# 29 Neuropsychological Functioning in Affective and Anxiety-Spectrum Disorders in Adults and Children

*Bernice A. Marcopulos*

## Neuropsychology in Psychiatry

Over the past 20 years, there has been a great expansion in the literature devoted to mental illness and neuropsychological functioning. A quick perusal of the major journals in psychiatry reveals a plethora of neuropsychology related articles, reflecting the intense interest in neurobiological mechanisms of mental illnesses. The National Institute of Mental Health (NIMH) has sponsored several initiatives, in collaboration with academic institutions and industry, to understand these neurocognitive mechanisms and more precisely devise new medications and behavioral treatments (Carter & Barch, 2007). Cognitive endophenotypes may advance our understanding of mental illness, placing neuropsychology in a prominent role in psychiatric research (Bilder et al., 2009; Bilder, Howe, & Sabb, 2013; also see Bilder, Chapter 8 in this volume). Grouping patients on the basis of core cognitive characteristics may be more productive than grouping by symptom characteristics which are based on subjective self-report. The World Health Organization (Mathers, Fat, & Boerma, 2008) lists mental disorders as a major source of disease burden. Cognitive impairment associated with these mental illnesses is believed to cause much of the burden (Whiteford et al., 2013). Neuropsychology is critical in evaluating the cognitive impairments that are present in nearly all the major mental illnesses because cognitive deficits are a strong predictor of functional outcome (Green, 1996; Keefe, 1995). Clinical neuropsychological interventions such as cognitive remediation have been specifically designed for psychiatric illness (see Medalia, Revheim, & Herlands, 2009) to address this burden.

Current training models in psychiatry emphasize neurobiology and neurochemistry and the logic of using medications to “correct” the underlying neurochemical defect. Perhaps as a result of their neurobiological focus, psychiatry has also recognized the importance of neurocognitive deficits in mental illness. Psychiatrists have devised their own screening methods to identify cognitive impairment (Gómez-Benito et al., 2013), but consult neuropsychologist colleagues for a more comprehensive evaluation. According to Sweet, Meyer, Nelson, and Moberget al. (2011) approximately 20% of neuropsychologists are employed in psychiatry departments,

where they play an important role in the diagnosis, treatment, and clinical research of mental disorders.

## *Scope and Aim of This Chapter*

There is a vast literature on mental illness and neurocognitive functioning, with several volumes dedicated to the neuropsychology of psychiatric disorders (e.g., Grant & Adams, 2009; Marcopulos & Kurtz, 2012; Wood, Allen & Pantelis, 2009). Since a chapter in the previous edition of this textbook covered schizophrenia in adults (Marcopulos et al., 2008), this chapter will focus on neuropsychological research on affective and anxiety disorders, which are more commonly encountered in any neuropsychologist’s clinical practice. The goal of this chapter is to translate the research on bipolar, depressive, anxiety, and obsessive-compulsive disorders into a coherent summary that will be directly useful for the practicing clinician. The clinical presentation and epidemiology will be briefly described for each disorder, in addition to the nature of cognitive deficits and the mechanisms for impairment, if known. Since many, if not most, of the major psychiatric disorders have their origins in childhood and follow a developmental course, their neuropsychological manifestations will be considered across the life span. The incidence of psychiatric disorders peaks in late adolescence and young adulthood, with a significant number starting in childhood (Jones & Tarrant, 1999; Newman et al., 1996). There is some evidence that an early onset of a mental disorder may be associated with greater symptom morbidity and cognitive deficits that persist over the lifetime. Finally, and most importantly, the functional significance of cognitive deficits for daily functioning will be discussed.

An important question is whether the cognitive deficits associated with affective and anxiety disorders occur primarily during acute symptoms (state) or whether the cognitive deficits are evident even during stable phases (trait). In other words, are the cognitive deficits in a given mental disorder related to “state” or “trait”? These primary psychiatric disorders not only have their own neuropsychological manifestations, but also complicate neurological disorders such as stroke, dementia, or traumatic brain injury. Depression and anxiety, as a reaction to a brain injury, must be considered

when interpreting neuropsychological test data. Understanding the unique impact of affective or anxiety disorders on neuropsychological functioning can help disentangle these psychiatric complications in primary neurological disorders.

### **Anxiety Disorders**

Anxiety disorders are extremely commonplace, affecting approximately 11% of the U.S. population in any given year (12-month prevalence; Grant et al., 2004) and 28.8% experiencing an anxiety disorder over the lifetime (Kessler, Berglund et al., 2005). Anxiety disorders include a disparate array of clinical syndromes, including generalized anxiety disorder, obsessive-compulsive disorder (OCD), posttraumatic stress disorder, agoraphobia, and panic disorder. One of the primary symptoms of anxiety disorders is poor attention and concentration, which could negatively affect cognitive test performance. Some patients become extremely anxious during any medical procedures and in particular in response to cognitive testing. Acute situational anxiety can affect cognitive tests—even in patients without a diagnosis of anxiety—by impairing working memory (Darke, 1988). According to Attentional Control Theory (ACT; Eysenck, Derakshan, Santos, & Calvo, 2007), anxiety impacts working memory because of increased processing effort. Acute anxiety in healthy individuals impacts both verbal and visuospatial working memory by reducing executive resources needed to focus attention (Shackman et al., 2006). In patients with chronic anxiety, one might expect even more deficits, especially if they are taking medications to control their anxiety.

Airaksinen, Larsson, and Forsell (2005) examined the effects of anxiety disorders on neuropsychological functions. They tested a mixed clinical sample with panic disorder with and without agoraphobia, social phobia, generalized anxiety disorder, specific phobia, and OCD. The group as a whole exhibited deficits in executive and memory function. However, when the researchers examined the specific diagnoses, they found that individuals with generalized anxiety disorder and specific phobia did not show deficits, while individuals with panic disorder and OCD were impaired. Another study done in Finland (Castaneda et al., 2011) found that a history of anxiety disorder was not associated with neuropsychological impairment in a sample of young adults. However, the individuals in their sample with a current anxiety diagnosis, who were taking psychotropic medication, were impaired on tests measuring executive function (Trail Making Test A and B), psychomotor processing speed (Wechsler Adult Intelligence Scale–R [WAIS-R] Digit Symbol) and visual short-term memory (Visual Span Wechsler Memory Scale–R [WMS-R]). These patients also received lower ratings on a global rating of psychosocial functioning (Diagnostic and Statistical Manual Global Assessment of Functioning [DSM GAF] score). Acute administration of lorazepam

has been found to negatively affect computerized cognitive test performance (CNS Vital Signs) in a small sample of 32 participants (Loring, Marino, Parfitt, Finney, & Meador, 2012). Older participants in the study were more affected than younger.

In summary, simple symptoms of anxiety do not seem to significantly affect neuropsychological function (O’Jile, Schrimsher & O’Bryant, 2005). However, there is some evidence that older patients might be more affected by anxiety and that medication to treat anxiety may impair functioning. More severe anxiety spectrum disorders such as OCD, panic disorder, and posttraumatic stress disorder are more likely to be associated with impairment than generalized anxiety or specific phobia.

### **Pediatric Considerations**

Although anxiety disorders are quite common in children, far less clinical research has been conducted on the cognitive effects of anxiety on children suffering from the disorder. The cumulative prevalence of any anxiety disorder found in a longitudinal community study from age 9 through 16 years was 9.9% (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003). In addition to primary anxiety disorders, children with brain injuries or disorders such as brain tumors are at risk of comorbid anxiety (Moitra & Armstrong, 2013). Approximately 25% of children diagnosed with attention deficit/hyperactivity disorder (ADHD) have a comorbid anxiety disorder (Jarrett & Ollendick, 2008).

Trait anxiety was found to impact working memory in preschoolers (Visu-Petra, Miclea, Cheie, & Benga, 2009; Visu-Petra, Cheie, Benga, & Packiam Alloway, 2011) affecting verbal more than visuospatial tasks. The results of these studies support the ACT model (Eysenck et al., 2007). Micco and colleagues (2009) found that children with current generalized anxiety showed poorer verbal memory and sustained attention, whereas children with social phobia had more omissions on a continuous performance task.

Toren and colleagues (2000) found that a small ( $N = 19$ ) sample of drug-naïve children and adolescents seeking treatment for anxiety disorders in a community outpatient clinic in Israel scored lower on the California Verbal Learning Test (CVLT) and made more errors on the Wisconsin Card Sorting Test (WCST) compared to healthy matched controls. They found no differences on the Rey Osterreith Complex Figure Test (ROCFT) or the Wechsler Intelligence Scale for Children–Revised (WISC-R). The authors concluded that anxiety inhibits encoding of linguistic information and tasks that require working memory.

The studies summarized so far did not specify how these cognitive findings impact children’s functioning, particularly in academic settings. Since 25% of children with ADHD have a comorbid anxiety disorder, how do we account for the “extra” cognitive impairment due to anxiety?

### **Obsessive-Compulsive Disorder**

Obsessive-compulsive and related disorders (OCDs) comprise a varied constellation of disorders in the anxiety spectrum diagnoses. OCD consists of disturbing intrusive thoughts (obsessions) and repetitive thoughts or behaviors (compulsions) that a person feels compelled to perform (APA, 2013). Prevalence in the United States is estimated to be between 1.5% and 3% (American Epidemiologic Catchment Area [ECA] survey, Karno, Golding, Sorenson, & Burnam, 1988; National Co-morbidity Survey, Ruscio, Stein, Chiu, & Kessler, 2010) but varies across settings. For instance, a recent prevalence and incidence study done in Europe (Veldhuis et al., 2012) in a primary care setting found a one-year treatment-seeking incidence of 0.016% (95% CI: 0.014–0.018) and a treatment-seeking prevalence of 0.14% (95% CI: 0.126–0.145). The one-year prevalence of OCD was only 0.084% (95% CI 0.080–0.089) in primary care patients enrolled in a large U.S. health maintenance organization.

An extensive literature exists on the neuropsychology of OCD. The disorder sometimes emerges after damage to the basal ganglia and inferior frontal cortex. Psychosurgery to treat OCD involves severing fronto-subcortical connections. Structural and functional neuroimaging tends to find abnormalities in the orbitofrontal cortex, anterior cingulate cortex, and caudate nucleus (see review by Chamberlain, Blackwell, Fineberg, Robbins, & Sahakian, 2005). These studies implicate the cortico-striatal-thalamic-cortical (CSTC) loop in the etiology of OCD (Insel, 1992; Mataix-Cols & van den Heuvel, 2006; Milad & Rauch, 2012; Rauch & Baxter, 1998).

In individuals diagnosed with primary OCD, executive dysfunction tends to be the primary finding, with memory impairment surmised to be secondary to executive dysfunction (e.g., Harkin & Kessler, 2011). However, a recent meta-analysis found heterogeneity across neurocognitive domains and no specific OCD profile (Abramovitch, Abramowitz, & Mittelman, 2013). Many studies show impairment in executive functions and nonverbal memory (Fontenelle, Mendlowicz, & Versiani, 2004; Penades, Catalan, Andres, Salamero, & Gasto, 2005; Savage & Rauch, 2000; Savage et al., 2000). There has been controversy regarding the presence and source of working memory impairment in OCD in adults. Deficits in visuospatial memory may be attributed to difficulties in organizing material. Segalàs et al. (2008) found that patients with OCD differed from healthy controls on a Spanish verbal memory test similar to the CVLT, as well as the Rey Complex Figure Test (RCFT). Older onset of OCD, and severity of depressive and obsessive symptoms (as measured by the Yale-Brown Obsessive Compulsive Scale) were associated with more impairments. The authors hypothesized that differing neurocognitive profiles based on age of onset suggest different neurobiological substrates. Unlike other studies (e.g., Savage et al., 2000; Deckersbach, Otto, Savage, Baer, & Jenike, 2000) they did not find that organizational

ability accounted for the poorer memory. There have been several ideas regarding the types of memory deficits in OCD: overall memory capacity impaired; modality specific, especially visuospatial, executive dysfunction, or metamemory. In addition, Simpson and colleagues (2006) did not find reliable neuropsychological deficits in OCD.

Researchers have found differences in cognitive functioning between OCD subtypes, with greater cognitive deficits for “checkers” (Nedeljkovic et al., 2009; Omori et al., 2007). Memory deficits might explain the compulsive checking behaviors (e.g., Woods, Vevea, Chambless, & Bayen, 2002). Grisham, Anderson, Poulton, Moffitt, and Andrews (2009) examined neuropsychological performance at age 13 and then followed individuals until age 32. The participants receiving a diagnosis of OCD at age 32 had shown impaired performance on visuospatial, visuoconstructive, and visuo-motor skills, though findings regarding executive functioning were mixed, with deficits noted in planning and organization but not in other areas such as set shifting.

There is some disagreement in the literature as to whether the deficits seen in executive functioning represent a stable trait-like characteristic of the illness, an endophenotype, or to state variables such as severity of symptoms and effects of treatments. Moritz et al. (2001) found that comorbid depression exacerbates executive deficits. Some studies have found persistent deficits even after pharmacological treatment (e.g., Kim, Park, Shin, & Kwon, 2002), while others have found improvement in cognition after a behavioral intervention (e.g., Mortiz, Kloss, Katenkamp, Birkner, & Hand, 1999; Kuelz et al., 2006).

### **Pediatric Considerations**

Far less clinical research has been conducted on the cognitive effects of OCD on children suffering from the disorder. An earlier study did not see significant cognitive deficits in children newly diagnosed who were not on medications (Beers et al., 1999). But other studies find similar deficits in children as adults (Shin et al., 2008), such as executive function deficits and impairments in visual memory, visual organization, and processing speed (Andrés et al., 2007).

Brennan and Flessner (2015) conducted a comprehensive review of OCD in adults and children. OCDs include disorders like skin picking, hair pulling, hoarding, and body dysmorphic disorder. Brennan and Flessner (2015) summarized the cognitive risk factors across pediatric disorders marked by obsessive, compulsive, and repetitive or ritualistic behaviors. The difficulty with this literature, as well as much of the literature on cognitive effects of mental disorders, lies in studies with small sample sizes that are not replicated. Abramovitch et al. (2015) conducted a meta-analysis on 11 studies meeting their criteria, looking at attention, executive function, memory processing speed, visuospatial abilities, and working memory. They found small and insignificant

effect sizes, concluding that there are no specific neuropsychological deficits in pediatric OCD.

Are the deficits seen in pediatric OCD state or trait? A study by Andrés and colleagues (2008) contradicts the endophenotype (e.g., trait) hypothesis by showing that cognitive deficits resolve with treatment. They compared 29 children ages ranging from 7 to 18 years, with OCD and a score of at least 20 on the Children's Yale-Brown Obsessive-Compulsive Scale (CY-BOCS; Scahill et al., 1997) with healthy controls and found that the differences resolved after "naturalistic" treatment. The treatment consisted of either a Selective Serotonin Reuptake Inhibitor (SSRI) or clomipramine and individual and parental counseling. More than half the patients also received cognitive behavioral therapy in addition to medication. The children received neuropsychological testing before treatment and again after six months. At baseline, the OCD patients showed deficits relative to healthy controls on visual and verbal memory, speed of information processing, and executive functions. On follow-up, only deficits in verbal memory remained significant relative to controls. Practice effects and a between subjects rather than within subjects design limit the impact of these findings.

## **Affective Disorders**

The 12-month prevalence of mood disorders in adults is approximately 9.21% (Grant et al., 2004). Lifetime prevalence is estimated at 20.8% (Kessler, Berglund et al., 2005). Neuropsychological deficits are very common in affective disorders and have functional significance. As in schizophrenia, neurocognitive deficits in affective disorders are not related to acute symptoms. The deficits persist even when symptoms have improved. This section will cover major depression and bipolar disorder in children and adults.

### ***Major Depressive Disorder***

The lifetime prevalence and 12-month prevalence for major depressive disorder are 16.5% and 6.7% respectively (Kessler, Chiu, Demler, & Walters, 2005). Women are much more likely to be diagnosed as depressed compared with men. The average age of onset is 32 years (Kessler et al., 2003) with younger adults having higher rates of depression than older adults (Husain et al., 2005). Depression frequently reoccurs in 50%–75% of diagnosed persons, and it is associated with more functional impairment (Kennedy & Paykel, 2004). Depression is an important cause of disease burden, and those individuals with a chronic disease and comorbid depression have the greatest health burden (Moussavi et al., 2007).

Since Kiloh's (1961) classic paper on "pseudo-dementia," clinicians have observed and remarked on the cognitive deficits related to depression. The relationship between depression and cognitive function is complex. Although psychotic depression has a more deleterious effect on cognition than

nonpsychotic depression (Basso & Bornstein, 1999) and fits the pattern of neuropsychological deficits seen in schizophrenia (Hill, Keshavan, Thase, & Sweeney, 2004), the severity of a depressive episode is not necessarily correlated with cognitive dysfunction. Other aspects of depression such as number and duration of episodes, presence of psychotic features, age of onset, and treatment resistance, are more important to consider (McClintock, Husain, Greer, & Cullum, 2010).

Much of the research on cognitive impairment in depression has focused on older adult populations, but younger adults have also been found to have deficits on cognitive testing. In their review of the literature from 1990 through 2006, Castaneda, Tuulio-Henriksson, Marttunen, Suvisaari, and Lönnqvist (2008) found that executive function is most commonly affected in younger adults with depression. Problems in attention, working memory, and psychomotor impairments were also reported in some studies they reviewed. Other risk factors for greater cognitive impairment include having multiple episodes and a relative who has bipolar disorder (Smith, Muir, & Blackwood, 2006).

Beblo, Sinnamon, and Baune (2011) reviewed the literature on neurobiological, clinical, and demographic factors affecting cognitive functioning in depression. Mood disorders have been found to impact cognition in several ways. Decreased concentration and difficulty making decisions are part of the diagnostic criteria. There is the common finding of depressed persons negatively evaluating their cognition. The negative affective bias in depression has been well established in the literature (Clark, Chamberlain, & Sahakian, 2009). Antidepressants may act by ameliorating these negative biases directly (Roiser, Elliott, & Sahakian, 2012). The effects of depression vary, with most studies finding little effect on neuropsychological functioning.

Attention and memory appear to be most affected by major depressive disorder. Earlier studies suggested that speeded tasks and "effortful" tasks were most affected in depression (Christensen, Griffiths, MacKinnon, & Jacomb, 1997; Den Hartog, Derix, Van Bommel, Kremer, & Jolles, 2003; Hasher & Zacks, 1979). Airaksinen, Larsson, Lundberg, and Forsell (2004) found that major depression and mixed anxiety and depression affected episodic memory and mental flexibility in a community sample of adults aged 10–64 in Sweden. Individuals in their sample had minor depression, dysthymia, and anxiety and depression. There were no effects of depression on verbal fluency (COWAT) or perceptual speed (Trail Making Test A). The depressed participants—particularly those with dysthymia—were slower, but not less accurate, on Trail Making B. Patients with minor depression did not differ from normal controls on any neuropsychological tests. They found that all groups benefitted from retrieval cues to the same degree to enhance episodic memory. Because the participants with major depression did not show more improvements with cues, they suggested that perhaps there are also encoding deficits. Airaksinen and colleagues (2004) found

that psychotropic medications did not negatively impact episodic memory but had a negative effect on mental flexibility (Trail Making B). Depression severity, number of episodes, and symptom clusters have all been shown to be related to the cognitive deficits seen in depression. In general the cognitive deficits seen in depression have been characterized as fitting a subcortical profile with primary deficits in processing speed. Mesholam-Gately et al. (2012) found that a group of elders with mild depression were similar to normals on the CVLT, but those with major depressive disorder showed decrements like a subcortical profile.

#### *State Versus Trait?*

A number of studies have found residual cognitive deficits even when depression was in remission (Baune et al., 2010; Nagane et al., 2014), indicating that these deficits are not secondary to mood state. Gallasi, DiSarro, Morreale, and Amore (2006) concluded in their study of the effects of antidepressants on memory that the deficits in depression were both state and trait. They found anterograde deficits on the WMS Logical memory and Paired Associates. In younger patients, deficits in executive function, verbal learning, and memory can persist even in remission (Smith et al., 2006). This seems to depend upon depression severity as some studies of outpatients with mild depression show no residual deficits in remission (Wang et al., 2006). Lee, Hermens, Porter, and Redoblado-Hodge (2012), in their meta-analysis on first-episode depression in adults ages 16 and over, found small to medium effect sizes for cognitive deficits. Deficits in psychomotor speed and memory were related to clinical state, whereas attention and executive function were enduring trait markers. In those patients with continued dysfunction, neurocognitive deficits were more important predictors than depression symptoms (Jaeger, Berns, Uzelac, & Davis-Conway, 2006).

Pharmacological treatments for depression have been found to have negative effects on cognition. Tricyclic antidepressants (TCAs), which are much less often prescribed since the advent of SSRIs, have anticholinergic side effects that negatively impact memory (Nagane et al., 2014). Nagane and colleagues evaluated three groups of patients with major depressive disorder (medicated with TCA, SSRI or unmedicated) with a control group. All three groups were more impaired on the WMS Logical Memory and Verbal Paired Associates. On the Visual Reproduction subtest, the two medicated depressed groups were impaired relative to unmedicated and healthy controls. On the Stroop, the groups taking TCAs scored lower than controls and the other two depressed groups.

Electroconvulsive therapy (ECT) is highly effective for treating severe, treatment-resistant depression and it is relatively safe (Lisanby, 2007). However, it is controversial as patients report that it impairs memory, especially autobiographical memory. Patients typically experience temporary

memory loss that recovers over time, although some patients have reported persistent impairment. McClintock and colleagues (2014) recently reviewed the literature on ECT and cognition. Unfortunately, since neuropsychological assessment is not a routine part of clinical ECT practice, data on cognitive outcome is sparse. Nevertheless, McClintock and colleagues were able to draw some conclusions and propose a model of the underlying factors mediating or moderating cognitive outcomes after ECT. The practice of ECT has changed over time in terms of type of treatment techniques and parameters for delivering the shock, such as electrode placement. McClintock and colleagues found that technique and electrode placement determines the extent of memory loss. Older methods for administering ECT, which used sine waves and bilateral electrode placement, have a much more persistent effect on cognition, particularly autobiographical memory, than more recent methods using ultra-brief pulse waveform and unilateral electrode placement. Age, education, premorbid intellectual ability, and cerebrovascular health are important moderator variables. In particular, patients with lower cognitive reserve and poor cognitive health are at higher risk for developing cognitive impairment post-ECT.

#### *Pediatric Considerations*

Children as young as 3 years have been diagnosed with depression (Luby, 2009). The cumulative prevalence of any depressive disorder in children ages 9–16 years in a longitudinal community study was 9.5% (Costello et al., 2003). The prevalence of depression in children younger than 13 has been reported as 2.8% but rises significantly during adolescence (Costello, Erkanli, & Angold, 2006). However, there is diagnostic uncertainty as some of these children presenting with unipolar depression will develop bipolar illness.

Livingston, Stark, Haak, and Jennings (1996) examined neuropsychological profiles in a small sample ( $N = 56$ ) of children and young adolescents with diagnoses of unipolar depression, anxiety disorder, or comorbid anxiety/depressive disorder. All three groups displayed reduced attention abilities, but children with comorbid anxiety and depression generally performed worse than those with only anxiety or depression. Cataldo, Nobile, Lorusso, Battaglia, and Molteni (2005) found depressed children performed more poorly on a verbal fluency task, and on interference on the Stroop Color-Word Test compared to a healthy control group of children. They also had poorer sustained attention, slower reaction times, and greater omission errors on the Continuous Performance Test (CPT). The Stroop and CPT were significantly correlated with severity of current depressive symptoms. Micco and colleagues (2009) found that symptoms of major depression were associated with poorer performance on working memory and processing speed measures from the WISC III, and cognitive flexibility from the WCST.

Matthews, Coghill, and Rhodes (2008) studied neuropsychological functioning of a referred sample of medication-naïve adolescent girls meeting criteria for a diagnosis of depressive episode. Depressed adolescent girls showed performance deficits on visual memory tasks (Pattern Recognition, Delayed Matching to Sample, and Paired Associates Learning), one measure of motor speed and on a test of Spatial Working Memory on the Cambridge Neuropsychological Test Automated Battery (CANTAB, a computerized assessment).

In summary, the few articles available on cognitive functioning in childhood depression suggest deficits similar to those found in adults. These studies must be viewed with caution as the sample sizes are small and they have not been replicated.

### Bipolar Disorder

Bipolar I disorder, popularly referred to as “manic depression” is characterized by the cyclical pattern of manic and then depressive episodes. Some bipolar patients do not have mood swings but present with mixed features of depression and mania simultaneously, referred to as a *mixed episode* (Suppes et al., 2005). Bipolar II is characterized by major depression and at least one manic or hypomanic episode. Bipolar disorder can occur any time throughout an individual’s lifetime but the mean age of onset is around age 18 (APA, 2013). The lifetime prevalence rate is 3.9% (Kessler & Wang, 2008). Using *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV criteria), the 12-month prevalence estimate in United States was 0.6% for Bipolar I with relatively equal prevalence for men and women (Merikangas et al., 2007). Bipolar disorder affects approximately 1% of the population (Birmaher, 2013). There is a very strong genetic component with a tenfold increase among close relatives (APA, 2013). Bipolar disorder and schizophrenia are thought to be genetically linked, as both serious mental disorders tend to run in families.

Bipolar disorder presents with extremes in mood that presumably could impact cognitive functioning directly. Bipolar illness has been associated with cognitive dysfunction, not only during the active phase of the illness (during a depressed or manic episode) but also when the patient is euthymic (e.g., Kurtz & Gerraty, 2009), consistent with trait abnormality. Thus, the neuropsychologist would be wise not to attribute an impaired profile to the current symptomatic affective state and expect that problems may resolve as the symptoms come under better control. More than half of individuals diagnosed with bipolar disorder have cognitive deficits. There is not a unique “bipolar profile” in terms of neurocognitive deficits, but commonly attention, working memory, verbal learning, and memory and executive functions are implicated (Torres, Boudreau, & Yatham, 2007).

Arts, Jabben, Krabbendam, and van Os (2011) followed a sample of bipolar patients over two years, testing them every two months. The patients performed more poorly than

healthy controls, but effect sizes were small. Cognitive performance varied, but did not vary with mood. Sustained attention and motor speed did not vary across the study period. Second-generation antipsychotic medications were associated with cognitive decrement in motor speed and information processing. Bipolar patients typically score between patients with schizophrenia and healthy controls on neuropsychological tests. Although patients with bipolar illness are not as cognitively impaired as those with schizophrenia, the pattern is similar (Harvey, Wingo, Burdick, & Baldessarini, 2010; Krabbendam, Arts, van Os, & Aleman, 2005; Schretlen et al., 2007). The nature of cognitive impairment in bipolar disorder is similar to that seen in schizophrenia—with attention, memory, intelligence, and psychomotor function deficits—but differs in severity and course (Vöhringer et al., 2013). Vöhringer and colleagues make the point in their review that negative symptoms are associated with poorer cognitive functioning in schizophrenia, but depression is not associated with poorer cognitive function in bipolar disorder. However, several studies have found just that. Cognitive difficulties in childhood are more common with schizophrenia than bipolar disorder. Cognitive difficulties in bipolar illness occur later in life after the onset of the illness and could exacerbate with each episode (Lewandowski, Cohen, & Öngur, 2011; Murray et al., 2004).

There have been several recent meta-analyses. Lee et al. (2014) reviewed 12 neuropsychological studies of patients with first onset bipolar disorder. They found medium to large effect sizes for psychomotor speed, attention, working memory, and cognitive flexibility. Small effect sizes were found in verbal learning and memory, attentional switching, and verbal fluency. Samamé, Martino, and Strejilevich (2014) performed a meta-analysis on longitudinal studies of cognition in bipolar illness. They found that cognitive functioning does not decline over time. The average retest interval for the 35 studies they included in the meta-analysis was 4.62 years. Robinson and Ferrier et al. (2006), Mann-Wrobel, Carreno, and Dickinson et al. (2011), and Torres et al. (2007) found cognitive impairment in euthymic bipolar patients, particularly in attention, processing speed, verbal memory, and executive functions. Mann-Wrobel and colleagues (2011) found that age and duration of illness were negatively correlated with deficits, and gender did not have an effect. More education was associated with fewer deficits. Vocabulary and word reading were preserved and did not differ from controls.

Like patients with schizophrenia, bipolar patients demonstrate deficits that impair social cognition. For instance, Van Rheenen and colleagues have found that persons with bipolar illness have difficulties processing facial affect. In a recent article Van Rheenen and Rossell (2014) found that bipolar patients were impaired in emotional processing and that this impairment was independent of mood state, again suggesting that neuropsychological deficits are “trait” rather than “state.” The deficits tend to be subtle, however, with

only modest effect sizes (Samamé, Martino, & Strejilevich, 2012; Samamé, 2013).

Older adults with euthymic bipolar disorder also show cognitive deficits, although not necessarily more than younger adults. Samamé, Martino and Strejilevich (2013) performed a meta-analysis looking at ten cognitive variables for euthymic older bipolar patients. There were no significant differences between older adults with or without bipolar disorder on global measures such as the Mini Mental State Examination (MMSE) or clock drawing, but bipolar patients showed moderate impairments (between 0.6 and 0.9 SDs) relative to controls in sustained attention tasks (i.e., Trail Making A, CPT), digit span (forwards and backwards), delayed recall (CVLT, CAMCOG, Signoret Memory Battery), serial learning (CVLT), cognitive flexibility (i.e., Trail Making B), and verbal fluency (category animal and letter). Bipolar disorder patients with later onset were more impaired relative to those with early onset. Compared to younger bipolar disorder patients, older euthymic patients did not show greater deficit, suggesting that there is no cognitive decline associated with the illness. Depp et al. (2008) found similar results, although they also found that the older bipolar patients showed more intraindividual variability.

Cognitive impairment contributes to disabilities in social and occupational functioning and ability to live independently (Depp, Mausbach, Bowie, 2012; Sanchez-Moreno et al., 2009; Torres et al., 2007). Depp and colleagues found that cognitive functioning was the strongest predictor variable for employment, followed by depressed mood. Similar to the research on schizophrenia, the functional outcome for bipolar illness is not well predicted on clinical variables such as number of manic episodes or severity of clinical symptoms. Rather, there is a closer association between neurocognitive variables and everyday functioning (e.g., (Depp, Mausbach, Harmell, 2012; Jaeger, Berns, Loftus, Gonzalez, & Czobor, 2007; Martínez-Arán et al., 2004; Torres et al., 2010; Wingo, Harvey, & Baldessarini, 2009).

Baseline cognitive functioning may predict later functioning, but the literature is not decisive on this point (Baune, Li, & Beblo, 2013). Baune et al. (2013) systematically reviewed the literature on neurocognitive impairment and general functioning in bipolar adults using PRISMA guidelines (Moher, Liberati, Tetzlaff, Altman, & Group, 2009). Baune and colleagues (2013) examined longitudinal and cross-sectional studies investigating a number of neurocognitive domains (attention, executive function, verbal learning and memory, verbal fluency, processing speed, working memory, visual learning and memory, psychomotor speed, and visuospatial ability) and activities of daily living, and social and occupational functioning. Depp, Mausbach, Harmell, (2012) also did a meta-analysis. They found that performance-based, real-world measures of functioning had higher correlation with neurocognitive variables than clinician or self-ratings. Gilbert and Marwaha (2013) utilized Meta-Analysis of Observations Studies in Epidemiology (MOOSE) guideline

to do their systemic review of the predictors of employment for persons with bipolar illness. They found that depression and cognitive impairment were most associated with occupational outcome.

Langenecker, Saunders, Kade, Ransom, and McInnis (2010) found that illness severity as measured by number of hospitalizations and number of years of illness correlated with cognitive test scores. Euthymic bipolar patients performed more poorly than healthy controls on several cognitive factors including processing speed, fine motor dexterity, and speed and visual memory. Bipolar patients taking antipsychotic medication performed more poorly than those treated with Lithium and mood stabilizers. Patients on antipsychotic medication had more psychiatric hospitalizations and more severe illness. Langenecker and colleagues did not find that verbal learning and memory distinguished euthymic bipolar disorder from the healthy controls. Patients in the active phase of the illness performed more poorly on verbal memory. Langenecker and colleagues found more decrements in executive function in the manic state, which is consistent with clinical observations of more impulsivity. Executive factor scores included tests of verbal fluency, processing speed with interference resolution, conceptual reasoning, and set-shifting and inhibitory control. Langenecker and colleagues defined the deficits seen in executive dysfunction in bipolar disorder. In particular, they concluded that processing speed with interference resolution, as demonstrated on the Stroop color-word test, which is scored based on time, is impaired in all phases of the bipolar disorder, whereas inhibitory control is primarily affected during the hypomanic phase. During the depressed phase, Langenecker and colleagues found decreased verbal learning and memory, verbal fluency processing speed, and fine motor function. Interestingly, this profile has also been reported in major depressive disorder (Rogers et al., 2004). Langenecker and colleagues (2010) concluded that there were both trait and state cognitive features in bipolar disorder.

Other authors have suggested that executive dysfunction is more trait than state (Bora, Yucel, & Pantelis, 2009). According to Bora et al. (2011), persons with Bipolar I are more impaired on memory and semantic fluency than those with Bipolar II, but overall impairment is equivalent. Depp, Salva, Vergel de Dios, Mausbach, and Palmer (2012) followed 42 outpatients with bipolar disorder and tested them at 6, 12, and 26 weeks. Affective symptoms were measured along with cognitive function. They found that affective symptoms did not covary with cognitive changes, but patients with bipolar disorder showed more intra individuality than normal controls. Martínez-Arán and colleagues (2004) utilized a cross-sectional design, using three groups of bipolar patients: euthymic, depressed, and hypomanic. They tested the three groups with the WAIS Vocabulary test, WCST, Stroop Color Word, COWAT, Trail Making tests, CVLT, WMS-R Logical Memory, and Visual Reproduction. Compared to healthy controls, all three bipolar groups were impaired,

especially on tests of verbal memory and executive functioning. Depressed patients had lower scores on verbal fluency, category fluency, and Trail Making A. Euthymic patients also scored lower on category fluency and Trail Making A. Psychosocial functioning correlated with neuropsychological variables but not clinical variables such as chronicity and number of hospitalizations. Social and occupational indicators were associated with cognitive variables, in particular the Stroop, WCST Digits Backwards, WMS-R, and CVLT.

Cognitive dysfunction has been studied as an intermediate endophenotype for mental illness. It is heritable, as first-degree relatives who do not have the diagnosis or clinical symptoms nevertheless show similar patterns on cognitive testing. For instance, verbal memory deficits are also present in relatives of bipolar patients (Quraishi et al., 2009). Memory, attention, executive functioning, and emotion processing tend to be most affected (Langenecker et al., 2010). Executive functioning, verbal learning, and memory have been proposed as viable endophenotypes (Glahn, Bearden, Niendam, & Escamilla, 2004). More recently, attention has been proposed as stable cognitive deficit in bipolar disorder (Burdick, Goldberg, Harrow, Faull, & Malhotra, 2006). Aminoff and colleagues (2013) described attempts to establish meaningful subtypes (endophenotypes) of bipolar disorder with characteristic cognitive features. For instance, they created subgroups based on presence of psychosis, and whether the primary feature is depression or mania, as well as age of onset. They found that the Bipolar I subgroup had lower scores on verbal learning and semantic fluency compared with Bipolar II. Bipolar I patients were more likely to take antipsychotic medications. Persons with bipolar disorder with psychosis performed more poorly on verbal memory and semantic fluency compared with patients without psychosis. Patients with depressive polarity performed better than elevated polarity on verbal learning and memory and had fewer intrusion errors on the CVLT. Age of onset had no bearing on cognitive test scores. They concluded that psychosis and mania had a more negative impact on cognitive than depression. Bipolar patients with psychotic features have more severe cognitive impairment, with executive processes being most affected (Allen et al., 2010). Solé et al. (2011) examined neuropsychological functioning in euthymic Bipolar II patients and found that attention, verbal memory, and executive functions were impaired.

Lithium, the oldest and most common medication used for bipolar disorder, has been found to affect cognition in some studies, but not others. Wingo, Wingo, Harvey, and Baldessarini (2009) performed a meta-analysis on studies done on lithium use between 1950 and 2008. They found small effect sizes (0.24) for immediate learning and memory. Attention, delayed verbal memory, visual memory, executive functions, psychomotor, and processing speed were relatively unaffected. More recently, López-Jaramillo and colleagues (2010) found that lithium had no effect on cognition. They found verbal and visual memory problems in bipolar patients

compared with healthy controls independent of medication status. Findings for mood stabilizers have been mixed, with some finding cognitive effects, particularly with attention and concentration and psychomotor speed (e.g., Park & Kwon, 2008). Some authors have suggested that lithium may even have a protective effect on cognitive functions, while benzodiazepines and antipsychotics have deleterious effects (Torrent et al., 2011).

Cognitive remediation is a well-established and efficacious strategy for cognitive impairment in schizophrenia (e.g., Wykes, Huddy, Cellard, McGurk, & Czobor, 2011). Recently, there have been several trials of cognitive remediation for bipolar illness (Deckersbach et al., 2010; Torrent et al., 2013). Torrent, Martínez-Arán, and colleagues (Martínez-Arán et al., 2011; Torrent et al., 2013) developed a cognitive intervention for bipolar patients. This intervention focusses on improving the functional consequences of cognitive impairment. They utilized a number of paper-pencil and group exercises to address attention, executive functions, and verbal learning and memory. In their randomized control trial (Torrent et al., 2013), neuropsychological test scores did not improve, but functional outcome did improve after this intervention. Patients in the functional remediation intervention improved their psychosocial and occupational functioning compared to the treatment as usual group.

### *Pediatric Considerations*

Pediatric bipolar disorder (PBD) is controversial, and diagnosis can be difficult. A full discussion of the diagnostic complexities of this disorder is beyond the scope of this chapter and the reader is directed to several recent comprehensive reviews (e.g., Birmaher, 2013). Briefly, however, young children often present in a rather undifferentiated way, typically exhibiting mood, behavioral, and cognitive symptoms. Psychotic symptoms may be present, as well as depression or elevated mood along with behavioral disturbance in the form of withdrawal and/or aggressive acting out. At a young age it is unclear whether such disturbances will evolve into a more differentiated bipolar disorder or schizophrenia.

There has been a dramatic increase in the diagnosis of bipolar disorder in children (Blader & Carlson, 2007; Moreno et al., 2007), with a concomitant increase in antipsychotic medication prescribed (Biederman, 2003; Biederman et al., 2003; Geller & Luby, 1997; Geller, Tillman, Craney, & Bolhofner, 2004). Bipolar illness in children is a heritable mental disorder characterized by extreme behavioral and affective dysregulation with aggression and severe irritability. A family history of bipolar disorder increases the risk 15-fold (Pavuluri, Henry et al., 2006). The risk of a child having bipolar disorder when one or both parents have the diagnosis ranges between 10% and 25% (Goldstein et al., 2010; Goodwin & Jamison, 2007). PBD has a chronic course and poor outcome, including higher rates of suicide and substance abuse (e.g., Geller et al., 2004). Neurocognitive

deficits and poor school performance are common (Pavuluri et al., 2006). The earlier the onset, the greater the neurobehavioral and cognitive impairment and the more likely it will persist throughout adulthood (Lim et al., 2013; van Os, Jones, Lewis, Wadsworth, & Murray, 1997). Perinatal risk factors such as birth complications or exposure to maternal medication use further increase risk. More than half of adult patients with bipolar disorder worldwide report that their symptoms started before they were 21 years old (Baldessarini et al., 2010). Although the majority of children recover from manic and depressive episodes, most have recurrences of mood disorder, especially depression (Birmaher, 2007). Poor outcome is associated with risk factors such as earlier onset, longer duration of symptoms, low socioeconomic status, environmental stress, and family psychopathology. The risk of suicide is very high, with at least one-third attempting during their lifetime (Goldstein et al., 2010). Suicide attempt is another possible cause for cognitive impairment in these patients (drug overdose, asphyxiation, etc.).

There has been more research conducted on the cognitive effects of bipolar disorder in children than on other mental disorders such as anxiety and depression. Dickstein and colleagues (2004) used the CANTAB to examine cognitive functioning in 21 children and adolescents with bipolar disorder. They found deficits in attentional set-shifting and visuospatial memory. Pavuluri, Schenkel, and colleagues (2006) concluded that neurocognitive deficits in attention, executive functioning, working memory, and verbal memory were trait rather than state and were not due to medication effects. They compared three groups of 28 children (medicated, nonmedicated, healthy controls), matched on demographic variables, with an average age of 11.7 years. The medicated children were either on lithium plus risperidone or divalproex sodium plus risperidone. Tasks involving shifting attention, processing speed, and problem solving were most affected, implicating dorsolateral prefrontal cortex dysfunction, as shown in neuroimaging studies (e.g., Adleman et al., 2012). Unlike Dickstein et al., they did not find visuospatial deficits. Illness state as measured by the Young Mania Rating Scale, and medication use did not affect the results, but comorbid ADHD was associated with greater neurocognitive dysfunction.

Joseph, Frazier, Youngstrom, and Soares (2008) reviewed the literature on neurocognition in PBD. They performed a meta-analysis on ten studies examining cognitive deficits in PBD. Effect sizes for Full Scale Intelligence Quotient (FSIQ) were small to medium compared with healthy controls. No FSIQ differences were found compared to other psychiatric disorders. They surmised that comorbid ADHD and oppositional defiant disorder (ODD) most likely played a role in lower IQ. Reading achievement also fell in the small to medium range of effect sizes. Effect sizes for attention were in the medium range. Motor speed effect size was small. Executive functioning was moderate, corresponding with parent report of executive dysfunction in adolescents

with bipolar disorder (Shear, DelBello, Rosenberg, & Strakowski, 2002). Working memory was in the medium to large range. Verbal fluency showed small to medium differences and visuo-perceptual functions showed medium effect sizes, but they included only four studies. The effect size for visual memory was medium and verbal memory was large. Joseph et al. concluded that their meta-analysis was similar to those conducted with studies on adult bipolar disorder with verbal memory showing the largest effect. However, they cautioned that the presence of comorbid ADHD, which occurs in as much as 62% in pediatric bipolar disorder (Kowatch, Youngstrom, Danielyan, & Findling, 2005), may be a significant confound.

There is considerable comorbidity between ADHD and bipolar illness, which complicates the neurocognitive picture (e.g., West, McElroy, Strakowski, Keck, & McConville, 1995; Wozniak et al., 1995; also see the chapter by Wasserstein et al. in this volume). Co-morbid ADHD, ODD, and substance abuse makes it difficult to interpret manic and hypomanic symptoms (Birmaher, 2013; Klein, Pine, & Klein, 1998). Increased energy, distractibility, and pressured speech are the most common symptoms of bipolar disorder in children, but these symptoms are also common in ADHD (Kowatch et al., 2005). Like other mental disorders, the symptoms must exceed normal expectations for developmental stage, affect functioning across several settings (school, home, peers), and not be explained by cultural or environmental factors. Although bipolar disorder with ADHD might represent a distinct subgroup, Pavuluri, Henry, Nadimpalli, O'Connor, and Sweeney (2006), did not find differences in risk factors of neuropsychological functioning between bipolar disorder with or without ADHD. One study of stabilized adolescents with bipolar disorder found fewer attentional deficits than adults and no increased incidence of ADHD (Robertson, Kutcher, & Lagace, 2003). They examined the Freedom from Distractibility (FD) Composite Index of the WISC III, Conners Continuous Performance Test (CPT), WCST, and a subjective cognitive/attentional problems checklist. Doyle et al. (2005) examined neuropsychological functioning in a sample of 57 youth aged 10–18 years with bipolar disorder, while controlling for comorbid ADHD. They used a variety of neurocognitive measures of sustained attention, processing speed, working memory, interference control, abstract problem solving and set shifting, visuospatial organization, and verbal learning. After statistically controlling for ADHD, which was present in 74% of the sample, youth with bipolar disorder showed deficits in processing speed, sustained attention, and working memory and had lower academic achievement in arithmetic. Digit Symbol, and Stroop Color Word subtest showed the largest effect sizes.

In summary, children and adolescents with bipolar disorder are at risk for neurocognitive impairment that will impact academic and social functioning and have implications for future occupational achievement as well as independent living. Medications for bipolar disorder do not appear to

either explain, or exacerbate these deficits. Early intervention is believed to mitigate some of these functional deficits and help these children and their families manage the disease and its implications over the long term. Educational interventions such as individual education plans (IEPs) or 504 plans that recognize and address the cognitive deficits in these children as well as their affective challenges will be most helpful in their academic success.

## Conclusions

A neuropsychologist evaluating a patient with a psychiatric disorder or prominent psychiatric symptoms should be aware of associated cognitive deficits. As seen in this review, cognitive dysfunction is very common, but there are no unique cognitive profiles for specific affective and anxiety diagnoses. An important question is how acute symptoms impact test results. For example, depressed patients may be unwilling or unable to exert sufficient effort on tests, compromising validity. In most cases, it is advisable to wait until the patient is stable before starting a test battery. However, the research presented in this review shows that cognitive deficits are not merely epiphenomenon, but are enduring features of many psychiatric disorders. The cognitive effects are present even when the acute symptoms have abated. Not only do cognitive deficits persist, in some cases—especially in the more severe disorders like bipolar disorders—they impact daily functioning. In other cases, such as depression, cognitive issues might have minimal functional impact and primarily be subjectively experienced. Treatments for mental disorders can also negatively impact cognition although not as much as the illness itself. Except for ECT, which has been reported to impair memory, most medical treatments for mood disorders and anxiety disorders have only a modest effect and cannot entirely explain alterations on testing. An interesting question concerns how psychotherapy, behavioral therapy, or cognitive remediation may improve cognition in mental illness.

In many cases, symptoms of a serious mental disorder begin in childhood and persist into adulthood (Newman et al., 1996). Individuals whose mental illness starts in childhood are at greater risk for cognitive impairment. Disorders with a strong genetic component tend to start early in life, during predictable developmental epochs. These disorders tend to have more neurocognitive sequelae, particularly with executive functioning. The literature on children is sparse compared to the literature on adults, but suggests that there can be significant cognitive effects that impair learning. Also, childhood onset of major mental illness is also associated with poorer cognitive functioning and generally poorer prognosis.

Many primary psychiatric illnesses are associated with cognitive impairment that impacts social and occupational functioning. Given the functional impact of cognitive deficits, neuropsychological assessment should be an integral

part of the management of psychiatric disorders. It is also important for neuropsychologists to appreciate how anxiety or mood symptoms can exacerbate cognitive test impairment in neurological disorders (e.g., Gillespie, 2015; Brown et al, 2014). Grosdemange et al. (2015) found that state anxiety was more deleterious to working memory for stroke patients compared with controls, although both groups were affected. Thus, state anxiety should be taken into account when evaluating patients with neurological disorders. It is critical that neuropsychologists have an appreciation of how psychiatric illness impacts cognition. Cognitive functioning impacts treatment adherence, community functioning, and employability.

# 30 Dementia<sup>1</sup>

Glenn Smith and Alissa Butts

## Overview

Recent scientific insights and technological advances in the field of dementia have provided compelling evidence that neurodegenerative diseases have a decades-long prodrome that includes reliably identifiable epochs preceding the manifestation of the full syndrome of dementia. These advances in science and technology have spurred demand for new consensus diagnoses. For example, Alzheimer's disease (AD) research criteria now recognize preclinical and prodromal periods in AD development. The syndromic phases of neurodegenerative dementing illnesses are not etiologically specific, thus most neurodegenerative dementias could be seen as having parallel syndromic stages. This chapter discusses these recent reformulations of clinical and research diagnostic criteria related to dementia generally and will use AD in particular to demonstrate the trend of these reformulations. Newer clinical criteria for diagnosing dementia are presented in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) of the American Psychiatric Association. Updates to AD research criteria have been promulgated jointly by the National Institutes on Aging and the Alzheimer's Association. The criteria serve to more clearly delineate the distinction between syndromes (e.g., preclinical state, mild cognitive impairment and dementia) and etiologies (e.g., AD, vascular dementia, Lewy body disease frontotemporal dementia). After an overview of syndromes, we review etiology-specific criteria in separate sections that will also provide an overview of the neuropsychological phenotypes of each etiology. Last, we discuss behavioral interventions to improve outcomes in neurodegenerative disease. Note that these interventions align with the syndromes rather than the etiologies.

## Syndromes

### Clinical Criteria

The American Psychiatric Association panel on neurocognitive disorders decided to sunset the term *dementia* (Ganguli et al., 2011) and to elevate the concept of *mild cognitive impairment* (MCI) to more formal status in DSM-5. The respective terms *major neurocognitive disorder* (MND) was

included in DSM-5 to replace the dementia and *mild neurocognitive disorder* (mND) and was elevated from use in research only to full clinical criteria. The DSM-5 criteria for major and mild neurocognitive disorder are as follows (American Psychiatric Association, 2010).

### Major Neurocognitive Disorder

- 1 Evidence of significant cognitive *decline from a previous level of performance* in one or more cognitive domains (enumerated as complex attention, executive ability, learning and memory, language, visual constructional-perceptual ability, and social cognition) based on:
  - a reports by the patient or a knowledgeable informant, or observation by the clinician, of clear decline in specific cognitive abilities;
  - AND
  - b clear deficits in objective assessment of the relevant domain, which is typically > 2.0 standard deviations below the mean (or below the 2.5th percentile) of an appropriate reference population (i.e., age, gender, education, premorbid intellect, and culturally adjusted).
- 2 The cognitive deficits are sufficient to interfere with independence; at a minimum requiring assistance with instrumental activities of daily living (ADLs; and i.e., more complex tasks such as finances or managing medications).
- 3 The cognitive deficits do not occur exclusively in the context of a delirium.
- 4 The cognitive deficits are not wholly or primarily attributable to another Axis I disorder (e.g., major depressive disorder, schizophrenia).

### Mild Neurocognitive Disorder

- 1 Evidence of minor cognitive decline from a previous level of performance in one or more of the domains outlined above based on:
  - a reports by the patient or a knowledgeable informant, or observation by the clinician, of minor levels of decline in specific abilities as outlined for

the specific domains described in Item 1 in the Major Neurocognitive Disorder list;  
AND

- b** mild deficits on objective cognitive assessment, typically 1.0 to 2.0 standard deviations below the mean (or in the 2.5th to 16th percentile) of an appropriate reference population (i.e., age, gender, education, premorbid intellect, and culturally adjusted). When serial measurements are available, a significant (e.g., 0.5 SD) decline from the patient's own baseline would serve as more definitive evidence of decline.
- 2 The cognitive deficits are not sufficient to interfere with independence (instrumental ADLs are preserved), but greater effort and compensatory strategies may be required to maintain independence.
  - 3 The cognitive deficits do not occur exclusively in the context of a delirium.
  - 4 The cognitive deficits are not wholly or primarily attributable to another Axis I disorder (e.g., major depressive disorder, schizophrenia).

These criteria underwent field testing to establish inter-rater and test-retest reliabilities at two primary sites: the University of California, Los Angeles, and Mayo Clinic in Minnesota (Regier et al., 2013). The primary author (GES) of this chapter led the field trial at Mayo. The inter-rater reliabilities obtained for these diagnoses are listed in Table 30.1.

Note that while both the UCLA and Mayo Clinic sites had acceptable and comparable inter-rater reliabilities for MND, kappa values were discrepant between the sites for mND. This may have resulted from several differences in the conduct of the field trial at each site, including the following:

- Mayo Clinic recruited predominantly from a neuropsychological assessment lab, whereas UCLA recruited from a geriatric psychiatry clinic.
- Therefore, Mayo Clinic had neuropsychological data in adjudication of a vast majority of its cases. UCLA used neuropsychological data to render diagnoses in far fewer cases.
- Two neuropsychologists were the clinicians independently applying the diagnostic criteria in the vast majority of cases at Mayo Clinic, whereas at UCLA a

psychiatrist and a neuropsychologist generally were the independent raters.

- Because Mayo Clinic had two neuropsychologists as the independent clinicians, they could view the same neuropsychological data set, thus ensuring the kappa values were based on the reliability of the criteria rather than the reliability of neuropsychological measures. At UCLA even when neuropsychological data was available, the neuropsychologist was competent to view more and interpret this more extensive and sensitive data while the expertise of the psychiatrist limits the cognitive data set to only the mental status result.

Ultimately, the differing kappa values between the two sites strongly suggests the importance of neuropsychological data in making a reliable DSM-5 diagnosis of mND. This is entirely expectable given that mND criterion 1b specifies a range of cognitive performance detectable on neuropsychological tests that is not likely to be discerned with simple mental status screening. Conversely, the kappa values suggest that extensive neuropsychological testing might not be required to make a reliable diagnosis of MND syndrome. Here, even though criterion 1b also specifies a range of cognitive performance, the degree of cognitive impairment is so substantial that simple mental status testing likely captures the impairments. In MND, neuropsychological data may have more value in determining etiology as opposed to the presence of the syndrome.

### Research Criteria

A task force of experts from the United States and Europe empanelled by the National Institute on Aging (NIA) and the Alzheimer's Association convened to propose updated and revised guidelines for the evaluation of AD related diagnoses (Jack et al., 2011). Although the mission of these panels was to specifically advance research and clinical understanding of AD, the principles apply to other forms of dementia as well. By clearly specifying that the syndromic phases *may* be due to AD the criteria acknowledge that these same syndromes may not be due to AD but rather due to another etiology. The two most notable differences of the new criteria relative to the AD criteria published in 1984 (McKhann et al., 1984) are the incorporation of underlying disease biomarkers and the recognition of different syndromic phases of disease: pre-clinical AD, MCI, and dementia of the AD type.

### Preclinical Stage

A variety of scientific advances are permitting the possibility of identifying biomarkers for neurodegenerative disease that can or might be detected years before symptoms arise. For several decades this has been true in Huntington's disease (HD) where detection of tri-nucleotide repeats predicted with accuracy who would eventually develop symptoms

Table 30.1 Field testing inter-rater reliability of DSM-5 neurocognitive disorder diagnoses (Regier et al., 2013)

	<i>DX</i>	<i>Kappa</i>	<i>CI</i>	<i>Interpretation</i>
Mayo Clinic	MND	.75	.59–.9	Very good
	mND	.76	.6–.88	Very good
UCLA	MND	.8	.65–.9	Very good
	mND	.18	.03–.32	Unacceptable
Dallas VA	mND	.43	.12–.66	Unsuccessful estimate

(Snell et al., 1993). Causative genetic mutations have also been established for variants of fronto-temporal dementia (Baker et al., 2006), cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) (Peters et al., 2005), as well as for AD (Hutton & Hardy, 1997). A variety of susceptibility genes for AD (Ertekin-Taner, 2007), particularly the apolipoprotein E (APOE) gene (Corder et al., 1993), and for Parkinson's disease (PD; see Lesage & Brice, 2009) have also been detected that appear to increase the risk of disease development.

In addition to genetic markers, neuroimaging technologies now permit identification of additional biomarkers, such as amyloid (Quigley, Colloby, & O'Brien, 2011) and phosphorylated tau accumulation (Zhang et al., 2012) in the brain, as well as cerebral hypometabolism (Mosconi et al., 2008) and disintegration of nodal network resting state function (Rombouts, Barkhof, Goekoop, Stam, & Scheltens, 2005) that have been shown to be associated with AD. These various technologies permit increasing accuracy at identifying people with a neurodegenerative process even if they are asymptomatic. An important analysis by Knopman suggests that more than 50% of a population-based sample of people over the age of 70 had indicators of neurodegeneration in spite of being found cognitively normal on full neurological and neuropsychological evaluation (Knopman et al., 2013).

#### *Generic Mild Cognitive Impairment Criteria*

The NIA Alzheimer's Association work group on MCI (Albert et al., 2011) proposed a two-step process as a clinical diagnosis of "generic" MCI, suggesting that MCI is identified first then biomarker information is used to consider the etiology (of AD) with increasing levels of confidence. The "generic" criteria for MCI are as follows.

- 1 Concern regarding a change in cognition: There should be evidence of concern about a change in cognition, in comparison to the person's prior level. This concern can be obtained from the patient, from an informant who knows the patient well, or from a skilled clinician observing the patient.
- 2 Impairment in one or more cognitive domains: There should be evidence of lower performance in one or more cognitive domains that is greater than would be expected for the patient's age and educational background. If repeated assessments are available, then a decline in performance should be evident over time. This change can occur in a variety of cognitive domains, including: memory, executive function, attention, language, and visuospatial skills.
- 3 Preservation of independence in functional abilities: Persons with MCI commonly have mild problems performing complex functional tasks they were once able to perform, such as paying bills, preparing a meal, or shopping at the store. An individual with

MCI may take more time, be less efficient, and make more errors at performing such activities than in the past. Nevertheless, individuals with MCI generally maintain independence of function in daily life with minimal aids or assistance.

- 4 Not demented: These cognitive changes should be sufficiently mild that there is no evidence of a significant impairment in social or occupational functioning. It should be emphasized that the diagnosis of MCI requires evidence of intraindividual change. If an individual has only been evaluated once, change will need to be inferred from the history and/or evidence that cognitive performance is impaired beyond what would have been expected for that individual. Serial evaluations are optimal to document cognitive change over time, but may not be feasible in all circumstances.

Clinically, MCI has traditionally been further divided into four subtypes: amnesic MCI-single domain, amnesic MCI-multiple domains, nonamnesic MCI-single domain, and nonamnesic MCI-multiple domains based on the nature of the cognitive impairment (Petersen et al., 2004). While the amnesic and nonamnesic MCI types are roughly as prevalent, the MCI-single domain type is more prevalent than the MCI-multiple domains type (Busse, Hensel, Guhne, Angermeyer, & Riedel-Heller, 2006). Roughly 12% of patients diagnosed with MCI convert to dementia each year, whereas 1%–2% of the general population is thought to convert from cognitively intact to dementia in one year (Crutch et al., 2013). Many studies have examined the rate and patterns of conversion from the clinical syndrome of MCI to dementia. The exploration of models predicting conversion to dementia continues. It appears that the MCI subtype helps to inform the probability of converting to a certain dementia etiology (Busse et al., 2006; Ferman et al., 2013; Knopman, 2013; Petersen et al., 2001; Smith & Bondi, 2013). Because the different dementia etiologies are now thought to include prodromal stages of MCI, the nature of the mild cognitive impairments associated with the dementia syndromes will be discussed with the differing etiologies, respectively. Suffice it to say, if the generic criteria for MCI are met, the clinician then endeavors to determine the cause or etiology of the MCI.

#### *Generic Dementia*

The updated criteria for the syndrome of dementia (McKhann et al., 2011) remain much as they have since the McKhann criteria of 1984 (McKhann et al., 1984) and as generally stated in DSM-5 (American Psychological Association, 2011). Namely, dementia is diagnosed when there is evidence of the following.

- Impairment in two or more aspects of cognitive function that

- represent a decline from a previously higher level of cognitive functions and
- are sufficient to interfere with normal daily function and
- do not occur exclusively in the context of delirium.

Dementia syndromes broadly classified as “cortical” or “subcortical.” This classification is a heuristic and it should be acknowledged that on autopsy “cortical” dementia will often include neuropathology in the subcortical regions and vice versa. The classification is largely based on the distribution and overall pattern of typical cognitive impairment (Crutch et al., 2012; Salmon & Filoteo, 2007). In general, “cortical” dementias tend to produce cognitive deficits affecting learning and memory, language, visuospatial skills, and executive functioning. “Subcortical” dementias, in addition to motor dysfunction, tend to produce slowness of thought, and also include early prominent deficits in executive function, and visuoperceptual and constructional abilities. Interestingly, the “subcortical” dementias tend to show only mild or moderate memory and language impairments that are both quantitatively and qualitatively different from those of cortical dementia patients. For example, compared to what can be seen in “cortical” dementias, such as AD, losses in semantic knowledge, or in its organization, do not occur in subcortical dementia syndromes, such as HD or PD. In addition, subcortical dementia patients appear to benefit more from phonemic cues because the cues help to obviate word retrieval difficulties whereas “cortical” dementias do not.

It is not uncommon for a patient to present with both “cortical” and “subcortical” features on neuropsychological testing, resulting in a mixed “cortical/subcortical” dementia picture. Typical AD is often considered a “cortical” dementia, whereas vascular dementia and PD are generally classified as “subcortical.” Fronto-temporal dementia and dementia due to Lewy body disease commonly appear as with a mixed cortical/subcortical presentation. The specific neuropsychological profiles of these particular syndromes will be discussed later in this chapter, in the sections entitled the “Neuropsychological Profile of . . .” Subcortical dementias, such as PD dementia, in addition to the motor disorder, usually demonstrate slowness of thought and deficits in executive functions and visuoperceptual and constructional abilities.

## Etiologies

### *Alzheimer’s Disease*

As discussed, updated guidelines now propose definitions for preclinical AD (Sperling et al., 2011). This asymptomatic stage is assumed to be present well before the development of dementia or even MCI. These operational research criteria for preclinical stages rely on different biomarkers, which are

not yet validated for clinical use. These stages are described as follows:

- 1 Stage 1. Biomarker evidence of amyloid- $\beta$  accumulation (asymptomatic cerebral amyloidosis), including
  - a elevated tracer retention on PET amyloid imaging, and/or
  - b low A $\beta$ 42 in cerebrospinal fluid (CSF) assay.
- 2 Stage 2. Additional biomarker evidence of synaptic dysfunction and/or early neurodegeneration (i.e., evidence of amyloid positivity + presence of one or more additional AD markers), including
  - a elevated CSF tau or phospho-tau,
  - b hypometabolism in an AD-like pattern (i.e., posterior cingulate, precuneus, and/or temporo-parietal cortices) on Fluorodeoxyglucose-Positron Emission Tomography (FDG-PET), and
  - c cortical thinning/gray matter loss in AD-like anatomic distribution (i.e., lateral and medial parietal, posterior cingulate and lateral temporal cortices) and/or hippocampal atrophy on volumetric magnetic resonance imaging (MRI).
- 3 Stage 3. Evidence of subtle cognitive decline, but does not meet criteria for MCI or dementia (i.e., amyloid positivity + markers of neurodegeneration + very early cognitive symptoms), including
  - a demonstrated cognitive decline over time on standard cognitive tests, but not meeting criteria for MCI; and
  - b subtle impairment on challenging cognitive tests, particularly accounting for level of innate ability or cognitive reserve but not meeting criteria for MCI.

### *Criteria for the Diagnosis of MCI Due to AD*

As discussed, directly preceding the dementia stage, the MCI stage is characterized by mild changes in cognition that are noticeable and measureable but do not disrupt day-to-day functioning. Biomarker ascertainment is used to establish level of confidence that the MCI is due to AD. Low confidence is reflected in the term *MCI with neurodegenerative etiology*. Intermediate confidence is described as MCI with presumed AD, and highest confidence is termed *prodromal AD* (Albert, et al., 2011).

### MCI OF A NEURODEGENERATIVE ETIOLOGY

The criteria outlined on p. 717 for MCI with a presumed degenerative etiology represents the typical presentation of individuals who are at an increased risk of progressing to AD dementia (Petersen et al., 1999). These individuals typically have a prominent impairment in episodic memory (i.e., amnesic-MCI), but other patterns of cognitive impairment can also progress to AD dementia over time (e.g., executive

dysfunction/nonamnesic MCI or multidomain MCI). Negative or ambiguous biomarker evidence (from either topographic or molecular biomarkers) is still consistent with the possibility that the patient with MCI has underlying AD pathology. However, if the biomarkers are negative for AD neuropathology, the likelihood that the diagnosis is due to AD, as opposed to an alternate cause, is low (Albert et al., 2011).

#### MCI OF THE ALZHEIMER TYPE

If the subject meets the MCI criteria on p. 717 but, in addition, has one or more topographic biomarkers associated with the “downstream” effects of AD pathology (e.g., MRI evidence of medial temporal atrophy, or FDG PET evidence of decreased temporoparietal metabolism, adjusting for age), then there is increased likelihood that the outcome will be AD dementia. In the absence of molecular biomarker information (or equivocal findings from molecular biomarkers) the presentation of cognitive impairment may still be consistent with an intermediate level of certainty that the individual will progress to AD dementia over time.

#### PRODROMAL ALZHEIMER'S DEMENTIA

If the subject meets the MCI criteria on p. 717, and in addition has a positive biomarker for the molecular neuropathology of AD (e.g., lower CSF A $\beta$ -42 and raised CSF tau measures), this provides the highest level of certainty that over time the individual will progress to AD dementia. This level of certainty would be increased even further if the individual has positive topographic biomarker evidence of AD. However, the absence of such topographic biomarker evidence (or equivocal or normal findings) is still consistent with the highest level of certainty that the individual will progress to AD dementia over time.

#### *Dementia Due to Alzheimer's Disease*

This stage is the most recognizable due to clear impairments in memory, cognition, and behavior that affect a person's ability to function independently in everyday life. The criteria for the diagnosis of AD dementia are based on the same criteria created almost three decades prior (McKhann et al., 1984) and attempt to update and clarify the diagnosis of dementia due to AD from other causes. These revised 2011 criteria (McKhann, 2011) include the following.

- 1 Insidious onset, in that symptoms have a gradual onset over months to years, and the onset was not sudden over hours or days; and,
- 2 clear-cut history of worsening cognition by report or observation; and

- 3 cognitive deficits are evident on history and examination in one of the two categories, including the following:
  - a Amnesic presentation. The most common syndromic presentation of AD dementia. The deficits should include impairment in learning and recall of recently learned information. There should also be evidence of cognitive dysfunction in other cognitive domains.
  - b Nonamnesic presentation:
    - i Language presentation: The most prominent deficits are in word-finding, but dysfunction in other cognitive domains should be present.
    - ii Visual presentation: The most prominent deficits are in spatial cognition, including object agnosia, impaired face recognition, simultagnosia and alexia. Deficits in other cognitive domains should be present.
    - iii Executive presentation: The most prominent deficits are in impaired reasoning, judgment and problem solving. Deficits in other cognitive domains should be present.

In addition, characterization of AD dementia based on level of certainty was proposed with the introduction of a novel neuropathology qualifier (McKhann et al., 2011).

#### PATHOLOGICALLY PROVEN AD DEMENTIA

Meets clinical and cognitive criteria for probable AD dementia during life AND is proven AD by pathological examination.

#### CLINICAL AD DEMENTIA

The “Probable” and “Possible” qualifiers of the 1984 (McKhann et al., 1984) criteria were retained:

#### PROBABLE AD DEMENTIA

Meets clinical and cognitive criteria for AD dementia given on p. 719, AND without evidence of any alternative diagnoses, in particular, no significant cerebrovascular disease. In persons who meet the basic criteria for probable AD dementia, the diagnosis of probable AD dementia can be enhanced by one of these three features that increase certainty:

- 1 *Documented decline*: Has evidence of progressive cognitive decline on subsequent evaluations based on information from informants and cognitive testing in the context of either brief mental status examinations or formal neuropsychological evaluation;  
OR
- 2 *Biomarker positive*: Has one or more of the following supporting biomarkers.
  - a Low CSF A $\beta$ 42, elevated CSF tau or phospho tau

- b** Positive amyloid PET imaging
  - c** Decreased FDG uptake on PET in temporoparietal cortex
  - d** Disproportionate atrophy on structural MRI in medial temporal lobe (especially hippocampus), basal and lateral temporal lobe, and medial parietal isocortex;  
OR
- 3** *Mutation carrier*: Meets clinical and cognitive criteria for AD dementia and has a proven AD autosomal dominant genetic mutation (PSEN1, PSEN2, APP).

#### POSSIBLE AD DEMENTIA

- 1** *Atypical Course*: Evidence for progressive decline is lacking or uncertain but meets other clinical and cognitive criteria for AD dementia;  
OR
- 2** *Biomarkers Obtained and Negative*: Meets clinical and cognitive criteria for AD dementia but biomarkers (CSF, or structural or functional brain imaging) do not support the diagnosis;  
OR
- 3** *Mixed Presentation*: Meets clinical and cognitive criteria for AD dementia but there is evidence of concomitant cerebrovascular disease; this would mean that there is more than one lacunar infarct; or a single large infarct; or extensive and severe white matter hyperintensity changes; or evidence for some features of dementia with Lewy bodies (DLB) that do not achieve a level of a diagnosis of probable DLB.

#### Not AD Dementia

- 1** Does not meet clinical criteria for AD dementia;  
OR
- 2** Has sufficient evidence for an alternative diagnosis such as human immunodeficiency virus (HIV), HD, or others that rarely, if ever, overlap with AD.

#### A Note on Biomarkers

It has become increasingly clear that certain biomarkers, like those that associate with amyloid levels, are specific to etiology but do not associate well with disease burden (Knopman et al., 2013). Others, like levels of tau in CSF, are not etiologically specific but do associate with degree of brain involvement and therefore with cognitive, behavioral, and functional changes. Current etiological and disease burden biomarkers are listed in Table 30.2. Although used primarily to define syndrome phases, cognition itself can be thought of as a disease burden biomarker as neuropsychological measures meet the definition of a biomarker (Fields, Ferman, Boeve, & Smith, 2011).

Table 30.2 Etiological and disease burden biomarkers

<i>Etiologic</i>	<i>Burden of Disease</i>
Genes	Structural MRI
Amyloid Burden	Functional MRI
	CSF Tau
REM Sleep Behavior Disorder	Cognition

#### Neuropsychology of Alzheimer's Disease

Conventional wisdom holds that the pathophysiologic changes of AD begin years prior to the clinically evident manifestations of the disease (Crutch et al., 2013). As noted, more than 50% of older adults in a population-based sample with confirmed cognitive normality are positive for neurodegenerative biomarkers on neuroimaging (Knopman et al., 2013). The distribution of etiologic versus neurodegenerative biomarkers in this population-based sample is presented in Table 30.2. The significant number of older adults with positive biomarker findings but ostensibly normal cognition is used to suggest a late appearance of cognitive changes in AD (Jack et al., 2010). This proposed late staging of the cognitive decline in AD would appear to ignore the large body of literature on preclinical episodic memory changes and its predictive power for the development of AD some years later. In fact, data from the Alzheimer Disease Neuroimaging Initiative (ADNI) suggests that memory changes are the first measurable "biomarker" for AD (see Figure 30.1) (Jedynak et al., 2012).

Three other studies from ADNI compared the utility of genetic, CSF, neuroimaging biomarkers and neuropsychological measures, as well as their combinations, to predict progression from MCI to AD. Interestingly, these studies found cognitive, rather than the other biomarkers, had the strongest predictive power for progression to dementia (Gomar et al., 2011; Heister et al., 2011; Landau et al., 2010).

#### Earliest Neuropsychological Changes of Alzheimer's Disease

##### OVERVIEW

The pattern of performance on measures of episodic and semantic memory, visuospatial skills, and specific aspects of attention, working memory, and executive function, is important in the differential diagnosis of AD compared to other, predominantly subcortical, dementias. The general profile of impairment in the cortical dementia of typical AD is characterized by prominent deficits in new learning and delayed recall with additional challenges to language and semantic memory, abstract reasoning, executive functions, with possible later involvement of attention, constructional and visuospatial abilities (Salmon & Bondi, 2009; Salmon & Filoteo, 2007; Smith et al., 2007).

#### MEMORY

Episodic memory changes have long been documented to appear in AD *prior* to the diagnosis of either dementia or MCI (Albert, Moss, Tanzi, & Jones, 2001; Bäckman, Small, & Fratiglioni, 2001; Chen et al., 2001; Fuld, Masur, Blau, Crystal, & Aronson, 1990; Grober & Kawas, 1997; Howieson et al., 1997; Jacobs et al., 1995; Lange et al., 2002). On average, individuals with preclinical AD show a significant decline in the retention aspects of episodic memory about four to five years prior to diagnosis (Chen et al., 2001; Lange et al., 2002). Following this decline in retention, retention stabilizes before it precipitously declines about one year prior to diagnosis of the dementia syndrome (Smith et al., 2007). In contrast to retention, encoding (or learning efficiency) appears to decline monotonically prior to diagnosis (Smith et al., 2007).

#### FLUENCY AND NAMING

AD patients exhibit a more pronounced impairment on category fluency than letter fluency, suggesting a breakdown in semantic knowledge access in AD (Henry, Crawford, & Phillips, 2004). AD patients also tend to make semantically based errors on confrontation naming (Salmon & Filoteo, 2007) though naming impairments are not consistently present in AD (Testa, Ivnik, & Smith, 2003).

#### EXECUTIVE FUNCTION

Early executive function impairments in AD occur in cognitive processes involved in divided attention, working memory, concept formation, and problem solving (Aretouli & Brandt, 2010; Salmon & Bondi, 2009).

#### VISUOSPATIAL SKILLS

Deficits in visuospatial skills and constructional praxis, though commonly observed in AD, tend to emerge later in the course of the disease (e.g., Mielke et al., 2007) except in the visual variant of AD, also known as posterior cortical atrophy (PCA) (Tang-Wai et al., 2004). That is, the PCA variant of AD differs from the typical AD neurocognitive profile in that the visuospatial deficits are most generally the presenting concern and most salient cognitive dysfunction causing disruption to ADLs, while memory and language skills are relatively preserved (Crutch et al., 2012; Crutch et al., 2013).

#### ASSOCIATED CLINICAL FEATURES

Behavioral disturbances are common in AD. Indeed, delusions of infidelity were the presenting complaint of Dr. Alzheimer's original AD patient, Auguste D (Alzheimer, 1906). Behavioral symptoms can contribute to differential diagnosis of dementia type, and it is often the absence or late onset of these symptoms that characterizes AD (McKeith et al., 2005). For example, disinhibition is often an early symptom of behavioral variant fronto-temporal dementia but a late symptom in AD. Moreover, late onset hallucinations is one feature distinguishing AD from Lewy body disease, in which hallucinations are an early phenomena (Ferman et al., 2003).

Rates (presumably point prevalence) of neuropsychiatric behavior in AD range from 57% for apathy, 28% for delusion, 13% for hallucination rates, and 5% for euphoria (Johnson, Watts, Chapin, Anderson, & Burns, 2011). Cumulative incidence of hallucinations and delusions is reported as 20% at one year, 36% at two, 50% at three, and 51% at four years post-baseline testing (Paulsen et al., 2000). However, the classification of neuropsychiatric symptoms using standard

psychiatric nomenclature oversimplifies and often mislabels behavior. A person with dementia may forget storing valuables and deduce they have been stolen when he or she cannot find the items. Calling this paranoid or delusional ignores that the essence of this problem is memory and reasoning failure, not the persecutory bias or paranoia. Failure to identify the cognitive deficits of AD and/or apply psychiatric nomenclature that may ignore these deficits can lead family and health professionals to mislabel and mistreat behaviors. Furthermore, this misattribution of the cognitive deficits may lead to inflated prevalence estimates for psychosis in AD. Other behavioral disturbances that may occur throughout the different stages of AD are wandering, repetitive questioning, shadowing, aggressiveness, apathy, sleep disorder, hoarding, and resistance to help with daily activities (Johnson et al., 2011).

Behavioral and psychological disturbances in AD often also relate directly to the cognitive symptoms. Importantly, these noncognitive symptoms may be responsive to specific behavioral therapies and approaches (Rodda, Morgan, & Walker, 2009; Rovner, Steele, Shmueli, & Folstein, 1996; Schneider, Pollock, & Lyness, 1990; Small et al., 1997; Sultzer et al., 2008; Teri et al., 1992). Some specific examples and strategies are offered in the Intervention section.

### ***Vascular Dementia***

In 2011, a joint American Heart Association/American Stroke Association workgroup published consensus definitions and recommendations for the vascular contributions to cognitive impairment and dementia (Gorelick et al., 2011). This statement introduces vascular cognitive impairment (VCI) to include the range from MCI syndrome (denoted as VaMCI) to dementia (denoted as VaD). These criteria excluded persons with active drug or alcohol abuse/dependence in the last three months and those with delirium.

### ***VaMCI***

As discussed with the general criteria for MCI, the diagnosis of VaMCI may be further described as single domain amnesic, amnesic plus other domains, nonamnesic single domain, and nonamnesic multiple domains based on the cognitive domain(s) impaired by vasculopathy. These criteria require assessment of the same four domains listed earlier (executive/attention, memory, language, and visuospatial functions). Instrumental ADLs could be normal or mildly impaired, independent of the presence of motor/sensory symptoms.

#### PROBABLE VAMCI

- 1 There is cognitive impairment and imaging evidence of cerebrovascular disease, and
  - a There is a clear temporal relationship between a vascular event (e.g., clinical stroke) and onset of cognitive deficits; or,

- b There is a clear relationship in the severity and pattern of cognitive impairment and the presence of diffuse, subcortical cerebrovascular disease pathology (e.g., as in CADASIL).

- 2 There is no history of gradually progressive cognitive deficits before or after the stroke that suggests the presence of a nonvascular neurodegenerative disorder.

#### POSSIBLE VAMCI

There is cognitive impairment and imaging evidence of cerebrovascular disease, but,

- 1 There is no clear relationship (temporal, severity, or cognitive pattern) between the vascular disease (e.g., silent infarcts, subcortical small-vessel disease) and onset of cognitive deficits.
- 2 There is insufficient information for the diagnosis of VaMCI (e.g., clinical symptoms suggest the presence of vascular disease, but no CT/MRI studies are available).
- 3 Severity of aphasia precludes proper cognitive assessment. However, patients with documented evidence of normal cognitive function (e.g., annual cognitive evaluations) before the clinical event that caused aphasia could be classified as having probable VaMCI.
- 4 There is evidence of other neurodegenerative diseases or conditions in addition to cerebrovascular disease that may affect cognition, such as the following.
  - a A history of other neurodegenerative disorders (e.g., Parkinson disease, progressive supranuclear palsy, dementia with Lewy bodies);
  - b The presence of AD pathology is confirmed by biomarkers (e.g., PET, CSF, amyloid ligands) or genetic studies (e.g., PS1 mutation); or,
  - c A history of active cancer or psychiatric or metabolic disorders that may affect cognitive function.

#### UNSTABLE VAMCI

Subjects with the diagnosis of probable or possible VaMCI whose symptoms revert to normal should be classified as having “unstable VaMCI.”

### ***Dementia***

The 2011 criteria include the standard diagnosis of dementia, based on a decline in cognitive function from a prior baseline and a deficit in performance in two cognitive domains from among the set executive/attention, memory, language, and visuospatial function (Gorelick et al., 2011). The requirement that the deficits are of sufficient severity to affect a person's ADLs includes the caveat that the impairments in

ADLs are independent of the motor/sensory sequelae of a vascular event.

Criteria required to meet the respective stage and diagnostic confidence of VaD are:

#### PROBABLE VAD

- 1 There is cognitive impairment and imaging evidence of cerebrovascular disease.
- 2 There is a clear temporal relationship between a vascular event (e.g., clinical stroke) and onset of cognitive deficits, or there is a clear relationship in the severity and pattern of cognitive impairment and the presence of diffuse, subcortical cerebrovascular disease pathology (e.g., as in CADASIL).
- 3 There is no history of gradually progressive cognitive deficits before or after the stroke that suggests the presence of a nonvascular neurodegenerative disorder.

#### POSSIBLE VAD

There is cognitive impairment and imaging evidence of cerebrovascular disease, but:

- 1 There is no clear relationship (temporal, severity, or cognitive pattern) between the vascular disease (e.g., silent infarcts, subcortical small-vessel disease) and the cognitive impairment.
- 2 There is insufficient information for the diagnosis of VaD (e.g., clinical symptoms suggest the presence of vascular disease, but no CT/MRI studies are available).
- 3 Severity of aphasia precludes proper cognitive assessment. However, patients with documented evidence of normal cognitive function (e.g., annual cognitive evaluations) before the clinical event that caused aphasia could be classified as having probable VaD.
- 4 There is evidence of other neurodegenerative diseases or conditions in addition to cerebrovascular disease that may affect cognition, such as the following.
  - a A history of other neurodegenerative disorders (e.g., Parkinson disease, progressive supranuclear palsy, dementia with Lewy bodies);
  - b The presence of AD biology is confirmed by biomarkers (e.g., PET, CSF, amyloid ligands) or genetic studies (e.g., PS1 mutation); or
  - c A history of active cancer or psychiatric or metabolic disorders that may affect cognitive function.

#### *Neuropsychology of Vascular Dementia*

As noted in the AD section on p. 720, distinct patterns of performance on tests of episodic and semantic memory,

visuospatial skills, and specific aspects of executive function, are important in the differential diagnosis of AD versus VaD. Some investigators express doubt that cognitive profiles are useful in separating AD from VaD (Schneider, Boyle, Arvanitakis, Bienias, & Bennett, 2007; Schneider, Wilson, Bienias, Evans, & Bennett, 2004; Wilson et al., 2011), not only because cerebrovascular disease contributes to some of the same domains of cognitive impairment as in AD (e.g., executive function), but also because of the common occurrence of mixed pathologic processes (Mielke et al., 2007). Some authors suggest that many cases of dementia meeting the original criteria for the clinical diagnosis of probable AD (McKhann et al., 1984) have been shown to arise from mixed pathologies (Schneider, Arvanitakis, Leurgans, & Bennett, 2009; Sonnen et al., 2007).

The cortical versus subcortical neuropsychological patterns, as described on p. 718 (Salmon & Filoteo, 2007), are helpful in considering diagnoses of “pure” AD versus VCI versus “mixed” pathologies if there is sensitivity to the notion that cognitive domains may have subcomponents that are differentially impaired with the cortical/subcortical heuristic. For example, episodic memory includes learning efficiency and recall/retention. A simple difference drawn between impaired retention in the case of AD (i.e., rapid forgetting) versus impaired learning efficiency in the case of subcortical ischemic VaD (i.e., retrieval deficit) can help contribute to differential diagnosis.

#### EPISODIC MEMORY AND EXECUTIVE FUNCTIONS

Patients with subcortical VaD are generally more impaired than those with AD on tests of executive functions, whereas patients with AD are more impaired than those with subcortical VaD on tests of episodic memory (Desmond, 2004; Graham, Emery, & Hodges, 2004; Kertesz & Clydesdale, 1994; Lafosse et al., 1997; Lamar et al., 1997) but see Reed and colleagues (Reed et al., 2004; Reed et al., 2007) for a differing opinion. These studies also suggest that executive dysfunction is the most conspicuous deficit associated with subcortical VaD, perhaps because the subcortical pathology frequently interrupts fronto-subcortical circuits that mediate this aspect of cognition. VaD patients with significant white matter abnormalities on imaging demonstrate a profile of greater executive dysfunction and visuoconstructive impairments than impairment of memory and language abilities (Cosentino et al., 2004; Price, Jefferson, Merino, Heilman, & Libon, 2005; Reed et al., 2004; Reed et al., 2007). The executive dysfunction observed in small vessel ischemic VaD is also qualitatively distinct from that in AD (Seidel, Tiovanetti, & Libon, 2011). The executive control deficits seen in VaD tend to be ubiquitous not merely limited to the types of executive function problems noted in the AD section above.

VaD patients tend to demonstrate better episodic memory performance relative to patients with AD (Duke & Kaszniak, 2000) and the time course of the deficit profiles differ. That

is, although executive function impairments are present in AD, they are less prominent than the episodic memory disorder during mild stages of AD and tend to become more pronounced later in the course of the illness. In contrast, patients with VaD may demonstrate executive dysfunction earlier in the disease progression and it tends to be greater than or at least equal to the degree of memory dysfunction (Reed et al., 2004; Reed et al., 2007).

#### FLUENCY AND NAMING

The output on tests of letter fluency produced by VaD patients is reduced relative to AD patients while the output on category (animal) fluency is similar to AD patients (Canning, Leach, Stuss, Ngo, & Black, 2004; Carew, Lamar, Cloud, Grossman, & Libon, 1997; Lafosse et al., 1997). The selective loss of semantic knowledge in AD impacts category fluency but mostly spares lexical fluency, whereas lexical fluency and other speed tests often are impaired in VaD due to "subcortical slowing" and not due to loss of semantic knowledge. Language disturbance is rarely specifically characterized in many studies of VaD, though one study failed to show group differences between AD and VaD on a confrontation-naming task (Laine, Vuorinen, & Rinne, 1997). Of course, in the absence of left middle cerebral artery infarction affecting language function, subcortical ischemic VaD would not be expected to impair object naming.

