now also being reported, seen for example, in the *BCHE* gene (Elia et al., 2010; Lesch et al., 2011; Lionel et al., 2011; Jacob et al., 2013), which is expressed in cholinergic neurons and is involved in regulating vigilance (Darvesh, Hopkins, & Geula, 2003). Genetic variants associated with conferring risk for ADHD have also been reported in other neuropsychiatric disorders such as autism (Lionel et al., 2011). This suggests that rare variants may be symptom- and not syndrome-specific and associated with numerous comorbid syndromes.

#### EPIGENETICS

While gene sequence remains the same throughout life, the regulation of gene activity and gene expression can be changed by a number of nongenetic factors, referred to as *epigenetics*. Animal studies have led research in this area, implicating factors influencing prenatal development, such as malnutrition, maternal stress, infection, and toxicity, in altered brain function and behavior in the offspring. For example, dopaminergic and serotonergic deficiencies were reported in young adult rats that were prenatally exposed to bacterial lipopolysaccharide (Wang, Yan, Lo, Carvey, & Ling, 2009). Other examples include the following: low-dose prenatal and neonatal bisphenol exposure resulted in deficits in development of synaptic plasticity in rat dorsal striatum (Zhou, Zhang, Zhu, Chen, & Sokabe, 2009), and size and distribution of midbrain dopaminergic populations were permanently altered by perinatal glucocorticoid exposure in a sex-region and time-specific manner (McArthur, McHale, & Gillies, 2007). Hyperactivity and alteration of the

midbrain dopaminergic system were reported in maternally stressed male mice offspring (Son et al., 2007).

Reviews of human studies (Archer, Oscar-Berman, & Blum, 2011; Elia, Laracy, Allen, Nissley-Tsiopinis, & Borgmann-Winter, 2012; Latimer et al., 2012; Thapar, Cooper, Eyre, & Langley, 2013) also indicate a number of suspected prenatal, perinatal, and postnatal potential risk factors for ADHD, such as prematurity, maternal smoking, family adversity, and exposure to toxins and low birth weight. For example, low birth weight has consistently been associated with ADHD (Szatmari, Saigal, Rosenbaum, Campbell, & King, 1990; Breslau & Chilcoat, 2000). Further supporting its role is the lower birth weight associated with ADHD in monozygotic birth weight-discordant twin pairs (Sharp et al., 2003; Asbury, Dunn, & Plomin, 2006; Lehn et al., 2007) where the lighter twin from both the monozygotic and dizygotic birth weight-discordant twins also showed higher ADHD ratings (Hultman et al., 2007). Elucidating the impact of such risk factors in humans is complicated since it's often difficult to separate confounding factors. For example, the role of prenatal nicotine and alcohol exposure in ADHD is less clear than that of low birth weight since exposure to these substances also increases risk for low birth weight (Mick, Biederman, Prince, Fischer, & Faraone, 2002). Studies in larger cohorts that allow data analyses in subgroups are providing further clarification. For example, genetic variations within latrophilin (*LPHN3*), a gene that codes for G-protein coupled receptors that are involved in the regulation of neurotransmitter transmission (Silva, Suckling, & Ushkaryov, 2009) and neurodegeneration following hypoxia (Bin Sun, Ruan, Xu, & Yokota, 2002) have been reported to be associated with ADHD in several independent studies. Further investigation indicates that this association appears primarily in the subgroup of mothers exposed to minimal but not significant stress during pregnancy, regardless of whether they smoked (Choudhry et al., 2012). Studies are also showing that some of the well-known mechanisms implicated in increasing or decreasing gene expression (i.e., DNA methylation, (Robertson, 2005), histone modifications (Berger, 2007), transcription factors (Latchman, 1997), miRNAs (Pasquinelli, 2012) may be playing a role in ADHD.

The 3 billion base pairs of the human genome are formed by adenine-thymine (ApT) and cytosine-guanine (CpG) nucleotides bound by a phosphate. Methylation of cytosine (mCpG) occurs in about 2%–6% of the CpG dinucleotide pairs and usually results in transcriptional repression or silencing (Robertson, 2005). Differences have also been reported in human brain where methylation in non-CpG nucleotides (G is replaced by A, C, or T) accounts for 53% versus 47% CpG in neurons (Lister et al., 2013) and these forms are also thought to inhibit transcription (Varley et al., 2013). Cortical neuronal methylation increases during the first two years after birth and continues up to adolescence (Lister et al., 2013), overlapping the same time frame for synaptogenesis and synaptic pruning (Huttenlocher &

Dabholkar, 1997) rendering this time frame particularly vulnerable to environmental factors that could confer risk for ADHD. Methylation differences between monozygotic and dizygotic twins on several genes implicated in ADHD (i.e., DRD4, SLC6A/SERT, MAOA) have already been reported (Wong et al., 2010). Also, lower DNA methylation of several genes, including DRD4, derived from cord-blood leucocytes at birth was associated with higher ADHD symptoms during early childhood (van Mil et al., 2014).

Inside the nucleus, DNA is coiled around histone proteins that when condensed prevent transcription. DNA can open to an active state by various mechanisms including methylation, acetylation, phosphorylation, ubiquitylation, and sumoylation (Berger, 2007). The transcription of DNA to RNA is mediated by regulatory proteins called *transcription factors* that bind to specific regions of the DNA and stimulate or inhibit transcription (Karin, 1990). Several transcription factors, including sp1 have been reported to mediate hormone-dependent gene activation for DAT, known to play a role in ADHD (Shumay, Fowler, & Volkow, 2010). More recently, a group of small molecules (20–22 nucleotides) referred to as *miRNAs* (micro RNAs) have been identified that suppress the translation process, or effect mRNA degradation. These control the activity of about 50% of protein-encoding genes, indicating a potentially significant role in neuropsychiatric disorders (Tardito, Mallei, & Popoli, 2013). Sequence variants at a miRNA affecting serotonin receptor genes have been associated with ADHD in adulthood (Sanchez-Mora et al., 2013).

Most epigenetic changes are limited to an individual over the course of an individual's lifetime. However epigenetic changes that cause DNA mutations in progeny cells are inherited from one generation to the next (Chandler, 2007) adding another layer of complexity in deciphering the underlying genetic and epigenetic factors in ADHD. Taken together, any environmental processes which disrupt DNA expression in somatic (Wong et al., 2010; van Mil et al., 2014; Shumay et al., 2010) or germ-lines (Chandler, 2007) could precipitate or worsen the clinical picture, for either the individual and/or his or her progeny.

### Neural Correlates of ADHD

#### THE FRONTO-STRIATAL SYSTEM

Guided by models derived from clinical neuropsychological studies of the effects of frontal lobe lesions (Mattes, 1980), as well as preliminary functional neuroimaging findings (Lou, Hendrickson, et al., 1989), early structural neuroimaging studies found reduced volume in fronto-striatal brain structures of ADHD probands compared to age-matched controls, specifically the caudate and globus pallidus. Some studies reported that this effect was greater in the left hemisphere (Hynd et al., 1993; Aylward et al., 1996; Filipek et al., 1997) while others described larger reductions in the right

(Castellanos et al., 1994; Castellanos et al., 1996; Casey et al., 1997). Supplementing their findings with functional neuroimaging, Casey et al. (1997) noted that diminished volumes in the right caudate nucleus and inferior frontal cortex were correlated with poorer task performance on measures of response inhibition, and suggested that deficiencies in right fronto-striatal circuitry may be particularly related to poor inhibitory controls in ADHD.

With some exceptions (Hill et al., 2003), subsequent studies have generally confirmed volume reductions in striatal structures in ADHD individuals. However, the findings have been inconsistent regarding which basal ganglia structures are affected and whether the diminished volume is apparent predominantly in the right or left hemisphere, or both (Mataro et al., 1997; Garrett et al., 2008; Nakao, Radua, Rubia, & Mataix-Cols, 2011; Proal et al., 2011; Seidman et al., 2011; Onnink et al., 2014; Semrud-Clikeman, Pliszka, Bledsoe, & Lancaster, 2014). Studies using a *regions of interest* (ROI) approach, have most consistently implicated the caudate, although diminished volume of globus pallidus (Aylward et al., 1996; Castellanos et al., 1996; Qiu et al., 2009) and the putamen (Lopez-Larson et al., 2009; Qiu et al., 2009) have also been described. Two meta-analyses seem to provide partial resolution of these inconsistencies. Both demonstrated greater volume reductions in right striatal structures, with one showing diminished caudate volume (Valera, Faraone, Murray, & Seidman, 2007) and the other pointing to reductions in the putamen/globus pallidus region (Ellison-Wright, Ellison-Wright, & Bullmore, 2008). To some extent, these inconsistencies may relate to a variety of factors, including subjective judgments in manually tracing structures on MRI that are inherent in the ROI methodology.

Subsequently, a number of studies have utilized whole-brain voxel-based morphometry (VBM), which employs an automatized segmentation algorithm and does not require a priori hypotheses regarding which regions are of interest. A recent meta-analysis of VBM studies in children demonstrated reduced right globus pallidus and putamen volumes, but differences in caudate volumes failed to remain significant (Frodl & Skokauskas, 2012). The results also confirmed suggestions (from a number of previous reports) that the observed differences in basal ganglia volume diminished over time from childhood to adulthood. However, an independent meta-analysis suggested that the volume reductions in basal ganglia—specifically right caudate and globus pallidus/putamen—continue to be a robust finding in adulthood (Nakao et al., 2011). Despite some inconsistency, reductions in basal ganglia volume remain one of the more prominent and replicable structural abnormalities in ADHD.

Prefrontal and premotor cortex volume has also been reported as relatively diminished in individuals with ADHD. Most studies have shown that these reductions are apparent in both gray and white matter (Mostofsky, Cooper, Kates, Denckla, & Kaufmann, 2002; Seidman et al., 2006; Narr et al., 2009; Mahone et al., 2011). Subsequent investigations

examined whether the biological basis for these volumetric differences was driven by differences in cortical thickness or surface area, or a combination of both. Cortical thinning was identified in medial, dorsolateral, orbital frontal, and inferior frontal cortex (Shaw et al., 2006; Makris et al., 2007; Gilliam, et al., 2011; Ducharme et al., 2012), particularly in the right hemisphere (Makris et al., 2007; Narr et al., 2009; Proal et al., 2011; Gilliam, et al., 2011; Langevin, MacMaster, et al., 2014). These decreases in cortical thickness were correlated with key symptoms of ADHD such as hyperactivity and impulsivity (Shaw, Malek, et al., 2012). In addition, the right anterior cingulate also appears smaller and thinner in ADHD compared to age-matched controls (Pliszka et al., 2006; Bledsoe, Semrud-Clikeman, & Pliszka, 2013). Notably, the anterior cingulate forms part of a cortico-limbic component to fronto-striatal circuitry, having connections to both lateral prefrontal and parietal cortex as well as to the amygdala, nucleus accumbens, hypothalamus, and insula.

Mahone et al. (2011) reported that in school-aged (8 to 13 years) children with ADHD, the left supplementary motor cortex (SMC) was also reduced in volume, and was evident in both boys and girls. This difference, which was evident in both gray and white matter volumes, was associated with significantly higher commission rates on a go/no-go task, providing an important and relevant functional correlate to the anatomical findings. Given other evidence that the SMC, particularly the rostral portion, is critical to response control and selection (Mostofsky & Simmonds, 2008), it was argued that abnormal fronto-striatal development including SMC may underlie one of the key impairments in ADHD: inhibitory control (Wodka et al., 2007). More broadly, deficits in response inhibition may reflect abnormal function of a circuit that includes SMC and its connections to basal ganglia, which are critically involved in inhibiting competing motor programs and disinhibiting intended behaviors (Mink, 2003).

Overall, these findings implicate dysfunction of multiple structures in fronto-striatal brain regions in the etiology of ADHD. Key components appear to include ventromedial, dorsolateral and orbital prefrontal cortex, premotor and supplementary motor cortex, the basal ganglia and cingulate gyrus. Given that the caudate nucleus, globus pallidus, and prefrontal cortex contain a high density of dopaminergic receptors, pathophysiology of this network is consistent with evidence from other sources (neuropsychological, and genetic, neurochemical, and neuroimaging) implicating dysfunction of dopamine pathways in ADHD (Seidman, Valera, & Bush, 2004; Durston et al., 2005; Kieling, Goncalves, Tannock, & Castellanos, 2008). Studies that are more recent have raised alternative pharmacologic mechanisms, specifically a polymorphism in a noradrenalin transporter gene (Chamberlain, Hampshire, et al., 2009). The neuroanatomical findings may relate to decreased GABA<sub>A</sub> mediated short-term inhibitory influences that frontal motor regions exert on functions of the basal ganglia (Gilbert, Isaacs, Augusta, MacNeil, & Mostofsky, 2011). Particular anomalies do

remain evident in adulthood and in some cases appear to be predictive of neuropsychological impairment in specific functions. For example, Depue, Burgess, Bidwell, Willcutt, & Banich (2010) observed that in young adults, decreased frontal gray matter volume was correlated with poor processing speed and difficulties with response inhibition.

Together these data provide some support for previous speculation that the inhibitory and attentional difficulties experienced by individuals with ADHD may particularly relate to right-sided dysfunction of the fronto-striatal system (Heilman, Voeller, & Nadeu, 1991; Stefanatos & Wasserstein, 2001). Anatomical evidence compatible with this assertion includes the greater volume reductions in right basal ganglia (Castellanos et al., 1994; Casey et al., 1997), right cingulate (Makris et al., 2010), and cortical thinning in right inferior frontal areas in ADHD (Makris et al., 2007; Gilliam, et al., 2011). In addition, recent meta-analyses of both structural and functional MRI (fMRI) studies have supported the view that dysfunction of the right fronto-striatal system as a key role in ADHD (Nakao et al., 2011; Hart, Radua, Mataix-Cols, & Rubia, 2012).

#### PARIETAL LOBE

Right-hemispheric involvement in ADHD is also consistent with several studies demonstrating that individuals with ADHD can show subtle signs of inattention to the left side of space (Voeller & Heilman, 1988; Dobler et al., 2005). Manifestations include disproportionately slow reaction time to left-sided targets on computerized target detection tasks (Nigg, Swanson, & Hinshaw, 1997), reduced attention in the left hemifield on Posner's valid/invalid cueing task (Carter, Krener, Chaderjian, Northcutt, & Wolfe, 1995), increased left-sided omissions on cancellation tasks (Malone, Couitis, Kershner, & Logan, 1994), and a rightward bias on line bisection tasks (Sheppard, Bradshaw, Purcell, & Pantelis, 1999; Boles, Adair, & Joubert, 2009). These anomalies are reminiscent of the spatial neglect problems commonly seen in patients with acquired lesions of right parietal cortex. It has therefore been suggested that these anomalies may reflect parietal lobe dysfunction in ADHD. Alternatively, the problems with spatial attention may simply reflect a spatial bias arising from deficiencies in more general attentional processes such as sustained attention and vigilance for which the right hemisphere also plays a crucial role (Robertson, 1989). Aman, Roberts, and Pennington (1998) have suggested that performance is more impaired on frontal than parietal tasks in ADHD, although improvements are evident on both in response to medication.

Right parietal involvement in ADHD is consistent with a number of recent structural neuroimaging findings that have shown volume reductions and cortical thinning in the parietal lobe, particularly on the right side (Makris et al., 2007; McAlonan, Cheung, et al., 2007; Narr et al., 2009). In addition, white matter anomalies have been identified in right

inferior parietal occipital cortex, suggestive of decreased neural branching (Silk et al., 2009). Tractography suggested that these anomalies involved pathways connecting parietal cortex to basal ganglia and a larger neural network including the cerebellum. Several recent fMRI studies have demonstrated that individuals with ADHD exhibit reduced activation of parietal association cortex during performance of tasks requiring relational reasoning (Silk et al., 2008) and fluid intelligence (Tamm & Juranek, 2012).

#### CEREBELLUM

It has become increasingly clear that differences in brain structure and function in individuals with ADHD exists beyond the fronto-striatal and parietal systems just described. Volumetric reductions have been identified in the thalamus and cerebellum (posterior inferior cerebellar vermis; see Proal et al., 2011). These observations have coincided with a dramatic increase in our understanding of the role of the cerebellum in regulating the speed, consistency, and appropriateness of various aspects of cognitive processes (e.g., complex reasoning, judgment, attention, working memory, and language) (1991, Schmahmann; 2004 #3676; Schmahmann & Pandya, 1997). The influence of the cerebellum on cortical functioning is thought to be mediated through major fiber tracts connecting multiple areas in the prefrontal and parietal association cortex to the pons and through feedback loops mediated via the thalamus and basal ganglia. These findings add an additional layer of complexity to models of the pathophysiology associated with ADHD since reductions in volume of the basal ganglia could be shaped by modulatory influences from the cerebellum (Giedd, Blumenthal, Molloy, & Castellanos, 2001; Seidman, Valera, & Makris, 2005).

#### WHITE MATTER

Some of the earliest structural neuroimaging studies identified reductions in the anterior portions of the corpus callosum (Hynd, Semrud-Clikeman, et al., 1991; Giedd et al., 1994), the major fiber tract connecting orbital regions of the left and right frontal cortex. This finding has been replicated, although not consistently (Overmeyer et al., 2000). Nevertheless, it is regarded as one of the more replicable findings in ADHD, having shown significant results in two independent meta-analyses (Valera et al., 2007; Hutchinson, Mathias, & Banich, 2008). The study of white matter in ADHD expanded to implicate other major white fiber tracts. A picture has now emerged that neural anomalies associated with ADHD are more widespread than had previously been considered. Some propose these neural anomalies may best be conceptualized in terms of a breakdown of widely distributed large-scale brain networks, including the default mode network (DMN; see e.g., Castellanos & Proal, 2012).

Recent advances in diffusion tensor imaging (DTI) have allowed more detailed exploration of changes in white matter.

The most commonly cited index of anomalies of white matter is fractional anisotropy (FA), which reflects a combination of tissue properties including axonal density, ordering, and myelination. While FA does not directly measure white matter integrity, it does reflect physical differences in white matter structure. DTI studies of individuals with ADHD have disclosed reduced white matter connectivity in subregions of the corpus callosum (Ashtari et al., 2005; Langevin, MacMaster, et al., 2014). The corpus callosum itself may undergo an abnormal growth trajectory in ADHD, particularly in its anterior extent (Gilliam et al., 2011). White matter anomalies have also been identified in the right external and internal capsules, right premotor and striatal regions (Adisetiyo et al., 2014), insula, and bilateral frontal (Mostofsky et al., 2002) and parietal lobes (Filipek, Semrud-Clikeman, et al., 1997), particularly in deep white matter. Involvement of deep white matter suggests anomalies in long association and projection fiber bundles. Interestingly, some areas in prefrontal cortex show decreased connectivity, while other areas, specifically orbitofrontal-striatal circuitry, show increased connectivity. The decreased connectivity in the left prefrontal circuitry has been found to be significantly correlated with inattention, while the increased connectivity of orbitofrontal-striatal circuitry was correlated with hyperactivity/impulsivity (Cao et al., 2013). In keeping with such observations, a recent review article by Konrad and Eickhoff (2010) noted a major shift in the research on the neuroscience of ADHD, from focus on abnormalities in isolated brain regions to abnormalities in organization and functioning of distributed brain regions.

van Ewijk, Heslenfeld, Zwiers, Buitelaar, and Oosterlaan (2012) recently reported the results of a meta-analysis of nine studies using a voxel white whole-brain analysis (VBA), which utilizes an automatized segmentation of the whole brain. This analysis yielded five significant clusters, suggesting disturbances of white matter integrity. This included the uncinate fasciculus (which connects anterior and mid temporal lobe to inferior frontal cortex) as well as widespread changes in the right corona radiata, which likely included fibers of the superior longitudinal fasciculus. The second-largest cluster was found in the left cerebellar white matter and smaller clusters were identified in the internal capsule bilaterally and in an area close to the genu of the corpus callosum. These findings only partially map onto results obtained in various ROI analyses. This again underscores some of the difficulties in evaluating the significance of structural correlates of neurodevelopmental disorders, including the possibility that some variation in results may relate to differences in the methods used. This general issue underscores the need to obtain corollary evidence from neuropsychological, neurophysiological and functional neuroimaging studies.

#### *Functional Implications*

Overall, this area of research has made significant headway in identifying the distinct functional role of the structures

comprising the fronto-striatal system and their contribution to symptomology associated with ADHD. The basal ganglia form a highly interconnected network within the forebrain that interacts with and influences multiple neural systems through large-scale loops (Alexander, DeLong, & Strick, 1986; Utter & Basso, 2008). The caudate, putamen, and nucleus accumbens receive excitatory input from the entire cortex and interlaminar nuclei of the thalamus. In contrast to the putamen, which receives input from primary somatosensory and motor cortex, the caudate head receives input mainly from prefrontal, premotor, and supplementary motor areas. The caudate body receives parietal-occipital cortex projections and temporal lobe connects to the caudate tail. This pattern of connectivity suggests that the putamen is primarily concerned with motor control, while the caudate appears more involved in higher-order aspects of motor programming and cognitive control. Outputs of the basal ganglia project mainly from the substantia nigra and the globus pallidus that in turn connect indirectly and directly to the thalamus, which then influences cortical activity. This circuitry is thought to play a fundamental role in action selection, motor control, and sequence learning, but is also critically involved in cognitive function, supporting executive processes such as response inhibition and cognitive control, and the allocation of attention and timing functions (Rubia, Halari, et al., 2009; Aron, Robbins, & Poldrack, 2014; Botvinick & Cohen, 2014).

Functional neuroimaging studies in healthy adults have recently suggested that different aspects of inhibition may be mediated by distinguishable neural circuits. Motor response inhibition appears to be mediated by overlapping fronto-striato-thalamo-parietal networks involving predominantly right inferior frontal cortex, supplementary motor area, anterior cingulate cortex, caudate, thalamus, and inferior parietal regions (Miller, Nigg, & Miller, 2009). By contrast, interference inhibition tasks, which typically have a higher cognitive load due to the need for some aspect of conflict detection and inhibition from distraction, tend to be associated with greater activation of left hemisphere activation (Bernal & Altman, 2009) particularly in AAC and left IFC (Nigg et al., 1997).

When there is the need for high levels of mental effort, the anterior cingulate appears to be involved in coordinating with prefrontal cortex in evaluating how and when to exert cognitive controls, determining the significance of outcomes, and anticipating a course of action (Carter, Botvinick, & Cohen, 1999; Bush, 2011). It is not only involved in executive processes, but also its connections to limbic structures and the nucleus accumbens point to its role in incorporating information regarding emotional and motivational or reinforcement significance of actions or outcomes (Williams, Bush, Rauch, Cosgrove, & Eskandar, 2004; Makris et al., 2009). The result is a highly complex system that plays a role in dynamically and adaptively parsing and evaluating incoming information, suppressing responses to salient but

irrelevant events, and choosing the most appropriate motor, cognitive or emotional response or action.

Several studies have noted that individuals with ADHD have fairly consistent deficits in various behaviors contingent on timing (Rubia, Taylor, Taylor, & Sergeant, 1999; Levy & Swanson, 2001; Smith, Taylor, Rogers, Newman, & Rubia, 2002; Toplak & Tannock, 2005). This is evident in relatively poor performance on simple tasks requiring maintenance of information regarding temporal order or duration (Radonovich & Mostofsky, 2004; Toplak & Tannock, 2005; Himpel et al., 2009). In addition, it is also been argued that timing issues may underlie the tendency of individuals with ADHD to demonstrate premature or poorly timed responses, difficulties in delaying gratification, and inadequate consideration of future implications of their actions (Rubia, Halari, et al., 2009). In a recent meta-analysis of time related implications (Hart et al., 2012), the most reliable deficits in ADHD individuals relative to controls were reduced fMRI activations in areas commonly associated in timing aspects of cognitive operations. During cognitive tasks requiring timing, the left fronto-parieto-cerebellar areas showed less activation. By contrast, right fronto-striatal anomalies were evident during tasks requiring inhibitory and attention functions.

Overall, a picture has emerged suggesting that ADHD deficits may partially represent the effects of a maturational lag in brain development (e.g., El-Sayed, Larsson, Persson, Santosh, & Rydelius, 2003). From a developmental perspective, the volume reductions of whole-brain gray and white matter, frontal cortex, caudate nucleus, and anterior cingulate have been observed in childhood and adolescence, while the reductions in some of these areas ceased to differentiate individuals with ADHD from controls in adolescence (Swanson, Castellanos, Murias, LaHoste, & Kennedy, 1998; Castellanos et al., 2002). In addition, a number of studies appear to suggest that individuals with ADHD have performance patterns or brain responses that appear very similar to patterns produced by younger neurotypical individuals. This hypothesis has received some support from behavioral (Berger, Slobodin, Aboud, Melamed, & Cassuto, 2013), electrophysiological (Clarke, Barry, McCarthy, Selikowitz, & Brown, 2002), and neuroimaging data (Shaw, Eckstrand, et al., 2007; Shaw, Gogtay, et al., 2010; Sato, Hoexter, Castellanos, & Rohde, 2012). In most cases, however, the developmental data are cross-sectional rather than longitudinal. Given considerable individual differences in responses and often small sample sizes, these studies are not ideally suited to identify maturational changes. By contrast, Doehnert, Brandeis, Imhof, Drechsler, and Steinhausen (2010) conducted a longitudinal study examining electrophysiological markers considered to assess the integrity of anterior and posterior attentional brain networks. While the behavioral data appeared to support a maturational lag, the ERP data suggested that these effects were unrelated to variations in neural activation. In other words, the anomalies evident on the ERPs did not resemble responses evident in younger

control children. Similarly, Shaw and colleagues (2006, 2012) followed ADHD and normal control children into early adulthood using longitudinal MRIs. They found delays in regional cortical maturation that appeared to be correlated with key symptoms of ADHD such as hyperactivity and impulsivity (Shaw, Malek, et al., 2012). Notably, lag in the maturation of many cortical surface areas, sometimes as large as two to three years, was especially evident in the right frontal lobe. By extension, children with ADHD are often many years behind their peers in inhibitory control and self-regulation. This finding may again point to a differential importance of right hemisphere dysfunction in the condition (Stefanatos & Wasserstein, 2001). Other anomalies, nevertheless, do remain evident in adulthood and in some cases appear to be predictive of neuropsychological impairment in specific functions. For example, Depue et al. (2010) observed that decreased gray matter volume was correlated with poor processing speed and difficulties with response inhibition in young adults.

An exciting thread in the neuroscience of ADHD concerns evidence suggesting that to some extent, the neural correlates of ADHD can be altered by treatment. A meta-analysis by Hart et al. (2012) confirmed findings from previous studies suggesting that diminished activation in right dorsolateral prefrontal cortex can potentially normalize with long-term psychostimulant treatment. In addition, Ivanov, Murrough, Bansal, Hao, and Peterson (2014) recently found that stimulant use was associated with greater neural development in the left cerebellum.

It has been suggested that the neuroanatomical findings may relate to decreased GABA<sub>A</sub> mediated short-term inhibitory influences that frontal motor regions exert on functions of the basal ganglia (Gilbert et al., 2011; Wu, Gilbert, Shahana, Huddleston, & Mostofsky, 2012). Earlier functional brain imaging studies pointed to hypoperfusion of frontal cortex (Zametkin et al., 1990) and basal ganglia, particularly the caudate nucleus (Lou et al., 1984), and considered this related to reductions in the density of dopamine receptors. Treatment with methylphenidate resulted in increased activity in basal ganglia but decreases in frontal motor areas. More recent functional neuroimaging studies have implicated right inferior frontal cortex in impulse control and its disorders (Aron et al., 2014) and have raised alternative pharmacologic mechanisms, specifically a polymorphism in a noradrenalin transporter gene (Chamberlain, Hampshire, et al., 2009).

## ***Neurobiology of LD—Dyslexia***

### *Genetics of Dyslexia*

Genetic factors are probably the single most important factor in the etiology of dyslexia (Pennington, Gilger, et al., 1991; Gayan & Olson, 1999). Early familial studies suggested that inheritance of reading disability is autosomal dominant (Hallgren, 1950; Finucci, Guthrie, et al., 1976)

with genetic heterogeneity. Early on, the Colorado Family Reading study found that the reading performance of the relatives of children with dyslexia was substantially lower than in controls (DeFries, Singer, Fich, & Lewriter, 1978). In later twin studies, a higher concordance rate for reading disability was noted for monozygotic (68%–100%) compared with dizygotic (20%–38%) twins (DeFries & Alarcon, 1996; DeFries, Alarcon, & Olson, 1997). Taken together, estimates of the risk to first-degree relatives are 35%–45%. Genetic transmission is probably complex and nonexclusive.

Molecular genetic linkage studies in families with dyslexia have identified chromosome regions in which the presence of dyslexia susceptibility genes is suspected, including links on chromosomes 15, 6 (Grigorenko et al., 1997; Fisher et al., 1999; Gayan et al., 1999), and 2 (Fagerheim et al., 1999). Similarly, complete quantitative trait loci analysis based on genome-wide scans for dyslexia in two large independent sets of families found linkage for chromosome 6, 2, 3, and 18 (Fisher et al., 2002). Altogether, linkage analyses in families with dyslexia have reported nine chromosomal regions where the presence of susceptibility genes is suspected: dyslexia susceptibility 1 (DYX1) to dyslexia susceptibility 9 (DYX9), on chromosomes 1, 2, 3, 6, 15, and 18 (Schumacher, Hoffmann, Schmäl, Schulte-Körne, & Nöthen, 2007). The most significant dyslexia candidate genes are DCDC2 and KIAA0319, both identified within DYX2 on chromosome 6p22. DCDC2, associated with reading disability, contains a double cortin homology domain, modulates neuronal development in the brain, is possibly involved in cortical neuron migration, and is expressed in the fetal and adult central nervous system. ROBO1 (i.e., roundabout *Drosophila* homolog1) was discovered through mapping of a translocation in a Finnish family. Another candidate gene, DYX1C1 was cloned in a two-generation Finnish family with a translocation, in a region on chromosome 15. It is expressed in the brain and may be involved in the functional cell state. Almost all these candidate genes are implicated in global brain development processes such as neural migration and axonal guidance. DCDC2, DYX1C1, and KIAA0319 are involved in cell migration.

Importantly, early on, the contribution of phonological coding to the heritability of reading deficit, tested by single-word reading, was established to be high in a twin study, whereas orthographic coding did not contribute to this heritability (Reynolds et al., 1996). In a similar vein, shortly thereafter Grigorenko et al. (1997) demonstrated linkage between phonological awareness, single-word reading and two different chromosomal regions on chromosomes 6 and 15 respectively. The chromosome 6 locus had a role in phonological awareness, and to a lesser extent in single-word reading, whereas the locus on chromosome 15 affected single-word reading only. Other genetic studies with phenotyping support these findings, with a positive linkage between dyslexia and measures of phonological processing with genetic markers on chromosomes 1, 2, 3, 6, 15, and 18 (Cardon et al., 1994; Grigorenko, Wood, Meyer, & Pauls, 2000).