#### ATTENTION AND WORKING MEMORY

Patients with cerebral small vessel disease perform worse on processing speed measures (e.g., Digit Symbol) than patients with prodromal AD (Zhou & Jia, 2009). Those with cerebral small vessel disease also perform less accurately on tests designed to measure the capacity to establish and maintain a mental set through a series of tasks (Libon et al., 1997) and on measures of mental manipulation and temporal re-ordering (Lamar, Catani, Price, Heilman, & Libon, 2008; Lamar et al., 2007).

#### VISUOSPATIAL ABILITIES

Typical AD variant patients (i.e., not PCA) perform better than VaD patients on the Rey-Osterrieth Complex Figure Test (ROCF) copy portion, such that VaD patient drawings tend to be more fragmented and contain numerous perseverations and omissions (Freeman et al., 2000). VaD patients also make more clock drawing errors than AD patients (Cosentino, Jefferson, Chute, Kaplan, & Libon, 2004; Price et al., 2005).

#### *Lewy Body Disease*

Lewy body substrates are intraneuronal inclusions made of alpha-synuclein (McKeith et al., 2004). When seen in high enough concentration in the substantia nigra, these inclusions

associate with parkinsonism (e.g., idiopathic PD). When also present in the cortex they can produce Lewy body disease. Often the acronyms LBD and DLB are used interchangeably. The subtle difference between these acronyms as used herein, is that LBD for Lewy body disease can be applied to any of the syndromes preclinical, MCI, or dementia, and while DLB applies only to the dementia syndrome due to Lewy body disease.

At the time of writing this chapter, the most recent consensus diagnostic criteria for Lewy body disease were updated in 2005 (McKeith et al., 2005), though revised criteria are anticipated in the near future. These 2005 criteria differed from the original with the inclusion of additional suggested features, most notably, REM sleep behavior disorder (RBD). Interestingly, in a more recent autopsy validation study, each of the three core features of LBD (parkinsonism, hallucinations, and fluctuations) increased the odds of autopsy-confirmed DLB up to twofold, while RBD increased the odds by sixfold (Ferman et al., 2011).

#### *Preclinical Lewy Body Disease*

In vivo imaging of the presence of alpha-synuclein in the brain is not yet available. There is emerging evidence that detection of abnormal dopamine transporter levels—currently via Iodine-123 fluoropropyl ([123I]FP-CIT) single photon emission computed tomography (SPECT)—scanning can identify people at risk to display cardinal features of LBD in the near future (Siepel et al., 2013). However, the most compelling "preclinical" marker for LBD is likely RBD (Ferman et al., 2011). Here, "preclinical" refers to the period preceding cognitive, behavioral, and functional change, but after the development of RBD.

As shown by case studies (Boeve et al., 2007; Turner, D'Amato, Chervin, & Blaivas, 2000), RBD may precede the onset of other symptoms of neurodegenerative diseases by years and even decades (Boeve et al., 1998; Plazzi et al., 1997; Schenck, Bundlie, & Mahowald, 1996; Turner, Chervin, Frey, Minoshima, & Kuhl, 1997). The estimated 5-year risk of developing PD or LBD in a cohort with idiopathic RBD is 17.7%, and the 12-year risk is 52.4% (Postuma et al., 2009). Twelve of 15 patients with a diagnosis of RBD and a neurodegenerative disorder that came to autopsy had Lewy body disease while the other three had multiple system atrophy (MSA), another known synucleinopathy. These findings provide compelling evidence that RBD reflects an underlying synucleinopathy (Boeve et al., 2003; Hulette et al., 1995). Therefore, RBD may serve as a valuable potential 'etiologic biomarker' identifying persons at high risk for MCI and ultimately dementia due to synucleinopathy.

#### *MCI due to LBD*

When people meet generic criteria for MCI, and RBD is present, no matter whether parkinsonism or visual hallucinations are present, the cognitive pattern is

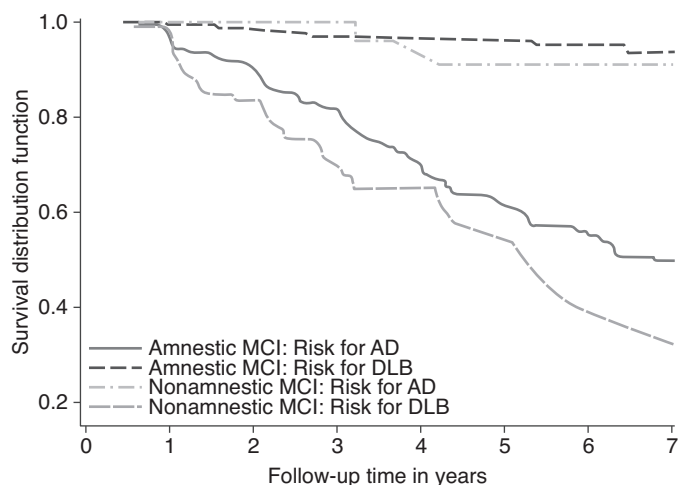

Figure 30.2 Progression of amnestic and nonamnestic MCI to dementia due to AD versus dementia due to Lewy body disease. Reproduced from (Ferman et al., 2013) with permission.

indistinguishable from LBD. Further, the cognitive profile of both those with MCI and RBD only and those with MCI plus the two or more cardinal symptoms of LBD significantly differs from AD (Ferman et al., 2002). In each case (RBD only or RBD plus cardinal features), Lewy bodies are present on autopsy (Molano et al., 2010). Thus RBD and cognitive change is one form of the MCI due to LBD.

The MCI phenotype for LBD tends to involve visuospatial and/or attention deficits (Ala, Hughes, Kyrouac, Ghobrial, & Elbie, 2001; Ballard et al., 1999; Calderon et al., 2001; Ferman et al., 1999) though memory impairments may also be present. This is understandable given that Lewy bodies and neuritic plaques and neurofibrillary tangles are all common in Lewy body dementia. Nevertheless relative to an amnestic MCI profile, a nonamnestic profile MCI is far more likely (Ferman et al., 2013). See Figure 30.2.

#### Criteria for Dementia Due to Lewy Body Disease (McKeith, et al., 2005)

- 1 Central feature (essential for a diagnosis of possible or probable DLB) is dementia defined as progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function.
  - a Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression.
  - b Deficits on tests of attention, executive function, and visuospatial ability may be especially prominent.

- 2 Core features (two core features are sufficient for a diagnosis of probable DLB, one for possible DLB):
  - a Fluctuating cognition with pronounced variation in attention and alertness.
  - b Recurrent visual hallucinations that are typically well formed and detailed.
  - c Spontaneous features of parkinsonism.
- 3 Suggestive features (if one or more of these suggestive features is present in the presence of one or more core features, a diagnosis of probable DLB can be made. In the absence of any core features, one or more suggestive features is sufficient for possible DLB. Probable DLB should not be diagnosed on the basis of suggested features alone):
  - a REM sleep behavior disorder.
  - b Severe neuroleptic sensitivity.
  - c Low dopamine transporter uptake in the basal ganglia demonstrated by SPECT or PET imaging.
- 4 Supportive features (commonly present but not proven to have diagnostic specificity):
  - a Repeated falls and syncope.
  - b Transient, unexplained loss of consciousness.
  - c Severe autonomic dysfunction, e.g., orthostatic hypotension, urinary incontinence.
  - d Hallucinations in other modalities.
  - e Systematized delusions.
  - f Depression.
  - g Relative preservation of medial temporal lobe structures on CT/MRI scan.
  - h Generalized low uptake on SPECT/PET perfusion scan with reduced occipital activity.
  - i Abnormal (low uptake) metaiodobenzylguanidine (MIBG) myocardial scintigraphy.
  - j Prominent slow wave activity on EEG with temporal lobe transient sharp waves.
- 5 A diagnosis of DLB is less likely in the following circumstances:
  - a In the presence of cerebrovascular disease evident as focal neurologic signs or on brain imaging;
  - b In the presence of any other physical illness or brain disorder sufficient to account in part, or in total for the clinical picture; or
  - c If the parkinsonism only appears for the first time at a stage of severe dementia.
- 6 Temporal sequence of symptoms:
  - a DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism (if it is present). The term *Parkinson's disease dementia* (PDD) should be used to describe dementia that occurs in the context of well-established Parkinson's disease. In a clinical practice setting, the term that is most appropriate to the clinical situation should be used and generic terms such as *LB disease* are often helpful. In research studies in which distinction needs to be made between DLB

and PDD, the existing one-year rule between the onset of dementia and parkinsonism, DLB continues to be recommended. Adoption of other time periods will simply confound the data pooling or comparison between studies. In other research settings that may include clinicopathologic studies and clinical trials, both clinical phenotypes may be considered collectively under categories such as LB disease or alpha-synucleinopathy.

### *Neuropsychology of Lewy Body Disease*

Impairment in basic attention, visual perception, visual construction and memory distinguish LBD from normal aging (sensitivity of 88.6%, specificity of 96.1%) (Ferman et al., 2006). However, impaired visual construction and attention plus relatively spared memory and naming skills can distinguish dementia due to DLB from AD (sensitivity of 83.3% and a specificity of 91.4% (Ferman et al., 1999; Ferman et al., 2002; Ferman et al., 2006). These findings highlight that the degree of visual perceptual and attentional impairment relative to memory impairment helps identify dementia due to LBD. In early typical AD, memory impairments are far more pronounced than attention or visual perception problems, but in LBD, attention and visual perception impairments are more salient.

### *Visuospatial Ability*

LBD is associated with significant deficits in higher order visual processing, a finding that is not attributable to motor slowness associated with parkinsonism. Interestingly, people with LBD who experience visual hallucinations tend to do more poorly on visual tasks (Mosimann et al., 2004). Nonetheless, some studies have not found differences between AD and DLB on visual tasks (Forstl, Burns, Luthert, Ciarns, & Levy, 1993; Gnanalingham, Byrne, Thornton, Sambrook, & Bannister, 1997). One explanation is that the inclusion of patients in the advanced stages of dementia can obfuscate group differences due to generalized impairment.

Alternately, impaired performance on visual tasks may be the result of differential impairment of other task demands. For example, visual problem solving may be negatively affected by executive difficulties in AD, and by perceptual difficulties in DLB. Mori and colleagues examined this issue and revealed deficits in DLB but not AD on basic visual tasks that did not require executive function (Mori et al., 2000). Anatomical differences may also be contributing to poor performance on visual tasks. For example, reflexive saccadic eye movements responsible for shifting the fovea towards visual targets show greater impairment for the PD with dementia (PDD) and LBD groups compared to AD, PD without dementia groups, and normal controls (Mosimann et al., 2005). Also, flash electroretinography reveals abnormalities of the photoreceptors in the retina that may

interfere with signal transmission to the bipolar cells (Devos et al., 2005). Regional blood flow has been shown to be lower in occipital regions in DLB but not AD (Imamura et al., 2001; Lobotesis et al., 2001). Overall, these findings suggest that the etiology of the visual impairment in DLB may not be entirely due to disruption of the cortical extra-striate association areas, but may also have an afferent or earlier neural contribution before reaching the cortex for further processing.

### *Episodic Memory*

Memory difficulties, when present in early DLB, appear to be fairly mild and stand in direct contrast to the pronounced amnesic disturbance of AD. The memory problems are more likely to show a pattern of poor initial learning without the rapid forgetting that is typically observed in AD (Hamilton et al., 2004; Salmon, 2004). When people with pure AD (i.e., without concomitant Lewy bodies) were compared to those with pure LBD or mixed AD and LBD, they performed worse on tasks of verbal memory, while patients with pure LBD pathology performed worse on tasks of visual spatial skills. Those with combined pathology had poor visual spatial performance and nonverbal memory challenges but not verbal memory deficits (Johnson, Morris, & Galvin, 2005).

### *Fronto-temporal Lobar Degeneration*

As is important for AD, vascular disease and LBD, there is need to distinguish the dementia syndromic phase of fronto-temporal lobar degeneration (FTLD) process. FTLD remains a heterogeneous collection of syndromes and associated neuropathologies, whereas the nomenclature *FTD* refers more specifically to the clinical aspects of the syndrome (Josephs, 2008). FTLD nosologies include different ranges of diagnoses (e.g., Pick's disease or primary progressive aphasia), syndromes (e.g., dementia with motor neuron disease), and etiologies (e.g., tauopathies vs. TDP-43 proteinopathies) (Josephs, 2008; Smith & Bondi, 2013). Currently, most nosologies include three main phenotypes: behavioral variant-FTD (bvFTD), semantic dementia, and primary progressive aphasia (PPA). PPA can be further subdivided into three variants, including logopenic (lvPPA), semantic (svPPA) and agrammatic (agPPA) (Gorno-Tempini et al., 2011), with the later sometimes referred to as *nonfluent progressive aphasia* (PNFA). The variant of PPA is classified based on clinical findings, with speech pathologists currently providing the most sensitive diagnostic differentiation. Recent pathology studies suggest that the svPPA and agPPA variants of PPA are more consistently predictive of FTLD spectrum disorders (i.e., tauopathies, TDP-43) while the lvPPA variant is strongly associated with AD pathology (Harris et al., 2013). Providing diagnostic criteria for all of these syndromes is beyond the scope of this chapter, in part because these criteria are dynamic and consensus remains a bit elusive. Indeed,

with the rapidly progressive understanding of these clinical entities, there has been increasing incentive to update the diagnostic criteria of PPA (Mesulam & Weintraub, 2014; Wicklund et al., 2014). For a more extensive review of this topic, the reader is referred to other sources (see (Josephs, 2008; Miller, 2013).

### *Preclinical FTD*

In the past five years several genetic mutations associated with FTD have been discovered. These include mutations in the MAPT, GRN, and C9ORF72 genes (Rohrer, Warren, Fox, & Rossor, 2013). These genes provide etiological markers that can be identified in the presymptomatic state. In addition, PET imaging of tau is currently under study and *may* soon provide to be a biomarker of FTD-associated accumulation.

### *Mild Cognitive Impairment and FTL D*

As the name, behavioral variant-FTD implies, the MCI phase of FTD often presents as impairments in “social cognition” with combinations of obsessions, disinhibition, apathy irritability, elation, lack of empathy or egocentrism, and aberrant motor behavior (de Mendonca, Ribeiro, Guerreiro, & Garcia, 2004; Miller et al., 2003). In contrast, the temporal variants of FTD, including the PPA variants, demonstrate early deficits in predominantly language, semantic knowledge or speech (Josephs, 2008; Machulda et al., 2013; Perry & Hodges, 2000; Wicklund, et al., 2014), though other neurocognitive deficits in the logopenic variant, in particular, may be affected though to a lesser degree than language (Rohrer et al., 2010; Butts et al., 2015). Yet most variants of FTL D show some similarities in behavioral disturbances, and significantly increased behavior disturbance when compared to AD patients matched on age and severity (Liu et al., 2004).

### *Neuropsychology of FTD*

There are at least five challenges to describing “the” neuropsychology of FTD (Wittenberg et al., 2008). As previously described, (a) the diagnostic criteria for FTD have evolved and (b) remain confusing because (c) FTD is rare and sample sizes in descriptive studies are small, leading to variable findings, and (d) studies tend to lump bvFTD, semantic dementia, and PPA types to increase sample size, and finally, (e) to compare and contrast within FTL D syndromes and with other dementias, one must equate for severity. This is challenging since severity scales tend to be disease specific. Additionally, because many neuropsychological tests are mediated by language, assessing neurocognitive functioning beyond language in PPA patients can be particularly challenging. Thus, the known neuropsychological profiles associated with specific FTD syndromes are discussed in the rest of this section.

### LEARNING AND MEMORY

FTD syndromes all contrast with AD in the relative preservation of memory early in the illness (Hutchinson & Mathias, 2007). In general, FTD patients have better free and cued recall, as well as better recognition memory than typical AD patients. A study examining learning and memory in PPA patients found evidence for impaired encoding and retrieval of verbal information in a pattern that differed from AD patients (Weintraub et al., 2013). Furthermore, we have also shown differing neuropsychological profiles among the three variants of PPA, including impaired learning and complex retention in lvPPA relative to svPPA and agPPA variants (Butts et al., 2015). Of course, as dementia worsens, all of the FTD variants show worsening memory performance, due not just to deterioration of attention and language skills, but due to eventual disease encroachment on mesial temporal structures. This highlights the notion that neuropsychological tests may have their greatest value in MCI and early dementia states and lose discriminative value as disease worsens.

### FLUENCY AND LANGUAGE

There is, of course, variability in the regional atrophy of FTL D (Whitwell et al., 2009). As expected, this is associated with variable patterns of cognitive performance such that more frontal atrophy is associated with greater lexical fluency problems relative to more temporal patterns of atrophy that show greater challenges in naming. Overall, FTL D patients tend to display comparable deficits in semantic (category) and lexical (letter) fluencies (Rascovsky, Salmon, Hansen, Thal, & Galasko, 2007), whereas selective category fluency deficits commonly occur in AD (Monsch et al., 1992). While this impression may derive mostly from the inclusion of PNFA and semantic dementia patients in past FTL D studies, it also appears to hold for bvFTD cohorts (Rascovsky et al., 2007). While, the neurodegenerative syndrome of primary progressive apraxia of speech (PPAOS) is differentiated from primary progressive aphasia (Josephs et al., 2012), PPAOS is a known FTL D syndrome associated with tauopathy (Caso et al., 2014). This syndrome is characterized by impaired speech motor planning and/or organization resulting in dysfluent speech rather than a language deficit (Josephs et al., 2013; Josephs et al., 2012). Multiple neuroimaging modalities isolate PPAOS to the superior lateral premotor and supplementary motor area, which differentiates it from PPA that may affect additional frontal, temporal, parietal, and subcortical regions depending upon PPA variant (Josephs et al., 2013; Josephs et al., 2006; Whitwell et al., 2013).

### LANGUAGE/SEMANTIC KNOWLEDGE

By definition (i.e., required for the diagnosis), the progressive aphasia variants of FTL D have deficits in aspects of language that cause disruption in daily function (Mesulam, 1982). In addition to fluency problems, lvPPA patients have problems

with confrontation naming, repeating, and comprehending sentences, relatively preserved single word comprehension, with evidence of anomia, slowed rate of verbal expression due to pauses for word retrieval or verbal formulation, and possible phonemic paraphasias (Gorno-Tempini et al., 2011; Machulda et al., 2013). The aphasia in svPPA is dominated by anomia, poor word comprehension, and loss of single word and object meaning. Interestingly, the repetition and fluent speech is relatively preserved though the content may lack specificity (Gorno-Tempini et al., 2011).

#### EXECUTIVE FUNCTION

While FTLD patients have impairments on executive function tests, these tests have limited utility in differential diagnosis (Miller et al., 2003). FTLD and AD patients cannot be reliably distinguished by Trail Making Test Part B or the Stroop test (Hutchinson & Mathias, 2007). This may arise in part from the problem of mixing different FTLD syndromes, as described, but also may reflect that fairly early there is involvement of the frontal lobes in the typical AD process (Braak & Braak, 1997). However, studies also suggest that executive function tests may not be that good at distinguishing FTLD patients from normally aging samples. FTLD patients often score in the normal range on Wisconsin Card Sorting Test, Stroop, Digits Backwards from the Digit Span subtype, and on the Letter-Number Sequencing tasks (Wittenberg et al., 2008). Thus, traditional “frontal” measures have inconsistent sensitivity and poor differential specificity for the broad class of FTLD syndromes.

#### VISUOSPATIAL SKILLS

Tests of visuospatial skills tend to be preserved in FTLD syndromes, given the relative sparing of posterior cortices. For example, visuoconstructional deficits, but not memory deficits, have been shown to help distinguish AD from FTD (Razani, Boone, Miller, Lee, & Sherman, 2001). An earlier study from this group suggested AD and FTD groups differed on the discrepancy between nonverbal memory and letter fluency. Specifically, they found AD patients tended to have greater memory deficits relative to letter fluency problems, and FTD patients demonstrated the reverse pattern of

greater fluency deficits relative to memory (Pachana, Boone, Miller, Cummings, & Berman, 1996).

### Interventions

There are numerous strategies that can be deployed to try to prevent or delay progression from preclinical status to MCI to dementia. Table 30.3 provides a conceptual framework for these interventions.

#### Primary Prevention

The evidence supporting a role for primary prevention interventions in dementia is accumulating. Nearly all primary prevention models involve lifestyle modifications that improve overall health. A population-wide 25% reduction in midlife diabetes, obesity, hypertension, and physical and cognitive inactivity could potentially alleviate 500,000 cases of dementia (Barnes & Yaffe, 2011). The conceptual basis for these primary prevention strategies is likely the enhancement of cognitive reserve or resilience (Stern, 2006, 2009).

Two general approaches for maintaining or improving cognitive function in older adult have been studied. The first approach involves instruction in putatively useful strategies. This method yields improvement on cognitive test scores specific to the strategy instruction, but gains do not typically generalize to other tests or areas of function (Fillit et al., 2002). This ability to generalize a learned skill to other skills is a concept known as *transfer* (Rebok, Carlson, & Langbaum, 2007). Transferring from one skill to another may be “near” or “far” based on the relatedness of the tasks. Far transfer of putative techniques is poor (Zelinski et al., 2011), and older adults do not generally continue to use learned strategies over time (Rebok et al., 2007). Due to the relatively limited generalizability of “new” skills, strategy-training programs have not been widely adopted as a primary prevention approach. However, emerging literature suggests that information processing system improvement can occur via intensive learning and practice (Mahncke, Bronstone, & Merzenich, 2006). For example, computer training in information processing speed produces improvement in working memory related to neuropsychological tests (word list total score, digits backwards, letter-number sequencing) and in

Table 30.3 A conceptual framework for prevention and treatment interventions in AD

	<i>Prevention</i>		<i>Treatment</i>	
	<i>Behavioral/psychological</i>	<i>Pharmacological</i>	<i>Behavioral/psychological</i>	<i>Pharmacological</i>
Cognition	Brain fitness/physical fitness/	–	–	Acetylcholinesterase
Daily Function	social engagement	–	Compensation training	Inhibitors ?
Mood		–	Psychotherapy	SSRIs
Disruptive Behavior	Person centered, activity-based care	–	Person centered, activity-based care	Neuroleptics

participant-reported outcome measures (Smith et al., 2009; Zelinski et al., 2011). This improvement in working memory function may serve to enhance cognitive reserve.

The overall benefits of physical exercise are extensive, and there is growing evidence that physical exercise is an important factor in maintaining cognitive and cerebral health. For example, in healthy individuals, physical activity has been shown to help maintain healthy brain volume and provide protection against volume loss (Colcombe et al., 2003; Colcombe et al., 2006). Furthermore, higher levels of physical activity is correlated with larger volumes of the hippocampus, a region essential for memory (Erickson et al., 2009), and acts to increase hippocampal volume (Erickson et al., 2011). As assessed by a functional MRI (fMRI) paradigm examining patterns of activation during a semantic memory task, increased physical activity appears to be particularly beneficial for individuals who are at risk for AD (Smith et al., 2011).

### **Secondary Prevention**

The focus on pre-clinical and MCI syndromes permits a concurrent focus on secondary prevention models aimed at delaying (or ideally preventing) progression to dementia. Interventions in the preclinical stage align with the primary prevention strategies noted in the previous section. The approaches that follow focus on different aspects of the MCI syndrome as described in Table 30.3.

#### *Behavioral/Psychological Interventions for MCI*

##### COGNITIVE/FUNCTIONAL/MOOD SYMPTOMS

Memory rehabilitation can take two forms: (a) “memory building” or restorative techniques in which the goal is to regain memory function through repetitive training paradigms; or, (b) “memory compensation” or techniques focused on using external aids to help compensate for memory loss. Memory notebooks are a form of memory compensation with validated efficacy in TBI patients (Sohlberg & Mateer, 1989). There has been relatively little research regarding cognitive rehabilitation techniques in patients with MCI. Recent trials of a computer training program have suggested only modest benefit or no change in cognition and mood in patients with MCI (Barnes et al., 2009; Rozzini et al., 2007; Talassi et al., 2007; Unverzagt et al., 2007). However, in at least one study (Barnes et al., 2009), the observed effect size for those patients who completed a cognitive training intervention was nearly the same as the significant effect size reported for normal older adults (Smith et al., 2009). This suggests that some MCI studies may be underpowered to see the modest beneficial effect of computer training.

As noted, a second strategy involves using an external memory compensatory strategy for MCI patients comparable

to that used in traumatic brain injury (Sohlberg & Mateer, 1989). There is emerging evidence that a memory compensatory strategy using external aides can benefit daily function and quality of life in persons with amnesic MCI (Greenaway, Duncan, & Smith, 2013; Greenaway, Hanna, Lepore, & Smith, 2008).

Physical activity interventions may also serve minimize cognitive decline in MCI (Ahlskog, Geda, Graff-Radford, & Petersen, 2011; Lautenschlager et al., 2008). Additionally, a brief 12-week exercise intervention for individuals with MCI showed normalization of brain activation during a semantic memory fMRI task, suggesting that exercise may help to improve neuronal efficiency in MCI (Smith et al., 2013). The emerging trend, however, is to provide multicomponent interventions for persons with MCI (Rapp, Brenes, & Marsh, 2002). Mayo Clinic investigators, including this chapter’s lead author (GES), have created a program for MCI that includes five components: (a) memory compensation training with a calendar/journaling tool; (b) Brain Fitness with a well-studied computerized tool (Barnes et al., 2009; Smith et al., 2009); (c) physical fitness; (d) caregiver and patient support groups; and, (e) wellness education. This ten-day, 50-hour program is called Healthy Action to Benefit Independence and Thinking (HABIT). This intervention has had positive impact on self-efficacy and quality of life outcomes for patients and caregivers (Greenaway et al., 2013).

### **Tertiary Prevention: Nonpharmacological Interventions**

#### *Cognitive and Functional Symptoms*

Memory rehabilitation in dementia has also focused on memory building techniques, with mixed results of effectiveness (Clare, Woods, Moniz Cook, Orrell, & Spector, 2003). Memory compensation in dementia using notebooks and calendars as a way of orienting significantly impaired individuals to date, basic schedules, and personal information has also showed mixed success (Loewenstein, Acevedo, Czaja, & Duara, 2004). A recent multicomponent rehabilitation approach demonstrated that individuals with MCI, but not early dementia, showed improvements in mood, memory, and functional abilities (Kurz, Pohl, Ramsenthaler, & Sorg, 2009). These data suggest primary and secondary prevention interventions may have more potential than tertiary interventions to impact cognition and function.

#### *Mood*

Diagnostic criteria for depression include dysphoria and vegetative changes in sleep, appetite, and activity level. There is a tendency to interpret the term *dysphoria* as “sad mood,” but the term may also involve irritability. While DSM-5 (Association, 2013), specifically includes both sadness and irritability as components of depression in adolescents, this

accommodation has not been applied to patients with cognitive impairment. A significant proportion of the cases of "agitation" in dementia are likely cases where the irritability of depression is present along with vegetative changes. Estimates suggest that 40% of AD patients may experience symptoms of depression at some point during the course of their illness (Burns, Jacoby, & Levy, 1990). Ascertaining depression can be difficult, even in MCI stages, because patients are challenged to reliably report mood over time. In dementia, the patient's ability to understand concepts like "feeling blue" or "having low self-esteem" also may deteriorate. Informant report, while typically reliable, may not be valid since the informant must infer the patient's subjective state. In dementia, the full range of evidence—including self- and informant-report and behavioral observations—needs to be considered when evaluating for mood disorder in dementia. Agitated patients often responded well to antidepressant medication in combination with behavioral activation.

### *Disruptive Behaviors*

Behavioral disturbance is common in AD, and nonpharmacologic approaches to disruptive behaviors are the first-line treatment. These approaches can be effective in managing behavioral and psychological symptoms at home and in institutional settings. A recent meta-analysis of nonpharmacological interventions for neuropsychiatric symptoms of dementia revealed that studies generally used multiple types of interventions, including the following elements: (a) skills training for caregivers, (b) education for caregivers, (c) activity planning and environmental redesign, (d) enhancing support for caregivers, and (e) self-care techniques for caregivers, as well as (f) exercise for the patient and (g) collaborative care with a health professional (Brodaty & Arasaratnam, 2012). Given the range of interventions, it is clear why establishing efficacy on nonpharmacological interventions is difficult. Yet, it is evident from the list of available interventions that successful interventions are typically oriented towards the caregiver rather than the patient with dementia. Caregivers who learn what to expect as the disease progresses can anticipate cognitive and functional limitations and the expected behavioral effects as the dementia progresses.

One approach to conceptualizing management interventions for disruptive behaviors involves the following:

- 1 Understanding the etiology of the dementia syndrome
- 2 Assessing the severity of the illness
- 3 Recognizing that behavior is a form of communication and it is important to try to understand what is being communicated based by the behavior:
  - a Identifying environmental, physical, psychological, or social factors that may be the impetus for behavioral communication
- 4 Managing antecedents, not consequences

- 5 Using what the dementia "gives": taking advantage of the key features of the dementia syndrome to enhance contentment
- 6 Focusing on activity-based care
  - a Avoidance of efforts to create a behavioral vacuum

### UNDERSTANDING THE ETIOLOGY OF THE DEMENTIA SYNDROME

Often, patients in care facilities have a generic dementia diagnosis without benefit of evaluation of the etiology of the dementia. Establishing etiology can avoid iatrogenic mistakes like oversedation from antipsychotic medications. Understanding that different behavioral profiles associate with dementia etiologies, (e.g., fully formed visual hallucinations are common early in LBD, but only later in AD) it is possible to more effectively consider whether comorbidities may be present. For example, observing visual hallucinations would raise concern about delirium early in AD, whereas these symptoms would be an expected part of the disorder in early DLB. Or, disrobing might be understood as simple disinhibition in an early FTD, versus communicating the need to use the bathroom in advanced AD. Understanding the nature and extent of the dementia can help provide the context for understanding what behavior may be communicating.

In dementia, understanding that new learning is often impossible helps caregivers understand why frequent reorientation is an exercise in futility and may well be agitating to the person with dementia (and her or his caregiver!). Understanding this cognitive deficit can also clarify behaviors that otherwise get mislabeled. The case of a person with AD forgetting where she placed valuables, like a purse, then assuming she is being robbed reframes "paranoia" to rather be poor memory and poor reasoning. Likely the most appropriate intervention here is to have caregivers unobtrusively search living quarters for the purse instead of giving psychotropic medication for psychosis. Understanding these patterns facilitates appropriate intervention plans. Helping caregivers understand these patterns aids their adherence to intervention plans.

### ASSESSING THE SEVERITY OF THE ILLNESS

The severity of dementia may predispose people to different mediators of disruptive behavior. Persons with very mild dementia are often understimulated (i.e., bored) in typical long-term care settings where activities involved large groups and limited cognitive challenge. If bored, a patient may become restless and wander, attempt to escape, or become involved in self-stimulating behaviors, such as repeatedly calling out to caregivers (Hellen, 1992). Activities-based care may reduce understimulation. However, standard care center activities can also be overstimulating (i.e., agitating) to persons with severe dementia

who can no longer understand verbal explanations, correctly interpret social interaction, or accommodate noise. Completing a simple but formal mental status evaluation can help to determine environmental mediators of disruptive behavior and assess for the appropriate level of activities-based care.

#### RECOGNIZING BEHAVIOR AS A KEY FORM OF COMMUNICATION

Communication is an adaptive means towards need fulfillment. In patients with dementia, as reasoning and language skills are lost, overt behavior will increasingly become a primary form of communication. Just as a preverbal child uses crying as a means of communicating hunger, pain, or fear, patients with dementia may use wandering, calling out, swearing, or other behaviors to communicate pain, anxiety, boredom, loneliness, etc. Even when speech is intact, verbal communication is often limited by difficulties in expressing desired thoughts correctly. The behavior of patients with advanced dementia often represents an attempt to express feelings and needs that cannot be verbalized adequately. These behaviors often represent an attempt to communicate regarding environmental, physical, psychological, or social factors that are distressing to the person with dementia. Calling such behaviors “inappropriate” or “disruptive” ignores the adaptation efforts reflected in that behavior.

#### IDENTIFYING ENVIRONMENTAL, PHYSICAL, PSYCHOLOGICAL, AND SOCIAL MEDIATORS

The same calling out, wandering, restlessness, aggression, and other difficult behaviors might be the expression of an inner emotional state in one patient, a long-standing behavioral pattern in another, an unrecognized physical need in a third patient, and a reaction to an external stimulus in a fourth. If clinicians observe only the behavior itself and ignore the complex mediators that may be at play, intervention is unlikely to be effective.

#### Environment

It is common for patients temporarily admitted from nursing homes to geriatric psychiatry units to have no problem behaviors while in the hospital but to have rapid re-emergence of the behaviors upon return to the nursing home. This A-B-A behavioral design routinely demonstrates that environmental factors are the primary mediators of that person's disruptive behavior. Often that admission could be avoided by considering environmental factors in the first place. This is more easily accomplished by evaluating the person in his or her typical living environment when possible. Multiple, simultaneous, or unnecessary stimuli may be difficult for the patient to interpret or may be overwhelming. For example,

loud and repeated noise may lead to agitation (Robinson, Spencer, & White, 1988). Extraneous stimuli, such as television shows, may be misunderstood or mistaken for reality and cause patients with dementia to be frightened or angry. “Disembodied” voices from radios or overhead paging systems, or that result from whispering or laughing out of view, can similarly contribute to confusion, misperceptions, suspiciousness, and agitation. “Old-fashioned” music may be soothing to the patient, but modern music preferred by the young-adult care provider may be agitating. As a patient's language skills degenerate, he or she may become distressed in situations where there is high demand for language, such as congregate dining.

Familiar cues or personal belongings in the environment may reduce confusion, fear, and agitation. To compensate for sensory losses, environmental modifications such as reducing glare, increasing lighting, and using contrasting colors may enhance appropriate behavior (Whall et al., 1997). At latter stages, dementia patients may need to take meals and engage in activities in social settings with smaller groups and less talking. A simple, consistent, and predictable environment will provide familiarity and comfort for the patient. Conversely, an environment poorly adapted to cognitive losses may cause the patient to misinterpret surroundings and events and either behave in socially inappropriate ways or withdraw (Dawson, Kline, Wiancko, & Wells, 1986).

#### Physical Factors

Physical mediators of disruptive behavior can be iatrogenic and reflect a failure to consider palliative approaches in advanced dementia care. A patient with dementia placed on salt restriction for blood pressure control may dislike the food in congregate dining and become agitated because he or she is left to sit in the dining hall though he or she has no interest in the food. The importance of tight blood pressure control in late-stage dementia may be dubious, and making more the food more palatable could reduce “agitation.” It is worthwhile to analyze the benefits versus risks of tight hypertension control in people with advanced dementia with the appropriate medical and family decision makers. One of the most helpful aspects of psychological consultation is simply to get all the care stakeholders together to facilitate such communications (Smith & Bondi, 2013).

Other physical factors include unrecognized infection (e.g., urinary tract infection) and pain. Dementia patients are often unable to describe the pain or physical symptoms that alert the care team to these factors. Although standard nursing home practices generally provide better support for assessing physical factors, compared to the environmental and social factors, it is still incumbent on the psychological consultant to consider physical factors during her or his assessment.

## Social Factors

Social factors include the life experience of patients, their values, culture, family structure, history of preferences, etc. Despite progressive cognitive loss, older adults with dementia retain basic human needs, including the need to belong, to be loved, to be touched, to follow their values, and to feel useful. Unfortunately, meaningful relationships and appropriate social groups can be unavailable or insufficiently matched to the functional level of such patients. Psychologists can help family and facilities identify ways to help the person with dementia feel social connections.

### MANAGING ANTECEDENTS, NOT CONSEQUENCES

Applied behavioral analysis reminds us that all behavior occurs in a context. This has been described as the ABCs of behavior management: antecedent, behavior, consequence. For each behavior, there are antecedent conditions that provide a setting for the behavior and, in many cases, may increase the probability of the behavior occurring. Then there is the behavior itself, followed by the consequences of behavior. Much of traditional behavior management has focused on controlling the consequences in order to shape behavior. However, the ability of an event happening after a behavior (consequence) to influence the future probability of that behavior requires the consequence to form a new association with the behavior. In other words, new learning must be possible. But in dementia, of course, the ability to form that association is increasingly impaired as the dementia progresses and the likelihood of behavioral disturbance increases. Thus, managing antecedents, as opposed to consequences, has the greater probability of success in dementia behavior management. Antecedent cues are an overlearned association between the cue and the behavior. For instance, the connection between silverware and eating does not dissipate until very late stage dementia. Managing antecedents requires being proactive, not reactive, and it requires an understanding of the intact abilities of the patient so that the cues result in behaviors within her or his capabilities.

### USING WHAT THE DEMENTIA "GIVES"

Managing disruptive behavior in dementia is challenging. Successful intervention plans rarely eliminate disruptive behavior. Success involves reducing the frequency and/or intensity of the challenging behavior. Success is often predicated on putting the cognitive deficits of the dementia to use. For example, redirection is the most commonly used method of behavior management in most facilities. Redirection is often used when patients enter restricted areas, attempt to escape, or engage in problematic interpersonal exchanges. Bad redirection is often an antecedent to agitated or aggressive behavior, because bad redirection represents a thwarting of the goal-directed behavior. Good redirection will take

advantage of the memory and attention impairments of the person with dementia and includes a three-step process. First, caregivers validate the apparent emotional state of the patient (e.g., "You look worried"); this involves assessing the feeling state the behavior is communicating (see "Recognizing Behavior as a Key Form of Communication"). It also helps to establish rapport. Next and critically, the caregiver joins in the patient's behavior. For example, "You want to go home? Well, I am ready to get out of here myself. Let's get our things together." Finally, once a common goal is established, distraction is easier (upon returning to the patient's room for his or her things the caregiver distracts, "Well, look at these pictures here, tell me about these people"). Distraction works best with patients who have substantial memory or attention problems. Most patients with dementia have such problems. This strategy may seem to require more time than simple redirection. However, facile caregivers can perform all steps quickly and ultimately save time because agitated behavior does not need to be managed.

### FOCUSING ON ACTIVITY-BASED CARE

Adapting activities to the ability level of a person with dementia can address his or her desire to feel useful and serves to avoid unsuccessful attempts to create a behavioral vacuum (Hellen, 1992). Activities compete in real time to displace disruptive behavior and are thus a key part of a proactive approach. Planned activities should be "failure free," promoting a sense of success by accommodating the ability level of the patient. Meaningful activities should correspond to individual's life history, current abilities, and attention span when possible. Exercising existing abilities in a failure-free manner will provide reassurance and contribute to a sense of competence.

## Conclusions and Future Directions

Modern nomenclature clearly recognizes different syndromes that occur across neurodegenerative diseases that lead to dementia. This includes new possibilities for identifying neurodegenerative diseases even when a person is asymptomatic (i.e., in the preclinical phase). There is now recognition of the MCI phase for all or nearly all neurodegenerative etiologies. The different etiologies produce different neuropsychological profiles in the MCI and early dementia stage. But late stages of dementia and cognitive, functional, and behavioral challenges converge and common strategies may aid in dementia management. The recognition of preclinical and MCI states are foundational to engaging prevention strategies in an effort to prevent or delay progression to dementia. Prevention strategies incorporating physical and cognitive exercise, social engagement and compensation strategies likely have greater near term potential than medication strategies for impacting the morbidity of neurodegenerative diseases.

# 31 Complexities of Metabolic Disorders

*Marc A. Norman, Olivia Bjorkquist Harner, and S. Joshua Kenton*

Metabolism is the breakdown of food into its more elementary components. These functions govern the transport, storage, and distribution of energy throughout the body, and abnormalities may not only create organ and tissue dysfunction, but also cognition may be altered. Complex chemical reactions create the processes that break down substances that the body no longer needs or make those it lacks. For this process to work efficiently, enzymes are needed to break down food into its constituent parts, so an enzyme deficiency can create metabolic abnormalities and dysfunction.

The majority of metabolic disorders are due to single genes that code for enzymes. While some metabolic dysfunction is relatively mild, other disorders can create severe changes. The course of the dysfunction can be acute or chronic, and the consequences can lead to the buildup of harmful substances if it is too low or if it is missing entirely. Disorders can occur in various ways, including inborn errors of metabolism, congenital metabolic disorders, and inherited metabolic disorders, although onset may occur in late life. In most disorders, problems arise due to the accumulation of substances that are toxic or interfere with normal function, or they may be due to the effects of reduced ability to synthesize essential compounds. One of the most common metabolic disorders in childhood is phenylketonuria (PKU) and in adulthood, diabetes.

With new and evolving technologies, tests, and science, the understanding and classification of metabolic disorders has changed. In the past, inherited metabolic diseases were categorized as disorders of carbohydrate metabolism, amino acid metabolism, organic acid metabolism, or lysosomal storage diseases; however, more recently hundreds of new inherited metabolic disorders have been discovered and the categories have expanded (see Table 31.1).

Inborn errors of metabolism affect about one in every 5,000 babies born, and some inborn errors of metabolism are more often found in certain racial and ethnic groups. Sickle cell anemia, for example, is found among those of African descent, and those of European heritage are more likely to pass on malfunctioning genes for cystic fibrosis. Children of women with inborn errors of metabolism are at risk because of exposure in the womb. Because of the wide range of metabolic disorders, there are myriad symptoms and syndromes

that may be associated with specific conditions. These symptoms often present in childhood and almost any presenting complaint may have a congenital metabolic etiology (see Table 31.2).

Treatments for metabolic disorders vary by specific conditions and may include dietary restriction (i.e., phenylalanine), dietary supplementation or replacement (e.g., cornstarch for glycogen storage diseases), vitamins (e.g., for some disorders causing lactic acidosis), enzyme replacement, dialysis, medications, gene transfer, symptom treatment, or bone marrow or solid organ transplantation. Other treatments may focus on symptoms (i.e., antiepileptics, surgery, etc.).

While many etiologies are genetic, metabolic disorders can be secondary to other factors, such as a combination of inherited, environmental, or secondary medical factors. Examples of acute or chronic medical illnesses that may cause metabolic disorders include alcohol abuse, diabetes, diuretic abuse, gout, ingestion of poison or toxins—including excessive aspirin, bicarbonate, alkali, ethylene glycol, or methanol. Conversely, metabolic abnormalities may result from kidney failure, pneumonia, respiratory failure, collapsed lung, HIV/AIDS, or sepsis. This dynamic relationship between etiologies and symptoms may further result in complications including metabolic acidosis and kidney failure (with possible tertiary complications such as neuropathy, retinopathy, and nephropathy).

In addition to systemic dysfunction, metabolic abnormalities may cause changes in mental status and cause metabolic encephalopathies. These syndromes may vary along the continuum of acute versus chronic and reversible versus permanent. Examples of these metabolic encephalopathies include Wernicke's encephalopathy (deficiency of thiamine typically in setting of alcohol disorder), uremic encephalopathy (resulting from kidney toxins, but rare when dialysis is used), hepatic encephalopathy (resulting from liver dysfunction and possibly related to elevated ammonia), and mitochondrial encephalopathy (caused by mitochondrial DNA dysfunction).

Metabolic disorders constitute a large, heterogeneous group of medical conditions with high rates of comorbidities. In addition to physical effects on the body, many of these disorders impact cognition, behavior, and/or psychiatric

*Table 31.1* Major classes of congenital metabolic diseases, with examples of each class

Disorders of carbohydrate metabolism
E.g., diabetes insipidus, hereditary fructose intolerance, galactosemia, pyruvate metabolism disorders, von Gierke's disease, McArdle disease, Pompe's disease, and Forbes' disease, glycogen storage disease
Disorders of amino acid metabolism
E.g., glutaric acidemia type 1, Tay-Sachs disease, PKU, tyrosinemia, maple syrup urine disease, and homocystinuria
Urea cycle defects/disorders
E.g., Carbamoyl phosphate synthetase I deficiency
Disorders of organic acid metabolism (organic acidurias)
E.g., alcaptonuria
Disorders of fatty acid oxidation and mitochondrial metabolism
E.g., Gaucher's disease, Niemann-Pick disease, Fabry's disease, and medium-chain acyl-coenzyme A dehydrogenase (MCAD) deficiency
Disorders of porphyrin metabolism
E.g., acute intermittent porphyria
Disorders of purine or pyrimidine metabolism
E.g., Lesch-Nyhan syndrome
Disorders of steroid metabolism
E.g., lipoid congenital adrenal hyperplasia, congenital adrenal hyperplasia
Disorders of mitochondrial function
E.g., Kearns-Sayre syndrome
Disorders of peroxisomal function
E.g., Zellweger syndrome
Lysosomal storage disorders
E.g., Gaucher's disease, Niemann Pick disease

status, and neuropsychological evaluation may be warranted. However, given etiological heterogeneity and comorbidity, elucidating the neuropsychological profiles of these disorders remains a challenge in the literature. The following describe neurocognition in select metabolic disorders that are more commonly seen in neuropsychology clinics, though this is not exhaustive.

*Table 31.2* Possible manifestations/presentations of metabolic disorders

Growth failure	Pain	Developmental delay	Deafness
Blindness	Stroke	Dementia	Failure to thrive
Delayed puberty	Agnosia	Encephalopathy	Lack of pigmentation
Precocious puberty	Hypothyroidism	Psychosis	Skin rash
Ambiguous Genitalia	Adrenal insufficiency	Immunodeficiency	Excessive hair growth
Congenital malformations	Diabetes mellitus	Seizures	Abnormal pigmentation
Dental abnormalities	Hypogonadism	Renal failure	Lumps and bumps
Unusual facial features	Weight loss	Enlarged spleen	Abnormal behavior
Dehydration	Hypotension	Enlarged lymph nodes	Enlarged heart
Edema	Thrombocytopenia	Many forms of cancer	Cardiac failure
Hypertension	Abdominal pain	Recurrent vomiting, diarrhea	Myocardial infarction
Hyperventilation	Anemia	Excessive urination	Hepatomegaly
Respiratory failure	Cramps	Depression	Liver failure
Joint pain	Muscle weakness		Jaundice

## Phenylketonuria

One of the most well-described metabolic disorders in children is PKU, a hereditary disorder characterized by inefficient metabolism of phenylalanine. It has multiple effects on the central nervous system, including dopamine deficiency and white matter abnormalities. Treatment of PKU involves early and continuous implementation of a low-phenylalanine diet. Left untreated, the disease causes structural brain damage with severe, irreversible cognitive decline. Even when treated early and continuously, children with PKU evidence generally average intelligence with subtle neuropsychological impairments, thought to reflect reduced dopamine and white matter abnormalities. The most prominent deficit reported in the literature is executive dysfunction (Janos, Grange, Steiner, & White, 2012; for review, see (Christ, Huijbregts, de Sonnevill, & White, 2010; DeRoche & Welsh, 2008), but studies also report reduced processing speed, fine motor skills, and visuospatial abilities, with mixed results regarding language, learning, and memory in children with PKU (Albrecht, Garbade, & Burgard, 2009; Janzen & Nguyen, 2010). In adults with PKU, these deficits are more subtle, and reduced processing speed is thought to be the most prominent characteristic (Channon, Mockler, & Lee, 2005). The severity of neurocognitive impairment in PKU depends on a number of factors, including timing of initiation of treatment, duration of treatment, and blood phenylalanine levels.

## Diabetes Mellitus

In adults, the most common disorder of metabolism is diabetes mellitus. This disease is characterized by elevated blood glucose levels related to insulin abnormality. Type 1 diabetes is an autoimmune disorder with destruction of pancreatic cells, leading to insulin deficiency, and treatment includes insulin, eating healthy foods, regular exercise, maintaining a healthy weight, blood sugar monitoring, and carbohydrate, fat, and protein counting. It typically presents in childhood

or early adulthood and accounts for approximately 5%–10% of diabetes cases. In contrast, Type 2 diabetes results from insensitivity to insulin with adult onset and increased prevalence with age, and treatment may include a healthy diet, regular exercise, blood sugar monitoring, and a diabetes medication or insulin. Diabetes mellitus may affect cognition via multiple pathways. First, insulin and insulin receptors are found throughout the brain, and insulin affects mechanisms related to neuronal activity and related cognitive functions. For example, insulin receptors are found in the hippocampus, and studies suggest insulin involvement in normal memory function (Craft & Watson, 2004). Second, disease characteristics such as chronic hyperglycemia and microvascular disease affect cognition in diabetes as well. Accordingly, neuropsychological impairment is reported in the diabetes literature.

In Type 1 diabetes, studies find subtle deficits in general intelligence, psychomotor efficiency, and mental flexibility, with smaller deficits in visual perception and sustained attention, and typically no impairment in learning and memory; cognitive dysfunction emerges early in the disease, effects are relatively consistent over time, and dementia risk is unclear (Brands, Biessels, de Haan, Kappelle, & Kessels, 2005; McCrimmon, Ryan, & Frier, 2012). In Type 2 diabetes, similar mild changes in attention, executive functions, and processing speed are reported, with one important difference: impaired learning and memory (e.g., McCrimmon et al., 2012; Palta, Schneider, Biessels, Touradji, & Hill-Briggs, 2014; Sadanand, Balachandar, & Bharath, 2015). Cognitive impairment may emerge in prediabetic stages and progresses over time (van den Berg et al., 2010), with some evidence of accelerated aging in those with more severe disease (Yaffe et al., 2012). Type 2 diabetes increases risk of dementia 1.5–2.5-fold (Strachan, Reynolds, Marioni, & Price, 2011), with increased rates of mild cognitive impairment, Alzheimer's disease, and vascular dementia (Cheng, Huang, Deng, & Wang, 2012).

### Metabolic Syndrome

Metabolic syndrome is defined as co-occurrence of certain vascular risk factors, requiring three or more of the following: abdominal obesity, hypertriglyceridemia, low high-density lipoprotein level, hypertension, and hyperglycemia. Reduction of these risk factors may include maintaining a healthy weight and diet, smoking cessation, pharmacologic agents (e.g., statins, niacin, fibrates, etc.), anti-hypertensive agents, and diabetic medications. In addition to the previously described effects of diabetes on cognition, individual components of the syndrome have each been associated with impaired cognition, including hypertension (Novak & Hajar, 2010; Peters & Beckett, 2009), obesity (Dahl et al., 2013), hypertriglyceridemia (Farr et al., 2008), and impaired glucose tolerance (Takahashi et al., 2011), with impairment ranging from subtle changes to dementia. Studies investigating

metabolic syndrome as a whole have variable findings, including decreased intellectual functions, memory, executive functions, visuospatial abilities, and processing speed, although a few studies have reported no associations between metabolic syndrome and cognition (for review, see Yates, Sweat, Yau, Turchiano, & Convit, 2012). The heterogeneity of study results likely relates to differences in sample characteristics (e.g., comorbid medical conditions, demographics), sensitivity of test batteries, and differences in definition of metabolic syndrome. Metabolic syndrome poses an elevated risk for vascular dementia (Panza et al., 2010) and Alzheimer's disease (Kim & Feldman, 2015). The relative importance of each component varies across studies, though insulin resistance appears to play a central role in cognitive impairment and increased risk for dementia (Kim & Feldman, 2015). Additional proposed mechanisms include neuroinflammation, oxidative stress, abnormal brain lipid metabolism, and impaired vascular reactivity (Yates et al., 2012).

### Thyroid Disease

The thyroid gland secretes hormones that act throughout the body and influence metabolism, amongst other functions. Thyroid hormone receptors are widely distributed throughout the brain, and proper function of this system is crucial for brain development. These hormones interact with multiple neurotransmitter systems throughout the life span, influencing cognition, mood, and behavior (Bauer, Goetz, Glenn, & Whybrow, 2008). Abnormal thyroid function has been shown to alter brain structure and function in rat models through a number of mechanisms, including reducing hippocampal granule cells and synaptic plasticity and altering neurotransmitter, neuromodulator, and growth factor systems (Samuels, 2014b). Dysfunction of the thyroid may arise from a number of etiologies, resulting in hypothyroid or hyperthyroid conditions. Hypothyroidism is characterized by low production of thyroid hormones, is most commonly caused by autoimmune-associated thyroid damage, and is treated with thyroid hormone medications. Hyperthyroidism involves excess thyroid hormones, is most commonly caused by Grave's disease, and is treated with antithyroid medications.

Without treatment, congenital hypothyroidism may be associated with profound mental retardation with severe cognitive impairment; although early identification and treatment improves cognitive outcome, studies report impaired attention, visuospatial abilities, motor dexterity, and comprehension that persist throughout childhood (Dugbartey, 1998). In adult-onset hypothyroidism, studies most consistently find impairment in verbal memory, in addition to deficits in general intelligence, psychomotor speed, and visuospatial abilities, with less impact on motor abilities, language, and sustained attention (Bauer et al., 2008; Dugbartey, 1998; Samuels, 2014a, 2014b). These deficits range from minimal to severe. Hypothyroidism is also

commonly associated with depression and anxiety, although some studies fail to find this relationship (Samuels, 2014a). Generally, studies report reversal of cognitive and emotional symptoms with treatment, though subtle deficits may persist. In contrast, hyperthyroidism is not consistently associated with cognitive impairment, though some studies show subtle impairment in attention and executive functions, and patients often report cognitive problems (Bauer et al., 2008; Samuels, 2008). Increased rates of depression and anxiety are reported in hyperthyroidism as well. Controversy exists regarding subclinical hypo- and hyperthyroidism; patients often report cognitive and mood problems, but data are sparse and inconsistent, and it has been suggested that mood difficulties are likely unrelated to thyroid abnormality (Samuels, 2014a, 2014b).

### Vitamin B12 Deficiency

Nutritional factors such as vitamin intake may affect neuropsychological functioning. Research suggests possible associations between cognition and levels of Vitamin D, folate, homocysteine, and B vitamins, for example (Etgen, Bickel, & Forstl, 2010). There is considerable overlap between vitamin deficiencies, as imbalance in one system may alter function in another. Vitamin B12, or cobalamin, is involved in a number of central nervous system functions, and its deficiency affects glial cells and myelin, and results in cytokine and growth factor imbalance (Scalabrino, 2009). B12 deficiency results from poor dietary intake (e.g., sometimes associated with vegetarianism), absorption or distribution (e.g., related to certain medical diseases such as Crohn's, or metformin use), and is more common in elderly patients.

Given its prevalence in the elderly, a majority of the literature on B12 focuses on older adults, though there is some evidence that early B12 deficiency may impair cognition in childhood and adolescence (Louwman et al., 2000). In healthy older adults, low B12 levels have been associated with impaired spatial copying (Riggs, Spiro, Tucker, & Rush, 1996) and information processing speed (Bohnen, Jolles, & Degenaar, 1992; Jelacic, Jonker, & Deeg, 2001); other studies showed no effect on memory (Goodwin, Goodwin, & Garry, 1983; Wahlin, Hill, Winblad, & Backman, 1996). Low levels of B12 are found in individuals with mild cognitive impairment, Alzheimer's disease, vascular dementia, and Parkinson's disease in cross-sectional studies (for review, see Moore et al., 2012), and one large longitudinal study found B12 deficiency preceded decline in MMSE score (Clarke et al., 2007).

While supplementation may normalize B12 levels, it is unclear whether or not it improves cognition. One literature review concluded that cognition may improve marginally in people with B12 deficiency who are cognitively impaired (Moore et al., 2012) while another concluded that B12 supplementation does not appreciably change cognitive function (Health Quality, 2013). Still, B12 deficiency is widely considered a reversible cause of dementia. One striking study found

that, of 18 individuals with dementia and B12 deficiency who were treated with B12 supplements, 12 markedly improved and were cognitively equal to controls, while seven markedly declined after one year (Osimani, Berger, Friedman, Porat-Katz, & Abarbanel, 2005). In terms of psychiatric status, low B12 levels are associated with depression in the elderly (e.g., Hin et al., 2006), with no resolution of symptoms following B12 supplementation (Hin et al., 2006). Overall, the literature generally supports an association between B12 deficiency and neuropsychological impairment, though the exact nature of the relationship remains unclear.

As opposed to the direct affect of the aforementioned causes of metabolic dysfunction, the interrelationship between organ functioning and metabolic functioning is more complex. Metabolic disorder may result in organ failure (e.g., diabetic nephropathy), and organ failure may result in metabolic dysfunction (e.g., secondary hyperparathyroidism from renal disease). Additionally, there are many potential causes for organ failure, and these etiologies may exert different patterns of cognitive impairment.

### Kidney Failure

The kidneys regulate the volume and composition of fluids. In addition to excreting metabolic waste, they have a pivotal role in regulating calcium, phosphorus, and parathyroid hormone levels, and they act as a stimulus for red blood cell production. Renal functioning is generally measured by creatinine (Cr), glomerular filtration rate (GFR), and creatinine clearance (CrCl). Creatinine is a breakdown product of creatinine phosphate, and it is a common indicator of kidney functioning. GFR measures kidney filtration and toxic substance clearance efficiency. The amount of creatinine excreted by the kidneys is measured by 24-hour creatinine clearance. Together, these markers in addition to others (e.g., serum urea nitrogen: BUN) estimate renal functioning. Individuals with compromised renal functioning may receive hemodialysis or peritoneal dialysis. Dialysis is a procedure to remove waste through either filtering blood through an external machine (hemodialysis) or filtering blood through the abdominal lining (peritoneal dialysis).

Most renal disease is secondary to other medical diseases and conditions (e.g., diabetes mellitus, hypertension, glomerulonephritis, polycystic kidney disease, etc.). The mechanisms of renal dysfunction on the brain vary as do the etiologies (Huber, 2008). Direct affects of toxin clearance or secondary complications and risk factors may affect cognition (i.e., vascular disease, anemia, hyperparathyroidism, sleep disturbance, dialysis hypotension etc.) (Madero, Gul, & Sarnak, 2008). For example, diabetes may affect vasculature resulting in microangiopathy or alterations in the blood-brain barrier, but lupus may result in cerebritis or vasculitis (Hailpern, Melamed, Cohen, & Hostetter, 2007; Kurella, Chertow, Luan, & Yaffe, 2004). Hypertension and diabetes mellitus are the leading causes of renal failure, and the onset

of these disorders is typically later in life. Because of this, the affects of renal failure on cognition are interrelated to age. Research is further complicated by the lack of ethnicity studies. African Americans and Hispanics are at higher risk of developing diabetes, but they are generally underrepresented in research samples.

Several studies have found a relationship between chronic kidney disease and renal functioning, and it has been identified as an independent risk factor for cognitive impairment (Kurella et al., 2005; Kurella et al., 2004; Kurella, Yaffe, Shlipak, Wenger, & Chertow, 2005). Most studies use brief instruments that do not allow for detailed profile analysis (Kurella Tamura et al., 2011; Yaffe et al., 2010); however, more literature exists about some of the primary causes of renal failure. For example, diabetes is associated with microangiographic changes, which are related to deep white matter change (Huber, 2008). Overall, there are many cross-sectional and longitudinal studies, but they contain significant methodological limitations (i.e., limited screening, older adults, individuals with numerous coexisting illnesses, publication bias, poor demographic representation, etc.) (Madero et al., 2008).

### Liver Failure

The liver is a life-sustaining organ that performs more than 500 functions, many of which are not fully understood. Metabolizing alcohol, toxins, medications, fats, and proteins as well as synthesizing clotting factors, bile production, and glycogen/glucose storage are among some its most important functions. Common causes of liver failure include viral infection (i.e., hepatitis B and hepatitis C), biliary dysfunction (primary biliary sclerosis, primary sclerosing cholangitis), autoimmune hepatitis, and nonalcoholic steatohepatitis (e.g., fatty liver).

Direct etiological factors on the liver and brain may cause cerebral compromise in addition to secondary hepatic failure on the brain. Direct causes such as viral infections (e.g., viral hepatitis) and alcohol may cause direct brain dysfunction, but they may also create liver compromise resulting in further cognitive impairment. Liver disease can cause systemic failure to clear toxins. In particular, the failure to clear ammonia, may cause acute cerebral dysfunction (i.e., hepatic encephalopathy) (Norman, 2011). Hepatic encephalopathy (HE) may occur as an acute, possibly reversible disorder or as a chronic disorder associated with chronic liver disease. Recent studies suggest that HE may be more persistent than once recognized, even after liver transplant (Campagna, Biancardi, Cillo, Gatta, & Amodio, 2010; Patel et al., 2015). Mild HE symptoms include irritability and sleep/wake difficulty, but this can progress to worsened mental status, confusion, coma, and death.

Because there are many causes of liver failure, no one pattern of neuropsychological function is specifically associated with liver-related cognitive dysfunction. It is difficult

to measure the direct affects of liver failure on cognition because underlying etiologies may directly affect cognition (i.e., hepatitis C virus [HCV]). The most studied cognitively liver-related etiology is HCV. In a review, the most common areas of cognitive impairment were in attention and concentration, suggesting frontal-subcortical white matter involvement (Perry, Hilsabeck, & Hassanein, 2008).

The most common causes of acute liver failure in the United States are viruses and toxins. Possible viral causes include cytomegalovirus, Epstein-Barr, herpes simplex, human herpes virus 6, parvovirus B19, and varicella-zoster, viruses that cause hemorrhagic fever, and, rarely, hepatitis A or E. The most common toxin is acetaminophen/paracetamol toxicity, but other toxic causes include amoxicillin/clavulanate, halothane, iron compounds, isoniazid, nonsteroidal anti-inflammatory drugs, some ingredients in herbal drugs, and *Amanita phalloides* mushrooms. In contrast, alcohol, hepatitis B, hepatitis C, and nonalcoholic steatohepatitis are the most common chronic forms of failure and cirrhosis (Demir, Lang, & Steffen, 2015). The epidemiology is dramatically changing with an increase in nonalcoholic steatohepatitis (i.e., fatty liver disease) and better treatments to eradicate HCV viral load (Demir et al., 2015; Van Nuyes et al., 2015).

### Lung and Heart Failure

Similar to kidney and liver cognitive-related impairment, the interaction between lung and heart dysfunction and cognition is complex and not fully understood. Pulmonary and cardiac failure primarily compromise cerebral perfusion, although other conditions place individuals at higher risk for stroke (i.e., atrial fibrillation).

There are causes of pulmonary failure, but chronic obstructive pulmonary disease (COPD) is one of the leading causes of morbidity and mortality (Schou, Ostergaard, Rasmussen, Rydahl-Hansen, & Phanareth, 2012). Hypoxemia and hypercapnia have been associated with cognitive dysfunction in COPD (Antonelli-Incalzi et al., 2006). While low levels of oxygen in the blood and carbon dioxide retention are two possible causes of cognitive impairment, low blood flow (hypoperfusion) is another possible mechanism, and a direct effect of cognitive dysfunction has been described with hypoperfusion (Antonelli-Incalzi et al., 2003; Hynninen, Breivite, Wiborg, Pallesen, & Nordhus, 2005). A significant complicating feature of COPD is fatigue, and fatigue is known to have an relationship with cognitive impairment in COPD (Crews et al., 2001).

Cognitive impairment is estimated to occur in 30%–80% of persons with heart failure (Bennett & Sauve, 2003; Pressler, 2008). The pattern of cognitive impairment in heart failure is somewhat more clear than the kidneys and liver. The neuropsychological pattern appears to demonstrate subtle deficits in memory, attention, psychomotor speed, and executive functioning, and these are independent from age, sex, alcohol

consumption, education and other comorbidities (Almeida & Tamai, 2001; Pressler et al., 2010; Vogels, Scheltens, Schroeder-Tanka, & Weinstein, 2007). This clearer pattern may be, in part, to there being less metabolic dysregulation attributed to cardiac functioning.

Case I.Z., later in this chapter, will highlight a relatively rare metabolic disorder, but in the larger picture, it will illustrate the medically complex interaction between metabolic functions and outcomes. Methylmalonic acidurias, also called *methylmalonic acidemias* (MMA), are a heterogeneous group of autosomal recessive inborn errors of organic acid metabolism. First described in 1967, MMA affects one in 50,000 to one in 8,000 births (Oberholzer, Levin, Burgess, & Young, 1967; Sniderman et al., 1999). MMA is characterized by deficient activity of methylmalonyl-CoA mutase, the B12-dependent enzyme responsible for converting methylmalonyl-CoA to succinyl-CoA (Fenton & Rosenberg, 2001). Seven distinct forms have been described on the basis of biochemical and somatic cell studies (Shevell, Matiaszuk, Ledley, & Rosenblatt, 1993). Dysfunction in this system causes the accumulation of MMA, which is most readily detected in urine, although elevated levels can be found in the blood and cerebrospinal fluid (Oberholzer et al., 1967; Stokke, Eldjarn, Norum, Steen-Johnsen, & Halvorsen, 1967). Children with MMA commonly present in the first year of life with recurrent episodes of vomiting, failure to thrive, muscular hypotonia, and encephalopathy (Nicolaidis, Leonard, & Surtees, 1998). Other phenotypic expressions include ketoacidosis, developmental delay with mental retardation, and in severe cases, death (Fenton & Rosenberg, 2001; Matsui, Mahoney, & Rosenberg, 1983). Within this heterogeneous population, outcome is variable and plasma and urinary methylmalonate concentrations do not predict outcome well (Nicolaidis et al., 1998).

MMA treatment may include vitamin B12 supplementation, but the majority of patients do not respond to this. Also, nutritional management includes high-energy diet with supplementary amino acids in some cases (Morioka et al., 2007). A less commonly used—and controversial—treatment has been liver transplant, because this offers only partial enzyme replacement and MMA fluid concentrations do not become normal, with no decrease in CSF MMA.

There is little literature on the cognitive affects of MMA, and most of this literature describes those in early life. Rarely, the less severe *mut-* form has been associated with normal neurodevelopment in asymptomatic cases or possibly mild to moderate cognitive deficits (Baumgartner & Viardot, 1995; Ledley, Levy, Shih, Benjamin, & Mahoney, 1984; O'Shea et al., 2012; Varvogli, Repetto, Waisbren, & Levy, 2000). In contrast, the *mut0* form is seen neonatally and death occurs in early infancy, or children have very poor neurological outcomes (Matsui et al., 1983). O'Shea et al. (2012) found that early disease onset, presence of elevated ammonia, and history of seizures was associated with more greater impairment in aspects of processing speed (O'Shea et al., 2012). In a series of seven patients under age 8 (with one postoperative

death), Morioka et al. (2007) described that all of the children undergoing living donor liver transplants had lethargy and cognitive deficits. These authors claim that cognitive deficits were “cured”; however, while the McCarthy General Cognitive Index significantly improved in their sample, the Denver Development Quotients improved slightly. All of these children were treated with pre- and postdietary restrictions and metabolism-correcting medications. Short of this study, there is little pre-/post-cognitive data in the literature, and none with adults who have undergone liver transplant.

### *The Case of I.Z.*

The patient is a 30-year-old, right-handed bilingual Hispanic. His MMA resulted in a toxic buildup of amino acids that was thought to eventually lead to eventual coma and irreversible neurologic damage. He was referred by a liver transplant team as part of a liver transplant workup. This case will highlight the challenges of highly complex medical cases with primary and secondary metabolic issues.

### *Preoperative Evaluation*

I.Z.'s preoperative liver transplant evaluation occurred when he was age 27, and his cognition waxed and waned frequently. It was unclear to what extent this was secondary to metabolic fluctuations, complications, or hepatic encephalopathy (Norman, 2011). According to his wife, he began to experience cognitive and functional decline within the preceding six months. The team questioned the potential efficacy of liver transplant, because there is limited outcome data in adults with MMA. The preponderance of data is in transplanting children to protect their neurologic status. In this case, this adult was already neurologically compromised, so the potential benefits of transplant were unknown.

Around the time of the work-up I.Z. experienced increased episodes of acidosis and pancreatitis with numerous hospitalizations. Additionally, his functioning was variable. For instance, when he was doing well, he could shower, make his own food, and assist with other chores around his home. However, when not doing well, he reportedly was more withdrawn, aggravated and noncompliant. He expressed hesitation about following through with the liver transplant, because he questioned potential benefits of the procedure. At times he stated he did not want a transplant, so several evaluations for decision-making capacity were undertaken. I.Z. was able to explain basics about MMA, but did not appear to fully understand the transplant procedure and recovery process. In addition, he had limited insight into his cognitive dysfunction. Preoperatively, his medical history was significant for seizures of unclear etiology, gastritis, depression, hepatic encephalopathy, hypertension, ketoacidosis, pancreatitis, and bilateral ear surgery. His medications included megestrol, melatonin, allopurinol, amoxicillin/clavulanic acid, metoprolol, lisinopril, aspirin, lacosamide, levetiracetam,

and albuterol. His MMA had been managed for many years with a low-protein diet with carnitine supplementation.

I.Z. reported a history of depression, but denied receiving mental health treatment. Following the neuropsychological evaluation, his depression improved with olanzapine 5mg. He reportedly smoked until age 20 and quite drinking alcohol at age 22. Also, he had a history of marijuana, methamphetamine, and cocaine use, with his last use of illicit drugs at the age of 23 or 24.

I.Z. graduated from high school and completed one year of college. He was two classes away from completing an Associate's Degree when he became ill and dropped out. He denied being diagnosed with a learning disorder, but acknowledged that he was a "slow learner." His education was interrupted by his frequent hospitalizations during his childhood and teen years. He worked for a brief time as an inventory clerk. He had not been employed since around age 25.

#### PREOPERATIVE TESTING RESULTS

During the first testing (following his noted cognitive decline), I.Z.'s affect was flat but became more irritable as testing progressed. He was a poor historian and had problems discussing complicated subjects such as his medical condition. His speech was hypophonic and slow in rate. He was noted to mumble to himself and displayed poor eye contact. His effort appeared to be good at the beginning of testing, but he displayed low frustration tolerance and wanted to quit.

I.Z. was administered a brief battery of neuropsychological tests and a clinical interview was conducted to assess compliance, social support, and mental health to determine his appropriateness for transplant. He was administered a brief cognitive screening, the Montreal Cognitive Assessment

(MOCA), and his results were not scoreable secondary to comprehension problems and low frustration tolerance. On the Rey Osterrieth Complex Figure copy, he did not use a Gestalt approach or attend to details. He did not attempt to draw the figure following a 30-minute delay. On a test of fine motor dexterity, he refused to participate secondary to frustration during the test, and therefore the test was discontinued. Finally, his performance in semantic fluency was severely impaired. Computed tomography (CT) 18 months prior to the transplant demonstrated ventricular enlargement of uncertain significance, without increased intracerebral pressure (Figure 31.1—left image).

Even in the context of severely impaired cognition (with additional poor assessment effort), the patient was ultimately listed for liver transplant. It was believed that his liver was otherwise functioning normally (i.e., no cirrhosis), so the team elected to list I.Z. for a cadaveric transplant and implant his native liver into another individual needing a liver transplant. With more than 16,000 people waiting for liver transplants in the United States and 20% mortality while waiting, a "domino" liver transplant allowed two lives to be saved with one cadaveric organ. I.Z.'s liver had a genetic metabolic disorder, but a new recipient's body would be able to clear the amino acids and the person would be symptom free. A week prior to transplant I.Z. was admitted secondary to hypokalemia and dehydration.

#### Post-Operative

I.Z.'s posttransplantation course was complicated by multiple infections as well as vascular, renal, and metabolic abnormalities. Within a week following transplant he developed hypotension and low kidney output, and he was placed on

Figure 31.1 CT 18 months pretransplant (left), and T2 MRI 3 months posttransplant (right)

continuous veno-venous hemodialysis. He had (what ended up being recurrent) *Pseudomonas aeruginosa* pneumonia and acute kidney injury secondary to dehydration and acute tubular necrosis. The following week he underwent a tracheostomy and was placed on a ventilator with a Glasgow Coma Scale (GCS) of 11T. His agitation was managed with benzodiazepines and aripiprazole, transitioning to olanzapine.

Two months posttransplant, while still hospitalized, he had a partial occlusion of the pulmonary artery and had large plural effusions and suspected chest abscesses. Two weeks later he underwent a balloon dilatation (and later angioplasty) to repair a stricture in the inferior vena cava and subsequently had further mental status deterioration. Over the following two months he was found to have multidrug resistant *Klebsiella*, leukocytosis, and renal improvement.

Posttransplant month three, while still hospitalized, I.Z. experienced what was thought to be a partial seizure. While the etiology was unclear, two of his medications, tacrolimus and meropenem, were known to lower seizure threshold. He had bacteremia and hypercarbia. His GCS improved to 14, although his mental status continued to wax and wane. At 3.5 months following transplant, he was transferred to an acute rehabilitation unit. At that time he was off of dialysis but had continued hyperkalemia and ascites. His ventricular dilation remained stable as demonstrated in the 3-month posttransplant MRI (Figure 31.1—right image).

About three weeks following admission to rehabilitation, I.Z. was again admitted with cardiomegaly, osteopenia, and

persistent acidemia. The following month he was noted to have increased liver function tests and hypothyroidism, and a kidney transplant work-up was initiated. In the following months he had multiple readmissions with pneumonia.

Six months posttransplant, I.Z. experienced the next significant neurologic event. He was found to have cytomegalovirus (CMV) meningitis with intraparenchymal, subarachnoid, and intraventricular hemorrhages, and he had a cluster of seizures (Figure 31.2). The etiology of the meningitis was unclear; however, this is a known risk in immunosuppressed individuals. He continued to make slow improvement and was discharged about two weeks later. Over the following four months he had multiple admissions with leg pain, myalgias, weakness, shortness of breath, and hypoxia. Multiple episodes of respiratory failure led to brief periods of ventilator support.

I.Z. underwent postoperative evaluation approximately 20 months following his liver transplant. He was not confused and communicated appropriately. I.Z.'s primary complaint was worsening central vision, with relatively better peripheral vision. He was followed by a neuro-ophthalmologist for optical nerve damage and had been deemed legally blind one month prior to postoperative evaluation. He indicated that his mood had been affected by his visual problems, including episodes of feeling depressed, worthless, and inadequate because he was unable to do the things he previously enjoyed. He and his wife reported, however, that his mood had improved after he started to attend a vision rehabilitation

Figure 31.2 T2 (left) and gradient-echo (right) MRI demonstrating intraventricular and intraparenchymal hemorrhage six months posttransplant

service (two to three months prior). He indicated that the service was designed to improve independent living skills. He noted "I am really at a good point now" and that this has been the longest time span without a hospitalization.

The couple denied prominent changes in his cognition since the liver transplant. He had long-standing problems with speech (stutter) since age 6, but denied new problems with word finding or paraphasias. Functionally, he was assisted by his wife with household chores (e.g., laundry) and was responsible for his own hygiene. He required help from his wife to manage his medications, appointments, and finances. He did not drive. When he was not hospitalized or attending medical appointments, a typical day included taking walks, doing household chores, and listening to music.

I.Z. reported that he saw a psychiatrist between his pre-operative testing and liver transplant. He was reportedly started on escitalopram and olanzapine. He was started on olanzapine based on episodes of altered mental status and "talking to himself." He denied frank psychotic symptoms. According to the couple, the escitalopram had been discontinued because his insurance did not cover it. I.Z. reported intermittent mild depressive symptoms (i.e., fatigue, frustration, feelings of worthlessness, sadness) and denied prominent emotional changes since liver transplant. He indicated that the mild depressive symptoms were exacerbated by his multiple medical conditions including his vision problems. He denied prominent symptoms of anxiety and indicated that his overall emotional condition had improved during the previous two to three months. He denied a history of suicidal or homicidal ideation, intent, or plans. He denied psychiatric hospitalizations.

I.Z. sometimes used a walker to ambulate, but at other times used a wheelchair to avoid episodes of shortness of breath associated with exertion. He complained of frequent fatigue, weakness in his legs/left hand, poor coordination, and problems with balance. He reported falls, but denied

head injuries or loss of consciousness associated with the falls. He denied problems with numbness, dizziness, nausea, vomiting, or incontinence. He indicated that he had loss of hearing in his left ear, but it was unclear what percentage of hearing loss he sustained. He denied problems initiating sleep, but acknowledged that he slept more often, particularly if he had nothing scheduled for his day.

His posttransplant medications included sirolimus, cyclosporine, dapson, nifedipine, metoprolol, lacosamide, levetiracetam, olanzapine, levothyroxine, levocarnitine, K-Phos Neutral, fludrocortisone, magnesium plus protein, sodium bicarbonate, ergocalciferol, Nephrocaps, omeprazole, albuterol, fluticasone, oxycodone hydrochloride, omega-3, and megestrol.

#### POST-OPERATIVE TESTING RESULTS

During the second testing he used a wheelchair. He was oriented to person, time, and situation, but not to place (an unfamiliar office). His recall was fair for recent events, but he requested that we ask his wife for specific details. Similar to the first testing, he appeared to become agitated as the tests progressed, but his frustration tolerance was better compared to his first testing session. He became somnolent at times. No psychotic symptoms or homicidal ideation was noted. His thought processes were logical, linear, and goal directed. His speech was characterized by slow rate with evidence of (pretransplant) stutter. He did not mumble or talk to himself. He displayed limited eye contact, and a vision pocket chart was used to estimate his vision. Based on his visual disturbance, some of the tests had to be administered in a nonstandardized manner for him to see the stimuli. His effort during testing was variable, though likely not intentional. His postoperative neuropsychological testing was more comprehensive than pre-transplant (Table 31.3).

I.Z. did not perform above the established cutoffs on the TOMM (Trial 1 = 35/50, Trial 2 = 40/50; Retention Trial = 44/50). He did, however, score above the established cutoff on the CVLT-II Forced Choice (16/16). His performance on a premorbid intellectual estimate (Wechsler Test of Adult Reading; WTAR) predicted that his full scale IQ was in the

mildly impaired range. His Montreal Cognitive Assessment (MOCA) total score was 11/30. On a task of psychomotor number sequencing (Trail Making Test Part A), I.Z. performed within the severely impaired range. On the Sensory Perceptual Exam, he did not demonstrate extinction from double simultaneous tactile, auditory, or visual stimulation,

Figure 31.3 Rey-Osterrieth complex figure copy

Figure 31.4 Rey-Osterrieth complex figure delay

but he did make multiple errors bilaterally on fingertip number writing and on tactile finger recognition. With regard to attention, he scored within the mildly to moderately impaired range on the Wechsler Adult Intelligence Scale–III (WAIS-III) Digit Span subtest. His complex figure drawing (Rey-O Copy; Figure 31.3) was within the severely impaired range ( $T < 20$ ).

On a measure of confrontation naming, the Boston Naming Test, his performance was within the moderately impaired range. On a measure of lexical word generation, the Letter Fluency test, he performed within the low average range. His performance on the Category Fluency test was within the mildly impaired range. It should be noted that African American norms were used for fluency and Trail Making to take a conservative approach and because there were inadequate norms for a Hispanic individual. His academic skills, as measured by the Wide Range Achievement Test–fourth edition (WRAT-4), placed his word reading performance within the moderately impaired range and spelling within the mildly impaired range. His math computation subtest was discontinued after eight minutes after he indicated that he was having trouble seeing the items and that the items were becoming “too hard.”

I.Z. completed the California Verbal Learning Test–II (CVLT-II), a measure of verbal list acquisition and memory. He recalled a total of 35 words from Trials 1–5, which was within the mildly impaired range. His Short Delayed Free Recall performance was within the mildly to moderately impaired range. His Long Delayed Free Recall performance was within the mildly impaired range (Figure 31.4). He committed no free recall intrusions and committed an average number of repetition errors. On recognition testing, he correctly identified eight out of 16 words, which was within the severely impaired range. He committed one false positive error. His overall recognition discriminability was within the mildly impaired range.

His immediate and delayed recall performances of a complex figure (Rey-O) were within the severely impaired range. On the Beck Depression Inventory-II, he scored a 15, which was within the mild range of depression.

## Discussion

Because of the large number of metabolic disorders and even larger number of potential effects, this chapter provides an overview of the relationship between disorders of metabolism and cognition. The majority of metabolic disorders are due to single genes that code for enzymes, but this seemingly simple fact belies the complexity and variability of metabolic disorders. A case example provided an illustration of these complexities.

The manifestations of metabolic disorders vary widely. Effects can be primary, secondary or tertiary, and a disturbance in one physiologic system may produce new metabolic or systemic dysfunction. The metabolic abnormalities may not exist in isolation, and multiple disorders can co-exist. Cognitive effects secondary to metabolic dysfunction may be insignificant to profound. For example, a short-term or mild blood sugar elevation may not affect cognition, but a metabolic abnormality leading to seizures with status epilepticus or respiratory failure with anoxia/hypoxia could produce severe cognitive impairment.

In addition to severity, a critical factor in how these disorders cognitively manifest is when the abnormality occurs. Inherited metabolic disorders may affect brain and cognitive development, so issues may be evident in early life. In other cases, brain development is normal, because the onset and effects of metabolic dysfunction is later in life. For example, PKU is associated with changes to the developing brain, while diabetes mellitus Type 2 is more likely to occur in later life. In the former example, effective treatment may still result in cognitive reduction, but in the the latter example

effective control of diabetes mellitus may not result in cognitive change.

Treatment of metabolic disorders vary by specific conditions. In the example of PKU, treatment involves a low-phenylalanine diet. In the case of diabetes mellitus, treatment involves dietary and medication management, in addition to maintaining a healthy weight. Even with adherent treatment, cognitive reduction may occur, but there is generally inadequate literature to describe a direct relationship between lab abnormalities or treatment with cognition. Even with this limitation, metabolic treatments often involve reducing secondary health risks. In the case of Metabolic Syndrome, the focus of treatment typically involves dietary, weight, medication, and lifestyle management. Managing obesity, triglycerides, lipoprotein, hypertension, and glycemia may reduce the risk of stroke and cardiovascular disease.

Another example of an inherited metabolic disorder that can lead to later life issues is Methylmalonic Aciduria.

The overall prognosis of MMA has improved over the last 30 years in part due to earlier diagnosis and better treatment options (Baumgartner & Viardot, 1995). Prognosis remains to be dependent on the mutant class and responsiveness to interventions. With this said, outcomes of children and adults with this specific disorder, and more generally, those with metabolic disorders, is complicated by complex metabolic interactions (i.e., body chemistry, neural chemistry, organ dysfunction with secondary features, etc. (Yohannes, Baldwin, & Connolly, 2006).

The chapter's case example highlights the complexity of metabolic disorders. This patient had cognitive impairment and psychiatric disturbance even prior to transplant, and he then had pulmonary, cerebrovascular, renal injury, additional metabolic changes, and infection complications. The interactions of these medical conditions render causal mechanisms difficult or impossible. Adding to this picture, there is existing, albeit limited, literature on the positive cognitive outcomes with liver transplantation in children, but not adults. It was hoped that liver transplantation would reverse the cognitive decline in I.Z., and it is unclear if it would have given his complicated posttransplant course.

The pretransplant work-up evaluated his medical and surgical risks, in addition to his social support, medication, and medical recommendation compliance. I.Z.'s substance use, depression, and anxiety were not considered to be contraindications to transplant. It was noted that his cognition was impaired prior to transplant, so concern was raised as to whether or not he would be able to manage his posttransplant medications. These medications, including immunosuppression, require complex scheduling (e.g., some medications on an empty stomach others with food, taken at specific times, refilling prescriptions etc.). Because his family and wife were considered to be well-informed, engaged, and supportive throughout his life-long illness, the team felt he would be able to appropriately take his medications. From a cognitive perspective, testing provided the transplant team with

important information, but testing was limited because of the patient's significantly impaired mental status and effort.

The ultimate goal of transplant is to maximize successful outcomes. Had the patient not had strong family support, his impaired cognition would likely have been felt to be a contraindication to transplant. Generally, patients undergoing liver transplant do not have significant posttransplant cognitive improvement; however, pediatric literature with transplant in MMA suggests there might be cognitive benefit. This was unclear for an adult. Unfortunately, the current case does not shed definitive light into this question because of I.Z.'s complicated course (e.g., repeated hypoxia, intracerebral/intraventricular hemorrhage, etc.).

As in all transplant cases, the risks and benefits of transplant were weighed. Unlike most cases, the patient did not have end-stage liver disease, but the MMA was felt to contribute to significant problems (e.g., gastritis, vision, mental status, hearing) and worsening cognitive course. These risks were thoroughly discussed with the patient and his family. Because his mental status waxed and waned throughout his course, his decision-making capacity was evaluated multiple times to ensure his wishes were being met. There were times when the patient stated he did not want transplant, but these were at times of his greatest confusion. Ultimately, the patient and his family were agreeable to transplant and the domino procedure.

Another issue in this case, as with many metabolic presentations, is that I.Z.'s metabolic dysfunction is lifelong. There were likely unknown metabolic affects on cerebral development during critical neurodevelopmental periods. Although he had significant cognitive impairment when he was referred to the transplant team, this was not lifelong. I.Z. graduated from high school and attended some college, suggesting that his current status was a significant decline.