A few studies have implicated shared genetic risk in dyslexia and ADHD. Specifically, twin studies have pointed to evidence that genetic influences that are associated with increased risk for dyslexia also increase risk for inattention symptoms of ADHD (Gayan et al., 2005; Willcutt et al., 2007). However, the specific genetic mutations or variants involved in both disorders have not yet been identified (Smith, 2007).

### *Neural Correlates of Dyslexia*

#### EARLIEST STRUCTURAL FINDINGS

Discovery of structural anatomical asymmetries in the region of the Sylvian fissure and the planum temporale represents some of the earliest research in the neuroscience of dyslexia. Path-breaking work by Geschwind and Levitsky (1968) found the planum temporale to be larger on the left in most people, but not in dyslexics. This loss of the usual hemispheric asymmetry in dyslexia was thought to reflect a failure of the postulated asymmetrical cell loss during gestation. Later, Hynd and colleagues demonstrated reversal of the usual planum temporale asymmetry seen in two-thirds of normal adult brains (Hynd et al., 1995), and found correlations between planum temporale asymmetry patterns and measures of language processing and reading. While such findings were not universal (e.g., Best & Demb, 1999), together these observations led to one of the first theories of dyslexia based on neuroscience: That is, the observed developmental abnormality of the left hemisphere led to loss of dominance for language, developmental language processing abnormality, reading abnormality, a shift of motor dominance from the left to the right hemisphere, and left handedness (Geschwind & Galaburda, 1985; Habib, 2000). Other early studies reported differences in size of the corpus callosum between dyslexics and normally reading individuals (Duara et al., 1991), including a smaller anterior part (genu) in dyslexic children (Hynd et al., 1995).

#### CYTOARCHITECTURAL ABNORMALITIES IN DYSLEXIA

Pathological studies of the brains of people who had developmental dyslexia are uncommon. Nevertheless, three types of neuroanatomic abnormalities have been described: absence of the normal cerebral asymmetries, the presence of cortical developmental abnormalities including microdysgenesis (ectopias and cell loss), and abnormalities of the visual pathways. For example, Geschwind and Galaburda (1985) found abnormalities in (a) the arrangement of neurons from one cortical layer to another or in the same layer, and (b) a high frequency of microdysgenesis (including focal microgyria, neuronal nests, missing or duplicated gyri, and fewer layers and primitive orientation of neurons), in addition to loss of the usual hemispheric asymmetry in the planum temporale. Cohen, Campbell and Yaghai (1989)

also found gliosis. Generally, such microstructure abnormalities are most frequently seen in the temporal lobes, especially on the left. Ectopias and dysplasias suggest anomalous migration during stages of brain development when neurons migrate from their place of birth, in the subcortical periventricular areas, to their appropriate location in the cortex. The second type of brain pathology (i.e., the presence of glial scars) suggests potential injury to the brain and neuronal loss during a later part of brain development in utero.

#### CEREBELLAR ABNORMALITIES IN DYSLEXIA

The cerebellum was traditionally thought to only have a role in motor coordination, motor planning, and motor learning. Recent evidence, however, points to a broader role that includes perceptual and cognitive processes. Functional neuroimaging studies of unimpaired subjects report cerebellar activation during a variety of cognitive tasks, including problem solving, working memory, verb generation, attention tasks, and nonword reading (e.g., Fulbright et al., 1990). Anatomic connections between the cerebellum and the cerebral cortex include connections to the frontal, temporal, and parietal lobes (Middleton & Strick, 1994; Schmahmann, 1996), thereby providing extensive structural underpinning for a role in cognition. These regions are all also areas that are well-known to be engaged during reading. The cerebellum may be affected in both dyslexic adults and children (Zeffiro & Eden, 2001). Notably, a volumetric MRI study of dyslexic children reported significantly smaller brain volume and right anterior lobe of the cerebellum, pars triangularis bilaterally. These anomalies correctly classified 72% of the dyslexic subjects and 88% of controls, and were significantly correlated with reading, spelling, and language measures related to dyslexia (Eckert et al., 2003). Taken together, such findings are consistent with Nicolson, Fawcett and Dean's cerebellar deficit hypothesis of dyslexia (Nicolson, Fawcett, & Dean, 2001). This model proposes that through its role in motor control during the articulation of speech, the cerebellum contributes to the phonological processing deficits, which often cause dyslexia. They also proposed that weakness of the cerebellum can disrupt learning of grapheme-phoneme relationships, and that it contributes to automatization of learned behaviors (Nicolson, Fawcett, & Dean, 2001).

However, considering that the structural anomalies in dyslexia are not isolated to the cerebellum, and that the tasks used in functional imaging studies involved a much broader distributed network, the findings cannot be considered to specifically implicate the cerebellum. Many, if not most, individuals with dyslexia do not have cerebellar signs and most cerebellar patients do not have reading problems. It seems that the effects on cerebellum may reflect a more general pattern of anomalies involving the distributed reading network, so impaired cerebellar function is unlikely a primary causal factor in dyslexia (Stoodley & Stein, 2013).

## STRUCTURAL NEUROIMAGING

VBM is an MRI technique measuring regional cerebral volume and tissue concentration. VBM studies have found decreased brain gray matter in dyslexics—in cerebral, cerebellar, and basal ganglia areas—and at least one study demonstrated smaller total brain volume in the dyslexic subjects (Eckert et al., 2003; Brambati et al., 2004). Anatomical variables that differentiated dyslexic from normal readers were correlated with real word reading, pseudo-word reading, and spelling, the same three language skills on which the dyslexic children were reliably different from the controls.

As described previously, DTI is an MRI method that provides information about integrity of white matter tracts. DTI studies have found that, compared with good readers, poor readers had lower white matter diffusion anisotropy (i.e., FA) in a region of the temporo-parietal lobe. This was seen bilaterally in adults and in the left parietal occipital area in children. Dyslexics also had white matter abnormalities in the region of the supramarginal gyrus. The FA values correlated with reading skills (e.g., Klingberg et al., 2000; Deutsch et al., 2005). Finally, a recent DTI study of children who were poor readers showed functional improvements after intense remediation (Feldman, Yeatmen, Lee, Barde, & Gaman-Bean, 2010). DTI results imply structural abnormalities in the connections between various cortical regions in dyslexia.

## FUNCTIONAL NEUROIMAGING

As phonological processing appears to be a main cause for dyslexia, much of the functional neuroimaging research, both positron emission tomography (PET) and fMRI, has focused on letter- and word-reading tasks that involve phonological processing. Results of such studies, performed mostly in adults, point to reduction of brain activation in response to reading- or language-related tasks. That is, compared with normal readers, dyslexics generally underactivate brain regions, mostly in the left hemisphere and especially in the temporal lobe, inferior parietal cortex (near angular/supramarginal gyrus), and frontal operculum (Brunswick, McCrory, Price, Frith, & Frith, 1999; Rumsey et al., 1997). The studies vary in the exact location and the type of alteration, and presence of activation in corresponding areas of the right hemisphere.

The classic neurologic model for reading—based on studies of patients with acquired alexia—hypothesizes functional linkages between the angular gyrus in the left hemisphere and visual association areas in the occipital and temporal lobes. A number of studies indicate disruption of this system in dyslexia. For example, an early PET study during single-word reading showed strong connectivity between left angular gyrus and other left hemisphere regions in normal controls, but not in dyslexics. This suggested a functional disconnection of the left angular gyrus

from visual areas, Wernicke's area, and the inferior frontal cortex (Horwitz, Rumsey, et al., 1998). Similarly, regional cerebral blood flow (rCBF) in the left angular gyrus, during single-word reading, has been positively correlated with level of reading skill in normal readers. By contrast, these same correlations were negative in dyslexic men, also suggesting an important role for this region in developmental reading disorder (Rumsey et al., 1997). In addition, despite their inherent differences in language systems, dyslexics in French-, Italian-, and English-speaking countries all show less activity than controls at the occipito-temporal junction of the left hemisphere during word processing (Paulesu et al., 2001). Based on such observations, Demonet, Taylor, and Chaixet (2004) suggested that the left inferior temporal region, at the junction between lateral and mesial aspect, is possibly an interface between regions associated with processing visual features of written words, regions involved in complex visual processing, and more dorsal language areas in the middle and superior temporal gyri. Thus it may mediate the visual entry into the linguistic system (Demonet et al., 2004).

fMRI research has identified cortical areas, mostly in the posterior part of the left hemisphere—especially temporal and parietal lobes—that are activated during different stages of “normal” reading. Notably, different regions in the left hemisphere, termed *pathways* (but subsuming both gray and underlying white matter), are engaged at different stages of reading development. The left “dorsal” parietal-attention pathway is activated during reading in children who are learning to read. It includes the angular and supramarginal gyri, which were typically underactive in dyslexic children during PET studies, and mediates a slow, phonologically based, assembly process. There is evidence also for a faster “posterior/ventral” pathway. This left occipital-temporal pathway is centered in the posterior fusiform gyrus, activating a “visual word form” area. The ventral pathway is involved with the development of fluent reading, when word recognition skills become more automatic and direct visual access to the mental lexicon is the predominant reading strategy (Pugh et al., 2000; Shaywitz et al., 2002). It is a rapid whole-word system (McCandliss, Cohen, & Dehaene, 2003) and brain activation in this region increases as reading skill increases (Shaywitz et al., 2002). Activation during reading-related activity can also be found less frequently in the left inferior frontal gyrus connected to the two posterior pathways, implicated in the output of phonological and articulatory aspects (Demonet et al., 2004). Taken together, the left angular, supramarginal, fusiform, and inferior frontal gyri, as well as the “where” and “what” visual pathways, appear essential in reading acquisition and fluent reading.

Consistent with the discussion so far, fMRI and magnetoencephalographic studies of dyslexics have shown reduced activity of multiple left hemisphere brain systems during reading (Horwitz, Rumsey, et al., 1998; Brunswick,

McCrary, Price, Frith, & Frith, 1999; Helenius, Tarkiainen, Cornelissen, Hansen, & Salmelin, 1999; Paulesu et al., 2001). Reduced activation is seen in both the parietotemporal region (including the posterior aspects of the superior and middle temporal gyri, and the supramarginal and the angular gyri) and in the occipital-temporal region of the left hemisphere, including the left fusiform gyrus (Brunswick et al., 1999; Paulesu et al., 2001; Shaywitz et al., 2002). For example, Shaywitz and associates (1998) carried out a detailed investigation of regional metabolic activity in 29 dyslexic adults and 32 controls. fMRI demonstrated significant group-task interactions in four regions: the posterior superior temporal gyrus (Wernicke's area), angular gyrus, striate cortex, and inferior frontal gyrus (Broca's area). Unlike normal readers, dyslexics did not show an increase in activation as phonologic coding demands increased. In addition, differences between the two groups were present also in anterior brain areas where dyslexics showed a pattern of over activation. Meaning Shaywitz et al. (1998) proposed a general explanation of posterior hypo-activation in dyslexics during phonological processing, suggesting a disruption of this system. Similar results were found later in a similar fMRI study done with a large group of normally reading children and dyslexic children (Shaywitz et al., 2002). Activation of left inferior frontal area in dyslexics is more variable—less active in some studies and higher than normal activation in other studies (Brunswick et al., 1999; Paulesu et al., 2001; Pugh et al., 2000). Higher than normal activation suggests the presence of compensatory engagement. Similarly, activation of areas in the right hemisphere during reading related tasks in dyslexics is variable and may be the result of compensation (Demonet et al., 2004).

Another line of research grows out of therapy for reading disorders. A number of studies found that successful reading remediation is accompanied by increased activity in multiple brain areas, bringing activation in these regions closer to that seen in normal readers. For example, Eden and colleagues (2004) described differences in brain activity of adult dyslexic subjects during a phonological manipulation task, before and after behavioral intervention. They found that behavioral improvements were associated with signal increases in left-hemisphere regions usually activated by normal readers (i.e., left parietal cortex and left fusiform cortex), as well as in areas in the right perisylvian. Another fMRI study, in dyslexic children during phonemic processing, demonstrated brain plasticity in response to remediation. Activation in parietal, temporal, frontal, and cerebellar areas partially normalized after treatment. Remediation may also produce additional compensatory activation in other brain regions (Temple, Deutsch, et al., 2003). Thus, successful reading therapy can produce both normalization of brain regions usually involved in reading and compensatory overactivation in other brain changes in other brain areas. Compensatory systems may recruit areas around the inferior frontal gyrus in both hemispheres and perhaps the

right-hemisphere homologue of the left occipital-temporal word form area as well.

#### ELECTROENCEPHALOGRAPHY, EVENT-RELATED POTENTIALS, VISUAL EVOKED POTENTIALS AND MAGNETOENCEPHALOGRAPHY

In general, regular clinical EEG does not reveal specific abnormalities in dyslexic people. Quantitative EEG studies, however, demonstrate increased amount of slower background frequencies, in the theta and delta range, and reduced amount of alpha frequency waves (Harmony et al., 1995). Similarly, Brain Electrical Activity Mapping (BEAM), which provides regional quantitative EEG power spectra, recorded during resting and during cognitive activity, has demonstrated electrophysiological differences between dyslexic and nondyslexic boys. Similar to findings from other methodologies, differences have been found in the left temporal and left posterior quadrant regions and in the frontal areas bilaterally. Findings suggest aberrant neurophysiology is present in dyslexia in a number of cortical areas, anteriorly and posteriorly, and in the right as well as the left hemispheres (Duffy, Denckla, Bartels, Sandini, & Kiessling, 1980).

ERPs are brain electrical responses to specific stimuli, recorded over the scalp at characteristic times after stimulus onset. Mismatch negativity (MMN) is a frontal central negativity that appears when a deviant physical stimulus occurs within a group of ongoing stimuli. It is an automatic change-detecting response, is preattentive, and appears 150–200 milliseconds after the event. Using speech stimuli (i.e., /da//ba /wa) it was found that dyslexic children could not discriminate speech sounds as well as normal readers. Impaired discrimination was associated with diminished MMN, and differences between dyslexics and controls were found for language stimuli but not for pure tone discrimination (Leppanen & Lyytinen, 1997). In another electrophysiological study, dyslexics showed increased latency and smaller amplitude in the P3 wave, an ERP response to an “odd ball” cognitive stimulus (Frank, Seiden, & Napolitano, 1996). Studies using word presentations, including nonsense words and rhyming, demonstrated ERP abnormalities in dyslexics compared with slow readers and ADHD children who read normally. This pattern was manifested mostly in N450 (Ackermann, Riecker, et al., 2001). ERP elicited when words are presented usually include a later surface negative late wave (N400–450). The characteristics of this wave depend on the subject's phonetic skills. Together such findings clearly indicate processing differences in dyslexics which occur at a very fundamental level. Moreover, results are also entirely in line with phonemic processing models of dyslexia.

Magnetoencephalography (MEG) records the magnitude and topography of spontaneous or evoked brain electrical activity. Although it has lesser resolution and lower ability to precisely localize brain activity than fMRI, it has the advantage of ability to time electrical brain activities in response

to stimuli. MEG studies of pseudo-word reading in normal readers show early activity in lateral occipito-temporal regions bilaterally; after a delay, this is followed by near-simultaneous peaks of activity in the fusiform, angular, and middle temporal gyri. Subsequent activity peaks are seen in the right inferior frontal gyrus and later in left inferior frontal gyrus. By contrast, dyslexics failed to activate the left inferior temporo-occipital region, suggesting either an inability to achieve early operations of global word form perception or inefficient immediate phonological extraction (Salmelin, Service, Kiesila, Uutela, & Salonen, 1996; Simos et al., 2008). Furthermore, a left inferior frontal area was activated within 400 milliseconds in dyslexics but not in normal readers, a finding interpreted as a compensatory activity in the dyslexic subjects. Abnormalities in the degree and timing of cortical activation associated with phonological decoding in dyslexics were also found.

Finally, studies using visual evoked potentials (VEP) have also found evidence for visual system abnormalities in dyslexia. VEP is primarily used to assess functional integrity of visual pathways and refers to electrical potentials initiated by presentation of brief visual stimuli and extracted from the EEG. A number of VEP studies suggest that dyslexics generally process visual information more slowly than normal readers. Starting in the retina, the visual system divides into major pathways that can be distinguished based on the kind of information that the pathways conveyed to visual cortex. Two of the major pathways are the magnocellular pathway, which rapidly conveys low contrast information that is important for processing motion (but not color), and the parvocellular system, which conveys high contrast information about color and fine detail. This division continues in the lateral geniculate nucleus, the primary visual cortex, and higher-order visual cortices. The parvocellular system contributes to the ventral or “what” pathway from visual cortex to inferotemporal cortex that is involved in object recognition. The magnocellular system predominantly contributes to the dorsal or “where” pathway from visual cortex to inferior parietal lobule, which is involved in motion analysis and spatial processing. Livingstone, Rosen, Drislane, and Galaburda (1991) found abnormalities in dyslexics’ response to low contrast, high frequency stimuli, which would correspond to letters. The same dyslexic children responded normally to targets of lower frequencies and higher contrast (Livingstone et al., 1991). The pattern of results suggested an abnormality specifically affecting the magnocellular pathway of the visual system. Histological measurement of neurons of the magnocellular and parvocellular layers of the lateral geniculate nucleus in five dyslexic and five control brains also revealed that the usually larger magnocellular cells were smaller in this dyslexic group, complementing the physiological findings. The parvocellular layers in the same brains were normal. However, these findings have not been replicated, and the evidence

for these abnormalities as the basis of dyslexia has not been consistent (Kubova, Kuba, Peregrin, & Novakova, 1996).

## *Neurobiology of LD—Dyscalculia*

### *Genetics of Dyscalculia*

Substantially fewer studies have been directed to understanding genetic contributions to the acquisition of arithmetic skills compared to reading disability. Several molecular genetic studies have shown that certain genetic disorders (e.g., Williams syndrome) are associated with particular deficits in math performance (Mazzocco, 2011). In addition, several family studies have suggested that there is a high prevalence of developmental dyscalculia among siblings (Alarcon, DeFries et al., 1997). Heritability estimates have ranged from .2 to .9 (Oliver & Plomin, 2007). This enormous variability may be explained by the fact that different aspects of mathematic ability may have different genetic contributions. However, according to recent multivariate genetic analyses, the genetic correlation between various aspects of mathematics is .91, suggesting that the same set of genes are largely responsible in different areas of mathematics performance (Kovas, Harlaar, et al., 2005). These genetic influences appear to covary with general cognitive ability and reading skills as well as with other genetic influences. Finally, a number of recent studies have suggested that there is significant longitudinal stability in math performance (Jordan, Hanich, et al., 2003). Shalev et al. (2005), for example found that 95% of children diagnosed with dyscalculia in the fifth grade continued to perform poorly in arithmetic in the 11th grade. This implies likely underlying genetic control.

### *Neural Correlates of Dyscalculia*

#### INTRAPARIETAL SULCUS AND UNDERSTANDING QUANTITY AND SPACE

Behavioral studies in animals reveal number perception, discrimination, and elementary calculation abilities in chimpanzees, showing that a sense of numerosity (the number of objects in a set) exists even in animals. Similar core numerical skills also develop in infants without formal schooling. These types of observations led Dehaene and Cohen (1997) to propose that “number sense” is a basic capacity of the primate brain with dedicated built-in brain circuits, which are engaged in recognizing numerosity. From this perspective, the pathophysiology of dyscalculia is explained by the presence of a selective deficit in the fundamental representation of numerosities (Piazza, Facoetti, et al., 2010). Both human and monkey studies relate the processing of quantity information to the posterior parietal cortex, especially the intraparietal sulcus (IPS; see Dehaene et al., 2004). Electrophysiological recordings from monkey parietal cortex reveal that neurons in the lateral intraparietal cortex respond more

when more objects are presented. Similarly, the human IPS is activated in most neuroimaging studies of number processing and may therefore constitute a central nervous system region for amodal representation of quantity (Dehaene, Piazza, Pinel, & Cohen, 2003). Notably, the IPS activates whether the numbers are spoken or written, and is independent of the form in which numbers appear (Nacchache & Dehaene, 2001; Eger, Sterzer, Russ, Giraud, & Kleinschmidt, 2003).

fMRI studies further demonstrate that the IPS is involved in various aspects of calculation, including processing of numerical quantities, number detection, magnitude comparison, number comparison, and simple quantity manipulations (Dehaene, Dehaene-Lambertz, & Cohen, 1998; Dehaene et al., 2003). Notably, the IPS is more strongly activated in approximate calculation than in exact calculation, and more strongly activated in subtraction than in multiplication (Stanescu-Cosson et al., 2000). Research using fMRI has found that children with DD have less gray matter in the left IPS (e.g., Kucian et al., 2006). Such observations led to the proposal that the IPS, bilaterally, is the crucial area for the representation of quantities (Piazza, Pinel, LeBihan, & Dehaene, 2007), as well as for understanding of some arithmetic operations. Consistent with this, a more recent study has shown that electrical activity in a particular group of IPS nerve cells spiked only when subjects were performing calculations, in the laboratory or outside (Dastjerdi, Ozker, Foster, Rangarajan, & Parvizi, 2013). Quantitative stimuli included simple arithmetic and even quantitative references such as *some more, many, or bigger than the other one* (Dastjerdi et al., 2013).

#### ANGULAR GYRUS AND MATH FACTS AND CALCULATION

The left angular gyrus belongs to the language system, is critical in reading, and may relate more to linguistic than to quantity processing. Yet it is activated during some arithmetic tasks such as retrieval of arithmetic facts, multiplication, and exact calculation (Grabner et al., 2009). Additionally, stronger left angular gyrus activation has been seen on fMRI in mathematically more competent subjects (Grabner, Reishofer, Koschutnig, Ebner, & Parvizi, 2011). Since some arithmetic operations are more dependent on language-based fact retrieval (and thus more on the angular gyrus) and others on quantity processing (and thus on the IPS) (Piazza et al., 2007), it has been proposed that the left angular gyrus supports the retrieval of previously learned and verbally stored arithmetic facts (like multiplication tables) from memory (Grabner et al., 2011). By contrast, in a PET study, multiplication activated a number of brain areas, including the left and right inferior parietal gyri, the left fusiform and lingual gyri, and the right cuneus, as well as preferentially left lenticular nucleus, and precentral and inferior frontal gyri (Dehaene et al., 1996). This suggests that multiplication and comparison may rest on a number of distinct and differing neural and functional networks.

#### INFERIOR PREFRONTAL CORTEX

Neurons in the lateral prefrontal cortex of the monkey are also selectively tuned to numerical rank and numerical quantity, but typically later than IPS neurons (Nieder, Freedman, & Miller, 2002; Nieder, Diester, & Tudusciuc, 2006). In humans, the inferior prefrontal cortex (Stanescu-Cosson et al., 2000) has a function in more demanding mathematical calculations. For example, learning to solve new and complex arithmetic problems which require reasoning and working memory leads to greater activation in the inferior prefrontal gyrus. By contrast the IPS is required for the representation of the magnitudes of the numbers involved, and when comparing them to previously learned facts (Delazar et al., 2003; Krueger et al., 2008). Developmental changes when performing routine calculations include shifting from frontal areas to parietal and temporal-occipital regions.

The IPS, therefore, appears to be pivotal in fundamental appreciation of quantity, irrespective of modality. As such it holds a format-independent representation of numerical magnitude and is systematically engaged in any task drawing on magnitude manipulations—from basic number comparison to complex calculations (Dehaene, Piazza, Pinel, & Cohen, 2003, 2004). By contrast, the left angular gyrus is pivotal in retrieval and/or understanding of verbal mathematical information. Thus the language-based left angular gyrus verbal system and the posterior parietal attention system most probably mediate different aspects of mathematical thinking. For example, the left angular gyrus, as well as the left prefrontal regions, may be mainly implicated in retrieval of arithmetic facts and in exact verbal-memory based and language-dependent calculation, while the IPS is the place for understanding of quantity, relative size and position of figures. Prefrontal regions are likely involved in the more executively demanding aspects of all of the above. Dyscalculia may consequently be the result of a structural brain abnormality in either the size or cellular composition of one of these areas specific to mathematics—or in its connectivity. Similar to dyslexia, compensation may require either recovery of weakened regions or recruitment of other regions.

#### DEVELOPMENTAL ASPECTS AND THE DYSCALCULIC BRAIN

Developmental studies reveal that in tasks involving numerical symbols normal children rely more than adults on prefrontal regions (Rotzer et al., 2008). As children grow up, however, the IPS and the left temporal-parietal cortex become more specialized for numerical magnitude processing and calculation (Ansari, 2008), with a concomitant decrease of reliance on general purpose (frontal) areas. Thus during the process of normal learning of calculation skills, neural organization shifts from one network to the other, similar to that which occurs in learning to read. Developmental changes include the shifting from frontal areas to parietal and temporal-occipital areas. Learning new arithmetic facts

involves primarily the frontal lobes and the IPS, while using previously learned facts involves the left angular gyrus.

Morphometric studies in subjects with developmental dyscalculia have shown reduced gray matter in the left, right, and bilateral IPS and frontal regions (Mazzocco, 2011; Isaacs et al., 2001; Rotzer et al., 2009). Reduced connectivity between parietal areas involved in numerosity, and between these areas and occipito-temporal areas involved in the processing of symbolic number forms, has been demonstrated using DTI (Zhou, Zhang, Zhu, Chen, & Sokabe, 2009). Brain activation studies in dyscalculic children have revealed reduced activation in neural networks, including the IPS, and the middle and inferior frontal gyrus of both hemispheres. Notably, the left IPS, the left inferior frontal gyrus, and the right middle frontal gyrus often seemed to play crucial roles during comparison of numerosities, comparison of number symbols, and arithmetic, since brain activation correlated with accuracy rate in these regions (Price et al., 2007; Mussolin, De Volder et al., 2010). Consequently it has been suggested children with dyscalculia suffer from deficient recruitment of neural resources when processing analog magnitudes of numbers (Kucian et al., 2006). Other studies have shown abnormal brain function and structure in the parietal cortex, especially in the interparietal sulcus (Rubinstein & Henik, 2009; Butterworth, Varma, & Laurilland, 2011).

MEG revealed that, compared to controls with normal mathematical ability, students with dyscalculia had increased neurophysiological activity in inferior and superior parietal regions in the right hemisphere, as well as increased early engagement of prefrontal cortices, while the left hemisphere activity was delayed and did not show the expected task-related changes (Simos et al., 2008). Finally, differences in the IPS region, in isolation or as a part of a more extensive brain abnormality, are also found in a number of genetic conditions associated with mathematical dysfunction, including Turner syndrome, Ffragile X syndrome, and velocardiofacial syndrome (Rivera, Menon, White, Glaser, & Reiss, 2002), and Williams syndrome (Hoeft et al., 2007).

### ***Summary of Neuroscience and Concluding Thoughts***

Despite being extremely heritable, the search for genes conferring risk for ADHD, has proven challenging. Conclusions vary depending on the symptoms chosen and the raters used, although hyperkinesis/impulsivity and inattention are generally dissociated. Importantly, ADHD in most individuals is not due to a single gene variant but is more likely due to potentially thousands of rare variants that disrupt neuronal pathway function. There may also be a few not-yet-identified common genetic variants that disrupt similar regions. Gene expression likely fluctuates with age, sometimes decreasing and at other points increasing. Both genetic and epigenetic variables contribute to the fluctuation. This temporal

variation in genetic expression may account for instances of later onset of this neurodevelopmental disorder.

The posited disruption in neuronal pathway function, in turn, produces a similar endophenotype (i.e., characteristic cognitive, neurophysiological, biochemical, neuroanatomical, and/or neuropsychological profiles) that translates into core traits of the diagnosis. Thus, ADHD is the result of cumulative and complex genetically mediated dysfunction in multiple neural regions or pathways. In addition, expression of some genes can vary with development, which can further complicate clinical presentations and course.

Given the diversity of the genetics associated with the ADHD endophenotype, it is not surprising that similarly diverse neural regions and systems have been identified as correlates. Early structural imaging research used a ROI method that introduces biases in the choice of brain volumes to investigate. Many of these studies focused on frontal regions and failed to provide evidence that observed volumetric differences correlated with specific behaviors evident in the ADHD individuals studied. The importance of obtaining direct behavioral correlates to observed anatomical differences grew as further studies revealed other areas in which volumetric differences existed in individuals with ADHD. These areas expanded to include the basal ganglia, corpus callosum, and cerebellum. Furthermore, differences in the age and the gender composition of the groups contributed to inconsistencies that undermined a consensus regarding which volumetric differences are associated with ADHD (Valera et al., 2007). Later studies incorporated independent and unbiased markers of neurodevelopmental anomalies in ADHD, such as anomalies of cortical density and thickness. More recent functional neuroimaging studies have generally confirmed that behavioral deficits associated with ADHD are most frequently related to poor activation and functional connectivity of circuits in dorsolateral frontal cortex that regulate attention, planning, and working memory. Areas of inferior frontal cortex that mediate cognitive control, including inhibitory control, interference control, and cognitive flexibility also show lack of activation (Pliszka et al., 2006; Cubillo et al., 2010). Lateral orbital and ventromedial prefrontal cortex circuitry is involved in emotional regulation and emotion (Price, Carmichael, & Drevets, 1996; Best, Williams, & Coccaro, 2002). These areas have strong connections with subcortical structures involved in processing emotion such as the amygdala, hippocampus, and nucleus accumbens. Default mode network dysregulation, or differential right hemisphere dysfunction, are other proposed neural correlates of ADHD.

Continuing limitations of this body of research exist. Firstly, the vast majority of studies have predominantly or exclusively studied males with ADHD (Yang et al., 2008). Given known gender differences in brain development (Lenroot et al., 2007), it is unclear whether the morphological anomalies identified in these reports are apparent or differ in substantial ways in females with ADHD. Qiu et al. (2009),

for example, it is recently reported that volumetric decreases in specific regions of putamen and caudate observed in males were not apparent in females with ADHD. It has also been noted that frontal lobe volumetric differences observed in males with ADHD were equivocal among females with ADHD (Castellanos, Giedd, et al., 2001). Secondly, concerns have also been raised that the observed structural differences may be epiphenomena of the behavioral symptoms. Some of the identified structural changes may reflect the effects of having problems with attention and impulse control. While it is no doubt important to consider the environmental effects, several lines of evidence suggest that these factors cannot be a full account of the findings. A study by Durston et al. (2004), for example, allayed these concerns to some extent by showing that affected first-degree relatives exhibited similar but more subtle volumetric differences in both gray and white matter volume. This suggested that observed morphological differences in ADHD were based more in genetic than epigenetic factors. Similarly, Ent et al. (2007) contrasted volume loss in concordant and discordant twins and found that the concordant high-risk pairs showed volume loss in orbitofrontal subdivisions. High-risk members from the discordant twin pairs exhibited volume reduction in the right inferior dorsolateral prefrontal cortex. In addition, the posterior corpus callosum was compromised in concordant high-risk pairs only. Ent et al.'s findings indicated that different components of the distributed action-attentional network system are differentially affected by genetic versus environmental influences.