I. Z.'s testing results demonstrated global deficits across domains of language, attention, visuospatial skills, memory, and psychomotor functioning. From one perspective, he showed some signs of improvement when comparing his postoperative results to the brief initial testing session. For instance, his category fluency performance doubled in number of animals he named and his Rey-O copy was a more recognizable figure. Another significant factor to consider, as it relates to his overall profile, was I.Z.'s visual disturbance. During the postoperative testing some of the visual tests had to be administered in a nonstandardized way in order for him to see the stimuli. Despite these accommodations he still demonstrated impaired performances. One could argue that his overall performance may have been aided by use of measures that did not include a visual component, but his nonvisual test scores were also impaired. Also, he was more cooperative during the testing, showing better frustration tolerance. Overall, however, postoperative testing revealed persistent severe cognitive deficits, without appreciable improvement.

A striking issue with testing was I.Z.'s low scores on effort measures. The reasons for this were unclear and much

debate revolves around this issue, especially in medically ill patients. During the postoperative testing his effort testing was not above the established cutoffs. It is unlikely that he was intentionally malingering or feigning impairment. Additionally, there was no identified secondary gain for I.Z. to perform poorly on the testing, and in fact, most transplant patients desire to be seen in the most positive light. A more plausible explanation is that his effort was affected by other cognitive and/or motivational factors (i.e., waxing and waning attention, fatigue etc.). Although he was on multiple medications, including oxycodone, at the time of testing, his baseline cognitive status and months of cognitive decline did not suggest that these medications or intermittent depression significantly contributed to his cognitive profile. The role of metabolic syndromes and metabolic change is still poorly understood, and the timing (i.e., developmental vs. acquired), severity, and complicating factors make neuropsychological interpretations difficult, but important.

## 32 Clinical Assessment of Posttraumatic Stress Disorder

*Jim Andrikopoulos*

### Preface

We conclude that the concept of PTSD has moved the mental health field away from, rather than towards a better understanding of the natural psychological responses to trauma. A return to prior standards of diagnostic practice and therapeutic planning would greatly benefit patient care.

(McHugh & Treisman, 2007, p. 211)

Posttraumatic stress disorder (PTSD) has been plagued by more controversy than any other psychiatric disorder, at least in the United States. This comes as no surprise since it was coined in the aftermath of, and was a direct result of, an American event: the Vietnam War. While there is a pre-Vietnam historical precedent and clinical merit in having a disorder devoted to a stress syndrome, the profound social, legal, and political repercussions of the diagnosis have paradoxically had an iatrogenic consequence for the patient it was intended to benefit and for American society as a whole. The diagnosis has evolved in such a way that it now bears little resemblance to the definition first provided in the *Diagnostic and Statistical Manual*, third edition (DSM-III), of the American Psychiatric Association (APA, 1980). Because the diagnosis was originally an idiosyncratic by-product of an event in U.S. history, it is no surprise that our definition of PTSD might be dissimilar to that found in the *International Classification of Diseases* (ICD-10) as defined by the World Health Organization (WHO, 1992). If events that are generally “outside the range of usual human experience” (APA, 1980: 236) of non-Western cultures such as torture, terrorism, and war have a PTSD prevalence rate of 30% or less, why do some Western societies experience a comparable or higher PTSD prevalence rates from a motor vehicle accident? Is the disparity in prevalence from two very disparate human events a reflection of an ascertainment bias, assessment technique, cultural differences, or capricious views of what constitutes PTSD? It is the contention here that the last explanation is the most likely one.

### Chapter Overview

The ICD-10 proposals are thus a product of collaboration, in the true sense of the word, between very many individuals and agencies in numerous countries. They were produced in

the hope that they will serve as a strong support to the work of the many who are concerned with caring for the mentally ill and their families.

ICD-10 Classification of Mental and Behavioral Disorders (WHO, 1992, p. 6)

Let me outline the scope of the chapter. The assessment of PTSD will focus on the adult instead of the child. The discussion will be on the civilian literature and not PTSD arising out of military service. It is difficult to assess the nature, extent, and outcome of a condition when the possibility of compensation is omnipresent as is the case in the military. There is no requirement by the veteran to provide evidence of a stressor. The veteran’s own testimony is sufficient evidence to make a claim of PTSD so long as a mental health care professional makes the diagnosis (Department of Veterans Affairs, 2008). Thus the burden of proof in the military is lower for the veteran than the civilian. In addition, there is a rather marked difference of opinion as to the prevalence of malingered PTSD in the military. The following is an illustration.

A study done at the National Center for PTSD at the Boston Veterans Administration (VA) using veterans to look at dissociation found 50% of the veterans currently had PTSD, but more surprising was that 20% of their spouses or intimate partners had current PTSD. The lifetime rates were 72% and 38%, respectively (Wolf et al., 2012). It is not clear how they were recruited or if they were treatment-seeking veterans. They were described as being “enrolled in recent studies.” These rates equal or exceed the best of epidemiological studies done in other countries looking at events that are truly horrific (Bayer, Klasen, & Adam, 2007; North et al., 1999; Pham, Weinstein, & Longman, 2004; Verger et al., 2004). One has to question to what extent these incidence and prevalence rates are valid. Given the compensation context in which many of these veterans are seen there is no mention of this factor. The malingering prevalence rate falls closer to 40%, “plus or minus 10” (Larrabee, Millis, & Meyers, 2009; Mittenberg, Patton, Canyock, & Condit, 2002). In clinical neuropsychology there is an obligation outlined in practice guidelines to assess for malingering (Heilbronner et al., 2009).

With that said, no discussion of PTSD is complete without an understanding of the role the Vietnam War played in the

introduction of the term into the psychiatric nomenclature. A historical discussion of PTSD in a military context is necessary. Without the Vietnam War, PTSD would not have found its way into DSM-III. This historical fact, however, does not diminish the clinical importance of the term.

The chapter will focus on the clinical assessment of PTSD with only a cursory overview of topics that deserve more attention than can be devoted to here. These topics are covered in more detail in our earlier chapter on PTSD (Andrikopoulos & Greiffenstein, 2012). In that chapter the task was to familiarize neuropsychologists with what they excel in, the clinical application of forensic principles, but to the context of a nonneuropsychological event, namely PTSD. Therefore, the medicolegal aspects of PTSD will not be covered here but instead commented on as needed. This chapter has the reverse goal in mind: to update the neuropsychologist on the important clinical issues surrounding PTSD outside a medicolegal context. At the risk of redundancy some population-based epidemiological studies will be repeated, while other sections that are more clinically relevant are new (i.e., cross-cultural issues). This leaves us with the two chief goals of this chapter.

The first is captured in the quote that leads off this section and is the heart of this chapter: to convince the reader that it is time to move from PTSD as defined by DSM-5 and transition to ICD. The evolution of the term *PTSD* as defined and shaped by U.S. psychiatry and psychology has radically changed from its initial inception 35 years ago. PTSD as currently defined by DSM-5 no longer captures the essence of the traumatic stress syndrome clinicians and researchers initially conceptualized as being a distinct psychiatric entity. The current ICD-10 definition of PTSD falls closer to what was envisioned when Gross Stress Reaction was introduced in DSM-I (APA, 1952) and PTSD in DSM-III. This chapter offers a modest proposal for assessing PTSD that conforms to the proposed ICD-11 definition. The proposal is “modest” to the extent that what is being proposed in regard to the assessment of PTSD is somewhat novel and not altogether empirically based. However, the same can be said regarding the updated assessment methods (i.e., the revised Clinical Administered PTSD Scale, or CAPS-5) of the new DSM-5 PTSD definition, which have been published but are in need of independent validation (Hoge, 2015). The proposed definition of PTSD in this chapter comes very close to what it will likely look like based on the current published ICD-11 literature. Additionally, practically speaking, if I were to focus on ICD-10 now, this chapter would be dated in 2018 when ICD-11 is scheduled to be released. The meaningful and important change to the definition of PTSD in ICD-11 deserves our attention now.

The second major goal is to propose a structured clinical interview that involves the application of the Clinical Administered PTSD Scale (CAPS), which is DSM-based, and how it might be applied to ICD-11. This is a chapter on clinical assessment. *The assessment of PTSD is the structured*

*clinical interview.* Psychological testing is ancillary and cognitive testing is needed only in certain circumstances. Therefore, cognitive testing will be reviewed briefly. Formal testing in the case of PTSD is needed more in a medicolegal context. Finally, treatment should be something clinical neuropsychologists should know about, but it is not something they typically do. Nothing has changed in regard to the treatment of PTSD since the previous chapter was written. It will not be covered here. The treatment section is rather thorough, covering psychotherapy, psychopharmacology, and case consultation (Andrikopoulos & Greiffenstein, 2012).

### ***The Harmony of Illusions: Inventing PTSD***

I will argue that this generally accepted picture of PTSD, and the traumatic memory that underlies it, is mistaken. The disorder is not timeless, nor does it possess an intrinsic unity. Rather it is glued together by the practices, technologies, and narratives with which it is diagnosed, studied, treated, and represented and by the various interests, institutions, and moral arguments that mobilized these efforts and resources.

(Young, 1995, p. 5)

The book by Allan Young is one of a handful of books and multiple articles that tell the story of how PTSD came into existence. The title of this subsection and Young’s quote are not meant to downplay the clinical significance the syndrome can have to an individual experiencing a genuinely traumatic event. Young states that his job as an ethnographer is not to deny the reality of PTSD but explain how it was made real. An accomplished PTSD researcher, Chris Brewin, phrased the history as a debate between the “Saviors” and the “Skeptics” (Brewin, 2003). In his book *Posttraumatic Stress Disorder: Malady or Myth*, Brewin states that the myth is not the unreality of the disorder but the argument of the Skeptics that already existing diagnoses capture the symptoms of PTSD, which are not unique to PTSD, with the possible exception of flashbacks. An anxiety or depressive disorder would suffice as a diagnosis without having to coin a new one. As a career-long student of neuroscience history, reading the history of PTSD, especially the history before the term was coined, has been the most enjoyable part of this project.

The criteria that eventually became part of DSM-III, more or less intact, were first published in the *New York Times* on May 6, 1972 in an article titled “The Post Vietnam Syndrome” (Shatan, 1972). The author, Chaim Shatan, was a New York University psychiatrist and codirector of its post-doctoral psychoanalytic training program. He outlined six basic themes he observed in the group psychotherapy sessions (“rap groups”) he held with Vietnam veterans. Among those themes specifically mentioned were guilt, rage, numbing, and doubting their ability to love others (Nicosia, 2001). These were the symptoms that Dwight Johnson, a Medal of Honor winner, was said to be experiencing following his discharge from the service. He was shot in a robbery attempt and on

May 26, 1971 Johnson's story was told on the front page of the *New York Times* (Nordheimer, 1971): "From Dak to Detroit: The Life and Death of a Troubled Vietnam Hero." Shatan had been unsuccessful in getting his piece published earlier by the *New York Times*, but this event served as the impetus for its publication (Nicosia, 2001).

Shatan would eventually join forces with another psychiatrist, Robert Lifton. Lifton was an already accomplished Yale psychiatrist with a half-dozen books to his credit. He had as his mentor Erik Erickson, who was Anna Freud's student. Lifton, not unfamiliar with trauma, won the National Book Award for an earlier book, *Death in Life: Survivors of Hiroshima* (Lifton, 1968). In 1970 Lifton and Shatan started the first Vietnam rap-group session, unorthodox psychotherapy outside the confines of the VA system. The by-product of this work for Lifton was his book, *Home From the War* (Lifton, 1973). Lifton the theorist and Shatan the therapist were the nucleus of the movement to get PTSD in DSM-III.

In 1969 a Boston VA social worker named Sarah Haley reportedly met, in her first week on the job, a veteran who claimed to be at the March 1968 My Lai Massacre. She wrote in 1974 the most influential paper of the time in the *Archives of General Psychiatry*, "When the Patient Reports Atrocities: Specific Treatment Considerations of the Vietnam Veteran" (Haley, 1974). This caught the attention of many, but most importantly Shatan, who invited her in 1975 to be part of a symposium at the American Orthopsychiatry Association meeting. She was also invited that summer to be part of an American Psychiatric Association Vietnam veteran panel session. More importantly, at that latter meeting discussions were beginning regarding DSM-III. The chairperson for the DSM-III task force was Robert Spitzer. Shatan contacted Spitzer only to discover that Spitzer had no interest in including combat-related stress disorder in DSM-III (Nicosia, 2001). A confluence of events would change that.

There was a lawsuit following the Buffalo Creek dam break in West Virginia. A coal mining company built a dam that burst, killed 125 people, and injured over a thousand. The judge chastised the American Psychiatric Association for not having a more proper psychiatric diagnosis to assign to survivors that would be more fitting than anxiety or depressive reaction. At the same time Nazi concentration camp survivors were seeking war reparations for the trauma they endured. The American Psychiatric Association decided to hold a symposium at its 1975 meeting. Researchers were invited to present their findings on the Buffalo Creek disaster. Shatan mobilized a team of 45 professionals from across the country to present data on Vietnam veterans. Jack Smith, a former Marine sergeant and Vietnam veteran, assisted Shatan (Nicosia, 2001). He was at the first rap session held by Shatan and Lifton and became the eventual president of the Vietnam Veterans Against the War (Scott, 1990). A Vietnam Veterans Working Group was formed (Nicosia,

2001). At that same meeting, opposite the "delayed-stress advocates," was the "St. Louis group" that included sociologist Lee Robins, a very influential epidemiology and clinical researcher from Washington University in St. Louis. She and her colleagues had already been publishing about Vietnam veterans. The alcohol and drug issues they were observing were for the most part minimal: While experimentation was common in the service, upon their return it was essentially at prewar levels (Robins, Helzer, & Davis, 1975). However, it was acknowledged that depression seemed a problem postdischarge (Helzer, Robins, & Davis, 1976). Spitzer invited some members of the Vietnam Veterans Working Group to join the Reactive Disorders Subcommittee of the DSM-III task force. University of Iowa psychiatrist Nancy Andreasen headed this latter committee. She was chosen partially because of her experience with burn victims. After a 1977 presentation by Shatan and his group at the American Psychiatric Association meeting, Spitzer agreed that a stress diagnosis should go into DSM-III (Nicosia, 2001).

The zealous advocacy and commitment more than anything else led to the success of Shatan, Lifton, and Haley. Not only did they manage to get a stress disorder in DSM-III, but also—and more important—a delayed variant of the disorder. Shatan was tireless and an anti-Vietnam war campaigner. Shatan opened his most well-known Vietnam paper, "The Grief of Soldiers," with the following: "Atrocities perpetrated upon the Vietnamese while saving them from Communism are now almost as well known as those of Hitler's extermination camps" (Shatan, 1973, p. 640). Lifton's similar sentiments and academic credentials made him the perfect public relations representative for the group. He testified numerous times before Congress leading up to the publication of DSM-III. As for Haley, her professional experience up until DSM-III was devoted to the Vietnam veteran cause. The paper that led to her national recognition as a PTSD clinician concluded in the second-to-last paragraph: "The only report that should not be accepted at face value, although one may choose not to challenge it initially, is the patient's report that combat in Vietnam had no effect on him" (Haley, 1974, p. 196). In the *Journal of Traumatic Stress Studies*, the official journal of the International Society for Traumatic Stress Studies, Shatan wrote her obituary, "A True Child of Trauma" (Shatan, 1990). The inclusion of Jack Smith, a non-health care professional, in the DSM-III deliberations was rather unprecedented. He eventually became a psychologist (Bloom, 2000). Two additional individuals merit special mention: Charles Figley and Mardi Horowitz.

*Stress Disorder Among Vietnam Veterans* represented the collective thoughts of the advocates at the time. Charles Figley edited this 1978 book and invited Shatan, Lifton, and Haley to contribute (Figley, 1978). Figley served in Vietnam in 1965 and later became a psychologist. He organized Vietnam symposia at the American Psychological Association and the American Sociological Association meetings (Bloom, 2000). He declined the offer to be the director of the

newly formed national Vet Centers (Nicosia, 2001). In 1983, Figley sent out more than 60 letters to trauma researchers suggesting the formation of an organization devoted to assessment, treatment, and research in traumatic stress. This organization was formed in 1985 and eventually became the International Society for Traumatic Stress Studies, the principal organization devoted to stress disorders. Figley became the organization's first president (Bloom, 2000). While Figley, more so than the others, was a researcher, he was no less an advocate. When the controversial Report of Findings from the National Vietnam Veterans Readjustment Study was published suggesting that as many as 30% of Vietnam veterans had the full PTSD syndrome, Figley wrote the following editorial note as the editor of the book series that published the findings:

Most important, perhaps when next confronted with the prospect of sending citizens to fight a war—the purpose of which is questionable—policymakers will consider these findings. Perhaps they will be moved to acknowledge the vast and enduring costs of such a war to an entire generation of this country's children. Perhaps.

(Kulka et al., 1990, p. xxi)

Mardi Horowitz, another contributor to Figley's book, can reasonably be considered the father of modern stress studies. In 1976 he published *Stress Response Syndromes* (Horowitz, 1976). For the advocates, as crucial as getting any stress syndrome in DSM-III was including one that recognized that the symptoms could have a delayed onset of months to years. Shatan (1973) went so far as to say that it is "commonly not apparent until a considerable amount of time (nine to thirty months) after discharge" (p. 645). Part of the reason Shatan gave for forming the rap groups is that the veterans "had been told their disturbances manifested themselves too late to prove the 'service connection' required for VA treatment" (p. 641). Horowitz, like Lifton and Shatan, was heavily influenced by psychodynamic theory. Horowitz, in the first paper devoted to a delayed stress syndrome invoked a psychodynamic explanation, a "denial-numbing tendency" (Horowitz & Solomon, 1975: 68).

How much of an influence did the advocates have? If you believe the leading authority on the topic, Gerald Nicosia (2001), in his excellent book *Home From the War: A History of the Vietnam Veterans' Movement* (the title was given to him by Haley), he tells us the influence was immense:

What occurred next was on the order of a major miracle. Andreasen, rather than writing the definition herself, invited Shatan, Smith, Haley and the other leading combat stress agitators to write whole sections for her, and agreed merely to "edit" their work. Shatan recalls that they were "practically dictating" the new definition of post-traumatic stress disorder into DSM-III.

(p. 209)

## From DSM-IV-TR to DSM-5

In the first author's work on three DSMs over a period of 20 years, never once did he recall an expert make a suggestion that would reduce the boundary of his pet disorder. In contrast, they very often clamored for expansions.

(Frances & Widiger, 2012, p. 118)

The harshest critic of DSM-5 is Duke University professor emeritus Allen Frances. Frances served as chairperson of the DSM-IV Task Force. In a series of commentaries posted to the *Psychology Today* website under the title series "DSM-5 in Distress," and in his book *Saving Normal* (Frances, 2013), Frances outlines the difficulties with DSM-5 in general; these go well beyond the problematic PTSD diagnosis. Frances maintains when he chaired the task force "the null position was always to keep things stable" via a three-stage process: a literature review, data reanalysis and field testing (Frances, 2009: 1). While beyond the scope of this review, his criticisms of DSM-5 can be summarized as follows: (a) the inclusion of new categories (i.e., major cognitive impairment when dementia would suffice) together with lowering of the threshold of existing disorders will result in higher rates of mental illness diagnoses; (b) there are significant forensic implications to the latter (Frances, 2010); (c) the DSM-5 process was not transparent (Frances, 2009); (d) field trials focused on reliability versus validity (Frances & Widiger, 2012); (e) and lowering the reliability standard—in the past, kappa values of 0.6 or above were "acceptable" whereas in DSM-5 kappa values at dramatically lower values of 0.2 to 0.4 were deemed acceptable (Frances, 2012a).

As DSM-5 was being developed, experts proposed changes in anticipation for what likely were to be more changes to the existing PTSD criteria. Before the reader is asked to adopt ICD-10 and the yet-unpublished ICD-11 PTSD definition in lieu of DSM-5, understanding the changes to DSM-5 will help to validate the need for the transition. Ironically, the best changes that were eventually proposed for DSM-5 but not adopted could be found in the already existing ICD-10 definition: namely, dropping symptoms that are not specific to PTSD. Table 32.1 lists the DSM-5 criteria in amended form. Let us begin by examining the changes that were recommended for PTSD in DSM-5, beginning with the suggestions of Robert Spitzer, the person who had been ultimately responsible for the introduction of the diagnosis. He has provided insightful and regular commentary on the DSM process over the years.

### Proposed Changes to DSM-5

As with each release of the DSM, a spirited discussion preceded the release of DSM-5. What garnered the most attention, as has always been the case, were proposed changes to all aspects of Criterion A. Second, whether to exclude non-specific PTSD symptoms (e.g., sleep problems, poor memory

Table 32.1 \*DSM-5 criteria for posttraumatic stress disorder

- 
- A Exposure to actual or threatened death, serious injury, or sexual violence by:
- 1 Directly experiencing the traumatic event(s)
  - 2 Witnessing, in person, the event(s) as it occurred to others
  - 3 Learning a violent or accidental event(s) occurred to a close family member or close friend
  - 4 Experiencing repeated or extreme exposure to aversive details of the event(s) but this does not apply to electronic media or TV unless work related
- B Presence of one (or more) of the following intrusion symptoms associated with the event(s):
- 1 Recurrent, involuntary, and intrusive distressing memories of event(s)
  - 2 Distressing trauma-related dreams
  - 3 Dissociative reactions (e.g., flashbacks)
  - 4 Distress at exposure to internal or external cues that symbolize or resemble the event(s)
  - 5 Physiological reactions to internal or external cues that symbolize or resemble aspects of the event(s)
- C Persistent avoidance of stimuli associated with the traumatic event(s), beginning after event(s) occurred, as evidenced by one or both of the following:
- 1 Avoidance or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the event(s)
  - 2 Avoidance or efforts to avoid external reminders that arouse distressing memories, thoughts, or feelings associated with the event(s)
- D Negative alterations in cognitions and mood associated with the event(s) as evidenced by two (or more) of the following:
- 1 Inability to remember an important aspect of the event(s)
  - 2 Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world
  - 3 Persistent, distorted cognitions about the cause or consequences of the event(s) that lead the individual to blame self or others
  - 4 Persistent negative emotional state (e.g., fear, horror, anger, guilt or shame)
  - 5 Diminished interest or participation in significant activities
  - 6 Feelings of detachment or estrangement from others
  - 7 Persistent inability to experience positive emotions
- E Marked alterations in arousal and reactivity associated with the event(s) as evidenced by two (or more) of the following:
- 1 Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects
  - 2 Reckless or self-destructive behavior
  - 3 Hypervigilance
  - 4 Exaggerated startle response
  - 5 Problems with concentration
  - 6 Sleep disturbance
- F Duration of the disturbance (Criteria B, C, D, and E) is more than one month.
- G Disturbance causes distress or impairment in social, occupational, or other important areas.
- H Not attributable to the physiological effects of a substance or medical condition.
- Specify whether:*
- With dissociative symptoms: Persistent or recurrent symptoms of either of the following:
- 1 *Depersonalization*: Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as if in a dream; feeling a sense of unreality of self or body or of time moving slowly).
  - 2 *Derealization*: Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).
- 

*Specify if delayed expression:* If the full diagnostic criteria are not met until at least six months after the event (although the onset and expression of some symptoms may be immediate).

\* Modified from the DSM-5 (pp. 271–272).

for the event) in Criteria B, C, and D in DSM-IV-TR. This section summarizes these much-discussed pre-DSM-5 debate themes by reviewing some of the relevant literature. In doing so, the value of the PTSD literature cited to argue for or against these issues will be discussed by asking a rarely asked question in PTSD research: *Do PTSD studies, especially epidemiological research, help guide clinical practice?* It will be argued the generalizability and representativeness of some of this research has fallen short of the mark.

It is logical to assume that Spitzer would speak against the psychiatric nosological expansionism that Frances warned

about, especially in reference to PTSD. The larger psychiatric community has come to accept PTSD—if not the term at least the concept—but has not universally embraced the manner in which it has evolved. Spitzer, in summarizing the proposed changes for DSM-5, understandably began with what to do with A1, the stressor criterion (Spitzer, First, & Wakefield, 2007). Adding the qualifier “directly experienced” in DSM-5 in reference to the event would strengthen Criterion A1. “The person experienced” terminology in DSM-IV-TR does not necessarily imply directly experiencing the event. Spitzer argued “being exposed” to an event might apply, for

example, to witnessing 9/11 on television. Harvard psychologist Richard McNally (2009) suggested among a number of important recommended changes, requiring that the patient be present in the event. "Virtual trauma," he stated, does not cause PTSD (McNally & Breslau, 2008).

The historical precursor to PTSD, Gross Stress Reaction, was a disorder that was caused when the person was "under conditions of great or unusual stress" due to either combat or "civilian catastrophe" (APA, 1952: 40). DSM-III inherited that definition: "a psychologically traumatic event that is generally outside the range of usual human experience" (APA, 1980: 236). The "outside the range of usual human experience" terminology was omitted in DSM-IV (APA, 1994). The person needed only to be "exposed to a traumatic event," and not necessarily directly experience it. McNally called the evolution of the stressor criteria "conceptual bracket creep," the most often quoted phrase in the PTSD debate (McNally, 2003). Rosen (2004a) later modified the term to "criterion creep." It refers to the watering down of what constitutes a traumatic event from the initial "outside the realm of human experience" definition. The broadening of A1 diminishes the significance of the stressor by giving a concentration camp survivor and someone in a motor vehicle accident the same diagnosis (Andreasen, 2004). This is the core problem, whereas the other issues are of relatively less consequence.

Frances and Widiger (2012) make a related argument. The diagnostic system of psychiatry as defined by the organizers and developers of DSM is worried about false negatives. There is a preference for an inclusive diagnostic system, hence the broadening of A1. Weathers and Keane (2007) argued that A1 should be sensitive, casting a wide net to identify anyone who might have the diagnosis. It should minimize false negatives. This inclusivity is a synonym for criterion creep. McNally (2009), perhaps rhetorically, asks if we can "fix PTSD in DSM-V?" I believe we can if the A1 Criterion is fixed.

Brewin recommended a dramatic change: dropping A1 in toto. He suggested focusing instead on PTSD's central symptoms versus those that overlap with other disorders (Brewin, Lanius, Novac, Schnyder, & Galea, 2009). From the 17 core PTSD symptoms, Brewin proposed retaining only six. Reexperiencing would include recurrent nightmares and daytime images. Avoidance consists of avoiding internal (i.e., thoughts) and external (i.e., activities) reminders. Hyperarousal includes hypervigilance and the startle response. Brewin acknowledged that the two most valid reasons arguing against the elimination of Criterion A1 was that it would constitute a marked departure from the very spirit that defines PTSD (namely the stressor) and the absence of the gatekeeper criteria might trivialize the disorder. A fair but less compelling argument by Friedman (2013) was that removing the nonspecific symptoms (e.g., attention and sleep symptoms) would be analogous to removing pain and fever from a medical diagnosis because they are found in other

diseases. The first study to test the Brewin criteria in an outpatient treatment-seeking sample found the overall PTSD prevalence rate did not change but an equal number of participants, 13%, had a change in diagnostic status, both losing and gaining the diagnosis (van Emmerik & Kamphuis, 2011).

While ridding A1 from PTSD practically eradicates the meaning of the disorder, the same cannot be said for dropping A2. Fear (to different degrees), helplessness, and horror have been part of the diagnosis from the start. In DSM-I, Gross Stress Reaction, "overwhelming fear" was a core feature of the condition (APA, 1952) and this has always been an important part of PTSD in every edition of DSM as a descriptor in the text. In DSM-IV fear, helplessness, and horror officially became Criterion A2 (APA, 1994). As will be discussed, while what defines the A1 Criterion is the core of the PTSD debate, there seems to be near universal agreement that it cannot be eliminated. As for A2, the definition is clear but there appears to be general agreement that it can be eliminated.

Studies employing both interview and self-report measures with various populations have concluded that A2 had very little effect on PTSD rates. This was found in a nonrandom community sample of non-treatment-seeking women using a structured interview (Anders, Frazier, & Frankfurt, 2011); a nonrandom community sample of non-treatment-seeking women responding to an advertisement reporting trauma histories using a PTSD checklist (Bedard-Gilligan & Zoellner, 2008); a randomly selected population based study using a structured interview (Breslau & Kessler, 2001); a random worldwide (21 countries) community sample of non-treatment-seeking subjects using a structured interview (Karam et al., 2010); consecutive hospital admissions following a traumatic injury using a structured interview (O'Donnell, Creamer, McFarlane, Silove, & Bryant, 2010); and a longitudinal cohort of nurses administered a PTSD checklist in the form of an interview (Roberts et al., 2012). This diverse literature would suggest removing the A2 Criterion would not impact PTSD rates.

There are two points to be made regarding the studies just listed. The first point requires a paradigm shift that asks the psychologist to query if certain kinds of research inform clinical practice. The second point involves A2 and the circumstances under which we can remove it.

This first point is captured by a title of a commentary piece by Williams (2005): "Does clinical epidemiology have a role in clinical practice?" Jelinek (2005) argues the term *clinical epidemiology* is an oxymoron. It is instead the study of a community in which average effects within that population are studied. Certain clinical questions can be answered only by studies that examine subjects that approximate the circumstances of an actual patient. The dual concerns regarding epidemiological research are representativeness and generalizability. Kukull and Ganguli (2012) discuss how these latter two principles may not apply to the epidemiological dementia literature. Having examined close to 1,000

Alzheimer patients, I believe the mild cognitive impairment literature and the registries throughout the world that track these patients will not inform me of what to do about a patient brought in by his or her daughter because of perceived cognitive symptoms. To illustrate, Hannaford and Owen-Smith (1998) sought to answer a commonly asked clinical question by reviewing the most sound methodological studies that might provide an answer to the following: "What is the risk of cardiovascular disease among users of currently available, low dose, combined oral contraceptives who are aged less than 35 years, do not smoke, and do not have a medical condition known to increase the risk of vascular disease?" They could not answer the question based on their review and suggested that this state of affairs is not likely unique to their clinical question. This is not to deny the importance of epidemiology research, as it is critical in informing us about the incidence and prevalence of a disease, possible causes, and risk factors.

The research-recruited subject who may in the remote past have had a questionable PTSD-causing event, whom the academician is now researching and writing about but never actually examined, is not the same patient arriving at the doctor's office seeking treatment for a psychological trauma. Who and what type of person might respond to a call for research subjects? To give an extraordinary example, in a very innovative PTSD study, McNally advertised for research subjects kidnapped by aliens so their physiological response, a biomarker of their PTSD, to the alien abduction could be measured. Results confirmed the hypothesis that alien abductees can generate emotional responses similar to that of combat veterans with PTSD (McNally, Lasko, Clancy, Macklin, Pitman, & Orr, 2004). Allen Frances, in his first commentary on the DSM-5 process, observed that those responsible for revising the DSM spent their careers in academic psychiatry. He maintained that a basic tenet of clinical epidemiology is that the research and clinical experience of tertiary-care centers may not generalize to the average clinic. "Experts are absolutely necessary to the development of a diagnostic system but are also a serious threat to its generalizability and safety" (Frances & Widiger, 2012, p. 118). This perception of disengagement of the PTSD academician from the clinical process was shared by enough clinician members of the International Society for Traumatic Stress Studies to cause a rift in the early 1990s resulting in some members resigning and forming their own organization, The Association for Traumatic Stress Specialists (Bloom, 2000). A large portion of PTSD research is conducted by recruiting subjects via advertisements or non-treatment-seeking subjects (e.g., undergraduate students reporting "traumas") and diagnosed with PTSD may not be generalizable. In one study (Pfaltz, Michael, Meyer, & Wilhelm, 2013), subjects recruited through newspaper advertisements reported an average of 17 traumatic memories. It is hard to imagine that there is any clinical generalizability in recruiting Alzheimer's disease patients from newspaper advertisements. This author

cannot say if he has ever seen such a study in the neurology literature. In PTSD research this is common. Valid clinical research is examining a consecutive series of treatment-seeking patients.

The safety concerns Frances was referring to earlier are the iatrogenic consequences of an inclusive psychiatric diagnostic system that produce more patients than may actually exist (Frances, 2010). It has been argued, rather persuasively, that the sociology of psychiatric stigma is one in which psychiatry has not been an innocent bystander (Summerfield, 2001). Parenthetically, one also has to ask the question: Do researchers have an obligation to secure treatment for those patients diagnosed with PTSD in these epidemiological studies?

The studies previously reviewed that concluded A2 had very little effect on PTSD rates might look different in a patient sample. The first prospective longitudinal study to examine if A2 predicts PTSD was done by Brewin, Andrews, and Rose (2000). The patient sample was crime victims assaulted or threatened with assault by a nonhousehold member. They were recruited via police reports and hospitals. As predicted, all three emotions predicted the development of PTSD: fear, helplessness, or horror. The shortcoming of the study is that PTSD was diagnosed via a PTSD self-report measure versus an interview and that of the 2,161 eligible victims only 11% participated. One conclusion of the study is that it validated the new DSM-IV Criterion A2 (APA, 1994). In a population-based study, Creamer, McFarlane, and Burgess (2005) looked at the role of subjective experience via a structured interview in the development of various psychiatric disorders. Using DSM-IV, they identified ten A1 trauma categories. They concluded that meeting Criterion A2 varied with the type of trauma, with virtually anyone (97%) experiencing a rape meeting the A2 Criterion. Second, the prevalence rates of all psychiatric disorders are higher for those meeting both A1 and A2 versus just A1. A2 emotions at the time of the event not only predict PTSD, but psychiatric morbidity in general. In an aging study of well-adjusted (study entrance required good physical health and mental health at the time of admission) military veterans of World War II and the Korea War suggested that meeting A2 was a function of the nature of the A1 event. Sexual assault and war-zone exposure had the highest probability, between 75% and 80% meeting A2 criteria given A1 (Schnurr, Spiro, Vielhauer, Findler, & Hamblen, 2002). In summary, the first point addressed earlier concerned the epidemiological studies that are cited to support changes in DSM-5, especially in regard to Criterion A. These studies have to meet the litmus test of approximating the clinical situation. Second, in reference to Criterion A, the types of trauma should be identified since meeting A2 is a function of the type of A1 trauma.

The second point in regard to A2 comes from McNally (2009), who accurately phrased what should be the fate of A2: "In the language of behaviorism, it confounds the response with the stimulus. In the language of medicine, it

confounds the host with the pathogen” (p. 598). On the surface it might ironically appear that the author of criterion creep might be advocating the further watering down of the stressor criteria by eliminating the fear, helplessness, and horror emotions that define trauma. However, McNally argues that the removing of A2 is contingent upon tightening up A1 by requiring that the person be physically present at the scene of the trauma. I would instead go further and argue that dropping A2 be contingent upon returning to the original definition of the type of event that constitutes trauma. If we stipulate that the A1 event must be beyond the realm of human experience as advocated by DSM-I and DSM-III, then the A2 criteria introduced in DSM-IV is indeed not necessary. A2 studies addressing the issue between A2 and the development of PTSD become obsolete. As the definition of the PTSD-producing events in A1 expands and the less representative the subjects are in terms of representing actual help-seeking patients, like university student volunteers responding to a PTSD checklist (Boals & Schuettler, 2009), the less likely the relevance of A2. The worse scenario is removing A2 and keeping A1 unaltered. That is what essentially happened in DSM-5. I say “essentially” because there has been at least some attempt to try and better operationally define the stressor in DSM-5. While applauded by some, it fails to resolve completely the Criterion A issue (Rosen, Lilienfeld, Frueh, McHugh & Spitzer, 2010).

Returning to the issue of the nonspecificity (i.e., irritability, anhedonia, attention problems, insomnia, and poor memory) of some PTSD criteria, one study with blinded raters found that 78.6% of patients enrolled in antidepressant clinical trials with an identified stressor met the B, C, and D DSM-IV PTSD criteria. However, an equal number, 80%, without trauma (or equivocal trauma), also met the criteria (Bodkin, Pope, Detke, & Hudson, 2007). This finding was repeated using a nationally stratified sample, the National Co-Morbidity Survey Replication and the DSM-IV definition (Elhai, Grubaugh, Kashdan, & Frueh, 2008). Following the deletion of nonspecific PTSD symptoms, they found the lifetime prevalence rate of PTSD changed very little (6.81% to 6.42%), but a sizable minority (13%) no longer met the DSM-IV criteria using the revised Spitzer criteria. One argument made by the authors for the lack of overall change in prevalence is that depression, a common comorbid condition, is part of PTSD, rather than a source of error in the diagnosis. Finally, a major problem in dropping Criterion A1 is its medicolegal implications. It does serve as a gatekeeper, albeit a weak one as currently defined.

### ***PTSD Defined in DSM-5***

The DSM-5 criteria are briefly summarized, and are listed in Table 32.1. Criterion A was maintained, requiring exposure to a trauma via four ways. As was expected, the A2 Criterion in DSM-IV-TR was dropped. Unlike the previous DSM, these four qualifiers are listed. The first would be exposure

to an actual traumatic event (A1) or witnessing it in another person (A2). If the patient learned about the event it had to have happened to a close family member or friend and had to be of a violent or accidental nature (A3). Completely new is the addition of repeated exposure to traumatic events such as might be found in certain occupations, such as collecting human remains, or law enforcement personnel exposed repeatedly to traumatic events associated with their occupation (A4). This last criterion has potential medicolegal implications. This could assign a PTSD diagnosis to someone just by virtue of the everyday duties associated with his or her occupation.

A change welcomed by all was the splitting of the intrusion (Criterion B) and avoidance (Criterion C) symptoms. Only one symptom from each is needed to meet the criterion within each category. Criterion B requires the presence of recurrent, involuntary, and intrusive memories of the event (B1); recurrent dreams (B2); flashbacks (B3); distress to internal and external cues that symbolize the event (B4); and finally, a physiological reaction to those cues (B5). One or more of the criteria have to be met. Criterion C consists of avoiding internal and external reminders, respectively. Internal reminders are distressing memories, thoughts, and feelings about the event (C1) or the avoidance of external reminders (C2). At least one of the two criteria has to be met. Criterion D, negative alterations in cognitions and mood associated with the traumatic event, consists of organizing seven symptoms previously in DSM except for two that were added: exaggerated negative beliefs (D2) and distorted cognitions (D3). Two of the seven symptoms listed must be met. Two of six symptoms must be met in Criterion E. Unlike B and C, Criterion D and E symptoms are rather nonspecific in regard to PTSD with the exception of D1 (inability to recall important aspects of the event), E3 (hypervigilance), and exaggerated startle response (E4). Added to Criterion E (previously Criterion D) in the previous DSM was reckless or self-destructive behavior (E24, a symptom not in the previous DSM). Criterion F (duration of symptoms greater than one month), Criterion G (impairment in daily activities), and Criterion H (not due to another medical condition) remain relatively unaltered from the previous edition. The one change (Criterion F) is that there is no longer an acute (duration less than three months) versus chronic (longer than three months) subtype that needs to be specified. Instead of three clusters and 17 symptoms in the previous DSM, there are now four clusters and 20 symptoms.

Once the diagnosis is made the clinician would specify the dissociative subtype of PTSD: depersonalization or derealization is not included in the previous DSM. Finally, the clinician is asked to code if there is delayed onset PTSD present. Second only to the debate over what constitutes a trauma (Criterion A), delayed PTSD perhaps is the most problematic and remains problematic in DSM-5. The requirement to code a dissociative subtype now moves PTSD from the anxiety disorder camp, where some convincingly

argue it should be, and makes it a dissociative disorder that is not in the Dissociative Disorders section but is instead in the new Trauma and Stressor-Related Disorders section. Despite arguable evidence that a dissociative subtype should be included, it is introduced and despite compelling evidence that delayed PTSD is rare it remains in DSM.

### *What to Do With Criterion A: The Stressor?*

As has always been the case, the majority of the pre-DSM-5 debate centered on Criterion A: A1, the traumatic event and A2, fear, helplessness and horror. A review of the research that has been cited to justify revision of the criteria in DSM-5 is in order followed by an overview of the DSM-5 field trials that solidified these changes. As already noted, British psychologist Chris Brewin has commented extensively on what to do with the stressor criteria. His commentary has some empirical basis, but more importantly provides a perspective outside of North America, where the DSM has been viewed by some a chauvinistic, unpredictable, and proprietary enterprise.

What was novel about the new PTSD diagnosis in DSM-III was that a psychiatric syndrome was linked to a distinct class of stressors. The event more or less defined the syndrome. Furthermore an early critique of the DSM-III argued that there was no epidemiological evidence for linking a particular syndrome to extraordinary stressors versus ordinary stressors. It is the personal characteristics and social milieu of the individual that defines how a stressor will affect the individual (Breslau & Davis, 1987). Breslau and Davis argued that this notion in DSM-III had only face validity with no epidemiological studies to support the notion. I would argue that epidemiology is not a prerequisite for defining a syndrome. Alois Alzheimer was the first to link a neuropsychiatric syndrome to a neuropathology and he did this in one patient. While no seminal and or definitive epidemiological study was offered as evidence for the newly minted PTSD diagnosis, it is clear that exposure to extraordinary stressors can have a psychiatric consequence. What has been argued is if that psychiatric consequence needed a new label: PTSD. Some have suggested removing from the criteria the very definition of PTSD—the stressor criteria. Brewin and colleagues (2009) suggested that Criterion A be eliminated completely. An individual meeting a stringent DSM symptom cluster makes Criterion A unnecessary (Kraemer, Wittmann, Jenewein, Maier, & Schnyder, 2009; Maier, 2007). The counterargument is that this essentially eliminates the very essence of the diagnosis. PTSD does not occur spontaneously in nature. It must follow a stressor, and specifying the stressor informs us which stressors are likely to produce the diagnosis (Kilpatrick, Resnick, & Acierno, 2009). There is heuristic value in identifying stressors that produce symptoms independent of PTSD.

It is argued here that Criterion A needs to be maintained. First, the dropping of Criterion A is moot for clinicians in

North America who have decided to continue using DSM-5. Second, the stressor criterion was present and preceded the debate that surrounded the new PTSD diagnosis. The stressor was the very definition of what Gross Stress Reaction was under DSM-II. Third, the ICD-10 PTSD criteria is consistent with the Gross Stress Reaction definition and what it means to have a stressor outside the realm of everyday experience as embodied in DSM-III. What is left to do is operationally define what those stressors might be.

The research regarding Criterion A2 (the fear, horror, and helplessness criteria) has been much more controversial. The biggest conceptual shift in the A1 and A2 criteria happened in DSM-IV. DSM III-R continued to define A1 as an extraordinary traumatic experience but the DSM-IV dropped the “outside the range of usual human experience” delineation. The DSM-IV field studies did not require the respondent to link symptoms to a traumatic event (Kilpatrick et al., 1998). To offset what would be perceived as a watering down of the stressor, A2 was added.

The standard was no longer an event that almost anyone would find traumatic, but the individual’s subjective reaction to that event now became important. The field trials suggested this strongly correlated with PTSD (Kilpatrick et al., 1998). Since DSM-IV the tide has turned against the inclusion of A2 in DSM-5, so it was eliminated. Here I survey the evidence for its omission.

The Brewin study was the first longitudinal study to assess how the subjective reaction as to the intensity of the trauma predicted PTSD (Brewin et al. 2000). It largely supported the introduction of A2 in DSM-IV. Others have found a relationship as well. Creamer et al. (2005) persuasively argued that if we identify what constitutes a valid PTSD-producing A1 stressor the subjectivity of A2 is irrelevant. In this Australian population-based study virtually everyone experiencing rape as the A1 event also met criteria for A2 (97%). Next in line was sexual molestation and physical assault. This is in contrast to those who reported combat as the A1 event. Approximately 65% also met A2. While this may appear counterintuitive at first glance, this possibility was anticipated in DSM-III. The reason for including delayed PTSD was that in the course of combat, fear, helplessness, and horror are not very adaptive (Andreasen, 2004). It was only in the aftermath of battle that the emotional consequence would manifest itself. What delayed PTSD was not intended to do, and what makes little clinical sense, is for symptoms to be reported months or years after the precipitating event. Additionally, in the Creamer study, overall psychiatric morbidity (e.g., clinical depression) was higher for those that met both A1 and A2 criteria. The flipside to the A2 debate is that while A2 does not predict the presence of PTSD, the absence of it virtually rules out the presence of PTSD (Bedard-Gilligan & Zoellner, 2008; Breslau & Kessler, 2001). If it is not to be used as a core criterion, A2 is at least a risk factor (Karam et al., 2010). Since the absence of A2 strongly predicts the absence of PTSD, it should be retained in some form or another (Weathers &

Keane, 2007). A patient not volunteering horror, fear, and helplessness in response to an open-ended question means PTSD is unlikely.

The studies that argue against the utility of either A1 and A2, or both, in predicting PTSD are based on nongeneralizable samples of undergraduates and subjects responding to research advertisements reporting trauma histories (Bedard-Gilligan & Zoellner, 2008; Boals & Schuettler, 2009; Roemer, Orsillo, Borkovec, & Litz, 1998) or population or community-based studies in which subjects are asked to retrospectively recall potential trauma causing events from years ago (Anders et al., 2011; Breslau & Kessler, 2001; Karam et al., 2010). These studies are negligibly helpful in our clinical understanding of PTSD. Those that argue that the absence of fear, helplessness or horror do not predict PTSD use clinical samples that experience stressors that questionably meet the stressor criterion. A quarter of mild head injured patients who presumably have PTSD did not report A2 emotions (O'Donnell et al., 2010).

One valid reason for removing both A1 and A2 is that the diagnosis would be based on the core symptoms without reference to an event—just like any other psychiatric disorder. Niessen and Large (2011: e21) remind us doing this tends to ignore the fact “the diagnosis as it exists serves an important cultural purpose in acknowledging and compensating many forms of emotional distress.”

### *The Dissociative Subtype*

The Working Group Chair of ICD-11, Andreas Maercker, exclaimed in reference to DSM-5, “a new dissociative subtype with no research at all until last year has been included” in reference to the proposal to add this subtype (Maercker & Perkonig, 2013: 561). Many of the major validity studies addressing Criterion A and dissociation appeared in close proximity to the release of the DSM-5 (Karam et al., 2010; O'Donnell et al., 2010; Stein et al., 2013; Steuwe, Lanius, & Frewen, 2012; Wolf et al., 2012) as did a number of review articles arguing for changes that eventually predicted most of the revisions that would occur (Carlson, Dalenberg, & McDade-Montez, 2012; Dalenberg & Carlson, 2012; Lanius, Brand, Vermetten, Frewen, & Spiegel, 2012). A review by Mathew Friedman, the then Executive Director for the National Center for PTSD, predicted some of these changes:

A new set of diagnostic criteria is proposed for DSM-5 that: (a) attempts to sharpen the A1 criterion; (b) eliminates the A2 criterion; (c) proposes four rather than three symptom clusters; and (d) expands the scope of the B-E criteria beyond a fear-based context. The final sections of this review consider: (a) partial/subsyndromal PTSD; (b) disorders of extreme stress not otherwise specified (DESNOS)/complex PTSD; (c) cross-cultural factors; (d) developmental factors; and (e) subtypes of PTSD.

(Friedman, Resick, Bryant, & Brewin, 2011 p. 750)

Dissociation is said to be a defense mechanism by which the dramatic experience is minimized by restricting the awareness of the experience. The most dramatic dissociative symptom to be introduced was when PTSD was introduced in DSM III: the flashback. DSM III-R introduced the second symptom: amnesia for the event. Peritraumatic dissociation may be important at the time of the trauma. It is said to be a risk factor for the development of PTSD (Ozer, Best, Lipsey, & Weiss, 2008). But Bryant (2007: 187) asks the provocative question, “Is dissociation necessarily bad?” He argued that it could be protective because it limits one's awareness of the experience.

Proponents have suggested that dissociation should be included as a subtype in DSM-5 (Dalenberg & Carlson, 2012). The same authors did a review of the literature and concluded there is a strong relationship between dissociation and trauma exposure, and the presence of dissociation is strongly related to the presence and severity of PTSD (Carlson et al., 2012). Despite this conclusion, the majority of the studies they cited were not PTSD samples per se but general psychiatric samples. A large sample of rape and sexual assault victims suggested that 13% evidenced a dissociative subtype of PTSD. This investigation was the first to be conducted in a European nonmilitary adult rape-victim sample (Armour, Elklit, Lauterbach, & Elhai, 2014). The largest study that involved a homogeneous clinical sample of rape victims found no association between dissociation and PTSD. This relationship is found instead in a comparison group of nonsexual assault victims (Dancu, Riggs, Hearst-Ikeda, Shoyer, & Foa, 1996). This would appear to be counterintuitive if it is true that dissociation is a PTSD risk factor and when considering that rape results in the highest rates of PTSD reported in the literature.

Since most studies on dissociation were done in Western countries, an international study was conducted, showing 14.4% of subjects have the dissociative subtype. This was the first large population-based study using layperson interviews (Stein et al., 2013). The authors acknowledge the use of layperson interviewers as a weakness given the very conceptual nature of dissociation. The presence of dissociation was based on answering two questions regarding depersonalization and one on derealization. Even before this most recent dissociation research, Bryant cautioned that these rates of dissociation are frequently obtained from questionnaires and checklists (Bryant, 2007). An additional problem with the later study is that the dissociation items were chosen post hoc versus for the purposes of operationalizing dissociation for DSM-5. Their finding that dissociation was more common in men contradicted previous studies that found it is higher in women or found no gender difference. In another study, a civilian sample was assessed for dissociative subtypes using the Dissociative Experiences Scale, the CAPS, and the Structured Clinical Interview for DSM Disorders. Depersonalization criteria were met by 25% of the sample and the same number met criteria for present derealization symptoms.

While the strength of the study was the use of structured interviews, the sample was recruited through advertisements posted in the community and in mental health centers (Steuwe et al., 2012). The DSM-5 field trials were equally controversial.

### ***The DSM-5 Field Trials***

Mathew Friedman was chairperson of the Trauma/Stress-Related and Dissociative Disorders Sub-Work Group for DSM-5. It consisted of five members and a subcommittee of 30 national experts in PTSD. The International Society for Traumatic Stress Studies was also well represented. The reason DSM “5” was chosen over DSM “V” is the expectation that over the next few years there may be updates (e.g., DSM-5.2; see Friedman, 2013). The DSM-5 field trials focused on test-retest reliability among clinicians, different than for the DSM-IV, which conducted field trials on the validity and reliability of the PTSD criteria. Two Internet surveys were designed to test the new criteria in order to compare with DSM-IV. The major findings were that prevalence was comparable to DSM-IV, the four-factor DSM-5 structure proved a better fit than the three-factor DSM-IV factor model, and symptoms within each diagnostic cluster loaded well together. Test-retest reliability for the PTSD criteria was examined at two VA sites in Dallas and Houston in veterans and not civilians. The kappa values at both sites were 0.63 and 0.69. These values were greater than for other DSM-5 conditions including major depression (Regier et al., 2013). The high kappa values for DSM-5 PTSD in the field trials were second only to major neurocognitive disorder. This was viewed as a “historic accomplishment” (Freedman et al., 2013).

Frances criticized these trials. His reasons include focusing on reliability versus how mental disorders will be diagnosed more often due to the lowering of diagnostic thresholds. Additionally, the kappa values for the present trials were different from past trials. Kappa values of 0.40 to 0.59 that would be considered poor in the past were now considered good (Frances, 2012b). These latter criticisms, in addition to others, were summarized by Jones (2012).

### ***From DSM to ICD***

“The American Psychiatric Association’s classification is designed to meet the needs of one, or perhaps two, professions—psychiatrists and clinical psychologists—in a single country” (Kendell, 1991, p. 299). While it was always the intent that DSM and ICD would work toward a harmonized diagnostic system, the tension between the two was seen early. DSM-III, as innovative and as revolutionary as it was, broke ranks from the international community to put forth a system that was radically different from DSM-II. Regardless, the intent was for DSM-IV to be produced in conjunction with ICD-10. That did not occur as ICD-10 was practically

completed before DSM-IV members met (Kendell, 1991). At present, the well-intended harmonization between the two diagnostic systems is no longer possible. PTSD as defined in ICD-10, and the further changes that will occur in ICD-11, will necessitate having to choose between the two (First & Pincus, 1999). The differences will be greater between DSM-5 and ICD-11 than they were between DSM-IV and ICD-10. In the United States many organizations are navigating away from DSM-5. The controversies that accompany each DSM, including DSM-III (Vaillant, 1984), have increased exponentially with each edition. DSM-5 is the crossroads. Legislation has provided much of the impetus for converting to ICD-11.

WHO member countries, including the United States, report health statistics to the WHO via the ICD classification system. Aside from impacting public health, two practical goals of the ICD have been to be a multilingual and multidisciplinary publication (Reed, 2010). The ICD should be multilingual because one of every five Americans over the age of 5 in the United States speaks another language other than English in the home (Camarota & Ziegler, 2015). As Zimmerman notes: “Ironically, a country as ethnically diverse as the United States is perhaps the most likely candidate for a system such as the ICD, which is designed for cross-cultural use” (Zimmerman, 1990: 975). The ICD should be multidisciplinary because, worldwide, less than 10% of patients will see a psychiatrist (Reed, 2010). Federal regulations in the United States (Medicare and the Health Insurance Portability and Accountability Act) require the use of ICD codes. By federal law, all entities and health care professionals are required to convert to ICD-10. Additional developments are precipitating the move away from DSM-5, but not necessarily toward ICD-10. The release of DSM-5 initiated at the National Institute of Mental Health (NIMH) a plan to introduce their own psychiatric classification (the Research Domain Criteria), adding that the project cannot succeed if DSM-5 criteria are used as the “gold standard” (Insel et al., 2010). The American Psychological Association is making the clinical transition to ICD (American Psychological Association, Practice Central, 2012). The National Alliance of Professional Psychology Providers, a professional practice organization that represents psychologists in the United States, has encouraged its members to adopt ICD-10, citing as one reason an effort to eliminate the political debates that adversely impact the frequent revision of DSM (Bradshaw, 2012). There are three versions to ICD-10: The ICD-10 *Clinical Descriptions and Diagnostic Guidelines* is the “conceptual core” that outlines the disorders (referred to as the *Blue Book*), the ICD-10 *Diagnostic Criteria for Research* operationally defines the disorders (the *Green Book*), and the WHO *Guide to Mental Health in Primary Care* is meant to be used in a primary care context to diagnose a handful of core disorders so the latter does not include PTSD (Jablensky, 2009). The clinical version of ICD-10 is difficult for researchers to use because the criteria are not operationally defined as they have been in the DSM since DSM-III.

Table 32.2 \*F43.1 Posttraumatic stress disorder—research criteria

- 
- A Exposure to a stressful event or situation of an exceptionally threatening or catastrophic nature, which is likely to cause pervasive distress in almost anyone
- B Persistent remembering or “reliving” the stressor by flashbacks, vivid memories, dreams, or by being exposed to circumstances resembling or associated with the stressor
- C Actual or preferred avoidance of circumstances resembling or associated with the stressor
- D Either (1) or (2):
- (1) Inability to recall, either partially or completely, some important aspects of the event
  - (2) Symptoms of increased psychological sensitivity and arousal shown by two of the following:
    - a difficulty in falling or staying asleep;
    - b irritability or outbursts of anger;
    - c difficulty in concentrating;
    - d hyper-vigilance;
    - e exaggerated startle response.
- E Criteria B, C and D all occurred within six months of the stressful event (for some purposes delayed more than six months may be included but this should be clearly specified)
- 

\*Modified from ICD-10 (Green Book)

Similar to DSM-I and DSM-II, the ICD-10 consists of clinical text descriptions that may be open to interpretation (Farmer & McGuffin, 1999). The PTSD ICD-10 research criteria operationally define PTSD (Table 32.2). Four things merit comment. First, the stressor should be “exceptionally threatening or catastrophic,” similar to DSM-I and DSM-III. Second, the core features of the disorder of intrusive memories and avoidance of the event are prominent. Third, delayed PTSD is considered under special circumstances only. In ICD-10 delayed PTSD can be seen in a few weeks to months but “rarely exceeds six months.” Finally, notable for its absence is the requirement that PTSD result in some functional impairment. On the one hand the requirement that the PTSD-causing event must be of an exceptional nature in some ways nullifies the need to include a functional impairment criterion. On the other hand, someone experiencing a catastrophic event may have had PTSD symptoms for some period of time, never felt the need for treatment, and had no appreciable functional consequence. Should such a person be included in a prevalence study? As with DSM-5, PTSD will be placed in a stress disorders section in ICD-11.

With each successive revision, the WHO is fine-tuning the PTSD definition to the approval of the majority of its users (Evans et al., 2013; Reed, Correia, Esparza, Saxena, & Maj, 2011). There have been considerable improvements when one considers that there was no PTSD diagnosis in ICD-9. ICD-9 was published in 1979, before PTSD was coined in 1980 for use in DSM-III. PTSD was introduced in ICD-10. The original release for ICD-11 that was meant for 2011/2012 (Frances, 2013) is now planned for release in 2018 (WHO, 2015a). Whereas there are now 20 core PTSD symptoms in DSM-5, ICD-11 is likely to have only six. Chris Brewin

Table 32.3 Proposed diagnostic criteria for PTSD in ICD-11

- 
- Reexperiencing: either (i) or (ii)
- (i) Recurrent distressing dreams related to an event now perceived as having severely threatened someone’s physical or psychological well-being, from which the person wakes with marked fear or horror
  - (ii) Repeated daytime images related to an event now perceived as having severely threatened someone’s physical or psychological well-being, experienced as recurring in the present and accompanied by marked fear or horror
- Avoidance: either (i) or (ii)
- (i) Efforts to avoid thoughts, feelings, conversations, or internal reminders associated with the reexperienced event(s)
  - (ii) Efforts to avoid activities, places, people, or external reminders associated with the reexperienced event(s)
- Hyperarousal: either (i) or (ii)
- (i) Hypervigilance
  - (ii) Exaggerated startle response
- Impairment: The symptoms must last for at least several weeks and cause significant impairment in functioning
- 

From Morina, van Emmerik, Andrews, and Brewin (2014)

provided a convincing rationale for only six PTSD symptoms (Brewin et al. 2009). Table 32.3 outlines what at the time of this writing are the planned changes to the PTSD diagnosis in ICD-11. The essence of the change is removing the non-specific PTSD symptoms as advocated by Brewin (Brewin et al., 2009). Spitzer et al. (2007) first directly advocated the removal of the nonspecific symptoms. Attention, sleep problems, irritability, and anhedonia should be eliminated as they overlap with mood and anxiety disorders. The fifth symptom (lack of or poor memory for the event) can occur for reasons other than repression or dissociation. While yet not finalized, it appears ICD-11 will have three core criteria: intrusions, avoidance, and hyperarousal. Intrusions will require the presence of one of two symptoms: nightmares and flashbacks. Avoidance will consist of avoiding either thoughts and/or feelings of the event or actual avoidance of people, places, or activities that remind the patient of the event. Finally, there will be two hyperarousal symptoms: startle response and hypervigilance. Meeting one of the two symptoms within each category will be required. It would appear that Criterion A will remain, while others have suggested that clinical judgment will play a role in defining the stressor more so than was the case in ICD-10 (Maercker et al., 2013; O’Donnell et al., 2014). At the time of this writing, the ICD-11 Beta Draft contains the language “extremely threatening or horrific event” (WHO, 2015b). Finally, functional impairment will be required in ICD-11 to differentiate it from normal reactions to extreme stress. The diagnosis should be made within a month. The focus will be on functional impairment rather than a specific class of stressors (Maercker et al., 2013). Like ICD-10, ICD-11 will have a section for specialty settings (Clinical Description and Diagnostic Guidelines) and a

section for use in primary care, but it has not been decided if there will be a version for research purposes (Luciano, 2014).

### *ICD and DSM PTSD Studies*

A logical place to start is the reliability of the PTSD diagnosis using the two diagnostic systems. The pivotal international ICD-10 field trial that included 568 clinicians and 2,460 patients from 39 countries yielded a modest kappa value for PTSD of 0.62. As a diagnostic group, the personality disorders yielded the lowest, a kappa value of 0.51 (Sartorius et al., 1993). When North American clinicians were compared to clinicians outside of Canada and the United States, the kappa value was 0.72 among North American clinicians versus 0.52 for the rest of the world. The Canadian and U.S. clinicians were more likely to assign more diagnoses (2.1 vs. 1.7). The caveat here is that the number of PTSD patients examined ( $N = 19$ ) was far lower than other diagnostic categories, suggested that the kappa value might not be a reliable estimate of agreement (Regier, Kaelber, Roper, Rae, & Sartorius, 1994). The reliability of the PTSD diagnosis was not tested in the DSM-III field trials ( $N = 400$ ), but in DSM-IV the kappa value was 0.71 (Kilpatrick et al., 1998). In the ICD-10 trials, the clinical and not research ICD-10 criteria were used. The ICD-10 field trial was repeated with an equally impressive sample using the ICD-10 research criteria for major disorders, but PTSD was not one of them. Kappa values in this study for major diagnostic categories were better for all major diagnostic categories (organic, schizophrenia, mood, dysthymia and anxiety disorders) when research criteria were used. Interestingly the largest difference was for the anxiety disorders: 0.74 when the research criteria were used versus 0.55 for the clinical criteria (Sartorius, Ustün, Korten, Cooper, & van Drimmelen, 1995). This suggests operationally defining the criteria increases reliability, especially for PTSD, and that this is most important for the anxiety disorders.

What are the prevalence rates of PTSD when comparing ICD-10 to DSM? Studies reporting prevalence within the last 12 months will be used. There are problems in making the comparison. Recalling traumatic events over a lifetime and what if any symptoms accompanied those events is subject to recall bias. A community based study ( $N = 1,264$ ) used a structured interview, the Composite International Diagnostic Interview (CIDI), by comparing ICD-10 and DSM-IV (Peters, Slade, & Andrews, 1999). This resulted in a concordance rate of only 35%, with ICD-10 resulting in twice as many persons diagnosed with PTSD: 6.9% versus 3.0%. This was partially attributed to DSM-IV requiring functional impairment whereas ICD-10 did not. When the functional criteria were applied to ICD-10, the rate was 4%. Another problem is that numbing is a criterion of DSM-IV but not of ICD-10. The more criteria that are needed, the less likely the diagnosis is going to be made. This is further complicated by the fact that numbing is described in the ICD-10

clinical criteria, but it is not listed in the ICD-10 research criteria. It is not clear that the stressor criterion was adhered to in this study as applied to ICD-10. Per this study “exposure to a stressor” was required for both diagnostic criteria. Since DSM-IV requires an emotional response to the stressor (A2) and ICD-10 does not, this further accounts for the higher prevalence in ICD-10. In comparison the concurrence for major depression was 16.6% and 15.6% between ICD-10 and DSM-IV, respectively (Andrews, Slade, & Peters, 1999).

When we compare ICD-11 to DSM-5 we see the reverse pattern. O’Donnell and colleagues (2014) examined a clinical sample ( $N = 510$ ) of trauma patients admitted to four hospitals following an accident or other injury. The CAPS was used to assess for the presence of PTSD. The PTSD definition followed by the prevalence of PTSD in parentheses was as follows: DSM-IV with A2 (5.9%), DSM-IV without A2 (8%), DSM-5 (6.7%), ICD-10 (9.0%) and ICD-11 (3.3%). The authors are operating under the assumption that the stressor as defined in ICD-11 would not be described as one that likely causes pervasive distress in almost anyone. The drop in prevalence from ICD-10 to ICD-11 was attributed to requiring that the patient meet one of the intrusion and hyperarousal symptoms. Again, requiring functional impairment also accounted for the decrease. More than 80% of the hospital admissions were following a motor vehicle accident or fall. Of these patients, 41% had a mild head injury. The ICD-10 stressor criteria would not appear to have been applied in this study. Were it applied, PTSD would be rare to nonexistent in this patient sample except for those with life-threatening injuries. This latter clinical study was the first comparing DSM-5 to ICD-11. The first large-scale international population-based study involving 13 countries employed the CIDI as administered by lay interviewers. It revealed the following prevalence rates: ICD-10 (4.4%), DSM-IV (3.3%), ICD-11 (3.2%), and DSM-5 (3.0%). Again, the reason given for the high ICD-10 prevalence rate is that it is the most narrowly defined criteria. The low prevalence in DSM-5 is likely a function of the opposite: a greater number of criteria that need to be met (four criteria and 20 symptoms) versus ICD-11 (three criteria and six symptoms). Again, what impact on how the stressor is defined in reference to the PTSD prevalence rates is not discussed.

### *Complex PTSD*

The only major controversy surrounding ICD-11 is the introduction of complex PTSD (CPTSD). This was considered for inclusion in DSM-IV under Disorders of Extreme Stress Not Otherwise Specified (DESNOS) and more recently in DSM-5. It was not included in DSM-5. Whereas inside the United States there was enthusiasm for a dissociative subtype, internationally there was instead a keen interest in including CPTSD in ICD-11. CPTSD was in ICD-10 as “enduring personality change after catastrophic experiences”

(Maercker & Perkonig, 2013: 199). It will be called CPTSD in ICD-11.

CPTSD was first clearly articulated by Herman (1992). Courtios (2004) summarized the work of Herman (1992) in reference to CTPD: The seven problem areas are poor regulation of affective impulses (e.g., anger); alterations in attention (e.g., dissociation); alterations in self-perception (e.g., guilt and shame); perception of the perpetrator (e.g., identification with their belief system); relationship with others (e.g., lack of trust and intimacy); somatization (e.g., can involve any body system); and alterations in a loss of meaning (e.g., feeling misunderstood). Unlike patients suffering from PTSD secondary to a discrete event such as rape, there are patients, Herman argues, who have a different clinical phenotype as a consequence of repeated and prolonged exposure to trauma. The most common and the one Herman focused on was repeated sexual and physical abuse. These are patients with persistent depression, suicidal thoughts, episodes of self-mutilation, substance abuse, and impulsivity. Somatization, dissociation, and the pathological relationship that they develop with their abuser alter their personality. The other class of traumas where CPTSD would be found includes refugees, victims of prolonged torture, or concentration- or labor-camp survivors. Herman notes Horowitz suggested a similar concept in the form of “post traumatic character disorder” (Horowitz, 1986, p. 49).

In order to appreciate the issues surrounding CPTSD, an overview of how the debate unfolded in the United States is in order. The June 2012 issue of the *Journal of Traumatic Stress Studies* was partially devoted to the topic. The lively and informative debate was around the merits of including CPTSD in DSM-5. The debate began with an invited article by Resick and colleagues (2012) that concluded that the weight of the evidence argues against inclusion in DSM-5. Resick provided a number of compelling arguments. The most salient is the most simple: First, there is no precedent in psychiatric diagnostic systems for splitting off a more severe form of the same disorder. Second, the DSM-IV field trials indicated that practically everyone (over 90%) who met criteria for complex PTSD also met criteria for PTSD (Roth, Newman, Pelcovitz, van der Kolk, & Mandel, 1997). Third, those meeting complex PTSD criteria overlap with borderline personality disorder (as well as major depression). The overlap with other disorders makes it less distinctive. Here one can just simply assign a comorbid diagnosis.

Some of the offered rebuttals raised issues that further confused the debate. CPTSD was originally conceptualized as being related to trauma that was prolonged and repeated versus an isolated traumatic event such as a rape event. Bryant (2012) argued that it is not necessary to focus on the nature of the event but instead on the symptoms. In response to Bryant, Resick argues that the nature of the stressor is the very basis for CPTSD. It is a different type of trauma than the one that typically produces PTSD. Finally, Resick takes issue with the arguments of Herman (2012) and Lindauer

(2012) who make a plea for advocacy arguing that “the scientific basis should be adequate but are we being a little too strict?” (Lindauer, 2012, p. 259). There has been an appeal to broad consensus opinion in support of the diagnosis. A small survey was undertaken of experts in CPTSD and PTSD regarding complex PTSD in which there was general agreement as to the symptoms and the type of treatment (Cloitre, 2011). Conspicuously absent in the discussion was the nature of the stressor needed to produce CPTSD. In ICD-10 the stressor for both PTSD and CPTSD is the foundation upon which the diagnosis rests.

CPTSD in ICD-10 (enduring personality change after catastrophic experiences) is very clear on the nature of the stressor: “The stress must be so extreme that it is unnecessary to consider personal vulnerability in order to explain its profound effect on the personality” (WHO, 1992, p. 163). The same descriptor of the stressor is provided in the ICD-10 research criteria. CPTSD as outlined in the research criteria is outlined in Table 32.4. Catastrophic events such as concentration camp exposure, torture, a refugee in a war zone,

Table 32.4 \*F62.0 Enduring personality change after catastrophic experience

- 
- A A persistent change in perceiving, relating to, and thinking about the environment and oneself following catastrophic stress (i.e., concentration camp, torture, prolonged exposure to life-threatening situations).
  - B The personality change should be significant and represent inflexible and maladaptive features as indicated by the presence of at least two of the following:
    - 1 Permanent hostile or distrustful attitude in a person without such traits premorbidly
    - 2 Social withdrawal not due to another mental disorder
    - 3 Constant feeling of emptiness and/or hopelessness, not limited to a discrete episode of mood disorder, and which was not present before the catastrophic stress experience
    - 4 An enduring feeling threatened without cause as evidenced by an increased vigilance and irritability in a person who previously showed no such traits, which may be associated with substance abuse
    - 5 Permanent feeling of being different from others (estrangement) and may be associated with emotional numbness
  - C The change should cause either significant interference with functioning.
  - D The personality develops after the catastrophic experience with no history of a preexisting personality disorder or trait accentuation that could explain the current personality traits.
  - E The personality change must have been present for at least three years and not related to other disorders.
  - F The personality change is often preceded by PTSD. The two conditions can overlap and the personality change may be a chronic outcome of PTSD. However, an enduring personality change should not be assumed in such cases unless, in addition to at least two years of PTSD there has been a further period of no less than two years during which the above criteria have been met.
- 

\*Modified from ICD-10 Research Criteria

and prolonged captivity are experiences outside the range of usual human experience in North America. This may be the reason CPTSD may not have been adopted in DSM-5. The very definition of CPTSD revisits an issue that has been officially settled in the opinion of some in the DSM, namely whether the stressor needs to be of a catastrophic nature. The ICD-10 definition of CPTSD considers “prolonged exposure to life-threatening circumstances” a catastrophic event. In North America that prolonged exposure leading to CPTSD, by default, is primarily repeated sexual and physical abuse of children. In the CPTSD survey study cited earlier eight treatment studies were identified, all of which involved childhood abuse (Cloitre, 2011). The other clinical scenario in which to diagnose CPTSD involves refugees and political prisoners with traumatic experiences who have relocated to North America. In the ICD-11 draft version “prolonged domestic violence and repeated childhood sexual or physical abuse” is specifically mentioned (WHO-ICD-11). In ICD-11 the name change will be official: from “enduring personality change after catastrophic experience” to CPTSD.

CPTSD was tested in the DSM-IV field trials (Roth et al., 1997) using criteria arising from the observations of Herman (1992). Kilpatrick et al. (1998) described the DSM-IV PTSD field trial. Most of the 400 treatment-seeking patients were being seen for exposure to a possible traumatic event. Of these patients, 234 reported physical and sexual abuse. Of these, 163 were diagnosed with PTSD ( $n = 45$ ), PTSD or CPTSD ( $n = 113$ ), or just CPTSD ( $n = 5$ ). Given that the conditions are comorbid and it is rare to having just CPTSD without PTSD, the diagnosis was not included in DSM-IV. As to risk for CPTSD, women who suffered both sexual and physical abuse were 14.5 times more likely to be diagnosed with the disorder. Age of onset for both men and women did not predict CPTSD. A reanalysis of the DSM-IV field trial data yielded different results. The early onset abuse group was more likely to carry a dual diagnosis of PTSD and CPTSD versus PTSD alone. Surprisingly there was no attempt to reconcile these findings with the earlier findings of Roth et al. (1997)—this despite using the same patient sample and that Roth was one of the coauthors of the reanalysis (van der Kolk, Roth, Pelcovitz, Sunday, & Spinazzola, 2005). Elklit, Hyland, and Shelven (2014) carried out a larger and more representative study. The sample was composed of bereaved parents after the death of a child ( $n = 607$ ), rape victims ( $n = 449$ ), and victims of physical assault ( $n = 214$ ). The major drawback was the diagnoses were made via self-report questionnaires: the Trauma Symptom Checklist and the Harvard Trauma Questionnaire Part IV. Sexual trauma victims, physical trauma victims, and bereaved parents had CPTSD rates of 20.7%, 13%, and 10.4%, respectively. Another study sought to provide support for the concept of CPTSD in ICD-11 by performing a latent class analysis on 280 females seeking treatment for childhood abuse to shore up support for including CPTSD in ICD-11. They identified four groups: a low-symptom group, a group high in PTSD

symptoms but low in self-organization and borderline personality disorder symptoms, a CPTSD group with high PTSD symptoms and self-organization symptoms and low borderline personality symptoms, and a borderline personality group high on these symptoms in addition to PTSD and CPTSD. The discrimination among the groups was described as “acceptable.” Of note is that these groups did not differ on any demographic variables, including age and employment status (Cloitre, Garvert, Brewin, Bryant, & Maercker, 2013). The major shortcoming was that CPTSD was measured by employing 21 questions across two structured interviews (CAPS and SCID-II) and a self-report instrument, the Brief Symptom Inventory. The proper method is to operationally define CPTSD using either the DSM-IV or ICD-10, which are very explicit, followed by a structured clinical interview to establish that these patients meet the clinical diagnosis of CPTSD before any statistical technique is applied to the sample. A similar approach was used by the same author in a sample of patients seeking treatment for interpersonal violence (Cloitre et al., 2013). A more extensive critique and possible solutions are suggested to the question of not only PTSD, but also CPTSD at a later point in this chapter (“PTSD Defined: A Hybrid Model”).

### The Epidemiology of PTSD

“Like mental retardation, posttraumatic stress disorder appears to be the extreme end of a normal distribution” (Robins, 1990: 1675).

In this section, the idea that the epidemiology of PTSD is problematical is elaborated upon. It is reasonable to ask if population-based epidemiological studies answer practical clinical questions. Among the many questions that can be asked, the most basic is that of the prevalence of PTSD. First, prevalence studies within the general population are discussed, followed by the prevalence in clinical samples. In the latter case, this will include treatment-seeking patients and cohorts of persons who have been exposed to an event truly outside the realm of every day experience (i.e., war, rape, torture, terrorism). Only when studying both types of populations can we answer the question of clinical relevancy. It will be argued that population-based studies magnify the prevalence of PTSD and ignore what is relevant to the clinician: the prevalence of disability and distress. With the transition to an international classification system and with the immigrant population of the United States increasing, we need to be more cross-culturally literate regarding PTSD in non-English speaking populations. Reviewing some of this literature is the second purpose of this section. The final purpose is to answer clinical questions that epidemiological studies are supposed to answer: risk factors, comorbid conditions and outcome. The outcome here is in reference to the chronicity of PTSD in these epidemiological studies as opposed to outcome following treatment.

### Population Studies

With the support of the NIMH, a nationwide study was undertaken to look at the prevalence of psychiatric disorders in the United States: the National Comorbidity Survey (NCS). The results were published in 1994 (Kessler et al., 1994) with a ten-year follow-up (Kessler et al., 2005). The NCS was the first national population-based study, and it included 8,098 respondents (82.4% participation rate) from 48 states and 176 counties. The NCS included a separate publication on PTSD that used a subsample ( $n = 5,877$ ) of participants (Kessler et al., 1995). Ronald Kessler, a sociologist by training, is the most often cited mental health researcher in the world (Horwitz & Gold, 2011).

To diagnose PTSD, a structured clinical interview was used that followed the DSM-III-R criteria (APA, 1987). The face-to-face interview was a modification of the Diagnostic Interview Schedule (DIS). Kessler et al. (1995) modified the DIS as follows. First, instead of asking a single question about a lifetime occurrence of a number of traumatic events to oneself (and others), they inquired about events with 12 different questions “in an effort to focus memory search” (Kessler et al., 1995: 1040). The 12th question asked about “any other terrible experience that most people never go through” (p. 1040). The answer was coded as meeting Criterion A or not. Second, because the participants might be embarrassed by the traumatizing events, the 12 events were presented in a checklist booklet format and the participant was asked about “event number 1” in the book, and so on. The third modification was that Criteria B through D were evaluated regardless whether Criterion A was met. This allowed researchers to assess if relaxing Criterion A affected prevalence. Finally, only one index event per respondent was assessed. If participants reported more than one trauma, they were asked to pick the most upsetting. The estimated lifetime prevalence of PTSD was 7.8% versus 8.4% if Criterion A was loosened. The most common traumas were witnessing someone being badly injured or killed; being involved in a fire, flood, or natural disaster; and experiencing a life-threatening accident. The study concluded that PTSD “is more prevalent than previously believed, and is often persistent” (p. 1048)—more than one third fail to recover after years of the disorder. This study had a profound influence not so much because of the scope of the survey, but because it contradicted earlier studies that found a significantly lower prevalence of PTSD.

The methodology of the NCS in reference to psychiatric disorders was actually first carried out by Lee Robins (coincidentally also a sociologist) and her colleagues from Washington University in St. Louis. In the Epidemiological Catchment Area (ECA) study they reported on the prevalence of 15 psychiatric disorders (Robins et al., 1984). Here we are going to take a brief detour to provide a brief historical synopsis of the research at Washington University that preceded the influential ECA study, which had a lasting influence on American psychiatry.

The psychiatric research done at Washington University group was influential for many reasons. First, as already reviewed, the Washington University group was engaged in the early controversy around the diagnosis of PTSD in DSM-III. In contrast to the PTSD advocates, they were actively researching the psychiatric adjustment of Vietnam veterans. I believe it is fair to say that the Washington University group ushered clinical psychiatry in the United States into the modern era. Their reputation in academic psychiatry was unmatched. First, in a seminal paper, Robins and Guze (1970) insisted we needed a rational and valid diagnostic classification system in psychiatry (I should note that the Robins in this study was Eli Robins, a psychiatrist at Washington University, and the spouse of Lee Robins). A second landmark paper operationally defined common psychiatric disorders with precise criteria. They provided criteria for 15 disorders (Feighner et al., 1972). Spitzer, inspired by what was popularly referred to as the “Feighner criteria,” partnered with Eli Robins to develop the Research Diagnostic Criteria, which expanded the psychiatric disorders to 25 (Spitzer, Endicott, & Robins, 1978). In the midst of writing this paper, Spitzer was appointed DSM-III Task Force Chair. Spitzer would break fully from DSM-II by implementing the ideas of the Washington University group. The Research Diagnostic Criteria was the precursor to DSM-III (Decker, 2013). While on the one hand the Washington group conceded the inclusion of PTSD in DSM-III, on the other hand the field of psychiatry accepted their classification schema. A third paper by Lee Robins laid out the method by which not only the clinician, but also the lay interviewer, can collect clinical data and assign a diagnosis in a valid and reliable way: the structured clinical interview in the form of the DIS (Robins, Helzer, Croughan, & Ratcliff, 1981). Finally, they published, in *The New England Journal of Medicine*, a very influential PTSD study (Helzer, Robins, & McEvoy, 1987). In my opinion it remains the seminal epidemiological study.

This first population-based study, post DSM-III, looked at the prevalence of PTSD (Helzer et al., 1987). The researchers used their DIS to conduct three waves of interviews. The final wave consisted of 2,493 randomly selected St. Louis residents who were similar demographically to the rest of the nation based on the 1980 census. They were asked if they had experienced an event that had freighted them to the degree that they experienced one of the PTSD symptoms in DSM-III (APA, 1980). Consistent with the DSM-III definition, the event had to be outside the range of usual human experience. It had to fall into one of seven categories: combat, serious accident, physical attack (including rape), natural disaster, being threatened or almost seriously injured, witnessing someone being killed or injured, and “other.” Onset, duration, and frequency of symptoms were ascertained. The lifetime prevalence was 1%. Chronic PTSD (greater than six months duration) was seen in half of that 1%, with one-third having symptoms more than three years. The researchers concluded: “This study of posttraumatic stress disorder in the

general population has found that it exists but is uncommon except among wounded Vietnam veterans” (Helzer et al., 1987, p. 1633). It may not be a coincidence that Lee Robins chose mental retardation as the analogy for PTSD (Robins, 1990). The prevalence of mental retardation in the general population is said to be 1% per the DSM-5 (APA, 2013). To expand on the analogy, if we described PTSD to someone who has never heard of it, we would say it is an event that someone directly experienced or witnessed. That event was so traumatic that in the worse-case scenario, in the months and the years to come, a month does not go by (the CAPS requires the symptoms to be present over the last month) without it impacting his or her life in a clinically meaningful way. A description of the syndrome, without using the PTSD label per se, would suggest a truly catastrophic rare event (in DSM-II the examples were two: combat and “civilian catastrophe”). I suspect that the average person (including myself) is not likely to know personally more than one or two people out of 100 who are mentally retarded. Similarly, it is not likely that the average American would know one or two people who experienced such a life-altering stressor. The analogy between mental retardation and PTSD in regard to prevalence is apropos. PTSD should be a rare event, especially in civilians. Two additional early community studies, which also employed the DIS, yielded similar low prevalence rates.

The first study surveyed two rural northwest logging communities in the states of Washington and Oregon, one of which had been affected by the Mt. Saint Helens volcano eruption (Shore, Vollmer, & Tatum, 1989). The nonaffected community ( $N = 477$ ) was compared with the affected community ( $N = 548$ ). The latter group consisted of a high exposure group ( $n = 138$ ). These were residents with \$5,000 of property damage or those who experienced the death of a family member or close relative. The remainder ( $n = 410$ ) was the low exposure group. They also required that at least one of the DSM-III symptoms interfere with the respondent’s life or that they had told a doctor about the symptom. Using the DIS, lifetime prevalence was 3% and 2.5% if we exclude the Mt. Saint Helens residents with PTSD. The second early study surveyed 2,985 residents from five counties in North Carolina (Davidson, Hughes, Blazer, & George, 1991). Using the DIS, the lifetime prevalence was 1.3% and the six-month prevalence less than half a percent (0.44). In regard to outcome, for 46% of the sample, the symptoms were chronic (lasting greater than six months).

I now ask if population-based epidemiological studies answer practical clinical questions by using the Kessler study, the NCS, as an example. The most often quoted PTSD paper deserves a closer critical look. For the purposes of comparison I compare the Helzer ECA and Kessler NCS studies. What might explain the higher prevalence rate of PTSD in the NCS? The logical place to start is the interview instrument used and how the questions were phrased. In letters to the editor the ECA study was criticized primarily for its use

of the DIS (Keane & Penk, 1988; Haber-Schaim, Solomon, Bleich, & Kottler, 1988). The validity of the instrument was questioned. All studies cited so far have used the DIS. In the ECA study the respondents were asked if they experienced an event that “frightened” them and was coded in one of nine categories that by definition are outside the realm of human experience. Not asking them directly about the nine categories may result in an underestimate of PTSD. Helzer and Robins (1988), in their response clarified that respondents were directly asked about each of the nine traumas. The NCS study asked about 12 types of traumas. DSM-III (used in the ECS study) and DSM-III-R (used in NCS) have similar definitions. How closely was Criterion A adhered to? This is the crux of the issue and the first major problem with epidemiological studies. In the NCS the most common causes of PTSD were the following: witnessing someone being badly injured or killed (25%), being involved in a life-threatening accident (19%), and being involved in a fire, flood, or natural disaster (17%). How “badly injured” must someone be to meet Criterion A? Can all car accidents that have rendered the vehicle inoperable be considered life threatening? If there was a fire in an empty house while someone was outside gardening, were they involved in a fire? Breslau and Kessler (2001) investigated the new two-part definition of PTSD introduced in DSM-IV. Criterion A2, the subjective component to PTSD, was now required. Nineteen events were used to operationalize Criterion A1. This resulted in a 59% increase in the number of events that can be used to diagnose PTSD leading them to conclude, “almost everyone has experienced a PTSD-level event” (Breslau & Kessler, 2001: 703). Even before Criterion A2 was added in DSM-IV, Breslau argued that within an urban setting (Detroit) PTSD-level events are common: 39% of young adults (21 to 30 years of age) are exposed to trauma. Of those 23.6% will develop PTSD, leading to a lifetime prevalence of 9.2%. Approximately 9.4% experienced at least three traumatic events.

Here is a possible worse-case scenario for a man raised in an urban setting. As early as grade school he witnessed violent fights among rival gangs after school let out. In high school he learned (but did not witness) that his brother was walking feet ahead of another student when that person was murdered in a drive-by shooting. In college he was held up at gunpoint while working at a sandwich shop. A few years later he was mugged walking home at night and his jewelry taken. At the age of 45 he was in a remote rural region in southern Europe that was ravaged by 3,000 fires that destroyed 1,000 square miles and killed approximately 80 people. The neighboring village five miles away was in danger but no fire could be seen due to poor visibility from the smoke. He put his mother in a cab with nothing else but his laptop so she could flee as he waited with his father for additional transportation to take them out of the village. These are my own experiences. Most would consider these traumas. If I were a subject in a research study, I would first have to recall what my reaction and symptoms were to events that happened years ago.

I experienced some fear. There was some avoidance of the neighborhood I was mugged in. I cannot recall any other symptoms. I could have been killed or badly injured but I was not. These traumas had no clinically meaningful adverse consequence.

Aside from the questionable adherence to Criterion A, the preceding clinical scenario suggests four problems with epidemiological research aside from what has already been mentioned. Using a rather loose definition of “trauma,” we can say trauma is common and PTSD symptoms are common. In the ECA study, 15% of participants who had been exposed to trauma had some PTSD symptoms (Helzer et al., 1987). Traumatic events and PTSD symptoms are not synonymous with a PTSD diagnosis. So to solve the first problem, we should not equate the two. The second problem is deciding what constitutes a traumatic event. What is needed in epidemiological studies and in clinical practice is to explicitly say what traumatic events qualify for a PTSD diagnosis. Norris (1992: 409) provides a succinct answer (*italics included*): “Traumatic *events* are thus defined objectively leaving their consequences for subjective states of *stress* as an empirical question.” The traumatic events need to be operationally defined, just like the criteria that define the disorder. Once the stressor-qualifying events are decided upon, the next step is determining their clinical impact on that patient’s life, which leads us to what is probably the biggest shortcoming of in epidemiological research. The third problem is that the level of disability and distress must also be operationally defined. The Kessler NCS study does what few epidemiological studies do: It identifies what portion of patients actually sought treatment as a result of the PTSD. This indirectly tells us that the stressor was of sufficient severity to cause at the very least distress, if not disability. Of the 5,877 persons, 266 sought professional help. If help seeking is used as an indirect measure of significant distress and or impairment (Criterion F), the lifetime prevalence of PTSD is now cut by half (4.5%) in the NCS. Help seeking or reporting “a lot” of impairment cuts the PTSD prevalence by half (Beals et al., 2004). We could only assume that those studies finding a 1% prevalence rate, without any discussion of distress or disability, would likely lower the prevalence. The fourth problem of epidemiological studies is they do not provide the clinical context. Understanding the clinical context (in addition to fund of knowledge and clinical experience) is critical in making the correct clinical diagnosis (Bowen, 2006). The lay interviewer assisting in the study does not have the clinical acumen, or frankly the permission by virtue of the study design, to actually clinically diagnose PTSD in the study participant. The DIS follows a fixed algorithm specifically designed for epidemiological studies to be used by lay interviewers. This line of reasoning was offered by Robert Spitzer as the rationale for the development of the Structured Clinical Interview for DSM (Spitzer, Williams, Gibbon, & First, 1992). To address this fourth problem epidemiological studies must be complemented by prospective clinical studies.

### **Clinical Population and Cohort Studies**

These first set of studies are not clinical per se because they do not originate in the clinic. They instead, as was originally intended per DSM-III, represent truly horrendous events that “would evoke significant symptoms of distress in most people.” Unless otherwise mentioned, they employ structured clinical interviews to determine PTSD prevalence rates up to 12 months preceding the interview. This includes point prevalence rates (the presence of PTSD at the time of the interview). Five well-done large epidemiological studies employing a structured clinical interview indicate one-third of victims directly exposed to horrific, seldom-experienced events will develop PTSD: 34.9% of child soldiers (Bayer et al., 2007), 31% of terrorist bombing victims (Verger et al., 2004), 34.3% of those in the Oklahoma City bombing (North et al., 1999), 26.1% of those injured in September 11 (Bonanno, Galea, Bucciarelli, & Vlahov, 2006), and 24.8% of those surviving the Rwandan genocide (Pham et al., 2004).

Smaller studies employing interviews consisting of homogeneous clinical cohorts show similar prevalence rates: 31% of burn victims (Bryant, 1996) and 21% surviving the world’s worse oil platform disaster (Hull, Alexander, & Klein, 2002). One month after a mass shooting in Killeen, Texas 136 survivors were interviewed (24 persons including the gunman were killed) and 28.8% were diagnosed with PTSD. A review of ten disasters comprising 712 survivors using similar methodology yielded a prevalence of 26% (North & Oliver, 2013). A meta-analytic review that surveyed refugees and conflict-affected populations yielded a PTSD prevalence rate of 24.9% (Steel, Chey, Silove, Maranen, Bryant, & Ommen, 2009). This review was thorough to the extent that it looked at many data points. The most interesting include those that illustrate how methodology affects PTSD rates. The most important of these points is that PTSD prevalence was 10% higher when self-report instruments were used (34.6% vs. 24.9%). Additionally, studies with more than 1,000 respondents versus less than 100 produced prevalence rates of 15.7% and 39.4%, respectively. These were the two most important determinants of prevalence. Overall methodological characteristics between studies accounted for 13% of study variance. Less severe traumas yielded lower prevalence rates. A review of the literature in rescue workers was 9.30% (Berger et al., 2012). A literature review of refugees limited to those that have resettled in Western countries yielded a 9% prevalence rate (Fazel, Wheeler, & Danesh, 2005).

Population-based studies surveying all inhabitants that could have potentially, but not necessarily been exposed to trauma yield lesser numbers. A random survey of Manhattan residents living south of 110th Street suggested that 7.5% were suffering from PTSD one month post-September 11. Six months later it was 0.6% (Galea et al., 2003). Two locations in East Timor thought best to be representative of the country (no census data was available) found a point prevalence rate of PTSD of 1.47% (Silove et al., 2008). The

lifetime prevalence of PTSD in a national sample of Iraqis carried out in 2006–2007 by lay interviewers using the CIDI was 2.5% (Alhasnawi et al., 2009). When considering that 1.5 million Iraqis were internally displaced within Iraq and 2.5 million were living in other countries, this number is quite small.

### Cross-Cultural and Racial Issues

Here I begin with the population-based PTSD epidemiological studies from other countries and then differential prevalence rates specific ethnic groups within the United States. Using a structured layperson or clinical interview of some type, the country followed by the current or 12-month estimated PTSD prevalence are listed: Australia, 1.3% (Creamer, Burgess, & McFarlane, 2001); Spain, 0.6% (Olaya, Alonso, Atwoli, Kessler, Vilagut, & Haro, 2015); and Canada, 2.4% (van Ameringen, Mancini, Patterson, & Boyle, 2008). The recent World Mental Health Survey assessed PTSD 12-month prevalence in 20 low, medium, and high-income countries (Karam et al., 2014). Twelve of these countries had a less than 1% prevalence rate. The highest, understandably so due to the civil strife, was Northern Ireland, with 3.8%. This was followed by the United States with 2.5%. High-income countries had twice the rate of PTSD: 1.5% versus 0.8 for low income and 0.7 for middle income. Looking at lifetime PTSD prevalence, developed countries have an almost three times higher prevalence rate than developing countries: 4.4% versus 1.6% (Kessler et al., 2011).

Population-based studies provide the best estimates for prevalence among different and racial and ethnic groups. In the National Comorbidity Survey, there was 11.4% African American and 9% Hispanic representation (Kessler et al., 1995). When controlling for age, gender, marital status, and the interaction among these potential predictors, no association was found between PTSD and racial group. This confirmed the findings of earlier population-based studies (Davidson et al., 1991; Helzer et al., 1987) and a subsequent study, the Detroit Area Survey of Trauma (Breslau, Kessler, Chilcoat, Schultz, Davis, & Andreski, 1998). Of note is that the Davidson et al. and Breslau et al. studies were regional, undertaken in the Piedmont region of North Carolina and in Detroit, Michigan, respectively, in which the samples included a high percentage of African Americans: 37.2% and 28.2%, respectively.

The National Survey on Alcohol and Related Conditions included a large national sample ( $N = 34,563$ ) (Roberts, Gilman, Breslau, Breslau, & Koenen, 2011). The lifetime prevalence rates for PTSD are as follows: African Americans, 8.7%; Whites, 7.4%; Hispanics, 7%; and Asians, 0.7%. Whites had a lower prevalence than African Americans but a rate similar to Hispanics. It was noted however that while the conditional risk for developing PTSD once exposed to an event was statistically significant between African Americans and Whites, the difference was small (adjusted odds

ratio = 1.21 vs. 1) The higher socioeconomic status of Asian Americans is one explanation provided for the lower risk as is the possibility of underreporting stigmatizing events such as rape and sexual abuse (Roberts et al., 2011). What is of interest was the very low prevalence rate despite the facts that Asian Americans reported being more likely to be refugees and civilians in a war zone. Alcántara, Casement, and Lewis-Fernández (2013) found a higher risk for PTSD in Latinos versus non-Latinos in their review of 28 studies. The significance of using self-report instruments or layperson interviews versus clinician-administered interviews is illustrated best in their review. The three studies that used clinician-administered diagnostic interviews did not find an increased risk of PTSD in Latinos, consistent with Roberts et al. (2011). Of note, however, is that these later three were all in veteran samples. The remainder used layperson-administered structured diagnostic interviews or self-report instruments. Additionally, only a small percentage of the clinician and layperson interviews were done in Spanish (between 1% and 4%). Based on this review we can conclude very little about the risk of developing PTSD in Latinos versus non-Latinos in the United States other than they have higher rates of self-reported PTSD symptoms.

In another review American Indians and Alaskan Natives had a higher prevalence than Whites but whether this difference could be explained by the diagnostic method used (self-report versus structured interview) was not addressed. There were 16 comparison studies, but the diagnostic measure used in 11 was some version of the DSM without stating the specific diagnostic interview measure (Bassett, Buchwald, & Manson, 2014).

For a thorough assessment of cross-cultural issues, the reader is directed to an article by Hinton and Lewis-Fernández (2011) that was commissioned by one of the DSM-5 workgroups. They concluded what was suggested earlier: The results are mixed. Population-based studies are less likely to show differences (Breslau et al., 1998; Norris, 1992) while studies that compare groups experiencing the same trauma are more likely to find differences. Hispanics were more likely to be diagnosed with PTSD following September 11 than Whites, but there were no differences between African Americans, Whites, and Asians (Galea et al., 2002). Following Hurricane Andrew, Hispanics and African Americans had higher rates of PTSD. This was based on a self-report measure (Perilla, Norris, & Lavizzo, 2002). What was clear, however, from the Hinton and Lewis-Fernández (2011) review is that there are clear differences in PTSD prevalence rates between countries, but they conclude by stating: “It is unclear why the U.S. prevalence is considerably higher” (p. 5). As noted in the Karam et al. (2014) multinational study, the prevalence in the United States is 2.5%, exceeded only by Northern Ireland. Mexico and Colombia, which have a great deal of illicit drug and other civilian violence, have a rate of 0.3%. Lebanon, which has been in an almost constant state of

war since the 1970s, has a rate of 1.6%. In Israel the rate is 0.4%.

A possible explanation is offered here for why the United States has such a high prevalence rate: "No diagnosis in the history of American psychiatry has had a more dramatic and pervasive impact on law and social justice than posttraumatic stress disorder" (Stone, 1993, p. 23). It has been argued herein that PTSD occupies a special place in the history of American psychiatry. It is as much a sociopolitical event as it is a psychiatric diagnosis. British psychiatrist Derek Summerfield, who has clinical experience with all forms of atrocity worldwide, has written scores of the most insightful commentary on this topic over the last two decades. His core argument: "Trauma is a growth industry in the West and thus fertile terrain for fashion." He wonders to what extent Western concepts of mental illness impute "inappropriate sick roles" to communities and cultures very different from our own (Summerfield, 1995: 509).

### **Risk Factors and Comorbid Conditions**

To establish risk factors, I first begin with the epidemiological studies followed by two major reviews. The most consistent PTSD risk factor is female gender. In the NCS study, women were twice as likely to be diagnosed with lifetime PTSD: 10.5% versus 5% (Kessler et al., 1995). A doubling of PTSD (13% in women vs. 6.2% in men) was also found by Breslau et al. (1998). A literature review found this same doubling of PTSD rates in women regardless of type of study, population studies, or methodology that was employed (Tolin & Foa, 2006). This is contrary to other studies that may have found a higher rate in women but not at a level of statistical significance (Davidson et al., 1991; Helzer et al., 1987; Shore et al., 1989). The negative association in these latter studies is likely the result of the small number of cases that were actually diagnosed as PTSD, limiting the ability to detect a statistical difference. These gender differences were found in a consecutive series of patients ( $N = 1,132$ ) seeking psychiatric treatment in an outpatient private practice within a hospital setting. A greater percentage of women (14.1%) were diagnosed with PTSD relative to men (9.1%; see Zlotnick, Zimmerman, Wolfsdorf, & Mattia, 2001).

Using the NCS sample, Bromet, Sonnega, and Kessler (1998) looked at nine risk factors. They found that there were many more risk factors in women than there were in men. In examining risk factors it is important to control for other variables that might affect PTSD prevalence. The first three factors were preexisting affective, anxiety and substance abuse disorders. This is followed by four indicators of childhood adversity which included parental aggression toward the patient, aggression between parents, lack of a confiding relationship with the mother and parental separation and/or divorce. The final two risk factors of PTSD were parental history of mental illness and substance abuse. Risk factors in both men and women included preexisting affective disorder

and mental illness in the parents. A nonconfiding relationship with the mother was an additional risk factor in women. However, when trauma type was controlled, only a previous history of affective disorder remained significant in women and in men a previous history of anxiety disorder and mental illness in parents. For both men and women, the greater the number of risk factors, the greater the likelihood of PTSD. Taking sexual trauma as an example, in women PTSD was found in 11.7% in women and 5.1% in men who had no risk factors, but both genders had a similar risk of developing PTSD with one risk factor (approximately 30%), two risk factors (approximately 40%), and three or more risk factors (approximately 50%). In Davidson et al. (1991), those with PTSD were 2.7 to 3.3 times more likely to have experienced early childhood adversity characterized by parental poverty, mental illness in a family member, early parental separation, and child abuse.

Two meta-analytic studies have identified risk factors for the prediction of PTSD. Brewin, Andrews, and Valentine (2000) identified the following 14 risk factors followed by their respective effect size: gender (0.13), age at trauma (0.06), socioeconomic status (0.14), education (0.10), intelligence (0.18), race (.05), previous psychiatric history (0.11), childhood abuse (0.14), previous trauma (0.12), adverse childhood events (other than abuse) (0.12), family history of psychiatric illness (0.11), trauma severity (0.23), lack of social support (0.40), and life stress (0.32). While all were statistically significant, only the last three were associated with significant effect sizes. Brewin, Andrews, and Valentine (2000) then examined six sample and study characteristics (military versus civilian trauma, gender, retrospective or prospective study, PTSD diagnosis based on absence or presence of the disorder or continuous symptom scores, use of interview or questionnaire and if trauma occurred in childhood or adulthood) and how they might modify the 14 risk factors that were identified. Because of the many possible permutations (i.e., risk factor by study characteristic) the reader is directed to review the article for a detailed understanding of the results. With the Brewin, Andrews, and Rose (2000) review in mind, Ozer et al. (2008) decided to look at a separate set of variables with their own factor analysis. They found that peritraumatic dissociation, perceived support, peritraumatic emotions, and perceived life threat had the highest effect sizes (ranging from 0.35 to .026) while prior trauma, prior adjustment, and family psychiatric history were all equal predictors (0.17 effect size for all three).

It has been argued that, "There is perhaps no other Axis I disorder for which the issue of co-morbidity is more relevant than PTSD" (Spinazzola, Blaustein, & van der Kolk, 2005, p. 426). In the NCS study the comorbid psychiatric disorders included anxiety or depressive disorder, antisocial personality disorder, and alcohol and substance abuse and/or dependence.

Lifetime prevalence of at least one of these disorders was found in 88.3% of men and 79% of women (Kessler

et al., 1995). Among those with PTSD, 14.9% carried one diagnosis; 14.4%, two diagnoses; and 59%, three diagnoses. Approximately 48% of men and women had a major depressive episode along with similar rates of dysthymia (21.4% of men and 23.3% of women).

The rate of substance-use disorders was higher in men—including both abuse and dependence—especially for alcohol (51.9% in men and 27.9% of women). For drug abuse and dependence, the rates were 34.5% in men and 26.9% in women. As might be expected, antisocial personality disorder was much more common in men than women (43.3% vs. 15.4%). In the ECS study, those with a PTSD diagnosis were twice as likely to have another disorder (Helzer et al., 1987). In Davidson et al. (1991), 62.3% of those with PTSD were likely to have another disorder. Anxiety disorders (social phobia, obsessive-compulsive disorder, and generalized anxiety disorder) and major depression were ten times more likely to occur in PTSD respondents. Panic disorder was 20 times more likely. Surprisingly, schizophrenia and schizophreniform were also found to co-occur with PTSD at this latter rate. Unlike in the NCS (Kessler et al., 1995), dysthymia, alcohol abuse/dependence, and mania were not found to be any more prevalent in Davidson et al. (1991). In a treatment-seeking sample, men diagnosed with PTSD are more likely to be diagnosed with a substance abuse or personality disorder (Zlotnick et al., 2001).

Of the comorbid disorders that might predict the development of PTSD, acute stress disorder (ASD) is of the most relevant. Australian psychologist and researcher Richard Bryant has been the most active in studying ASD. In a review in anticipation for DSM-5, Bryant (2011) reviewed all prospective ASD studies. He concluded that the ability of the ACS diagnosis to identify those who will eventually develop PTSD is poor. Of note, however, is that 13 of the 22 studies identified involved motor vehicle accidents, “brain injury,” or injuries as measured by consecutive referral to a hospital, many of which were conducted by Bryant and his colleagues. These events would not be of sufficient severity to meet the stressor criteria under the definition of PTSD as proposed in this chapter. The only study that clearly met the stressor criteria assessed rape victims (Elklit & Christiansen, 2010). In this study, the sensitivity of the ASD diagnosis in predicting PTSD was 0.72.

I conclude by considering PTSD as a risk factor for the ultimate comorbid psychiatric condition, completed suicide. The first study to examine the association in a population-based sample was a nested case-control study of the whole population of Denmark (Gradus et al., 2010). Between 1994 and 2006, 9,612 cases of suicide were identified. Among suicide cases, 40% had been diagnosed with PTSD versus 5% of controls. As expected, the presence of depression modifies this risk by increasing suicide risk. As anticipated, suicide cases were primarily male (71%) and single (58%).

As for clinical outcome, two epidemiological studies suggested that PTSD could be chronic (Helzer et al., 1987;

Kessler et al., 1995). The NCS study treated this subject more thoroughly, probably because of the significant higher prevalence rate that was found. Of note was a steep drop in PTSD prevalence in the first year in both those who did and those who did not seek treatment, but the median time to remission was 36 months in those who sought treatment and 64 months in those who did not. As already noted, about a third failed to remit after many years (Kessler et al., 1995). In the ECS study, about one-third of subjects had symptoms that lasted more than three years, particularly in combat veterans (Helzer et al., 1987).

### The PTSD Interview

“If you have 30 minutes to see a patient, spend 29 on the history, one on the physical examination, and none on the x-rays”: I first heard the advice above during neurology rounds from the director of the neurology clinic where I spent 15 years of my career. This simple axiom made an impression on me. It was taught to him during his neurology residency at the University of Iowa but he could not attribute it to any particular individual. I eventually tracked down the source: Adolph L. Sahs, the second chair of neurology at the University of Iowa from 1948 to 1974, and one of the four founders of the American Academy of Neurology (Joynt, 2001). It is of note that the diagnostic directive was made prior to the advent of computed tomography (CT). It continued to be followed long after the most sophisticated of neuroimaging techniques were introduced. The neuropsychology caveat relative to this quote is that we as neuropsychologists place disproportionate emphasis on tests, whereas in neurology, despite major advances in neurodiagnostic testing, it is implicit that the interview takes precedence. I regularly state in my medicolegal reports there are advantages of the interview over formal neuropsychological testing.

First, the interview narrative does not require any detailed explanation or prerequisite knowledge (e.g., testing procedures), only common sense. An interview is easier to explain and for a referral source, the reader, or for a jury to follow. The often technical and impenetrable narrative that characterizes most neuropsychological reports should be absent in an interview narrative. Second, while the cognitive impairment may have different etiologies that are beyond the control of the patient (e.g., medication effects, brain damage, pain, lack of motivation, etc.) the benefit of the interview is that the symptoms that the patient reports are under his or her control: They are volitional. While a borderline memory score may be due to pain symptoms beyond the patient’s control, what the patient chooses to report in terms of symptoms is entirely under his or her control. That low verbal memory score may be due to many factors, yet there is only one explanation why a patient might report they now read at the fourth grade level as a result of their concussion: malinger. The patient just has to be provided the opportunity to report such improbable symptoms. Third, psychological and

cognitive testing is often referred to as more “objective” than the clinical interview. What is objective is test administration and scoring. A score requires an interpretation that some might argue is subjective even though it should be based on the published literature. In the case of malingering, the test score is far from objective when the test is malingered.

This chapter can artificially be separated into two sections. This portion begins the second section: the PTSD evaluation, which is in essence the interview. As neuropsychology delves more into PTSD, what is needed is a clear conceptualization of the disorder. This was the chapter goal up to this point. The end goal, however, is to present how to conduct a competent PTSD evaluation.

DSM-III revolutionized clinical psychiatry by operationally defining syndromes. Among the “unintended consequences” was that it reduced the DSM to a symptom checklist (Andreasen, 2007). This accusation preceded DSM-III. The Feighner criteria and Research Diagnostic criteria were characterized as belonging to the “Chinese menu system of diagnosis” (Robins et al., 1981: 382). A neurologist would not simply record the absence or presence of a symptom without characterizing it. In clinical neuropsychology this has been referred to as the “bean counting” of symptoms (Bieliauskas, 1999). In my experience, it is rare in the evaluation of PTSD for the clinician to have at least inquired if each symptom is either present or absent, much less to conduct an exhaustive examination of each symptom similar to how a neurologist might examine the simplest of all movement disorders—tremor (i.e., onset, course, unilateral or bilateral, resting or intention, family history of tremor, any accompanying motor symptoms, etc.). The DSM criteria is no more than a grocery list that serves as a reminder to the examiner of what symptoms to inquire about, but to then do it in an exhaustive way, not in a binary fashion as might be found on a self-report depression screening. The goal of this section is to operationally define what is an exhaustive interview. The hallmark of any good clinical exam, psychiatric or otherwise, is a good interview. Before a new clinical interview for the diagnosis for PTSD is proposed, we need to define PTSD.

### ***PTSD Defined: A Hybrid Model***

One approach to harmonization of the ICD and DSM criteria suggested by First (2009) is to construct hybrid criteria that draw upon the best features of both. That is the approach being proposed here. First acknowledges that the drawback to this approach is that the new criteria are essentially untested. This can also be said for the CAPS-5 (Clinician-Administered PTSD Scale 5), which has been constructed to coincide with the new DSM-5 criteria, but studies have yet to be published.

The argument has been made to not adopt the DSM-5 PTSD definition but to instead move to ICD-10 and eventually, to the much-improved PTSD definition in ICD-11, which is due to be published in 2018. What the final product

will look like is not precisely known. What follows is a very close approximation of the ICD-11 definition. First, the disorder must develop “following exposure to an extremely threatening or horrific event or series of events” (Maercker et al., 2013, p. 200). As Norris (1992) argues, “Traumatic events are thus defined objectively leaving their consequences for subjective states of stress as an empirical question. (p. 409)” The CIDI is a structured interview developed by the WHO that corresponds to both ICD-10 and DSM-IV. It assesses lifetime and 12-month prevalence and has been translated into other languages. It can be used by laypersons (Andrews & Peters, 1998). Since the current ICD-10 considers only events that are “exceptionally threatening or catastrophic in nature” the first step is to identify what those events should be for ICD-11.

There are 26 questions on the CIDI that correspond to traumatic events that could produce PTSD. Consistent with the international focus of the CIDI, some of these events are catastrophic experiences not seen in the United States (i.e., civilians in a war zone, being a refugee). These questions can be administered as a checklist. This is similar to the 17 questions that precede the administration of the CAPS: the Life Events Checklist. The neuropsychologist will know what the traumatic event is they are assessing. The purpose for the checklist is to see if there are any other traumas in addition to the one the patient is being examined for. In a medicolegal context this can be important. One referral seen by this writer had the patient claiming PTSD from a minor vehicle accident. On the CAPS checklist, however, he reported being a combat veteran yet never experiencing PTSD. In a clinical context, past trauma exposure is a risk factor for PTSD. We want the patient’s complete trauma history.

As previously noted, the understanding is that ICD-11 will have six symptoms that belong to three clusters: reexperiencing, avoidance, and hyperarousal. Reexperiencing requires that the patient report either recurrent dreams or recurrent “daytime images.” Of note is both of these symptoms are accompanied by both “fear and horror” (Morina, van Emmerik, Andrews & Brewin, 2014). Whether this wording will appear in ICD-11 is uncertain. Avoidance requires avoiding either thoughts about the events or activities or people that remind the patient of the event. Finally, hyperarousal requires either hypervigilance or an exaggerated startle response. One symptom in each category must be present to meet the diagnosis. The symptoms must last several weeks (here we are going to assume at least one month) and cause significant impairment in functioning (Maercker et al., 2013; Morina et al., 2014).

What about functional impairment or disability? If one were to meet all the criteria of a psychiatric diagnosis yet function without there being any impairment in social and occupational functioning one would be hard pressed to consider that to be a disorder. Functional impairment must also be included as this is a common question in a medicolegal context. DSM-5 requires that it be present, as will ICD-11.

In the past the most common method was found in DSM on Axis V, the Global Assessment of Functioning (GAF). For reasons that are arguably not convincing, both the Axis system and the GAF were dropped in DSM-5. Functional impairment needs to be operationally defined. The functional disability corollary to ICD is the WHODAS, the World Health Organization Disability Assessment Schedule 2.0. (WHOc, 2015a). Like ICD-11, DSM-5 supports the use of the WHODAS (APA, 2013, p. 16). Unfortunately, since the introduction in DSM-IV of Criterion F, the DSM does not necessarily require “impairment,” “clinically significant distress” would also meet the criterion. The clinician should define *disability* or impairment while the patient can define *distress*, but the two should not be confused (Vázquez-Barquero, 2009; Ustün & Kennedy, 2009). The WHODAS has an interview version that takes five to ten minutes to complete, and also has a self-administered version. The time period to be evaluated is the past 30 days. The full version has 36 items. The 12-item short form is recommended as it explains 81% of the variance of the longer version. As for the choice of which structured PTSD interview to use, that decision is relatively straightforward: The CAPS is the most frequently used structured interview by both researchers and clinicians (Elhai, Gray, Kashdan, & Franklin, 2005).

### *The Clinical Interview*

What DSM-III did was solve the problem of criterion variance, one major source of unreliability in psychiatric diagnosis. That is to say we need inclusion and exclusion criteria for a disorder. What the structured clinical interview does is to solve any problem, which is that of information variance. It gives clinicians the same amount and kind of information about the patient (Endicott & Spitzer, 1978). The DIS was the first instrument to make DSM-III diagnoses (Robins et al., 1981). Robins expanded on the latter interview by developing the CIDI for the WHO (Robins et al., 1988). One option is to simply adopt the questions from the CIDI that correspond to the six PTSD symptoms in the ICD-11 classification. In this proposed hybrid model we should instead incorporate a PTSD interview that has a long history and much research behind it: the CAPS (Weathers, Keane, & Davidson, 2001; Weathers et al., 2004). The CAPS has been updated (CAPS-5) to correspond to DSM-5 (Weathers et al., 2015). Since government employees created the CAPS-5, it is not copyrighted and can be obtained by writing to the National Center for PTSD. The CAPS has the advantage of assessing both frequency and severity of symptoms. The disadvantage is that it could take as long as an hour to give. With additional PTSD symptoms in DSM-5, the CAPS-5 could take longer. It is proposed here that a modified CAPS be used to assess ICD-11 PTSD criteria.

On the CAPS (not the CAPS-5) the six core criteria are already included. They are reexperiencing in the form of dreams (Item 2) and flashbacks (Item 3); avoidance in the

form of thoughts (Item 6) and activities or places that are reminders of the event (Item 7); and hyperarousal in the form of hypervigilance (Item 16) and startle reaction (Item 17). The wording for each question would be the same as on the CAPS with additional modifications. A mock sample question accompanied by the frequency and intensity rating to be completed by the patient is shown in Table 32.5 and illustrates what an item might look like. The *first* modification is that for each symptom, the question of onset would be asked and if the symptom has gotten better, same or worse since it began. These two questions are rather basic with regard to any symptom inquiry. The *second* modification is adding questions to the six core symptoms. On the CAPS there is an Associated Features section that asks about additional PTSD symptoms (i.e., guilt) that can be features of PTSD but are not necessarily needed to make the diagnosis (Items 26–30). The following questions from the CAPS can be added in the following order: unwanted memories (Item 1), emotionally upset when reminded of the event (Item 4), and physical reactions (Item 5). At the time of this writing it is unclear how the “daytime images” will be defined in ICD-11. It will involve flashbacks but it is uncertain if simply reexperiencing memories, thoughts, and feelings about the event will qualify. A “flashback” is not the same as unwanted memories and reminders. Hence Items 1 and 4 from the CAPS can be retained. More important however is Item 5. In defining this hybrid model of PTSD, it is the contention here that PTSD is an anxiety disorder and should have remained in the anxiety disorders section of DSM. A trauma category of disorders was unnecessary. “Across the main theoretical models for understanding the development of PTSD is the centrality of classical conditioning of fear as a necessary, but not sufficient, mechanism for the development of PTSD” (Zoellner, Rothbaum, & Feeny, 2011, p. 853). In the family of anxiety disorders is panic disorder. Patients who report PTSD actually volunteer “panic attacks.” The presence of the ten physical symptoms of panic needs to be assessed. The last three of the DSM panic symptoms (derealization, fear of losing control, or fear of dying) in my experience are rarely endorsed in a PTSD context. Items 26 and 27 of the CAPS are associated features and should be added when applicable to the individual case. They refer to guilt of what the patient did or did not do and survivor guilt, respectively. These two questions are very applicable as they are signature questions to be asked in rape victims and combat veterans (or any other trauma in which someone else was killed), respectively. There are then a total of 11 questions in the interview; six core questions needed for the diagnosis and five (Items 1, 4, 5, 26 and 27 of the CAPS) that I will term *ancillary questions*. The five ancillary questions are optional depending on the clinical circumstance. The *third* modification is adding additional follow-up questions beyond the core CAPS questions within each item to more thoroughly characterize the symptom. Nothing precludes a clinician from adding questions to clarify the symptom. This is not

a research study or clinical trial but a clinical examination. The questions in italics are not CAPS questions but added to further clarify the symptom. The *fourth* modification is to record the emotional reaction that the patient volunteered at the time of the trauma. The presence of fear is a strong predictor of PTSD (Brewin et al., 2000). The *fifth* modification is to record if delayed onset is present, onset of PTSD six months after the incident event. Delayed onset has no practical clinical meaning (despite its continued use in DSM-5) but is practically pathognomonic for malingered PTSD. The *sixth* and final modification borrows the best feature of the CAPS and that is the assessment of the frequency and intensity of the symptom, which allows the examiner to then calculate a severity score. The major change here is allowing the patient to rate the severity and intensity of the six core PTSD symptom, instead of ratings by the examiner. After the full interview is complete the patient is asked to rate each symptom endorsed in the interview. As noted at the bottom of Table 32.5, the frequency question remains the same but intensity statements are reworded for this purpose and presented to the patient to complete. The item is scored

Table 32.5 Mock CAPS interview question

---

Have you had hallucinations over the last month? Yes No

*Onset:*

*Course: Better Same Worse*

*Do you hear or see things, or both?*

*Do you ever talk, yell or act out the hallucinations? Yes No*

Describe your typical hallucination

*Are the hallucinations exactly the same? Yes No*

*Frequency Rating*

How often have you had hallucinations in the past month?

- 0 None
- 1 Once or twice a month
- 2 Once or twice a week
- 3 Several times a week
- 4 Daily or almost every day

*Intensity Rating by Examiner*

How much did they interfere with your activities?

- 0 None
- 1 Mild, minimal distress or disruption of activities
- 2 Moderate, distress present, some disruption of activities
- 3 Severe, considerable distress, significant disruption of activities
- 4 Extreme, incapacitating distress, unable to continue activities

*Intensity Rating Reworded for Patient Rating*

- 1 These hallucinations cause minimal distress or disruption of my activities.
- 2 These hallucinations are present but I can manage with some disruption of my activities.
- 3 These hallucinations caused distress and significant disruption of my activities.
- 4 These hallucinations caused distress making me unable to continue my activities.

---

in the standard way (Weathers et al., 2004). The frequency and intensity score are added to obtain a severity score. The frequency and intensity of the symptom conveys the patient's subjective distress similar to many of the PTSD checklists. This new six-item PTSD symptom checklist is directly tied to the CAPS questions. There is also nothing to preclude the examiner from doing the rating as per standard CAPS directions. However, both the examiner and patient rating may be affected by the additional questions that are asked in the interview. With the introduction of DSM-5, PTSD self-report instruments must be changed accordingly. Because the reliability and validity of the most common PTSD self-report instruments has yet to be established vis-à-vis the DSM-5, it is proposed to modify the CAPS interview to six questions accompanied by a six-item frequency and intensity rating, which will similarly need clinical validation.

### ***Psychological Testing***

A whole discipline within medicine, psychiatry, has essentially only the interview in its diagnostic armamentarium. While psychological testing is secondary, it provides supplementary information that can be important. The International Society for Traumatic Stress Studies has put out a practice guideline that emphasizes that multiple methods should be used to assess PTSD (Weathers, Keane, & Foa, 2008). There are essentially two additional methods: the self-report instrument and personality testing. The self-report instrument serves four purposes. First, while the clinician is formulating her or his diagnostic impressions of the patient, the patient is afforded an opportunity to do the same absent any input, bias, or preconceived notions of the examiner. We want the patient's diagnostic impression of himself or herself. Whether that impression does or does not coincide with the impression of the clinician is not relevant. Both convergence and divergence of opinion are sources of useful information. Second, self-report instruments help track treatment progress. Third, they help facilitate information across studies. Finally, the primary purpose for which they were designed was to serve as screening instruments. In regard to this last purpose, neuropsychologists—especially those who see forensic cases—are not unaware of the tendency to over-report on self-report instruments (Edens, Otto, & Dwyer, 1998). This inclination is also present in clinical cases (Mittenberg et al., 2002). In fact, as screening instruments, they fulfill the goal that they set out to meet: the minimization of false negatives. A negative screening negates the need for a clinical interview. The only instruction to giving any self-report instrument is when to give it relative to the interview. In a medicolegal context, all self-report instruments are given after the interview. The item content is obvious and there is the tendency to over-report. This is less of an issue with the clinical interview. In a clinical context, when used as a screening, it can be given first and shorten if not exclude the interview. Even in a clinical context, it is best to start with

the interview. A checklist indirectly “coaches” the patient by providing them the test items in advance of the test (i.e., the interview).

In choosing a screening instrument we turn again to the practice survey of Elhai, Gray, Kashdan, and Franklin (2005). The most commonly preferred instruments among PTSD researchers are the PTSD Checklist, or PCL (Weathers, Litz, Herman, Huska, & Keane, 1993), and the Posttraumatic Stress Diagnostic Scale (PDS) by Foa (1995). The PCL has been updated by the National Center for PTSD, to the PCL-5, to mirror the DSM-5 criteria (Weathers, Marx, Friedman, & Schnurr, 2014). A critical review of the PCL provided generally favorable comments as a screening instrument (McDonald & Calhoun, 2010). Previously, Greiffenstein and I had recommended the PDS over the PCL (Andrikopoulos & Greiffenstein, 2012). The three advantages of the PDS are that the questions are tied directly to the 17 symptoms of DSM-IV-TR, and the instrument has quite a bit of research behind it, as does the PCL. But it measures functional impairment, making it preferable to the PCL. The PDS can be computer- or hand-scored. Unlike the PCL, which is free, the PDS is sold commercially (Foa, 1995). Foa has recently updated the PDS to coincide with DSM-5; the PDS-5 (Foa, 2013). This version has only 20 items that correspond directly to DSM-5, versus 49 items on the original version. The instrument will now be offered free of charge to qualified professionals by writing to Foa (Foa, 2013).

The PTSD instruments that are preferred here are those that have the most research. Referencing the research allows one to compare their patient’s score to that of patients with similar traumas by comparing scores to assess severity and/or improvement. In a medicolegal context it allows for the assessment of a dose-response relationship (Bianchini, Curtis, & Greve, 2006). A head injury resulting in a Glasgow Coma Scale (GCS) 14 cannot result in a cognitive performance similar to a patient with an initial GCS of 6. Similarly, in a case that went to trial, the plaintiff that I evaluated was claiming PTSD from sexual harassment. Her somatic and cognitive complaints (as measured by the Somatic/Cognitive scales from the Minnesota Multiphasic Personality Inventory-2-Restructured Format [MMPI-2-RF]) exceeded that of a sample of multiple sclerosis patients with particularly bad disease who had not responded to the first-line multiple sclerosis drugs. The jury understood the point. This was much easier to explain than the Fake Bad Scale (Lees-Haley, English, & Glenn, 1991).

The most preferred instrument by clinicians (23%) was actually the Trauma Symptom Inventory (TSI; see Briere, 1995), followed by the PDS and PCL, both at 16%. However, for the reasons stated earlier, the instruments with the most research are preferred. Aside from the cost of purchasing the TSI there are other factors to consider. It is a 100-item questionnaire, with ten clinical scales and three validity scales. It can be computer scored. It takes longer to give. The TSI

items are not directly tied to DSM-IV and functional impairment is not measured. It is considered more of a measure of traumatology versus a PTSD measure (Elhai et al., 2005). It covers a six-month time frame instead of the traditional one month of other scales. One perceived advantage is that the validity scales include a response bias scale. Per Elhai et al. (2005) the scale is a measure of general validity not specific for assessing malingered PTSD.

With the separation of PTSD in ICD-11 into three clusters, the preferred self-report instrument as part of any standard PTSD assessment should be the Impact of Events Scale (IES) (Horowitz, Wilner, & Alvarez, 1979). It is the perennial PTSD self-report instrument with over 35 years of research behind it tapping the core symptom cluster of PTSD. In the original version, avoidance and intrusion were the clusters measured. In the revised IES-R version, five hyperarousal symptoms were added (Weiss & Marmar, 1996) making this ideal for ICD-11. This is the second most commonly used instrument among researchers after the PCL (Elhai et al., 2005). It contains 22 items answered in a 5-point Likert format. It is freely available and has been translated into a number of languages. It does not, however, translate directly into a DSM diagnosis since at the time it was developed PTSD had not been coined.

Given the high prevalence of comorbid depression and anxiety disorders in PTSD, this should always be assessed with self-report measures. Spitzer and colleagues have developed the Patient Health Questionnaire-9 (Kroenke, Spitzer, & Williams, 2001) to screen for depression and the generalized anxiety disorder-7 (Spitzer, Kroenke, Williams, & Löwe, 2006). The advantages are threefold: they are publicly available, they are tied to the DSM-IV criteria, and they assess for the possibility that the DSM-IV criteria for depression and anxiety criteria may have been met. I give these two instruments to all patients, medicolegal or clinical, at the conclusion of the testing and interview.

The International Society for Traumatic Stress Studies mentioned the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) in the assessment guidelines when it recommends using multiple measures and when measuring response bias (Weathers et al., 2008). In the context of a PTSD forensic evaluation, the limitations of the MMPI-2 are as follows: there are few studies in PTSD civil litigants; many are simulation studies; most involve veterans; and the most robust litigant profile, that of somatic malingering (Larrabee, 1998), involves the assessment of exaggerated or malingered physical symptoms, not PTSD. In a previous chapter, Greiffenstein and I found no PTSD studies on the MMPI-2-RF (Andrikopoulos & Greiffenstein, 2012). For the present review, no studies could be located using a PTSD civilian sample in a nonlitigation context. We do not know what the MMPI-2-RF profile of a PTSD patient should look like. Ideally, the best place to start would be with the archetypal civilian PTSD patient, that of the rape victim. This state of affairs is not all that surprising since a traumatologist

seeing a rape victim would have no useful reason to administer any personality testing if the goal is simply to diagnose and treat the PTSD. It might serve to identify some, as of yet unknown, personality profile or comorbid condition that might facilitate or hinder treatment. If there is a reluctance to administer personality testing when it is part of a guideline, there is little hope of administering cognitive testing if it is not recommended.

### **Cognitive Testing**

The crux of the issue in regard to the administration of cognitive testing in the context of PTSD, (or any psychiatric disorder) was captured in the subheading of an editorial: “Case proven, but what is the significance?” (Hotopf & Wessely, 2006). U.S. soldiers returning from Iraq were found to have subtle neuropsychological impairment relative to nondeployed military personnel in sustained attention and visual and verbal memory. In fine motor speed, executive aspects of attention, and cognitive efficiency there were no differences (Vasterling, Proctor, Amoroso, Kane, Heeren, & White, 2006). No clear reason emerged that could explain these findings. Despite the absence of an explanation, the authors recommended that a post-deployment neuropsychological screening program be implemented, even in the absence of a negative medical workup. One might argue that this is an attempt to “neurologize” a psychiatric disorder (David, 1992).

There is no obvious reason to conduct neuropsychological testing on psychiatric patients as a matter of routine unless there is a compelling clinical and/or neurological reason. One legitimate reason might be to assess if a cognitive impairment might impact the psychiatric patient’s academic or occupational functioning. In a medicolegal context, if cognitive impairment is what is forming the basis for the claimed disability, it needs to be assessed. The modal reason for cognitive testing in the context of a psychological or pain evaluation is that it affords the opportunity to administer malingering tests. An unequivocally failed malingering that takes five minutes to give might negate the need for an interview.

Because cognitive testing is more likely to be administered in a medicolegal context, this topic was addressed in my previous forensic chapter (Andrikopoulos & Greiffenstein, 2012) and will not be repeated here. The sparse literature in civilian nonlitigating PTSD patients was summarized there as follows: PTSD patients do cognitively worse than trauma patients without PTSD on most tests, trauma patients without PTSD do not differ from controls, PTSD patients do worse than normal controls, those with more PTSD symptoms do worse than those with fewer symptoms, and PTSD patients do not differ from non-PTSD psychiatric patients. The level of impairment is mild (i.e., low average scores). In reference to veterans that I examine in the context of a PTSD claim, I limit my cognitive evaluation to a screening (i.e., the Montreal Cognitive Assessment [MoCA], Nasreddine

et al., 2005) and one malingering test. The remaining time, approximately two hours, is spent on a neuropsychological interview that covers a broad range of cognitive, motor, and sensory and psychiatric symptoms followed by a PTSD interview.

### **Concluding Commentary**

Our future success hinges upon acquiring a comparable clinical and research PTSD knowledge base on the accurate diagnosis of PTSD.

(Andrikopoulos & Greiffenstein, 2012, p. 393)

To close this chapter there are five issues that deserve to be elaborated and commented upon: malingering, disparate cultural perspective of PTSD, “our clinical mind set,” the neurobiology of PTSD, and a direction for neuropsychology in the study of PTSD.

The first issue is what Gerald Rosen has repeatedly voiced concern about—the “contaminated published rates of PTSD” (Rosen, 2004b, p. 1291). Epidemiology and clinical cohort studies are needed to understand any syndrome and disease process. Controlling for moderator variables that can affect prevalence rates is elemental research methodology. In 2008, the International Society for Traumatic Stress Studies published its second practice guideline (Weathers et al., 2008). Its ninth and final bullet point was that malingering “should be assessed routinely in *all* clinical and *research assessments* of PTSD” (p. 52, [emphasis added]), something not even mentioned in its first guideline (Foa, Keane, & Friedman, 2000). It has been my experience that the concept of malingering is foreign to our colleagues in medicine. It occupies no space in their journals. When unexplained symptoms are present, the response is to reflexively invoke the unconscious and diagnose conversion disorder. Only once have I seen the term *conversion* been critically questioned as a construct, and by none other than C. Miller Fisher, who until the time of his death in 2012, was arguably the most accomplished neurologist of our time (Fisher, 1995). In academic neurology, my unofficial survey of epileptologists (pseudoseizures) and movement disorder specialists (psychogenic movement disorders) at national meetings is that there is a consensus that malingering is rare (under 5%). The National Vietnam Veterans Readjustment Study has been revisited many times over the years, including a series of articles and editorials in *Science* (Dohrenwend et al., 2006; McNally, 2006). Recently a follow-up study was conducted wherein it was shown that 10.8% of male veterans still have PTSD (Marmar et al., 2015). After 40 years, most notable was that twice as many reported a worsening of symptoms rather than improvement (16% vs. 7.6%). Malingering or compensation status was not mentioned in a single instance in the article or in the accompanying editorial (Hoge, 2015). The National Center for PTSD is charged with addressing the clinical needs of veterans and conducting the research that provides for an evidence-based approach to

meeting their needs. While Frueh, Grubaugh, Elhai, and Buckley (2007) suggest malingering is as high as 50% in veterans claiming PTSD, the contention of the Center is that malingering is practically nonexistent (0.6%) (Marx, Miller, Sloan, Litz, Kaloupek, & Keane, 2008). Clearly this contention is grossly inaccurate based on the literature within clinical neuropsychology, namely forensics, which occupies the largest space in our journals (Sweet, King, Malina, Bergman, & Simmons, 2002). Going forward, PTSD studies not assessing or addressing malingering in their methodology cannot be considered valid.

As has already been stated, the introduction of the term PTSD into the psychiatric nomenclature was a direct result of the Vietnam War. We must acknowledge this as a historical fact, then looking forward, be more cognizant of what forces unduly shape the science of PTSD. One such force is that of culture. The complete failure of the ICD/DSM harmonization process is culturally based (with some degree of politics to be sure). Trauma in the rest of the world may mean torture, civil war, genocide, and a regular flow of refugees fleeing from where the trauma happened. To fully capture the trauma associated with events that might be persistent, repeated, and outside everyday human experience, it is argued that something more than PTSD is needed. ICD-11 will be adopting CPTSD to serve this purpose because such events are not uncommon, while DSM will not be adopting the term, as such events are rare to nonexistent in the United States. The modal PTSD patient in the United States is the veteran; this is where resources and research are directed via the National Center for PTSD. The DSM-5 definition has arguably been altered so as to best accommodate this modal PTSD patient. Since blast injury is considered the “signature wound” of contemporary warfare, perhaps it should come as no surprise that traumatic brain injury is listed in the PTSD differential diagnosis, seemingly due to symptom overlap. It is hard to imagine that any neurologist could confuse the common cold with meningitis because fever can be present in both conditions. The literature in which mild head injury and PTSD coappear in the title has skyrocketed in the United States. The compensation implications of either disorder separately are known, much less the synergistic effect of combining both. It is hard to imagine in what possible clinical circumstance a clinician would consider head injury in the PTSD differential outside the idiosyncratic circumstance of serving in the U.S. military. More than 80% of mild head injuries in the military do not occur in the combat theatre (Tsao, Alphonso, Griffin, Yurkiewicz, & Ling, 2013). The arranged marriage between PTSD and mild head injury is unfortunate and iatrogenic. In the case of CPTSD and the mild head injury–PTSD amalgamation, culture shaped the science, more so in the latter case.

“Clinical Neuropsychology: It is not about the testing. The only prerequisite for conducting neuropsychological testing is literacy, while knowledge of the syndrome and disease requires an experienced and knowledgeable clinician.” This

adage, which I call *Reflection #3*, is part of a lecture I put together on the principles and myths in neuropsychology. I called it a reflection and not a principle, as there are probably very few things that a jury of neuropsychologists in a room can agree on when it comes to the brain. By the very nature of what we study, we are not as uniform in our clinical mindset as we should be as to how to assess the brain as are our neurology colleagues. Our focus is on the cognitive testing. To be sure, testing is of variable importance. The clearest dichotomy is between pediatric and adult neuropsychology. An accurate intelligence and achievement score in a child is more often necessary than it is in an adult. As an adult neuropsychologist, in an outpatient neurology setting where the goal is primarily diagnosis, the clinical approach is different. In the case of dementia, the majority of my clinic referrals, the testing can continue up until the point that you have answered the referral question. In the first minute of the exam, when the patient gives the wrong year, given the proper clinical context and reliable collateral history, a diagnosis is made and the remainder of the formal testing can be terminated. In behavioral neurology this occurs daily. Our testing mindset is best illustrated by how a neuropsychologist might present a case to colleagues versus a neurologist. We typically give a cryptic history that includes demographics and the listing of a handful of symptoms followed by a flurry of test scores (as is sometimes the case on our discussion list serves). A neurology resident in case conference asking or reporting the test results at the onset, absent the detailed history first, will not likely complete the residency successfully. The take-home message is we need to think more like clinicians and not terminally degreed psychometricians, even within the framework of traditional clinical neuropsychology. In the case of PTSD, we have no choice. There are no required tests.

A topic of interest is the neurobiology of PTSD. As a predoctoral intern in 1989, I recall a lecture in which I was shown a single positron emission computed tomography (SPECT) image of an Alzheimer's patient. I learned that hypoperfusion seen in the temporal and parietal areas is a biomarker of the disease. In 2004, a positron emission tomography (PET) imaging technique used a novel tracer that was able to image amyloid in the brain, one of the pathological hallmarks of Alzheimer's disease (Klunk et al., 2004). At the time of this writing, no advanced imaging technique is recommended as standard practice in the evaluation of dementia. The most elementary application of translational research is the biomarker. When used clinically, a biomarker is a laboratory finding that reflects disease activity (Katz, 2004). Let us take the example of magnetic resonance imaging (MRI), the most popular biomarker of multiple sclerosis activity. To the extent that the MRI is used in lieu of a clinically meaningful endpoint in multiple sclerosis, that biomarker becomes a validated biomarker (some call it a *validated surrogate marker*). The MRI should predict some clinically meaningful outcome, or in the case of a drug trial, predict the effect of therapy. So blood pressure is a validated biomarker of a disease process,

namely hypertension. Antihypertension drugs have a direct effect on the validated biomarker, blood pressure, which if uncontrolled may lead to an adverse clinical outcome. We are not required to test that clinical outcome because the biomarker of high blood pressure does a good enough job. While some areas of medicine have validated biomarkers, the problem in neurology and psychiatry is there are no validated biomarkers that are used in lieu of a clinical outcome. The exception is in genetics when used to diagnose a disorder like Huntington's disease absent a clinical examination (MacDonald et al., 1993). No treatments for any neurological disorder have been approved based solely on the use of a biomarker. There are no valid biomarkers accurate enough to displace the clinical examination. The founder and first president of the International Society for Traumatic Stress Studies wrote in a book review on the neurobiology of PTSD that the topic may be more of interest to "neuroscientists and libraries" versus the clinician (Figley, 2010). There are nevertheless, some research findings (i.e., hippocampal volume, physiological reactivity, and cognitive function twin studies) that may be of interest to neuropsychologists (we previously covered these; see Andrikopoulos & Greiffenstein, 2012). The seminal studies in this area were recently reviewed and commented on by the National Center for PTSD (Rasmusson & Abdallah, 2015). The review of Roger Pitman, who has done a great deal of work in this area, is also recommended (Pitman et al., 2012). While there can be no advances in diagnosis and treatment without the prerequisite success in the basic sciences, Satel and Lilienfeld (2013) remind us in their appropriately subtitled book, "The Seductive Appeal of Mindless Neuroscience," to remain skeptical.

Where do we go from here? Armed with a little bit more conviction on the topic of PTSD than was the case a few years ago, I would like to offer a handful of remarks regarding the direction we might want to consider if we are going to enter the PTSD space. To be successful, we first need to acquire a comparable clinical and research PTSD knowledge base to that of our PTSD colleagues. Our medicolegal PTSD chapter (Andrikopoulos & Greiffenstein, 2012) had the title "Something to Talk About," perfectly chosen by Greiffenstein to reflect the trepidation we felt when asked to write on PTSD in a popular forensic neuropsychology text. After all, we are both neuropsychologists with a special interest in forensic neuropsychology, with some experience conducting PTSD medicolegal evaluations. Since that first writing project, I have become less timid. Neuropsychology should be doing more than just talking about PTSD. This perhaps false bravado is owing to a confluence of two factors: an understanding of the clinical context and acquiring a greater fund of knowledge (Bowen, 2006). As for context, the request for a PTSD evaluation nowadays is almost exclusively done within a medicolegal context, and nobody understands that context better than neuropsychologists. Unlike the history of clinical neuroscience (a personal avocation of mine), knowledge of the history of PTSD is a precondition for an informed

clinical opinion. Knowing the history is just as important as knowing the PTSD literature. A neophyte clinical psychologist would have little reason to question the content of the DSM. Understanding that it was not entirely science that shaped the PTSD concept emboldens one to express opinions that otherwise might not be articulated. I think neuropsychologists are generally more skeptical of their science than the average clinical psychologist. When that skepticism involves a diagnosis that is almost exclusively forensic, our scientific contribution carries weight. Our opinions on this topic can be expressed more readily and with more conviction despite the fact that we are not traumatologists. Our advantage is that we bring to the table a critical mindset that puts us in a position to test some hypotheses about this very interesting and controversial topic.

### Acknowledgment

The author wishes to thank Anthony Risser for his invaluable assistance with this chapter.

# 33 Military Service–Related Traumatic Brain Injury

*Louis M. French, Alison N. Cernich, and Laura L. Howe*

## Introduction

Traumatic brain injury (TBI) has been described as the “signature wound” of operations Enduring Freedom (OEF), Iraqi Freedom (OIF), and New Dawn (OND). The large number of military casualties in those conflicts coupled with the public’s emerging interest in sports concussion, has fueled considerable interest in TBI and research related to its causes, treatment, and long-term effects. In the military, the most frequent cause of TBI in service members has been the explosive device. Explosive devices inflict injuries through a number of mechanisms, including dispersion of metallic fragments, the displacement of the individual through the air, the displacement of objects against the person, or the pressure and thermal blast wave itself. Other deployment-related health conditions such as stress or other emotional consequences, along with things like comorbid physical injuries, play a role in symptom expression and can complicate or mitigate the TBI recovery process.

TBI can be devastating for those affected and often places an enormous burden on their caregivers. TBI in civilians is considered a major public health concern. For example, the Centers for Disease Control and Prevention (“Surveillance for Traumatic Brain Injury-Related Deaths—United States, 1997–2007”, 2011) estimates that about 1.1% of the U.S. civilian population, or roughly 3.2 million people, are living with long-term disability due to TBI. These estimates largely reflect those who have suffered more severe TBIs. However, much more common is mild TBI (mTBI; i.e., concussion), which is sometimes excluded from epidemiological studies concerning TBI. Although in the vast majority of cases, these mTBIs have no obvious enduring consequences, a minority of individuals will have persistent difficulties, which may relate to comorbid conditions.

TBI and its neuropsychological consequences are well described in Chapters 17 and 18 in this book. Our focus will be on TBI in a military population, including some typical injury mechanisms for this population, especially blast, comorbid conditions (including posttraumatic stress disorder) that are common, and long-term concerns in this group.

## TBI Severity

TBI is typically defined as penetrating or closed. Penetrating TBI involves penetration of the dura by an object (e.g., bullet, metallic fragment, knife blade). These injuries, like more severe closed TBI, may require emergent neurosurgical intervention. The nature of these injuries is often very different from closed TBI (Carey, Sacco, & Merkler, 1982; Raymont et al., 2008), and have been the subject of extensive study in military settings (Grafman et al., 1996; Schwab, Grafman, Salazar, & Kraft, 1993; Sweeney & Smutok, 1983). Closed TBI can be differentiated as mild (also known as concussion), moderate, or severe, typically based upon acute injury characteristics that are used to determine the severity of the particular TBI. These injury characteristics include the duration of loss of consciousness (LOC), if any, Glasgow Coma Scale score (GCS; see Teasdale & Jennett, 1974), and the duration of posttraumatic amnesia (PTA), which is memory disruption following an injury that results in the inability to store or retrieve new information and ends when clear continuous memory encoding returns. There exists some slight variability in how practitioners differentiate the classifications (Ruff & Jurica, 1999). Very importantly, however, all the established severity level classification systems use characteristics determined at the time of injury and the postacute period. Characteristics or symptoms that emerge or endure weeks or years later are never utilized to determine the severity level classification. Additionally, the severity of symptoms manifested does not change the injury severity classification. While impairments years after an injury can characterize a person’s current functioning, they cannot determine if an initial injury occurred or the severity of that injury, as many intervening personal or environmental factors contribute to a person’s current level of functioning aside from the history remote TBI. In general, however, TBI severity correlates with recovery and long-term symptom expression, with those with more severe TBI having more long-term consequences of their injury. However, there are some individuals with catastrophic injuries who ultimately do quite well, while others with much more minor injuries report lasting consequences from the trauma.

There is generally good consensus on how practitioners define moderate and severe injuries. Acute injury

Table 33.1 TBI Severity Classification

Criteria	Mild	Moderate	Severe
Structural imaging	Normal	Normal or abnormal	Normal or abnormal
Loss of consciousness (LOC)	0–30 min	> 30 min and < 24 hrs	> 24 hrs
Alteration of consciousness/mental state (AOC) *	A moment up to 24 hrs	> 24 hours. Severity based on other criteria	
Posttraumatic amnesia (PTA)	0–1 day	> 1 and < 7 days	> 7 days
Glasgow Coma Scale (best available score in first 24 hours)	13-15	9-12	< 9

characteristics such as prolonged coma make identification of the moderate to severe level injuries relatively apparent. Much less consensus exists on how mTBI is classified (McCrea, 2008). The mild classification severity level is more difficult to clearly and accurately identify because the boundary between hitting one's head and obtaining an actual mTBI is sometimes blurred. In addition, within the military milieu there exist many contextual variables (e.g., extreme stress or fatigue, adrenaline surge, physical injury) that can mimic some of the symptoms typically associated with mTBI (e.g., confusion). If one of the latter events occurs simultaneously while one is exposed to a blast or hits his or her head, there exists a risk that symptoms associated with the other event (e.g., dehydration, stress, fatigue, stress) may be attributed to the potential TBI when the symptoms are not actually caused by a brain-related event.

The American Congress of Rehabilitation Medicine defines mTBI as (a) associated diminished or altered state of, or loss of, consciousness for less than 30 minutes; (b) PTA for less than 24 hours, and (c) a GCS score of 13 or greater quantifying level of consciousness (Kay et al., 1993). How the U.S. Department of Defense (DoD) and Veterans Health Administration (VHA) categorize the three severity levels is presented in Table 33.1.

### Brief History of Military TBI

TBI is as old as warfare. Its treatment has a remarkably long history too. The Egyptian Edwin Smith Papyrus from the 17th century B.C. describes the treatment of battlefield injuries, including a large number of TBI (Linley & Joseph, 2004). In modern military medicine much of the focus has been on the effects of bullets and metallic fragments upon the brain (French, 2010). In World War I, for example, the English neurologist Sir Gordon Holmes detailed his observations of more than 2,000 cases of head injury, including a detailed analysis of 23 cases involving penetrating injury to the visual cortex (McDonald, 2007). Teuber made significant contributions to our understanding of the effects of penetrating brain injury in warfare by studying those injured in World War II (Guy, Glover, & Cripps, 1998). Alexander Luria, whose work contributed much to the beginnings of what is now known as *neuropsychology*, also studied injured soldiers during World

War II (Luria, 1976, 2004). His rehabilitation work centered on focal brain injury and how it affected cognition, language, and motor functioning. Later, the work of Grafman and colleagues through the groundbreaking Vietnam Head Injury study (Grafman et al., 1988; Raymont et al., 2008) and Carey (Carey et al., 1982) during the Vietnam era helped increase our understanding of both the acute effects and the late neurobehavioral changes of brain injuries. Partly because of the nature of current warfare and its weaponry (Owens et al., 2008) and partly because of increased awareness (and associated diagnosis) in the military, the health care community, and the public, much of the research and clinical focus has shifted to mTBI (concussion).

### Epidemiology

With approximately 2.65 million deployments in support of OEF/OIF/OND through June of 2014 (OSD Press Office, 2014), there is a significant portion of the population that is placed at high risk for incurring a TBI (French, 2009). In addition, approximately 1.2 million individuals have had more than one deployment, increasing their risk for incurring a deployment related injury (OSD Press Office, 2014). Surveillance from the Defense and Veterans Brain Injury Center (DVBIC) reflects 313,816 incident TBIs coded in the military medical record from September of 2001 through the third quarter of 2014. The vast majority of those injuries have been mild (82.5%). Interestingly, the incident diagnosis of TBI is higher in nondeployed or noncombat settings (DVBIC, 2014).

Though larger numbers have been reported in the literature and in the media, these may be overestimates of the true incidence and prevalence of injury as they reflect screening data for TBI and likely include a number of false positives (Iverson, Langlois, McCrea, & Kelly, 2009a). Prevalence rates of TBI in service members are estimated to be between 10% and 20% of those who are currently serving in the military (Polusny et al., 2011a; Schneiderman, Braver, & Kang, 2008; Terrio et al., 2009) In many of these studies, there is some question as to whether the finding of continued symptoms associated with an injury event with either loss of, or alteration of, consciousness truly reflect mTBI and not another associated disorder (e.g., posttraumatic stress disorder, or

PTSD; pain related disorder; or depression) (Hoge et al., 2008b).

Returnees who report symptoms of mTBI through survey indicate being injured by a blast/explosion more so than any other mechanism (Hoge et al., 2008a; Owens et al., 2008). A blast TBI results from the service member being proximal to an explosive, such as an improvised explosive device (IED), rocket-propelled grenade, land mine, or other artillery or bombs (Okie, 2005a). Following blast-related TBI, the other major causes of deployment-related TBI are consistent with the major causes of TBI in the civilian population, with motor vehicle accidents or land transport accidents, falls, and sports and recreational injuries rounding out the major causes of TBI within the military population. In those with severe and penetrating TBI, the four most common etiologies are blast, motor vehicle accident, falls, and gunshots to the head or neck (Meyer, Helmick, Doncevic, & Park, 2008).

For those service members who were more severely injured, most injuries are related to combat activities (Galarneau, Woodruff, Dye, Mohrle, & Wade, 2008). A comprehensive review of records from OIF by the Naval Health Research Center for the period of March through September of 2004 noted ICD-9 codes consistent with TBI-related diagnoses in 115 personnel. Most of the injuries were due to combat activities (71%) with a smaller proportion related to nonbattle injuries (16%). Seven percent of the injuries were secondary to vehicle accidents. Thirteen percent of TBI patients were killed in action or died of their wounds. Concussion was the most common injury code, especially among the nonbattle injuries (94%). Skull fractures and other head wounds were prominently noted in those wounded in action or killed in action (26%–33%). The majority of injuries were caused by IED (52%); in those who died, gunshots and mortar rounds made up a larger proportion of this group (40%). The leading causes of noncombat injuries were blunt trauma and motor vehicle accidents. Most often those who were wounded in action had a higher percentage of other bodily injury, with face (50%) and extremity injuries (31%) representing the majority of other areas of injury. Return-to-duty rates were relatively high in the population, with 46% of those wounded in action returning to duty and 67% of those with nonbattle injuries returning to duty.

Though combat-related TBI is viewed as a common injury in the cohort of service members who have served in Iraq and Afghanistan, TBI has historically been a significant cause of hospitalization for service members prior to the current conflicts and remains a significant cause of hospitalization in the nondeployed population, with the rate exceeding that of combat-related TBI (74.6 vs. 50.3 per 100,000 service members; see Ivins, 2010a). In a ten-year study of TBI hospitalizations in the Continental United States (CONUS) or European MTF's conducted with records from 1997–2006, 110,392 service members had at least one medical encounter for TBI and there were 15,372 hospitalizations for TBI, with

falls and land transport accidents representing the primary etiology for injury. Hospitalization rates have increased over the course of the conflict, vary by service branch and phase of the conflict, and reflect a higher rate of weapons related injuries. The service member hospitalized with TBI is generally a younger man, who is at the rank of junior enlisted or noncommissioned officer (E1–E5), and tends to serve in the Army or Marines. In examining the early stages of the conflict, Heltemes, Dougherty, MacGregor, and Galarneau (2011) determined an incident inpatient hospitalization rate for TBI of 10.4 service members per 10,000 troop strength (1,213 personnel in total) in either the Landstuhl Regional Medical Center (in Germany) or in the CONUS Regional Medical Center. This study found that of the sample, only 3% died of their injuries during hospitalization. The majority of the diagnoses were intracranial injury without skull fracture (59.7%), with 39.3% suffering a fracture of the skull. These data likely represent an underestimate of incident TBI hospitalizations as they did not account for in-theater deaths or hospitalization.

More recently, a study of all TBI hospitalizations in the U.S. Army for the period of September 2001 to September of 2007 documented that 46% of the hospitalizations were for severe TBI, 54% for moderate, and less than 1% were for mild (Wojcik, Stein, Bagg, Humphrey, & Orosco, 2010). Though 65% of the severe injuries were related to explosions, almost half of the injuries were related to noncombat causes. Overall, about 0.14% of service members in OEF and 0.31% of those serving in OIF had TBI-related hospitalizations. In a separate study of the Army hospitalization rates, Ivins and others (Ivins, 2010b) found a 105% increase in TBI hospitalizations in the Army from 2000 to 2006, with a 60-fold increase in those injuries attributed to weapons. Of the 2,959 cases that presented to an Army medical treatment facility, the majority of cases was mild in severity and was associated with extracranial injuries. Finally, studies that have assessed for TBI in those who were hospitalized for other conditions that warranted inpatient treatment noted about 20%–30% have TBI in addition to their other injuries (French, 2009; Gaylord et al., 2008). With reduced combat operations, there has been a related decrease in deployment related TBI, falling to a rate of 214 per month in 2013 to 92 per month in 2014. This is in contrast to a high of more than 564 per month in 2008 (Armed Forces Health Surveillance, 2014).

Data from the Department of Veterans Affairs (VA) reflect a high incidence of TBI in addition to other, significant bodily injury (Sayer et al., 2009) in its subacute rehabilitation facilities. Of 188 consecutive patients admitted to a VA Polytrauma Rehabilitation Center (PRC) between 2001 and 2006, 93% were diagnosed with a TBI in addition to their other injuries. In addition, pain disorders and mental health conditions were noted to have a high rate of co-occurrence (100% and 39%, respectively).

Both the Department of Defense (DoD) and the VA have active screening programs to detect potentially undiagnosed

injury following deployment to enable treatment referral. In the DoD, screening data are usually obtained from the Post-Deployment Health Assessment/Post-Deployment Health Reassessment (PDHA/PDHRA). These measures are used to determine if the service member or veteran was involved in events that placed him or her at risk for TBI and if he or she continues to have symptoms at the time of screening; follow-up evaluations with a provider are used to determine presence of TBI and etiology of current symptoms. As the military continues to develop its care model in theater, there are now mandatory evaluations in place for those who are felt to be at risk for TBI with prescribed algorithms for follow-up care (Johnson, Hawley, & Theeler, 2014; Logan, Goldman, Zola, & Mackey, 2013). Screening data from the PDHA/PDHRA have not been published to date.

The Veterans Health Administration (VHA) TBI Screening Questionnaire (Brenner, Vanderploeg, & Terrio, 2009b) is utilized at the first visit for any individual who was in the military beginning September 11, 2001 and served in a combat environment. Approximately one out of five of the Iraq and Afghanistan war veterans who present to the VA screen positive for TBI. For the period from April of 2007 to March of 2011, the VA screened approximately 518,775 veterans of the current conflicts who have presented to VA medical facilities (DePalma, Cross, Beck, & Chandler, 2011). Of that number, 97,000 individuals have screened positive and were referred to secondary level evaluation. Of those, who screened positive, 72,623 individuals were referred for a secondary evaluation, during which their symptoms were examined in more detail and full clinical evaluation was performed. Following that secondary evaluation, 40,154, or 7% of the total of those screened, were found to have a symptom presentation and history consistent with mTBI.

Data from the VA's Polytrauma and Blast Related Injury Quality Enhance Research Program (PT/BRI QUERI) reflect that among 327,388 OEF/OIF veterans using VHA services in 2009, 6.7% were diagnosed with TBI. Among those with TBI diagnoses, 89% were diagnosed with a psychiatric diagnosis (the most frequent being PTSD at 73%), and 70% had a diagnosis of head, back, or neck pain. The rate of comorbid PTSD and pain among those with and without TBI was 54% and 11%, respectively. The median annual cost per patient was nearly four times higher for TBI-diagnosed veterans as compared with those without TBI (\$5,831 vs. \$1,547). Within the TBI group, cost increased as diagnostic complexity increased, such that those with TBI, pain, and PTSD demonstrated the highest median cost per patient (\$7,974) (Taylor et al., 2012).

### **Blast Physics**

Investigations have reported 78% to 88% of military injuries occurring in Afghanistan and Iraq result from explosive mechanisms such as IEDs and land mines (Hoge et al., 2008a; Murray et al., 2005; Owens et al., 2008). This injury

mechanism has been the focus of significant speculation and scientific inquiry (Bhattacharjee, 2008; DePalma, Burris, Champion, & Hodgson, 2005). Given the importance of this issue, a review of basic blast physics is presented in this section.

Explosions are dynamic, with multiple events occurring both in succession and simultaneously. Initially, the blast wave created from an IED spreads from a point source and consists of a high-pressure shock wave (overpressurization) and a subsequent blast wind that closely follows the shock wave (DePalma et al., 2005). Then, as the outward spreading energy dissipates, there results a reversal wind back toward the point source, which ultimately causes underpressurization of the area (DePalma et al., 2005). Several factors including type of explosive, peak overpressure, duration of the overpressure, impulse (complex wave-forms), location of explosion, proximity of the person to the explosion, environmental hazards, body orientation to the blast, and barriers must be considered when evaluating what damage may have occurred due to a blast exposure (DePalma et al., 2005; Hirsch, 1968; Horrocks & Brett, 2000; Wightman & Gladish, 2001). Explosions result in four potential mechanisms of injury and are usually labeled as primary, secondary, tertiary, and quaternary effects. The primary effects include consequences directly attributable to the blast wave itself, which include the intense overpressurization and then underpressurization created by the blast waves. Primary blast injury can occur when direct or reflective waves impact body surfaces and potentially result in anatomical or physiological changes. Secondary effects include damage caused by projectiles such as flying debris and bomb fragments. IEDs used in the war in Iraq are often loaded with metallic objects to inflict penetrating injuries as well (DePalma et al., 2005). Body armor has been reported to be ineffective or even to potentially increase the severity of primary blast wave injuries because it provides a reflective surface even though it protects against secondary impacts of projectiles (Jensen & Bonding, 1993; Lipschutz, Pascuzzi, Bognanno, & Putty, 1991; Mayorga, 1997). Tertiary effects include effects due to structural collapse and effects directly attributable to the blast wind that follows closely behind the blast wave that may result in an individual being thrown resulting in a wide range of potential injuries such as fractures, traumatic amputations, crush injuries, or TBI (DePalma et al., 2005; Warden et al., 2006). Quaternary effects include all other explosion-related effects not accounted for within primary, secondary, and tertiary effects such as burns, asphyxia, and exposure to toxic inhalants as well as exacerbation of preexisting illnesses (DePalma et al., 2005; Taber, Warden, & Hurley, 2006).

In an outdoor setting, the intensity of the blast wave initially dissipates by a cubed root of the distance from the source (Cernak et al., 1996; Cernak et al., 1996). For example, a person who is 3 m from the point source experiences a ninefold increase in pressure compared to a person who is 6 m from the point source. At further distances, the

dissipation transforms to a linear model of decay (Cernak et al., 1996). Solid surfaces reflect blast waves, which may result in someone being somewhat protected by a wall if he or she is on one side of it, and injuries may be compounded if he or she is on the other side because the wave would be reflected by the solid object and result in a more serious injury (Goh, 2009; Kaur et al., 1995). In enclosed spaces, the physics of blast waves are more complex (Cooper, Maynard, Cross, & Hill, 1983).

The secondary, tertiary, and quaternary mechanisms of blast injuries can be characterized as mechanical injuries, which would be expected to be similar to brain injuries sustained from falls or motor vehicle accidents (Belanger, Kretzmer, Yoash-Gantz, Pickett, & Tupler, 2009). The prognosis and recovery for moderate and severe TBIs sustained from secondary, tertiary, and quaternary impacts is similar to what the literature demonstrates for mechanical injuries such as motor vehicle accidents (Sayer, Chiros, et al., 2008). Controversy exists, however, surrounding the effects of the primary blast wave on the brain (Taber et al., 2006). Exposure to a blast wave is a unique aspect of explosion exposure. When considering the bulk of the scientific literature regarding the mechanism of injury of how TBIs occur (e.g., projectile missile, acceleration-deceleration forces, blunt force, something hitting the head), primary blast wave injury emerges as a different injury variable. It is important to note that blast exposure does not equate with blast-induced TBI. While researchers continue to examine the question of exposure, blast TBI is diagnosed only in the presence of traditional brain injury markers (i.e., alteration or LOC, etc.).

### Physical Blast Effect and Barotrauma

Primary blast injuries are *barotraumas*. Barotraumas are injuries caused by pressure differences between the outer surface of the body and internal organs when the primary blast wave impacts the body (Bowen, Fletcher, Richmond, Hirsch, & White, 1968). Primary blast waves can cause injury by either overpressurization or underpressurization in relation to atmospheric pressure (DePalma et al., 2005).

When the blast wave reaches a living object three events occur at once: (a) part of the wave is reflected; (b) part of the wave is deflected; and (c) most of the wave is absorbed and propagated through the body as a stress wave, because the human body is a compliant surface (Cernak et al., 1996; Gruss, 2006). These dynamic pressure changes result in a high-frequency stress wave and a low-frequency shear wave at tissue-density interfaces (DePalma et al., 2005; Rahman, Timofeev, & Kleine, 2007). A shear wave results from compression of the body wall and structures underneath; this is hypothesized to be the main source of injury to solid abdominal viscera, mesenteries, and large bowel (Richmond, Yelverton, & Fletcher, 1981).

In contrast to shear waves, a stress wave has a high amplitude and travels at approximately the speed of sound. It can

potentially injure tissue via spalling (i.e., cavitation created by reflections of a blast wave at the junction of media that consist of different densities or acoustic impedances), implosion (i.e., the process by which objects are destroyed by collapsing on themselves), and/or pressure differentials (Cernak et al., 1996). The pressure differential creates an external force that causes a sudden acceleration of a surface (e.g., tympanic membrane) (Cernak et al., 1996; Yang, Wang, Tang, & Ying, 1996). Air-filled organs and air-fluid interfaces within the body such as the middle ear, lungs, and gastrointestinal (GI) tract are the most susceptible to damage from high-force blast waves (DePalma et al., 2005; Glasser, 2007).

The body structure that is the most susceptible to injury due to minor increases in pressure, and therefore the most frequently injured structure in the human body via a primary blast wave mechanism, is the tympanic membrane (TM) (Bauman et al., 2009; DePalma et al., 2005). Because the eardrum is the most frequently impacted organ at the lowest pressure differential, it represents an ideal site for detecting minimum threshold effects from the primary blast wave alone. If the TM has not been ruptured, then the likelihood that the person experienced a significant blast is decreased (Argyros, 1997). Logically then, the likelihood that other air-filled organs have experienced any damage due to the primary effects of an explosion is also significantly decreased. For example, a study in 2000 investigated 647 bus explosion survivors and found that of the 193 with primary blast injuries, 142 (73.5%) experienced perforation of the eardrum only and 18 presented with isolated pulmonary injuries (9%). Likewise, when investigating injuries sustained during a train bombing, of 243 victims, Gutierrez de Ceballos, Turegano Fuentes, et al. (2005) found 99 (40.7%) who experienced TM ruptures and four who experienced pulmonary injuries without ruptured TMs (1.6%). Some interpret these data and similar studies to indicate that rupture of the TM is not a reliable marker as a threshold injury because studies have demonstrated other organ injuries in absence of TM rupture (Goh, 2009). Nevertheless, it appears that TM rupture may function as a guideline until a more robust and reliable marker is developed. Xydakis et al. (2007) found a significant association between TM perforation and LOC in the combat zone (relative risk, 2.76), although TBI occurred in some subjects in the absence of TM rupture and did not occur in some that did suffer TM rupture, limiting the predictive value of the measure. Because the TM is the most vulnerable structure and may be damaged even when other organs are not, sensory impairment may be an important part of the clinical picture in those injured (Lew et al., 2009).

The second body part most susceptible to primary explosion effects is the lungs, with pulmonary barotrauma being the most common critical injury of those close to the center point (DePalma et al., 2005). Primary blast injury to the brain has been hypothesized to include concussion and

barotrauma from acute gas embolism (DePalma et al., 2005). With regards to the effects of the primary blast wave itself, it remains controversial whether brain injury occurs via the blast wave itself as it interacts with the brain or whether a brain injury occurs via a secondary process such as blast-induced dysfunction in the circulatory or pulmonary systems (Cernak et al., 1996). For example, it has been hypothesized that the primary blast effects (i.e., changes in pressure) can lead to cavitation in blood vessels, which can result in air or gas emboli causing a cerebral infarct (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995; Okie, 2005b). Air or gas emboli result when gas bubbles enter arteries, veins, and/or capillaries. An air or gas embolism results in reduced blood flow resulting in poor oxygen delivery to the areas supplied by the affected circulation. Potential symptoms can include weakness or paralysis of the limbs, impaired vision, and organ damage with the outcome ranging from death or severe, long-standing and irreversible physical and emotional disabilities at one end of the continuum to less severe symptoms at the other end of the continuum depending on what area is obstructed.

### Animal Studies on Blast Injury

The majority of the research conducted regarding blast injury has been conducted on animals. Animal studies suggest primary blast waves by themselves without secondary, tertiary, and quaternary effects can cause damage to brain tissue and result in cognitive deficits (Breslau, Davis, Andreski, & Peterson, 1991). Contrary to the belief that the skull protects the brain from the primary blast wave impact, researchers have found that shock wave amplitude and waveform did not significantly decrease when passing through animal skulls (Chavko, Koller, Prusaczyk, & McCarron, 2007; Clemedson & Pettersson, 1956).

Enclosed spaces and reflective surfaces introduce numerous variables that can have an impact on the initial injury severity. The importance of the direction of impact was demonstrated in animal studies, which showed different blast energy dissipation mechanics depending on the orientation of the head to the blast (e.g., Chavko et al., 2007). Five repeated blast waves in succession have been shown in animal models using sheep and swine to reduce the injury threshold from peak overpressures as compared to one blast exposure (Cernak et al., 1996; Rosen et al., 2004).

Bauman and colleagues (Bauman et al., 2009; Macedonia, Zamisch, Judy, & Ling, 2012) developed a swine model of explosive blast injury to the brain during Phase I of the Defense Advanced Research Projects Agency (DARPA) Preventing Violent Explosive Neurotrauma (PREVENT) blast research program that could be used to “recreate the salient pathophysiological, neuropathological, neurological, and memory impairments of human TBI resulting from exposure to IED-explosions in simple and complex blast scenarios.” Three situations were modeled: a blast tube that

equated with a free-field blast situation, a humvee surrogate, and the four-sided building with an entrance and no roof. Each design took measures to minimize significant movement of the swine during blast exposure. They found that structure variables (e.g., size, percent enclosed) significantly impacted the amplitude, frequency, and time to decay of the blast waves and that the pressures were conducted into the brain as measured by fiber optic pressure transducers that were implanted within the brain and vasculature. Two weeks after blast exposure the swine demonstrated reduced coordination of the metacarpals of the forelimbs although it was not clear if the disruption in functioning was due to brain injury, peripheral neuromuscular injury, or a combination of both. Cernak, Wang, Jiang, Bian, and Savic, (2001) found the formation of cytoplasmic vacuoles and myelin alterations in the hippocampus of primary blast-exposed rodents, even when the blast was focused on the thorax and the head was protected. The extent of cognitive impairment and biochemical changes were correlated with blast injury severity.

Similarly, Bauman et al. (2009) found white matter fiber degeneration and astrogliosis in swine exposed to primary blast waves. Extrapolations from animal research to humans are limited by numerous factors including concerns regarding the blast wave generators themselves and anatomical differences such as skull size, shape, and geometry between animals and humans. Recent work (Marion & Regasa, 2014) suggests that human brain vulnerability to blast is actually higher than for any other mammalian species, which is in distinct contrast to previously proposed scaling laws based on body or brain mass. While animal models have distinct limitations (Panzer, Wood, & Bass, 2014) there is general consensus that many of the experimental TBI models demonstrate progressive changes in brain histopathology and behavior and contribute to our understanding of chronic TBI pathology in humans.

### Differences in Blast Injury

Warden et al. (2009) report a case study of primary-blast-wave-associated TBI with no secondary and tertiary blast wave effects. The patient was exposed to multiple blast waves within a few hours. It is known that no secondary or tertiary blast effects co-occurred during her exposure to the primary blast waves because although she experienced altered awareness, she remained conscious throughout the event. She experienced concussive symptoms including headache, balance problems, dizziness, and vomiting. Magnetic resonance imaging (MRI) three months later was consistent with intracranial injury. In clinical practice, this is quite rare however, and most cases of blast injury involve blast with another mechanism.

It is unclear of the relative contribution of primary blast to symptom expression when it is coupled with mechanically induced brain injury. Taber and colleagues recently

demonstrated brain changes in individuals exposed to blast even without associated TBI. In that study they conducted neuropsychological testing and MRI diffusion tensor imaging on 123 individuals who had been exposed to primary blast without TBI symptoms, six having primary blast with mTBI, and 16 unexposed blast. Those individuals exposed to primary blast both with and without mTBI it showed significantly lower functional anisotropy and higher radial diffusivity than those who experienced unexposed blast. More recently, one study examining functional connectivity to the posterior cingulate cortex in 134 military veterans demonstrated that exposure to a blast at close range (< 10 m) was associated with decreased connectivity of bilateral primary somatosensory and motor cortices, and these changes were not different from those seen in participants with blast-related mTBI. These results remained significant when clinical factors such as sleep quality, chronic pain, or PTSD were included in the statistical model. In contrast, differences in functional connectivity based on concussion history and blast exposures at greater distances were not seen (Robinson et al., 2014).

Relevant to this discussion is the examination of a unique group of military and law enforcement personnel called “breachers.” Breachers are individuals who are routinely exposed to low-level blast during training and operations. As many of the blast events to which they are exposed are well quantified, they present a useful population for blast exposure studies. One recent study (Tate et al., 2013) of a group of breachers in the New Zealand Defense force selected those individuals who showed the greatest serum concentration of three biomarkers thought to be related to TBI. Those individuals showed poorer neurocognitive test performance and greater self-reported postconcussive symptoms than those with the lowest biomarker load following a two-week training course. The authors suggest that there is a measurable degree of brain dysfunction that can be linked to low-level blast exposure. Similar studies are ongoing in other breacher populations. In a study of Swedish military officers who were experimentally exposed to repeated detonating explosions or firing of heavy weapons (including repeated firing of a FH77B Howitzer or a bazooka or to 100 charges of detonating explosives of 180 dB) there was no neurochemical evidence of brain damage (Blennow et al., 2011) in the cerebrospinal fluid (CSF).

One difference in blast injuries is the high rate of comorbid physical injury. When comparing blast versus non-blast-induced injuries, Sayer, Chiros, et al. (2008) found that patients injured via a blast exposure had more soft tissue, eye, oral and maxillofacial, otologic, penetrating brain injuries, auditory impairments, and symptoms of PTSD than patients injured through another mechanism. However, mechanism of injury did not predict outcomes as measured by Functional Independence Measure (FIM) scores. Similarly, Warden (2006) found patients injured via blast were more likely

to have acute stress disorder, lower limb amputations, seizures, and skull fracture.