There are similar concerns regarding LD. Genes that affect a quantitatively measured trait such as reading are termed *quantitative trait loci* (QTL). Because reading is a complex construct, reading disability may have a polygenetic and multifactorial etiology and no single QTL is either necessary, nor sufficient, to cause the disorder (McGrath et al., 2006). A number of QTL genes likely underlie the transmission of both the normal variations in reading skill and dyslexia. Different genes may be implicated in different aspects of the reading disorder, with the final result being a deficit in the ability to integrate the information needed for learning to read (Mitchell, 2011). However, those genes that affect various aspects of phonological processing (e.g., coding, awareness, discrimination, or expression) show the most consistent linkage with dyslexia. Finally, since dyscalculia is associated with some genetic conditions, general heritability of this LD is also likely.

Dyslexia is associated with both macroscopic and microscopic structural abnormalities, preferentially evident in the left hemisphere. The earliest findings implicated gross anatomical asymmetries in the planum temporale in superior posterior temporal cortex, as well as cytoarchitectural abnormalities in structure and/or cell migration. Subsequently, other abnormalities have been observed in white matter tracts such as the cerebellum and/or the corpus callosum. Functional neuroimaging has supplemented this research and most consistently identified dysfunction in the

left hemisphere fusiform gyrus, angular gyrus, and supra-marginal gyrus, and bilaterally in inferior frontal gyri. These regions are part of two posterior visual pathways (i.e., dorsal or ventral, where or what, slow effortful or whole word), which engage differentially depending on the stage of learning to read and/or the fluency/automaticity of decoding. Electrophysiological studies document disturbances in either phonemic processing (via MEG) and/or visual processing (VEP), consistent with both linguistic and visual vulnerabilities. Notably, remediation/compensation is associated with normalization of regional brain activation, as well as engagement of ancillary regions, including on the right.

The neurocognitive deficits in dyscalculia include impaired understanding of quantity and space, impaired recall of math facts and calculation, and general attention to execution and sequencing. Correlated with these are the left IPS, the left anterior gyrus, and the inferior prefrontal cortex, respectively. Given the overlap between some of these regions and those implicated in dyslexia (e.g., left angular gyrus, inferior prefrontal cortex) and the close proximity between others (IPS and supramarginal gyrus), comorbidity between dyscalculia seems highly probable but not inevitable. Moreover, since (as in dyslexia) different neural pathways are activated or required at different times or for different stages, it is not surprising that clinical manifestations and even diagnoses change over time.

This chapter has reviewed the history of conceptualization and diagnosis of these extremely common neurodevelopmental disorders, their presentations across the lifespan, and the underlying neuroscience. When possible threatment options have been discussed, a number of issues are especially challenging. For example, diagnosis of LD in the high aptitude individual remains controversial. In addition, many of these conditions co-exist, leading to shifting diagnosis over time, depending on the developmental challenges the individual is faced with as well as their underlying neural maturation. Research in dyslexia, dyscalculia and dysgraphia is greatly limited by poor consensus regarding diagnosis. Such complications make generalization between studies extraordinarily difficult. With coordinated work between disciplines and researchers, presumably these complicated issues will become clearer.

## Notes

- 1 One of the authors of this chapter, R. Mapou, has proposed a definition for LD (2009a) that responds to the different needs of adults and attempts to incorporate concepts from neuropsychology and the 1990 Americans with Disabilities Act.
- 2 The DSM-5 recognized this concern and lowered the number of required symptoms for adults.
- 3 Thanks to Jessica Moriah Dean for technical assistance.

# 15 Consciousness

## Disorders, Assessment, and Intervention

*Kathleen T. Bechtold and Megan M. Hosey*

*I think therefore I am.*

—Descartes

Human consciousness is a complex and relatively poorly understood process of the brain. The majority of clinical attention has been given to the disorders of consciousness that occur most commonly with severe brain trauma leading to severe arousal/vigilance issues. However, consciousness extends well beyond basic arousal to some of the most

complex abilities of the brain to understand the self in ways that are possibly unique to humans. Consciousness is not only the basic level of alertness, but also the ability of the brain to have a concept of self, a personal past and future, and an awareness of one's strengths and weaknesses.

When one delves into the cognitive psychology and neuroscience literature, a rich tapestry unfolds to reveal the many colors and textures of consciousness. However, digesting the theoretical models, the comparative animal studies, and the human case studies leads to many more questions than answers about consciousness and how we need to address impairments in consciousness clinically. To begin the discussion, we must define what we are talking about by establishing our terminology. It may appear obvious at first glance what consciousness is, but once one steps back to truly contemplate consciousness, the complexities arise and one's philosophical and religious biases may sneak in. Although the contemplation of consciousness is firmly rooted historically in philosophy and religion (see Figure 15.1), this is not for discussion in this text. The nod to Descartes at the beginning of this chapter is more in acknowledgement of the long history in which humans have contemplated their own selves, than any foreshadowing of a philosophical bent to the discussion to come. Nor will we delve into theoretical physics and the attempts to apply quantum theory to the understanding of consciousness. The interested reader is encouraged to see Hameroff and Penrose (2013) for a discussion of Orch-OR theory and Pribram (1991) for a discussion of holonomic brain theory. For the sake of the current discussion, we will restrict our digestion to the realm of cognitive science, neuroscience, neuropsychology, and rehabilitation with the goal of trying to understand consciousness enough (given the state of the field) to guide clinical practice with individuals with neuropathology.

Once we have defined our terminology and taken a brief walk through both evolution and human development, then we can discuss what we know about the variety of disorders of consciousness and how as neuropsychologists we can attempt to assess and intervene to assist individuals in truly engaging in life after the onset of neuropathology. Finally, we will make some suggestions about where the field should go from here to push the envelope of our understanding of human consciousness in order to broaden our understanding

Figure 15.1 17th century conceptualization of consciousness

Source: Wellcome Images ([http://wellcomeimages.org/indexplus/obf\\_images/58/ea/0f84202fa8ff58b9bc4819f8fe04.jpg](http://wellcomeimages.org/indexplus/obf_images/58/ea/0f84202fa8ff58b9bc4819f8fe04.jpg))

of the brain and how we can better address the needs of our patients clinically.

### Consciousness and Its Elements

Consciousness is a very complex and somewhat abstruse subject that challenges us all to think about our ability to conceive, plot, plan, reflect, to be “on-line.” Consciousness broadly defined for the current discussion is the state of being aware of one’s thinking and being. It has been defined by terms such as *sentience*, *awareness*, *subjectivity*, and *selfhood* (Farthing, 1992). In an attempt to capture the essence of consciousness, in his *Search after Truth*, Descartes refers to consciousness as *internal testimony* (Heinämaa, Lähteenmäki, & Remes, 2007). It is likely that all these terms are accurate as they each capture some aspect of consciousness: the human ability to have a sense of self; to be aware and experience the world around through our senses; and to think about ourselves, our past, and our future.

In order to define consciousness, particularly for understanding disorders of consciousness, one must identify the underlying processes. There is somewhat a forest for the trees issue though, and so the reader is asked to keep in mind that we know so little about consciousness that we get caught up in mostly focusing on the elements of consciousness rather than understanding the overarching construct. With that said, we may not be thwarted in our aim of understanding how disorders of consciousness manifest and thus still be able to establish a framework to guide our discussion. Such a framework incorporates the elements of consciousness and captures the interrelationship among the elements, which we propose is hierarchical in nature with the elements building upon one another such that higher order, more complex processes are reliant on intact (at least to some degree) lower-level processes (see Figure 15.2).

### Arousal/Vigilance

Consciousness at its birth relies upon a certain level of arousal. Where does consciousness begin? It is not known, or more accurately, it is open for debate. What is known is

Figure 15.2 Hierarchical model of the elements of consciousness

that neuropathology and chemical and mechanical effects on the brain can render a human *unconscious* or to lack sufficient arousal and the ability to have a sense of self, to be aware and experience the world around through the senses, and to think about his or herself, past, and future. There is a threshold level of neuronal excitement that must be crossed for consciousness to be birthed. *Vigilance* refers to this level of excitement in cortical and thalamic networks that is the foundational element of consciousness. It is a state with many gradations and thus has been referred to as *intransitive consciousness* (for a review, see Dehaene, 2014).

### Sensory Perception

Our senses are our gateway to experiencing the world around us. They allow us to compare what we see to what we tactilely feel to what we hear to what we taste and smell. However, we think one would be hard pressed to argue that an individual who has impairment in one or more of the senses has an impairment in consciousness. With that said, the senses are needed to some degree in order for the individual to develop a sense of self that is based upon experiencing and interacting in the world. Molyneux’s problem—a thought experiment posed to John Locke by William Molyneux (Locke, 1690)—gives us a chance to consider sensory input in light of our ability to experience the world around us (see Table 15.1).

Table 15.1 Molyneux’s problem (Locke, 1690)

I shall here insert a problem of that very ingenious and studious promoter of real knowledge, the learned and worthy Mr. Molyneux, which he was pleased to send me in a letter some months since; and it is this:—“Suppose a man born blind, and now adult, and taught by his touch to distinguish between a cube and a sphere of the same metal, and nighly of the same bigness, so as to tell, when he felt one and the other, which is the cube, which the sphere. Suppose then the cube and sphere placed on a table, and the blind man be made to see: quare, whether by his sight, before he touched them, he could now distinguish and tell which is the globe, which the cube?” To which the acute and judicious proposer answers, “Not. For, though he has obtained the experience of how a globe, how a cube affects his touch, yet he has not yet obtained the experience, that what affects his touch so or so, must affect his sight so or so; or that a protuberant angle in the cube, that pressed his hand unequally, shall appear to his eye as it does in the cube.”—I agree with this thinking gentleman, whom I am proud to call my friend, in his answer to this problem; and am of opinion that the blind man, at first sight, would not be able with certainty to say which was the globe, which the cube, whilst he only saw them; though he could unerringly name them by his touch, and certainly distinguish them by the difference of their figures felt. This I have set down, and leave with my reader, as an occasion for him to consider how much he may be beholden to experience, improvement, and acquired notions, where he thinks he had not the least use of, or help from them. And the rather, because this observing gentleman further adds, that “having, upon the occasion of my book, proposed this to divers very ingenious men, he hardly ever met with one that at first gave the answer to it which he thinks true, till by hearing his reasons they were convinced.”

Molyneux was highlighting the difference between our perceptions and true understanding of what we are perceiving. Research has demonstrated that Molyneux and Locke were indeed correct in the sense that individuals who are blind and then gain sight have no understanding of what they are perceiving through sight (Held et al., 2011). However, there is greater complexity here because our brains do not operate based solely on unimodal information. The adaptivity of human behavior is rooted in the integration of sensory information to finely tune our behavior. Our senses not only allow us to *access* the world around us, they allow us to have feedback in-the-moment, which can guide our behavior. Without information from our senses, information from our world around us cannot be perceived and thus cannot inform our conscious concept of that world and ourselves. There is no information to guide behavior or sense of self. Is it possible that if a child is restricted in his or her experiences or incurs injury to the brain during key developmental periods leading to sensory impairment that he or she may be impaired in some aspects of consciousness? Is autism a disorder of consciousness because of the limitations imposed by the impairments in processing sensory information? It is clear that how individuals with autism experience the world around them differently from individuals without autism. Again, we have no clear answers, but for understanding how to approach assessment and interventions of individuals that have suffered an insult to the brain or have a developmental disorder, we must consider the possible impact of sensory impairment on consciousness. One might argue that in order to have awareness of being, one must have a concept of the relationship between others and the world around her- or himself. Without sensory input, that would not be possible. Thus for the current discussion, we assume that intact sensory input in some way shape or form is needed in order for the human being to gain information about his or her environment and to interact with that environment in meaningful ways and have a sense of self.

### ***Attention and Conscious Access***

In order to process information in our internal environment (in our minds) and our external environment (the world around us), we need to attend to that internal or external environment. When we focus our mental resources on a particular object or thought, we can bring that information into our awareness and report it to others. Attention is controlled by the individual. The focus of attention depends upon what that individual is drawn to. There can be incredible occurrences that pass right before our eyes that do not gain our attention and thus do not enter consciousness. Absorption of our consciousness on one point leads to blindness, of sorts, to the rest of the external world, which has been dubbed *inattention blindness* (for a larger discussion, see Dehaene, 2014). A classic demonstration of inattention blindness is the “invisible gorilla experiment” (Simons & Chabris, 1999),

which everyone should experience at least once ([www.theinvisiblegorilla.com/gorilla\\_experiment.html](http://www.theinvisiblegorilla.com/gorilla_experiment.html)). This is one of many reasons that humans are not good eyewitnesses. What information is processed consciously depends upon where we have focused our attention, what information we have accessed. It is the *access* of the information into awareness that allows one to perceive it, contemplate it, talk about it, act in response to it. This process of *conscious access* relies upon sufficient arousal of the system and attention of cognitive resources onto the information (Dehaene, 2014). Without conscious access, the ability to process information is extremely limited.

### ***Knowing (Semantic Memory)***

The role of memory in consciousness has been theorized for centuries. The sense of self is bound to the continuity of self even with changes in the physical body through development and aging and the evolution of personality, skills, and abilities across time (Locke, 1690; Searle, 2005). For continuity of self, we must have memory to record the events, to record what we *know* about ourselves and the world around us and to update the knowledge as needed across time. That which is *known* is mentally experienced and can be behaviorally expressed, although behavioral expression is not necessary. This catalogue of information is the semantic (declarative) memory system, which is a large, complex, multimodal system capable of fast, single-trial encoding (Squire, 1992). The information from this system has truth value, is accessible, and can form the basis for inferences about other objects and events in the world; however, it is not time-linked and is not dependent on any sense of self, although self-relevant information is stored in this system (Tulving, 2005).

### ***Remembering (Episodic Memory)***

Remembering is the ability to link the episodes of life with time and place such that one can think about past experiences (whether thought about or directly experienced) and possible future experiences (Tulving, 1985). As far as we know, no other species has the ability to mentally travel into the past and into the future. Tulving has long grappled with the potential uniqueness of the human episodic memory system and how it affords us the ability to conceptualize self in light of having a past and a future (for in-depth discussion, see Tulving, 1985). He argues that episodic memory allows mental time travel, which gives each of us a sense of *self*; we are the *owner* of our past and future experiences. Conscious recollection of personal happenings is the essence of *autonoesis* and what Tulving calls *autonoetic consciousness* (Tulving, 1985). Episodic memory is reliant upon semantic knowing (e.g., knowledge of ourselves and the world), but it has the distinct process of remembering the events, the episodes in the context of time and place. Without remembering, an

individual does not have the capacity to think in terms of his or her past or the future and understand the implications of the past for the future.

### ***Inner Speech and Self-Monitoring***

As humans traverse daily life experiences, there is a running internal monologue. We think through problems, analyze the situation at hand, think about what has happened, and muse to ourselves—all without others knowing what is going on inside our heads. From time to time, we may even vocalize the “voice in our heads” but most frequently, we mentally process what has caught our attention. This “inner speech” is the silent production of words in one’s mind and is argued to play a key role in human consciousness at the interchange between language and thought (Morin, 2011). There is evidence that inner speech plays a notable role in various cognitive functions, including working memory (Marvel & Desmond, 2012), episodic memory retrieval (Morin, 2011), planning (Sokolov, 1972), and self-awareness (Morin & Michaud, 2007). The inner monologue may be a foundational aspect of our ability to self-monitor and direct behavior, such as for planning of behavior (Agnati et al., 2012), problem solving (Baldo et al., 2005), and task switching (Emerson & Miyake, 2003). However, it also can be maladaptive by distracting cognitive resources and mental energy from behaviors that are productive, such as the case in depressive rumination (Davis & Nolen-Hoeksema, 2000) or the inner voices of schizophrenia (Farrer & Franck, 2007).

Searle (2005) argues that one element of consciousness that underlies our sense of self is our ability to guide/determine our own behavior, our *free will*, our inner voice that guides our behavior. When I consciously engage in a voluntary action, I am choosing to do this action versus another. Thus, I am mindfully directing my behavior. In the field of psychology, there has been increased interest in *mindfulness* with the goal of guiding humans to think before they act and be aware of how thoughts and feelings drive behavior and to develop more healthy response patterns. When impairments in working memory, episodic memory, or awareness are present, it is likely that the individual is going to be challenged in his or her ability to be mindful. The individual’s inner voice may not have access to accurate, up-to-date information. That is not to say that individuals with neurodevelopmental disorders or acquired brain injuries cannot be mindful. However, how they are likely to be challenged in being mindful and self-monitoring their behavior.

### ***Self-Awareness***

The ability to know oneself, one’s abilities, strengths, weaknesses is deeply reliant upon all the other elements of consciousness, from the very basic understanding of our own motor and sensory functioning to the very complex

comprehension of our cognitive-behavioral abilities, idiosyncrasies, foibles, and talents. Without feedback through our sensory systems of our interactions with the world around us, we would know very little about ourselves or even have a sense of self. And what we *know* about ourselves is stored in our semantic memory system (e.g., “I know how to play volleyball.” “I am the mother of two children.” “I have tasted Coche-Dury Meursault Chardonnay from the Burgundy region of France”). But in order to judge meaning of one’s abilities, to determine whether something is a strength or weakness, to determine personal likes and dislikes, the individual must have the ability to review the past for episodes of success and failure and project into the future consequences of behavior (“I play volleyball well because I remembering playing in many leagues and winning quite frequently.” “I am a mother because I remember birthing and taking care of my daughters over the years and will do so for many years to come.” “I remember going to Beaune, France, and tasting the beautiful nutty, creamy, buttery flavor of the Meursault Chardonnay, which I very much enjoyed”). Although the individual may have a distorted view of her or his strengths or weaknesses, likes and dislikes, these judgments are still grounded in what the individual *knows*, *remembers*, and *predicts* about her or his own behavior and experiences. The meaningfulness of behavior for that person influences her or his interpretation of the behavior on a continuum of strengths to weaknesses. If one does not find meaning in a behavior, then she will not incorporate that behavior into her self-definition and sense of self. That does not imply that she cannot answer the question can she do X activity or does she have Y skill, but rather that in her self-conceptualization and self-description, she will not include those skills and attributes and note them as strengths or weaknesses or likes or dislikes.

### **A Little Bit About the Neuroscience of Consciousness**

There is little to no consensus on how the brain produces consciousness. For the interested reader who would like to grapple a little more in depth how a biologic process can result in the production of *self*, the experience of *me*, the ability to time travel from one’s past and into the future, there have been a number of conferences that have resulted in summary works (Boly et al., 2013; Feinberg & Keenan, 2005; Terrace & Metcalfe, 2005). However, at least a cursory understanding of the possible neuroscience of consciousness will assist in the understanding of how disorders of consciousness develop with the onset of neuropathology.

There have been some critical findings over the last three decades that help us ground consciousness in brain functioning (rather than some philosophical or religious conceptualization of a soul). As the basis of consciousness, arousal is related to the functioning of the reticular formation, specific brain stem nuclei, and thalamo-cortical projections.

However, as we consider the broader conceptualization of consciousness, the overarching evidence supports that consciousness is not “located” somewhere in the brain (hearken back to Descartes’ thought of the pineal gland being the seat of the soul), but rather is the product of integration of information from across the brain. It is produced by the brain’s ability to integrate sensory, memory, emotional information from both hemispheres of the brain to create a unified experience. As argued by Searle (2005), consciousness has a unified field that allows the individual to incorporate the whole experience (forest) rather than just experience the constituent parts (trees). To make this more tangible, consider a daily life experience, such as eating a delicious meal in a restaurant and carrying on a conversation with your dinner companion. The unified field of consciousness allows you to experience the taste of the food while experiencing the conversation within the beautiful setting (forest) as opposed to sitting in a restaurant, eating the food, and having the conversation (trees). The unified field allows humans to have a higher level, integrated experience.

Sperry (1984) also saw human consciousness and unified sense of self as the product of the sum rather than the constituent parts and argued that consciousness is not in the nerve cells or in the molecules or the atoms of brain processing. He concluded that consciousness is the product of the dynamic emergence of brain activity and to be the “crowning achievement . . . of evolution” (Sperry, 1977). There is interesting evidence of this unified sense of self in the split-brain experiments of Sperry and Gazzaniga (for a review, see Gazzaniga, 1985), who demonstrated that cutting the corpus callosum leads to patients to demonstrating behaviors of having two separate conscious fields.

This type of advanced higher order integration of information would need to be subserved by the phylogenetically most advanced regions of the brain. Evolutionarily, rostral migration of functions fostered the forebrain—and in humans, the cerebral cortex—to become those regions (Sanides, 1975) with the prefrontal cortex subserving the highest order behavior (Mesulam, 2002). The human frontal system is a heteromodal brain region, which is the most well integrated, most complex, and least reflexive and hard wired (Mesulam, 2002). The human frontal systems are ontologically developed later (Lebel, Walker, Leemans, Phillips, & Beaulieu, 2008), are the most well developed in humans (Semendeferi, Lu, Schenker, & Damásio, 2002), and when damage occurs, it leads to the impairments in the elements of consciousness.

Researchers have attempted to identify the circuitry by conducting innovative studies of self-awareness of own mental states, first-perspective, self-concept, autobiographical memory, and sense of agency (for a review, see Gillihan & Farah, 2005). Overall, research on the underlying neural circuitry of consciousness consistently reveals an integration between limbic regions and the frontal systems. There are neuronal subtypes in these regions (anterior cingulate and

insular cortex) called *Von Economo neurons* (VENs) that are found in the greatest numbers in the human brain, but also have been identified in great apes (Allman et al., 2010), cetaceans (Butti et al., 2009), and elephants (Hakeem et al., 2009)—all species that have been shown to have some level of self-awareness (Byrne & Bates, 2010; Craig, 2009). Investigations of clinical populations have revealed that individuals with fronto-temporal dementia (FTD) have a significantly reduced number of VENs. The behavioral variant of this dementia is characterized by social deterioration and impaired self-monitoring of behavior (Seeley et al., 2010), whereas individuals with autism have a larger number of VENs and this disorder is characterized by dysfunctional social interactions and impaired self-awareness (Santos et al., 2010). Although further work needs to be conducted, there are interesting findings implicating the role of the anterior cingulate (e.g., Lane, Fink, Chau, & Donlan, 1997) and frontal operculum (e.g., Gusnard, Akbudak, Shulman, & Raichle, 2001). As noted previously, it is unlikely that consciousness resides in one location in the brain. A conscious sense of self and thinking about one’s thinking, past, and future is not a combination of any brain regions per se, but an integration of information not only in the moment of processing, but also in the amalgamation of information stored in the brain over time, which combines to create a unity of selfness (Pinker, 1997).

### Clinical Disorders of Consciousness

Within the field of neuropsychology, we have applied the greatest efforts to understanding and creating clinical assessments and interventions for the least sophisticated but foundational elements of consciousness (i.e., arousal, conscious access, sensory perception, attention), whereas there is a relative dearth of information regarding the higher level, more complex elements of episodic memory, self-monitoring, and self-awareness. It is true that if our patients are not able to maintain a sufficient level of arousal or attend well to the world around them, then it is challenging for those patients to interact in meaningful ways. It is also true that these more foundational elements of consciousness are more tangible and behaviorally manifested. Thus, it has been of great importance, interest, and to some degree, relative ease to study and develop assessments and interventions to address impairments in arousal, sensory perception, conscious access, and attention. However, one might argue that the human ability to navigate daily life successfully is highly reliant upon the higher order elements of consciousness and so the relative inattention to these elements is somewhat surprising. Of course, the complexity of these elements and their inherent subjectivity has made objective experimentation of them challenging, to say the least (Dehaene, 2014). The reader should be mindful of this state of the field when digesting the following discussion of assessment and intervention for disorders of consciousness.

### Arousal Disorders

After brain trauma, there are a range of disorders of impaired consciousness that are characterized by reduced arousal and ability to process external and internal stimuli at the basic level (for a review, see Laureys & Schiff, 2012). The three main types of arousal disorders are coma, vegetative state (VS), and minimally conscious state (MCS). Within the last two decades, work groups and conferences have been assembled to aggregate diagnostic and intervention guidelines for the appropriate treatment of individuals with persistent arousal disorders of consciousness, including VS and MCS. The International Working Party on the Management of the Vegetative State (Andrews, 1996), the American Academy of Neurology (The Multi-Society Task Force on PVS, 1994), and the American Congress of Rehabilitation Medicine (Giacino et al., 1995) each published position statements about nomenclature, diagnosis, and management of these two persistent arousal disorders. In an attempt to rectify the differences in recommendations among these position statements for VS and MCS and provide evidence-based guidelines, the Aspen Neurobehavioral Conference was organized (Giacino et al., 1997; Giacino et al., 2002). The participants concluded that there is a paucity of research regarding assessment and intervention, thus precluding the development of evidence-based guidelines. Instead, they developed consensus-based guidelines

identifying behaviors consistent with those in MCS or VS (see Table 15.2).

It is important to consider that initial studies examining the functional outcomes and mortality of individuals with severe arousal disorders were bleak. These studies reported high death rates, short windows of recovery before reaching “plateau,” and minimal need for rehabilitation in patients with minimal or vegetative consciousness. However, recent studies with larger sample sizes reveal that many patients admitted to the hospital with severe arousal disorders can benefit from rehabilitation interventions, and can regain higher levels of consciousness and continue to demonstrate gains for at least two years (Whyte & Nakase-Richardson, 2013; Whyte et al. 2013). These recent findings highlight the importance of proper diagnosis and treatment in arousal disorders, so that families can be adequately prepared to make decisions for loved ones and so that patients receive the treatment they need to achieve maximal recovery. Additionally, every clinician should bear in mind that there is so little that is known about recovery from severe arousal disorders that we cannot conclude the outcome for any one person based upon the existing literature. The interested reader is referred to a *New York Times* article documenting the recovery course of Terry Willis, a man who had remained in an MCS for 19 years when he began to spontaneously and consistently communicate with family members (Carey, 2006).

Table 15.2 Characteristics of disorders of arousal and attention and conscious access

Diagnosis	Arousal	Attention	Conscious Access	Sleep Cycles	Communication	Sensory-Motor Function	Auditory Processing	Visual Processing
<b>Coma</b>	None	None	None	No	None	Postural responses	None	None
<b>VS</b>	None	None	None	Yes	None; vocalizations but no language	Nonpurposeful, posturing, withdrawal from noxious stimuli	Startle response, brief orienting to sound	None
<b>MCS</b>	Partial	Partial	Minimal	Yes	Inconsistent, intelligible, stimulus reliant	Localize noxious stimuli, reach for objects, automatic movements	Localize sound location, inconsistent response to commands	Visual fixation, visual pursuit
<b>Post-Confusional State</b>	Extended periods of wakefulness	Inconsistent, waxing/waning	Variable	Yes	Speaks in sentences intelligibly, reveals disorganized thinking, sometimes perseverative	Use of objects, may be slowed or hyperactive	Easily orient and recognize sounds, consistent one-step command following	Object recognition
<b>Delirium</b>	Extended periods of wakefulness	Inconsistent, waxing/waning	Variable	Yes	Intelligible, may be disorganized and difficult to interpret	Use of objects, May be slowed or hyperactive	Easily orient and recognize sounds, reductions in multi-step command following	Fixation, pursuit, potential for presence of hallucinations

### Coma

*Coma* refers to a state in which individuals maintain neither arousal nor awareness. Eyes are closed during coma, and patients do not demonstrate periods of arousal or wakefulness in response to even noxious stimuli. Additionally, there is no evidence of sleep/wake cycle on electroencephalogram. This state must persist for at least one hour, lest it be categorized as concussion or another transitory change in consciousness. After several days or weeks of survival in this state, individuals with a coma diagnosis usually progress to improved levels of consciousness. See Table 15.2 for general diagnostic criteria and behaviors exhibited during coma. For additional clinical diagnostic coma criteria, refer to Plum and Posner (1982), which is a seminal article with the most widely regarded criterion.

### Vegetative State

It should first be noted that a current trend in discussions of disorders of consciousness, the term *vegetative state* is increasingly considered a depreciatory term. Although providers initially coined the term to be consistent with patients' behavior during this state (i.e., "to vegetate"), patients, their families and sensitive clinicians have been aware of the fact that it may be confused with or used as a noun (e.g., "my loved one is a vegetable"). New terminology has been brought to the fore by the European Task Force on Disorders of Consciousness and *unresponsive wakefulness syndrome* is under consideration (Laureys et al., 2010). For the current discussion, we will persist with the use of VS.

VS refers to the state of consciousness in which an individual displays some signs of arousal, but demonstrates no signs of awareness of self or the environment. In this state, patients will open their eyes, have intact sleep-wake cycles, have preserved autonomic and hypothalamic function, and maintain cranial nerve reflexes, but make no reproducible or voluntary response to environmental stimuli, demonstrate no ability to interact with others, and demonstrate no language comprehension or expression. These patients may demonstrate some behavioral signs of arousal, including blinking, eye movement, sound utterance, poorly sustained visual pursuit, yawn, swallowing of saliva, nonpurposeful movement, startle myoclonus, auditory startle, withdrawal from painful stimuli, and facial expressions (Jennett & Plum, 1972; Bernat, 2006).

### Minimally Conscious State

MCS involves partial recovery of awareness (sensory processing and attention) and arousal (Giacino et al., 2002, 2014). Generally, individuals in MCS are able to demonstrate purposeful behaviors, but are unable to consistently communicate effectively. One working group has suggested still further subcategorization of individuals in MCS. Depending on the

individual's behaviors, they may be categorized as MCS plus (MCS+) or MCS minus (MCS; see Bruno, Vanhaudenhuyse, Thibaut, Moonen, & Laureys, 2011). Individuals who engage in nonreflexive movement, orient to noxious stimuli, smile or cry in response to relevant stimuli, or track visual stimuli in the environment are categorized as MCS-. Alternatively, individuals who would be diagnosed MCS+ are inconsistently able to follow simple commands, speak intelligibly, and can provide yes/no responses.

### Assessment in Coma, VS, and MCS

As one may have gathered, proper assessment and diagnosis of individuals with severe arousal disorders can be challenging as it relies almost entirely on behavioral observation of the patient. As of yet, there is no "gold standard" in this type of evaluation. Nevertheless, accurately characterizing an individual's level of consciousness through evaluation of the individual's awareness of self and the environment, and ability to interact with others and the environment, is a critical aspect of care and recovery. For thorough guidelines and review of clinical criteria and measures most useful in assessment and diagnosis of arousal disorders, the reader is referred to the most recent State of the Science review (Giacino, Fins, Laureys, & Schiff, 2014).