In a review of military service members injured in 2001 through 2006 (87% of these by explosive device), 5.2% of all serious injuries and 7.4% of major limb injuries underwent amputation. This rate is similar to that of previous conflicts (e.g., 8.3% in Vietnam; see Stansbury, Lalliss, Branstetter, Bagg, & Holcomb, 2008). Individuals with traumatic limb amputations typically require extensive rehabilitation, and a variety of medical, emotional, and social issues can influence recovery (Messinger, 2009; Pasquina et al., 2008). Blast-induced limb loss with resulting loss of blood, as well as with high numbers of individuals who have sustained penetrating bodily injuries with at least some degree of hemorrhage, have raised concerns around some aspects of the trauma and its potential effects on outcome. More than 80% of the patients treated by one U.S. Marine forward resuscitation surgical unit were in hemorrhagic shock (Blanchard & Veazey, 2001). This raises the possibility of hemorrhagic or hypoxemic insults on the central nervous system. Inadequate cerebral blood flow can contribute to increased morbidity after TBI (DeWitt & Prough, 2009). Hypotension is a significant risk factor for death following trauma, even in the absence of a TBI (Shafi & Gentilello, 2005). Following TBI, the brain appears to be especially vulnerable to posttraumatic hypoxemia (DeWitt & Prough, 2009). Despite this, the long-term effects of severe hemorrhage (with or without co-occurring TBI) on cognition, emotion, or other neurobehavioral symptoms are largely unknown.

Modern body armor and advanced helmet design have dramatically reduced combat injuries. Casualties wearing a combat helmet are 2.7 times less likely to sustain a fragmentation wound to the head than those who were unprotected. Casualties wearing a body armor vest are 4.1 times less likely to sustain a fragmentation wound to the chest or abdomen than those who were unprotected, and casualties wearing pelvic protection are 10 times less likely to sustain a fragmentation wound to the pelvis (Blanchard et al., 2003). However, protection is not complete.

In a study of British service members, face and eye injuries were found in 33% and 10% of all battle-injured servicemen respectively, with 27% of eye wounds from explosions resulting in blindness and a further 17% in permanently reduced visual acuity. The lower third of the face was most commonly injured (60%), followed by the upper third (24%) (Blanchard et al., 2003). In a group of military polytrauma patients injured by blast (Goodrich, Kirby, Cockerham, Ingalla, & Lew, 2007) the rates of visual impairment were more than double compared to other causes of polytrauma. Overall, the rate of visual impairment in blast-related injury was 52% compared with 20% for all other sources of injury. Eye injuries are also connected to TBI. In a group of patients with TBI and comorbid combat ocular trauma at Walter Reed (Weichel, Colyer, Bautista, Bower, & French, 2009) (with blast accounting for 79% of the TBI-associated ocular

## Military Acute Concussion Evaluation

Patient Name: \_\_\_\_\_

Service Member ID#: \_\_\_\_\_ Unit: \_\_\_\_\_

Date of Injury: \_\_\_\_\_ Time of Injury: \_\_\_\_\_

Examiner: \_\_\_\_\_

Date of Evaluation: \_\_\_\_\_ Time of Evaluation: \_\_\_\_\_

### CONCUSSION SCREENING

Complete this section to determine if there was both an injury event AND an alteration of consciousness.

#### 1. Description of Incident

##### A. Record the event as described by the service member or witness.

Use open-ended questions to get as much detail as possible.

\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_  
\_\_\_\_\_

##### Key questions:

- Can you tell me what you remember?
- What happened?

##### B. Record the type of event.

Check all that apply:

- Explosion/Blast     Fragment     Motor Vehicle Crash  
 Blunt Object     Sports Injury     Gunshot Wound  
 Fall     Other \_\_\_\_\_

##### C. Was there a head injury event?

- YES     NO

##### Key questions:

- Did your head hit any objects?
- Did any objects strike your head?
- Did you feel a blast wave?  
(A blast wave that is felt striking the body/head is considered a blow to the head.)

*Figure 33.4*

trauma), severe TBI was more frequently associated with combat ocular trauma than milder TBI. TBI occurred in two-thirds of all combat ocular trauma, and ocular trauma was a common finding in all TBI cases. In another sample of Iraq and Afghanistan veterans treated in a VA polytrauma center and injured by blast, 62% complained of hearing loss and 38% reported tinnitus. This compares to rates of 44% with hearing loss and 18% with tinnitus in those injured through some mechanism other than blast (Lew, Jerger, Guilory, & Henry, 2007).

For those with impairments in both hearing and vision, the difficulties may be even more significant. Dual sensory impairment has been associated with increased rates of depression (Bryant, Harvey, Dang, Sackville, & Basten, 1998) and lower overall health-related quality of life (Fecteau & Nicki, 1999). Lew (Lew et al., 2009) describes a VA sample in which hearing impairment was identified in 19% of the sample, visual impairment in 34% of the sample, and dual sensory impairment in 32% of the sample. Those with dual sensory impairment had difficulties participating in the rehabilitation process and showed an overall reduction in both FIM scores at discharge.

While it might be expected that greater comorbid physical injuries would be associated with greater symptom burden, two recent studies have shown that as the severity of bodily injuries increases, symptom burden decreases. In the first (French et al., 2012), 137 service members who had been evaluated and treated at Walter Reed Army Medical Center following medical evacuation from the combat theater of OEF and OIF were administered questionnaires measuring postconcussive symptoms and posttraumatic stress symptoms. All had sustained an uncomplicated mTBI and concurrent bodily injuries. The service members were divided into four groups based on severity of extracranial injury. The group with the most severe bodily injuries reported the fewest postconcussive and stress symptoms while the group with the bodily injuries of the least severity reported the greatest number of stress and postconcussive symptoms.

In an expansion of that study (Brickell, Lange, & French, 2014a), 579 individuals with uncomplicated mTBI and concurrent bodily injuries across two military medical centers were examined. Using linear regression to examine the relation between symptom reporting and injury severity across the six ISS body regions, three body regions were found to be significant predictors of the neurobehavioral symptom inventory total score (face,  $p < 0.001$ ; abdomen,  $p = 0.003$ ; extremities,  $p < 0.001$ ). For the PTSD Checklist–Civilian, two body regions were significant predictors of the PCL-C total score (face,  $p < 0.001$ ; extremities,  $p < 0.001$ ). There was an inverse relation between bodily injury severity and symptom reporting in this sample. The reasons for this are unclear but may include underreporting of symptoms in those most severely injured, increased peer support for those with very visible wounds, disruption of fear conditioning because of acute morphine use in the acute injury period, or symptom

expression may follow a different time course in those more severely injured.

Investigations of neuropsychological profiles after blast have failed to find differences for the most part. Belanger, Kretzmer, Yoash-Gantz, et al. (2009) compared individuals with TBI due to blast versus TBI due to nonblast-related mechanisms looking at select neuropsychological measures and found severity of injury and not mechanism of injury was predictive of performance on verbal learning and memory measures. This was replicated in a later study (Lange, Pancholi, Brickell, et al., 2012) in an active duty military population. In that study, subjects with “traditional” mTBI were compared to those who received an mTBI through a mechanism in which blast was a component on 14 clinical scales from the Personality Assessment Inventory (PAI) and 12 common neurocognitive measures. For the PAI, there were no significant differences between groups on all scales. However, medium effect sizes were found for the Depression ( $d = .49$ ) and Stress ( $d = .47$ ) scales (i.e., Blast Plus > Nonblast). On the neurocognitive measures, after controlling for the influence of depression and stress symptoms, there were no differences between the Non-blast and Blast Plus groups on all measures. This study suggested little evidence that blast exposure plus secondary blunt trauma results in worse cognitive or psychological recovery than blunt trauma alone.

Whether symptom profiles are different in those with a blast-related injury has also been investigated in a number of studies, both in acute and more chronic populations. One prospective cohort study (Macdonald et al., 2014) examined active duty U.S. military personnel evacuated from Iraq or Afghanistan to Landstuhl Regional Medical Center in Germany. Four groups of participants were enrolled from 2010 to 2013: (a) blast plus impact complex mTBI ( $n = 53$ ), (b) non-blast-related mTBI with injury due to other mechanisms ( $n = 29$ ), (c) blast-exposed controls evacuated for other medical reasons ( $n = 27$ ), and (d) non-blast-exposed controls evacuated for other medical reasons ( $n = 69$ ). Subjects were assessed 6–12 months following the injury with neurological exam, headache questionnaires, neuropsychological test battery, combat exposure and alcohol use surveys, and structured interview evaluations for PTSD and depression. Global outcomes, headache severity, cognitive performance, and PTSD severity and depression were indistinguishable between the two TBI groups. Both TBI groups had higher rates of overall disability than the control groups. Additionally, the blast-exposed controls had worse headaches and more severe PTSD than the non-blast-exposed controls. The authors concluded that overall outcomes were most strongly correlated with depression, headache severity, and number of abnormalities on neuropsychological testing. TBI itself, independent of injury mechanism and combat exposure intensity, was a primary cause of adverse outcomes. Overall disability was substantially greater than typically reported in civilian non-blast concussive patients with TBI, even with polytrauma.

## Co-Occurring Disorders Including PTSD

PTSD and the anxiety spectrum disorders are another important high-base-rate differential in the combat-exposed population. It has been demonstrated that combat service may result in PTSD (Kang, Natelson, Mahan, Lee, & Murphy, 2003) and many studies have demonstrated the high prevalence of PTSD and other psychiatric illness resulting from OIF/OEF (Erbes, Westermeyer, Engdahl, & Johnsen, 2007; Grieger et al., 2006; Haagsma et al., 2012; Hoge, Auchterlonie, & Milliken, 2006; Hoge et al., 2004; McCarroll, Ursano, Fullerton, Liu, & Lundy, 2001; Milliken, Auchterlonie, & Hoge, 2007; Sundin, Forbes, Fear, Dandeker, & Wessely, 2011; Thomas et al., 2010; Verfaellie, Lafleche, Spiro, & Bousquet, 2013). PTSD symptoms in active duty military are around 5% prior to deployment (Hoge et al., 2004), however, estimates of PTSD after return from OIF are estimated to range from 13% to 17% (Hoge et al., 2004; Hoge, Terhakopian, Castro, Messer, & Engel, 2007). Physical injury while in combat is a risk factor for developing PTSD (Hoge et al., 2004; Hoge et al., 2007; Koren, Norman, Cohen, Berman, & Klein, 2005). Studies comparing injured versus noninjured soldiers from Vietnam found two to three times higher rates of PTSD in soldiers who were injured (Kulka et al., 1990; Pitman, Altman, & Macklin, 1989). Additionally, combat-related PTSD has been associated with more severe functional impairments in some studies (Prigerson, Maciejewski, & Rosenheck, 2001).

Similar to other studies, Schneiderman (Schneiderman et al., 2008) found reporting multiple injury mechanisms and combat mTBI were associated with PTSD. In fact, the strongest factor associated with postconcussional syndrome (PCS) was PTSD. Similarly, Hoge (Hoge et al., 2008a) found that 44% of soldiers with mTBI and associated LOC also met criteria for PTSD. After adjusting for PTSD and depression that mTBI was no longer significantly associated with PCS symptoms (except headache) or physical health outcomes. Patients with combat related PTSD often present with comorbidities (Brady, Killeen, Brewerton, & Lucerini, 2000; Hryvniak & Rosse, 1989) and PTSD, unlike mTBI, has been demonstrated to be associated with long-term negative health consequences such as cardiovascular disease and premature death (Ahmadi et al., 2011; Compare, Gondoni, & Molinari, 2006; Dirkzwager, van der Velden, Grievink, & Yzermans, 2007; Kang & Bullman, 1996). PTSD clearly needs to be considered in the differential diagnoses of soldiers returning from deployment.

Prevalence estimates of PTSD vary between studies. Based upon the DMS-III-R definition of PTSD, the National Comorbidity Survey (Turnbull, Campbell, & Swann, 2001) found that although the lifetime prevalence of exposure to traumatic events was 60.7% for men and 51.2% for women, the estimated lifetime prevalence of development of PTSD was overall only 7.8%. They found higher rates in women. The most common traumas associated with development of

PTSD were combat exposure for men and rape and sexual molestation for women (Kessler et al., 1995). Likewise, Breslau et al. (1991) found the lifetime prevalence of exposure to traumatic events to be 39.1% but the lifetime prevalence of PTSD was only around 9%. This is consistent with the DSM-IV-TR, which reports the adult lifetime prevalence of PTSD to be around 8% in community-based studies (American Psychiatric Association, 2000).

It is important to note that PTSD develops in only a minority of individuals who are exposed to traumatic events (see e.g., Breslau et al., 1991). PTSD prevalence rates, however, have been shown to vary significantly according to the type of trauma experienced from as high as 80% in rape victims (Breslau et al., 1991) to 21%–24% for seeing someone killed or seriously hurt, news of sudden death or accident of a close relative or friend, experiencing a physical assault, or experiencing a threat to life (Breslau et al., 1991) to 15% in combat veterans (Kulka et al., 1990) to 9%–12% in motor vehicle accidents based upon epidemiological surveys (Breslau et al., 1991; Kessler et al., 1995). Epidemiological research has suggested MVAs are likely the leading cause of PTSD in the United States (Kessler et al., 1995; Norris, 1992) in part due to the high number of MVAs per year. Specific to MVAs, approximately 50% of the individuals who were injured and prospectively followed demonstrated a remission of symptoms within six months post-MVA (Blanchard & Hickling, 1997). Intervention consisting of cognitive behavioral techniques, and treatment or prolonged exposure has been shown to increase the rate of remittance of symptoms after an MVA even further (Bryant, Sackville, Dang, Moulds, & Guthrie, 1999; Price, Kearns, Houry, & Rothbaum, 2014).

There has been some debate in the literature regarding whether an individual can experience both PTSD and TBI with LOC from the same incident. Some have argued the presence of one precludes the development of the other; however, the majority of authors believe both diagnosis can develop from the same incident. For a review see (Hegde, Hegde, Parajuli, Kamath, & D, 2012; T, D, & V, 2012). On one side of the debate is the argument that individuals who cannot recall the traumatic event because of LOC or amnesia cannot “reexperience” the incident through flashbacks or intrusive memories. Therefore, individuals with significant amnesia around the time of the event are at low risk for developing PTSD (Bombardier et al., 2006; Levin et al., 2001; Sbordone & Lister, 1995).

Other researchers maintain that PTSD can occur despite memory impairment and can therefore exist as a comorbid condition with TBI (Harvey & Bryant, 2000; Mather, Tate, & Hannan, 2003; Mayou, Black, & Bryant, 2000). Several potential mechanisms have been postulated. Fear conditioning models of PTSD suggest that extreme fear at the time of trauma is conditioned with events and experiences occurring at the same time. These associations between the reminders of the emotional trauma and the anxiety responses cause subsequent PTSD (Balaji & D, 2011). It has been observed

that people can reconstruct traumatic experiences in ways permitting them to compensate for impaired memory (Kress et al., 2010) (Singh, Srivastava, Kapoor, R., & R., 2009). Another possible mechanism is sustaining a TBI and later suffering traumatic experiences following the resolution of the PTA. A fourth possible mechanism involves dysfunctional neural functioning secondary to the TBI (Bryant, 2008). For example, damage to the medial prefrontal cortex may prevent inhibition of an exaggerated amygdala response (Balaji & D, 2011).

Turnbull et al. (2001) examined emergency department cases and demonstrated that having a memory of the trauma was not required for the development of symptoms associated with PTSD. In some studies, the level of PTSD-like symptoms that developed was associated with the length of PTA (less than one hour vs. greater than one hour) with a greater number of symptoms developing with a shorter PTA, but even extended periods of PTA of more than one week were associated with development of PTSD-like symptoms (Feinstein, Hershkop, Ouchterlony, Jardine, & McCullagh, 2002).

The continuing challenge for clinicians working with military service members with TBI is the high level of co-occurring disorders that are noted in the population, especially mental health difficulties, including PTSD and pain-related disorders. For example, in a sample of veterans who screened positive for TBI within the VA, those with clinically confirmed diagnosis of TBI were more likely than those without confirmed TBI to have clinical diagnoses of PTSD, other anxiety disorders, and adjustment disorders (Pizzo et al., 2008). Co-occurring mental health and TBI diagnoses in the VA setting varied by sex. Of those veterans with a confirmed TBI diagnosis, PTSD was the most common co-occurring psychiatric diagnosis, with men more likely to have a PTSD diagnosis than women (Neil, S., & Hanton, 2006). Women were two times more likely to have a depression diagnosis and 1.5 times more likely to have PTSD with co-occurring depression. In addition, women were noted to report more severe neurobehavioral symptoms than men. Screening-based survey data reflects a high overlap of TBI and mental health difficulties, especially PTSD, with overlap between the two estimated to be about 30% of all those who screen positive for TBI (Hoge et al., 2008b; Polusny et al., 2011b). The noted co-occurrence of PTSD tends to be associated with longer symptom duration following injury, especially in those with mTBI (Hoge et al., 2008b; Schneiderman et al., 2008).

With respect to other mental health diagnoses, there are fewer empirical studies. Veterans who have a history of clinically diagnosed TBI are 1.55 times more likely to die of suicide than those without TBI history and this rate was further increased in those with milder injuries (1.95) (Brenner et al., 2009b). Concurrent diagnosis of major depression was greater in those who died of suicide regardless of severity. Only one study specifically examined the rate

of alcohol abuse following TBI in a military cohort: It found no relationship between alcohol abuse and TBI when other comorbid psychological health difficulties and demographics were controlled in a comparative model (Elsayed, Gorbunov, & Kagan, 1997). Finally, pain is a major complaint in this population, with a prevalence rate of pain disorders at 43.1% based on a meta-analysis of veterans. Though PTSD was thought to potentially mediate the relationship between TBI and pain, TBI continued to demonstrate an independent correlation with pain disorder diagnosis when mental health diagnoses were controlled for in the comparative model (Nampiarampil, 2008).

### Context of Injury

Additional factors that co-occur within the blast-exposure milieu within the military context at the time of potential injury and after need to be explored because the context in which any injury occurs may potentially impact symptom severity and course of recovery. The situational context in which blast exposures occur and the postdeployment environment are important in symptom creation, maintenance, and recovery. The contextual variables that add to the complexity of blast injuries and exposures will be reviewed. Some of these variables may account for why a percentage of individuals with blast related mTBI appear to be reporting symptoms in excess of what would be expected and for durations longer than would be expected.

One study has demonstrated a postdeployment effect on cognitive abilities within the first few months of return (Vasterling et al., 2006). The study administered select cognitive tests to 654 soldiers before and after deployment and compared them to a matched sample of 307 soldiers who were not deployed and found positive deployment status was associated with an increased negative affect state and decreased neuropsychological test scores on sustained attention, verbal learning, and visuospatial memory tasks with an increase in reaction time scores. Interestingly, experiencing a TBI between Time 1 and Time 2 testing and an increase in PTSD symptom levels *did not* have a significant impact on the neuropsychological findings. This study controlled for poor effort on testing; however, the mTBI were not differentiated based upon blast or other mechanism of injury, so conclusions cannot necessarily be extended to blast injuries.

A large web-based survey of Florida National Guard soldiers conducted an average of 31.8 months after deployment showed strong, statistically significant associations between self-reported military deployment-related factors and current adverse health status. Deployment-related mTBI was associated with depression, anxiety, PTSD, and postconcussive symptoms. Statistically significant increases in the frequency of depression, anxiety, PTSD, and a postconcussive symptom complex were seen comparing single to multiple TBIs. Associations between blast exposure and abdominal pain, pain on deep breathing, shortness of breath, hearing

loss, and tinnitus suggested residual barotrauma. Combat exposures with and without physical injury were each associated with PTSD and numerous postconcussive and non-postconcussive symptoms. The experience of seeing others wounded or killed or experiencing the death of a comrade was associated with indigestion and headaches but not with depression, anxiety, or PTSD (Vanderploeg et al., 2012).

### Postconcussional Syndrome

As described elsewhere in this volume, mTBI, even in the context of a combat environment, typically involves time-limited symptoms and complete recovery. Some individuals, for a variety of clinical reasons, show more persistent symptoms. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV), and *International Statistical Classification of Diseases and Related Health Problems*, 10th edition (WHO, 1992) clinical criteria for PCS are: a history of TBI with LOC and symptoms from three or more of the following categories developing within four weeks of the TBI: (a) headache, dizziness, malaise, fatigue, and noise intolerance; (b) irritability, depression, anxiety, and emotional lability; (c) subjective concentration and memory or intellectual difficulties without neuropsychological evidence of marked impairment; (d) insomnia; (e) reduced alcohol tolerance; and (f) preoccupation with the listed symptoms, and adoption of the sick role (WHO, 1992).

Studies have demonstrated that postconcussive symptoms are not specific and diagnostic of mTBI because patient groups without mTBI histories and the general population endorse PCS symptoms (e.g., Landre, Poppe, Davis, Schmaus, & Sobbs, 2006; Meares et al., 2006; Meares et al., 2008). For example, individuals in psychotherapy who do not have a history of head injury report elevated levels of PCS symptoms (Fox, Lees-Haley, Earnest, & Dolezal-Wood, 1995). Additionally, (Suhr & Gunstad, 2002) reported that a positive depression status accounted for elevated levels of PCS symptoms including cognitive symptoms more so than a history of head injury. Lees-Haley, Fox, and Courtney (2001) found symptoms associated with a mTBI diagnosis such as feeling dazed, confusion, and subjective memory complaints were endorsed in similar levels in patients exposed to traumatic events without TBI. Similarly, Iverson and McCracken (1997) found 39% of an outpatient pain sample met criteria for PCS even though none had a history of head injury.

Additionally, because cognitive complaints form part of the clinical picture, it is important to realize that subjective complaints of cognitive difficulties are often not related to actual performance on neuropsychological test measures (French, Lange, & Brickell, 2014; Schwartz, Kozora, & Zeng, 1996). Researchers have also reported a high correlation between self-reported cognitive symptoms and depression and anxiety in samples with (Maria, Pinkston, Miller, & Gouvier, 2001) and without history of head injury (Gfeller, Gripshover, & Chibnall, 1996; Tiersky, Johnson, Lange,

Natelson, & Deluca, 1997). Frenisy (Frenisy et al., 2006) found that polytrauma patients who had not experienced a TBI endorsed high rates of neurobehavioral symptoms including attention and memory complaints, concept organization difficulties and mood symptoms such as irritability, mood swings, suspiciousness, decreased motivation, and guilt.

In a study of 1,600 U.S. service members who had sustained a mild-to-moderate TBI and who had been evaluated by the Defense and Veterans Brain Injury Center at one of six military medical centers, four of 22 factors were statistically and meaningfully associated with clinically elevated postconcussion symptoms: (a) low bodily injury severity, (b) posttraumatic stress, (c) depression, and (d) military operation where wounded. The combination of depression and posttraumatic stress symptoms accounted for the vast majority of unique variance and were strongly associated with, and predictive of, clinically elevated postconcussion symptoms. Five factors were statistically and meaningfully associated with clinically elevated posttraumatic stress symptoms: (a) low bodily injury severity, (b) depression, (c) a longer time from injury to evaluation, (d) military operation where wounded, and (e) current auditory deficits. Depression alone accounted for the vast majority of unique variance (60.0%) and was strongly associated with, and predictive of, clinically elevated posttraumatic stress symptoms (OR = 38.78; RR = 4.63). There was a very clear, strong, and clinically meaningful association between depression, posttraumatic stress, and postconcussion symptoms in this sample. Brain injury severity, however, was not associated with symptom reporting following TBI (Lange et al., 2014).

Sophisticated techniques of genetic analysis hold promise to increase our understanding of TBI and chronic postconcussive symptom reporting (Shen, Loo, Wanner, & Loo, 2014). Heinzemann and colleagues (2014) examined expression profiles of transcripts across the genome to determine the role of gene activity in chronic symptoms following blast-TBI. There were 34 transcripts in 29 genes that were differentially regulated in blast-TBI participants compared to controls. Up-regulated genes included epithelial cell transforming sequence and zinc finger proteins, which are necessary for astrocyte differentiation following injury. Tensin-1, which has been implicated in neuronal recovery in preclinical TBI models, was down-regulated in blast-TBI participants. Protein ubiquitination genes, such as epidermal growth factor receptor, were also down-regulated.

### Comorbid Deployment-Related Health Conditions and Concerns

Because many conditions and diagnoses can produce symptoms associated with PCS, it is important to know which conditions and situations occur within the postdeployment and blast-exposure milieu that may potentially account for the reported PCS symptoms that occur months to years

postinjury. Differential diagnosis of persistent PCS symptoms in the blast exposure population includes (but is not limited to) brain injury; chronic pain secondary to physical injury (e.g., back pain, headaches); physical injury even without chronic pain (e.g., ear drum rupture, traumatic amputation); sleep disturbances; anxiety spectrum disorders, including but not limited to PTSD; depression; substance abuse disorders; somatoform disorders (e.g., conversion disorders, somatization disorders, hypochondriasis); factitious disorders; medication side effects; misattribution bias; diagnostic threat; symptom embellishment for secondary gain (i.e., malingering); and premorbid factors (e.g., learning disabilities). All these differentials may present with symptoms that overlap with PCS (Blennow et al., 2011; Gunstad & Suhr, 2004; Hoge et al., 2008a; Iverson & McCracken, 1997; McCauley, Boake, Levin, Contant, & Song, 2001; Melcer et al., 2014; Schneiderman et al., 2008; Smith-Seemiller, Fow, Kant, & Franzen, 2003; Vanderploeg et al., 2014).

For example, concussion, PTSD, and chronic pain share the same symptoms of fatigue, sleep disturbances, mood disturbances, psychosocial distress, and cognitive complaints (e.g., concentration and short-term memory), which can lead to role changes and impairments in everyday functioning. It is also important to realize the differential diagnoses are not all mutually exclusive. For example, a patient may have chronic pain due to physical injuries (e.g., knee pain or back injury), PTSD, a history of remote mTBI, and also embellish symptoms for secondary gain (e.g., to increase service connection).

Chronic pain is an important differential diagnosis when considering prolonged PCS symptom presentations. All of the mechanisms of blast exposure (e.g., primary, secondary, tertiary, and quaternary) can result in injuries that lead to transient or chronic pain (e.g., flying debris, falling, pressure changes). Significant transient pain can mimic symptoms associated with PCS and lead to a misdiagnosis of mTBI. Chronic pain can impact physical, social, cognitive, and emotional domains of functioning with resultant negative consequences for peer and family relationships. Chronic pain can disrupt sleep patterns and negatively impact sexual functioning. Patients with chronic pain may also potentially be taking medications that result in side effects, which could be incorrectly attributed to residual mTBI symptomology.

Substance abuse disorders, depressive disorders, conversion disorders, hypochondriasis, and factitious disorders can all produce symptoms associated with PCS. Sleep disturbances that co-occur or are caused by many of these diagnoses can produce PCS symptoms (e.g., irritability and fatigue) as well. Medication side effects can also produce symptoms associated with PCS. Even symptoms that some may believe are unique or indicative of mTBI—such as visual changes, vertigo or other balance problems, and auditory deficits and tinnitus—may actually be associated with some of the physical impacts of blasts and not even necessarily indicate a mTBI (e.g., tympanic membrane rupture). Iverson (2006)

reported that substantial minorities of civilians with depression report “classic” postconcussion-like symptoms such as dizziness (31%), nausea (41%), and noise sensitivity (50%). As mentioned, symptoms of tympanic membrane rupture may mimic and be misidentified as symptoms related to an mTBI (e.g., dizziness, temporary hearing decrease).

It is important to realize that many of the diagnoses and symptoms are interrelated. For example, medication side effects may result in sleep disturbances, which negatively impact mood, which can intensify subjective distress related to chronic pain symptoms, which may result in increased doses of pain medication, which may further worsen sleep patterns. It is crucial to treat patients with a biopsychosocial or mechanism of injury approach (Scott, Belanger, Vanderploeg, Massengale, & Scholten, 2006) that does not solely treat the presenting symptoms but is mindful of the context and base rates of comorbidities, and views the patient holistically. When treating symptoms in isolation, there is a risk of decreasing one symptom (e.g., pain) while increasing others (e.g., sleep disturbances, mood disturbance, and cognitive complaints).

Due to the complexities of combat blast exposure, practitioners should be aware of the differential diagnoses, their associated symptoms, base rates, and the trajectory of recovery from each potential comorbid condition. This will aid the practitioner when diagnosing the patient and creating treatment plans.

### External Incentives to Symptoms

External incentives are known to shape behavior. In legal and administrative situations where the possibility of external gain exists, fabrication and embellishment of symptoms and or situations have been widely reported. There are theoretically external incentives to claim an injury or embellish the severity of an injury while on active duty. In the combat environment an injury can excuse a service member from duty for a certain period of time or result in a change of duties. In extreme cases, an injury may result in the service member being medically boarded out of the service. Within the VHA and DoD, benefits vary depending on the nature and severity of the injuries sustained. Within the VHA system, recognition of an injury can result in a veteran obtaining a service-related disability rating ranging from 0% to 100%. The amount of disability awarded has an impact on disability payments, access to health care, copayments for services, and access to vocational training and educational expense reimbursement. New programs are developed to cater to the needs of the soldiers and veterans to make sure they are properly compensated for injuries obtained in the line of service. One example is the service members’ Group Life Insurance Traumatic Injury Protection Program (TSGLI), which can result in a large one-time sum of money (up to \$100,000) being dispersed to those who are injured.

Numerous researchers have reported that diagnoses that rely solely on self-report and subjective evidence can be feigned and misrepresented, and that symptom embellishment is a concern within a compensation context (Greiffenstein & Baker, 2008; Mittenberg, Canyock, Condit, & Patton, 2001). Some have argued the VHA disability program can have unintended consequences of promoting illness due to financial incentives and the structure of the system (Mossman, 1996). Veterans claiming disability status due to PTSD claims is one area that has raised concerns about secondary gain incentives in the VHA disability system (Sayer, Spont, Nelson, Clothier, & Murdoch, 2008). Sayer et al. hypothesized this may have been due to the fact that a PTSD diagnosis depends heavily on self-report and there are no objective markers for PTSD. This is problematic even with honest reporting as individuals, including service members, have been shown to be poor judges of their objective deficits (Petit et al., 2014; Schiehser et al., 2011). Self-reported cognitive difficulties may be more related to mood or diminished insight than objective evidence would suggest. Based on review of military records, Burkett and Whitley (1998) estimated approximately 75% of Vietnam veterans who receive disability due to PTSD were never even exposed to combat. Symptoms associated with PTSD are widely known and readily accessible to the general public, and a diagnostic presentation of PTSD can be easily coached. Coaching is when an examinee is given information regarding a diagnosis that could result in his or her being able to alter his or her presentation to appear a certain way. Even if individuals are not coached, however, several investigators have demonstrated that individuals not familiar with the diagnostic criteria for PTSD can qualify for a diagnosis of PTSD 86%–94% of the time when instructed to do so on checklist questionnaires (Burgess & McMillan, 2001; Lees-Haley & Dunn, 1994; Slovenko, 1994). PTSD can be completely fabricated and/or exaggerated due to the subjective nature of its diagnostic symptoms (Elhai & Frueh, 2001; Lees-Haley, 1986).

Burkett and Whitley (1998) suggested that some veterans use the VHA mental health system to establish a basis for their PTSD claims and then withdraw from services once their claim is finalized. Several studies have shown veterans who are seeking disability status for PTSD report more severe PTSD symptoms and show symptom exaggeration on MMPI-2 validity indices compared to veterans with PTSD who are not seeking disability status (Frueh, Gold, & de Arellano, 1997; Frueh, Hamner, Cahill, Gold, & Hamlin, 2000; Frueh, Smith, & Barker, 1996; Gold & Frueh, 1999). Studies investigating service utilization and disability-seeking status have shown mixed findings, with some studies finding a decrease in service use after an increase in PTSD service connection rating to 100% (Office of Inspector General, 2005), whereas another study found an increase in service usage after individuals became service connected for PTSD—but they did not control for continued compensation

seeking (Sayer, Spont, & Nelson, 2004). Sayer, Spont, and colleagues (2008) investigated changes in reported symptoms, functioning, and service utilization as moderated by compensation-seeking status after their first PTSD claim was adjudicated in 101 participants. In their sample, reported symptom levels and mental health service utilization did not decrease when participants were no longer compensation seeking. In contrast, they found an increase in mental health service usage among participants who were no longer compensation seeking, which suggests services were not being used merely to justify a PTSD claim. In contrast, however, when administering symptom validity measures to Vietnam veterans with chronic combat-related PTSD diagnosis who presented for PTSD treatment in a VA residential setting, Freeman, Powell, and Kimbrell (2008) found a 53% clear symptom exaggeration rate on the SIRS, and the SIRS scores correlated significantly with self-reported PTSD symptom severity on the Clinician Administered PTSD scale (CAPS).

This is also a concern in mTBI diagnosis and compensation. As the diagnosis is often made based on self-report, it is important for clinicians and policy makers to be aware of the potential for symptom embellishment and malingering of mTBI. Researchers have reported that external incentives such as monetary gain from litigation correlate with persistent or worsening symptoms associated with PCS overtime (Belanger, Curtiss, Demery, Lebowitz, & Vanderploeg, 2005). In a meta-analysis, Binder and Rohling (1996) demonstrated that financial incentives had more of an impact on neuropsychological test performance than did mTBI. In a veteran population, one study showed that 17% (four of 23) of patients evaluated at a polytrauma network site performed below cutoffs on a symptom validity measure (Whitney, Shepard, Williams, Davis, & Adams, 2009). In another VA sample (Armistead-Jehle, 2010), 58% of 45 individuals assessed scored below the Medical Symptom Validity Test (MSVT) cut scores on subtests more sensitive to effort than to neurological insult. In that sample there were no differences among those who did and those who did not pass the MSVT as a function of gender, age, education, ethnicity, previous PTSD or substance use disorder diagnoses, or PAI validity scales designed to measure negative impression management. However, a higher number of those who were service connected and previously diagnosed with a depressive condition failed the measure at a higher rate than those who were not.

More recently, in Lange, Pancholi, Bhagwat, Anderson-Barnes, and French (2012) a sample of 143 U.S. service members who sustained a TBI were divided into three groups based on injury severity and performance on the Word Memory Test and four embedded markers of poor effort: mTBI-pass ( $n = 87$ ), mTBI-fail ( $n = 21$ ), and severe TBI-pass ( $n = 35$ ). The patients in the mTBI-fail group performed worse on the majority of neurocognitive measures, followed by the severe TBI-pass group and then the mTBI-pass group. Likewise, on the PAI, the mTBI-fail group had

higher scores on the majority of clinical scales ( $p < .05$ ). The authors concluded that effort testing is an important component of postacute neuropsychological evaluations following combat-related mTBI, and those who fail effort testing are likely to be misdiagnosed as having severe cognitive impairment. Their symptom reporting is likely to be inaccurate if taken at face value (Lange et al., 2012). Studies have illustrated that when clinicians were made aware of potential threats to assessment validity this increased their detection of simulation (Hickling). It is important for clinicians to screen for poor effort and symptom validity and to be aware of the potential pull for symptom embellishment that is created by the system due to multiple external incentives when an injury can be established. Because knowledge of potential symptom embellishment can increase practitioners' ability to detect symptom embellishment (possible because they attend to the possibility) it stands to reason that education regarding this possibility should be provided to practitioners within the DoD and VHA system of care for all levels of practitioners, not just neuropsychologists and rehabilitation specialists. It is also important to clarify that stating clinicians should remain cognizant of potential symptom embellishment and malingering in no way infers individuals who sustained real injuries while on active duty should be denied benefits. It simply means individuals should be compensated at the level of injury they obtain and for what actually occurred to them.

### **Iatrogenic Illness, Diagnostic Threat, and Misattribution Bias**

Several studies have found an increase in symptom endorsement over time (Belanger, Kretzmer, Vanderploeg, & French, 2009; Milliken et al., 2007). Various explanations have been advanced including (a) recovery from TBI may be associated with increased recovery of memories, (b) physiological changes that persist (e.g., vestibular changes, hearing loss, tinnitus) may result in increased anxiety responses overtime, and (c) awareness of symptoms may increase with time. While these are possibilities, it is also possible that the system and the public milieu may be functioning in a way to create, maintain, and/or accentuate the symptoms in some select cases.

As discussed, it is unlikely that persistent symptoms are related to a remote mTBI for the overwhelming majority of cases. Symptoms that are shared with other diagnoses such as substance abuse, sleep disorders, and mood disorders can persist, however, if not properly treated. Additionally, symptoms associated with mTBI can occur in normal healthy adults. These facts combined with the fact that misinformation about mTBI—including its base rate, recovery trajectory, and future implications—in the public domain creates a situation where expectations may result in individuals misattributing their symptoms to an improper source (e.g., remote mTBI) when they are actually caused by other

comorbid conditions or everyday life fluctuates. Studies have investigated this phenomenon, which is called *misattribution bias* (Mittenberg, DiGiulio, Perrin, & Bass, 1992b).

Patients with a history of mTBI have been shown to under report preinjury levels of PCS symptoms (Mittenberg et al., 1992b). When study participants without a history of TBI were asked to imagine the symptoms of a mTBI, they reported symptoms typically endorsed by patients after a mTBI (Mittenberg et al., 1992b). With ambiguous stimuli such as internal states, individuals interpret the event based largely upon their expectation of that experience. Taken together, this suggests if there is an expectation of initial and continued symptoms that some individuals will in fact experience these symptoms (Mittenberg et al., 1992b). It has been suggested that Mittenberg's "expectation as etiology" hypothesis may be too specific and perhaps a "good old days" hypothesis would be more appropriate: After a negative event, people may attribute all symptoms to that negative event.

Misattributing symptoms to an incorrect etiology is problematic. Misdiagnosis can prevent the individual from obtaining the appropriate treatment. For example, if an individual's PCS symptoms are primarily due to an anxiety spectrum disorder, a sleep disorder, and narcotic use for chronic pain control, but the symptoms are misattributed completely to a remote mTBI, the individual may be misinformed the deficits are permanent and nothing can be done. In contrast, with proper differential diagnosis, evidence-based interventions such as cognitive behavioral therapy for anxiety symptoms, physical therapy for the pain disorder, alternatives to narcotic use for pain control, and sleep hygiene for the sleep disturbance can be attempted. A misdiagnosis could also potentially significantly reduce a person's quality of life and goal attainment. For instance, the belief that persistent symptoms are attributable to a remote mTBI that will not resolve may result in a person not attempting to get a job or obtain an advanced degree. This would limit the person's ability to engage in meaningful life activities that could be personally rewarding and self-fulfilling. This by itself could lead to isolation or depression.

Misinformation in the public domain that does not differentiate the severity levels of TBI and suggests mTBI has long-term deficits similar to a severe TBI is harmful to those who experience a blast exposure. Increased media attention has brought with it increased awareness around the occurrence of concussion and TBI, especially in the sports arena. There is also increased awareness around potential long-term effects. The DoD and VA have developed extensive screening and education programs around TBI for all service members, but not without a potential cost around stigma, misattribution, or other negative effects (Logan et al., 2013; Scholten, Cernich, Hurley, & Helmick, 2013).

Previous work (Mittenberg, DiGiulio, Perrin, & Bass, 1992a; Suhr & Gunstad, 2005) has shown that some individuals with mTBI may expect to have persistent problems even

though they are showing a good recovery. While structured educational interventions have been shown to be effective in reducing postconcussive symptoms in both acute and more chronic TBI in active duty service members, veterans, and civilians (King et al., 2013), these interventions do not always reach the intended audience. In one study of veterans who screened positive for TBI (Spencer et al., 2013), “friends in the military” remained the most frequently source of information about TBI and its effects, with the second highest being the Internet. This heightens the possibility of misinformation about TBI and its possible consequences.

“Diagnostic threat” is similar but different than the “expectation as etiology” theory. Suhr and Gunstad (2002a, 2005) found when participants were randomly assigned to a group informed they were being assessed due to a history of mTBI, versus a group given neutral instructions that did not call attention to the remote mTBI, the group informed they were being assessed due to history of mTBI performed more poorly on neuropsychological test measures, which suggests a “diagnostic threat” when informing patients they are being evaluated for a particular reason. Expectations regarding a diagnosis can impact performance on some neuropsychological test measures (Suhr & Gunstad, 2005). This is especially problematic when the symptoms of the diagnosis are commonly occurring symptoms in the general public, because the experience of the symptoms—even though normal—can function to reinforce the thought the person is indeed “sick.” As shown, PCS symptoms occur frequent in the healthy population (Mittenberg et al., 1992b). As stated in one study while overinclusive screenings assure individuals who need help are ascertained, overinclusive screenings also have several drawbacks such as dramatically increasing needed resources, potentially overinflating estimates of brain injury that might be based upon screening, and—as has been suggested previously—the screening itself may have adverse consequences for some false positives (e.g., iatrogenic illness).

### **TBI Programs Within the Departments of Defense and Veterans Affairs**

In response to the number and types of injuries sustained during the conflicts, both the DoD and the Department of Veterans Affairs have established and expanded their systems of care to provide a network of services for individuals with brain injury. This includes protocols for care within the combat setting for those who do not require evacuation, and systematic stabilization and evacuation from theater for those who require more intensive surgical or medical services. Following the provision of acute care, each department provides acute and subacute rehabilitation, and in some cases, residential rehabilitation and community reintegration services.

An important part of these efforts has been the development of clinical practice guidelines, consensus papers,

and literature reviews of important topics in military TBI care. Chief among these is the VA/DoD Clinical Practice Guideline for the treatment of mTBI (Group, 2009) which provides the foundation for clinical care of this population. Other guidelines, largely produced by the Defense and Veterans Brain Injury Program (DVBIC) have included “A Parent’s Guide to Returning Your Child to School After a Concussion,” “Assessment and Management of Dizziness Associated with mTBI Clinical Recommendation,” “Assessment and Management of Visual Dysfunction Associated with mTBI,” “Indications and Conditions for In-Theater Postinjury Neurocognitive Assessment Tool (NCAT),” “Testing Indications and Conditions for Neuroendocrine Dysfunction Screening Post mTBI,” “Management of Sleep Disturbances Following Concussion/Mild Traumatic Brain Injury,” “Neuroimaging following mTBI in the Non-Deployed Setting Clinical Recommendation,” and “Progressive Return to Activity Following Acute Concussion/Mild Traumatic Brain Injury.” Fact sheets and educational handouts for patients are also available in a large number of languages. As these are all government-funded projects, they are available free on the DVBIC website (DVBIC.DCOE.mil).

### ***In-Theater Care***

The DoD has rapidly evolved a system of trauma care services over the course of the current conflicts for those who received moderate, severe, and penetrating injuries as a result of combat engagement or accident. This includes a series of evidence-based trauma care guidelines to include stabilization of intracranial pressure, decompressive craniotomy, supportive use of whole blood and blood products, and protocols for stabilization of the patient prior to evacuation ([www.usaisr.amedd.army.mil/clinical\\_practice\\_guidelines.html](http://www.usaisr.amedd.army.mil/clinical_practice_guidelines.html), 2014). Aeromedical evacuation procedures are tailored to flights of long duration at relatively high altitude with medical staff on hand for crisis management.

Many service members are wounded in theater and do not require evacuation to European or stateside hospitals, but instead receive triage and treatment services in the combat zone. A series of procedures have evolved to determine at what level an injury can be managed and by which types of providers. The immediate triage and treatment of a service member is often provided by a combat medic. The medic provides screening via the Military Acute Concussion Evaluation which consists of a brief neurological evaluation, documentation of the event and symptoms at the time of the event, and then, based on criteria related to those two evaluation portions, provides a brief mini-mental status examination and vestibular examination (balance evaluation and scoring system; see Guskiewicz, Ross, & Marshall, 2001) to assess other potential effects of the injury. If particular “red flags” are present during that evaluation (e.g., blown pupils) evacuation may be initiated. If no acute emergent needs are

identified, an algorithm has been adopted to guide the treatment and referral process for a service member.

There are three levels of care in theater—referred to as Role 1, Role 2, and Role 3—which increase intensity of services systematically and require in theater transport to higher levels of medical services. Also included in the system of care are Concussion Recovery Centers (CRCs). At one time during the conflicts there were nine CRCs located in different areas of Afghanistan that provided systematic rest and rehabilitation protocols to allow for recovery and that allowed for the return of approximately 97% of service members to full duty status (Logan et al., 2013).

Figure 33.2 Combat medic administers MACE to a Service Member in theater. A color version of this figure can be found in Plate section 3

**Acute and Subacute Rehabilitation**

Acute medical stabilization and surgical interventions continue upon arrival to medical centers that are based primarily in Germany (Jaffee & Meyer, 2009). At this point, the service member receives additional surgical services, may require addition stabilization of intracranial pressure to enable transport stateside, or may initiate rehabilitation care. Though some service members return to duty from the European medical support hospitals, most are transferred to hospitals in the CONUS.

The primary sites of care for service members who have moderate to severe brain injuries when they arrive stateside are Walter Reed National Military Medical Center in Bethesda, Maryland; Brooke Army Medical Center in San Antonio, Texas; and Balboa Naval Hospital in San Diego, California. The site of care is based on a number of factors, including the type and severity of associated injuries co-occurring with the brain injury (e.g., injury to the extremity/amputation, burn, severe eye/visual injury, or genitourinary injury), proximity to post or home, and bed availability. Following acute stabilization and initiation of rehabilitation in the acute-care setting, a plan of care is established for each individual that includes disposition and potential referral within the military health system to a medical setting nearer the patient’s military assignment or home, a private care setting that would be funded through a purchased care arrangement, or to the Department of Veterans Affairs Polytrauma System of Care.

Figure 33.3 Service Member receives rehabilitation treatment in theater. *A color version of this figure can be found in Plate section 3*

The VA Polytrauma System of Care consists of four levels of care that are dispersed throughout the nation (Sigford, 2008). The most intensive care is provided at Level I facilities, which provide acute and subacute management of brain and other major bodily injuries and serve as the hubs for the Polytrauma System of Care in their regions. The five Level I facilities are located in Richmond, Virginia; Tampa, Florida; San Antonio, Texas; Minneapolis, Minnesota; and Palo Alto, California. Each program provides 10–15 inpatient beds and has step-down programs that provide for outpatient day programs and residential rehabilitation programs.

The Polytrauma Network Sites, or Level II facilities, offer structured outpatient day programs and comprehensive outpatient services, as well as a limited number of inpatient beds for continuation of care within each of the VA's 21 Integrated Service Networks (VISNs). There is a full complement of rehabilitation staff, care management services, and augmented rehabilitation services to enable community reintegration and continuation of rehabilitation support.

At the Polytrauma Support Clinics, or Level III facilities, comprehensive rehabilitation services are offered on an outpatient basis. These services are tailored to patient needs and

potential consultation or referral to Level II facilities is considered where needed. The Polytrauma Points of Contact are primarily care managers who can facilitate care in the area in which the Veteran resides or coordinate care with higher levels of treatment located in the region.

#### *Emerging Consciousness*

All Level I facilities provide services for those individuals who remain in coma, a persistent vegetative state, or a minimally conscious state (McNamee, Howe, Nakase-Richardson, & Peterson, 2012). Known as the Emerging Consciousness Program, these services are geared toward promoting optimal stimulation and rehabilitation aimed at returning the individual to the highest possible level of function. They include: skilled nursing and rehabilitation medical services; individualized multimodal stimulation program; active therapy involvement; weekly monitoring of objective functional status; intensive social work and case management; and psychological support services, training and education to support families and caregivers (McNamee et al., 2012; Nakase-Richardson et al., 2013). There have been a relatively small number (fewer than 200) of individuals admitted to the Polytrauma Rehabilitation

System of Care with disorders of consciousness who have been enrolled in this program (Nakase-Richardson et al., 2013). Individuals admitted are primarily active duty men who entered the program with a median GCS of 3 on acute admission; 91% were on a ventilator during acute stay. Individuals in the program had a median acute length of stay of 51 days and a median rehabilitation stay of 132 days, with longer lengths of stay noted in individuals with blast injury. Many of the individuals had a high level of medical comorbidities including spasticity, autonomic nervous system dysregulation, and seizure. Of those enrolled, 64% have emerged to regain consciousness at the minimally conscious state as defined by coma recovery scale—revised or evidence of interaction communication, functional object use, or Rancho LCFS greater than or equal to 4. Thirty-eight percent of the sample regained full orientation. Functional improvement was noted in the sample in cognitive and motor domains of the FIM, though these were improvements above the rating scale floor in the other trauma group (non-blast or combat-related trauma). Those with neurotrauma secondary to blast were less likely to recover to full orientation, had higher levels of medical comorbidity, and had fewer functional gains.

#### *Residential Programs*

The VA offers residential rehabilitation programming at its Polytrauma Transitional Rehabilitation Programs. Located at each of the Level I facilities, they offer 15–20 residential beds in tiered levels of medical supervision to promote community reintegration and independent living skills through an intensive program. This includes vocational rehabilitation, driving rehabilitation, recreational therapy, compensated work therapy programs, and comprehensive rehabilitation services.

#### *The National Intrepid Center of Excellence*

The National Intrepid Center of Excellence (NICoE) for Psychological Health and Traumatic Brain Injury at Walter Reed National Military Medical Center specializes in treating service members with mTBI and co-occurring psychological health issues that have failed in more traditional treatment settings (Miller, 2011; Wesolowski, 2010). This four-week program relies heavily on an intensive, comprehensive assessment in a healing environment with a heavy emphasis on complementary and alternative medicine interventions to include acupuncture, art therapy, service dog programs, and other techniques (Foote & Schwartz, 2012; Garrison & Stewart, 2014; Yount, Olmert, & Lee, 2012). These techniques are not intended to supplant traditional interventions but to provide an alternative that may be useful for some who have failed other treatments, or need to pursue medication alternatives because of existing polypharmacy (Koffman & Helms, 2013).

### **Screening and Evaluation**

In contrast to moderate to severe TBI, the immediate symptoms of mTBI can be subtle and difficult to detect. This is particularly true within a combat situation when symptoms of mTBI may be mistaken for the stresses of deployment or other psychological trauma/shock. In the deployed environment, the DoD enacted a policy to require screening following potentially concussive events, standardized evaluation of symptoms, and documentation of the event, symptoms, and resultant diagnosis (Helmick, Baugh, Lattimore, & Goldman, 2012). Following the enactment of this policy, the DoD increased training of medics in appropriate screening for concussion and modified its clinical care algorithms to reflect recent evidence from theater-based research. The DoD continues to emphasize detection of mTBI by requiring screening at multiple time points (e.g., point of injury, prior to medical evacuation to the United States, and before redeployment). Survey questions targeting TBI detection at postdeployment and at postdeployment reassessment were recently refined to encourage symptom reporting in order to connect service members to care (Helmick et al., 2012). Looking forward, research efforts are under way to evaluate the efficacy of biomarkers, neuroimaging, and other novel approaches for unequivocal diagnosis of TBI (Maruta, Lee, Jacobs, & Ghajar, 2010; Mondello et al., 2011; Svetlov et al., 2009).

Due to the growing concern over the health consequences of TBI, all service members returning from combat are screened for TBI using the PDHA/PDHRA from the DoD or the VHA's TBI Screening Questionnaire (Brenner, Vanderploeg, & Terrio, 2009a). These measures screen for potential exposure to risk events and ongoing symptomology. However, the timing of administration of these measures can play an important role in what the service member is willing to report. Some service members may minimize symptoms so as not to delay their return home with lengthy

follow-up evaluations (Brenner et al., 2009a; Schneiderman et al., 2008). Others may not recognize the extent of their symptoms or may minimize the impact of their symptoms until they return home to their regular activities. Any delays in the initiation of treatment can negatively affect the path of symptom resolution and recovery; therefore, continued efforts to better identify injuries as close to the time of injury as possible are critical.

As the DoD continues to develop its care model in theater, there are now mandatory evaluations in place for those who are felt to be at risk for TBI (Ling & Ecklund, 2011), with prescribed algorithms for follow-up care. Refinements of the questions asked during the PDHA/PDHRA are also focused to address underreporting and to encourage acknowledgment of symptoms to connect service members to care (Helmick et al., 2012). The attention to screening and follow-up evaluation provides documentation of diagnosis of TBI, records multiple exposures and/or injuries in the population, and provides a better basis from which one can evaluate long-term outcomes and dementia risk.

Since 2007, VA provides screening and evaluation for all veterans accessing care who served in the Global War on Terror and separated from active duty service after September 11, 2001 (Scholten et al., 2013). This four-question screen is similar to the one used during the PDHA/PDHRA process and identifies events that place the individual at risk for TBI, a history of symptoms following injury if identified, and the presence of current symptoms. Following a positive screen the individual is referred to the Polytrauma System of Care and receives a comprehensive TBI evaluation that includes a history of the injury event, a physical evaluation, and a 22-item symptom questionnaire (the Neurobehavioral Symptom Inventory; see Cicerone & Kalmar, 1995) to determine current symptoms that are impacting functional ability. Diagnosis is provided at that time (if it is not specified in available records) and if concordant with history of injury and presence of symptoms at time of injury. In a recent analysis, of those 49,962 veterans with completed TBI evaluations, 59% (29,534) received a clinician-confirmed TBI diagnosis (Carlson et al., 2013). Among those diagnosed, 81% met criteria for mTBI, and clinicians' diagnoses reflected a high rate of comorbidity of behavioral health symptoms with current symptoms of mTBI (58%).

In the VA an integrated individual care plan is required for all patients and is entered into the medical record in a standardized format to allow for retrieval and analysis. In a recent evaluation of the presenting symptoms indicated on the initial evaluation and care plan, more than three-quarters of veterans reported moderate to very severe difficulty with irritability, sleep disturbance, forgetfulness, and anxiety (Scholten et al., 2013). The types of injury noted were blast exposure (36%), other trauma (19%) and both blast and non-blast for those remaining (44%). Thirty-eight percent of this sample did sustain their injury during deployment. Of note, about 23% of the population that had

symptoms and also were assigned a TBI diagnosis were felt to have symptoms more attributable to behavioral health conditions than to TBI.

Screening in the VA has not been universally accepted as beneficial. One recent paper concluded that the core conditions essential for beneficial medical screening—progressive disease, symptoms related to the identified disease, suitable tests or examinations for accurate diagnosis, and accepted and effective treatment—were not present within the context of TBI screening, and that the potential harms/costs outweigh any potential benefits of population-based screening for TBI. As postconcussion-like symptoms can be effectively treated in a symptom-specific manner, tying them to concussion through a screening and evaluation process is wasteful and potentially harmful (Vanderploeg & Belanger, 2013). This view has been countered by other clinicians in the VA system, saying that such screening identifies those who would have otherwise been missed and allows for individualized care (Scholten et al., 2013).

There has been some research indicating that informational techniques providing psychoeducation regarding the expected symptoms and trajectory of recovery from mTBI may minimize potential iatrogenic impacts from postdeployment screening for mTBI. Mittenberg, Tremont, Zielinski, Fichera, and Rayls (1996) investigated outcomes between two conditions and found that an intervention of extensive written instructions and a meeting with a therapist for information and to advise to gradually return to premorbid activities before discharge ( $n = 29$ ) versus routine discharge information with advice to rest ( $n = 29$ ) resulted in reduced symptoms and disability at six months postinjury via interview. Other studies have found that providing patients with information regarding the normal course and recovery trajectory expected for mTBI can decrease symptom prevalence in children (Ponsford et al., 2001) and adults (Ponsford et al., 2002).

Ponsford et al. (2002) compared the standard emergency department treatment, which did not include an informational booklet regarding the symptoms and expected recovery trajectory from mTBI ( $n = 123$ ), to a group who obtained an assessment and an information booklet outlining common symptoms associated with mild head injury, their likely time course, and suggested coping strategies, within one week after mTBI ( $n = 79$ ). They found that at a three-month follow-up looking at symptoms, psychological adjustment, and concurrent life stresses that the provision of an information booklet reduced anxiety and decreased reported level of ongoing problems. These and similar studies suggest that interventions that inform individuals of the expected symptoms, the trajectory of recovery along with suggested coping strategies within one week of sustaining a concussion will at later follow-ups result in patients reporting fewer symptoms and reduced anxiety (Mittenberg et al., 1996; Paniak, Toller-Lobe, Reynolds, Melnyk, & Nagy, 2000; Wade, Crawford, Wenden, King, & Moss, 1997).

These studies investigated informational interventions close in time to the actual injury. Few studies have investigated informational interventions with patients who have persistent symptoms several years post mTBI. It is not known if these approaches would work as well at a later time point (Belanger, Uomoto, & Vanderploeg, 2009). There are several reasons simple informational interventions may not be as helpful with persistent PCS symptoms in the blast exposure population as they have been in acute mTBI situations.

First, it is possible that misattribution over an extended period of time may lead to a psychological investment in the symptoms on multiple levels. Social roles, financial compensation, perceived self-efficacy, and personal life expectations may all be altered by prolonged periods of misattributed persistent PCS symptoms.

Second, in many cases, the persistent PCS symptoms may be due to comorbid condition(s) and simply informing the patients that they should not have symptoms due to a remote mTBI will not alleviate symptoms stemming from a different source. This underscores the importance of appropriate differential assessment and diagnosis based upon a mechanism of injury approach (Scott, Belanger, Vanderploeg, Massengale, & Scholten, 2006). In either situation, if symptoms stem from a different etiology or iatrogenic symptoms were created, symptom resolution will require a mental paradigm shift in the individual. It is important for clinicians treating these patients to get them “treatment ready,” which means aiding them with the mental paradigm shift and helping them to be willing to consider that persistent symptoms may be related to psychological or physical factors and not organically based. This process will likely take more than one discussion and individuals and their families may go through a range of emotions during and after these discussions. Expecting a soldier to easily transition the mindset would be naive on the part of the treatment provider. The reallocation of the long-standing misattribution of symptoms to a different cause requires some recreation of personal identity.

Tiersky et al. (2005) compared wait-listed controls ( $n = 9$ ) with patients enrolled in an 11-week program consisting of 33 sessions of individualized cognitive remediation and cognitive behavioral psychotherapy and found the intervention resulted in lowered levels of depression and anxiety, and improved performance on a measure of divided auditory attention, suggesting interventional techniques with more long-standing misattribution of symptoms is possible as well.

### The Role of Neurocognitive Testing

To aid in the detection of mTBI and its sequelae in the deployed environment, multiple policies and programs were initiated by the DoD, including the implementation of a neurocognitive baseline assessment program at predeployment that allows for postinjury comparison (USD P&R DoD 6490.13; U.S. House of Representatives H.R. 4986, NDAA 2008, Sec 1618). In 2008 Congress mandated a baseline

predeployment neurocognitive assessment for all U.S. service members to address increasing concern surrounding the risk of cognitive insult during military deployment (Cole et al., 2013; Ivins, Kane, & Schwab, 2009; Seegmiller & Kane, 2010). However, the empirical validity of baseline cognitive testing within concussion monitoring and management programs for preventing or mitigating concussion risk has been questioned (Kirkwood, Randolph, & Yeates, 2009).

Although some studies (Echemendia et al., 2012; Schmidt, Register-Mihalik, Mihalik, Kerr, & Guskiewicz, 2012) have suggested no added value of baseline testing in civilian concussion monitoring programs, there is evidence that baseline testing reduces the possibility of false positive detection of concussion in healthy service members. A large study of military service members ( $N = 8,002$ ) found that when norm-referenced postdeployment scores were considered in isolation, 66% of individuals classified as “atypical” actually showed no change from baseline. Baseline testing, especially testing that can be repeated over the life span, allows for longitudinal tracking of an individual’s cognitive trajectory and detection of factors that cause a change from baseline. Monitoring of these results over time, controlling for effects of aging, or other normative causes of cognitive change, could improve the sensitivity of dementia monitoring protocols (Roebuck-Spencer, Vincent, Schlegel, & Gilliland, 2013).

### The Intersection of Service Members and the Criminal Justice System

In the years following the war in Vietnam, popular perception linked military combat, PTSD, and criminal behavior. The veteran was perceived as more likely to commit crime because of high rates of unemployment, mental health issues, substance abuse, thrill-seeking behaviors, or other reasons (Sparr, Reaves, & Atkinson, 1987). In 1951 Lunden wrote:

In the aftermath of every major war certain people and some organizations give considerable credence to the idea that military service tends to create criminality in the men who have served in the armed forces of the nation after they return to civilian life. In some instances novels and movies popularize the notion that military duty fosters crime and disorder among men in arms after a war. After World War I such novels and plays as “What Price Glory?,” “They Put a Gun in My Hand,” “All Quiet on the Western Front” and “The Road Back” more than suggested that soldiering resulted in crime. Since World War II there has been less evidence of this idea, but when newspapers report a crime committed by some ex-G.I. his war record often appears in the account in such a manner as to intimate that military duty had something to do with the violation.

(Lunden, 1951, p. 766)

In reality, identifying whether there is a relationship between combat exposure or injuries and civilian violence

on return from deployment is complicated by differences in reactions of individuals to combat exposure, the overlapping effects of TBI and PTSD, and the low base rate of civilian violence after combat exposure (Sreenivasan et al., 2013). In a large cohort study of UK military personnel, 17.0% of 12,359 male UK military personnel had a criminal record for any offense during their lifetime. The prevalence was highest in men under 30 years old. Deployment was not independently associated with increased risk of violent offending, but serving in a combat role conferred an additional risk. Increased exposure to traumatic events during deployment also increased risk of violent offending. Violent offending was strongly associated with postdeployment alcohol misuse, PTSD (especially hyperarousal symptoms), and high levels of self-reported aggressive behavior (Macmanus et al., 2013). In a national survey of 1,388 Iraq and Afghanistan war era veterans, 9% of respondents reported arrests after returning home from deployment. Most arrests were associated with nonviolent criminal behavior resulting in incarceration for less than two weeks. Those who reported anger/irritability were more likely to be arrested than were other veterans. Arrests were found to be significantly related to younger age, male gender, having witnessed family violence, prior history of arrest, alcohol/drug misuse, and PTSD with high anger/irritability but were not significantly related to combat exposure or TBI (Elbogen et al., 2012).

A few high-profile cases, including that of SSG Robert Bales, have increased public perception that there is a link between PTSD and war atrocities. Bales is a former U.S. Army soldier who murdered 16 Afghan civilians in Kandahar, Afghanistan, in March, 2012. He later pleaded guilty to 16 counts of murder and six counts of assault and attempted murder, and was sentenced to life in prison without parole. His lawyer claimed that he suffered from PTSD symptoms (Leonnig, 2012). One recent study (Wilk et al., 2013) examined whether unethical battlefield conduct is a proxy for aggression and whether specific combat experiences and PTSD are independently associated with unethical behavior. The results of this study showed that aggression and specific combat experiences (particularly, witnessing war atrocities and fighting) were much more strongly associated with unethical conduct than was PTSD.

In response to concerns about military veterans entering the criminal justice because of actions related to deployment related health conditions (especially PTSD and TBI) many jurisdictions established Veterans Courts, intended to funnel those committed nonviolent offenses to treatment programs rather than punishment if appropriate (Hawkins, 2010; Holbrook, 2010; Pratt, 2010). This has not been without controversy, however. In some cases, there is concern over whether veterans courts unfairly shift the focus of justice away from the interests of victims to the rehabilitative interests of perpetrators (Holbrook, 2010).

## Research and Longitudinal Follow-Up

In 2013 the White House announced that the University of Texas Health Science Center–San Antonio and Virginia Commonwealth University would each lead new research consortia with more than \$100 million of support from DoD and VA to help better recognize and treat PTSD and the links between TBI and other mental health issues. More broadly, however, both the DoD and the VA are actively following service members with TBI longitudinally, in empirical studies to include the 15 Year Study by the Defense and Veterans Brain Injury Center (U.S. House of Representatives NDAA 2007, Sec 721) and the TBI Model Systems effort within VA (Brickell et al., 2014a; Brickell, Lange, & French, 2014b; Lamberty et al., 2014; Lange, Brickell, French, et al., 2012; Lange, Brickell, Ivins, Vanderploeg, & French, 2012; McGarity et al., 2013). Longitudinal follow-up and data monitoring is intended to help to clarify initial care that helped to improve outcome and the natural course of brain injury and polytrauma over the life span. This systematic monitoring of service members and veterans over their life span will lay the groundwork for tracking of cost of care and health care utilization for those individuals with premorbid brain injury, track the development of dementia and CNS illnesses, and monitor the efficacy of treatment programs among other things.

Primary to any major longitudinal monitoring effort is definition of key data elements that allow for integration of data from multiple studies and shared ontologies associated with that data to allow for reliable analysis and interpretation. DoD, VA, the National Institute on Disability and Rehabilitation Research (NIDRR), and the National Institutes of Health (NIH) have contributed to the development of common data elements for use in research related to TBI (Thurmond et al., 2010; Whyte, Vasterling, & Manley, 2010; Wilde et al., 2010). Many of these agencies now require the use of those data elements for their funded research. In addition, the NIH and DoD have sponsored a collaborative database aimed to integrate findings from funded research, especially clinical trials, which are available upon request for aggregated analysis and publication (<https://fitbir.nih.gov>). Similar to efforts in aging and autism, this increases available data to examine effective treatments, novel contributors to positive outcome, or evaluation of devices or methods for diagnosis and detection.

Other efforts under way include the Defense and Veterans Brain Injury Center's evaluation of the computerized cognitive tests available for postinjury assessment (Cole et al., 2013), a randomized controlled trial of cognitive rehabilitation in the military population, and an evaluation of the incidence and prevalence of multiple concussions in the military. In the VA, the Quality Enhancement Research Initiative in Polytrauma and Blast Related Injury (PT/BRI QUERI); Cifu, Cohen, Lew, Jaffee, & Sigford, 2010) is in the process of evaluating its screening and evaluation procedures, the effect

of comorbidities on the utilization of care for mTBI patients, and the impact of these injuries on the caregiver and family. In addition, the VA has funded VA Epilepsy Centers of Excellence to study and provide services for those individuals with epilepsy, including those who have posttraumatic seizures following mild to severe TBI.

### **Chronic Traumatic Encephalopathy**

One recently recognized long-term effect of repeated TBI is chronic traumatic encephalopathy (CTE). CTE is a progressive neurodegenerative disorder characterized by accumulation of hyper-phosphorylated tau deposits in neurons along with atrophy of brain tissue. CTE has been described primarily in professional athletes, although recently Goldstein and colleagues (2012) found CTE-like neuropathologic characteristics in the postmortem examination of brains from three military personnel who had been exposed to blast. Another study identified CTE in 21 military veterans (McKee et al., 2012). These studies have led some to suggest that there is a large emerging public health threat (Stern et al., 2011) for those in the military. However, a recent conclusion by the Institute of Medicine was that there is limited evidence of an association between recurrent blast TBI and chronic traumatic encephalopathy with progressive cognitive and behavioral decline (Medicine, 2014). While there are an increasing number of journal articles discussing the potential threat for service members, the studies of pathological changes in military service members are scant. Newly developed PET ligands (Gandy et al., 2014) that bind to tau will soon increase the number of potential subjects that can be examined for CTE-like brain changes after military service.

### **PTSD and Aging**

The Department of Veterans Affairs conducted a large, retrospective cohort study of over 181,000 veterans 55 years or older without dementia from fiscal years 1997 through 2000. In the follow-up period from 2000 to 2007, 17.2% veterans had diagnosed dementia. Patients with PTSD were more than twice as likely to develop dementia compared with those without PTSD. After multivariable adjustment, patients with PTSD were still more likely to develop dementia (hazard ratio, 1.77; 95% confidence interval, 1.70–1.85), even when those with a history of head injury, substance abuse, or clinical depression were excluded (Yaffe et al., 2010).

In a study of 637 veterans without known coronary artery disease (CAD), screening showed that in subjects with PTSD, coronary artery calcium (CAC) was more prevalent than in the non-PTSD cohort (76.1% vs. 59%,  $p = 0.001$ ) and their CAC scores were significantly higher in each Framingham risk score category compared to the non-PTSD group. PTSD was an independent predictor of the presence and extent of atherosclerotic CAD. During a mean follow-up of 42 months, the death rate was higher in the PTSD compared to

the non-PTSD group. The authors concluded that PTSD is associated with the presence and severity of coronary atherosclerosis and predicts mortality independent of age, gender, and other conventional risk factors (Ahmadi et al., 2011).

### **Conclusion**

TBI is an important concern in the military, both in peace and wartime. Because of the demographics of the military, mostly young men, there is an inherent risk for TBI. This risk is increased by combat operations and training. In both military conflicts and terrorism, the explosive device has emerged as a major cause of injury, including TBI.

In assessing or treating an individual injured in a military context, especially through blast, it is important to think in a comprehensive fashion taking into account the full range of possible consequences of that injury to include TBI, sensory impairment, pain issues, effort and motivation, and the emotional context in which the injury occurred. PTSD, mood changes, substance abuse, family dynamics, the disability process, and individual personality characteristics of the injured individual all have an impact on symptom presentation, rehabilitation, and recovery.

## 34 Pain and Pain-Related Disability

*Kevin W. Greve, Kevin J. Bianchini, and Steven T. Brewer*

### Introduction

Neuropsychologists will almost inevitably be confronted with issues of pain and pain-related disability in their practice. Pain is a feature of a variety of conditions commonly encountered by neuropsychologists such as multiple sclerosis, Parkinson's disease, and traumatic brain injury (TBI). Chronic pain after TBI, for example, occurs in 75% of mild TBI patients and 32% of moderate-severe TBI patients (Nampiarampil, 2008). Pain is an important prognostic indicator for TBI recovery (Alexander, 1995; Mooney, Speed, & Sheppard, 2005) and should be addressed in order to reduce residual disability and maximize functional outcomes. Moreover, the same psychosocial factors that influence disability and recovery from pain likely complicate the management of neuropsychological conditions. Therefore, it is essential for the neuropsychologist to have an understanding of pain and the factors that influence pain-related disability.

Pain affects more than 50 million Americans, incurring a cost of over \$70 billion annually in health care and lost productivity, and accounts for more than 80% of all clinical visits (Gatchel, 2004). Approximately 57% of adult Americans report experiencing recurring or chronic pain, 62% of whom were in pain for more than one year with 40% reporting constant pain (American Academy of Pain Management, 2003). Pain has a large impact on health-related quality of life (Morken et al., 2002) and back pain alone is thought to contribute to more than 100 million lost workdays yearly (Guo, Tanaka, Halperin, & Cameron, 1999). The total economic burden of pain-related health care and disability has been estimated to exceed \$150 billion a year (Gatchel & Okifuji, 2006; Mayer, Gatchel, & Polatin, 2000).

Pain is defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association for the Study of Pain, 1994: 209-214). The experience of pain is influenced by both psychological and contextual factors that are not necessarily dependent on tissue damage or specific nociceptive activation (Merskey & Bogduk, 1994). Loeser and Melzack (1999) describe three broad categories of pain: (a) transient, (b) acute, and (c) chronic. "Acute pain ordinarily has a useful purpose, such as signaling damage or that something is wrong. By contrast, chronic pain has no

such value, but is a disease in its own right, causing widespread suffering, distress, and disability" (Pappagallo & Werner, 2008, p. 17). Pain is termed *chronic* when symptoms do not follow the natural course of healing after injury or persist for longer than three months without biological value (Merskey & Bogduk, 1994). Psychological factors are important in the transition from acute to chronic pain Linton (2000). Chronic pain is due to stress as well as environmental and affective factors that may be superimposed on the original damaged tissue (Gatchel, Peng, Fuchs, Peters, & Turk, 2007; Loeser & Melzack, 1999).

Pathological findings from commonly used medical diagnostic techniques—e.g., magnetic resonance imaging (MRI) of the spine—are not sufficient to explain current or future pain-related symptoms or disability. For example, objective evidence of physical pathology does not always correlate with pain symptoms or disability, nor does it reliably predict who will become symptomatic in the future. Cervical and lumbar disc abnormalities, including some that would be considered surgical lesions, have been found in the cervical and lumbar spines of asymptomatic patients (Boden, Davis, Dina, Patronas, & Wiesel, 1990; Boden et al., 1990; Jarvik, Hollingworth, Heagerty, Haynor, & Deyo, 2001). Additionally, the presence of an identifiable abnormality of the disc or spinal canal in the lumbar spine of asymptomatic patients does not predict subsequent low back pain seven years later (Borenstein et al., 2001). What does predict the development of low back pain after three years in cases asymptomatic at baseline is self-reported depression at baseline (Jarvik et al., 2005). This applies not just to spinal pain. Incidental meniscal findings on MRI of the knee are common in the general population (Englund et al., 2008) and more than 60% of persons with one or more meniscal tears are asymptomatic. Further, a finding of meniscal pathology without frequent symptoms at baseline did not have a significant relationship with the development of knee symptomology 15 months later (Englund et al., 2007). Similarly, among persons with carpal tunnel syndrome there was no association between electrodiagnostic findings and symptoms/disability (Chan et al., 2007). In short, objective physical findings do not fully explain the symptom presentation of a large proportion of patients seen by physicians for complaints of pain. In fact, psychosocial factors may predict important outcomes

(e.g., return to work) better than physical variables such as MRI-identified morphologic abnormalities (Schade, Semmer, Main, Hora, & Boos, 1999).

Conversely, many people present to physicians with a variety of physical symptoms for which no medical explanation can be found. For example, 75% of the Englund et al. (2008) sample without meniscal pathology or radiographic evidence of osteoarthritis were symptomatic. Nearly 20% of patients seen in primary care clinics present with medically unexplained symptoms, a finding not explained by comorbid depression or anxiety (Barsky, Orav, & Bates, 2005). Among first-time referrals to a neurology service, 61% (59% of females, 63% of males) had at least one medically unexplained symptom (Fink, Steen Hansen, & Sondergaard, 2005). Thirty-four percent (41.3% of females, 27.7% of males; 20.5% of inpatients, 43.2% of outpatients) of the Fink et al. (2005) cases met the diagnostic ICD-10 criteria for a somatoform disorder. Neuropsychologists are familiar with psychogenic nonepileptic seizures, which are diagnosed in approximately 30% of patients evaluated using video-EEG monitoring (Benbadis, O'Neill, Tatum, & Heriaud, 2004; Gates, Ramani, Whalen, & Loewenson, 1985; Martin, Burneo, Prasad, et al., 2003).

In short, pain and pain-related disability are complex biopsychosocial phenomena, and consideration of psychosocial factors is essential for a comprehensive understanding and appropriate treatment of pain and patients with pain (Gatchel & Okifuji, 2006). This chapter will review the science of pain and pain-related disability including the neuroanatomy/neurophysiology of pain as well as the psychosocial/person factors and context/system factors that influence pain-related disability. Assessment of the patient with chronic pain will then be reviewed followed by a discussion of behavioral approaches to the management of pain-related disability.

## Neuroanatomy and Physiology

Pain is the unpleasant experience associated with tissue damage or potential tissue damage. As such, it is a neurobiological phenomenon. However, by its very nature, pain is a cognitive and emotional phenomenon as well. This section is intended to provide the neuropsychologist with some understanding of the neurobiology of pain and the neural mechanisms linking pain to important psychological factors such as anxiety and depression. A full discussion of the neurobiology of pain is beyond the scope of this chapter. The interested reader is referred to Deer et al. (2013), McMahan, Koltzenburg, Tracey, and Turk (2013) and Millan (1999), for a more in-depth review of this topic.

### Neural Systems of Pain

Nociception is the neural mechanism that allows the organism to detect possible tissue damage (Jaggar, 2005). Once a nociceptive event is detected, the neural signal is transmitted

primarily by two types of neuronal fibers, A $\delta$  and C fibers. A $\delta$  fibers are larger and more myelinated than C-fibers, which are generally unmyelinated but make up the majority of afferent nociceptive input (Cafferty, 2005; Millan, 1999). These two fiber systems transmit information of different types at different speeds. A $\delta$  signals are received as a first wave of pain and perceived as sharp in nature, while the unmyelinated C-fibers conduct a slower second wave of pain signals that are perceived as dull in nature (Cafferty, 2005; Millan, 1999).

This information is transmitted to the dorsal horn of the spinal cord and from there it is transmitted from the spinal cord to the thalamus primarily along a spinothalamic pathway (Hoffman, Harrington, & Fields, 2005). The thalamus projects to sensory areas (S1 and S2) of the cortex (Wager, 2005; Hoffman et al., 2005). Spinal cord and sensory area neurons also project to the anterior insula (AINS), and the anterior cingulate cortex (ACC), which are believed to be involved in the affective qualities of pain (Craig, Chen, Bandy, & Reiman, 2000; Wager, 2005). These pain signals are believed to be further processed and evaluated through complex interconnections within the orbitofrontal cortex (OFC), AINS, and ACC. These signals may be maintained and elaborated upon through cognitive processes (e.g., attention) in the dorsolateral prefrontal cortex (DLPFC) and ventrolateral prefrontal cortex (VLPFC) (Wager, 2005).

This emotional/affective information and attention-enhanced information is then transmitted back to the periaqueductal gray (PAG) and then to rostral ventromedial medulla (RVM), particularly the RVM's nucleus raphe magnus (NRM). The NRM, which is rich in serotonergic neurons, connects to interneurons in the dorsal horn of the spinal cord, forming a descending pain control pathway that can influence ascending pain signals (Hoffman et al., 2005). This has been referred to as the *Gate Control Theory of Pain* (Melzack & Wall, 1965). Thus, these higher level cortical/neurocognitive processes can inhibit or enhance ascending pain signals and thus influence the experience of pain.

In addition to providing a mechanism for pain relief, it also appears that aspects of this system can influence descending input that can increase pain sensitivity through mechanisms like anxiety and depression. Anxiety specifically is known to activate the hypothalamic-pituitary-adrenal (HPA) axis. The anticipation of pain is known to activate a pro-nociceptive neuropeptide known as cholecystokinin (CCK) and to be associated with a reduction in dopamine levels (Benedetti, 2009). These neurotransmitters will be briefly discussed in the next section; for a more in-depth discussion of dopamine, CCK, and anxiety the reader is referred to Benedetti (2009).

### Pain-related Neurotransmitters

#### Opioids

Opioids are powerful analgesics that can be classified generally into two categories, weak (e.g., codeine) and strong

(e.g., morphine), which describe their relative efficacy and receptor site affinity (Twycross, 1994). Opiates (derivatives of the poppy plant) and opioids (synthetic molecules) bind to opioid receptors producing an analgesic response relative to the category in which they belong. Opioid receptors are found throughout the brain, brain stem, and the spinal cord (Benedetti, 2009). Receptors are found to be particularly dense in the cingulate cortex, prefrontal cortex (Pfeiffer, Pasi, Mehraein, & Herz, 1982), PAG, and RVM (Fields, 2004). The latter two areas, as mentioned earlier, are particularly important for the blockade of ascending pain signals. The neurotransmitters described in the following subsections work through the opioid system by inhibiting or facilitating the release of endorphins and enkephalins, the brain's endogenous opioids.

#### *Cholecystokinin (CCK)*

Cholecystokinin (CCK) is an endogenous peptide. Its receptors are found in the same structures as opioid receptors and in approximately the same density. In the central nervous system, CCK is considered to be a pro-nociceptive neurotransmitter, increasing pain perception and exacerbating symptoms (Enck, Benedetti, & Schedlowski, 2008). CCK, for example, has been experimentally shown to reverse opioid analgesia (Mitchell, Lowe, & Fields, 1998; Heinricher, McGaraughty, & Tortorici, 2001) by acting on the pain-facilitating neurons within RVM (Heinricher & Neubert, 2004). CCK is also involved with the anticipatory anxiety specifically associated with impending pain rather than a global anxiogenic event (Benedetti et al., 2006; Koyama, Tanaka, & Mikami, 1998; Sawamoto et al., 2000).

#### *Dopamine*

There are two primary dopamine (DA) cell groups—the substantia nigra pars compacta and the ventral tegmental area—and each has disparate neuronal projections (Alexander, DeLong, & Strick, 1986; de la Fuente-Fernandez & Stoessl, 2002). The substantia nigra, which projects primarily to the dorsal striatum, is primarily involved in motor function (de la Fuente-Fernandez & Stoessl, 2002) and is not relevant for pain. The second major group of DA neurons originates in the ventral tegmental area (VTA) and projects to other brain structures via two pathways. The first projects via the mesolimbic pathway to subcortical limbic structures (ventral striatum, amygdala, hippocampus, olfactory tubercle, and septal region). The second projects via the mesocortical pathway from lateral regions of the VTA to frontal cortical regions (de la Fuente-Fernandez & Stoessl, 2002). Both the pathways are associated with pain sensitivity and inhibition. The limbic and prefrontal cortex can influence opioid release via DA input directly into the PAG (Christie, James, & Beart, 1986). The VTA also has direct projections to the PAG (Beitz, 1982). The nucleus accumbens (NA), which is

involved in pain-related placebo responses (de la Fuente-Fernandez & Stoessl, 2002; Scott et al., 2008), influences PAG via the hypothalamus (Yu & Han, 1989). In addition, the PAG has projections back to limbic structures including the VTA, NA, amygdala and limbic frontal areas (Cameron, Khan, Westlund, Cliffer, & Willis, 1995). These reciprocal connections indicate a relationship between dopamine release and the *perception* of pain (de la Fuente-Fernandez & Stoessl, 2002). There are DA-related pain systems separate from these cortical-subcortical pathways. The dorsal horn of the spinal cord is the site at which ascending sensory information, including pain signals, enters the spinal cord. Dopaminergic networks there have the capacity to inhibit or facilitate pain signaling in complex ways depending on the amount of DA released (Millan, 1999).

#### *Serotonin/Norepinephrine*

Serotonin (5-hydroxytryptamine, 5-HT) and norepinephrine (NE) are monoamine neurotransmitters whose association with depression is well known. In addition to the role 5-HT plays in depression, its role in the inhibition and promotion of pain is also well known, if less well understood. Moreover, depression and pain appear to be closely linked. There is a growing body of literature regarding what some have referred to as the “depression-pain syndrome” (Bair, Robinson, Katon, & Kroenke, 2003). Serotonin-containing neurons are found in the RVM (in particular, the NRM). These neurons project to dorsal horn interneurons and are involved in the inhibition of ascending pain signals (Sommer, 2004). Like 5-HT, NE is involved in the suppression of ascending pain signals from the dorsal horn of the spinal cord. The NE neurons that influence ascending pain signals originate in the dorsolateral pontine tegmentum (DLPT) and project to the RVM as well as directly to the dorsal horn (Bair et al., 2003). It appears that NE and 5-HT have a complex relationship in the inhibition of ascending nociceptive information. In this context, it is necessary to discuss two types of RVM interneuron: on-cells and off-cells. On-cells facilitate pain transmission from the periphery to the spinal cord; off-cells inhibit pain signals that are ascending from the spinal cord to higher levels of the nervous system. Both are activated by stimulation of PAG (Bair et al., 2003; Benarroch, 2008). It is thought that the role of this system is to prioritize attentional resources to external painful events and minimize attention to internal pain signals (Bair et al., 2003; Okada, Murase, & Kawakita, 1999). However, disrupting serotonergic and noradrenergic activity as occurs during depression may result in the amplification of internal pain states and increased perception of normally suppressed pain signals (Bair et al., 2003). This research offers a potential biological mechanism underlying the well-documented link between depression and pain. Therapeutically, selective serotonin reuptake inhibitor (SSRI) and serotonin-norepinephrine reuptake inhibitor (SNRI) drugs have differential effects on pain (Zhao et al.,

2007) with SNRIs being more effective than SSRIs (Benarroch, 2008).

### Summary

One of the take-home messages from this section is that complex ascending and descending neural systems can modulate nociceptive signals associated with specific injury so that the pain experienced is greater than that produced by the pathophysiology of the actual injury itself. Research using a placebo/nocebo methodology has contributed to the elucidation of the complex neurobiological systems that underpin pain experience. Moreover, this methodology has demonstrated how nonbiological factors can exert a powerful influence on these neurobiological systems. While there is debate over precise definitions (see for example, Stewart-Williams & Podd, 2004), for purposes of the following discussion, a placebo or nocebo, generally, is a substance or procedure that has no inherent power to produce the effect that is sought or expected. A placebo effect is a genuine *positive/beneficial* psychological or physiological response that is attributable to receiving a substance or undergoing a procedure, but is not due to the inherent powers of that substance or procedure. A nocebo effect is a genuine *negative/adverse* psychological or physiological response that is attributable to receiving a substance or undergoing a procedure, but is not due to the inherent powers of that substance or procedure.

Expectancy and classical conditioning are believed to be the principal processes responsible for the placebo/nocebo effect (Benedetti, 2008, 2009; Evans, 2004; Finniss, Kaptchuk, Miller, & Benedetti, 2010; Hoffman et al., 2005; Kirsch, 1999; Moerman, 2002; Montgomery & Kirsch, 1996, 1997; Price et al. 1999; Price, Finiss, & Benedetti, 2008; Stewart-Williams, 2004; Stewart-Williams & Podd, 2004; Voudouris, Peck, & Coleman, 1989, 1990). Expectancy is thought to be acquired in a number of ways including direct personal experience, verbal instructions (suggestion), observational learning, and contextual factors (Stewart-Williams, 2004). The use of the term *expectancy* does not imply a cognitive process of which the individual is aware; “expectancy” effects are also observed in animals. How do expectancies manifest? There can be a dose response in which two placebo pills are better than one and in which the color and a suggested meaning of the color (sedative vs. stimulant) of the pills influence perceived effects (Blackwell, Bloomfield, & Buncher, 1972). Placebo injections may be perceived as more powerful than oral placebos (de Craen, Tijssen, de Gans, & Kleijnen, 2000). Surgical intervention can have the most profound effect of all.

A surgical procedure of ligating internal mammary arteries to relieve angina pectoris in the 1950s was a common practice. This practice was called into question, and two independent teams of surgeons and cardiologists explored the practice by conducting double-blind trials (Cobb, Thomas, Dillard, &

Marendino, & Bruce, 1959; Dimond, Kittle, & Crockett, 1960). The surgeons performing the procedure were not informed until the moment of surgery whether the patient would receive the real or sham procedure, which involved everything except ligating the internal mammary arteries. A six-month follow-up by blinded cardiologists indicated 67% of patients receiving the full surgery reported substantial improvement while 82% of patients receiving the sham surgery reported substantial improvement. Improvement was measured as longer exercise times, fewer nitroglycerine tablets, reduction in pain, and in some cases improved ECG readings (Wall, 1996). In another surgical example, Moseley, Wray, and Kuykendall (1996) and Moseley et al. (2002) conducted two randomized controlled placebo trials using patients with osteoarthritis of the knee. Placebo patients were put to sleep, draped, injected with a local anesthetic and given three stab wounds to the skin, as would have been done in an arthroscopic debridement. The arthroscopic instruments were inserted and a debridement was simulated in case the patient was aware during the surgical procedure. Results measured at several time points for two years indicated placebo treatment was significantly better than debridement for up to a year and at two years there was no significant difference, although placebo still outperformed debridement. In addition the 2002 study included psychological measures evaluating anxiety, depression, optimism, health satisfaction, somatization, stress, and vitality. There were no differences between groups on any of these measures. It is worth highlighting the duration of perceived benefit here as placebos are often considered to be transient occurrences.

Can expectancy enhance effective therapy? Analysis of five widely administered postoperative analgesics (morphine, buprenorphine, tramadol, ketorolac, metamizole) using an open versus hidden paradigm have been conducted (Amanzio, Pollo, Maggi, & Benedetti, 2001; Colloca, Lopiano, Lanotte, & Benedetti, 2004). In these evaluations doctors would carry out an open administration (bedside) for each of these drugs, telling patients the injection was a powerful analgesic and the pain would subside after a few minutes. This was compared to an automatic infusion pump administering the same dose of each of the medications without patient awareness. The analyses found the dose required to achieve 50% pain reduction (ED50) was significantly increased when the administration was hidden for each of the five drugs. The only difference between groups was the presence of medical practitioners and verbal assurance.

Expectancy not only lends itself to symptom improvement but importantly to symptom worsening as well. Verbal suggestion alone can influence the perception of analgesia from nitrous oxide to that of hyperalgesia (Dworkin, Chen, LeResche, & Clark, 1983). Nocebo designed open/hidden paradigms have been explored as well. In a study of postoperative patients receiving morphine for 48 hours, some patients were told that their morphine had been stopped (open condition) and some patients were told nothing about

their morphine being discontinued (hidden condition). At 10 hours after morphine interruption, a significantly larger number of patients in the open condition requested more morphine than the hidden condition (Benedetti et al. 2003; Colloca et al. 2004).

Voudouris, Peck and Coleman (1989, 1990) conditioned subjects to painful electronic stimulation over a period of three days. On Day 1 a tolerance level was established. On Day 2, participants received a placebo cream and were told that it was an analgesic. In addition, they were told that the electrical stimulation intensity was the same as the day before; when in reality the voltage had been turned down or turned up. On Day 3, voltage was returned to Day 1 levels. Subjects who had experienced a lessened voltage on Day 2 reported much less pain, while subjects exposed to more voltage experienced heightened pain. In another study, Benedetti et al. (2003) conditioned two groups of subjects pharmacologically with ketorolac (a nonopioid analgesic) for two days while two other groups received no conditioning and a natural history group was included for comparative purposes. On Day 3 the conditioned groups were given a saline injection and were told it was a powerful analgesic or were told it was hyperalgesic. The unconditioned groups were simply given a saline injection and told that it was a powerful analgesic or hyperalgesic. Results indicated that for the conditioned analgesia group, they experienced a dramatic reduction in pain. The unconditioned analgesia group experienced a reduction in pain compared to the natural history group, but was nowhere near the magnitude of the conditioned group. The second conditioned group when administered saline and the suggestion of pain worsening experienced a complete reversal of all conditioned analgesia. A number of other studies have observed similar conditioning/abolishment results (Kirsch, 1999; Montgomery & Kirsch, 1996; Price, Milling, Kirsch, Duff, Montgomery et al., 1999).

Analgesia and hyperalgesia can be conditioned, and if verbal expectancy is combined with the conditioning process, analgesia can be greatly increased or conditioning can be completely abolished. In short, placebo/nocebo effects demonstrate how external factors can influence the activity of the neurobiological pain system such that experienced pain can be magnified or suppressed. This research offers a physiological mechanism by which nonbiological factors including personality style, psychological distress, psychosocial stress, and sociodemographic variables can influence the experience of pain and the degree of pain-related disability. The following sections review the research on the role of person-centered variables and system-centered variables in the clinical management of pain.

### Psychosocial/Person Factors

Consideration of person-centered psychosocial factors is essential for a comprehensive understanding and appropriate treatment of patients with pain (see the following for

detailed reviews: Gatchel, 2004; Keefe, Rumble, Scipio, Giordano, & Perri, 2004; Linton, 2000). Injury recovery is affected by person-centered physical characteristics such as age and weight as well as demographic factors such as education and income (Crook & Moldofsky, 1994; Rubin, 2007; Stover, Wickizer, Zimmerman, Fulton-Kehoe, & Franklin, 2007). Psychosocial factors serve as important prognostic indicators of cases that transition from acute to chronic pain (Carragee, Alamin, Miller, & Carragee, 2005; Dersh, Gatchel, & Polatin, 2001; Keefe et al., 2004; Linton, 2000; Pincus, Burton, Vogel, & Field, 2002). Psychopathology can increase perceived pain intensity, hamper rehabilitation efforts, and magnify perceived disabilities—all of which serve to reinforce and perpetuate pain-related dysfunction (Gatchel & Dersh, 2002; Holzberg, Robinson, Geisser, & Gremillion, 1996; Leeuw et al., 2007).

The relationship between psychosocial factors and pain-related disability is not simple cause-and-effect but is instead reciprocal and complex. Linton (2000) concluded that these factors are related to every aspect and phase of neck and back pain, and are particularly important in the transition between acute and chronic pain. The following subsection will review several of these factors and their relationship to outcome in pain-related conditions. The subsequent subsection will review the influence of socioeconomic factors in pain. While this chapter presents these factors in discrete sections, this should not imply independence. Many of the factors are closely linked conceptually and functionally, and recognition of their interrelatedness is important.

### Childhood Adversity

Childhood adversity in the form of abuse, neglect, and abandonment has proven an important predictor of current and future mental health (Arnow, 2004; Taylor & Jason, 2002; Widom, DuMont, & Czaja, 2007). Childhood sexual abuse in particular is associated with the presence of medically unexplained symptoms such as irritable bowel syndrome and chronic pain, and with high health care use (Nelson, Baldwin, & Taylor, 2012). Brown, Schrag, and Trimble (2005) found that physical/emotional abuse was more common and more extreme in patients with unexplained neurological symptoms who met *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria for somatization disorder than in those with a neurologically based dystonia. A higher degree of family conflict was present in the somatization group; however, there were no group differences for neglect, sexual abuse, or witnessing violence. Exposure to emotional abuse accounted for 50% of the variance in unexplained symptoms. These effects are not simply explained by psychiatric comorbidity. Spitzer, Barnow, Gau, Freyberger, and Grabe (2008) found that the odds of having been sexually abused in childhood were nine times higher in persons who met DSM criteria for somatization disorder than in those meeting criteria for major depressive disorder.

Childhood adversity is also an important predictor of pain symptoms (Davis, Luecken, & Zautra, 2005). For example, Walker, Gelfand, Gelfand, Green, and Katon (1996) found that women with both irritable bowel syndrome and chronic pelvic pain were significantly more likely to have a history of childhood sexual abuse as well as a variety of mood and anxiety disorders, somatization disorder, and hysterectomy. Childhood adversities are more common in somatoform pain disorder, and fibromyalgia is particularly associated with severe maltreatment in childhood (Imbierowicz & Egle, 2003; Walker et al., 1997; Wolfe & Hawley, 1998). Brown, Berenson, and Cohen (2005) surveyed a community sample and found that adult chronic pain was associated with a history of sexual abuse, and that this effect was not attributable to the presence of depression at the time the survey was completed. Walsh, Jamieson, Macmillan, and Boyle (2007) found that a history of physical and sexual abuse differentiated adult chronic pain patients with disability in some aspect of their life from those with pain but without disability.

A history of childhood adversity is also associated with outcomes in the treatment of pain (Linton, 2000). Two studies are particularly revealing. In the first study, Schofferman, Anderson, Hines, Smith, and White (1992) retrospectively examined 86 patients who underwent lumbar spine surgery. Five types of childhood trauma were considered: (a) physical abuse, (b) sexual abuse, (c) emotional neglect or abuse, (d) abandonment, and (d) a chemically dependent caregiver. Of patients who had experienced three or more of these types of trauma, 85% had unsuccessful surgical outcomes. In contrast, only 5% of the patients who had experienced none of these traumas had unsuccessful surgery. A similar study of patients who had undergone multidisciplinary evaluation for refractory back pain also found a high incidence of childhood traumas, especially in patients with minimal signs of pathology (Schofferman, Anderson, Hines, Smith, & Keane, 1993). Not surprisingly, health care utilization is greater in persons with a history of abuse, neglect, or serious family dysfunction in childhood (Arnow, 2004; Arnow, Hart, Hayward, Dea, & Barr-Taylor, 2000). Even disability retirement is associated with childhood adversity. Of nearly 9,000 community survey respondents ranging in age from 40 to 54, those with multiple childhood adversities were more than three times as likely to take disability retirement compared to those with no history of such adversity (Harkonmaki et al., 2007). Spitzer et al. (2008) concluded "childhood sexual abuse is an important factor in the multifactorial aetiopathogenesis of somatization disorder" (p. 335) and Arnow (2004) stated that "the more severe the abuse, the stronger the association with poor outcomes in adulthood" (p. 10).

The mechanisms underlying the translation of adverse childhood experiences into health-related phenomena are complex and multifactorial (Spitzer et al., 2008). Physiologically, childhood adversity is known to cause acute and chronic disruption of the HPA axis (Bremner & Vermetten,

2001; Tarullo & Gunnar, 2006; Teicher et al., 2003). It is also associated with the development of psychopathology and certain pain syndromes (i.e., chronic pelvic pain; see Heim, Ehler, Haker, & Hellhammer, 1998). Behaviorally, Waldinger, Schulz, Barsky, and Ahernet al. (2006) found that in women, fearful attachment mediated the link between childhood trauma and somatization. In men, attachment style and trauma each contributed independently to the development of somatization. The authors concluded that "childhood trauma shapes patients' styles of relating to others in times of need, and these styles, in turn, influence the somatization process" (Waldinger et al., 2006, p. 129). The process of somatization may be one link between childhood psychological trauma and problematic pain outcomes (Roelofs & Spinhoven, 2007).

### **Somatization**

Somatization and related terms (e.g., somatoform disorder) have a complex and sometimes controversial history (Lamberty, 2008). Nonetheless, as a narrow concept, somatization is a central factor in understanding disability attributed to chronic pain. Somatization refers to the way

certain patients use their physical symptoms as a way of dealing with, and communicating about, their emotional lives . . . in this type of symptom magnification, physical symptoms may be easier to accept as causing current unhappiness and discontent than admitting that some psychological reason is contributing to it.

(Gatchel, 2004, p. 204)

In short, somatization reflects the expression of psychological problems through physical symptoms and complaints, a tendency to complain of or develop physical symptoms and illness when under emotional stress, and be excessively focused on one's physical functioning. Somatization may be best viewed as a potentially maladaptive personality and/or coping style. As used here, *somatization* refers not to a diagnostic entity but to a mode of thinking about one's self and world that contributes to medically unexplained illness and excess disability. Somatoform tendencies include cognitive, perceptual, and behavioral features. Elements include excessive worry about serious illness (i.e., hypochondriasis), hypervigilance towards bodily sensations, negative interpretations or disease attributions for benign sensations, sensitivity to unpleasant somatic sensations, and excessive care seeking or need for illness validation. These factors are often viewed as a cycle in which cognitions, perceptions, and behaviors mutually reinforce and strengthen each other (Barsky & Borus, 1999). It is important to recognize that patients with somatoform tendencies and/or disorders are not necessarily consciously magnifying their symptoms, as is seen with factitious disorders and malingering, but instead hold a conviction that they are physically ill.

Among patients with chronic pain, somatization is associated with more medically unexplained symptoms, poorer response to treatment, and future development of disability. Elevations on scales 1 (Hypochondriasis) and 3 (Hysteria) of the Minnesota Multiphasic Personality Inventory (MMPI; Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989; Hathaway & McKinley, 1943) are considered indicators of somatization (Block, Gatchel, Deardorff, & Guyer, 2003; Blumetti & Modesti, 1976; Friedman, Gleser, Smeltzer, Wakefield, & Schwartz, 1983; Marks & Seeman, 1963). Block, Vanharanta, Ohnmeiss, and Guyer (1996) found a higher incidence of nonorganic symptom responses on discograms in patients with elevation on MMPI Scales 1 and 3. also found that these MMPI elevations were associated with poorer response to both surgery and conservative care (e.g., Block et al., 1996). Gatchel, Polatin, Mayer, and Garcy (1994) found that among acute back pain patients, elevations on MMPI Scale 3 predicted higher levels of disability one year later. Bigos et al. (1991) and Applegate et al. (2005) showed that early (preinjury) tendencies or predispositions for somatization, as measured by the MMPI, are linked to subsequent development of physical symptoms including back pain. Bigos et al. (1991) conducted a longitudinal study of 3,020 aircraft employees to identify risk factors for reporting acute back pain at work. About 16% of these workers developed back problems over the four-year follow-up period. The 20% of participants with the highest Scale 3 scores were twice as likely to report back problems as those with lower scores. Applegate et al. (2005) found that the MMPI at college admission ( $N = 2,332$ ) predicted pain-related conditions at 30-year follow up. Among men, MMPI Scales 1, 3, and 5 were most predictive of the number of chronic pain conditions. Among women, Scales 1, 3, and 6 were most predictive. For both men and women, Scales 1 and 3 predict chronic pain 30 years later.

### **Catastrophizing**

Over the past 25 years “pain catastrophizing” has emerged as an important predictor of pain experience and pain-related disability (Sullivan et al., 2001). Pain catastrophizing has been defined as a tendency to fear pain, have a fear-inducing understanding of the meaning of pain (e.g., the presence of pain is an indication of harm), and/or a tendency to allow pain to be a dominant focus of one’s life (Proctor, Gatchel, & Robinson, 2000). More simply, it is the interpretation of pain as being extremely threatening (Crombez, Eccleston, Baeyens, & Eelen, 1998). Psychometrically, pain catastrophizing has proven to be a stable construct that is related to but not redundant with depression and other forms of psychological distress (Sullivan et al., 2001).

Turner and Aaron (2001) suggest that catastrophizing reflects a relatively stable personality disposition whose manifestation may be influenced by situational variables such as changes in physical condition or implementation of

specific cognitive interventions. Theoretical formulations to explain pain catastrophizing and hypotheses regarding the mechanisms by which pain catastrophizing influence reports of pain and pain-related disability have only begun to emerge (Sullivan et al., 2001; Turner & Aaron, 2001). Edwards, Bingham, Bathon, and Haythornthwaite (2006) reviewed four mechanisms by which pain catastrophizing may act: (a) interfering with pain coping and beneficial health behaviors, (b) increasing attention to pain, (c) amplifying pain processing in the central nervous system, and (d) maladaptive impacts on the social environment.

Pain catastrophizing predicts the development of chronic pain complaints in the general population. Pain catastrophizing is associated with greater pain vigilance and preoccupation with pain and physical problems (Goubert, Crombez, & Van Damme, 2004), and it may mediate the reduced activity level seen in some clinical patients (Sullivan, Stanish, Sullivan, & Tripp, 2002). Pain catastrophizing is also related to a variety of important functional and outcome variables, pain intensity, psychological distress, and level of disability (Severeijns, Vlaeyen, van den Hout, & Weber, 2001; Turner, Jensen, Warms, & Cardenas, 2002; Woby, Watson, Roach, and Urmston (2004). This relationship is independent of the level of physical injury or impairment (Severeijns et al., 2001). For reviews of pain catastrophizing, see Sullivan et al. (2001) and Edwards et al. (2006). There is evidence that pain catastrophizing is a precursor to the development of pain-related fear (Leeuw et al., 2007).

### **Depression and Anxiety**

Depression and anxiety disorders are common in patients with chronic pain. In a large survey of the general population, approximately 18% of persons reporting chronic spinal pain were diagnosed with a comorbid mood disorder, while approximately 27% were diagnosed with some form of anxiety disorder (Von Korff et al., 2005). Patients seeking treatment for pain-related conditions are particularly likely to report symptoms of depression, as the prevalence of major depression in this population has been reported to be more than 50% (Dersh, Gatchel, Mayer, Polatin, & Temple, 2006; Mayer, Towns, Neblett, Theodore, & Gatchel, 2008).

Depression is a particularly important consideration in patients with chronic pain as studies have shown a near linear association between self-reported pain intensity and depressive symptoms (Carroll, Cassidy, & Côté, 2000; Currie & Wang, 2004). However, depression and chronic pain have a complex, reciprocal, relationship: (a) there is some overlap between symptoms (e.g., sleep disturbances or reduced activity levels); (b) they may share physiological mechanisms, specifically NE and 5-HT dysregulation (Bair et al., 2003); (c) the presence of either predicts future development of the other (Gureje, Simon, & Von Korff, 2001); and (d) comorbidity complicates treatment for both conditions (Moultry & Poon,

2009). Depression may be a particularly important predictor of pain-related disability (Alshuler, Theisen-Goodvich, Haig, & Geisser, 2008), with studies suggesting that it may serve as a moderator for the relationships between other psychological vulnerabilities discussed in this section and self-perceived disability (Boersma & Linton, 2005, 2006).

Anxiety can also influence perceptions of pain and response to treatment. Anxious expectations have been found to significantly increase the perceived intensity of painful stimuli by directly facilitating nociceptive transmission (Colloca & Benedetti, 2007). Anxiety also impacts outcome following surgery, as higher presurgical anxiety is associated with slower recovery and more complications postsurgery (Kiecolt-Glaser, Page, Marucha, MacCallum, & Glaser, 1998). Similarly, Trief, Grant, and Fredrickson (2000) found that higher levels of presurgical anxiety significantly predicted poorer functional outcome one year after receiving lumbar spine surgery to relieve pain. The negative effects of anxiety on patient outcome may be explained in part by the relationship between anxiety sensitivity and fear of pain (Martin, McGrath, Brown, & Katz, 2007).

### **Education**

Lower education is associated with the presence of chronic pain (Rashiq & Dick, 2009) and has been identified as a prognostic indicator of work-related disability (Abásolo et al., 2012; Breslin et al., 2008; Hagen, Holte, Tambs, & Bjerkedal, 2000). Lower education is associated with longer pain duration following back injury and a higher rate of pain recurrence (Dionne et al., 2001). Even after controlling for age, pain duration, sex, and incentive status, lower education is significant associated with higher self-perceived disability (Janowski, Steuden, & Kuryłowicz, 2010; Moffett, Underwood, & Gardiner, 2009; Roth & Geisser, 2002). Lower education is also associated with more misconceptions about back pain (Goubert, Crombez, & De Bourdeaudhuij, 2004). Roth and Geisser (2002) concluded that the relationship between education and disability was mediated by maladaptive pain beliefs and coping strategies. Arts, Kols, Onderwater, and Peul (2012) found that education was the only baseline characteristic associated (negative correlation) with outcome from spine surgery. To the extent that educational achievement and measured intelligence are correlated, measured intelligence would also likely be an important variable to consider.

### **Fear Avoidance**

Fear is a reaction that occurs in the presence of a specific, identifiable, immediate threat and often leads to escape or avoidance behaviors (Rachman, 1998). Fear-avoidance models of chronic pain-related disability hypothesize that the emotional, cognitive, and behavioral factors discussed earlier interact with the pain experience to contribute to a

reinforcing cycle of fear and anxiety towards pain-related stimuli (see Asmundson, Vlaeyen, & Crombez, 2004; Vlaeyen, Kole-Snijders, Boeren, & van Eek, 1995; Vlaeyen & Linton, 2000). Fears can be directed towards pain itself, reinjury, or specific activities such as movement (i.e., kinesiophobia). Avoidance of activities, in turn, contributes to the development and maintenance of functional disability (Leeuw et al., 2007; Woby et al., 2004). Fear-avoidance models of pain-related disability are similar to models of the development and maintenance of panic disorder and agoraphobia (Klein & Gorman, 1987). The maladaptive element of the Fear-Avoidance Model is reciprocal, which allows for increasing disability and the development of comorbid depression. Pain catastrophizing appears to be a critical element, or trigger, in the development of pain-related fear and anxiety (Vlaeyen et al., 1995). It is the emotional and coping response to the injury which determines whether recovery will be complicated. Coping strategies account for adjustment to chronic pain above and beyond what is predicted by pain-related history and tendency to somaticize (Rosenstiel & Keefe, 1983). Regardless of the specific trigger, fear avoidance is an obstacle to functional improvement in chronic pain patients (Smeets, van Geel, & Verbunt, 2009; Turner et al., 2006; Vlaeyen et al., 1995; Vlaeyen & Linton, 2000). The presence of the various factors of the Fear-Avoidance Model are associated with poor outcome following spine surgery (Alodaibi, Minick, & Fritz, 2013) and with increased disability in patients with chronic pain (Zale, Lange, Fields, & Ditte, 2013).

### **Context/System Factors**

The focus of the previous section was on the role of person-centered psychosocial factors associated with a complicated clinical pain presentation. However, when injuries are sustained on the job, treatment and recovery from injury occur within a complex social network (e.g., employers, insurance adjusters, and attorneys). In this context, complications can arise from a number of sources, including the injured worker's attitudes about his or her work or company, the relationship with the insurance company and claims adjusters, treatment delays, attorney involvement, and litigation. These contextual effects are not limited to persons whose presentation is complicated by the person-centered psychosocial factors already described. Rather, contextual factors are known to impact injury recovery even in patients with well-described and documented physical injuries who might otherwise lack psychological complication. These context effects have been shown in patients with significant and objectively documented physical injuries and in patients whose injuries are more ambiguous (Atlas et al., 2006; Carroll et al., 2008; Cassidy, Carroll, Cote, Berglund, & Nygren, 2003; Cassidy et al., 2000). In the past 20 years a sizeable literature has developed examining noninjury characteristics/risk factors associated with the injury context and how these factors affect symptomatic and functional outcomes.

### **Occupation and Work-Related Factors**

Physical work load and job satisfaction both are prognostic indicators of back pain-related work absences and disability (Bigos et al., 1991; Hagen et al., 2002; Hoogendoorn et al., 2002; Shaw et al., 2005). Hagen et al. (2000) found that unskilled workers are two to three times more likely to retire due to disability than professionals. McIntosh, Frank, Hogg-Johnson, Bombardier, and Hall (2000) and Stover, Wickizer, Zimmerman, Fulton-Kehoe, and Franklin (2007) found that working in the construction industry to be among several factors that predicted work disability. Volinn, Van Koevering, and Loeser (1991) found that lower pay is associated with longer back pain chronicity. Similarly, Tate (1992) found that younger workers with higher preinjury wages, greater seniority, and less severe injuries were more likely to return to work postinjury.

Elements of the relationship between the worker and the company, including job satisfaction and availability of accommodations can also impact outcome and even the initiation of symptom reports. For example, in a study of 3,020 aircraft industry employees, those who reported that they “hardly ever” enjoyed their work were 2.5 times more likely to report a back injury than those who reported more positive feelings about their job/work (Bigos et al., 1991). Shaw, Pransky, Patterson, & Winters (2005) examined psychosocial factors in patients referred to an occupational medicine clinic for back pain and found that job characteristics including job tenure, physical work demands, availability of modified duty, and earlier reporting to employer, were more predictive of outcome than physical examination. Similarly, Turner et al. (2007) found that baseline demographic variables, symptom severity, functional limitations, lack of job accommodation, job physical demands, job psychosocial conditions, and psychosocial characteristics predicted chronic disability following a claim for carpal tunnel syndrome. Each domain of variables (sociodemographic, clinical, psychosocial, work related) added significantly to the prediction of chronic disability.

Aside from the complexities of these interactions, the injured worker who is attempting to return to work may encounter obstacles. For the subset of patients who have performed heavy physical labor, returning to their previous level of work may no longer be possible and a return to even modified work can pose considerable challenges. The sometimes daunting obstacles for a worker to return to work include insufficient training or education to do work other than heavy work, advanced age, a feeling of uncertainty about other job tasks, poor information or misinformation about what would be required for a work return, unavailability of vocational rehabilitation, and financial disincentives for returning to work.

### **Delays in Treatment**

When a work injury occurs there are a number of different sources of delay in the ultimate rehabilitation of the patient.

For example, in many state worker’s compensation systems second opinions can be required before surgeries or rehabilitation can be funded. Conversely, when the worker has attorney representation the duration claim is longer, suggesting some mechanism of delay (Bernanki & Tao, 2008; Olney, Quenzer, & Makowsky, 1999). Olney, Quenzer, and Makowsky (1999) found that among patients undergoing carpal tunnel release, contested worker’s compensation claims (those requiring the intervention of an attorney) were associated with a higher risk of poor outcome while patients with uncontested worker’s compensation claims had outcomes nearly as good as noncompensation patients. Following the switch from a tort-compensation system to a no-fault system in Canada, the average time between injury and claim resolution for whiplash was more than halved (Cassidy et al., 2000). This finding implies that delayed recovery, to the extent that it is reflected in time to claim resolution, is often a function of the compensation system.

The effects of these delays are not minor or inconsequential: The longer the delay between injury and treatment, the greater the probability of disability. Crook and Moldofsky (1994) conducted a prospective, longitudinal, cohort study of patients with musculoskeletal soft tissue impairment following a work-related injury. Among their findings was a strong relationship between the passage of time and persistent disability. Moreover, early attempts at work return contributed to a decrease in overall work disability. McIntosh, Frank, Hogg-Johnson, Bombardier, and Hall (2000) also found that the lag time from injury to treatment was a strong predictor of chronicity. Interestingly, they also found that workers with a previous history of back problems who had returned to work were more likely to return to work than first-time injured workers. In a population-based retrospective inception cohort study of 81,077 workers who had four or more days of work disability resulting from workplace injuries over six years (Stover, Wickizer, Zimmerman, Fulton-Kehoe, & Franklin, 2007), the length of time from claim filing to medical treatment was among several factors predicting long-term disability.

### **Satisfaction With Care**

The satisfaction of injured workers with their medical care has important implications for recovery and return to work. Wickizer, Franklin, Fulton-Kehoe, et al. (2004) studied 681 workers who had ongoing follow-up care after initial treatment and examined their satisfaction with interpersonal and technical aspects of care. They found that satisfaction was strongly and positively associated with their ratings of their overall treatment experience, explaining 38% of the observed variance. Injured workers who were less satisfied with their treatment experiences were 3.5 times more likely to still be out of work six or 12 months after filing the claim compared to patients whose treatment experience was more positive. The authors observed that it was not clear whether

“dissatisfaction leads to poorer outcomes, or whether the types of people most likely to have poor outcomes are most likely to be dissatisfied with care” (Wickizer, Franklin, Fulton-Kehoe, et al., 2004: 743). The same group (Wickizer, Franklin, Turner, et al., 2004) found that satisfaction with claims administration procedures was a significant predictor of attorney retention or appeal filing by an injured worker. However, Wickizer, Franklin, Turner, et al. (2004b) found that attorney retention occurred about one year on average after the initiation of the claim. This led them to conclude that attorney retention was a correlate rather than a predictor of disability. This is important because it shows not only the relationship with the company but also that the relationship with treatment providers can be important for understanding and predicting outcome in injured workers.

### ***Financial Incentive Effects***

It is not uncommon for chronic pain cases to be seen in a context involving financial compensation such as personal injury litigation, workers' compensation, or disability determinations. The presence of financial incentive is a robust predictor of outcome in patients with pain. Patients seen in a compensated context report significantly more pain, depression, and disability than patients not involved in compensation (Chibnall & Tait, 1994; Rainville, Sobel, Hartigan, & Wright, 1997; Rohling, Binder, & Langhinrichsen-Rohling, 1995). Further, compensation status is associated with overall decreased treatment efficacy (Gatchel, Polatin, & Mayer, 1995; Rainville et al., 1997; Rohling et al., 1995), including worse surgical outcomes (Harris, Mulford, Solomon, van Gelder, & Young, 2005) even for clearly defined spinal pathology (Atlas et al., 2006; Atlas et al., 2006; Voorhies, Jiang, & Thomas, 2007). As an example of the systemic effects of compensated context, recent changes to a “no fault” compensation system in Canada were found to result in a lower incidence of lower-back pain and whiplash injuries following accidents and better prognosis for recovery (Cameron et al., 2008; Cassidy et al., 2003). Overland et al. (2008) found that reports of pain, anxiety, depression, sleep disturbances, and somatic symptoms steadily increased as a financial disability determination neared and then steadily decreased after the determination was made.

Pain often occurs in the context of a legally compensable event such as a work-related injury or incident in which some other party is potentially liable and there are financial incentives to appear disabled. Therefore, malingering is a potential issue. The prevalence of malingering in patients with pain who are referred for psychological evaluation is between 20% and 50% (Mittenberg, Patton, Canyock, & Condit, 2002; Greve, Ord, Bianchini, & Curtis, 2009; Kay & Morris-Jones, 1998) depending on the method of assessment and case-specific factors. These rates are consistent with those reported in other compensable conditions and contexts such as criminal forensic settings (Ardolf, Denney, & Houston,

2007), Social Security disability evaluations (Chafetz, 2008), toxic exposure (Greve, Bianchini, Black, et al., 2006), TBI (Larrabee, 2003), and among Vietnam-era veterans receiving services within the Veterans Administration system (Larrabee, Millis, & Meyers, 2008). These studies demonstrate that overall malingering, including in patients with pain, is not a rare event or trivial phenomenon despite earlier claims to the contrary (e.g., Fishbain, Cutler, Rosomoff, & Rosomoff, 1999; Sears, Wickizer, & Franklin, 2008). Using published base rates of malingering, Chafetz and Underhill (2013) estimated the cost of malingering on Social Security disability examinations to be about \$20 billion in 2011. Given the prevalence of pain-related complaints in the general population, malingering in patients with pain potentially has a very significant economic impact.

Many indicators of malingered cognitive, emotional, and physical disability have now been validated in patients with chronic pain (for reviews, see Greve, Bianchini, & Brewer, 2013; Greve, Curtis, & Bianchini, 2013). A striking feature of some of these data is that the rate of positive findings (i.e., test failure) is associated in a dose-response fashion with increasing objective evidence of malingering but not with injury characteristics (Ben-Porath, Greve, Bianchini, & Kaufmann, 2009; Greve et al., 2010; Greve, Bianchini, Etherton, Ord, & Curtis, 2009; Greve, Etherton, Ord, Bianchini, & Curtis, 2009). This finding in pain patients is complemented by the finding in TBI patients that the magnitude of potential compensation is associated with malingering test failures (Bianchini, Curtis, & Greve, 2006). Interestingly, in Canada, a change in personal injury liability law was followed by a nearly 50% decline in disability claims related to back pain (Cassidy et al., 2003). Taken together, these findings support the conclusion that empirically defined “improbable” test performance is motivated by financial incentive and reinforce the need to consider the potential role of malingering in patients whose persisting disability is poorly explained by objective medical factors.

### **Clinical Applications**

The influence of these psychosocial and system factors on pain-related disability has implications for psychological assessment and treatment of the patient with pain, and for behavioral approaches to treatment. The psychological pain evaluation has the potential to illuminate the clinical circumstances of a given patient in a way and to a degree that is not possible in the evaluations of other clinicians. In fact, it is not uncommon for a patient with pain to be referred for a psychological evaluation after years of failed medical treatment efforts that have often frustrated multiple treaters. Other times the evaluation is initiated because of concerns about depression, though this is still usually in the context of slow or atypical recovery. Sometimes a case is referred specifically because the treater has suspicions of malingering. Regardless of the specific referral question, the psychological

evaluation can clarify the case and lead to treatment recommendations that can improve overall treatment efficacy, functional capacity, and quality of life.

### ***Psychological Pain Evaluation***

The psychological pain evaluation requires a comprehensive approach, one that actively considers all of the factors that can complicate the management of pain. The assessment approach recommended in this chapter is one that most neuropsychologists will find familiar. It is flexible in scope and test battery composition while still assessing the multiple behavioral domains relevant to the referral question. This multidimensional approach allows a comprehensive assessment of an individual's functional status that can lead to detailed recommendations regarding the management of his or her pain and pain-related disability and supply valuable information to vocational experts and life-care planners. The specific procedures selected (especially the inclusion of cognitive measures) will depend on the context of the evaluation and likely future uses of the data (e.g., ability testing data has significant value for vocational rehabilitation). This section is intended to provide an overview of the conceptual approach to the assessment of the chronic pain patient and not to review comprehensively or in detail the many psychological tests that might be included in such an evaluation. Examples will be provided and a table of some of available questionnaires is included (see Appendix on p. 845).

A careful review of all available medical records and, when possible, any other records that may have bearing on subsequent conclusions (e.g., accident reports, personnel records, depositions) is a central part of the psychological pain evaluation. It is recognized that some records may not be available or be incomplete, in other cases the records may be voluminous, and in still others there may be no or limited reimbursement for record review. Nonetheless, these records provide important context including the nature of the injury, treatment efforts and complications (e.g., infection at a surgical site, overuse of pain medications), indications of complicating behavioral factors (e.g., symptom magnification, nonphysiological responses to diagnostic testing), and evidence of the influence of extrajury stressors that can have an adverse effect on the clinical presentation (e.g., death of a loved one, legal problems). The records can also reveal inconsistencies in symptom report between different doctors (e.g., reporting a decrease in pain to the spine surgeon while reporting the same or worsening pain to the pain management doctor who is writing the narcotic prescriptions) and changes in the description of the accident over time.

Like any psychological evaluation, the pain psychological evaluation will typically begin with a clinical interview. This will generally address the nature of the accident, efforts at treatment, and current status including symptoms and complaints. However, the interview should also assess the variety of complicating factors such as recent and ongoing

psychosocial stressors, past psychiatric history, childhood psychological trauma, and job factors that might predict poor outcome from treatments. Ideally, patients should not be given information regarding pain-related symptoms, including symptom checklists and direct questioning about symptoms, until after they have been asked to spontaneously report all of their symptoms in all domains so as to reduce the risk of suggesting symptoms that may bias subjective report.

After the clinical interview the patient is administered standardized psychological and neuropsychological tests and procedures. The composition of the test battery will depend on the referral question and context of the evaluation. Typically, patients referred in a clinical (noncompensate) context for psychological screening prior to some form of invasive surgical procedure (e.g., spinal fusion, implantation of a dorsal column stimulator or intrathecal morphine pump) will be the most streamlined and may include only questionnaires. In contrast, patients seen as part of their workers' compensation or personality injury litigation claims may require more comprehensive batteries. Pain patients may report disabling problems in multiple functional domains (e.g., physical, emotional, and cognitive; see Schnurr & MacDonald, 1995; Meyers & Diep, 2000; Ericsson et al., 2002; Wilson, Eriksson, D'Eon, Mikail, & Emery, 2002), all of which may have important implications for the decision making of various clinicians (Gatchel, 2004).

Therefore, the psychological pain evaluation should be designed to objectively assess the common cognitive, psychological, emotional, and physical complaints of patients with pain and pain-related disability. Among cognitive domains that are functionally important are attention and concentration, processing speed, learning and memory, general knowledge, intelligence, and problem solving skills. These cognitive domains have implications for return to work (e.g., poor attention would potentially limit the ability of a person to return to work in a safety-sensitive position such as a crane operator) and alternative work placement/retraining (e.g., a laborer with average intelligence who is limited to light duty by his or her injury will have more retraining options that if he or she had low average/borderline intelligence). Moreover, lower educational achievement/measured intelligence is a risk factor for increased disability. Thus, it is helpful to use broad measures of intelligence such as the Wechsler Adult Intelligence Scale-IV or Wechsler Abbreviated Scale of Intelligence as well as well-validated neuropsychological tests of memory (e.g., California Verbal Learning Test or subtests from the Wechsler Memory Scale or Neuropsychological Assessment Battery).

Typically, current emotional state and personality style as well as physical complaints and perceived pain-related disability are evaluated in the clinical interview as well as with questionnaires. The Minnesota Multiphasic Personality Inventory (MMPI; see Hathaway & McKinley, 1943) in its modern forms (MMPI-2, Butcher et al., 1989; MMPI-2-RF,

Ben-Porath & Tellegen, 2008), are the most widely used psychological assessment instruments (Lubin, Larsen, & Matarazzo, 1984; Rabin, Barr, & Burton, 2005; Sharland & Gfeller, 2007). They are among also the most commonly used in evaluating chronic pain patients in general (e.g., Robinson, Swimmer, & Rallof, 1989; Keller & Butcher, 1991; Deardorff, Chino, & Scott, 1993; Slesinger, Archer, & Duane, 2002) and to predict response to pain management interventions (Love & Peck, 1987), the likelihood of return to work (e.g., Bigos et al., 1991; Vendrig, Derksen, & de Mey, 1999), and outcome from spinal surgery (Block et al., 2003). It is also helpful to include specific behavioral health measures such as the Battery for Health Improvement-2 (BHI-2; see Bruns & Disorbio, 2003), the Millon Behavioral Health Inventory (MBHI; see Millon, Green, & Meagher, 1982). The BHI-2 (a 217-item multiple choice test normed on physical rehabilitation patients) is particularly useful because it was developed specifically to assess many of the psychosocial and contextual factors already discussed as relevant for pain management and functional outcome. This part of the evaluation is often supplemented by specific measures of pain and pain-related disability.

Finally, there must also be a comprehensive assessment of response and performance validity because the results of psychological tests can be invalidated by biased responding and/or poor effort. Malingering is an obvious risk when a patient is seen in a compensated context. However, even in cases not seen in a compensation-seeking context magnification of pain-related disability may also be motivated by the desire to obtain pain medication. The MMPI-2 has scales whose accuracy in detecting symptom magnification and malingering has been documented (Greve et al., 2013). The accuracy of validity scales of the BHI-2 has been examined in rehabilitation patients responding honestly and in patients asked to exaggerate their problems. Among specialty pain questionnaires, lack of validity scales tends to be the rule. If cognitive tests are included then it will be necessary to include performance validity measures as well. We have recently outlined our approach to the assessment of validity in the psychological pain evaluation (Greve et al., 2013).

### ***The Preprocedure Psychological Screen***

The preprocedure psychological screen is a special case of the psychological pain evaluation, but one that contains the critical elements of any psychological pain evaluation. This chapter has already summarized the literature showing that psychosocial factors influence pain complaints and pain-related disability. The importance of considering such factors in the context of invasive medical efforts to relieve pain, which involve damaging tissue and thus have the potential to do harm, is essential.

Spine surgery's ultimate effectiveness . . . depends on much more than the surgeons' diagnostic acumen and

technological skill. Psychological factors exert very strong influences—ones that can improve, or inhibit, the patient's ultimate recovery . . . surgical results can be greatly augmented by the inclusion of psychological components in the assessment and preparation of patients for spine surgery, as well as in post-operative rehabilitation.

(Block et al., 2003, p. 4)

Block et al. (2003) have argued that preprocedure psychological screening is an essential component in the medical diagnostic process of spine surgery candidates, especially when the major goal is symptomatic pain reduction. Further emphasizing this point, Lebovits (2000) has stated that

although the treatment of a patient with chronic pain mandates a comprehensive evaluation of the medical as well as psychological contributions to the etiology, maintenance, and exacerbation of pain, evaluating and treating patients with chronic pain with a unimodal, strictly medical approach still occurs. This, unfortunately, often leads to iatrogenic effects, such as failed surgical interventions and activity restriction.

(Lebovits, 2000, p. 126)

The psychological assessment of surgical risk is not simply a matter of determining if a patient is psychotic, has a pathological body image, has somatic delusions, or is depressed. While the presence of significant psychopathology that might lead to postsurgical psychological instability or problems with medical compliance is an issue of importance, this type of problem may be a minority in presurgical pain cases, particularly those seen in a medicolegal context. Nelson, Novy, Averill, and Berry (1996) have argued that in addition to active psychosis, suicidality, untreated major depression, and substance dependence, factors such as somatization, lack of social support, and cognitive deficits should exclude patients from receiving a spinal cord stimulator. They also noted that disincentive to recover related to compensation or litigation issues was a factor that would require exclusion.

There is now strong empirical research regarding what psychological factors predict outcome from surgery (e.g., Block, 1996; Block et al., 2003; Bruns & Disorbio, 2009; Voorhies, Jiang, & Thomas, 2007). See Bruns and Disorbio (2009) for a review of a number of preprocedure psychological screening methods. Block and colleagues (Block et al., 2001; Epker & Block, 2001) have demonstrated that the presence of certain psychosocial factors predicts poor outcome from lumbar disc surgery. Among these factors are financial incentive, history of abuse or abandonment, job dissatisfaction, problems with social support, substance abuse, preexisting psychopathology, depression/anxiety, and pain catastrophizing as well as compliance problems and deception. These psychosocial risk factors have been summarized and integrated into a pre-surgical screen risk factor checklist by Block et al. (2001). A similar medical risk factor checklist is part of their comprehensive presurgical screen.

The presurgical screening approach developed by Block et al. (2001) has been thoroughly explicated (Block et al., 2003; Block, 2013; Block, Ben-Porath, & Marek, 2013) and the ultimate process is laid out in the form of an easy-to-use flowchart. The Block algorithm has recently been revised for use with the MMPI-2-RF (Block et al., 2013) and expanded to include spinal cord stimulator implantation. This latest screening model is particularly helpful because it provides specific cut scores for all the psychometric variables. While the original risk factor checklist allowed for a determination of high risk of poor surgical outcome due to psychosocial and medical risk factors, it did not offer other guidance. In contrast, the more recent methods offer treatment guidance ranging from “good prognosis, no psychological treatment needed” to “poor prognosis, discharge recommended,” with specific forms of intervention recommended for intermediate levels of risk.

Similar approaches have been reported for screening of patients being considered for intrathecal morphine pump and dorsal column stimulator implantation (Bruns & Disorbio, 2009; Jamison & Edwards, 2013). The model outlined by Bruns and Disorbio (2009) is based on data derived from the BHI-2 (Bruns & Disorbio, 2003). “Exclusionary” and “Cautionary” risk scores based on BHI-2 responses have been identified. The “exclusionary” criteria include such things as active suicidal or homicidal ideation, active delusional thinking, active substance abuse, and litigation. The “cautionary” scores include depression, cognitive disorder or low education, diffuse somatic complaints, job or doctor dissatisfaction, and history of abuse. Higher scores were required for an “exclusionary” factor to be positive (i.e., score level observed in about 1% of patients) than for a “cautionary” factor to be positive (i.e., score level observed in about 16% of patients). However, the method also includes information derived from medical examination (e.g., medically impossible symptoms, major inconsistencies, noncompliance), history (e.g., multiple failures of the same treatment, violation of opioid contract), and science (i.e., evidence that the proposed medical treatment would be injurious or ineffective given the circumstances). The numbers of positive “exclusionary” and “cautionary” can be compared to those of patients and healthy community members. However, specific guidance regarding surgical risk and advisability of other forms of intervention like that found in the Block algorithms has not been provided for the Bruns and Disorbio model.

At a conceptual level, Bruns and Disorbio (2009: 143) have emphasized that the preprocedure screen is a “collaborative biopsychosocial decision-making process” involving both the psychologist and physician. They caution against setting up an adversarial process in which the surgeon sees the psychological screen as an obstacle imposed from the outside (e.g., insurance company). At the same time, the psychologist needs to recognize that certain factors related to medical necessity may trump the psychosocial risk factors (e.g., when there is imminent risk to life or function). For example, while

depression is a negative predictor of surgical outcome, a successful spinal cord stimulator implantation (defined as a 50% reduction in pain) can lead to improvement in depressive symptoms (Jamison, 2008). At this point, the research literature on predicting outcome in individual patients undergoing treatment with pumps or stimulators remains relatively small (Jamison & Edwards, 2013). Nonetheless, outcome related to pumps and stimulators is related to the same factors as outcome from spine surgery. In general, preprocedure psychological screening like that proposed by Block should identify those patients who would be expected to have a complicated course and delayed outcomes regardless of the specific intervention procedure being proposed. At the same time, it is also important to recognize that the medical risks of major spine surgery (e.g., spinal fusion) are different from those associated with a pump or stimulator, so the psychosocial risk may need to be weighed differently. The same may be true for the minimally invasive discectomy-fusion procedures that are becoming more common.

Even when specific surgical procedures are not being proposed, the psychological pain evaluations and preprocedure psychological screening have broad clinical utility and may provide significant benefits for those managing a pain case. Psychosocial factors are important to surgery outcome even in the context of clear and objective indications for surgery (Voorhies et al., 2007). In cases where there is disagreement or ambiguity related to the physical indications for surgery, the results of a preprocedure psychological screen may provide even more valuable guidance. Specifically, a psychological evaluation that identifies factors in a patient that would predict higher risk of poor outcome from surgical intervention may encourage continued conservative interventions and even a shift to functional restoration that incorporates active management of psychological risk factors and comorbidities. Finally, the variables assessed by these methods are relevant beyond preprocedure screening and even in patient groups whose primary complaint is not pain (e.g., concussion patients). In short, the preprocedure psychological screen model provides information about the complex psychosocial factors that can adversely affect treatment and recovery, and thus have value even when no specific “procedure” is being contemplated.

### ***Biopsychosocial Intervention Models***

As has been demonstrated, chronic pain is a complex biopsychosocial phenomenon. Biomedical interventions that focus solely on nociceptive mechanisms and pain symptoms are incomplete and unlikely to provide lasting benefit to persons with delayed recovery or chronic pain (Feinberg, Gatchel, Stanos, Feinberg, & Johnson-Montieth, 2013; Waddell, 2006). Currently, the most therapeutically and cost-effective method for treating chronic pain is functional restoration (Feinberg et al., 2013; Gatchel & Okifuji, 2006; Guzman et al., 2002). The features of functional restoration include

multidisciplinary treatment including physical therapy and psychological assessment/treatment for psychological comorbidities, an assessment of psychological and other risk factors for poor outcome, the systematic management of the risk factors, and an organized and systematic approach to work return (Westman et al., 2006). Excellent resources include *Clinical Essentials of Pain Management* (Gatchel, 2005), *Interdisciplinary Functional Restoration and Pain Programs* (Feinberg et al., 2013), and *Evidence-based Scientific Data Documenting the Treatment and Cost-effectiveness of Comprehensive Pain Programs for Chronic Non-malignant Pain* (Gatchel & Okifuji, 2006).

The critical feature of the functional restoration approach is a focus on whole-person rehabilitation and restoration of function, not necessarily symptom amelioration. In fact, the functional restoration approach is rehabilitative. This key feature is philosophical and practical. Ideally, functional restoration would be provided in an interdisciplinary setting housed under one roof, much like rehabilitation programs with which neuropsychologists are familiar. The absence of an integrated pain rehabilitation program does not mean that functional restoration is not possible as long as the necessary treating disciplines (e.g., physical medicine, psychology, physical therapy, occupational therapy) are involved. This multidisciplinary approach is, by nature, not as collaborative as an interdisciplinary program, and is thus likely to be less effective. Feinberg et al. (2013) and Gatchel and Okifuji (2006) present the outcome data on functional restoration. Overall, when dealing with motivated patients, the functional restoration approach is superior to symptom-focused treatment alone in reducing pain, increasing functional status including return to work, and decreasing lifetime medical costs. Moreover, interdisciplinary pain rehabilitation may obviate the need for surgical treatment of pain symptoms.

The ultimate goal of functional restoration is maximizing functional independence to the extent possible given the individual's objective physical impairments. As part of the comprehensive biopsychosocial assessment required to develop an appropriate functional restoration plan, determination of the individual's understanding of his or her condition is essential and misunderstandings should be corrected. Proper information and expectations should be developed. Often misinformation and misunderstanding can lead to unnecessary fear of reinjury, pain fear, and pain catastrophizing. This fear may be more disabling than the biomedical aspects of the injury itself. Learning to pace activities so as to not overdo, or reinjure, or to otherwise punish oneself for increasing activity is important. Patients commonly report trying to be "normal" when they are feeling good and then being laid up with increased symptoms for days after. Moreover, flare-ups of intense pain often occur and guidance in the management of these flare-ups is important. All treating disciplines can contribute to this educational process. The need for the treating disciplines to be on the same

page regarding the status and needs of the patient and the necessity to share information about progress and obstacles emphasizes the value of the single setting interdisciplinary program. This type of routine communication is possible, but it is more difficult when the treatment providers are in separate physical locations. The psychologist will be involved in these various functions and will also have the responsibility for direct treatment of affective and other comorbid psychological disorders and in providing stress management/coping skills training.

Functional restoration emphasizes improving functional capacity and encourages, to the extent possible, early work return. Early work return may be a particularly critical factor in the rehabilitation of patients with pain. Injured workers who stayed at work ("presentees") after their injuries were more likely than "absentees" (those who remained off work) to complete a functional restoration treatment program, to return to work, to retain work one-year posttreatment, and to not have a decreasing job demand from preinjury to post-treatment time periods (Howard, Mayer, & Gatchel, 2009). Among persons who failed to complete functional restoration, opioid dependence and personality disorder were the most important risk factors (Howard, Mayer, Theodore, & Gatchel, 2009). Ultimately, consideration of psychosocial and socioeconomic complexities of patients with pain in a comprehensive pain management program with a functional restoration focus can lead to a reduction in the need for invasive treatment procedures and overall improved outcomes (Gatchel & Okifuji, 2006).

### *Psychological Pain Management*

Psychological treatments, including cognitive behavioral therapy (CBT) and behavior therapy (BT), have been studied for their efficacy in dealing with pain, pain disability, and affective comorbidities, including depression. In early studies (e.g., Block et al., 2003; Gatchel et al., 2006), CBT has been demonstrated to be effective in improving clinical outcomes in clinical pain cases. Applied in isolation, these treatments have a weak effect on pain and disability, although they may be some help in altering mood outcomes (Eccleston, Williams, & Morley, 2009). However, recent reviews on the efficacy of psychological treatments is more promising.

Eccleston, Morley, and Williams (2009) conducted a systematic review of psychological interventions for pain, finding a benefit of CBT in comparison to other therapies (e.g., behavior therapy). Effect sizes of 0.48 were found for musculoskeletal pain and 0.34 for cancer pain, thus demonstrating an effective therapeutic benefit in adults. The most marked improvements were in quality of life issues (disability, psychological distress, depression) and to some extent the pain itself. In children and adolescents, psychological treatments for pain secondary to a variety of medical conditions (i.e., headache, abdominal pain, mixed pain, fibromyalgia, sickle cell disease, and juvenile idiopathic arthritis) have also

proven effective. All treatment types (relaxation, hypnosis, coping-skills training, biofeedback, CBT) were consolidated into one general class of “psychological therapies.” Overall, 49% of children receiving treatment experienced improvement contrasted to 17% improvement in children who did not receive therapy. Significant improvement in mood of the headache group was seen at follow-up and posttreatment disability significantly improved in nonheadache groups.

Eccleston et al. (2009) concluded that there is sufficient evidence showing that CBT does work in patients with pain and that research focus should shift to identifying those for whom it works most effectively and under what circumstances. Combining therapies in a multidisciplinary rehabilitation format has shown promise, particularly for treating patients at higher risk for poor outcome (Westman et al., 2006). The studies show that CBT contributes to lower levels of pain symptoms and higher levels of adaptive functioning, particularly when employed along with rehabilitation medicine and physical therapy as part of a functional restoration treatment model.

The presence of psychosocial risk factors argues for incorporating CBT into the treatment plan of patients whose chronic pain has failed to respond to medical/surgical interventions. CBT would reduce depression, increase self-efficacy, foster accurate and realistic beliefs regarding surgery and/or other medical pain management approaches and their possible outcomes, and develop and practice effective pain-coping strategies. Typically, the CBT component could be completed within 10–12 weekly appointments. It would emphasize observable, quantifiable behavior change, and be guided by the establishment and tracking of specific goals to be achieved on a week-to-week basis and over the course of the entire treatment program (including a plan for returning to work). With appropriate treatment compliance, the patient would be expected to gain an increased understanding of the psychological facets of chronic pain, master relaxation techniques, learn to identify and modify pain-magnifying thoughts, reduce depression, learn to better pace his or her behavior to avoid a cycle of overexertion and deactivation, manage stress and anger more effectively, improve sleep, and plan for and cope more effectively with intermittent flare-ups in pain.

The patient’s motivation and suitability for CBT treatment should be assessed over the course of a three-session trial focusing on goal setting, education, practice of basic relaxation techniques, and record keeping. If significant compliance problems are observed during the trial, no additional sessions would be recommended. If he or she demonstrated good compliance and was benefitting from treatment, an additional eight to nine sessions could be conducted to complete the entire treatment protocol. Regardless of the outcome, there is no indication for open-ended, supportive counseling secondary to the index injury. In a work-related context, if, at the conclusion of the CBT program for chronic pain, residual symptoms unrelated to the work injury remain,

treatment should be arranged outside the worker’s compensation system if the patient is interested in addressing those other issues.

### Psychiatric Management

Patients with pain conditions, particularly chronic conditions, have a higher incidence of affective disorders than the general public (Dersh, Gatchel, Mayer, Polatin, & Temple, 2006; Mayer, Towns, Neblett, Theodore, & Gatchel, 2008), and pain increases pain sensitivity and perception of disability. This recognition has led to the utilization of a variety of psychiatric and psychological therapies for the treatment of pain, pain related disability, and psychiatric comorbidities to pain conditions. Selective serotonin reuptake inhibitor (SSRI) and serotonin-norepinephrine reuptake inhibitor (SNRI) drugs, both antidepressants, have differential effects on pain (Zhao et al., 2007) with SNRIs being more effective than SSRIs (Benarroch, 2008). A full review of the role of psychopharmacology management strategies for pain and pain-related affective disorders is beyond the scope of this chapter. The reader is referred to Polatin and Dersh (2004) for a review of relevant issues and applications of these interventions. It is important to recognize that while treatment with psychiatric medications may be helpful for the management of psychiatric symptoms (especially affective symptoms) and even pain, traditional psychiatric care alone is insufficient to address the psychosocial issues that often complicate chronic pain cases.

### Conclusion

Pain is a complex biopsychosocial phenomenon that, for many persons, cannot be effectively and efficiently addressed by medical/surgical interventions alone. Failure of patients to progress is often confounding to clinicians, but psychological methods exist to identify persons at risk for chronic pain and to characterize the specific factors that are contributing to a specific individual’s slow or absent recovery. Psychosocial interventions can facilitate recovery and improved function, and reduce the risk of unnecessary physical and psychological morbidity secondary to difficulty recovering. It is essential that all clinicians involved in the treatment of persons with pain recognize the significant impact psychosocial factors can have on treatment outcome and quality of life.

Appendix: Table of common tests and measures

<i>Test</i>	<i>Purpose</i>
<b>Ominibus Measures</b>	
Millon Clinical Multiaxial Inventory-III (MCMI-III)	175 item measure. Assesses personality disorders and clinical syndromes.
Minnesota Multiphasic Inventory-2 (MMPI-2)	567 item personality inventory, symptom validity.
Minnesota Multiphasic Inventory-2-RF (MMPI-2-RF)	338 item personality inventory, revised form.
Personality Assessment Inventory (PAI)	344 Item measure. Assesses personality disorders and psychopathological syndromes.
<b>Specific Pain Measures</b>	
Brief Pain Inventory (BPI)	32 item measure. Assesses pain severity, location and global functioning.
Chronic Pain Coping Inventory (CPCI)	65 item measure. Assesses coping strategies.
Coping Strategies Questionnaire (CSQ)	50 item measure. Assesses behavior and cognitive pain coping strategies.
Dallas Pain Questionnaire (DPQ)	16 item measure. Assesses functional and emotional aspect of chronic low back pain.
McGill Pain Questionnaire(MPQ)	Scale of sensory, affective and evaluative pain dimensions
SF-McGill Pain Questionnaire (SF-MPQ)	15 item short form version
Modified Somatic Perception Questionnaire (MSPQ)	13 item scale of somatic and autonomic perception/coping style
Multidimensional Pain Inventory (MPI)	60 item measure. Assesses psychosocial functioning.
Neck Pain And Disability Scale (NPAD)	20 item measure. Assesses neck pain and associated disability.
Oswestry Pain Disability (OPD)	60 item measure. Assesses daily global functioning.
Pain Anxiety Sensitivity Scale-20 (PASS-20)	20 item measure. Assesses pain specific anxiety
Pain Catastrophizing Scale (PCS)	13 item scale of catastrophic thinking/coping style
Pain Coping Inventory (PCI)	92 Item measure. Assesses behavioral, cognitive and psychological dimensions of chronic pan.
Pain Disability Index (PDI)	7 item self-report that measures 7 areas of functioning.
Pain patient profile (P-3)	132 item measure. Assesses the depression, anxiety, somatization and validity index of pain patients.
Survey of Pain Attitudes (SOPA)	57 item measure. Assesses belief sets about pain.
Tampa Scale for Kenisiophobia (TSK)	17 item measure. Fear of movement scale.
Vanderbilt Pain Management Inventory (VPMI)	18 item measure. Assesses coping strategies of chronic pain patients.
West Haven-Yale Multidimensional Pain Inventory (WHYMPI)	52 item measure. Assesses pain perception and functioning among 12 scales.
<b>Other pain related measures</b>	
Battery for Health Improvement-2 (BHI-2)	31 item measure. Assesses biopsychosocial factors.
Millon Behavioral Health Inventory	150 items. provide information regarding a patient's likely style of relating to health-care personnel, problematic psychosocial attitudes and stressors, as well as an individual's similarity to patients with psychosomatic complications or poor responses to either illness or treatment interventions.
Beck Anxiety Inventory (BAI)	21 item measure. Assesses anxiety symptomology.
Beck Depression Inventory (BDI)	21 item measure. Assesses depression symptomology.
Short Form-36 Health Survey (SF-36)	36 item measure. Assesses general health perceptions.

# 35 Neuropsychological and Psychological Assessment of Somatic Symptom Disorders

Greg J. Lamberty and Ivy N. Miller

## Introduction

The neuropsychological tradition of characterizing disorders by describing patterns of deficit or impairment has not been edifying in the case of somatic symptom disorders. There is often a surfeit of self-reported cognitive dysfunction in individuals with such diagnoses, but quality studies identifying specific neurocognitive difficulties are rare. Attention has been paid to putative underlying mechanisms in disorders that have, at turns, been called *somatoform disorders*, *functional somatic syndromes*, and now *somatic symptom disorders*. What has *not* emerged is a clear pattern of neurocognitive dysfunction associated with any such syndrome (Suhr & Spickard, 2007). As the goals of the neuropsychological evaluation have evolved, localizing dysfunction has become less relevant, while determinations about the nature and extent of demonstrated difficulties has taken precedence. In particular, symptom and performance validity measures have assisted clinicians and researchers in identifying plausible and implausible performances. Thus, in the case of individuals with somatic symptom disorders, the neuropsychological evaluation is most often concerned with identifying a lack of cognitive dysfunction and describing the nature of the individual's numerous other symptoms, particularly those of a psychological or emotional nature.

Somatic Symptom and Related Disorders in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; American Psychiatric Association, 2013) represents a substantial revision of the Somatoform Disorders category that was initially introduced in the DSM-III (1980) and modified slightly in subsequent versions of the DSM-IV (1994, 2000). In practice environs and the clinical literature, references to somatization, conversion, and hysteria have abounded, but the accuracy and utility of such diagnoses has been vigorously debated (Engel, 2006; Mayou, Kirmayer, Simon, Kroenke, & Sharpe, 2005; Noyes, Stuart, & Watson, 2008; Voigt et al., 2010). Pre-DSM-5 deliberations resulted in clinical diagnostic criteria that are substantially more inclusive than their predecessors. Given that the Somatoform Disorders were never highly regarded as a diagnostic category (Lamberty, 2008), research efforts focused on more specific characterization of various debated clinical diagnoses such as chronic fatigue syndrome (CFS, see Deluca,

Johnson, & Natelson, 1993) and psychogenic nonepileptic seizures (Driver-Dunckley, Stonnington, Locke, & Noe, 2011), while others have discussed the impact of “medically unexplained symptoms” on neuropsychological assessment measures more broadly (Binder, 2005; Binder & Campbell, 2004).

Neuropsychologists are not typically asked to conduct neuropsychological assessments to characterize individuals identified as having a somatoform disorder. However, the presence of medically unexplained symptoms is increasingly recognized as common (Lamberty, 2008) and can often end up being a primary diagnosis. Thus, while the main purpose of an assessment may not involve the identification and delineation of a somatic symptom disorder, attention to a variety of unexplained symptoms is a very important element of the neuropsychological assessment. This is particularly true when individuals present with myriad concerns that have not been adequately ruled in or out by primary care providers or other specialists. Therefore, in clinical practice, knowledge of somatic symptom disorders and how they impact the gathering of assessment data is essential for all practitioners.

## Pathology and Clinical Presentations

In the time that elapsed between the publication of Briquet's (1859) monograph on hysteria and the inclusion of somatization disorder in the DSM-III, a significant shift in the understanding about what underlies the presentation occurred. Briquet and Charcot were of the opinion that there was a primary neurologic cause for hysteria, while the DSM-III was clear in indicating that somatization was characterized by a *lack of* underlying biological etiology. Absolute either/or distinctions are rare in clinical settings, but it is generally understood that patients with a primary diagnosis of somatoform or somatic symptom disorders do not have a characteristic underlying neuropathology (APA, 2013; Lamberty, 2008). Complicating things further is the occasional finding that patients with clear central nervous system disorders can also present with prominent unexplained somatic symptoms. Therefore, it is important to assess a wide range of cognitive and emotional/psychological symptoms in all assessments, irrespective of the presumed etiology of a patient's primary diagnosis.

Over the past 30 to 40 years the approach to studying somatoform disorders has varied and evolved. After DSM-III, investigators sought to validate the new construct of somatization. When it became clear that there was not a unitary etiology or presentation, attention shifted to different disorders that basically had medically unexplained symptoms as their hallmark (e.g., Binder, 2005). While we will not provide an extensive review of these conditions, it is important for the practicing clinician to be aware of such disorders. Individuals who present with these diagnoses often have strong biases and an expectation that their doctors will be similarly informed and oriented. An awareness of these dynamics can better prepare the neuropsychologist for a productive interview and assessment experience.

### ***Medically Unexplained Symptoms and Associated Disorders***

Among the more commonly diagnosed and long-standing disorders associated with medically unexplained symptoms are fibromyalgia, CFS (aka myalgic encephalomyelitis, post-viral fatigue syndrome, chronic fatigue immune dysfunction syndrome), idiopathic environmental intolerances (IEI; aka multiple chemical sensitivities), postconcussive syndrome (PCS), psychogenic movement disorders (PMD), and psychogenic nonepileptic seizures (PNES). Fatigue and chronic pain disorders in particular are more common in women (Jason et al., 1999) and are associated with a history of trauma/abuse (Walker et al., 1997). Mood and anxiety disorders are commonly comorbid with these diagnoses (Bagayogo, Interian, & Escobar, 2013; Mariman et al., 2013; Walker et al., 1997; Yalcin & Barrot, 2014). Neuropsychological studies of fibromyalgia, CFS, and IEI have failed to find consistent deficits that cannot be accounted for by psychological/emotional distress (Suhr, 2003). Methodological issues such as lack of symptom validity test (SVT) inclusion in test batteries have been highlighted across studies (Lamberty, 2008; Lamberty & Sim, 2014). As suggested by the cognitive symptom validity literature for all somatoform disorders, subjective cognitive complaints of fatigue and chronic pain disorders significantly outweigh documented impairments on neuropsychological measures (Binder & Campbell, 2004; Suhr, 2003). Brooks, Johnson-Greene, Lattie, and Ference (2012) found that SVT performance was significantly correlated with scores on the somatoform, depression, and anxiety subscales of the Millon Clinical Multiaxial Inventory (MCMI-III) in individuals with a fibromyalgia diagnosis. Cognitive and psychological symptom validity scores were significantly related, and authors suggested that neuropsychological evaluation of both cognitive and psychological symptom validity should be a part of a comprehensive diagnostic assessment for fibromyalgia (Brooks et al., 2012). Johnson-Greene, Brooks, and Ference (2013) found that 37% of fibromyalgia patients failed one or both of two performance validity tests (PVTs; Green's Word Memory Test/Test

of Memory Malinger and Reliable Digit Span) in a standard neuropsychological assessment. When analyses were conducted comparing individuals who exhibited two versus one, versus no failures, results were significant for daily and weekly pain, and sleep but not fatigue. Analysis of disability status (on disability, applying for disability, and not on disability) was significant for daily and weekly pain and fatigue but not sleep. The authors suggested that PVT performance and disability status was associated with exaggeration of noncognitive symptoms (Johnson-Greene et al., 2013).

Attention has been paid to pseudoneurological disorders such as PNES and PMD, with a goal of understanding possible relationships between PNES and PMD populations and in attempting to differentiate PNES from electric seizures (ES). In a retrospective study, Driver-Dunckley et al. (2011) found that there are more similarities than differences among PNES and PMD patients, suggesting that they are manifestations of the same psychopathology. For example, they had similar family histories (psychiatric disorders, drug and alcohol abuse), similar rates of unemployment/disability status, and prolonged time to diagnosis including multiple evaluations and unnecessary interventions. PNES patients were younger, more likely to have intermittent symptoms associated with altered consciousness, and had lower levels of education. Neuropsychological testing was part of the medical evaluation process for 82% of PNES but only 9% of PMD. Neuropsychological and personality assessment results were suggested in this study to be helpful in determining accurate diagnosis and in helping patients accept the somatoform diagnosis (Driver-Dunckley et al., 2011). Across studies, inclusion of PVTs, SVTs and personality inventories have been shown to help differentiate PNES and ES (Binder, Kindermann, Heaton, & Salinsky, 1998; Binder, Storzbach, & Salinsky, 2006; Drane et al., 2006). With regard to neuropsychological deficits, multiple studies have found that PNES patients may appear similarly impaired to ES patients (Lamberty, 2008), though one study found that PNES patients who passed Green's Word Memory Test exhibited less impairment on neuropsychological tests, imaging, and video-EEG monitoring (Drane et al., 2006). Similarly, in a PMD sample, individuals did not show worse performance on most neuropsychological tests from healthy control participants and patients with Gilles de la Tourette syndrome, but did report more cognitive complaints in daily life and performed worse on SVTs than the other two groups (Heintz et al., 2013).

## **Assessment**

### ***Cognitive Symptom and Performance Validity Tests***

Indistinct cognitive complaints are common among individuals with somatoform and other psychological and medical disorders, but they have been conceived of as a proxy for distress rather than objective cognitive difficulties (Binder, 2005; Heintz et al., 2013; Lamberty, 2008; Lamberty & Sim, 2014;

Wilson, Arnold, Schneider, Li, & Bennett, 2007). While various studies have reported cognitive deficits in attention/concentration, information processing speed, working memory, motor speed, and agility (Ambrose, Gracely, & Glass, 2012; Libon et al., 2010; Sjøgren, Christrup, Petersen, & Højsted, 2005), underlying mechanisms are not understood and there is little indication of neuropsychological deficits that are directly linked to central nervous system dysfunction in individuals with somatoform disorders (Heintz et al., 2013; Inamura et al., 2014; Lamberty, 2008; Lamberty & Sim, 2014). Previous reviews have highlighted the importance of inclusion of symptom and performance validity tests (SVTs, PVTs) and consideration of motivational factors (e.g., disability status) in neuropsychological assessment with patients with somatoform symptoms (Iverson & McCracken, 1997; Lamberty, 2008; Landrø, Stiles, & Sletvold, 1997; Suhr, 2003; Suhr & Spickard, 2007). Studies using the Minnesota Multiphasic Personality Inventory, second edition (MMPI-2) have described a relationship between cognitive effort measures and somatic personality configurations (Brauer Boone & Lu, 1999; Jones, Ingram, & Ben-Porath, 2012; Larrabee, 1998; Sellbom, Wygant, & Bagby, 2012).

Previous estimates of SVT failure in individuals with somatoform disorders vary based on disability and litigation status, with individuals with secondary gain likely to produce SVT failures (Gervais, Rohling, Green, & Ford, 2004). For example, a minority of nonlitigant patients with medically unexplained symptoms (11%) presenting to a neurology clinic fail effort tests (Kemp et al., 2008). It is possible that there are conscious and nonconscious reasons for failures in such patients. Other studies of patients and disability litigants have estimated SVT failure rates of 31%–35% (Gervais et al., 2004; Mittenberg, Patton, Canyock, & Condit, 2002). Roberson and colleagues (2013) found that b Test failures in credible patients with somatoform disorders (defined as nonlitigant, nondisability claimants who failed less than two PVTs) were common and attributable to slow processing and commission errors, indicating that this test may be valuable in detecting nonconsciously created cognitive dysfunction (Roberson et al., 2013). The mechanism behind nonconscious symptom reporting was recently explored in a series of experiments based on the residual effects of feigning (Merckelbach, Jelicic, & Pieters, 2011). Undergraduate students who had previously been asked to exaggerate symptoms continued to exaggerate even when later asked to respond honestly. Students then completed a symptom list of psychiatric complaints and were asked to explain why they had endorsed two target symptoms that they did not actually endorse. Fifty-seven percent of participants in this study did not detect the discrepancy between actual and manipulated symptom endorsement and tended to agree with the manipulated symptoms. The authors suggested that these studies might help to explain the susceptibility of individuals to suggestion and overreporting of somatic symptoms.

Despite significant evidence supporting inclusion of SVTs/PVTs in neuropsychological evaluations, particularly in assessing patients with medically unexplained symptoms, a recent survey of neuropsychologists in six European countries found that while most individuals had technical knowledge about symptom validity, there was little consensus about how to handle test failure (Dandachi-FitzGerald, Ponds, & Merten, 2013). There continues to be variability in the inclusion of SVTs in the research literature as well. Studies that do not include SVTs/PVTs when exploring neuropsychological impairments in somatoform disorders (e.g., Al-Adawi, Al-Zakwani, Obeid, & Zaidan, 2010; Onofrij, Bonanni, Manzoli, & Thomas, 2010) are limited in their ability to draw conclusions about reasons for cognitive differences and changes in somatoform populations.

### *Psychological/Personality Tests*

The relationship between psychological disturbance and somatoform disorders is well supported in the literature (Grover et al., 2015; Lahmann et al., 2015; Röhrlich & Elanjithara, 2014). Diagnostically, the most basic feature of somatoform disorders is the acknowledgement of numerous physical symptoms, along with a high level of distress related to these symptoms. While a basic clinical interview will usually uncover this, psychological assessment measures are useful for a more nuanced understanding of psychopathology. Further, in addition to the performance validity measures previously noted, it is also important to assess the validity of symptom reporting. Finally, tracking outcomes can be useful in the clinical intervention context, though this may not require a thorough personality assessment measure.

The Patient Health Questionnaire–15 (PHQ-15; Kroenke, Spitzer, & Williams, 2002) is used frequently as an index of the severity of somatoform symptoms in treatment outcome and epidemiological studies. It samples from a number of different somatic complaints including pain, dizziness, fatigue, and gastrointestinal complaints. In the clinical environment, the PHQ-15 can also serve as a screening measure for patients with multiple and difficult to characterize somatic concerns. While there is not an extensive literature on the PHQ-15 in the context of neuropsychological assessment, it is a freely available measure that is easy to administer and score. Such measures are useful adjuncts that can assist in decisions about referrals and more extensive personality assessment, especially in environments where time and resources are limited.

The MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989) has been used widely in the identification of somatoform disorders. Elevations on Clinical Scales 1 (Hypochondriasis) and 3 (Hysteria) from the MMPI-2 are associated with somatoform disorders, and with conversion disorder when Scale 2 (Depression) is considerably lower (“Conversion V”; Graham, 2012). A study describing prototypical somatoform validity score patterns on the MMPI-2

in a sample of litigants with idiopathic environmental intolerance (aka multiple chemical sensitivities) found that most validity scales, with the exception of L (the deliberate attempt to portray oneself in an unrealistically favorable way) and K (more subtle defensiveness/presentation of oneself in a favorable light), were not elevated, while one-fourth to one-half of participants exhibited elevations on the FBS (referred to as the Symptom Validity scale; Staudenmayer & Philips, 2008).

The utility of the MMPI-2 and MMPI-2-RF is well recognized in a number of assessment contexts and this is particularly true for somatoform disorders (Lamberty, 2008). The use of validity scales was an important advance in personality assessment and this tradition has been exemplified in the development and refinement of the MMPI over the years. The three original validity scales—Lie (L), Infrequency (F), and Defensiveness (K)—allowed insights into response bias that were unique in personality assessment, but were limited in scope. With successive revisions of the MMPI, additional scales were added to provide more specific and accurate information about response bias and its effects on profile validity and interpretation.

When the Restructured Clinical (RC) scales were introduced in 2003, Somatic Complaints (RC1) was the index that indicated overall level of physical symptom reporting. Elevations on RC1 are associated with preoccupation with physical symptoms, the development of symptoms in response to stressors and fatigue (Ben-Porath, 2012), and a diagnosis of somatoform disorders (Simms, Casillas, Clark, Watson, & Doebbeling, 2005), but not to any one specific somatoform diagnosis (Ben-Porath, 2012). Thomas and Locke (2010) found that RC1 scale is most precise for T score estimates between 55 and 90, and that the scale is well suited for the assessment of somatization (Thomas & Locke, 2010). Studies examining different samples have validated the utility of RC1 in distinguishing between samples (epilepsy and PNES) as well as characterizing what elevations mean in different samples (e.g., Arbisi, Sellbom, & Ben-Porath, 2008). The RC scales limited the need for and utility of codetype interpretation that became popular with the MMPI and MMPI-2. Improved psychometrics and a general lessening of the impact of distress or demoralization on the main clinical scales has reduced the need to combine scale elevations as a means of making important interpretations with the MMPI-2-RF.

The MMPI-2-Restructured Form (MMPI-2-RF; Ben Porath & Tellegen, 2011) is now in wide use and includes additional validity scales with direct relevance to individuals reporting high levels of somatic and cognitive symptoms (Ben-Porath, 2012; Ben-Porath & Tellegen, 2011). Of particular interest is the Infrequent Somatic Responses (Fs) scale, which is recommended as a general index of the credibility of somatic symptom reporting (Ben-Porath, 2012). Elevations of  $T \geq 100$  on Fs suggest exaggeration of symptoms at a level that is unrealistic under most circumstances and thus not likely valid. As a result, scores on the other somatically

oriented indices should not be included in the interpretive profile. Whether or not such elevations are associated with malingering is not yet clear, though certainly the validity of assessments with these kinds of elevations would seem questionable. A recent study attempted to use the MMPI-2-RF to differentiate between individuals with somatoform disorders and other individuals endorsing somatic complaints, a difficult task. For example, Sellbom et al. (2012) found that Fs and Fp-r were best at differentiating between individuals feigning physical health problems, patients with somatoform disorders, and medical patients without mental health disorders. The clearest distinctions were made by these scales in differentiating somatic malingering from somatoform and medical illness groups. MMPI-2-RF scales of interest could not distinguish between somatic malingering and somatoform patients (Sellbom et al., 2012), highlighting the need for evaluation of motivational/secondary gain factors during the clinical interview portion of a psychological assessment.

Two additional scales that emanated largely from the clinical neuropsychology literature: the Symptom Validity Scale (FBS, or FBS-r in the MMPI-2-RF) and the Response Bias Scale (RBS; Gervais, Ben-Porath, Wygant, & Sellbom, 2010), which are both sensitive to symptom overreporting (Ben-Porath, 2012). FBS-r is sensitive to general elevations in somatic symptoms, while RBS is elevated primarily by acknowledgement of memory and cognitive difficulties. All such symptom reporting is important in the context of neuropsychological exams. In his interpretive book on the MMPI-RF, Ben-Porath noted that overreporting on these validity scales does not necessarily mean the test taker is intentionally overreporting and may represent a somatoform disorder (Ben-Porath, 2012). A few papers have examined the extent to which these indices impact profile validity and cognitive test performances, though a more general understanding of such patterns remains to be elucidated. For example, in an investigation of the stability of FBS-r in a nonforensic Veterans Administration sample of neuropsychological referrals, Gass and Odland (2012) found two latent constructs within FBS-r—Somatic Complaints and Optimism/Virtue—that together accounted for 95% of the variance in FBS-r scores. They noted that FBS-r contains 15 items that were empirically keyed with conversion disorder and 13 items with hypochondriasis, and that scores are influenced by a denial of socially undesirable behavior and a rejection of cynical interpretations of people's motivations. Authors suggested that FBS-r is potentially unstable because it lacks a statistically coherent factor structure, though it does provide a rough estimate of anxiety severity and opinions about one's personal values and human nature (Gass & Odland, 2012). Jones and Ingram (2011) found that in a sample of military members the Henry-Heilbronner Index (HHI), RBS, FBS and FBS-r outperformed the F-family scales in classification accuracy analyses in predicting effort status on cognitive tests, with moderate effect sizes. Fs performed at the same level as F, the best performing F-family scale (Jones &

Ingram, 2011). RBS showed the strongest relationship with memory complaints in a sample of non-head-injury disability related referrals, and provided incremental contribution above and beyond the F-r, Fp-r, Fs, and FBS-r in predicting memory complaints (Gervais et al., 2010). Authors suggested that subjective memory complaints in the context of elevated RBS scores are unlikely to indicate objective memory deficits (Gervais et al., 2010). RBS also showed the largest effect size of all overreporting scales in a military sample completing neuropsychological evaluations for mild TBI, in which SVT failure was associated with linear increases in MMPI-2-RF overreporting scales and most substantive scales (Jones et al., 2012). With regard to the substantive scale analyses in this study, Cognitive Complaints (COG) had the largest effect size, followed by Somatic Complaints (RC1), Head Pain Complaints (HPC), Malaise (MLS), and Neurological Complaints (NUC). Participants who passed SVTs had clinically significant elevations only on COG and NUC. In another sample of TBI litigants, elevations on the Somatic/Cognitive scales profile were significant predictors of effort test failure, and were better predictors of effort test failure than the MMPI-2-RF validity scales. MLS arose as the single best predictor of effort test failure. Authors noted that all items on MLS were part of the MMPI-2 Hy scale. FBS-r was also significantly related to passing or failing effort tests, and there was only a modest, nonsignificant association with poor effort for Fs (Youngjohn, Wershba, Stevenson, Sturgeon, & Thomas, 2011). In a study using the Forensic Disability Claimant Sample from the MMPI-2-RF Technical Manual, SVT failure was associated with significant elevations throughout the MMPI-2-RF overreporting and substantive scales, including COG. Authors concluded that claimants appear to use both personality and SVT tests to communicate their claimed neurocognitive impairment, physical complaints, and emotional dysfunction (Gervais, Wygant, Sellbom, & Ben-Porath, 2011).

Among the newly developed Specific Problems Scales are the Somatic/Cognitive Scales, which are brief and focused indices of physical complaints including MLS, HPC, Gastrointestinal Complaints (GIC), NUC, and COG. In contrast to the overreporting validity scales and RC1, the Somatic/Cognitive scales assess more specific symptoms that might reasonably be associated with different kinds of clinical or medical problems. These scales should be interpreted in light of Fs, the validity score noting overreporting of somatic symptoms, as well as FBS and RBS, which note overreporting of cognitive symptoms. Literature on these scales is limited, though in the clinical context valuable descriptive information can be obtained through a careful review of the indices. Overall, studies utilizing the MMPI-2-RF to assess for somatic symptoms provide more detailed information than was previously available through earlier editions of the MMPI.

Outside of the MMPI literature, several other psychological studies have attempted to better characterize individuals

with somatic symptoms. For example, in comparing patients with somatization to control patients in an outpatient setting, Stonnington, Locke, Hsu, Ritenbaugh, and Lane (2013) found that somatizing patients exhibited a deficit in the experience of positive emotions and a tendency to not immediately make emotional attributions to their physical symptoms, which may explain the tendency to reject psychological explanations for symptoms (Stonnington et al., 2013). In another study, depression, anxiety, and somatization patients showed deficits in the ability to forget illness-related stimuli relative to neutral material (Wingenfeld, Terfehr, Meyer, Löwe, & Spitzer, 2013), suggesting a cognitive bias in these individuals. Other studies have related depressive symptoms to somatic presentations as well. In a sample of mild to moderate TBI patients, somatic symptoms and chronic stress explained variation in depressive symptoms (Bay & Covassin, 2012). Compared with nondepressed patients with medically unexplained symptoms, depressed patients had more severe somatic symptoms, more psychological symptoms, and more functional impairment (Hilderink et al., 2009). Alexithymia was strongly associated with the number of somatic symptoms and negative affect in patients with somatoform disorder (Tominaga, Choi, Nagoshi, Wada, & Fukui, 2014). Compared with patients with nonsomatoform mental disorders as well as patients with "organic" illness, somatoform patients reported greater frustration with ill health and higher utilization of care (Schmid et al., 2014). Less attention has been paid to the prevalence and characterization of somatoform disorders and medically unexplained symptoms in older adults (Lamberty & Bares, 2013). A recent review on this topic found that these symptoms are common in elderly individuals, but prevalence rates of somatoform disorders appear lower than in younger populations. Authors suggested that like depression in the elderly, it may be that subsyndromal somatoform disorders are more common than disorders that meet the full criteria (Hilderink, Collard, Rosmalen, & Oude Voshaar, 2013). These studies highlight potentially important characteristics of individuals with somatoform disorders and may provide insight into treatment potential for these complex patients.

## Intervention

Treating patients with somatic symptom disorders can be a challenge for even skilled therapists, though the nihilism associated with treating such patients appears to have lessened considerably in recent times (Lamberty, 2008). This is likely due to the emergence of empirically supported treatments that involve cognitive behavioral therapy (CBT), mindfulness-based approaches, complementary and alternative interventions, and physically oriented interventions like physical therapy and yoga (Lamberty & Sim, 2014; Lamberty, 2014; Lamberty & Bares, 2013). A recent Cochrane review examining the effectiveness of pharmacological treatments for somatoform disorders indicated that

the quality of evidence for new-generation antidepressants was very low, while evidence for natural products was low (Kleinstäuber et al., 2014). Further, to the extent that there were significant effects for antidepressants, these needed to be balanced against the high rates of adverse effects with those drugs (Kleinstäuber et al., 2014). In slight contrast, a Cochrane review of nonpharmacological interventions for somatoform disorders and medically unexplained physical symptoms (MUPS) indicated that psychological therapies were superior to usual care in terms of reduction of symptoms (van Dessel et al., 2014). Effect sizes were small and the highest quality studies were conducted with CBT (van Dessel et al., 2014). Showing strong evidence via comparative effectiveness reviews is a gold standard that is difficult for many interventions to achieve. The fact that “work needs to be done” should not be discouraging and it is impressive that there are studies of adequate quality to be reviewed in this often murky area.