Assessment of severe arousal disorders includes behavioral assessment that is guided by structured instruments, such as neurobehavioral rating scales and individualized quantitative behavioral assessment (IQBA). There are several neurobehavioral rating scales with acceptable levels of reliability and validity. However, there has not been extensive research to yield information about sensitivity, specificity, or predictive outcome. The most widely used measure continues to be the Glasgow Coma Scale (Teasdale & Jennett, 1974). This is a 15-point scale that assesses motor, verbal, and eye motor responses to determine level of functioning for each. Researchers have attempted to raise caution about this measure, as all-too-often practitioners use the total score, rather than scores for each of the three areas of function. This can be highly misleading, particularly regarding patients who are unable to respond sufficiently for reasons other than brain stem injury. For example, those who are ventilated, sedated, when eyes are swollen shut, or when they have been paralyzed during injury are unable to mount sufficient responses, but they may not meet criteria for coma or VS (Majerus, Gill-Thwaites, Andrews, & Laureys, 2005). Other promising and specified neurobehavioral rating scales include the Coma Recovery Scale-Revised (CRS-R; Giacino, Kalmar, & Whyte, 2004) and the Sensory Modality Assessment and Rehabilitation Technique (Gill-Thwaites & Munday, 2004). Each of these measures allows for more careful examination of recovery of consciousness by accounting for auditory function, communication, and eye-opening to stimulus. Honed assessment of an individual's ability to respond to external stimulus is a key means of differentiation in diagnosis.

In addition to rating scales, IQBA is another means of assessing recovery from coma and vegetative state and is typically used in combination with neurobehavioral rating scales. In IQBA, trained staff members conduct single-subject experimental designs to determine the level of volition a patient exerts to complete a behavior. Such methods require providers to document a behavior after commands, in response to multiple sources of stimulation (sound, touch, visual), and at rest. Statistical methods are employed to determine whether the behavior is exhibited at random chance, or in response to a given stimulus.

In addition to behavioral study, measurement of electrophysiology through electroencephalography (EEG) and measurement of event-related potentials (ERPs) have been used to capture brain activity as a window on level of brain functioning. EEG provides a means of visually investigating spontaneous electrical activity generated by the brain. ERPs refer to averaged EEG responses that are time-referenced to external stimuli. Using EEG or ERPs for differential diagnosis between VS or MCS is not yet possible (Giacino et al., 2014); however, these techniques may assist in other ways. For example, in patients with coma, EEG can be useful for identifying seizure activity. In individuals in VS or MCS, EEG can identify global electrical slowing. ERPs may be used to predict longer-term outcome. In patients in a coma, the dearth of electrical response to stimulation of median nerves corresponds to poor longer term outcomes (Wijdicks et al., 2006). The more far reaching utility of EEG and ERPs remains to be determined.

Structural and/or functional neuroimaging—computed tomography (CT), magnetic resonance imaging (MRI), functional MRI (fMRI), positron emission tomography (PET)—is increasingly being considered in the diagnosis and treatment of individuals with disorders of arousal. CT and MRI scanning are used to localize and determine the degree of structural damage in the brain. This guides treatment teams in their understanding of how impairments may present over the recovery process. There have been some interesting studies using functional neuroimaging attempting to capture cerebral response to stimulation when verbal and motor responses are not possible (see Giacino et al., 2014, for a review). Although there are only preliminary findings, there is some evidence to suggest that functional neuroimaging can detect the ability to follow commands without verbalization or motor activity as brain regions have been found to “light up” in response to yes/no questions. It should be stated that all studies of this nature have small sample sizes and the preliminary findings need further investigation.

### *Treatment of Coma, VS, and MCS*

Treatment strategies may vary based on the level of acuity of injury, duration of symptoms of arousal disorders, and availability of institutional resources. In the earliest stages of arousal disorders (i.e., during acute treatment), adequate medical management is a paramount concern (Seel et al., 2013). Because

multiple physiologic systems are likely to be affected by the brain injury, proper monitoring and treatment of respiratory, cardiac, renal, and musculoskeletal functions are essential. During this time, it is also important to monitor for infection, behaviors that endanger the patient (e.g., self-extubation), behaviors that suggest the patient is experiencing pain, and proper positioning to avoid skin breakdown. This type of management will involve observation from all members of the interdisciplinary team. Additionally, proper monitoring requires various types of imaging, proper administration of medications, and interventional strategies including respiratory support (e.g., intubation) and dietary administration (e.g., Percutaneous endoscopic gastrostomy (PEG) tube placement). Risk of medical complications trend down as the patient becomes more aroused and ambulatory. Patients who remain in a vegetative or minimally conscious state or with reduced mobility for an extended period of time will require ongoing monitoring.

Interventions to assist the patient in regaining consciousness are all based in provision of stimulation. When not contraindicated, medications may be administered to promote stimulation (e.g., amantadine or hydrochloride; Giacino et al., 2012). Stimulation to the body through movement and sensory input as well as direct stimulation of the brain are the main approaches.

### *Sensorimotor Regulation*

Several clinicians and researchers have noted the importance of sensory processing in recovery of consciousness. There is some literature—mostly in the form of case study and retrospective data analysis—that suggests assessment of frequency, duration, intensity of sensory stimuli, with gradual and scheduled exposure to sensory information assists patients as they become more aroused and begin to regain awareness of themselves and their surroundings (Giacino, Katz, & Whyte, 2013; Seel et al., 2013). This method of rehabilitation requires observation of patient’s ability to process sights, smells, visual information, and auditory cues, as well as documentation and attentiveness for proper execution. In an article detailing the rehabilitation program for arousal disorders at Sheperd Center in Atlanta, Georgia, Seel and colleagues (2013) outlined their strategies for scheduled sensory stimulation. Strategies include repeated, consistent use of same type of stimulation across therapies to increase the likelihood of habitual responding and incorporation of visual information, such as mirrors, pictures of family, computer programs, and bright objects (e.g., flashing mirrors). Auditory simulation includes familiar sounds, such as music and familiar voices. Tactile stimulation may include laying the patient on his or her side or seating the patient on a mat. Careful attention must be paid to the time of day and level of stimulation applied, given that level of stimulation varies across the day based upon biorhythms and light exposure. Balance of the stimulation is key so that the patient is not over- or understimulated. When patients are able, and not prone to overstimulation,

early mobilization has been demonstrated to be helpful in the recovery process (Seel et al., 2013).

### *Brain Stimulation*

Recent research has begun to examine the utility of both invasive and noninvasive methods of neural regulation through the application of stimulators. An invasive approach, deep brain stimulation (DBS), involves surgical implantation of electrodes that generate electrical impulses into prespecified areas of the brain. Generally, this type of treatment is reserved for patients who continue to present with arousal disorders some years after their injury (it is generally thought that DBS for patients in acute states of brain injury may disrupt the recovery process). DBS is thought to improve patients' behavioral control by reactivating cortical structures that were previously down-regulated after injury. This treatment remains in investigational stages, but shows early promise for individuals with persistent arousal disorders (Giacino et al., 2013; Lemaire et al., 2014).

In terms of noninvasive neural stimulation, case examples and small case studies have provided some evidence that application of repetitive transcranial magnetic stimulation (rTMS) may be another useful tool for assisting patients in improvements of level of awareness and arousal. rTMS involves the use of electromagnets to induce weak electrical currents in the brain. The magnetic energy passes through the skull and is thought to create electrical pulses in specified regions of the brain. This type of stimulation is theorized to assist in either up-regulation or down-regulation of affected neurons to assist patients in increasing arousal and awareness (Giacino et al., 2013; Louise-Bender Pape et al., 2009). This treatment continues to be in the early stages of research and is not without risk. Risks include induction of seizure, transient headache, and transient changes in hearing.

### *Disorders Involving Global Impairment of Attention and Conscious Access*

Brain trauma, infections, metabolic disturbances, and/or exposure to anesthesia or certain types of medications often results in persistent impairments in ability to focus, sustain attention, and consciously access information about oneself and the environment. These disorders are characterized by intact arousal periods punctuated by confusion secondary to impairments in the ability to attend, process, and encode information (see Table 15.2).

#### *Delirium*

Delirium is characterized by disturbed consciousness with a waxing and waning course, disruption of the sleep/wake cycle, global cognitive dysfunction, and psychomotor disturbances (Maldonado, 2008). There are many causes of delirium and it is generally conceptualized as a transitional

status of neurologic functioning secondary to acute metabolic disturbances, intoxication, and structural brain lesions (Maldonado, 2008; Ouimet, Kavanagh, Gottfried, & Skrobik, 2007).

Research suggests that there are two main behavioral patterns in delirium: a hypoactive subtype and a hyperactive subtype (Maldonado, 2008). The hypoactive subtype is characterized by withdrawal, decreased responsiveness, apathy (poor initiation), staring, and sparse or slowed speech. Alternatively, the hyperactive subtype is notable for agitation, restlessness, nightmares, wandering, combativeness, and emotional lability. However, it should be noted that some patients can display a mixed behavioral pattern notable for symptoms of both hypo- and hyperactivity. All types can be characterized by hallucinations and delusions (Maldonado, 2008; Meagher et al., 2011). However, the cardinal feature of delirium is attention impairment, not hallucinations or delusions (Meagher et al., 2011). Delirium is a particularly salient concern in hospitals, as the incidence rate ranges from 11% to 80% of patients in intensive care and acute medicine units (Ouimet et al., 2007). Not surprisingly, hyperactive delirium is detected and diagnosed more frequently than hypoactive delirium (Maldonado, 2008). Hypoactive is the most common, but is frequently missed because its behavioral features do not draw clinical attention as readily (McNicoll et al., 2003).

There are several medical markers and demographic characteristics that make individuals more prone to experience of delirium. These include very young or very old age (particularly in those with dementia), neurotransmitter imbalance, inflammation and infection, hypertension/hypotension, hearing/vision impairment, changes in sodium level, placement of restraints, impaired oxygen metabolism, and deliriogenic medications including opiates and benzodiazepines (Girard, Pandharipande, & Ely, 2008). Risky health behaviors that predispose individuals to delirium include poor hydration, smoking, and alcohol use (Ouimet et al., 2007). Careful evaluation of each of these factors is important to assist with resolution of symptoms. The presence of delirium during hospitalization has been associated with increased institutionalization after discharge in elderly patients (Neufeld et al., 2013) and the development of persistent cognitive impairments many years after the delirium has "resolved" (Jackson, Gordon, Hart, Hopkins, & Ely, 2004; Neufeld et al., 2013; Ouimet et al., 2007).

#### *Posttraumatic Confusional State*

Traditionally, the state of confusion that follows moderate to severe traumatic brain injury in which the individual has gross impairments in attention and encoding new information has been referred to as *posttraumatic amnesia*. However, this label captures only one of the neurobehavioral impairments that persons present with following TBI. More recently, this state—which occurs in persons with moderate

to severe TBI—has been thought of as a subtype of delirium and labeled *posttraumatic confusional state* (PTCS) (Sherer, Nakase-Richardson, Yablon, & Gontkovsky, 2005). There are a wide variety of behavioral disturbances associated with this state, including impulsivity, sleep disturbance, agitation, and disorientation to place and situation, which all can lead to safety concerns for patients and the staff who are caring for them. Additionally, up to 40% of patients with confusion have psychotic-type symptoms (e.g., hallucinations; Sherer, Yablon, Nakase-Richardson, & Nick, 2008). The individual's ability to focus, sustain, and shift attention is consistently impaired, similarly to the pattern of impairment found in early phase of recovery from delirium. Awareness of changes in motor, sensory, cognitive, and behavioral functioning is impaired and these patients do not readily take these impairments into consideration when making decisions. Consequently, their ability to plan, problem-solve, and guide their behavior in appropriate ways is markedly impaired.

Stuss and his colleagues (1999) were among the first to decipher cognitive recovery patterns in individuals after TBI and noted that the primary cognitive impairment in PTCS is in the realm of attention. They observed that simple and complex attentional processes typically recovered prior to efficient memory encoding and retrieval, which tend to linger the longest in the impaired range. Thus, the individual begins to attend to and process information in the environment and about him- or herself prior to being able to consistently encode that information. In similar findings, Sherer and colleagues (Sherer et al., 2008) found that with variability in PTCS symptoms, there does appear to be a predictable pattern of resolution of symptoms of confusion, with psychotic-type symptoms and sleep disturbance resolving first and the attentional impairments taking longer to resolve. Importantly, posttraumatic confusional state symptom severity and course have been shown to be independent predictors of important functional outcomes and community reintegration. For example, Nakase-Richardson, Yablon, and Sherer (2007) found that severity of confusion after brain injury was more strongly associated with one-year employment outcome than duration of the confusional state. Additionally, the presence of psychotic-type symptoms (e.g., hallucinations) has been found to be an independent predictor of poorer recovery (Sherer, Yablon, & Nick, 2014). These findings suggest that clinical attention to the characteristics of the PTCS, such as severity, not just its presence and duration of cognitive symptoms may assist the clinical team in predicting longer term care needs and assistance.

#### *Assessment and Interventions for Delirium*

Assessments of delirium and PTCS typically include behavioral ratings that are conducted by hospital staff. In acute care settings, the Confusion Assessment Metrics (CAM) is often employed, particularly in the intensive care

unit (i.e., CAM-ICU). The CAM-ICU is designed to capture data about acute changes in mental status, inattention, disorganized thinking, and altered level of consciousness (i.e., somnolence, sleep/wake disruption; Ely et al., 2001). The Confusion Assessment Protocol (CAP) was developed by Scherer and colleagues (Scherer et al., 2005) for assessing PTCS in particular. Key symptoms assessed with the CAP are orientation to time and situation, attention, vigilance, and working memory (complex attention), waxing and waning of symptoms, agitation, reversal of sleep-wake cycle (night-time arousal and decreased daytime arousal), and psychotic symptoms (e.g., suspiciousness, hallucinations).

The most important method for management of delirium is to identify and treat underlying pathophysiologic factors that perpetuate symptoms. In many cases, management of infection, correction of sedating medications, proper hydration and nutrition, and assessment and regulation of basic metabolic factors are critical in resolution of delirium. Pain is a frequent instigator of agitation and aggression in patients with delirium and PTCS; thus, pain management strategies are critical in resolution of confusion. Similarly, management of sensory deficits has also been shown to reduce symptoms of delirium and aid recovery. For example, ensuring that patients have their glasses and/or hearing aids dramatically reduces confusion (Inouye et al., 1999). Psychopharmacological interventions may be employed to improve safety of patients and staff and to ease the recovery course. However, pharmacological management of delirium is somewhat controversial, as several medications prescribed to alleviate agitation, sleep disruption, and symptoms can result in oversedation and circumstances that worsen confusion. In general, the current trend in the literature and recent clinical practice is to minimize the use of sedating medications. However, when necessary for the safety of patients and staff, randomized controlled clinical trials suggest that quetiapine (Devlin et al., 2010; Kim, Bader, Kotlyar, & Gropper, 2003) and haloperidol (Devlin et al., 2010) may be successfully used in hospitalized patients.

In treatment of delirium and PTCS, environmental support for symptoms is paramount. As in treatment for individuals in VS and MCS, management of stimulation and sensory input is important. When patients are able, and not prone to overstimulation, early mobilization has been demonstrated to be helpful in the recovery process (Seel et al., 2013). The primary tenets of environmental/behavioral management of delirium include training staff about how to modulate their own behavior to avoid stimulating agitation in patients, adapting the environment to avoid over- or understimulating the patient, and providing salient orientation cues so that the patient can begin to attend, process, and encode relevant information (Inouye et al., 1999). For a list of behavioral strategies for management of delirium and PTCS, see Table 15.3.

Table 15.3 Behavioral and environmental interventions for confusional states

Patient Symptom/Behavior	Staff/Environmental Intervention
<b>Agitation/Aggression</b>	<ul style="list-style-type: none"> <li>• Take on a calm, caring and soothing tone.</li> <li>• Listen patiently.</li> <li>• Instruct the patient. Do not ask “Do you want to. . .”</li> <li>• Use simple, concrete language.</li> <li>• Reduce noise in the room (e.g., TV turned off).</li> <li>• Clear clutter.</li> <li>• Limit visitors and visitor conversation in the room.</li> <li>• Allow plenty of personal space for the patient.</li> <li>• Attempt to avoid or discontinue use of restraints.</li> <li>• Monitor medical equipment, which can be agitating (e.g., beeping monitors, leads or lines that pull at the body).</li> <li>• Mobilize and assistance with ambulation, when possible.</li> </ul>
<b>Hallucinations/Delusions</b>	<ul style="list-style-type: none"> <li>• Avoid correcting the patient or telling them their experience is not real.</li> <li>• Acknowledge that you have heard the patient.</li> <li>• Reassure patient of their safety and your concern.</li> </ul>
<b>Disorientation</b>	<ul style="list-style-type: none"> <li>• Provide orientation cues in close proximity (clock, calendar, location, reason for hospitalization).</li> <li>• Provide gentle reorientation cues in conversation (e.g., “Now that it is noon, we will have lunch,” “Now that it is April, the flowers are blooming”).</li> <li>• Create consistent schedule in patient cares and activities.</li> </ul>
<b>Anxiety/Emotional Lability</b>	<ul style="list-style-type: none"> <li>• Lower yourself to patient’s eye level and take an open stance.</li> <li>• Provide frequent reassurance of care and concern.</li> <li>• Provide frequent, time-contingent checks.</li> <li>• Provide easy, distracting activities.</li> </ul>
<b>Sleep Disruption</b>	<ul style="list-style-type: none"> <li>• Regulate sleep/wake cycles (avoid allowing the patient to nap for significant portions of the day).</li> <li>• Curtains/blinds open during the day, closed at night.</li> <li>• Lights on during the day/ off at night.</li> </ul>

### Memory Impairments (Semantic vs. Episodic)

Memory provides the individual with a history and a future that is foundational to his or her sense of self. Consequently, impairments in memory can thwart the individual accessing past and current information about self and environment and situation and obstruct construction of an accurate sense of the present and the future.

#### Assessment and Intervention of Memory’s Role in Consciousness

The field of neuropsychology has focused primarily on semantic memory because breakdowns in *knowing* information have been linked to specific pathologies depending on whether the breakdown was in encoding, storage, and/or retrieval. Assessment of semantic memory has been traditionally structured to capture the encoding of verbal information (rote or within a context) or visual information and the later retrieval of that information within cued and uncued formats. For understanding consciousness, it is important for the clinician to realize that when there are impairments in *knowing*, then the individual will have difficulty with *remembering*. The breakdown may be in that information was never encoded in the first place or that the information cannot be retrieved efficiently from memory stores when needed. Either way, the individual will have limited or no access to up-to-date information about daily life experiences to incorporate

that knowledge in what she or he knows about her or himself (e.g., orientation to self) and her or his life (e.g., orientation to situation) and the world (e.g., orientation to time and place).

However, there has been much less attention to the assessment of *remembering*. Human success in daily life is highly reliant upon understanding the consequences of past behavior and anticipating, thinking about, and planning for the personal future (Atance & O’Neill, 2001; Kwan et al. 2013). Individuals with impairments in episodic memory will be impaired in their ability to act on the basis of their knowledge of the past and their expectations for the future (Tulving, 2005). The loss of awareness of future time means that the individual will be impaired in predicting what is to come, planning and goal-setting, and differentiating right from wrong. Without the ability to mentally time travel to their own personal futures, there is no basis for moral judgment. We then start to understand the potential reasons for the high rates of social disturbance, substance abuse, criminality, and risk-taking behavior in individuals with brain injury. Individuals without auto-noetic episodic memory cannot think about their futures, anticipate the challenges and rewards that may come depending on their behavior, and take action now to influence the future. Consequently, the rules guiding behavior are not future oriented; they are focused on the here and now. One might label those behaviors as pleasure seeking, impulsive, or disinhibited. Behavior is reactive based upon in-the-moment thoughts and environmental cues and is likely the root of responses that are deemed “impulsive.”

Proactive behavior is not possible because there is no thought of down-the-road implications. The individual may be described as having a change in his or her personality because he or she behaves in ways that are more linked to the here-and-now. Behavior is no longer guided by accurate information in-the-moment nor information to plan for the future.

The core interventions for memory impairments are founded in using external strategies and equipment to document scheduled activities and tasks to be completed so that the individual can follow a written schedule rather than rely upon an impaired memory system to recall what needs to be done. For a review of such strategies, see Haskins' and colleagues' (Haskins et al., 2012) *Cognitive Rehabilitation Manual*. However, the effectiveness of such a system for successful life management requires that the individual also considers what did not get accomplished yesterday, any changes in schedule given unexpected life situations, and planning for more infrequent life activities that may disrupt the routines of day-to-day life. With impairments in episodic memory, the individual will have difficulty pulling into consciousness information that is relevant about what was accomplished yesterday, what is planned for over the longer term, and the relevance of unexpected life situation to the daily life schedule. Compensation for these impairments in episodic memory again are rooted in using external aids to track the episodes of daily life that are of importance and to prompt the individual to review what has been accomplished and what still needs to get done in the day. However, because of the impairments in retrieving information in-the-moment from memory stores, the individual will also have to learn strategies for planning ahead, problem solving, and decision making. The best synopsis of cognitive rehabilitation strategies and approaches to address these types of breakdowns in cognitive functioning can be found in the *Cognitive Rehabilitation Manual* (Haskins et al., 2012).

### ***Impairments in Self-Monitoring***

Self-monitoring in the moment brings the activity, and to some extent, its elements, to conscious awareness and thus control. When we do not consciously self-monitor, we “lose track of time.” We go into “autopilot.” We rely upon overlearned behavior patterns. These overlearned skills and tasks have become so routinized that they do not require a high level of cognitive oversight. Our efficiency in daily life is linked to our ability to take certain tasks and activities out of conscious control. Multitasking, the holy grail of cognitive efficiency, is reliant upon certain complex action sequences becoming automatic, habitual, routinized. We can conceptualize consciousness as an ability of the brain to modulate how much monitoring is required to complete the task. When we are learning a new skill, we must focus on each step, practice the skill over and over, and are quite distracted by interruptions. However, with practice and repetition, the brain learns the steps so well that it no longer

needs to put conscious energy to it and then we are freed to do two tasks at once.

Conscious oversight can be a bit of a double-edged sword, though. When we self-monitor our behavior, then our error rate is reduced, but our efficiency, resistance to distraction, and ability to multitask is also reduced. One tangible example is learning to walk. Infants learn the patterned motor movements (and proprioceptive and vestibular sense) for bipedal ambulation and these patterns become overlearned through practice. Over time, we humans become so skilled on our feet that we can perform other complex acts while walking without any degradation in our walking pattern or efficiency per se. However, with cerebral damage leading to motor, sensory, vestibular, or motor planning impairments, walking becomes disordered. When learning to walk again, patients must apply conscious oversight. In the clinical setting, in which most environmental factors are controlled, an individual may successfully be able to regain safe, efficient ambulation. However, out in the community where the individual is barged with information, the patient's conscious oversight of safe ambulation is now competing with conscious oversight of where to walk, following directions, monitoring foot and car traffic, and processing a conversation with a companion, for example. Walking pattern and efficiency suffers.

### ***Assessment and Interventions of Self-Monitoring***

There are no distinct assessments for self-monitoring per se. As neuropsychologists, we focus more on the cognitive elements that underlie our abilities to self-monitor our own behavior, including working memory, attention, and speed of information processing. It is likely that patients who have impairments in these areas of cognitive functioning will have difficulty with self-monitoring and will complain of difficulties with multitasking. Interventions have focused on allocating attention resources and managing the rate of information processing in order to assist the patient in self-monitoring multiple task demands despite interruptions (Cicerone, 2002; Fasotti, Kovacs, Eling, & Brouwer, 2000; Sohlberg, McLaughlin, Pavese, Heidrich, & Posner, 2000; Sohlberg, Johnson, Paule, Raskin, & Mateer, 2001).

There is mounting evidence that *mindfulness*, the application of conscious oversight to a behavior, thinking pattern, or emotions, can assist in compensating and possibly even reducing the actual symptoms of certain disorders and cognitive impairments. In brief, interventions for increasing mindfulness are focused on teaching the individual skills for sustaining attention in the face of competing distractors on the task at hand. Mindfulness may be viewed as a type of sustained attention training and is proposed to be effective because of the skills influence on attention regulation, emotional regulation, somatic awareness, and distancing from a self-focused perspective (Hölzel et al., 2011). Interventions have been found to be effective in improving attention and self-regulation in attention deficit/hyperactivity disorder (Schoenberg et al., 2014). There is some evidence to

suggest that mindfulness techniques such as meditation can offset age-related cognitive decline (for a review, see Gard, Britta, Hölzel, & Lazar, 2014; Prakash, De Leon, Patterson, Schirda, & Janssen, 2014). Interestingly, there is one study that has found that mindfulness meditation techniques may positively affect cellular longevity by reducing cognitive stress and stress arousal and increasing positive states of mind and hormonal factors (Epel, Daubenmier, Moskowitz, Folkman, & Blackburn, 2009). Mindfulness training has also been shown to have positive effects on psychological health by increasing subjective well-being, reducing psychological symptoms and emotional reactivity, and improving behavioral regulation (Keng, Smoski, & Robins, 2011). A mindfulness stress reduction intervention has been found to reduce depression and the experience of pain and increase energy levels following traumatic brain injury (Bédard et al., 2012) and to reduce depression and anxiety in individuals with autism (Spek, van Ham, & Nyklíček, 2013). Overall, there is burgeoning evidence that mindfulness training may be a viable intervention technique for improving some aspects of self-monitoring in both healthy individuals as well as those with a range of cognitive disorders.

### ***Impaired Awareness (Anosognosia) and Denial of Illness, Impairments, or Disability***

Self-awareness is reliant upon three functions: (1) memory functioning to update the data about strengths and weaknesses and how these impact task completion and activity engagement, (2) sensory and proprioceptive functioning to provide feedback about how the system is operating (which is most key for motor functioning), and (3) emotional functioning to note the meaningfulness of the change for the individual. Through life experiences and learned behaviors, an individual learns to interpret the meaning of certain attributes, abilities, and skills in the context of others and society as a whole. The value that the individual puts on these, how the individual defines him- or herself, and how the individual copes with perceived weaknesses can all play a role in how the individual adapts and adjusts to the onset of impairment or disability.

As argued by Stuss and colleagues (Stuss, Rosenbaum, Malcom, Christiana, & Keenan, 2005), self-awareness is born from our experiences, which lead to the construction of a model, with each of us having our own concept of ourselves and the world around us. Our current experiences are then processed and conceptualized within the context of our model, thus facilitating efficient processing and reinforcement of the parameters of the model. However, the model becomes more rigid and less malleable after time, thus hindering modification when needed (Stuss et al., 2005). When the clinician considers this conceptualization of awareness, then the implications of neuropathology start to become clearer. The rigidity of the model makes incorporation of new information that is discrepant with the long-standing model difficult. Additionally, if there is damage that hinders the brain from integrating new

information (e.g., memory impairments) or getting feedback about changes in functioning (e.g., anosognosia for hemiplegia), then the individual's model does not change. So new information that is quite different is rejected as not possible, plausible. If the information is not deemed as meaningful (the deficit is seen as minor or not present at all), then the impact on functioning is not realized or perhaps accepted.

There are two main classes of awareness disorders: anosognosia, which is rooted in a neurological dysfunction, and denial, which is rooted in psychological response (Kortte & Wegener, 2004; Prigatano, 1999). The overarching element of both of these is a degradation in the self-understanding of illness, impairment, or disability. Although there is some aspect of the individual that has been affected (health, longevity, functioning, abilities), she or he does not appear to recognize the effect. For a thorough discussion of awareness disorders, the reader should refer to the edited works of Prigatano and Schacter (1991) and Prigatano (2010).

### *Assessment and Intervention of Awareness Disorders*

Assessment of awareness disorder depends upon the type of awareness problem that is present. An individual can be impaired in his or level of awareness of illness, disease, injury (e.g., schizophrenia, Alzheimer's disease, traumatic brain injury), an impairment in any realm of functioning (i.e., motor functioning, sensory, cognitive, behavioral, emotional), and/or the impact of that illness or impairment on daily life functioning. For clinical assessment, the clinician should focus in on assessing two levels of unawareness: what realm is impaired (motor, sensory, cognitive, behavioral, emotional), and is the individual taking into consideration the functional implications. See Table 15.4 for examples of tools for assessing these different realms in which awareness may be impaired. For a summary of the measurement of awareness syndromes, the reader is encouraged to read Orfei, Caltagirone, and Spalletta (2010).

### *Intervention During Impaired Arousal or Attention*

As noted previously, all disorders of consciousness that are subsequent to impaired arousal and/or attention also have a strong unawareness component to the behavioral presentation. Clinicians should take the unawareness component into consideration when making decisions on modifying the environment to maintain safety for the individual. Without in-the-moment understanding of areas of impairment, individuals may attempt tasks that put them at risk for additional harm. Individuals with reduced arousal may attempt to pull out tubes or IVs, or may scratch themselves. Use of the lowest level of restraint, such as hand mitts, will help to reduce the chance for inadvertent injury. Individuals with delirium are at risk for injury secondary to attempting activities without consideration of their motor, sensory, and/or cognitive impairments on their abilities. Consequently, these individuals have higher incidence

Table 15.4 Assessment of impairments of awareness

<i>Realm of Impaired Awareness</i>	<i>Example Assessment Tools</i>
<b>Motor</b>	<ul style="list-style-type: none"> <li>• Bisiach Scale (Bisiach, Vallar, Perani, Papagno &amp; Berti, 1986)</li> <li>• Anosognosia Questionnaire (Starkstein, Fedoroff, Price, Leiguarda, &amp; Robinson, 1992)</li> </ul>
<b>Sensory</b>	<ul style="list-style-type: none"> <li>• Bisiach Scale (Bisiach et al., 1986)</li> </ul>
<b>Cognitive</b>	<ul style="list-style-type: none"> <li>• Self-Awareness of Deficit Interview (Fleming, Strong &amp; Ashton, 1996)</li> </ul>
<b>Emotional/Behavioral</b>	<ul style="list-style-type: none"> <li>• Awareness Questionnaire (Sherer, Bergloff, Boake, High, &amp; Levin, 1998)</li> </ul>
<b>Functional Implications</b>	<ul style="list-style-type: none"> <li>• Patient Competency Rating Scale (Prigatano et al., 1986)</li> <li>• Self-Awareness of Deficit Interview (Fleming et al., 1996)</li> </ul>
<b>Denial</b>	<ul style="list-style-type: none"> <li>• Clinician's Ratings Scale for Evaluating Impaired Self-Awareness and Denial of Disability After Brain Injury (Prigatano &amp; Klonoff, 1998)</li> </ul>

of falls and attempts at elopement. Additionally, because they do not understand their impairments and possibly their need for hospitalization, these individuals may also become agitated in response to attempts to restrict their activities. It is important that these individuals receive frequent reassurance and reorientation to their current situation. Clinicians should take a errorless learning approach in order to both evaluate the patients current level of orientation to place and situation, but also to provide the needed reorientation to the accurate information (see Haskins, et al., 2012 for discussion of use of errorless learning techniques). With impairments in attention, memory, and awareness, it is critical that the patient not be allowed to make mistakes on which he or she may perseverate, thus reinforcing confabulated misinformation. With provision of a safe environment and feedback regarding the current situation, the individual will begin to incorporate new information about his or her situation and functioning as levels of arousal and attention improves. Once the individual is able to consistently lay down new memories, then intervention specifically aimed at enhancing awareness can be employed.

#### *Interventions for Enhancing Awareness*