Most neuropsychologists do not identify themselves as participating regularly in the provision of psychotherapy or intervention services (Sweet, Giuffre Meyer, Nelson, & Moberg, 2011). The ascendance of empirically supported treatment makes some forms of intervention seemingly more straightforward and applicable for neuropsychologists that might be reluctant to engage in intervention services. This may be particularly true for groups that have traditionally been perceived as clinically challenging and not likely to benefit from psychotherapy. Lambert and Nelson (2012) note that empirically supported treatments such as motivational interviewing (MI; Rollnick, Miller, & Butler, 2008) and other approaches like *therapeutic assessment* (Finn & Kamphuis, 2006) or *collaborative therapeutic neuropsychological assessment* (Gorske & Smith, 2009) might realistically fit into the practice models of some neuropsychologists. In the absence of taking on intervention cases, there is clear value in improving one’s awareness of efficacious treatments for challenging patients. At the very least, a strong knowledge base of appropriate and empirically supported interventions will bolster the neuropsychologist’s ability to remain responsive to his or her patients and referral sources and assure his or her practice viability into the future.

## Summary

Neuropsychologists frequently encounter individuals who meet criteria for a somatic symptom disorder, particularly since DSM criteria have changed substantially and are more inclusive. Traditional neuropsychological assessment does not reveal a characteristic pattern of cognitive difficulties in patients with somatoform concerns. Despite frequently expressed concerns about cognitive functioning in such patients, neuropsychological evaluations are most useful in identifying patterns of variable or suspect effort and symptom reporting that are associated with somatoform presentations. Elucidation of psychological and personality features

is an especially important element of the neuropsychological evaluation as this information can be used to guide patients and referral sources to more productive courses of treatment. The challenging qualities of such patients can lead to quick and dismissive encounters with providers, resulting in the common attribution that their doctors think their problems are “all in their head.” A thorough neuropsychological evaluation can serve as a useful intervention that assures a patient that his or her concerns have been extensively assessed and considered. The delineation of what are often multiple comorbid issues is an important part of a process that can lead to an integrated and interdisciplinary approach that is emerging as an evidence-based standard for managing complex patients.

# 36 Forensic Neuropsychology

## An Overview of Issues, Admissibility, and Directions

*Jerry J. Sweet, Paul M. Kaufmann, Eric Ecklund-Johnson,  
and Aaron C. Malina*

### Introduction

Professional surveys show that involvement in forensic activities has become a common part of professional practice for clinical neuropsychologists (e.g., Sweet, Peck, Abramowitz, & Etzweiler, 2003). For example, a survey by Sweet, Moberg, and Suchy (2000) found that attorneys are the number one referral source for private practice neuropsychologists, who now represent the majority of the field. As a specialty practice of psychology, clinical neuropsychology applies unique methods and legally protected test materials (Kaufmann, 2009) in conjunction with the brain-behavior knowledge base to evaluate, diagnose, and treat individuals with known or suspected neurological disease and/or injury (Kaufmann, 2012). Lawyers increasingly seek consultation with neuropsychologist experts on an expanding set of legal issues, in part, because neuropsychologists apply scientific approaches that meet judicial standards for expert testimony (Larrabee, 2012).

Forensic neuropsychology has also become prominent within the neuropsychological literature and at relevant professional meetings. More specifically, examination of publication content within the most important clinical neuropsychology journals from 1990 through 2000 has demonstrated that forensic neuropsychology is a common topic within journal articles and at professional meetings (Sweet, King, Malina, Bergman, & Simmons, 2002), accounting for up to 16% of journal content and 11% of conference presentations. Thus, because of its increasing prominence, presumably associated with increasing influence, it is appropriate within this comprehensive handbook on the practice of clinical neuropsychology to consider important issues and directions of forensic neuropsychology. The present chapter will describe the historical background, major activities, key issues, admissibility challenges, and future directions of forensic neuropsychology.

For the purposes of the present chapter, we will consider *forensic neuropsychology* to include all neuropsychological practice in which a clinician provides evaluation or consultative services to an individual involved in a proceeding that is potentially *adversarial* in nature. Adversarial proceedings are those that involve two or more interested parties who must reach a resolution of a common concern or disagreement

from potentially antagonistic positions. Adversarial proceedings may be either *formal*, often taking place in a courtroom and involving criminal, civil (including personal injury and medical malpractice), or family (including divorce and child custody) law, or *informal*, often involving administrative matters, such as disability determination, fitness for duty, and due process educational hearings. Greiffenstein and Kaufmann (2012) note the criminal, civil, administrative, probate, and alternative dispute resolution settings in which neuropsychologists are commonly asked to consult. In all these proceedings, the offering of specialty knowledge by the clinical neuropsychologist is to inform a "trier of fact" or a less-formal process regarding an individual who is designated a *litigant*, if involved in formal court proceedings, or as a *claimant*, if involved in less formal proceedings (e.g., seeking disability status or seeking special considerations in an educational system). As such, a forensic opinion occurs within a context that can be distinguished from the normal clinical routine in which a health care service is provided to a "patient" who is seeking treatment for a malady. Stated differently, forensic services are viewed as outside routine health care, which explains why these services are not reimbursed under health insurance benefits.

### Historical Background

As noted earlier, there is strong evidence from professional surveys that involvement in forensic neuropsychology has increased substantially over time, such that it is a common part of practice for most clinical neuropsychologists and a major portion of practice for some. The growth of forensic consulting in neuropsychology is well documented (Sweet et al., 2002; Heilbronner, 2004; Kaufmann, 2009), including pediatric populations (Sherman & Brooks, 2012). Braun et al. (2011) noted a 6% average rate of annual growth in Lexis cases referencing neuropsychology from 2005 to 2009, and an unprecedented 20% increase in 2010. Kaufmann has closely tracked these trends for the past decade, most recently showing how neuropsychology is outpacing every related area of brain-behavior expertise (Kaufmann & Greiffenstein, 2013). Recently, Kaufmann (2016) noted a 97% increase in time devoted to forensic consulting over the past decade when comparing professional practice survey data

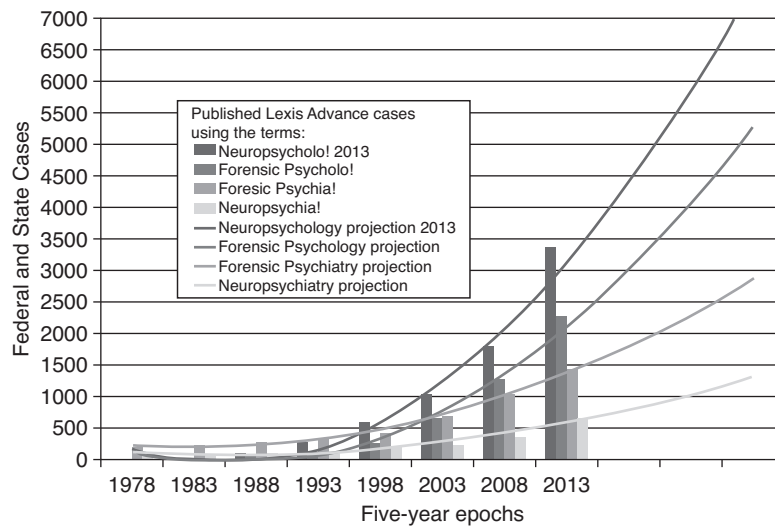

Figure 36.1 Number of U.S. federal and state cases using the root terms *Neuropsycholo!*, *Forensic Psycholo!*, *Forensic Psychia!*, and *Neuropsychia!* in five-year epochs for the past 35 years, used as a basis for polynomial regression projections for the next 15 years. These frequency counts represent the “tip of the iceberg” because the Lexis Advance database includes only appellate cases and narrowly selected trials introducing novel legal concepts. The interested reader may review the first references to these disciplines in published legal cases. See *Smith v. Metropolitan Life Ins., Co.* (1943) for neuropsychology, *Hovey v. Hobson* (1867) for forensic psychology, *State v. Knight* (1901) for forensic psychiatry, and *Hines v. Welch* (1928) for neuropsychiatry.

from Sweet and his colleagues (2006, 2011, and 2015). Figure 36.1 shows a steady upward trend in forensic consulting for neuropsychologists.

It is likely that these historical data pertaining to formal litigation proceedings are paralleled by equally impressive growth in separate informal adversarial proceedings, such as disability determination and due process educational hearings.

An interesting question is, what caused this impressive practice growth? In the sections immediately following, we explore possible causative factors.

### Health Care Advances and Resulting Societal Change

In discussing reasons for the growth of forensic neuropsychology, Taylor (1999) offered five factors that were deemed significant in explaining the emergence of neuropsychologists as litigation experts. These factors were (a) an increasing traumatic brain injury (TBI) population, (b) development of advocacy organizations, (c) advent of *neurolaw* (Taylor’s approach to proceedings involving neurological injury), (d) increasing supply of neuropsychologists, and (e) response of the legal system. In Taylor’s view, increased TBI survival rates stem directly from medical advances, which in turn impact society and result in items (a) through (c). Common causes of TBI include vehicular accidents and accidents in the workplace, which are often associated with subsequent litigation. Whereas if TBI results in death, neuropsychologists are an unlikely expert witness, TBI survivors can have

cognitive, emotional, and behavioral changes that are best assessed by neuropsychologists, who therefore become key witnesses in resulting litigation. Thus, a sizeable TBI survivor cohort leads to development of advocacy groups, such as the Brain Injury Association of America, which in turn leads to greater consciousness raising among the general public and politicians, and greater allocation of societal resources, such as resources for rehabilitation and residential living. Lawyers develop greater interest in the unique aspects of brain injury as pertains to litigation and increasingly need relevant expert witnesses. Demand for clinical neuropsychologists arises then out of both the clinical need and the litigation need to deal expertly with TBI survivors. These factors influence one another in a positive and synergistic fashion. As clinical neuropsychologists played a greater clinical role in dealing with TBI survivors, such that physicians and other health care providers relied upon them to assist in evaluating and treating TBI patients, ultimately, the court system acknowledged their role in the courtroom by promulgating common law (i.e., the rulings of judges) and statutory law that facilitate their involvement. As Taylor (1999) notes, “the law encourages that which it permits” (p. 424).

### Health Care Market Forces

In the same interval of time in which forensic neuropsychology has grown substantially, health care reimbursement models changed meaningfully. The era of *managed care* in U.S. health care greatly changed the means and amounts of

reimbursements for routine clinical services, including those of clinical neuropsychologists. Instead of indemnity insurance, managed care became a dominant force in U.S. health care. In a 2000 national survey of clinical neuropsychologists, managed care was identified as the number one reimbursement source for clinical services (Sweet et al., 2003). In response to the increased paperwork and reduced reimbursement associated with managed care, many U.S. clinicians, including neuropsychologists, pursued *self-pay* opportunities. Self-pay refers to non-insurance-based reimbursement, which of course includes forensic activities, which, as unrelated to health services, do not rely upon insurance. At this point, although varying greatly from one individual to another, forensic activities constitute a sizeable source of income to the field in general (cf. Sweet et al., 2000, 2003), to the point that some private practices are entirely based on forensic consultations.

### ***Scientist-Practitioner Model***

Based on the previous discussion of factors that may explain the growth of forensic neuropsychology, it already seems likely that multiple factors are involved. Sweet (1999a) has argued that a predominant factor in this growth is the scientist-practitioner conceptual foundation of the field. This viewpoint suggests that the well-recognized scientist-practitioner model (cf. Barlow, Hayes, & Nelson, 1984), which was originally developed to conceptualize the training of clinical psychologists and their subsequent idealized clinical practice methods, has resulted in neuropsychologist subspecialists being attractive and valuable experts for adversarial proceedings. Specifically, Sweet opines that among the “relevant by-products of a scientist-practitioner approach are: familiarity with disciplined scrutiny (i.e., peer review), clinical procedures emphasizing data-based decision-making (i.e., accountability), and comfort with hypothesis-testing (i.e., objective differential diagnosis)” (Sweet, 1999a, p. xviii).

As Lees-Haley and Cohen (1999) have noted, the fundamental contributions of experts, including neuropsychologists, to forensic adversarial proceedings are embodied in being a *scientific expert*. The empirical foundation, ability to entertain reasonable alternative hypotheses, ability to acknowledge limitations of method and research literature, and also to be open to reasoned criticism, among other characteristics, are the hallmarks of both a good scientist and a good expert witness. That clinical neuropsychology is rooted in science appears salient in making practitioners in the field attractive to triers-of-fact. It may well be that this scientific foundation in describing cognition, behavior, and emotion provides the essential attractive feature to attorneys, which when coupled with societal and health care changes that provided motivation for individual practitioners, explain the growth of forensic neuropsychology in the last two decades.

### ***Judicial Standards for Admissibility***

Although forensic consulting in neuropsychology began in the 1970s, Figure 36.1 shows that the rapid growth in preference for neuropsychologist experts did not appear in published legal cases until the early 1990s. Coincidentally, the U.S. Supreme Court handed down its landmark ruling in *Daubert v. Merrell Dow Pharm., Inc.* (1993) that changed the admissibility standards for expert witnesses. Even as some feared that *Daubert* might be used to exclude psychologist experts, the nonexclusive factors suggested by the Court have been favorable for neuropsychologist experts and likely contributed to increased utilization. Psychologists evaluate clinical impressions from an interview, behavioral observations, and informal assessment, with the added benefit of comparing the individual’s test performance to norms. Indeed, it is the integration of divergent sources of information with test findings that draws upon the unique skills of professional psychologists. The competent practice of modern neuropsychology requires current understanding and reasonable fluency in the behavioral and cognitive neurosciences. This brain-behavior knowledge base from the neurosciences, used in conjunction with standardized psychometric tests, neuroimaging results, neurodiagnostic findings, neurologic history, interviewing, behavioral observations, and informal assessment means that neuropsychological formulations and expert opinions are scientifically informed and refined by objective test results. These techniques easily fulfill state and federal legal standards for scientific methodology because psychological tests and neurodiagnostic techniques are widely accepted and, more importantly, experimentally verified. Kaufmann (2005) argued this practice distinguishes clinical neuropsychology in forensic settings, such that it has little or no redundancy with other health care disciplines or mental health expertise. Neuropsychologist experts who conduct evaluations using standardized, reliable, valid, and norm-referenced psychological tests with technical manuals easily fulfill *Daubert’s* nonexclusive evidentiary standards.

### ***Assessment of Response Bias, Effort, and Malingering***

The publication of Faust and Ziskin’s (1988: 33) blistering critique that experts in psychology and psychiatry “will most likely move the jury further from the truth, not closer to it,” highlighted the questionable methods used by mental health experts and set off alarm bells among consulting neuropsychologists. There were predictable rebuttals offered to the methods skeptics (Matarazzo, 1990; Barth, Ryan, & Hawk, 1991) and obligatory surrebuttals (Faust, 1991; Faust, Ziskin, & Hiers, 1991; Matarazzo, 1991). However, when methods skeptics suggested that “MMPI indices for malingering may sometimes aid the court” (Faust & Ziskin, 1988: 34) neuropsychologists took the criticisms seriously and began devising new methods to improve the relevance

and reliability of expert opinions. Shortly thereafter, the Minnesota Multiphasic Personality Inventory (MMPI) “fake bad” scale was introduced (Lees-Haley, English, & Glenn, 1991). The last two decades have witnessed an unprecedented effort by the neuropsychology community to develop and implement symptom validity and performance validity techniques to detect response bias, suboptimal effort, and malingering (Slick, Sherman, & Iverson, 1999; Bianchini, Greve, & Glynn, 2005), culminating in the American Academy of Clinical Neuropsychology (AACN) Consensus Conference statement (Heilbronner et al., 2009). In the 1980s, neuropsychologists were trained to give mild TBI patients the benefit of the doubt; but now they apply symptom and performance validity techniques, and work to reduce doubt. The increasingly successful neuropsychological methods for detecting malingering have captured the attention of the judiciary and contributed substantially to the preference for forensic neuropsychologist consultants in court.

### Key Issues in Forensic Neuropsychology

There are a number of important issues that relate to the practice of clinical neuropsychology within a forensic context. Many of these issues relate to the interface between the field of neuropsychology and the legal profession. Differences exist between the two disciplines in their underlying philosophies and expectations, and it is important that neuropsychologists understand how these differences are likely to affect their interactions with the legal system.

#### *Empirical Bases for Conclusions Based on Neuropsychological Tests*

Although empirically grounded practice is important for all neuropsychological activities, issues regarding the scientific bases for conclusions take on particular importance within the forensic context. This is largely because of standards for admissibility of evidence that have been developed to protect the legal system from the influence of “junk science” (i.e., pseudoscientific theories derived from unreliable methods; see Huber, 1991). While clinical neuropsychology enjoys a firm grounding in empirical research, issues remain with respect to the validity of our methods for forensic purposes.

#### *Evidentiary Standards*

For many years, the Frye standard (*Frye v. United States*, 1923), which stated that evidence provided by experts must be “generally accepted” within the particular field from which it was derived, was the prevailing standard governing the admissibility of expert testimony (Laing & Fisher, 1997). More recently, several U.S. Supreme Court rulings have addressed the issue of admissibility of expert evidence, beginning with *Daubert v. Merrell Dow Pharm., Inc.* (1993).

Under federal rules, courts must examine expert qualifications to determine the relevance of the expert opinions to the issue in dispute and the reliability of the bases for those opinions, before those opinions are admitted into evidence and heard by a jury. Judges must decide whether special experience is required to develop expert opinions that will assist the jury in resolving an issue in the case at bar.<sup>1</sup> Therefore, consulting neuropsychologists should understand the court standards for evaluating expert qualifications and the admissibility of testimony as addressed in FED. R. EVID. 104 Preliminary Questions and FED. R. EVID. 403 Relevance. Then, experts should understand how jurisdictions use *Frye*, *Daubert* and its progeny, and FED. R. EVID. 702 Testimony of Experts to make final determinations.

Although state Rules of Evidence vary somewhat, the legal basis for judicial review of expert methodology and testimony begins with FED. R. EVID. 104 (a) Preliminary Questions of Admissibility, and (b) Relevancy Conditioned on Fact, as follows:

- a The court must decide any preliminary question about whether a witness is qualified, a privilege exists, or evidence is admissible. In so deciding, the court is not bound by evidence rules, except those on privilege.
- b “When the relevance of evidence depends on whether a fact exists, proof must be introduced sufficient to support a finding that the fact does exist. The court may admit the proposed evidence on the condition that the proof be introduced later.”

Some courts refer generically to Rule 104 hearings when hearing *Daubert* or *Frye* challenges to expert testimony. Rule 104(b) refers to FED. R. EVID. 403, as follows:

Although relevant, evidence may be excluded if its probative value is substantially outweighed by the danger of unfair prejudice, confusion of the issues, or misleading the jury, or by considerations of undue delay, waste of time, or needless presentation of cumulative evidence.

(Fed. R. Evid. 403)

These federal rules (and state equivalents) set the stage for challenging expert testimony. However, not all state courts have adopted the *Daubert* framework, and a few still rely on *Frye*.<sup>2</sup>

The second-degree murder conviction in *Frye* was appealed, claiming the trial court erred when it excluded expert testimony on a “systolic blood pressure deception test” (*Frye v. United States*, 1923: 1013). Defense efforts to conduct the test in the court and admit expert opinions were denied. The *Frye* court affirmed the trial judge and created the following rule by quoting from the government’s brief:

when the question involved does not lie within the range of common experience or common knowledge, but requires

special experience or special knowledge, then the opinions of witnesses skilled in that particular science, art, or trade to which the question relates are admissible in evidence.

(*Frye v. United States*, 1923: 1014)

In a two-page unanimous opinion, the appellate court found that the deception test did not have “standing and scientific recognition among physiological and psychological authorities as would justify the courts in admitting expert testimony” (*Frye v. United States*, 1923: 1014). Essentially, the test was not admitted because it was not *generally accepted* in the relevant scientific community. *Frye* was the law governing experts for the next 70 years, and it is still used today to exclude evidence that is not generally accepted in the scientific community (e.g., restricting behavioral genetics evidence in federal and *habeas corpus* review; *Cullen v. Pinholster*, 2011).

In *Daubert v. Merrell Dow Pharm., Inc.* (1989), infants and guardians sued to recover for limb reduction birth defects caused by ingestion of the anti-nausea “morning sickness” drug Bendectin during pregnancy. Merrell Dow won on summary judgment<sup>3</sup> under *Frye* with the trial judge noting the “prevailing school of thought” (*Daubert v. Merrell Dow Pharm., Inc.*, 1989: 572) about Bendectin and legal authority that epidemiological studies are the most reliable causation evidence in this field of study. The plaintiffs failed to present “statistically significant epidemiological proof that Bendectin causes limb reduction defects” because their expert relied, in part, on *in vitro* animal and chemical studies (*Daubert v. Merrell Dow Pharm., Inc.*, 1989: 575). The plaintiffs appealed, arguing the trial court erred when excluding the scientific studies and reanalysis of the epidemiological data by their experts. The three-judge Ninth Circuit Appellate Court unanimously affirmed the trial court, *Daubert v. Merrell Dow Pharm., Inc.* (1992), citing *Frye* and following the precedent, referencing

a well-founded skepticism of the scientific value of the reanalysis methodology employed by plaintiffs’ experts; they recognize that “[t]he best test of certainty we have is good science—the science of publication, replication, and verification, the science of consensus and peer review.” P. Huber, *Galileo’s Revenge: Junk Science in the Courtroom* 228 (1991).

(*Daubert v. Merrell Dow Pharm., Inc.*, 1989: 1131)

The Ninth Circuit suggested *in vitro* studies were junk science, affirming the trial court decision to ignore this new scientific evidence because it failed *Frye’s* general acceptance test. The plaintiffs appealed and the U.S. Supreme Court granted *Certiorari*.<sup>4</sup>

In a landmark decision regarding expert testimony, the U.S. Supreme Court held that FED. R. EVID. 702 superseded *Frye’s* general acceptance test, thereby requiring all federal courts to admit any “scientific, technical, or other specialized knowledge” that assists the trier of fact to understand the

evidence (*Daubert v. Merrell Dow Pharm., Inc.*, 1989: 580). “General acceptance” was no longer required to admit scientific evidence in federal court. A 7–2 majority also found that District Court judges (gatekeepers) must evaluate the admissibility of expert testimony, although Honorable Chief Justice William Rehnquist disagreed on the trial judge’s role, writing

I do not doubt that Rule 702 confides to the judge some gatekeeping responsibility in deciding questions of the admissibility of proffered expert testimony. But I do not think it imposes on them either the obligation or the authority to become amateur scientists in order to perform that role.

(*Daubert v. Merrell Dow Pharm., Inc.*, 1989: 600–601)

Chief Justice Rehnquist was “at a loss” in understanding what “falsifiability” meant when applied to a scientific theory and he predicted other federal judges would too. Nevertheless, the Ninth Circuit decision was reversed and remanded for further proceedings.

For efficient justice, the Ninth Circuit conducted the “brave new world” of *Daubert* analysis of FED. R. EVID. 702, framing the question as follows: “How do we figure out whether scientists have derived their findings through the scientific method or whether their testimony is based on scientifically valid principles?” (*Daubert v. Merrell Dow Pharm., Inc.*, 1989: 1316). A unanimous Ninth Circuit affirmed the original summary judgment under Rule 702 and *Daubert* because the plaintiff presented only experts’ qualifications, their conclusions, and their assurances of reliability. *Daubert* plaintiffs received due process, equal protection, and justice, but no compensation, because the expert scientific evidence failed to show, with a preponderance of the evidence, that Bendectin caused the birth defects.

Two subsequent U.S. Supreme Court cases, *General Electric Co. v. Joiner* (1997) and *Kumho Tire Co. v. Carmichael* (1999), refined *Daubert* and extended its holding. In *Joiner*, a city electrician with lung cancer brought suit against the manufacturer of polychlorinated biphenyls (PCBs) and the manufacturers of electrical transformers and dielectric fluid, alleging his exposure to these materials caused his cancer. *Joiner* relied on an expert to prove his case. The District Court judge excluded the expert testimony, finding it “subjective belief or unsupported speculation” (*General Electric Co. v. Joiner*, 1997: 140) and *Joiner* appealed. Under a stringent standard of review, the 11th Circuit Appellate Court reversed the trial court, finding the judge erred in excluding the expert testimony. The U.S. Supreme Court reversed the 11th Circuit, thereby affirming and strengthening the gatekeeping function of the trial court, and directing appellate courts not to review admissibility of expert opinions unless the trial judge committed a clear abuse of discretion. Basically, appellate courts were ordered to show great deference to the gatekeeping judges in District Courts and to not disturb the

decisions of the trial judge regarding the admissibility of expert testimony absent gross error.

In *Kumho Tire*, a vehicle overturned when a right rear tire blew out, killing one passenger and injuring others. The plaintiffs sought to admit a tire analyst's visual and tactile tire inspection testimony, under the theory that the absence of at least two of four specific physical indicators meant a tire defect caused failure. The defendant moved to exclude the tire analyst testimony, claiming the methodology failed FED. R. EVID. 702 requirements. The trial court applied *Daubert* and the judge excluded the tire analyst after finding the methodology employed was insufficiently reliable. Carmichael appealed. The 11th Circuit held that the trial court erred in applying *Daubert*, believing that it only applied to scientific testimony. The U.S. Supreme Court reversed the 11th Circuit and clarified that *Daubert* factors apply to the testimony of engineers and other experts who are not scientists. Experts may also be evaluated and admitted to testify based on skill, experience, and other specialized knowledge, not only scientific knowledge. Even after broadening the criteria, the tire expert opinion was excluded.

In 2002, the U.S. Supreme Court holdings from the *Daubert* "trilogy" were codified into an amendment to Rule 702 governing expert testimony. Rule 702 reads as follows:

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case.

(Fed. R. Evid. 702)

In summary, *Daubert* incorporated the *Frye* "general acceptance" test and added other factors that federal court gatekeepers may consider when evaluating expert testimony. After general acceptance within the relevant scientific community, *Daubert* also encouraged judges to consider whether the methodology employed by the expert was subject to peer review, testable (falsifiable), and had a known error rate. Generally, psychologist experts have fared well under *Daubert* because standardized methods supported by data in a technical manual are favored. However, these factors are neither exhaustive nor exclusive, and subsequent federal courts have departed from the original *Daubert* list to consider more factors, such as

- Whether experts are proposing to testify about matters growing naturally and directly out of research they have conducted independent of the litigation, or whether they have developed their opinions expressly for purposes of testifying. *Daubert v. Merrell Dow Pharm., Inc.* (1995).

- Whether the expert has unjustifiably extrapolated from an accepted premise to an unfounded conclusion. *General Elec. Co. v. Joiner* (1997).
- Whether the expert has adequately accounted for obvious alternative explanations. *Claar v. Burlington N.R.R.* (1994).
- Whether the expert "is being as careful as he would be in his regular professional work outside his paid litigation consulting." *Sheehan v. Daily Racing Form, Inc.* (1997).
- Whether the field of expertise claimed by the expert is known to reach reliable results for the type of opinion the expert would give. *Kumho Tire Co. v. Carmichael* (1999).

*Daubert* clearly provides the court greater flexibility in its analysis of new science and although it offers courts greater protection against junk science, it also places a greater burden on trial court judges. Chief Justice Rehnquist described that burden when noting the "amateur scientist" role implicit in the gatekeeping function. Nevertheless, *Daubert* flexibility is considered to have liberated courts to seek relevant and reliable expert opinions to assist the trier of fact. With each passing year, more jurisdictions adopt its basic framework, while restricting or completely abandoning *Frye*.

Early legal experts believed that *Daubert* would tighten the evidentiary standards for admissibility (Dixon & Gill, 2002; Grove & Barden, 1999), and there has been some empirical evidence to suggest that it has had or is beginning to have the desired effect (Dixon & Gill, 2002; Johnson, Krafka, & Cecil, 2000; Krafka, Dunn, Treadway Johnson, Cecil, & Miletich, 2002). For instance, Dixon and Gill (2002) found that the proportion of cases in which the reliability of expert evidence from various types of experts was challenged, including health care/medicine and social/behavioral science, appears to have increased significantly since the *Daubert* ruling to 62% and 84%, respectively during the most recent period examined, which was July 1997 to June 1999, as compared to 23% and 56% during the period immediately prior to *Daubert*, which was July 1989 to June 1993. Furthermore, Dixon and Gill (2002) found that the proportion of successful challenges to social and behavioral science evidence also increased significantly during the same time period, from 8% of cases challenged between July 1989 and June 1993 to 47% between July 1997 and June 1999 (although the period of July 1989 to June 1993 appears to be somewhat of a statistical outlier, as 43% of challenges were successful during the decade of the 1980s). Interestingly, the proportion and success rate of challenges to physical science evidence were highest relative to all other types of evidence (health care/medicine, engineering/technology, social/behavioral science, and business/law/public administration) during most of the time periods examined by Dixon and Gill (2002). In spite of these apparent changes, it appears that the *Daubert* standard may not be applied consistently to behavioral science

evidence (Shuman & Sales, 1999; Tenopyr, 1999), and that judges in many jurisdictions may continue to rely primarily on the *Frye* standard (Krafka et al., 2002). Furthermore, individual judges and attorneys vary considerably in their level of sophistication in dealing with issues of admissibility and their knowledge of scientific methods. These issues highlight what might appear to be a confusing state of affairs

confronting the neuropsychological expert witness. A table of admissibility decisions that pertain to *Daubert* and related federal and state standards involving neuropsychological testimony, taken from the *Daubert Tracker* online database (MDEX Online, 2017), have been included, and provide some idea of the challenges facing neuropsychologists who serve as expert witnesses (see Table 36.1).

Table 36.1 Results of *Daubert* and other related evidentiary challenges to testimony of neuropsychologists

Case	Year	Court	Plaintiff/Defense	Outcome	Reason for Challenge	Other expert testimony admitted/denied
<i>Hutchison v. American Family Mutual Insurance Co.</i>	1994	Iowa, Supreme Court	Defense	Testimony admitted	Neuropsychologist not qualified to testify regarding causation	Neuropsychologist was only expert challenged
<i>Maritime Overseas Corp. v. Ellis</i>	1994 <sup>a</sup>	Texas, Court of Appeals	Defense	Testimony admitted in two separate hearings	Admissibility not an issue, but <i>Daubert</i> cited in dissenting opinion	Medical and other psychological testimony also admitted
<i>Goewey v. United States</i>	1995/1997 <sup>a</sup>	South Carolina/4th Circuit	Plaintiff	Testimony denied	Neuropsychologist unable to make clear causal link	Medical and scientific testimony also denied
<i>Hose v. Chicago Northwestern Transport Co.</i>	1995	8th Circuit	Plaintiff	Testimony admitted	Neuropsychologist not qualified to determine medical causation	Medical testimony also admitted
<i>Summers v. Missouri Pacific Railroad System</i>	1995/1997 <sup>a</sup>	Oklahoma Eastern District/10th Circuit	Plaintiff	Testimony denied	Neuropsychologist not expert in medicine or toxicology	Medical testimony also denied
<i>Sanderson v. International Flavors &amp; Fragrances</i>	1996	California, Central District	Plaintiff	Testimony denied	Neuropsychologist unable to make clear causal link	Medical and scientific testimony also denied
<i>Valentine v. Pioneer Chlor Alkali Co.</i>	1996	Nevada	Plaintiff	Testimony denied	Neuropsychologist unable to make clear causal link	Medical testimony also denied
<i>Brafford v. Brafford's Construction Co.</i>	1997	North Carolina, Court of Appeals	Plaintiff	Affirmed lower court ruling to admit testimony	Neuropsychologist inappropriately based opinion on plaintiff's self-report of premonitory function	Neuropsychologist was only expert challenged
<i>Doe v. Provident Life and Accident Insurance Co.</i>	1997	Pennsylvania, Eastern District	Defense	Testimony Admitted	Neuropsychologist not qualified to comment on appropriateness of medical treatment	Neuropsychologist was only expert challenged
<i>Huntoon v. Cablevision</i>	1997	Colorado, Court of Appeals	Plaintiff	Lower court should have excluded testimony	Neuropsychologist not qualified to determine cause of physical injury	Neuropsychologist was only expert challenged
<i>Nations v. State of Texas</i>	1997	Texas, Court of Appeals	Defense	Testimony admitted	Neuropsychologist's testimony based on unreliable methods	Neuropsychologist was only expert challenged
<i>United States v. Gigante</i>	1997 <sup>a</sup>	New York, Eastern District	Both	Testimony denied/ later Admitted	Neuropsychologist's testimony speculative	Medical and other psychological testimony initially denied/ admitted in later hearings
<i>Chrissafis v. Continental Airlines</i>	1998	Illinois, Northern District	Defense	Testimony admitted in part	<i>Daubert</i> cited by defense in response to plaintiff attempt to exclude testimony as not relevant	Neuropsychologist was only expert challenged
<i>Louderback v. Orkin Exterminating Co.</i>	1998	Kansas	Plaintiff	Testimony admitted in part	Neuropsychologist not qualified to testify about cause	Scientific testimony also admitted
<i>Johnson Electric Co. v. Wiley</i>	1999	Texas, Court of Appeals	Plaintiff	Testimony admitted	Testimony based on unreliable methods and insufficient to show causation	Neuropsychologist was only expert challenged

(Continued)

Table 36.1—Continued

<i>Case</i>	<i>Year</i>	<i>Court</i>	<i>Plaintiff/Defense</i>	<i>Outcome</i>	<i>Reason for Challenge</i>	<i>Other expert testimony admitted/denied</i>
<i>Miller v. Conrail</i>	1999	Pennsylvania, Eastern District	Defense	Set up a pre-trial voir dire	Neuropsychologist not an expert on Lyme disease	Medical and scientific testimony also subjected to voir dire
<i>United States v. Willis</i>	1999	6th Circuit	Defense	Testimony denied	Testimony not relevant	Neuropsychologist was only expert challenged
<i>Young v. American Reliable Insurance Co.</i>	1999	Louisiana, Eastern District	Defense	Pre-trial hearing to determine whether admissible	Opinion based on unreliable methods	Other professional testimony admitted or admitted in part
<i>Anello v. Shaw Industries</i>	2000	Massachusetts	Plaintiff	Testimony admitted	Opinion based on unreliable methods	Medical and scientific testimony admitted, admitted in part, or denied
<i>Coe v. State of Tennessee</i>	2000	Tennessee, Supreme Court	Court appointed	Testimony admitted	Opinion based on unreliable methods—tests not normed for death row inmates	Neuropsychologist was only expert challenged
<i>Minner v. American Mortgage &amp; Guaranty Co.</i>	2000	Delaware, Superior Court	Both	Testimony admitted in part	Flexible battery approach challenged; neuropsychologist not qualified to testify regarding causation	Medical testimony admitted or admitted in part
<i>In Re: New Orleans train car leakage fire litigation</i>	2000	Louisiana, Court of Appeal	Plaintiff	Testimony admitted	Study of psychological effects of event conducted by expert not submitted to peer review	Medical testimony also admitted
<i>Ruckman v. State of Texas</i>	2000	Texas, Court of Appeals	Plaintiff	Upheld lower court exclusion	Opinion based on unreliable methods	Neuropsychologist was only expert challenged
<i>United States v. Bridges</i>	2000	4th Circuit	Defense	Testimony denied	Testimony not relevant	Neuropsychologist was only expert challenged
<i>Villalba v. Consolidated Freightways Corp.</i>	2000	Illinois, Northern District	Defense	Testimony admitted	Neuropsychologist did not disclose norms on which decisions were based	Neuropsychologist was only expert challenged
<i>Walker v. Conrail</i>	2000	Indiana, Northern District	Plaintiff	Testimony admitted	Neuropsychological test results not sufficient to determine that TBI was sustained	Medical testimony also admitted
<i>Walker v. Soo Line Railroad</i>	2000	7th Circuit	Plaintiff	Testimony Admitted	Opinion based on unreliable methods—relied partially on inaccurate educational history	Medical and scientific testimony also admitted
<i>Bonner v. ISP Techs., Inc.</i>	2001	8th Circuit	Plaintiff	Testimony Admitted	Scientific basis for neuropsychologist's testimony challenged	Scientific testimony also admitted
<i>New Haverford Partnership v. Stroot</i>	2001	Delaware, Supreme Court	Plaintiff	Testimony admitted	Neuropsychologist did not "scientifically eliminate" other possible causes of injury	Medical and scientific testimony also admitted
<i>Sea Robin Pipeline Co. v. Mew Medico Head Clinic Facility</i>	2001	Louisiana, Court of Appeal	Plaintiff	Reversed lower court exclusion	Dissenting opinion suggested expert opinions were speculative and not based on reliable evidence	Medical and other psychological testimony also should not have been excluded
<i>Abron v. Dean Lumber Co.</i>	2002	Texas, Eastern District	Plaintiff	Motion to exclude testimony denied	Neuropsychologist's opinion did not meet Daubert standard	Motion to exclude medical and other expert testimony also denied
<i>Alder v. Bayer Corp.</i>	2002	Utah, Supreme Court	Plaintiff	Reversed lower court exclusion	Opinion regarding cause of injury based on unreliable methods	Medical and scientific testimony also admitted
<i>Allison v. Fire Insurance Exchange</i>	2002	Texas, Court of Appeals	Plaintiff	Upheld lower court exclusion	Neuropsychologist's opinion based on unreliable methods	Medical testimony also denied
<i>Blansett v. BP Exploration &amp; Oil, Inc.</i>	2002	Ohio, Court of Appeals	Both	Testimony admitted	Some of the tests used in forming opinion regarding malingering have been "scientifically discredited"	Medical, other psychological, and scientific testimony also admitted

<i>Case</i>	<i>Year</i>	<i>Court</i>	<i>Plaintiff/Defense</i>	<i>Outcome</i>	<i>Reason for Challenge</i>	<i>Other expert testimony admitted/denied</i>
<i>Chu v. American Airlines</i>	2002 <sup>a</sup>	8th Circuit	Plaintiff	Case settled without ruling on admission	Defendant appealed failure of lower court to submit expert testimony to test of evidentiary standards	Medical, scientific, and other testimony also challenged in prior case, which was dismissed prior to ruling on admissibility
<i>Commonwealth of Massachusetts v. Montanez</i>	2002	Massachusetts, Appeals Court	Defense	Testimony should not have been excluded at original trial	Diagnostic category (dissociative trance disorder) not scientifically reliable	Neuropsychologist was only expert challenged
<i>Floyd v. McGill</i>	2002	North Carolina, Court of Appeals	Plaintiff	Affirmed lower court ruling to admit testimony	Neuropsychologist lacked expertise on biomechanics of closed head injury to determine cause	Medical and other experts also ruled appropriately admitted by lower court
<i>Akers v. United States</i>	2003	Oregon	Plaintiff	Testimony admitted—methods not challenged	Defendant raised question of admissibility, but did not specifically challenge underlying methods	Medical and other experts also admitted
<i>Fini v. General Motors Corp.</i>	2003	Michigan, Court of Appeals	Plaintiff	Testimony admitted	Functional neuroimaging on which expert relied not a reliable means of diagnosing injury	Neuropsychologist was only expert challenged
<i>Grenitz v. Tomlian</i>	2003	Florida, Supreme Court	Plaintiff	Upheld lower court's exclusion	Neuropsychologist not qualified to determine cause of birth defect	Neuropsychologist was only expert challenged
<i>Martinez v. Dretke</i>	2003	Texas, Southern District	Defense	Testimony admitted	Neuropsychologist did not have scientific basis for conclusions and was not qualified at time of initial examination of defendant	Psychological and other experts also admitted
<i>Roberti v. Andy's Termite and Pest Control, Inc.</i>	2003	California, Court of appeals	Plaintiff	Testimony should not have been excluded at original trial—Daubert not applicable under CA law	Methods used in forming opinion not supported by peer-reviewed research	Medical and other experts were also improperly excluded in lower court trial
<i>Taylor v. American Fabritech, Inc.</i>	2004	Texas, Court of Appeals	Plaintiff	Affirmed lower court ruling to admit testimony	Defendant challenged scientific basis for neuropsychologist's conclusions admitted in lower court	Medical and other experts also admitted
<i>Amos v. Keller Transfer Line, Inc.</i>	2005	Michigan, Court of Appeals	Plaintiff	Affirmed lower court ruling to admit testimony	Neuropsychologist formed opinion without obtaining records to establish premorbid function	Neuropsychologist was only expert challenged
<i>Bado-Santana v. Ford Motor Co.</i>	2005	Puerto Rico	Plaintiff	Testimony excluded pending Daubert hearing	Neuropsychologist not qualified to determine causation	Medical experts excluded or partially excluded; scientific and other experts admitted
<i>Hufford v. Harris Corp.</i>	2005	Florida, Middle District	Defense	Testimony admitted	Neuropsychologist who performed an IME did not base opinion on scientific evidence and was biased by virtue of being paid by defendant	Medical and other experts also admitted
<i>Marmo vs. IBP, Inc.</i>	2005	Nebraska	Defense	Testimony moot in part, admitted for certain issues	Neuropsychologist failed to consider possible alternative explanations in reaching opinion	Medical, scientific, and other experts' testimony either admitted or considered moot

(Continued)

Table 36.1—Continued

Case	Year	Court	Plaintiff/Defense	Outcome	Reason for Challenge	Other expert testimony admitted/denied
<i>McCarthy v. Atwood</i>	2005	Virginia, Circuit Court	Defense	Testimony admitted in part (not allowed to comment on cause)	Neuropsychologist not qualified to determine causation	Neuropsychologist was only expert challenged
<i>Blair et al. v. U.S. Steel Corp.</i>	2005	Indiana, Superior Court of Lake County	Plaintiff	Testimony denied	Neuropsychologist's opinion not sufficiently based on reliable factual/scientific principles	Neuropsychologist was only expert challenged
<i>Baxter v. Temple</i>	2005 <sup>b</sup>	New Hampshire, Merrimack County Superior Court	Plaintiff	Testimony denied	Boston Process Approach as employed by neuropsychologist deemed unreliable for forensic purposes	Neuropsychologist was only expert challenged

<sup>a</sup> Denotes a case in which multiple evidentiary decisions were rendered (e.g., initial rulings appealed to higher courts).

<sup>b</sup> This case was not yet listed in the *Daubert* Tracker database at the time the other cases were reviewed, but came to the attention of the authors and was included because of its obvious relevance.

Note: Information within this table was used with permission and derived from a proprietary legal database called MDEX Online Daubert Tracker<sup>®</sup> at [www.dauberttracker.com](http://www.dauberttracker.com). IME = Independent Medical Examination.

The *Daubert* decision and other similar rulings have caused some concern among neuropsychologists that such standards might lead to the exclusion of neuropsychological tests and expert witnesses. However, Table 36.1 shows that this is not the case, as neuropsychologists do not appear to have fared worse than other experts. It is important to recognize that decisions involving evidentiary standards are case-specific and are influenced by the individual expert, the procedures he or she uses, and the underlying scientific evidence in a particular case. Thus, it is quite possible that a particular expert's testimony might be accepted in one instance and denied in another, depending on whether his or her assertions in each specific case are judged to have a valid scientific basis. Mainstream scientist-practitioner neuropsychologists have never been threatened by the need to provide empirical justification for their work, and should applaud such standards, as they target witnesses from fields without a firm grounding in science.

Since publication of the first edition, two civil cases heard by state supreme courts illustrate the nature of admissibility challenges confronting expert neuropsychologists under *Daubert*. The first case showed how neuropsychologist opinions may be wrongfully excluded (*Baxter v. Temple*, 2008); the second suggested that expert opinions about brain-behavior relations may be wrongfully admitted (*Bennett v. Richmond*, 2012).

In *Baxter v. Temple* (2005), the defense filed a motion *in limine*<sup>5</sup> to exclude the testimony of Barbara Bruno-Golden, Ed.D. as insufficiently reliable under *Daubert*. During the evidentiary hearing Bruno-Golden described the Boston Process Approach (BPA) she employed in the

neuropsychological evaluation of a child exposed allegedly to lead poisoning. The defendants argued successfully that her testimony should be excluded because her BPA methodology is not generally accepted in the appropriate scientific literature, has not been subject to peer review and publication, and has no known or potential error rate. Hearing testimony reveals how a trial judge used *Daubert* factors to exclude expert neuropsychological evidence and how such outcomes may be avoided (Desmond, 2007).

All three neuropsychologists, Bruno-Golden, Sandra Shaheen, and David Faust, testified that the BPA methodology employed was untested (*Baxter v. Temple*, 2005, p. 8). Bruno-Golden added that the BPA she used in this evaluation, "has never been . . . and *cannot be tested*, because it varies from practitioner to practitioner" (p. 9) [*emphasis added*]. In fact, Bruno-Golden testified that she "could not recall if she had ever administered the same test battery" (p. 9) on the thousands of other patients she evaluated during her career. The trial judge ruled that Bruno-Golden's BPA cannot be and was not tested in this case.

The neuropsychologist experts also agreed that the BPA methodology employed was not subjected to peer review, nor described in published articles. Although Bruno-Golden offered a professional position paper supporting the BPA, Faust noted it was not in a peer-reviewed publication. Shaheen noted learned treatises on BPA general acceptance in clinical neuropsychology practice, yet admitted that Bruno-Golden's specific methodology had not been subject to peer review or described in published articles. Finally, Bruno-Golden admitted she had not previously used the methodology employed and it was likely that no other clinician

had either. Therefore, the trial judge found the BPA as employed in this case had not been subject to peer review and publication.

The BPA error rate was essentially unknowable and no evidence was offered. Bruno-Golden testified that she disregarded standardized time constraints in order to “test the limits” of the child’s performance on selected tests. No experts offered any evidence on the reliability of testing the limits. Faust noted that variations in the standardized instructions interfere with test interpretation and destroy the normative comparisons of the child’s performance to like-aged peers, making it impossible to determine an error rate. Faust testified that when Bruno-Golden modified the BPA she created an “idiosyncratic combination, if not hodgepodge of multiple influences” (p. 11). The court detailed some departures from standardized techniques. Faust concluded, the methodology employed was “not scientifically validated . . . founded on guesswork, speculation, and conjecture, which sometimes flies directly in the face of scientific literature” (p. 11). Hence, the judge ruled the methodology employed by Bruno-Golden did not have a known or potential error rate.

The *Baxter* trial court concluded its analysis by distinguishing between appropriate scientific literature for clinical assessment and “a ‘forensic’ approach to assessing children with lead poisoning” (p. 13). Faust explained how a clinical or forensic referral changes the expert neuropsychologist role. This important distinction between the clinical provider and forensic examiner has been described often (Greenberg & Shuman, 1997; Heilbrun, 2001). Although most authorities agree that clinical and forensic roles are irreconcilable and every effort should be made to avoid conflicts of interest (Greenberg & Shuman, 2007), others’ approaches are more situational (Woody, 2009), and a minority even suggest that the roles are potentially compatible (Heltzel, 2007). In the end, neuropsychologists in forensic practice must employ objective methods that allow them to be unbiased truth seekers.

Upon reviewing the *Daubert* hearing testimony, the *Baxter* trial court seemingly had overwhelming undisputed evidence that Bruno-Golden’s methodology was not sufficiently reliable for forensic analysis (Desmond, 2007). The trial court judge found her methodology failed to meet any *Daubert* factors. Therefore, the motion *in limine* was granted, Bruno-Golden’s testimony was excluded, and the jury never heard her opinions in the case. The plaintiff appealed and the New Hampshire Supreme Court certified three questions for judicial review, asking whether the trial court erred when excluding: (a) the neuropsychologist’s testimony based on the BPA, (b) the IQ test testimony, and (c) the pediatrician’s testimony that reasonably relied upon the neuropsychologist’s report.

In a unanimous decision that includes a thorough analysis of neuropsychological test administration errors, the New Hampshire Supreme Court reversed the trial court on the first question and vacated the subsequent questions as moot. The *Baxter* court reasoned, “the *Daubert* test does not stand

for the proposition that scientific knowledge must be absolute or irrefutable” (citing *State v. Dahood*, 2002). Referring to the trial court’s conclusion, it

focused upon the plaintiff’s failure to demonstrate that the specific battery—the entire series of tests viewed as a whole—employed by Dr. Bruno-Golden in this case was, or could not be, tested, was subject to peer review and publication, or has a known or potential error rate.

(*Baxter*, p. 174)

The high court cited *Kumho Tire* language that *Daubert* factors “do not constitute a definitive checklist or test,” but even if they did, “the BPA meets three of four *Daubert* factors.” (p. 184). The *Baxter* court expressly rejected the battery as a whole argument, finding “that the individual tests he or she administered as part of the battery, not the battery as a whole, have been tested, have been subject to peer review and publication, and have a known or potential error rate” (p. 184). The *Baxter* court wrote, “we reject the defendant’s assertion that Dr. Bruno-Golden’s methodology, the BPA as a flexible battery approach, is not a sufficiently reliable methodology to assist the fact finder in understanding the plaintiff’s neuropsychological status” (p. 187). The case was remanded back to the trial court with the instruction to admit Dr. Bruno-Golden’s opinions based on the BPA.

The *Baxter* court relied, in part, on an Amicus Brief from the AACN. Justices referred to the AACN brief during oral arguments, raising questions about the standard of care for clinical neuropsychology. AACN drew an analogy between the specialty practices of clinical neuropsychology and neurology, arguing that neurologists do not “conduct either an invariant exam procedure or order an invariant set of diagnostic tests for each and every patient” (p. 9). AACN asserted “that administering the same set of tests to all patients and litigants, regardless of the known or suspected condition is uninformed and inappropriate practice” (p. 9). Further, AACN noted “a standardized battery runs counter to an acceptable standard of care in neurology” and “we know of no area of specialty or subspecialty in clinical medicine in which a routine, invariant battery of tests across all medical conditions being evaluated would be acceptable practice” (p. 9). Although not explicitly written, AACN was seemingly advocating for a flexible battery standard of care for clinical neuropsychology. For most referral questions, a flexible battery approach is the predominant form of practice, even as the fixed battery method remains a respectable minority practice in clinical neuropsychology. In what is probably the best example of the application of *Daubert* factors to neuropsychological methodology, *Baxter* illustrates how federal courts and most state courts would address admissibility based on battery selection. *Baxter* also illustrates how neuropsychology is approaching early questions about standards of care for the profession.

Although *Baxter* resolved admissibility questions of flexible batteries in forensic practice for New Hampshire, Dr. Bruno-Golden withdrew and her testimony was never heard, in what was the oldest pending case in New Hampshire (McCrystal, September 23, 2012). Indeed, *Baxter* was a plaintiff in a second lawsuit alleging that state budget cuts resulted in an unconstitutional delay of justice (*Baxter et al. v. State*, 2010). The second lawsuit was promptly dismissed and a retrial took place in September 2012. In the end, the Temples were negligent landlords in not providing notice of lead paint to the Baxters, but no money damages were awarded to Shelby Baxter or her parents. Despite elevated lead levels as an infant, the jury found that the negligence identified did not cause any damages. This case was the first lead case in New Hampshire that went to trial.

On May 24, 2004, John Richmond was sitting in his van, stopped for a school bus, when it was rear-ended by Henry Bennett, who was driving a 42,000-pound roll-off container truck for his employer. Upon collision, Richmond's one-ton van was propelled 300 feet from a stopped position. Richmond sustained head and neck injuries. In December 2004, Richmond sustained a back injury in the course of employment that exacerbated injuries incurred during the May 2004 accident. Apparently, he was a self-employed builder-contractor. In December 2005, Richmond and his wife sued Bennett and his employer for injuries Richmond sustained to his neck and back in the collision. Upon referral by his attorney, Richmond underwent a neuropsychological evaluation with Dr. Sheridan McCabe in October, 2006.

McCabe obtained a M.A. degree in General Psychology in 1956 and a PhD in Counseling Psychology in 1958. McCabe testified that Counseling Psychology was an applied field "working with people who were not psychiatric patients, but rather kind of regular people who had some sort of problem and counseling dealt with that," and that it involved "the assessment of a patient's psychological well-being." (Appellant's App., p. 235). He attended continuing education workshops specializing in forensic applications of psychology that "touched on subjects that relate to evaluation of traumatic brain injuries" (p. 69). McCabe reported that two neurologists referred cases to him for "specific aspects of brain behavior relationship questions" (p. 70), and other general practitioners referred cases to him for insight into the "relationship between the presenting psychological problems and . . . underlying medical issues" (p. 70). McCabe's route to clinical neuropsychology practice reflects a bygone era of exclusive reliance upon workshop training that does not meet modern standards for neuropsychology training (Hannay et al., 1998).

The defense hired a board-certified clinical neuropsychologist, David Kareken, PhD, ABPP, to conduct an independent neuropsychological evaluation of Richmond. Kareken's evaluation used modern approaches to forensic neuropsychology (e.g., using symptom validity techniques), which disputed McCabe's findings. Both parties filed motions to

exclude the opposing experts. The trial court denied both motions. However, Kareken did not testify as an expert witness, presumably because the defense decided to challenge whether a psychologist could render an opinion about the cause of brain damage. If the defense strategy was to argue that psychologists cannot render causation opinions, then it would not make sense to call a psychologist expert to rebut such opinions.

The court denied defense motions to exclude McCabe's opinion before and during the trial. McCabe testified that Richmond suffered a TBI in the accident and the jury returned a \$200,000 judgment in his favor. Bennett appealed the judgment, claiming the trial court abused its discretion by permitting a psychologist to testify as to the cause of a brain injury. In a unanimous opinion, the appellate court agreed with Bennett, and reversed and remanded for a new trial (*Bennett v. Richmond*, 2010). The court added,

no medical doctor or other qualified practitioner diagnosed Richmond with a brain injury. Rather, based upon neuropsychological testing given more than two years after the accident, Dr. McCabe opined that Richmond had sustained a brain injury as a result of the accident. The trial court should have exercised its discretion as gatekeeper prior to trial to exclude Dr. McCabe's proffered causation testimony based upon his lack of qualifications to give such testimony.

And the evidence regarding Richmond's damages other than the alleged brain injury is not sufficient to support the \$ 200,000 jury verdict.

(*Bennet v. Richmond*, 2010: 712)

The defense strategy worked, then Richmond appealed.

In a stunning reversal, a unanimous Indiana Supreme Court vacated the appellate court opinion and affirmed the trial court's determination that McCabe's opinion testimony was admissible. That is, it was not an abuse of discretion for the trial court to admit, as sufficiently reliable, a psychologist's opinion that the rear-end collision caused the motorist to suffer TBI. (*Bennett v. Richmond*, 2012). Such dramatic swings in judicial opinion warrant further consideration of McCabe's credentials, methodology, and bases for his expert opinions.

Dr. McCabe denied being a neuropsychologist, yet clearly asserted his expertise regarding TBI. He reviewed medical records before and after the accident, including a radiologist's impressions of a December 13, 2007 brain magnetic resonance imaging (MRI) report, as follows:

The MRI report indicates small chronic lacunar infarction in the head of the left caudate nucleus. While this type of finding is more indicative of ischemic episodes, it does not rule out the possibility of other causes such as the closed head injury that I suggested in my report . . . [T]his MRI finding is consistent with the sort of brain damage that could produce memory problems.

(Appellant's App., p. 255)

Despite these equivocal impressions, McCabe concluded that the MRI results “were consistent with *his* findings of brain injury.” [emphasis added] (Appellant’s App., p. 252.). However, other brain structures, such as the frontal/temporal poles or the corpus callosum, are more commonly vulnerable to damage following closed head injury than the head of one caudate nucleus. McCabe selectively misconstrued the radiologist’s opinion.

What was the basis for McCabe’s findings of brain injury? McCabe administered, scored, and interpreted a battery of neuropsychological tests. However, his opinion also relied upon clinical and collateral interviews, that is, the self-report of interested parties. Specifically, the trial court heard McCabe’s impressions based on clinical interviews, but also testimony provided by Richmond’s wife, Jennifer, and Richmond’s brother, Andrew. Richmond also relied on the testimony of a treating chiropractor, Gary McLeod. All of these witnesses testified about injuries sustained in the accident and problems that evolved after the accident. For example, Richmond called his wife Jennifer from the accident scene and she reported he “sounded shaken-up and was slurring at the time and sounded like he was hesitating on what he was trying to say” (Appellee’s App., p. 120; Tr. 447). After the accident, Jennifer also noticed that her husband “was always forgetting things and leaving sticky notes all over the place to remind him of things” (Appellee’s App., p. 122; Tr. 449). Richmond also complained of persistent headache.

McCabe administered the Wechsler Adult Intelligence Scale, Third Edition (WAIS-III), the Wechsler Memory Scale, Third Edition (WMS-III), and the Halstead-Reitan Neuropsychological Test Battery (HRB). His brain injury findings were inferred from discrepancies noted among subtest scores on the WAIS-III and the WMS-III that he characterized as “cognitive inefficiency” and “some sort of interference with [Richmond’s] cognitive process” (Appellant’s App., pp. 89–90; Tr. 331/24–25; 332/1–5). Dr. McCabe also found a mild to moderate impairment on the HRB with special emphasis on category test performance, noting “the first test . . . is a test of problem-solving thinking ability, very sensitive to brain damage” (Appellant’s Appendix, p. 91; Tr. 333/1–10). From these findings, McCabe inferred that Richmond

sustained a diffuse axonal injury [in the course of the rear-end accident in which he was involved]; that is to say, that kind of motion to the head caused damage to the connections between the cells of the brain through the axons. They were sufficiently messed up to provide him with these processing problems that he has manifested—by the time I saw him two years later.

(Appellant’s App., p. 92; Tr. 334/6–13)

However, McCabe also agreed that depression and/or anxiety could have caused the cognitive inefficiency noted in his evaluation (Appellant’s App., p. 154; Tr. 396).

McCabe testified that Richmond sustained a diffuse axonal injury, which he offered, “as a kind of explanation of the damage [Richmond] sustained” (Appellant’s App., p. 145; Tr. 387). However, when asked what he meant by diffuse brain damage, McCabe responded, in part, that

the pattern of functioning revealed by the tests is that the damage that underlies it is of a diffuse character. That is, its across various areas of the brain . . . I would infer, not assert, but suggest that the damage is in the axonal connections in the frontal lobe between the cortex and the lower brain centers, providing this kind of inefficiency: not localized to the visual cortex or the auditory cortex or so on.

(Appellant’s App., p. 145; Tr. 387)

McCabe expressly refused to testify to a reasonable degree of medical certainty. Similarly, when asked whether he could testify to a reasonable degree of psychological certainty, McCabe responded, “No. I am asserting it upon the pattern of functioning.” (Appellant’s App., pp. 146–147; Tr. 388–389).

When asked to further explain his opinion that Richmond sustained a diffuse axonal injury, McCabe said that it was an inference he drew from “the pattern of what I call ‘cognitive inefficiency’ that I saw in the test results” (Appellants App., p. 172; Tr. 414). In commenting on the physician’s impression about a “small chronic lacunar infarction in the head of the left caudate nucleus” on the MRI, McCabe agreed that such a finding was more often indicative of ischemic episodes and not a closed head injury. However, McCabe maintained that the MRI results did not rule out the possibility of other causes, such as the closed head injury he suggested (Appellant’s App., pp. 254–255).

McCabe did not testify about symptom or performance validity. There was no reference to EMT records from the accident scene and there was no description of Richmond’s acute neurologic status following the collision. Again, as a counseling psychologist, McCabe’s evaluation and inferences about brain damage causation reflected a bygone era of neuropsychological test interpretation. His conclusions were not consistent with those of a board certified clinical neuropsychologist who had conducted an evaluation that defense counsel elected not to file. Ultimately, defense counsel made two strategic errors. First, the defense failed to call for a *Daubert* hearing to challenge the reliability and relevance of McCabe’s credentials, methodology, and basis for his expert opinions. Second, the defense should have called a board certified neuropsychologist to dispute McCabe’s testimony at trial.

*Baxter* and *Richmond* are not easily harmonized, in part, because the defense strategies were so different. In *Baxter*, the defense aggressively attacked the plaintiff expert by retaining an opposing expert to testify at a pretrial *Daubert* hearing about the inadequacies of her methodology. This strategy was initially successful in excluding the plaintiff expert. Even

though the trial court erred in excluding Bruno-Golden, in the final analysis, she withdrew and never testified. Even though the defendant landlord was found negligent, this was a defense verdict because the insurance company was not required to pay any damages.

Defense counsel in *Richmond* took a very different approach. Rather than attack the specific methodology of the plaintiff expert in a *Daubert* hearing, the defense elected to pursue a failed attack on the profession of psychology as a whole on appeal. Initially, that strategy was successful and the defense may have felt they simply needed to shore up a win. Basically, the defense argued that psychologists and neuropsychologists are not qualified to render expert opinions about the causes of brain damage. No *Daubert* hearing was conducted and no opposing neuropsychologist testified, even though a defense neuropsychological evaluation consistent with modern practice was performed and readily available. By failing to call an opposing board certified neuropsychologist at trial to detail the inadequacies in McCabe's methods, the *Richmond* defense missed an opportunity to distinguish the outdated methods of a counseling psychologist using a fixed battery from the modern methods of a board-certified neuropsychologist using a flexible battery with symptom validity techniques. Moreover, there was no record developed by the defense to show the plaintiff's acute neurologic status immediately after the collision. Appeals can only review facts presented at trial.

The heterogeneity that exists in the application of evidentiary standards makes it difficult to draw general conclusions about admissibility of neuropsychological evidence. However, it is clearly in the best interest of neuropsychologists who engage in forensic activities to have solid empirical support for their opinions and to resist the temptation to speculate beyond what is apparent and can reasonably be inferred from the data. As clinical neuropsychologists, we often take great pride in the scientist-practitioner tradition embodied in our field, but there are a number of challenges related to the validity of our methodology that must continue to be addressed through research and continued refinement of methods, including the quality and applicability of available norms for many neuropsychological instruments, inferences about changes in cognitive functioning, and current limitations of neuropsychological tests in predicting functional outcome.

#### *Quality and Applicability of Norms*

Normative studies provide empirical reference points for comparisons of patient performances, and are thus crucial to our ability to understand the meaning of test scores. Given the important role of norms for clinical (and forensic) decision making, it is perhaps surprising that relatively few neuropsychological tests have had large-scale normative studies performed on them (Mitrushina, Boone, & D'Elia, 1999). With the exception of a few very-well-researched measures,

neuropsychologists are often forced to rely on converging evidence from multiple less well-normed instruments, as well as patient history and behavioral observations. Even when relatively large normative studies are available, the validity of conclusions based on test performance may be attenuated if individuals tested are dissimilar to the normative sample in some way (e.g., in terms of age, education, racial/ethnic background), which can limit the conclusions that can be made based on test scores (Joint Committee on Standards for Educational and Psychological Testing, 1999). Furthermore, it is important to remember that no test is a pure measure of a particular neuropsychological function or neurological disorder, and most tests encompass a number of different functions (Rankin & Adams, 1999). For example, a low score on the learning trials of a verbal list-learning task could reflect poor encoding of information, poor attention span, language disturbance, or poor effort, among other possibilities. Thus, it is incumbent upon the forensic neuropsychologist to demonstrate that his or her conclusions fit the data better than plausible alternative explanations (Kay, 1999). This is best achieved through rational interpretation based on careful integration of various test results and other available data (e.g., behavioral, historical, collateral).

#### *Inferences About Premorbid Functioning*

In addition to comparing individuals' test performances to appropriate norms, conclusions about the impact of injuries on an individual's cognitive functioning also require comparison of current performance to inferred premorbid levels of performance. For example, simply relying on patient self-report of academic achievement is likely to be problematic and can lead to erroneous conclusions about the impact of injuries suffered (Greiffenstein, Baker, & Johnson-Greene, 2002). Several objective methods have been derived that can assist the clinician in estimating premorbid functioning, including regression equations based on demographic and/or test performance variables, and tests that are known to be relatively insensitive to brain injury (Franzen, Burgess, & Smith-Seemiller, 1997; Kareken, 1997). However, these methods give an estimate of the general level of intellectual functioning, and care must be taken in making inferences about premorbid abilities within more specific domains of cognitive functioning (Franzen et al., 1997). Furthermore, they fail to account for premorbid personality characteristics that might impact performance (Putnam, Ricker, Ross, & Kurtz, 1999).

#### *Limitations of Tests in Predicting Functional Outcome*

Neuropsychological test results, when interpreted by an adequately trained clinician, clearly improve the prediction and understanding of real world deficits relative to the level of prediction and understanding that would be possible

without objective data (Bieliauskas, Fasteneau, Lacy, & Roper, 1997; Bowman, 1997). However, neuropsychological performances often fall short of achieving fully accurate prediction of everyday functioning within the complexity of the real world environment outside of the testing context (LeBlanc, Hayden, & Paulman, 2000; Long & Collins, 1997; Sbordone, 2001; Sbordone & Long, 1996).

One particularly illustrative example of the difficulty in predicting functional outcome from neuropsychological test performance comes from the domain of executive functioning. Existing tests of executive functions often fail to provide an adequate representation of the novelty and complexity of the real world (Burgess, Alderman, Evans, Emslie, & Wilson, 1998; Goldberg & Podell, 2000). According to Goldberg and Podell (2000), the shortcomings are due in large part to the fact that objective tests are scored according to correctness/incorrectness of responses in an absolute sense, while decision making in a real-world context involves an ordering of possible choices according to priorities intrinsic to the individual. Another source of difficulty relates to the still incompletely understood and multifaceted nature of the domain of executive functioning itself. Within the domain of executive functioning, a given test may be sensitive to deficits within a particular subdomain only (e.g., shifting of attention or abstract reasoning) and may be insensitive to deficits in other subdomains (Burgess et al., 1998; Osmon, 1999). The imperfect relationship between test performance and real-world functioning underscores the need for caution in interpretation when performing forensic evaluations, as well as a need for further research on ecological validity within the field.

### ***Detection of Insufficient Effort and Malingering***

A major challenge to the forensic neuropsychologist's ability to draw conclusions based on test performance is the potential influence of insufficient effort or deliberate feigning, which in compensation-seeking populations is characterized as malingering. In fact, recent research suggests that insufficient effort can account for more variance in neuropsychological test performance among compensation-seeking individuals than objectively confirmed neurological injury (Green, Rohling, Lees-Haley, & Allen, 2001). Clinical observation, even by an experienced professional, has proven to be an inadequate method of detecting invalid test performance, necessitating the prospective assessment of the validity of test performance in all adversarial cases in which external motivating factors are present (Sweet, 1999b). Kaufmann (2012) summarized cases challenging the admissibility of some symptom validity techniques commonly used by neuropsychologists. Because the issue of malingering is discussed in detail in Millis and Kaufmann (Chapter 38 in this volume), only a brief overview is provided here.

Slick and colleagues (1999) have provided criteria to facilitate the clinical detection and empirical study of malingering. They suggest categorizing suspected malingering into

*definite, probable, and possible* malingering based on various types of evidence, including the existence of extrinsic motivating factors and demonstration of insufficient effort during testing. While it is often (although certainly not always) apparent when external motivating factors are present, neuropsychologists have only recently begun to develop sophisticated techniques for the objective assessment of effort during a neuropsychological evaluation. These techniques include a number of tests designed for the specific purpose of detecting insufficient effort (e.g., Green, Iverson, & Allen, 1999; Slick, Hopp, Strauss, & Spellacy, 1996) and examination of indicators derived from neurocognitive test performance (e.g., Demakis et al., 2001; Sweet & King, 2002). Indices have also been derived to detect overreporting of symptomatology by litigating populations on psychological inventories (e.g., Lees-Haley, English, & Glenn, 1991). In addition to Chapter 38 in this volume, numerous reviews have documented developments in the assessment of poor effort/malingering (Bordini, Chaknis, Ekman-Turner, & Perna, 2002; Franzen, Iverson, & McCracken, 1990; Haines & Norris, 1995; Hayes, Hilsabeck, & Gouvier, 1999; Iverson & Binder, 2000; Miller & Miller, 1992; Millis & Putnam, 1996; Nies & Sweet, 1994; Rogers, Harrell, & Liff, 1993; Sweet, 1999b; Vanderploeg & Curtiss, 2001).

### ***Expert Witness Role***

A major role that is played by neuropsychologists within the forensic setting is that of expert witness or expert independent examiner. Neuropsychologists are often asked to perform evaluations and render opinions about the existence and probable cause of cognitive impairments in litigants or claimants. This may require the neuropsychologist to provide testimony regarding his or her opinion, sometimes subjecting him or her to intense cross-examination from opposing attorneys (Bick, 1999). Another aspect of forensic neuropsychological practice that may be unfamiliar to many is the absence of a typical psychologist-patient relationship (Sweet, Grote, & van Gorp, 2002). The neuropsychologist who performs a forensic evaluation and/or provides expert testimony serves in a consultant role, rather than an assessing/treating clinician role, and it is important that this be made clear from the outset to all parties involved, particularly the litigant or claimant. A list of items that address the nonclinical aspect of the neuropsychologist's role can be found in Table 36.2. The individual should be informed that the usual expectation of confidentiality does not apply in this situation, and that he or she should not provide any information to the neuropsychologist that he or she does not want revealed to all parties involved. This role is very dissimilar to traditional clinical roles played by neuropsychologists, and may become uncomfortable if approached without careful thought. Because neuropsychologists have special expertise that can allow them to assist triers-of-fact in understanding complex issues related to cognitive dysfunction, and therefore can be of help to the

*Table 36.2* Points that can be discussed at the outset of a forensic examination to ensure that the claimant or litigant is fully informed about the nature of the examination about to be undertaken

- 
- 1 Clarification of the reasons for the evaluation
  - 2 Identification of the referral source and any relationship, or lack thereof, with the examiner
  - 3 A general description of the types of information that will be gathered during the evaluation
  - 4 A description of the lack of confidentiality within the examination, making it different from the normal "doctor-patient" relationship
  - 5 Clarification that no treatment will be offered to the examinee
  - 6 The intent of maintaining objectivity on the part of the examiner and clarification that the examiner is not acting as an interested party regarding the outcome of the claim or litigation
  - 7 The importance of the examinee being honest in providing information and also putting forth full effort on the formal testing
- 

decision-making process in such cases, their forensic activities make an important contribution. Neuropsychologists may also be retained as consultants to review the work of colleagues in cases where they do not evaluate the litigating patient directly, an area of practice that has received relatively little consideration from a perspective of ethical standards (Guilmette & Hagan, 1997; Johnson-Greene & Bechtold, 2002; McSweeney, 1997). Whether retained as an expert witness or to provide consultation to attorneys, the best way to accomplish the goal of assisting the courts is through maintaining objectivity and relying on the empirical foundations of the field (Guilmette & Hagan, 1997; Martelli, Zasler, & Grayson, 1999b; McSweeney, 1997). Issues involved in working within the legal system are covered in greater depth in Greiffenstein and Kaufmann (Chapter 37 in this volume), but an overview of major issues related to the expert witness role will be provided here.

#### *Covert and Overt Pressures and Deceptive Attorney Behaviors*

In contrast to the more familiar clinical setting, forensic work often introduces pressures on the neuropsychologist to arrive at an opinion that is favorable to one side or another. In fact, some of the values and ethics of attorneys and psychologists are fundamentally in conflict with one another (Gutheil & Simon, 1999; Martelli, Bush, & Zasler, 2003; Melton, Petrila, Poythress, & Slobogin, 1997). Psychologists tend to value detached objectivity in their assessments of patients, believing that this is the best method of arriving at an accurate understanding of an individual's functioning (i.e., detached objectivity is the best method for discovering the truth). In contrast, attorneys have an obligation to advocate vigorously for their clients, with the underlying assumption that the truth is best sought through adversarial proceedings.

In spite of the pressures placed on attorneys by this adversarial system, most treat expert witnesses in an ethical manner. Nonetheless, a minority of attorneys use unscrupulous methods to exert pressure on expert witnesses. These methods can range from subtle (e.g., profuse praise of the expert's work) to more overt means (e.g., bribery, threats) to influence experts to produce opinions favorable to the attorney's side (Gutheil & Simon, 1999; Gutheil, Commons, & Miller, 2001; Hess, 1998). Although most attorneys do not engage in such practices, it is apparently not unusual for experts who practice frequently in the forensic arena to experience them from time to time. In a pilot study of expert witnesses' experiences with such pressures, Gutheil and colleagues (2001) found that more than one-third of their sample said they had had an attorney attempt to influence them to provide a favorable opinion and almost one-fifth said they had been threatened (e.g., with a complaint about the expert to a state licensing board).

Some attorneys may attempt to influence the results of evaluations not through pressuring the evaluating expert, but by coaching patients to report selected information during the clinical interview or to perform on cognitive tests in a manner consistent with injury (Lees-Haley, 1997a; Wetter & Corrigan, 1995). Coached deficits may allow more sophisticated faking of deficits than would be possible without attorney input and can affect the ability to reach valid conclusions based on testing (Coleman et al., 1998; Youngjohn, Lees-Haley, & Binder, 1999). Information about neuropsychological methods is widely available through various textbooks and the Internet, and it is naive to think that this information will not be exploited by some individuals given the incentives and pressures associated with proving that an injury has occurred. In fact, some attorneys believe such preparations are consistent with their role as zealous advocates under ABA Model Rules of Professional Conduct 1.3 Diligence (American Bar Association, 2002). However, the requirement for diligent representation of clients must be reasonably balanced with Rule 3.3 Candor Toward the Tribunal (Ben-Porath, Greve, Bianchini, & Kaufmann, 2009).

#### *Importance of Maintaining Objectivity to the Individual and Field*

As unpleasant as it may be to confront perceived attempts at influencing the expert, and as difficult as it may be to maintain objectivity steadfastly in the presence of numerous pressures to the contrary, doing so is extremely important to the long-term viability of the expert's career, as well as to the broader field. Just as a minority of attorneys may compromise their ethics in the face of various pressures and incentives, it is generally recognized that some experts act as "hired guns," offering to advocate the desired opinion for the right price (Fisher, 1997; Gutheil & Simon, 1999). While it is clear that such behavior impacts the perception of the individual by his or her peers, it is also likely to be detrimental to the view of

neuropsychologists and the field of psychology in general if we are perceived by those in the legal profession as experts for hire (Boccaccini & Brodsky, 2002; Fisher, 1997). While it is relatively easy to detect and criticize obvious abuses, such as opinions for hire, the influence of the various pressures and incentives involved in the expert witness role are often much more subtle, and therefore more difficult to defend against. A number of strategies for debiasing, including self-examination regarding objectivity, have been proposed that can be helpful in ensuring the maintenance of a high level of objectivity for neuropsychologists involved in adversarial proceedings (Sweet & Moulthrop, 1999).

### *Forensic Neuropsychology and Ethics*

In addition to the ethical principles and standards that apply to all activities of psychologists, there are a number of issues that arise frequently in the forensic neuropsychological context that merit discussion. As mentioned in the previous section, because of the interactions with individuals from other professions that occur in the forensic arena, maintaining high ethical standards is important not only to the individual, but to the reputation of the field as a whole.

#### *Relevant Standards*

The American Psychological Association's code of ethics (APA, 2017) includes a number of ethical standards that are of particular relevance to the practice of forensic neuropsychology (for a more extensive review of standards relevant to forensic neuropsychological practice, see Martelli et al., 2003; Sweet et al., 2002; Grote et al., 2005). One of these is Standard 2.01 (Boundaries of Competence). Psychologists are admonished to practice only within those areas for which they are appropriately trained. Clearly, this standard speaks to the importance of obtaining appropriate training in clinical neuropsychology. However, the standard goes on to specify "when assuming forensic roles, psychologists are or become reasonably familiar with the judicial or administrative rules governing their roles" (APA, 2017: 5). The APA has also published *Specialty Guidelines for Forensic Psychology*, which was most recently updated in 2013.

There is continued debate about the appropriate definition of a neuropsychologist and the accompanying training trajectory, but there is currently general agreement that training in clinical neuropsychology should include (a) a doctoral degree in psychology from an accredited program, (b) a clinically relevant internship, (c) two years (at least one being postdoctoral) of supervised experience in neuropsychology, and (d) psychology and/or neuropsychology licensure in the state in which one practices. Furthermore, although it is not required to meet the definition of a neuropsychologist, board certification is recognized as the best method of establishing competence to practice clinical neuropsychology (NAN Policy and Planning Committee, 2003). It is also important

to recognize one's areas of competence within the broader field (e.g., areas in which the clinician has received supervised training and/or published original research). Attempts by neuropsychologists to extend these boundaries to include areas in which the neuropsychologist is not experienced are not only ethically dangerous, but also may open the clinician to unwelcome scrutiny in the courtroom. It should be noted that there are currently very few, if any, graduate programs that provide extensive formal training in the practice of forensic neuropsychology, forcing those wishing to acquire competence in the area to seek out less-formal training experiences and making it somewhat difficult to assess the competence of neuropsychologists to practice in the forensic context.

Also particularly relevant to forensic neuropsychology is Standard 2.04 (Bases for Scientific and Professional Judgments). As mentioned previously, while it is always important to have a solid empirical foundation, it is especially important to avoid speculating beyond the data within the forensic arena. Another important standard is Standard 4.02 (Discussing the Limits of Confidentiality), particularly as it applies to the lack of a typical doctor-patient relationship in forensic evaluations. Other important standards include 9.01 (Bases for Assessments), 9.02 (Use of Assessments), and 9.06 (Interpreting Assessment Results), which again underscore the importance of competence and the need for empirically sound bases for interpretations based on assessment instruments.

Two other standards, 9.04 (Release of Test Data) and 9.11 (Maintaining Test Security), merit discussion. The former is intended to allow appropriate access by patients to results of psychological tests that they have undergone, while the latter is intended to protect the integrity of test stimuli. Many psychologists agree that releasing raw test data that include test stimuli to nonpsychologists is inappropriate and breaches the security of these tests (Knapp & VandeCreek, 2001; Sweet et al., 2002; Kaufmann, 2005). Since the first edition of this book, Attix et al. (2007) provided an Official Position on Disclosure of Test Data from APA Division 40, AACN, and APPCN. Kaufmann (2009) framed the public policy debate and detailed legal and other persuasive strategies to protect test security and prevent wrongful release of psychological test materials to nonpsychologists. Possible negative outcomes of breaching test security include infringement on the rights of companies that develop and sell the tests and facilitation of future coaching by attorneys. Forensic neuropsychologists receive frequent requests for the release of raw data, sometimes in the form of a subpoena or even a court order. The National Academy of Neuropsychology (NAN) has provided a decision tree to aid in dealing with such requests in a manner that strives to maintain test security and prevent the misuse of raw test data (NAN Policy and Planning Committee, 2000). In brief, requests should be written, include a signed release from the patient, and include assurances that test security will be protected. If a request is

made in the form of a court order, neuropsychologists must respond in a timely manner, although strategies to preserve test security even in this instance are included in the decision tree. Importantly, both sides of an adversarial proceeding must and can have access and still maintain test security, and neuropsychologists should strive to balance this concern with the interests of test developers and users in preventing invalidation of tests.

#### *Responding to Ethical Dilemmas and Perceived Unethical Practices*

Despite the best efforts to develop broad and well-articulated ethical standards, situations arise in the course of day-to-day practice for which ethical standards do not provide a clear answer. This can be especially true when one is involved in forensic activities. One issue that forensic neuropsychologists may face is the confrontation of perceived unethical practices by colleagues. While general guidelines provided by the APA ethics code for responding to perceived ethical violations (Standards 1.04, Informal Resolution of Ethical Violations, and 1.05, Reporting Ethical Violations) are helpful, responding to perceived unethical practices of colleagues can be particularly delicate within a forensic context, given its adversarial and emotionally charged nature (Brodsky & McKinzey, 2002; Johnson-Greene & Bechtold, 2002; Sweet, 2003). In fact, the American Academy of Clinical Neuropsychology (AACN; the membership organization of neuropsychologists who are board-certified by the American Board of Professional Psychology) has published an official position paper regarding an unfortunate outcome related to involvement in adversarial proceedings as an expert witness, namely, having specious ethics complaints filed against the expert witness (AACN, 2003). It is important that forensic neuropsychologists consider these issues. In instances in which they believe an ethical violation has occurred, it is wise to consider waiting to pursue a decision regarding action until the conclusion of the litigation that brought the possible ethical violation to light. At such a time, when it is determined that an ethical violation has occurred (i.e., ethical principles/standards have been violated and harm has been done as a result), and it is clear that the confidentiality of individuals involved will not be compromised by addressing the perceived violation, it is incumbent upon the neuropsychologist to address it (Grote, Lewin, Sweet, & van Gorp, 2000). As suggested by the APA ethics code, an attempt should first be made to resolve the issue informally before registering a formal complaint.

#### **Examples of Major Forensic Activities and Roles**

This section will cover some of the major roles for neuropsychologists within the forensic arena. We will begin by discussing two common areas of acquired brain injury civil

litigation (e.g., TBI and toxic exposure). We will then discuss two common settings within which neuropsychologists frequently play a role (i.e., disability examinations and school consultations). Finally, this section considers the possible involvement of neuropsychologists in evaluation of competence and determinations specific to criminal litigation.

#### *Traumatic Brain Injury and Neurotoxin Litigation*

In the role of forensic evaluator/expert witness in the context of civil litigation, TBI and neurotoxin related injury are generally the most common referrals. Issues related to evaluation of these two types of referrals are discussed in this section.

##### *Traumatic Brain Injury*

Since the early 1990s, TBI civil litigation has increased dramatically with a related increase in referrals to neuropsychologists (Ruff & Richardson, 1999; Stern, 1997).

In cases of moderate to severe brain trauma with prolonged loss of consciousness, medical records documenting the extent of injury, and evidence of specific cerebral insult on neuroimaging, there is often no question whether a brain injury occurred. For these cases, the forensic issue is not the presence of injury, as it is clearly documented prior to the neuropsychologist becoming involved with the case, but rather the presence and severity of cognitive impairment, the functional implications, and ramifications for the person's quality of life.

With milder trauma, in which there is possible brief or transient alteration in consciousness with no clear signs of injury on imaging, the existence of brain damage is less clear (American Congress of Rehabilitation Medicine, 1993). The role of the neuropsychologist in litigation of milder brain injury is not just to clarify the effects of the injury, but additionally—and often more importantly—to clarify the existence of a brain injury. The determination of an initial injury is separate from the determination of persistent problems. Attorneys sometimes lose sight of this (Hartlage, 1997; Silver & McAllister, 1997).

##### *Neurotoxin Litigation*

Neuropsychological toxicology is the study of “human neurological, behavioral, cognitive and emotional concomitants of toxic and neurotoxic exposures” (Hartman, 1999, p. 339). Individuals who sustain toxin related neuropsychological injuries are often referred for an evaluation in the context of a toxic tort, “a legal cause of action after a plaintiff develops an injury or illness in response to a chemical, industrial product, metal, drug or other exogenous agent” (Hartman, 1999, p. 340).

For the neuropsychologist working within the arena of toxic torts, a thorough understanding of some of the more common toxicants (e.g., metals, lead, mercury, carbon

monoxide, organic solvents, pesticides, prescription drugs, etc.), their effect on the central nervous system, and cognition specifically, are essential. The reader is referred to other excellent sources for relevant description of such agents (Hartman, 1999; Miller, 1993).

Unlike brain injury, in which at least the more severe injuries and related deficits can be relatively focal and often are associated with well-documented acute effects in medical records and possibly even neuroimaging findings, the neuropsychological effects of toxicants are often more subtle and generalized, with the litigant/claimant frequently presenting with diffuse neurological and cognitive complaints. Neurotoxic exposure can impact the central nervous system on a neurochemical or cellular level that is less evident on broad examination. The role of the neuropsychologist in a toxic tort case is to clarify if there has been a neurotoxic injury and to quantify the effects of the injury, as well as emotional factors, directly due to the effects of the agents (Hartman, 1999; Lees-Haley, 1997b).

After exposure is confirmed, the expert seeks to determine whether the level and type of neuropsychological symptoms reported are consistent with the level of exposure. That is, are the claims credible or sensible from a toxicologic and neuropsychological perspective? Based on findings, common conclusions can include that symptoms are consistent/inconsistent with the type of exposure, symptoms are an emotional reaction to central nervous system changes, or symptoms are a reaction to the stress of being exposed even without central nervous system injury. As with TBI, other factors such as emotional functioning at the time of the evaluation, effects of pain and pain medications, fatigue, and external factors such as secondary gain and effort must be considered. (Hartman, 1995; Lees-Haley, 1997b).

#### *Commonalities in the Expert Role in TBI and Neurotoxin Litigation*

Prior to seeing the litigant, it is important to obtain records. When the neuropsychologist is working with an experienced attorney familiar with forensic neuropsychological evaluations, relevant records are often prepared and sent to the neuropsychologist as soon as he or she is retained. However, many attorneys are newer to the areas of TBI and neurotoxin litigation and less aware of what a neuropsychologist may need. Part of the neuropsychologist's role is to educate the attorney about relevant information and the types of records needed for the neuropsychologist to proceed effectively.

The overriding question presented to the neuropsychologist is whether there has been a decline in functioning related to the alleged injury and/or exposure. Understanding premorbid (e.g., preinjury/accident) factors is crucial in understanding the client's current presentation. Are reported deficits due to the injury or better explained by preexisting factors? Important information to obtain includes:

- 1 Records related to the injury including how the purported injury or exposure was sustained (motor vehicle accident, assault, work related, etc.). Was a loss of consciousness noted? What evaluations/tests were conducted and treatments/surgeries performed? The emergency room records are especially important. In reviewing records, those closest to the time of injury/exposure tend to be most valid with fewer effects of bias and rehearsal. Over time, incorrect information can be introduced into the chart.
- 2 Preinjury school and occupational history to establish gross baseline functioning (e.g., grade school, secondary and post secondary education, work history).
- 3 Premorbid medical history, including any previous brain injury or neurological illness.
- 4 Premorbid psychiatric history including that related to other traumas. Previous psychological/neuropsychological evaluations.
- 5 Premorbid alcohol and substance use history, including history of any chemical dependency treatments.

In conducting the clinical interview, the expert can assess the patient's account of the incident that caused the reported injury or exposure (being aware of any inconsistencies with the available records), as well as level of functioning, perceived cognitive strengths and weaknesses, emotional reactions to the incident, and pre- and postinjury stressors. It is important to be aware of secondary gain issues and, whenever possible, attempt to verify the validity of the interview information through collateral sources.

In conducting testing, one should consider the impact of noncerebral injury variables such as peripheral injury, pain, headache, and behavioral evidence of current emotional difficulties, fatigue, and the effects of medications. It is important to use well-accepted, standardized, and valid measures and use the most appropriate and accepted norms (Klonoff & Lamb, 1998; Murrey, 2000; Silver & McAllister, 1997; Williams, 1997; Zasler & Martelli, 2003).

A forensic evaluation should be a broad-based assessment of a range of cognitive and emotional functions in order to allow for a thorough differential diagnosis. That is, it is not only the deficits and intact abilities that are expected, but those that are not expected to be deficient or intact that must be considered, if one is to be able to "prove" cause and effect with regard to the forensic matter at issue. In litigation and other adversarial proceedings, large sums of money or other external incentives are often at stake. Inclusion of measures of effort is essential to clarify the client's level of engagement in the evaluation. In fact, the omission of effort testing when evaluating a possible neuropsychological injury with ability tests is no longer acceptable; such an omission is clearly not in keeping with current practice expectations expressed in the extensive literature on forensic neuropsychology (cf. Sweet

et al., 2002). Similarly, forensic psychologists evaluating emotional injury cases have been found to prefer instruments that contain validity scales (Boccaccini & Brodsky, 1999), which also has relevance to forensic neuropsychological evaluations.

In addition to the primary role of conducting an evaluation, the role of the neuropsychologist in a forensic brain injury case can include assisting the retaining attorney in evaluating the strengths and weaknesses of a case by reviewing records, advising on the expertise of other experts, quality of reports, and basis for findings. The neuropsychologist can perform these roles on behalf of either the plaintiff or defense; the goals are the same irrespective of which side retains the neuropsychologist. Examples of questions often asked of the neuropsychologist who conducts a forensic evaluation include: (a) Does the event at issue in the proceeding appear to be a credible cause of claimed problems? (b) Does the plaintiff present with relevant neuropsychological deficits on testing? (c) If deficits exist, are they proportional (i.e., reasonably expected) relative to the specific event at issue? (d) What is the functional impact of the injury and related deficits on the individual? (e) Are the identified deficits neurogenic, psychogenic, or due to other factors such as secondary gain? (f) What is the role of premorbid and comorbid factors?

These are complicated questions, but they are also very familiar as the common questions that can occur in routine clinical evaluations, in which the referral source, or consumer of the evaluation results, is typically a physician. As is the case with such clinical work, the neuropsychologist who participates as an expert in TBI or neurotoxic litigation needs to have knowledge of the relevant literature and practices within the field (Hartlage, 1997; Ruff & Richardson, 1999).

### ***Retained Expert for Independent Medical Evaluations***

Neuropsychologists are often asked to render an objective opinion on the diagnosis, status and/or prognosis of a patient by a third party, such as an insurance company or disability carrier, in an independent medical evaluation (IME). Although sometimes referred to as independent psychological evaluations (IPE), they are often referred to as IMEs regardless of the clinician's discipline.

There appear to be some differential applications of the term *IME* that also might prove confusing to the reader. Whereas all disability evaluations for a third party can be called IMEs, in some areas of the country, litigation-related evaluations, even though unrelated to determination of disability benefits, may also be referred to as IMEs. For the purpose of the present chapter, IME is used to refer more narrowly to evaluations for the purpose of determination of disability benefits.

The goal of an IME is to provide an objective assessment of the patient for some purpose, usually clarification of a

diagnosis, need for additional testing or evaluation, need for additional treatment, determination of functional limitations, likely impact of cognitive impairment on job performance, assessment of the severity of impairment, need for (continuation of) disability compensation, or to determine if maximal medical improvement (MMI; the person having received optimal treatment without expectation of further recovery through additional conventional treatment) has occurred. An IME must be objective, which therefore excludes a claimant's treating doctor from carrying out such an evaluation (Kraus, 1997). Although the content of the evaluation is often comparable to that of an extensive clinical evaluation, there are a number of unique issues involved in performing IMEs, and in this respect the earlier information pertaining to informed consent of litigants applies.

Within clinical settings, the clinician develops a relationship with the patient for the purpose of assessment and treatment. However, in an IME, the primary relationship is between the neuropsychologist and referring third party (e.g., insurance company, state agency etc.), who requested and is paying for the evaluation. The goal is *not* to provide treatment or treatment-oriented assessment for a patient, but instead to provide an objective evaluation of the factors underlying the claimant's functioning to the third party. Related to this goal, confidentiality is between the third-party referent and examiner. All information obtained during the record review, clinical interview, and testing will be communicated in the report to the third party. In most cases, the claimant will not be granted direct access to the report, and instead will receive this information from either the third party or his or her own lawyer, if the matter is being formally disputed. Additionally, no treatment will be offered to the patient—and even if treatment recommendations are part of the report, the examinee will not be made aware of these recommendations by the examiner directly (Grant, 1997; Martelli, Zasler, & Grayson, 1999a, 1999b; Perlo, 1996; Silver & McAllister, 1997).

The APA has no specific guidelines for psychologists/neuropsychologists involved in doing IMEs, but other organizations have developed guidelines and standards. An association of psychologists involved in IMEs and disability assessments in Canada, the Canadian Academy of Psychologists in Disability Assessment (CAPDA), has developed a set of standards entitled *Practice Standards for the Psychological Assessment of Disability and Impairment* (CAPDA, 2000). The reader is encouraged to review these standards, as they provide sound guidance. Similar to some of the matters described earlier, the standards deal with issues including the relationship with third-party referents and the role of the compensation process, need for objectivity, unique nature of confidentiality, competency of providers, importance of considering all relevant factors, components of an appropriate evaluation, and how findings are communicated.

Although not specifically applicable to neuropsychologists, the American Medical Association (AMA) also has IME-specific guidelines, such as those related to the

patient-physician relationship (i.e., Code 1.2.6: Work-Related and Independent Medical Examinations) and confidentiality (i.e., Code 3.2.3: Industry-Employed Physicians and Independent Medical Examiners) within IME contexts (American Medical Association, 2016a, 2016b). The AMA criteria are similar in many ways to common psychological practice, but differ in the nature of the clinical relationship viewing it as a limited doctor-patient relationship with release of confidential information still requiring patient consent, even in the context of a third-party payor.

Readers are encouraged to familiarize themselves with these guidelines and ways in which they differ from general neuropsychological practice. Attorneys may not be aware of differences between medical and neuropsychological practice, and it may be incumbent upon the neuropsychologist to clarify these differences.

Many aspects of conducting IMEs are still areas of discussion and controversy within the field. Although common practices do exist, the need for a well-defined set of standards and guidelines, such as those offered by the CAPDA, is clearly indicated. Although not as formal as standards and guidelines, both AACN and NAN have recently published position papers on issues related to IMEs (AACN, 2003; Bush et al., 2005).

### ***Retained Expert for Independent School Evaluations***

It may seem strange to include a section on the role of neuropsychologists in schools in a chapter on forensics. However, much of the activity of a neuropsychologist within the school system is directly related to federal legislation and court decisions. This section will briefly discuss the most pertinent legislation, specifically the Individuals with Disabilities Education Act (IDEA) and Section 504 of the Rehabilitation Act, as well as some of the roles of neuropsychologists within the schools.

IDEA (originally the Education Act of All Handicapped Children) was initially passed in 1975, and modifications were made over time. The reader is encouraged to review the most current version of IDEA, amended in 1997 (20 U.S.C. Sec 1401). The purpose of IDEA is to provide children with disabilities, from age 3 to 21, with the same education as non-disabled students, providing a “free appropriate public education” in the “least restrictive environment” (Braden, 2003; Melton, Petrila, Poythress, & Slobogin, 1997). According to IDEA, children with the following 13 disabilities are covered: Autism; Deaf-Blindness; Deafness; Emotional Disturbance; Hearing Impairment; Mental Retardation; Multiple Disabilities; Orthopedic Impairment; Other Health Impairment; Specific Learning Disability; Speech and Language Impairment; Traumatic Brain Injury; and Visual Impairment.

Children who are eligible to receive services under IDEA are also eligible for “related services,” which are intended to assist a disabled child to benefit from special education and

can include developmental services, psychological services, social work, counseling, therapeutic recreation, rehabilitation counseling, and some limited medical services. The student is eligible for related services only as they aid him or her in benefiting from special education. The act also requires that the student be educated in the least restrictive environment possible, emphasizing mainstreaming. Under the act, specific procedures are elucidated, including: (a) identification of the disabled child, the burden of which falls upon the school system or local educational agency (LEA); (b) evaluation of the child by a multidisciplinary team and development of the individual education plan (IEP), which includes a description of current levels, annual goals, educational services to be provided, the expected date when services will be started and expected duration, and criteria for evaluation on at least an annual basis; and (c) review. If parents are dissatisfied with the findings of the evaluation process, they can seek an independent evaluation, often with a neuropsychologist, for which (depending on circumstances) the school may be required to pay.

The questions to be answered by the evaluation include whether the child has one of the IDEA-listed disabilities that requires special education, what would constitute an appropriate education, what related services are necessary, and whether services can be provided within a regular classroom setting. The child’s placement must be determined annually, based on his or her IEP, and should be located as close to the child’s home as possible (Lorber & Yurk, 1999; Melton et al., 1997).

Section 504 of the Rehabilitation Act, a predecessor of the IDEA, enacted almost 25 years ago, is another major piece of school-related legislation. Section 504 is an antidiscrimination statute. Unlike IDEA, it is not a grant statute and does not have mandates for federal funding (U.S. Department of Education, 2003). Section 504 was designed to eliminate impediments or barriers to students with disabilities in the classroom, and requires that schools not discriminate against students with disabilities. Section 504 has a much broader definition of disability than the IDEA (Rosenfeld, 2003). It protects all individuals with a disability who have a physical or mental impairment that substantially limits one or more major life activities, a record of such impairment, and are regarded as having such an impairment.

The primary question under Section 504 is whether the student has an impairment that is limiting his or her ability to learn. Schools are required to provide a free appropriate public education to qualified students with determined disabilities (U.S. Department of Education, 2003).

Within both IDEA and Section 504, schools are responsible for identifying students who have disabilities and are in need of services. The initial screening evaluations are often accomplished by a multidisciplinary team at the school (Braden, 2003).

Neuropsychologists can play a significant role in the evaluation of and advocacy for students with disabilities under

both acts. Neuropsychologists can become involved in the process through referral from the school or child's parents. Through evaluations, neuropsychologists can help to clarify a student's cognitive achievement and emotional functioning, identifying learning strengths and weaknesses, and needs for remediation. The neuropsychologist, often in working with a multidisciplinary team, can help to diagnose and/or clarify if the student is in one of the protected categories and if so, in need of special education and related services. If the school and family are unable to agree on the need for services, a Due Process hearing, considered a federal hearing and adjudicated by an appointed and trained hearing officer, can be requested by either party. In these hearings, the neuropsychologist can advocate for the appropriate services dependent on evaluation results and also act as a consultant to either the family or school.

Another area under these acts in which the neuropsychologist can play a role is school disciplinary codes. All schools maintain disciplinary codes, often with predetermined consequences. Although these rules are appropriate for the general student body, they may not be appropriate for a child with a disability. When a child with a disability who is receiving special services breaks a school rule that requires disciplinary action, a multidisciplinary team must first meet to determine if the violation was related to the disability and if the student can understand the rule and consequences of the violation. In their role as experts in the assessment of cognition and behavior, neuropsychologists are uniquely suited to assist the team in determining if the rule violation was related to the disability (Lorber & Yurk, 1999).

IDEA and Section 504 of the Rehabilitation Act have significantly changed educational opportunities for students with disabilities. Under both acts, there are varied roles for neuropsychologists. Pediatric practice, especially within the school system, requires a broad understanding of the relevant legislation and related court decisions.

### **Referrals for Evaluations of Civil Competence**

The notion of competency is grounded in the societal ideals of autonomy versus beneficence, in which the independence of the individual is countered by the greater society's role of caring for those in need. Doctors have historically worked with patients from a *parens patriae* viewpoint, as if a parent and child. However, over time the relationship and decision-making process have become more collaborative (Melton et al., 1997), and in general there has been a societal trend toward maintaining the autonomy of the individual. In this context, neuropsychologists are often consulted to assess a patient's capacity to help medical staff, and at times, the courts, in clarifying his or her level of competence.

The terms *competency* and *capacity* are often used interchangeably, but in reality they differ significantly. *Capacity* is a nonlegal, clinical determination assessed by a health professional, such as a neuropsychologist or psychiatrist,

and is concerned with functional abilities. *Competency* is determined by a judge or other legal body, with capacity being only part of the consideration. A person is assumed competent unless proven otherwise. Although competency is ultimately a legal decision that varies under state law, in common practice, clinicians are regularly called upon to make decisions regarding patient capacity without a formal legal determination of competency ever occurring (Fellows, 1998; Kim, Karlawish, & Caine, 2002). Recently, Demakis (2016) edited a special section on civil capacities, including representative cases (Kaufmann, 2016). There are numerous capacities that have been differentiated (see Table 36.3).

For a finding of incompetence, there must be evidence of a clinical condition that is causative. At one time, psychiatric illness or significant cognitive impairment equaled incompetence, but this is no longer the case. The mere presence of a psychiatric illness or a neurological illness such as Alzheimer's disease or Parkinson's disease does not warrant a determination of incompetence (Department of Veterans Affairs, 1997; Haffey, 1989). If a disorder has been established, the question for the clinician is whether the person is sufficiently impaired as a result of it to be considered incompetent.

Capacity is not a static concept. Although some disorders, such as dementias, are progressive, in other conditions (e.g., delirium, acute brain injury, psychosis), the person may lack capacity at one point, but not at another (Hart & Nagele, 1996). With such conditions, serial assessments are often necessary.

Capacity can be brought into question in an individual of any age or diagnostic group (e.g., mental retardation, psychiatric illness, brain injury, etc.), but the group most commonly associated with the assessment of capacity is older adults. Older adults have a higher incidence of medical illnesses and therefore need to make more medically relevant decisions, and are most vulnerable to disorders impacting cognition (Marson & Harrell, 1999).

At this time, physician judgment is still the most common means of determining competence. However, physicians

*Table 36.3* Types of capacities (i.e., nonlegal, functional ability areas, the status of which is determined by clinical means)

- 
- 1 Medical decision making
  - 2 Consent to treatment (informed consent)
  - 3 Refusal of medications
  - 4 Driving
  - 5 Financial (capacity to manage own monetary funds)
  - 6 Activities of daily living and instrumental activities of daily living
  - 7 Manage medications
  - 8 Testamentary (i.e., wills)
  - 9 Contracts
  - 10 Parenting
  - 11 Return to work
  - 12 Live independently
  - 13 Consent to be a research subject
-

generally receive little training in this area and most judgments are impressionistic or based on brief assessment such as the Mini Mental Status Examination (MMSE; Folstein, Folstein, & McHugh, 1975). However, there has been greater appreciation over time for the need to develop more specific, valid, and reliable means for assessing competence (Department of Veterans Affairs, 1997).

The assessment of capacity and competency is an increasing area of involvement for neuropsychologists. As defined by Baker, Lichtenberg, and Moye (1998: 151), competency assessment is the “clinical assessment process to supply a cognitive, mental health, and functional evaluation when questions of legal competencies or capacities are raised.” There is a lack of consensus for neuropsychologists involved in these endeavors. As a result, clinicians often need to rely on clinical experience and varied research findings.

However, at least in the assessment of the older adult, guidelines have been developed that can generalize to other populations. *Assessment of Competency and Capacity of the Older Adult: A Practice Guideline for Psychologists* was developed by the Department of Veterans Affairs to assist clinicians with these evaluations (Department of Veterans Affairs, 1997). These guidelines, as well as other sources, recommend a multistep process in capacity assessment (Baker et al. 1998; Department of Veterans Affairs, 1997; Haffey, 1989; Hart & Nagele, 1996; Melton et al., 1997).

Referral questions are often vague, so first it is important to clarify the specific issue(s) to be addressed. The clinician must ask—competency or capacity for what? Second, informed consent and confidentiality need to be discussed. Patients have to be aware of the purpose of the evaluation. A thorough review of case history, not only including normal medical, psychiatric and social information, but also history specific to the question at hand should be completed.

The assessment should then include a clinical interview and evaluations of cognitive skills, mental health, and functional abilities. The mental health assessment should cover a broad range of psychological conditions with the understanding that limitations due to some conditions may be temporary. The cognitive and functional evaluations should focus on abilities/tasks specific to the capacity being questioned. Commonly relevant areas include perception and ability to understand relevant information without distortion, ability to retain and recall relevant information, ability to identify options and to logically reason and problem solve among them, and ability to make a decision based on deliberation regarding options.

In selecting measures for competency evaluations, clinicians should choose measures that tap the underlying skills that are relevant for the question being asked and also appropriate to assess the condition that may be compromising the patient’s capacity (Department of Veterans Affairs, 1997). Relevant areas may include any cognitive domain but especially language (receptive and expressive), new learning and memory, and executive functioning. An evaluation should be

broad-based to understand the person’s ability level specific to the question at hand.

The report should clearly delineate the referral for a capacity evaluation, relevant history, test results, and a rationale as to how the results support a finding of full or diminished capacity. Often, especially with conditions that can change or vary over time, follow-up is necessary to monitor the person’s capacity.

### *Retained Expert Witness for Criminal Proceedings*

Within the forensic arena, neuropsychologists play a prominent role in civil and educational proceedings, as previously described. Within the criminal arena, although a less common area of practice for neuropsychologists, there are a number of areas in which clinicians regularly contribute. This section will review some relevant areas of law related to criminal proceedings and the role of neuropsychologists within the criminal justice system.

In clinical practice, neuropsychologists objectively assess and describe the cognitive, behavioral, and functional aspects of brain injury and brain disease. In some criminal proceedings, attorneys need an objective means of explaining to a trier of fact that their client’s thinking or behavior has been or is currently being impacted by brain dysfunction. If during a criminal proceeding, there is suspicion by either the prosecution or defense that brain dysfunction had an adverse impact on the defendant’s behavior, a neuropsychologist may be called in as a consultant to provide quantifiable objective information about the defendant. In general, when a neuropsychologist is retained by an attorney who handles criminal cases, three main areas need to be addressed (Kirkish & Sreenivasan, 1999; Martell, 1992):

- 1 What are the appropriate diagnoses?
- 2 If present, what effects have the brain damage or disease had on the defendant either at the time of the alleged incident or within the court proceeding?
- 3 Is the defendant malingering?

There are nine primary areas in which the mental health or competence of a defendant can be of issue, and which therefore may merit a neuropsychological evaluation, including: (a) competence to waive Miranda, (b) competence to waive right to counsel, (c) competence to stand trial, (d) advisement of rights and validity of confessions, (e) entry of a plea, (f) determination of criminal responsibility, (g) advisability of defendant testifying, (h) sentencing, and (i) competence for execution.

### *Competence to Stand Trial*

Assessments related to competency to stand trial are one of the most common reasons for mental health evaluations within the criminal justice system. The courts recognize that

a defendant's cognitive, mental, or emotional difficulties might interfere with the defendant's right to a fair trial. A U.S. Supreme Court decision, *Dusky v. United States* (1960) laid out the parameters to assess whether a defendant is competent to proceed to trial. There is a two-pronged test, consisting of a cognitive prong and an interpersonal/communication prong. Under the cognitive prong the question is: Does the defendant, as a result of mental disease or defect, lack the capacity to understand the proceedings against him or her? This can involve an assessment of cognitive functions, including orientation, attention, comprehension, and memory. The question under the interpersonal/behavioral cooperation prong is: Does the defendant lack the capacity to meaningfully assist in his or her own defense? The issue here is to determine if the defendant maintains adequate communication and reasoning skills to communicate with his or her attorney to participate in the proceeding: Can the defendant participate in his or her defense? Are the requisite receptive and expressive language skills, memory, and executive functioning (including reasoning) skills present for the defendant to work with his or her counsel? (Grisso, 2003; Kirkish & Sreenivasan, 1999; Martell, 1992; Nestor, Daggett, Haycock, & Price, 1999).

#### *Entry of a Plea/Not Guilty by Reason of Insanity*

To be tried for a crime, the law requires that an individual engaged in an unlawful act and did so with unlawful intent. The law assumes free will, but also recognizes that there are individuals who have impaired cognitive or volitional abilities. If this is so, then their culpability may be diminished (Grisso, 2003). The purpose of the "not guilty by reason of insanity" defense is to prevent imposition of criminal sanctions on an individual who may not be fully responsible for his or her actions (Diaz, 1995).

"Insanity" is not a psychiatric term, but is instead defined by the legal system. Depending on the jurisdiction, there are different "tests" that are applied to determine if a person is legally insane, but the primary question involves determining if the person has a mental illness that resulted in decreased capacity to appreciate the wrongfulness of his or her action. Depending on the test, issues around impaired cognition and/or impulse control come into play. The neuropsychologist's role in these proceedings is to quantify the degree of impairment and assist the trier of fact in determining whether the deficits constitute a lack of capacity. It is not the role of the neuropsychologist to determine if the defendant is insane.

A related area is diminished capacity. Different from not guilty by reason of insanity, the defense tries to argue that the defendant lacked capacity to form the criminal intent for the crime for which he is being charged, but instead should be convicted of a lesser charge (e.g., manslaughter vs. murder). In this case, neuropsychological evaluation results could help the trier of fact to understand the cognitive limitations of the

defendant with regard to the cognitive skills needed to commit the relevant crime (Martell, 1992; Rehkopf & Fisher, 1997).

#### *Other Areas*

Advisement and waiver of rights and validity of confessions relates to the defendant's ability to understand his or her Miranda rights and knowingly consent, without coercion, to a police search. If the defendant's attorney questions whether his or her client lacked adequate mental skills at the time rights were waived or a search was done, a neuropsychologist may be asked to provide data to support this supposition. A neuropsychologist may be called in to determine if a defendant's cognitive or behavioral impairment limits his or her ability to testify. If the defense wants the defendant to testify, information about impairments (e.g., limited vocabulary, expressive speech impairments etc.) may help the trier of fact better understand the behaviors they are seeing on the stand. This information can also help the defense lawyer in preparing to examine his or her client on the stand.

Once a defendant is found guilty or not guilty by reason of insanity, the results of the neuropsychological evaluation can assist the trier of fact in determining the appropriate sentence by providing information on how the person may react in certain settings based on brain disease and, at times, assist with appropriate placement.

In *Ford v. Wainwright* (1986), the U.S. Supreme Court determined that the condemned, in order to be executed, must first understand that he has been sentenced to death and why. The neuropsychologist can again play a role in assessing the defendant's cognitive abilities to assist the trier of fact with answering the question of competency to be executed (Grisso, 2003; Rehkopf & Fisher, 1997).

In all proceedings related to the criminal system, it is essential for the neuropsychologist to remember that issues of insanity or incompetence are for the courts to decide. The neuropsychologist's role is to provide objective, quantifiable information to assist the trier of fact with this decision.

#### **Future Directions**

There is no reason to believe that interest in retaining clinical neuropsychologists to render expert opinions in adversarial proceedings will wane. In fact, because neuropsychologists offer unique information that is scientifically grounded, the trend is more likely to continue in the direction of increased interest. This may be especially true in the area of pediatric neuropsychology, which is beginning to receive the degree of attention shown in the area of adult neuropsychology (Wills & Sweet, 2006).

#### **Key Areas of Forensic Research**

Within pediatric and adult neuropsychology there are specific areas of knowledge that bear directly on issues commonly

addressed. Most, but not all, are areas within which clinical neuropsychologists have inherent, substantial interests. Areas in which continued research investigations are needed and likely to continue are: (a) continued development of techniques for evaluating effort, especially for use with children and adolescents, (b) improved normative studies that elucidate important variables such as minority status, influence of culture, and educational deprivation, (c) more specific research related to ecological validity that might enable more precise correlations between test findings and expectations of daily functioning, and (d) greater specificity in ruling in or ruling out the etiology of patterns of strengths and weaknesses found on formal ability and emotional testing. To be sure, there will never be a point at which further research will not be helpful in almost any health care or forensic endeavor. However, there are some areas, such as those listed here, in which the forensic questions neuropsychologists are often asked, and assuredly will continue to be asked, frequently seem to outdistance our ability to respond with empirically based answers.

### ***Need for Formal Training of Future Neuropsychologists***

The academic preparation of clinical neuropsychologists for participation in forensic activities remains generally absent. Almost all clinical psychology doctoral programs offer one or more courses pertaining to clinical neuropsychology, which has been true for many years (Wedding & Williams, 1983). However, at present, very few programs have substantive coursework preparing clinical neuropsychology practitioners for their inevitable involvement in forensic work. Because neuropsychologists have clinical interactions with individuals whose disorders stem from situations (e.g., accidents, assaults, environmental exposure, or medical errors) in which someone can be accused of being at fault, plus numerous individuals who because of possible disability are applying for some type of benefit, there is almost no way that a practitioner can avoid requests to provide relevant information to triers-of-fact. Academic preparation is necessary for the nearly unavoidable involvement in forensic activities. Kaufmann and Greiffenstein (2013) recently called upon neuropsychology to revisit and revise training requirements to respond to the growing demand for forensic consultation. It seems quite likely that clinical psychology training programs at the graduate school and internship levels with a strong commitment to training clinical psychologists will begin to develop curricula to facilitate knowledge and skill acquisition in this important practice area. Minimally, a graduate school curriculum for all doctoral students intending to enter clinical neuropsychology could include a required course in the fundamentals of forensic neuropsychology followed by an advanced seminar of special topics and controversial issues. Practicum experiences may be difficult to find at the graduate student level, both because of

scarcity in practicum sites and also because involving students in such evaluations is almost always contraindicated as mistakes by beginners should not be entered into such evaluations. Those practicum sites at which forensic cases are seen by staff can provide didactic exposure to students in case conference and group supervision formats. Actual practical experience in forensic neuropsychology can be included within clinical internships and residencies, many of which are housed in medical settings at which practitioners become involved in conducting IMEs or as retained experts in litigation cases.

### **Notes**

- 1 Meaning the current case being heard by the court.
- 2 Jurisdictions relying on a *Frye* standard include California, the District of Columbia, Florida, Illinois, Kansas, Maryland, Minnesota, New Jersey, New York, Pennsylvania, and Washington. Most recently, Arizona, Alabama, and Wisconsin abandoned *Frye*. California is likely next; see *Sargon Enters., Inc. v. Univ. of S. Cal.* (2012).
- 3 There is no genuine issue of material fact upon which the plaintiff could prevail as a matter of law. The trial judge rendered a verdict for Merrell Dow based on briefs without a trial.
- 4 The most common mechanism used by the U.S. Supreme Court chooses to hear a case by order directing a lower court to deliver the case record.
- 5 A motion to limit or exclude allegedly prejudicial evidence presented to the judge or during a trial.

## 37 Basics of Forensic Neuropsychology

*Manfred F. Greiffenstein and Paul M. Kaufmann*

Forensic neuropsychology is the practice of providing neuropsychological evidence and opinions for court systems on issues involving cognitive status. In almost all jurisdictions, neuropsychological assessment is recognized as assisting the trier of fact in resolving legal issues such as criminal culpability, mental injury, and competence to conduct affairs independently (Slobogin, 2003). In Shapiro's (1991) view, legal applications of neuropsychology have arrived and are here to stay.

Most neuropsychologists should agree with Sweet's (1999) observation that neuropsychologists neither anticipated nor prepared for courtroom involvement during their training. Bush (2003) argues neuropsychologists are naturally suited for legal activity. Perceived strengths of clinical neuropsychologists include multifaceted analytic abilities (nomothetic, quantitative, idiographic), a nonadversarial and objective ethos, and a multidisciplinary knowledge base (e.g., neuroanatomy, clinical neurology, medical terminology, psychometric methods). The neuroscience knowledge base, used in conjunction with standardized psychometric tests, neuroimaging results, neurodiagnostic findings, neurologic history, interviewing, behavioral observations, and informal assessment means that neuropsychological formulations and expert opinions are scientifically informed and refined by objective test results. As detailed in Sweet, Kaufmann, Ecklund-Johnson, and Malina (Chapter 36 in this volume), neuropsychological techniques easily fulfill state and federal legal standards for scientific methodology because psychological tests and neurodiagnostic techniques are widely accepted and, more importantly, experimentally verified. Kaufmann (2005) argued this practice distinguishes clinical neuropsychology in forensic settings, such that it has little or no redundancy with other health care disciplines or mental health expertise. The cognitive activity of the neuropsychologist underlying differential diagnosis may even be a microcosm of the jury process of sifting through competing hypotheses.

Forensic activities represent a growing percent of neuropsychology private practice (Sweet, Guiffre Meyer, Nelson, & Moberg, 2010). Kaufmann (2016) reported a 97% increase in time devoted to forensic consulting based on his analysis of sequential surveys. Many factors drive interest in forensic neuropsychology, including more income in a managed care era, intellectual curiosity, revenue diversification, and

ego gratification. However, there are also perceived impediments that inhibit involvement in forensic activity. These factors include perceptions that the adversarial system is too complex, ignorance of the law and courtroom practices, reluctance to criticize others, and fears of intense public scrutiny. After all, the term *forensic* derives from the Greek word *forensis*, meaning public debate.

The main goal of this chapter is to reduce the perceived complexity of the adversarial system into terms understandable to most neuropsychologists. Involvement in the legal system does not require encyclopedic knowledge of the law and court rulings. Goals of this chapter include describing differences between pure clinical and forensic neuropsychological evaluations, summarizing the empirical foundations of forensic neuropsychology and psychology, briefly describing the history of psychological evidence in the courts, and reviewing landmark rulings as they relate to neuropsychological practice. Other goals include discussion of ethical considerations unique to forensic practice, enumeration of the general and case-specific challenges of forensic work, and to provide practical guidelines for offering testimony. An earlier chapter (Greiffenstein & Kaufmann, 2012) emphasized purely practical aspects of forensic neuropsychology; this chapter better emphasizes the scientific and knowledge bases of the forensic neuropsychology endeavor.

### **Basic Legal Terminology**

Adjustment to any new intellectual endeavor requires a working vocabulary shared by persons engaging in that effort. Whole dictionaries are devoted to legal terminology, but the neuropsychologist should familiarize himself with a small set of terms. The following nomenclature is often encountered in legal filings, depositions, and case law.

*Admissibility* and *weight* are concepts referring to the legal treatment of evidence. Admissibility rules dictate what evidence is allowed before a jury and is strictly a matter of law decided by the judge. Weight is a jury issue and refers to the relative value assigned to a piece of evidence. Two different neuropsychological approaches may be legally admissible but viewed quite differently by the jury. Confusions between weight and admissibility are common, even among experienced attorneys.

*Prejudicial* and *probative* are related concepts referring to the relevance of evidence. Prejudicial evidence refers to facts potentially causing strong emotional reactions and is not admissible because of a negative halo effect coloring perception of all the evidence. Probative means the evidence is relevant because it has greater probability to affect a juror's ultimate decision than its presence. Probative evidence is always admissible. At times a piece of evidence may have both qualities, requiring a judge to weigh the probative versus prejudicial value. For example, the information that a plaintiff was imprisoned for a violent crime prior to a compensable head injury may be probative if he claims "dysexecutive and emotional dyscontrol syndrome due to frontal lobe damage" but could be more prejudicial if the damages claim was only headaches. Criminal history may be probative to the claim, but is highly prejudicial to most juries.

*Tort* and *administrative actions* describe the nature of the legal action. A tort is a civil wrong that justifies initiation of a lawsuit. The elements of a tort are duty, foreseeability, negligence, causation, and damages. A car accident is a tort. Administrative actions refer to legal compensation seeking where tort rights are suspended because fault is not an issue. The plaintiff makes an application for benefits to a government agency rather than civil court (e.g., workers' compensation). *Published* and *unpublished* court opinions denote the scope of a court's decision. Published opinions mean a broad scope of application that is binding on trial judges in future. An unpublished opinion typically means a ruling that is limited to a particular case. The case of *Daubert v. Merrell Dow Pharm, Inc.* (1993) is a U.S. Supreme Court published opinion, meaning it is the law of the land. The case of *Chappelle v. Ganger* (1998; discussed in depth in a later section) is an unpublished opinion about a trial judge's finding of fact applied to a single case. There is no generalizable law derived from an unpublished case.

Most legal research is a search for authority, law that prompts in a more favorable outcome for one party or the other in a dispute. The inherent structure of the law—hierarchy of legal authority—is not readily apparent, even to first-year law students. Legal authority takes several forms: primary and secondary, controlling (binding), and persuasive. *Primary* legal authority (case law, statutes, regulations, administrative agency decisions, executive orders, and treaties) comes directly from a governmental entity in the discharge of its official duties. Courts are constitutionally required to interpret law; for example, case law often requires statutory and regulatory interpretation as applied to specific facts. *Secondary* authority includes other legal research found in attorney general opinions, agency interpretations, law review articles, restatements, treatises, or other commentary. Although courts may accept guidance from a wide range of sources, only primary authority is *controlling* in its application. Whether primary authority is, or is not, controlling, depends on case-specific facts and the jurisdiction in which the case is being heard. That is, courts are bound only

by legal authority from the same jurisdiction (federal, state, county, or municipality) that is controlling for that particular type of case. Finally, the decisions of a particular court are controlling for any court lower in the same jurisdictional hierarchy. However, common errors in legal analysis include the mistaken notions that federal cases control state courts, or that federal law always preempts state law. Some federal law does not apply in state courts and is, therefore, not controlling. However, federal law may be *persuasive* in state courts. Case law from other states may be highly persuasive. There are numerous factors that make court decisions persuasive beyond its controlling jurisdiction: factual similarity, sound reasoning, judicial reputation, and level of the court.

*Ultimate* legal questions refer to those that can be answered by the trier of fact only ("This car accident caused this plaintiff's brain damage"), while *penultimate* testimony refers to opinions just short of the ultimate questions ("The plaintiff's scores are consistent with closed head injury"). There is considerable controversy in the forensic psychology literature as to whether psychologists allow themselves ultimate or penultimate testimony (Melton, Petrila, Poythress, & Slobogin, 1997). Ogloff (1990) discussed methods for testifying on malingering issues in a light of a penultimate-only requirement.

*Burdens of proof* vary in civil and criminal proceedings. Most civil proceedings use the preponderance of evidence (lowest) standard of proof. However, some probate proceedings require clear and convincing evidence. Criminal cases require proof beyond a reasonable doubt. Kagehiro (1990) estimated confidence levels for each standard as follows: preponderance (> 50%), clear and convincing (~ 75%), and beyond reasonable doubt (~ 90%). However, judges, jurors, and laypersons do not systematically apply such probabilities when rendering judgments (Wright, 2008) and most trial consultants advise that jurors will never decide cases on the basis of probabilities (Ball, 2008). It is also important to recognize which party carries the *burden of persuasion* to meet the burden of proof. In criminal proceedings, the defendant enters court with the presumption of innocence and the state has the burden of persuading the trier of fact that the defendant committed the crime beyond a reasonable doubt. However, when claiming insanity, the defendant must persuade the trier of fact that he or she was insane at the time of the crime. In many jurisdictions, insanity need only meet a clear and convincing standard of proof.

Latin terms are commonly used because much of the adversarial system stems from medieval law. *Stare decisis* is a legal principle dating from the Renaissance and means courts must apply past decisions (precedent) to current cases. *Certiorari* is an order issued by a superior court to a lower court, asking for a certified record of a case the superior court wishes to review. This is the method used by the U.S. Supreme Court to review cases. *In camera* and *in limine* refer to evidentiary hearings without the jury present. They are literally held in the judge's chambers and usually involve

admissibility issues. The concurrence of *mens rea* and *actus reus* refer to elements necessary to prove a serious crime: *Mens rea* refers to the mental state preceding a crime and *actus reus* refers to the physical act of the crime. *Mens rea* evidence is challenged in legal insanity defenses. *Amicus curiae* literally means “friend of the court,” a person or organization not party to an issue who provides information relevant to the case before bar. The American Psychological Association (APA) may file *amicus briefs* if organized psychology’s interests are at stake.

### Differences Between Clinical and Forensic Assessments

There is much overlap between forensic and clinical neuropsychology insofar as both rely on the same measurement and scientific bases, neurocognitive constructs, differential diagnosis of generally accepted disorders (Rankin & Adams, 1999), and balanced integration of actuarial (base rate) versus idiographic (clinical) considerations (Berent & Swartz, 1999; Rankin & Adams, 1999; Slobogin, 2003). However, the forensic examination is not just a clinical exam in a legal setting. Instead, there are differences that shape the data collection process, reporting style, interpretation, and dispositional options. An understanding of differences between neuropsychology in clinical and forensic settings is necessary for an effective courtroom role.

### Social Context of Evaluation: Expectancies

Symptom expectancies affect self-report and are associated with legal culture. Good arguments can be made that some disorders typically encountered in forensic neuropsychology settings are socially constructed, not disorders of the natural kind. Symptom report differs in societies offering few prospects for compensation or civil litigation. Mickeviciene, Schrader, Nestvold, Surkiene, Kunickas, et al. (2002) found little difference in symptom base rates between concussed and nonconcussed Lithuanian injury victims. Canadians, residing in an adversarial legal culture, reported expectations of more chronic symptoms following concussion than Greek (Ferrari, Constantoyannis, & Papadakis, 2001) and Lithuanian cohorts (Ferrari et al., 2001).

Symptom expectancies may have quantifiable impact on psychometric measures. The stereotype threat is that literature suggests negative expectations can lower test scores compared to groups given neutral invitations for examinations (Brown & Pinel, 2003; Steele, 1997). Suhr and Gunstad (2002) applied this methodology to undergraduates selected for histories of remote concussion. Undergraduates offered pretest neurocognitive expectancies for head injury performed worse on intelligence and memory measures than injured undergraduates given customary instructions. Terming this phenomenon “diagnosis threat,” Suhr and Gunstad (2005) later reported brain damage expectancies also negatively influenced

attention, psychomotor speed, and working memory tasks. Effort and self-report mood measures did not correlate with group differences. Although only speculative, one theory is that diagnostic threats activate behavioral and/or cognitive schema for acting out “brain damaged” behavior (Wheeler & Petty, 2001). More research is necessary to determine whether compensability augments diagnosis threat.

### Social Context: Postincident Exposures

A major contextual difference in forensic matters is postincident influences that are less frequent or prominent than in clinical situations (Greiffenstein & Kaufmann, 2012). There is good empirical evidence for Lees-Haley’s (2003) assertion that persons pursuing litigation act differently than nonlitigating patients undergoing evaluations for the same underlying disease. Postincident influences can create genuine-appearing syndromes at the level of clinical history in persons without residual injury, or postincident influences can distort the clinical picture in persons with genuine residual brain damage (Boone & Lu, 2003). Specific postincident influences include compensation, symptom education, forewarning, and coaching.

Compensation is an especially powerful reinforcer of postincident adaptive and illness behavior (Rogers, 1990). Inception cohort studies of patients matched in mild traumatic brain injury (mTBI) severity show those patients pursuing compensation take longer to return to work (Carroll et al., 2004); they also get more medications. However, they continue reporting nearly twice the symptoms of nonlitigating cohorts (Reynolds, Paniak, Toller-Lobe, & Nagy, 2003). The effect size relationship between subjective postincident pain and compensation ranged from 0.48 to 0.60 in a sample of 3,000 inpatients (Binder & Rohling, 1996). In a later meta-analysis of 211 surgery outcome studies, Harris, Mulford, Solomon, van Gelder, and Young (2005) reported poor outcome associated with compensation in a nearly 4:1 ratio relative to noncompensable causation. Pobereskin (2005) followed more than 1,000 whiplash patients and found that preaccident pain and compensation pursuit were the best predictors of one-year symptom status but initial injury severity the weakest.

Another potential influence is symptom education. Volunteer simulators given minimal information about concussion cannot be distinguished from genuinely injured patients on symptom self-report (Martin, Hayes, & Gouvier, 1996). One form of symptom education includes diagnosis-specific attorney coaching (Rosen, 1995; Youngjohn, 1995). The Internet provides another means of symptom information (Risser, 2003). Some attorneys pay fees to Internet companies so public searches of the term <traumatic brain injury> prioritize links to law firm websites. A search on the exact phrase <closed head injury> at Dell Computer’s My Way search engine conducted November 2, 2005, produced ten law firm websites at the top of the results screen (e.g., www.

BrainDamageAttorneys.com). All ten offered aggressive pursuit of brain injury claims irrespective of accident severity. A more direct Internet-facilitated threat compromising neuropsychological validity is test-specific information offering forewarning. Ruiz, Drake, Glass, Marcotte, & van Gorp (2002) demonstrated the ease with which focused Internet searches allow nonpsychologists to educate themselves on specific psychological tests such as the Minnesota Multiphasic Personality Inventory-2 (MMPI-2). Empirically, asking volunteers to simulate psychopathology after receiving sensitive task information lowers the diagnostic efficiency of the MMPI-2 validity scales (Lamb, Berry, Wetter, & Baer, 1994; Martin et al., 1996; Storm & Graham, 2000).

These postincident conditions can also make the plaintiff hypervigilant for minor cognitive errors and lead him or her to misattribute these errors to brain dysfunction. Yartz, Zvolensky, Gregor, Feldner, & Leen-Feldner (2005) showed that persons with poor health perception were more likely to engage in bodily oriented catastrophic thinking and symptom vigilance. That is not to say that symptom education is a blanketly negative influence. Indeed, such a psychoeducational approach can truly be helpful to legitimately injured persons (Miller & Mittenberg, 1998).

### *Status of Self-Report*

The self-reported history provides a wealth of information regarding causation and injury impact (Spren & Strauss, 1998), drives the assessment process, and contributes to diagnosis (Othmer & Othmer, 1989). In clinical settings, there is an assumption of veridicality: The patient is assumed to accurately report his or her inner state. In administrative or forensic settings however, there are stronger incentives to misrepresent one's psychological state, and much depends on the accuracy, honesty, and insight of the claimant (or criminal defendant). A bestselling book, *Stolen Valor*, documented frequent and gross misrepresentation of combat experience in pursuit of veteran's benefits (Burkett & Whitley, 1998). Self-report in litigation should be taken seriously but cannot be relied upon in the same uncritical way as in a pure clinical setting.

Retrospective or present self-report in compensable contexts may show strong perceptual bias. One form of biased reporting is mischaracterization of injury and health history. Schrag, Brown, and Trimble (2004) compared retrospective histories supplied by disability seekers with actual medical records and found so many inaccuracies, they warned, "reported previous diagnoses should not be taken at face value" (p. 608). As an illustration from the neurotoxicology literature, Korgeski and Leon (1983) showed an Agent Orange exposure effect on the MMPI (i.e., more elevated MMPI profiles) when based on veteran-reported estimates of exposure times. This effect disappeared when subjects were regrouped based on records showing actual deployment in areas where Agent Orange exposure was highest.

Other forms of skewed reporting include positive and negative bias. Positive bias refers to exaggeration of preincident attributes and virtues. The claimant may exaggerate his or her educational achievements (Greiffenstein, Baker, & Johnson-Greene, 2002) or report fewer premorbid forgetting episodes than uninjured controls (Mittenberg, Diguilio, Perrin, & Bass, 1992). In contrast, most clinical patients demonstrate conformity between self-report and school records, with the exception of substance abusers (Johnson-Greene et al., 1997). Negative bias refers to exaggeration of postincident symptoms relative to patients with the same claimed etiology. By way of illustration, the Fake Bad Scale (FBS) is an MMPI-based measure of symptom magnification designed for personal injury contexts to overcome drawbacks of traditional MMPI validity indicators (Lees-Haley, English, & Glenn, 1991). Persons with severe brain injuries seen clinically score very low on the FBS (Miller & Donders, 2001; Woltersdorf, 2005), but mildly injured groups pursuing financial benefits score very high (Greiffenstein, Baker, Donders, & Miller, 2002). Ross, Millis, Krukowski, Putnam, and Adams (2004) reported strong associations between the FBS and objective measures of incomplete effort on memory tests but found weaker association with MMPI-2 infrequency indicators.

### *Threats to Validity*

Neuropsychologists in both clinical and forensic settings are trained to be cognizant of threats to validity. A threat to validity is defined as any nonneurological factor that affects performance on a neuropsychological measure and gives a misleading picture of brain-behavior relationships (Suhr & Gunstad, 2002). The major threat to validity in both settings is physical problems peripheral to the central nervous system that affect input (sensory) or output (motor) modalities (Reitan, 2001). Examples of peripheral problems include carpal tunnel syndrome or arthritis affecting upper extremity motor skills tests and hearing loss affecting auditory processing tasks.

The main validity threat in the forensic setting is test-taking motivation (Heaton, Smith, Lehman, & Vogt, 1978). The forensic setting provides stronger incentives to underperform or distort responses (Rogers, 1997). Motivational distortions take the form of either insufficient effort or motivated distortion (malingering). Estimates vary as to the exact base rate of poor effort and/or malingering, but the weight of peer-reviewed studies indicate prevalence is high in persons persistently pursuing monetary and social benefits. Mittenberg, Patton, Canyock, and Condit (2002) surveyed board-certified neuropsychologists with a combined experience of more than 33,000 legal cases and reported a 40% base rate of suspiciously poor performance. Greiffenstein, Baker and Gola (1994) estimated prevalence ranging from 33% to 66% depending on definitional stringency. Writing in a neurotoxic compensability context, van Hout, Schmand,

Wekking, Hageman, and Deelman (2003) reported 46% of 145 litigants failed either the Amsterdam Short-Term Memory Test or the Test of Memory Malingering. Greiffenstein and Baker (2006) conducted a prevalence study considering both malingering type (memory, motor, and psychiatric) and criterion stringency (possible, probable noncredibility) in two large cohorts of persons claiming permanent disability following minor neck/head trauma. They found 80% prevalence of at least *one* atypical psychometric sign under a liberal “possible” rule and 60% prevalence under a stringent “probable” rule.

These threats to validity can only be addressed by reliance on (a) extra-test medical data and (b) symptom validity tests (SVTs). The use of SVTs should be standard in every forensic examination or in any clinical evaluation with a high risk of forensic involvement (Hartman, 2002; Greiffenstein & Kaufmann, 2012; Sweet, 1999b).

### Conflicting Paradigms

The law involves an epistemology differing markedly from the neuropsychology scientist-practitioner’s outlook (Greiffenstein & Kaufmann, 2012). Productive attorney-neuropsychologist relations and useful testimony require the forensic specialist to adjust to the inevitable conflicts between these professions (Blau, 1998). Table 37.1 summarizes the best-known structural conflicts, termed *structural* because they are endemic to every legal case and not subject to alteration.

The main conflict endemic to the forensic context is partisanship versus objectivity. Attorneys play an adversarial role, have no affirmative obligation to the complete truth, and strive to ignore or minimize evidence inconvenient to their medical-legal theories. In contrast, neuropsychologists operate under the ethos of objectivity, choosing clinical theories that best fit the facts irrespective of the social or financial implications of their conclusions.

The legal principle most antithetical to scientific psychology is *stare decisis*: Attorneys and courts consider past legal

decisions fundamentally determinative of current issues. It took a half-century to overturn the legal precedent of separate-but-equal schools for minorities. But under the canons of modern science, the goal is attempted falsification of scientific precedent (Larrabee, 2012a). Evidentiary thresholds and standards of proof differ under the law depending on case gravity. In civil cases, a preponderance of the evidence model is applied; meaning the prevailing party’s version of facts having at more than 50% of the evidence in its favor, while in criminal cases, the evidentiary threshold is “beyond a reasonable doubt,” which has been interpreted as a 90% confidence level (Kagehiro, 1990). In contrast, neuropsychologists use instruments derived from quasi-experimental research showing findings associated with 95%–99% confidence group differences are not due to chance. The courtroom also relies on anecdotal, single-case methodology, in which each side offers specific hypotheses to be tested, although the critical  $p$  value threshold is  $p > 0.50$ .

### Causation Analysis

Forensic neuropsychologists concern themselves with issues of causation to a degree not present clinically. Mental illness is multifactorial in nature, and clinicians rarely concern themselves with ultimate causation. With the exception of a few organic brain syndromes, the causes of mental illness in general and most cognitive disorders in particular are unknown. The forensic neuropsychologist, however, is required to state whether the legal cause of action (work or car accident, toxic exposure) is a factor in explaining abnormalities in test scores or subjective complaints. The law requires only that psychologists be reasonably confident in their conclusions.

### Admissibility of Neuropsychological Testimony

Neuropsychologists anticipating involvement in adjudicated cases need to have a core forensic knowledge database. This supports both understanding the legal process and

Table 37.1 Structural conflicts between the law and neuropsychology

<i>Issue</i>	<i>Courtroom Practice</i>	<i>Neuropsychology Practice</i>
Historical Approach	<i>Stare decisis</i> : Legal precedent is either dispositive or given dominant consideration	Prior studies provide pretext for research only; science advances by trying to falsify precedent
Role Orientation	Partisanship, zealous advocacy	Objectivity, unconcern over legal outcome
Goal Orientation	Winning a case; justice over truth	Truth over justice: Finding best fitting neuropsychological theory
Evidentiary Model	Variable evidentiary thresholds differing across legal setting	Conservative evidentiary thresholds constant across settings
Methodology model	Anecdotal, single case methodology	Experimental or quasi-experimental group studies, replicated over long time periods
Rhetorical approach	Persuasion through emotional impact	Persuasion by means of logic, facts, and supportable theory
Typical Audience	Judge and jury	Physicians and other professionally educated medical professionals

productively interacting with the retaining attorney (Greiffenstein & Kaufmann, 2012). Kaufmann (2012) describes and explains admissibility standards and a careful understanding of how these standards operate is important. Admissibility refers to the rules that govern admission and disqualification of evidence. The admissibility guidelines applicable to neuropsychologists cover three broad issues: (a) competence to testify, (b) scope of neuropsychological testimony, and (c) specific methodologies relied upon by neuropsychologists.

### **General Competence to Testify**

For most of the 20th century, courts took a dim view of psychological evidence (Blau, 1998). *Jenkins v. U.S.* (1962) was a watershed case for qualifying psychologists to testify. Vincent E. Jenkins mounted an insanity defense, introducing the testimony of psychiatrists and psychologists that he was suffering mental disease (schizophrenia) at the time of a sexual assault. The trial court instructed the jury to disregard psychometric evidence on the grounds that psychologists were disqualified from testifying about mental disease for lack of medical training. The appeals court for the Second District (Washington, DC) reversed the trial judge, ordering the new trial to include psychological testimony and psychometric findings. The appeals court noted a diverse array of nonphysicians regularly offered opinions, such as electricians and doctoral-level toxicologists. Judge Bazelon wrote the majority opinion, offering a two-pronged test of admissibility for psychologists' testimony: "The critical factors in respect to admissibility is the actual experience of the witness and the probative value of his opinion" (*Jenkins*, p. 646). This opinion implies a medical degree is neither sufficient nor necessary to testify as to mental state. The trial judge must determine a particular psychologist's qualifications through a context-specific, fact-intensive exploration of background, training, education, and knowledge.

Subsequent legal cases dealt specifically with the competence of neuropsychologists to testify on issues before a court. An early case involving testimonial competence is *Simmons v. Mullins* (1975). The minor plaintiff proffered neuropsychological evidence in support of a brain injury claim arising out of a car accident. The defendant objected to admission of this testimony, but both trial and appellate courts disagreed, ruling that neuropsychologists are competent to testify on cognitive damages associated with organic brain syndrome. As in *Jenkins* (1962), the courts noted that nonmedical persons have always been allowed to testify within their special knowledge, additionally pointing out the necessity of consultation with neuropsychologists in brain damage cases. Overall, the weight of legal authority strongly recognizes neuropsychologists as generally competent to testify, contingent on adequate demonstration of academic coursework, peer reviewed research, and supervised training experiences (Greiffenstein & Kaufmann, 2012; Shapiro, 1991).

### **Neuropsychologists' Scope of Testimony**

The scope of testimony refers to the range of subject matter that neuropsychologists may address in front of a jury (e.g., causation of deficits). Neuropsychologists offer testimony whether the cause of action is a contributing factor to weak test scores. In general, both trial and appellate court rulings appear to be divided on the issue of whether neuropsychologists can comment on general causation (the physical state of the brain) or specific causation (e.g., car accident).

A number of causation testimony cases challenged by civil defendants drew amicus briefs from the APA. In *Horne v. Goodson Logging* (1986), a neuropsychologist offered psychometric evidence of a logger's disabling brain injury. On appeal, both Workers' Compensation (WC) commission and appellate boards ruled that neuropsychologists are not competent to render opinions about physical bases. On higher appeal, the APA successfully petitioned a North Carolina appeals court to reverse the WC commission and rule neuropsychologists competent to render judgments about disability. *Landers v. Chrysler Corp.* (1997) and *Hunt-oon v. TCI Cablevision* (1998) had similar facts and allowed psychologist expert testimony on organic causation. In a role reversal, plaintiffs in *Martin v. Benson* (1998) argued neuropsychologists are categorically unqualified to render causation testimony regarding brain dysfunction, because a defendant's neuropsychologist convinced a jury that mood and medication effects better explained the plaintiff's presentation. The divided state appeals court overrode its own decision in *Horne v. Goodson Logging* and ruled neuropsychological testimony inadmissible. Defendants prevailed at the North Carolina Supreme Court only on narrow procedural grounds of the plaintiff failing to preserve his objection at trial.

Other jurisdictions provided stronger grounds supporting testimony about physical brain state. In the case of *Valiulis v. Scheffeos* (1989), an Illinois appeals court strengthened the logical basis for allowing neuropsychological testimony by noting:

It would be somewhat anomalous to conclude that [the neuropsychologist] would not be qualified to testify as to cause of plaintiffs injury when the neurologist and psychologist who sought out his expertise and assistance in diagnosing the disease would likely be qualified to do so.

(pp. 1267–1297)

The Iowa Supreme Court directly dealt with neuropsychologists' causation testimony in *Hutchison v. Am. Family Mut. Ins.* (1994). This court conducted a wide-ranging survey of practices in many jurisdictions and determined "there seems little dispute that a psychologist may testify as to the existence of a brain injury or at least the condition of the brain in general" (p. 886). However, this court fractionated the causation testimony issue into two parts: neuropsychologists' ability to testify on physical state of the brain versus causation of

altered brain state. The *Hutchison* court acknowledged that the causation issue divided most courts, but in general, such causation testimony was allowed.

Some courts drew different conclusions in contexts not involving closed head injury. The Ninth Circuit appeals court took up the issue of toxic causation in *Schudel v. General Elec.* (1995), a case involving the alleged poisoning of workers by organic solvents, detergents, and polychlorinated biphenyls (PCBs). The trial court ruled neuropsychologists could testify as to test scores and cognitive levels but could not infer physical causation. On appeal, the APA again filed an amicus brief arguing that Federal Rules of Evidence (FRE) 702 established relaxed standards biased towards admission of scientific evidence. Nevertheless, the Ninth Circuit affirmed the trial judge's ruling, limiting neuropsychology testimony to issues of (cognitive) damages but not causation. Neuropsychologists have also been barred from inferring neurophysiological causation of EEG patterns (*John v. Im*, 2002) and cerebral palsy (*Grenitz v. Tomlian*, 2003). Courts have properly limited neuropsychologist causation testimony in cases involving head trauma inflicted in distinctly separated incidents in the medical history (*Guzman v. 4030 Bronx Blvd. Assoc., L.L.C.*, 2008).

### Enter *Daubert*: Admissibility of Neuropsychological Methodology

The well-qualified neuropsychologist allowed broad scope of testimony might nonetheless be required to defend his or her particular selection of test instruments. Although

neuropsychologists have no greater obligation to validate an entire assessment process than a physician, there is important admissibility law that addresses the methodologies neuropsychologists rely upon in drawing conclusions. This is perhaps the most critical component of the forensic knowledge base with which neuropsychologists should be familiar. These important bases include the Federal Rules of Evidence and a trilogy of U.S. Supreme Court decisions.

#### *Frye (1923) Dominates*

For 70 years, a federal appellate court's *Frye* decision (1923) provided judges a simple analytic tool for guiding admission of scientific testimony. James Frye was convicted of murder and appealed a court's refusal to admit scientifically based exculpatory evidence. This evidence was an early polygraph that relied on blood pressure changes to detect the sympathetic arousal theoretically associated with lying. The *Frye* court affirmed the trial judges' *in limine* ruling, reasoning that the psychophysiological principle underlying the technique had not yet gained "evidential force" in the transition from "the experimental" towards the "demonstrable" stages. Although recognizing the ambiguity in determining the evolutionary stage of a principle or technique ("twilight zone" in this court's words), the court issued what is now known as the *Frye* rule to help resolve the ambiguity: Only scientific principles or techniques achieving general acceptance within a specific scientific community developing the technique are admissible (see Table 37.2 for full language of decision). The *Frye* rule is commonly named the "general acceptance" standard.

Table 37.2 Summaries of the *Frye* and *Daubert* trilogy decisions controlling admission of neuropsychological evidence

#### *Frye Test (1923)*

"While the courts will go a long way in admitting expert testimony, deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained *general acceptance* in the particular field in which it belongs." (Emphasis added)

#### *Daubert (1993)*

The admissibility of scientific principles or assessment methods is based on the following criteria.

General criteria: Whether the reasoning or methodology underlying the testimony is scientifically *valid* and whether that reasoning or methodology is *relevant* to the facts at issue.

Suggested logical characteristics:

- Falsifiability: In practice, the test or method can be disproved
- The principle or technique has been subjected to peer review and publication
- Known or potential error rate in classification
- Technique or principle generally accepted in the relevant field

#### *Joiner (1997)*

- Reiteration of *Daubert*'s relevance requirement: Whether scientific evidence (theory and method) fits the legal question presented
- Reinforces the role of trial judge as gatekeeper of scientific evidence
- Extrapolation from existing data to particular case requires a link more lucid than an *ipse dixit* (subjective speculation) argument

#### *Kumho (1999)*

- Extends *Daubert* to areas of technical and specialized knowledge
- Includes behavioral science
- The four main *Daubert* factors are not exhaustive; they are polythetic: one or more are sufficient grounds for admitting/rejecting scientific evidence

*Frye* is widely (but not universally) considered a conservative rule that bars “junk science” in that it rejects speculative approaches. But the general acceptance rule also bars recent or novel advances that are undeniably valid but not yet general knowledge (Melton et al., 1997). Other criticisms of the *Frye* rule include admission of invalid techniques just because a majority of scientists believes in them (see section on Myths of Forensic Neuropsychology that begins on p. 914), plus difficulties in determining which scientific community applies or degree of scientific consensus based on a small sample of expert witnesses in a particular case.

Increasingly few states still rely on *Frye* and its hybrids to regulate scientific admission. There is little published case law involving *Frye* challenges to neuropsychologist testimony. Anecdotal evidence suggests that attempts to find certain neuropsychological measures inadmissible have failed. McKinzey and Ziegler (1999) drafted a *Frye* challenge to a “flexible test battery” but the trial judge still allowed such a battery into evidence. It is reasonable to argue that most neuropsychological procedures easily pass the *Frye* rule of general acceptance. General acceptance is easily shown by peer-reviewed reports. The American Academy of Neurology (AAN) Therapeutics and Technology Subcommittee Report (1996b) amply demonstrates the acceptance of neuropsychological measurement by a respected scientific body independent of self-interested neuropsychologists. The AAN (1996b) report is especially powerful evidence when one considers the same committee rejected use of some medical procedures in detection of remote mild brain injury and advised against use in the courts (AAN, 1996a). Thus, it is likely that neuropsychological test procedures pass *Frye* because neurologists as well as neuropsychologists generally accept them. Other methods for supporting neuropsychological instrumentation under *Frye* include reliance on surveys of test usage patterns (Boccaccini & Brodsky, 1999; Lees-Haley, Smith, Williams, & Dunn, 1996), test encyclopedias summarizing multiple validation studies of commonly used instruments (Spren and Strauss, 1998), or the validation studies cited in standardized test manuals.

But certain neuro-medical procedures have a history of inadmissibility under *Frye*, such as quantitative EEG (QEEG; Nuwer, 1997) and brain single photon emission computed tomography (SPECT; AAN, 1996a). QEEG evidence has consistently been ruled inadmissible in many jurisdictions. Good examples include *John v. Im* (2002) and *Nadel v. Las Vegas Metro* (2001). Generally, courts have refused to admit QEEG results as proof of any diagnosis, physical or psychological. This outcome is noted early in civil (*Head v. Lithonia Corp.*, 1989) and criminal (*State v. Zimmerman*, 1990) cases and continues throughout the past two decades (*Ross v. Schrantz*, 1995; *Tran v. Hilburn*, 1997; *In re: Breast Implant Litigation*, 1998; *Craig v. Orkin Exterminating Co.*, 2000; *Feria v. Dynagraphics Co.*, 2004; *LaMasa v. Bachman*, 2005), despite claims of improved QEEG technology, data processing, and reliability. Additionally, *Craig* notes a

similar result for brain electrical activity mapping (BEAM) technology and *LaMasa* also reports on the exclusion of positron emission tomography (PET). Brain SPECT has also been ruled inadmissible insofar as diagnosis of multiple chemical sensitivities is concerned (*Summers v. Missouri Pac R.R.*, 1997). Although SPECT cannot be used for causation opinions and is routinely excluded for diagnostic purposes, some courts have admitted opinions, under *Frye*, based on SPECT used for more narrow purposes. For example, these *Frye* jurisdiction courts allowed experts to use SPECT to supplement opinions with findings “consistent with” diagnoses made using other tests. (*Fini v. General Motors Corp.*, 2003; *People v. Urdiales*, 2007; *Matuszak v. Cerniak*, 2004; *Donnellan v. First Student, Inc.*, 2008).

### Federal Rules of Evidence

Starting in the late 1960s, Congress rewrote evidence law for use in federal courts and in 1975 codified the new FRE and the Federal Rules of Civil Procedure (FRCP, 1975). The states slowly adopted FRE into their own evidentiary statutes and are now substantially in force in the court systems of 35 states. FRE articles 401, 402, and 702–705 (see Table 37.3) describe the rules permitting expert testimony. One caveat about the FRE is important to consider. The rules have a generally liberal thrust, designed to admit a broad range of evidence to ensure fairness and to avoid orthodoxy.

The federal rules in the 400 series define the relationship between proffered evidence and the legal issues involved in litigation. Rule 401 defines “relevant” evidence as any item introducing a fact having potential impact on legal decisions raised by a trial. In scientific terminology, FRE 401 is a Bayesian statement that a given piece of evidence has a nonzero probability of affecting a trial’s outcome (Mossman, 2000). It is Bayesian in the sense that the trial judge makes a determination based on what is already known about the case (“prior probability”) to assign a zero (irrelevant) or nonzero (probative) weight to proffered evidence (“posterior probability”). This means that any two neuropsychological methodologies of significant but different validities for a given diagnosis are given equal footing in an admissibility determination, as long as validities are not zero (see the Myths of Forensic Neuropsychology section in this chapter). Rule 402 qualifies that 401 requires probative evidence not be overly prejudicial. In criminal contexts, self-incriminating material inappropriately elicited by a neuropsychologist would be barred irrespective of whether this fact is relevant to brain-behavior relationships.

The rules in the 700 series define the vehicle (witnesses) for proffering evidence at trial. There are two types of witnesses: fact (“lay”) and expert witnesses. Rule 701 defines a lay witness as someone who conveys information gleaned through the senses only, also known as a fact witness. For example, “I saw Jones shoot Smith in the head.” Some limited inferences by lay witnesses are allowed, e.g., “Smith looked really

Table 37.3 Federal rules of evidence relevant to neuropsychological testimony

*Rule 401**Definition of "Relevant Evidence"*

"'Relevant evidence' means evidence having any tendency to make the existence of any fact that is of consequence to the determination of the action more probable or less probable than it would be without the evidence."

*Rule 402**Relevant Evidence Generally Admissible; Irrelevant Evidence Inadmissible*

"All relevant evidence is admissible, except as otherwise provided by the Constitution of the United States, by Act of Congress, by these rules, or by other rules prescribed by the Supreme Court pursuant to statutory authority. Evidence which is not relevant is not admissible."

*Rule 701**Opinion Testimony by Lay Witnesses*

"If the witness is not testifying as an expert, the witness' testimony in the form of opinions or inferences is limited to those opinions or inferences which are (a) rationally based on the perception of the witness and (b) helpful to a clear understanding of the witness' testimony or the determination of a fact in issue."

*Rule 702**Testimony by Experts*

"If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise."

*Rule 703**Bases of Opinion Testimony by Experts*

"The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence."

*Rule 704**Opinion on Ultimate Issue*

"(A) Except as provided in subdivision (b), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact. (B) No expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto. Such ultimate issues are matters for the trier of fact alone."

*Rule 705**Disclosure of Facts or Data Underlying Expert Opinion*

"The expert may testify in terms of opinion or inference and give reasons therefore without first testifying to the underlying facts or data, unless the court requires otherwise. The expert may in any event be required to disclose the underlying facts or data on cross-examination."

scared." A treating psychologist is technically considered a fact witness.

An expert witness is one who offers an opinion about what the evidence means. Rule 702 defines an expert witness as someone with "specialized knowledge" who helps the trier of fact in either one of two basic ways: (a) to understand the evidence, or (b) determine a fact at issue. In regards to (a), the forensic neuropsychologist could provide definitions of neuropsychological testing, discuss cognitive test development, or summarize functional organization of the brain. In regards to element (b), a fact at issue could be the permanency of cognitive deficits in the hypothetical victim Smith. The neuropsychologist could opine, "The gunshot wound to Smith's brain damaged his ventro-medial frontal lobes and took away his ability to judge risk or make appropriate decisions." Rule 702 also addresses the issue of bases for judging

expertise: not only scientific training or a higher degree but also experience and technical knowledge. Note the liberal thrust of the definition, especially by the term *experience*. Interestingly, the legislative reporter's notes to this rule do not even mention *Frye* (Sanders, Diamond, & Vidmar, 2002), while making reference to the *Daubert* factor of general acceptance.

Rule 703 provides a liberal definition of the bases on which experts can base their opinions. Some legal scholars term 703 the *hearsay* rule. Essentially, the neuropsychology expert is not limited to basing opinions of neuropsychological measures or procedures, but may also opine on other data as long as such data is "reasonably relied upon" by experts in a particular field. Essentially, Rule 703 permits opinions based on hearsay ("The plaintiff told me his memory is only bad for what his wife tells him") or evidence not gleaned from direct

observation (e.g., outside records). Rule 703 is especially important for mental health professionals, as their work depends on hearsay (what the examinee said during a diagnostic interview). Neuropsychologists also rely on medical records or medical opinions they themselves did not produce (e.g., EEG and computed tomography, or CT, scan reports). According to Rule 703, the neuropsychologist may integrate such outside neurological studies, as well as verbal behavior of the plaintiff, into an opinion.

Rule 704 dictates the boundaries of expert opinion and addresses the issue of penultimate versus ultimate opinions. Part A (see Table 37.3) allows the expert to give opinions similar to legal decisions made by the trier of fact. Part B offers the exception that experts may not offer ultimate opinions on a criminal defendant's state of mind. Under this rubric, a neuropsychologist can testify that an accident caused (or did not cause) permanent cognitive deficits but may not opine regarding the impact of neuropsychological deficits on criminal culpability. A neuropsychologist could answer a penultimate question, such as "He was suffering severe cognitive deficits around the time of the crime." Part B was added by Congress in the early 1980s and is known as the "Hinckley" exception.

### **Landmark Ruling: *Daubert***

Much of modern scientific admissibility law stems from a trilogy of cases, beginning with *Daubert*. The landmark U.S. Supreme Court case of *Daubert v. Merrell Dow Pharm., Inc.* (1993) and its two follow-on rulings are summarized in Table 37.2. *Daubert* has been adopted by the majority of states.

In *Daubert*, plaintiff alleged that the antiemesis drug Benedectin induced birth defects. Using a relatively new quantitative method known as *meta-analysis*, plaintiff's experts reanalyzed previously published data and offered a countervailing conclusion that the drug caused mutagenesis. The trial court granted the defense motion for summary disposition, ruling plaintiff's reanalysis of earlier data was novel and unpublished, therefore violating the "general acceptance" provision of *Frye*. The plaintiff appealed, arguing the FRE were designed to supplant *Frye*, were the law of the land, and offered more relaxed admissibility standards. The U.S. Supreme Court agreed with the plaintiff: The *Daubert* Court ruled that expert evidence must meet only two general prongs: *reliability*<sup>1</sup> and *relevance*. The court went on to provide trial judges with suggested, nonbinding indicia for reliability and relevance by further elaborating on FRE 702.

The *Daubert* factors, described more fully in Table 37.2, contain four basic elements: (a) falsifiability, (b) peer review, (c) known or potential error rate, and (d) general acceptance. Parsing of the principles suggest the *Daubert* court was guided by many different logical, practical, and philosophical sources. The "falsifiability" element obviously stems from Karl Popper's reasoning that no theory can ever be proven, one can only "fail to disprove." Thus, "falsifiability" means

an admissible scientific principle must be expressed in terms of the conditions under which it can be disproved. An explanation that cannot be disproved is a pseudoscientific theory and not admissible—a sufficiently obtuse factor that the Honorable Chief Justice Rehnquist was "at a loss" to understand. The peer review element means that a neuropsychological technique or principle was published in a print journal with a peer review process. Either the "error rate" can refer to a zero-order validity study or it can refer to errors in diagnostic classification. The final element is the *Frye* general acceptance rule. Beliefs to the contrary, *Daubert* did not invalidate the general acceptance standard. Instead, the *Daubert* court incorporated "general acceptance" as one element to consider among many.

The *Daubert* court provided some general contours of admissibility analysis. The court stressed that science admissibility should be based on the *existence* of studies, manuals, and desirable logical characteristics; admissibility should be not guided by the conclusions of any study. In other words, the mere existence of a validation study may be sufficient to gain admission into evidence of a neuropsychological measure, but the conclusions of the published study are not to be considered until trial, as they go to the weight of the evidence (see the Myths of Forensic Neuropsychology section on confusion between admissibility and weight). Chief Justice Rehnquist concurred in the outcome but issued a partial dissent warning the *Daubert* ruling restricted itself to the term *scientific* from FRE 702, ignoring the other key language of "experience" and "technical knowledge." This dissent was prescient.

### ***Kumho* Decision**

The *Daubert* decision contained some ambiguities begging for clarification. One issue was the necessary and sufficient features of the guidelines. Were they polythetic criteria requiring flexible combination of a minimal number of elements, or were the *Daubert* guidelines a checklist of exhaustive criteria, meaning every element had to be present?

The issue in *Kumho* (*Kumho Tire v. Carmichael*, 1999) was whether *Daubert* applies to scientific ideas only. Carmichael, the survivor of a deadly car crash, sued a tire manufacturer. The plaintiff's main witness was a self-described tire expert who asserted the defendant's tire was defective based on simple palpation ("tactile and visual exploration") of the blown tire, hence representing a combination of experiential and technological testimony. Using the *Daubert* analysis, the trial court excluded this form of engineering testimony as unreliable. The appeals court reversed, holding that a *Daubert* analysis was restricted to purely scientific testimony mentioned in FRE 702. The U.S. Supreme Court granted *certiorari*, ultimately reinstating the trial court's determination. The *Kumho* court reasoned that the trial judge's gatekeeper function extended to experiential and technical evidence, and that the same analytic tools used to determine scientific reliability

should be used to determine reliability of other methods. The Supreme Court also reaffirmed the flexibility of the *Daubert* criteria and ruled the trial judge appropriately rejected the expert even after a very liberal application of *Daubert*.

### ***Joiner Decision***

While the *Daubert* and *Kumho* decisions dealt exclusively with methodological bases underlying an opinion, the U.S. Supreme Court used the *Joiner* matter (*General Elec. v. Joiner*, 1997) to further expand the gatekeeper role to include admissibility of expert's *conclusions*. Electrician Robert Joiner developed lung cancer and sued the manufacturer of PCBs on the theory that exposure to mineral spirits caused his condition. The plaintiff's experts offered epidemiological and animals studies in support of their causation and damages theories. The trial judge ruled this testimony irrelevant because the conditions of the animal studies could not be generalized to humans, and the epidemiologic studies involved multiple chemical exposures in addition to PCB. The judge ruled that generalization from epidemiological studies to the plaintiff's condition was too large an analytical gap that was "bridged only by subjective belief or unsupported speculation." The plaintiff appealed, arguing *Daubert* required focus only on the scientific and logical characteristics of research (falsifiability, peer review, etc.) but explicitly barred admissibility judgments based on any study's conclusions (cf. *Daubert*, 1993, p. 595). The *Joiner* court disagreed, ruling it was within a trial court's discretion to disqualify *opinion evidence* based on no more than the fact the expert said it (*ipse dixit*), irrespective if the extrapolated-from studies were themselves scientifically sound and reliable. Any extrapolation from literature to individual legal cases has to be bridged by lucid links other than the expert's belief there is a link. This is simply a restatement of the *Daubert* court's requirement that the basis for expert testimony had to be relevant in addition to being reliable (valid). In neuropsychology terms, this could mean that introduction of valid and replicated neuropsychological principles could still be barred if not generalizable. For example, the finding that the General Neuropsychological Deficit Scale is sensitive to metastasized brain cancer (Wolfson & Reitan, 1995) is not automatically generalizable to remote mTBI cases.

### ***Empirical Impact of Daubert***

The impact of *Daubert* on trial court and appellate behavior has undergone quantified scrutiny. Groscup, Penrod, Studebaker, Huss, & O'Neil (2002) examined expert admission rates documented in published opinions before and after *Daubert*. They found little overall change in admission of expert evidence at either the trial or appellate levels. Even *Joiner*, with its emphasis on the relevance of an expert's conclusions, did not lower admission rates. Interestingly, trial and appellate changes devoted the least number of words to

four *Daubert* elements, but devoted more discussion to the FRE. Groscup, Penrod, Studebaker, Huss, & O'Neil (2002) concluded judges gave little more than passing attention to *Daubert's* analytic tools. Dahir et al. (2005) directly surveyed judge's treatment of mental health evidence following *Daubert*. They came to similar conclusions as Groscup et al.: Judges rarely made decisions based on falsifiability or error rate, expressing greater comfort with pre-*Daubert* guidelines, namely *Frye* and general acceptance.

There is case law bearing on *Daubert* challenges to neuropsychological measures. In *Villalba v. Consol. Freightways* (2000), the plaintiff lost a brain injury tort in part due to failing neurocognitive validity tests such as the Computerized Assessment of Response Bias (CARB) and Tests of Memory Malingering (TOMM). Plaintiff appealed, arguing this SVT evidence should have been excluded because of the witness's refusal to photocopy and disclose TOMM items or normative data. The appeals court found no factual basis for the appeal (the neuropsychologist presented bar charts at trial) and further noted that the plaintiff had not proven the unscientific basis for SVTs through application of the *Daubert* factors. In *Coe v. Tennessee* (2000), a death row inmate appealed the admission of malingering measures for lack of peer-reviewed studies demonstrating sensitivity to malingering among death row inmates specifically. The Tennessee Supreme Court affirmed the trial court, ruling that malingering measures are generally accepted and reasonably generalizable to a criminal context. Ironically, this court also noted the defense's own neuropsychologist used SVTs, rendering the appeal internally inconsistent.

### **Third-Party Observers**

No issue highlights science-law conflicts in neuropsychology like third-party observation (TPO). Most jurisdictions allow observers to be present during independent medical examinations (IMEs). Statutory language refers to having the plaintiff's "physician" or an attorney present during a "medical examination." For example, the Michigan Compiled Laws Annotated 600.1445(1) reads:

Whenever in any proceeding before any court, board or commission, or other public body or officer, requiring and commanding that a person shall submit to a physical examination, the order shall also provide that the attorney for such person may be present at such physical examination of the party to such examination desires than an attorney representing him be present.

Trial judges have considerable latitude in determining whether this language applies narrowly to physical examinations or broadly to any type of examination, including neuropsychological. Under Rule 36 of the Federal Rule of Civil Procedure (FRCP, 1975), an attorney can ask the court to place restrictions on an examination, including the time,

place, manner, conditions, and scope of the assessment; most states adopted this language. In some cases, the trial judge may even agree and allow for videotaping or TPO of the neuropsychological testing.

The neuropsychology community typically resists such requests on multiple scientific and practical grounds. Two major neuropsychology organizations have published official positions on TPO (Axelrod et al., 2000; American Academy of Clinical Neuropsychology, 2001). Empirically, the scientific evidence generated by social psychologists overwhelming shows TPO negatively affects performance (see McCaffrey, Fisher, Gold, and Lynch (1996) for review of social facilitation literature). Kehrer, Sanchez, Habif, Rosenbaum, and Townes (2000) and Constantinou, Ashendorf, and McCaffrey (2002) both showed negative impact on attention and speed measures. Butler and Baumeister (1998) reported that even warm, *supportive* third-party observers caused decrements on skilled tasks relative to unmonitored performance, disproving the common legal position that plaintiff-friendly observers are necessary. An entire issue of *Journal of Forensic Neuropsychology* was devoted to scientific studies of TPO (McCaffrey, 2005): All studies showed experimental evidence for significant, in some cases robust, effects for observers on neuropsychological domains.

There is considerable case law on this issue, although most decisions are unpublished, having little far-ranging application. The weight of authority of these cases recognizes the validity of psychological test responses are more affected by TPO than physical responses are in medical examinations. A number of appellate rulings barring plaintiff's intrusion into neuropsychological testing include *Cline v. Firestone Tire* (1988) and *Tomlin v. Holecek* (1993). In *Troiano v. John Hancock* (2003), the court ruled that the plaintiff did not show good cause why an observer should be present for neuropsychological testing. In *Ragge v. MCA/Universal Studios*, (1995), a California Federal District Court denied the plaintiff's request for both TPO and advance notification of which tests would be given. However, TPO is allowed in California state court by statute ("The examiner and examinee shall have the right to record a mental examination by audio technology" (C.C.C.P. § 2032.530(a), as directly applied to neuropsychological evaluations; see *Golfland Entm't Ctrs. v. Sup. Ct.*, 2003). Although this is not a comprehensive list, New York, Florida, Oregon, Washington, Kentucky, Alabama, and Alaska allow TPO for mental examinations under specified circumstances. States vary considerably on tolerance for third-party observers and practitioners are encouraged to understand appropriate jurisdictional rules.

### Common Settings for Forensic Neuropsychologists

There are four basic legal forums in which neuropsychologists can be asked to offer opinions: administrative, civil, probate, and criminal.

### Administrative Law

Administrative law courts represent a hybrid between a civil court and a governmental agency. Typically, a governmental agency is empowered to hold hearings in which magistrates or hearing officers determine findings of fact and law. The setting is more informal, and evidentiary rules are commonly relaxed. The government may be a party to this dispute, such as in license revocation and restoration.

WC disputes fall into this category and are a frequent source of neuropsychological damage claims in industrialized areas. WC cases involve two private parties, but are distinguished from civil actions by the absence of tort law: Both parties give up tort rights, so negligence and liability are not issues of fact to dissect. WC was historically adjudicated in civil court until the World War I era, but employers' strong liability defenses left severely injured workers and their families destitute, resulting in sweeping legal reform (Melton et al., 1997). Another distinguishing characteristic is the burden of proof: Although mostly equivalent to "preponderance of the evidence" model, the standard is even lower in some states. In Michigan, for example, the workplace incident must form a "vital component" of the claimant's present problems, meaning it can be a contributing factor, even if the workplace injury does not contribute more than 50% to symptoms.

### Civil Court

Civil courts involve disputes between two private parties where both liability and damages are the key issues. The government merely provides the forum for resolving the disputes. Typical civil suits encountered by neuropsychologists involve claims of psychological and cognitive damages stemming from motor vehicle accidents, toxic exposure, or medical malpractice. The issues of fact determined by the jury are (a) whether there was a neurological injury to begin with and (b) whether it resulted in cognitive or emotional deficits. The evidentiary threshold is the lower "preponderance of the evidence" model, because there are no liberty interests at stake as in probate or criminal matters (Melton et al., 1997). That is, the prevailing party is the one whose version of events is perceived at least 51% correct. Over the years, discovery rules have been broadened to avoid "surprise" at trial and to ensure verdicts are more strongly linked to objective evidence than to differences in lawyerly skill or resources (Lees-Haley & Cohen, 1999).

### Probate Proceedings

Probate proceedings originally evolved to certify wills and manage postmortem disposition of estates. *Probate* is derived from "probe," meaning to examine or test a will. Private parties may dispute the disposition of a decedent's property, and the dispute is adjudicated in a probate court much like a civil trial. Probate courts evolved to serve a second function,

namely assignment of guardians and conservators to physically or mentally incompetent persons. Competency is defined as an individual's legal capacity to make certain decisions and to perform certain acts (Marson & Hebert, 2005). Liberty interests are at stake here, as probate proceedings deal with the "taking" of property against the earlier wishes of a decedent, or the removal of a living person's rights as in a guardianship proceeding. Marson and Hebert (2005) identified three civil competency issues in which neuropsychologists can play roles: Capacity for medical consent, mental state of a will's creator, and capacity to manage financial affairs.

*Testamentary competence* (TC) is the legal term for the validity of a will as it relates to minimum cognitive capacity for wills creation. Most definitions of TC make some reference to mental ability, implying an ideal area for neuropsychologists' involvement. Opinions about TC may be requested antemortem, but more often questions about competence arise postmortem (Spar & Garb, 1992). Because liberty interests are at stake, the threshold for testamentary competence is set low, or put differently, the burden of proving lack of capacity is high (Greiffenstein, 2003a). Exclusive of some variants, the concept of testamentary competence is generally uniform across jurisdictions and consists of these four elements: (a) knowledge of the will's existence, (b) memory and comprehension of personal assets, (c) knowledge of potential heirs, and (d) anticipation of the will's effects on the heirs. Mapping these terms into neuropsychological terms suggest the following scheme: (a) recent and long-term memory, (b) object recognition and long-term memory, (c) facial recognition and long-term memory, and (d) executive-cognitive capacity. From a neuropsychological standpoint, some state variants are interesting. Minnesota law seems to require direct evidence of intact working and recent memory: The testator "must be able to hold [nature and extent of property] in his mind long enough to form a rational judgment concerning them" (*Estate of Congdon*, 1981). Kaufmann (2016) recently provided some representative cases illustrating the impact of neuropsychologist experts in probate cases.

A valid will also requires absence both "insane delusions" and "undue influence" (UI). UI means the testator's volition was undermined by an individual exercising inappropriate control. A neuropsychologist may for example provide evidence that the testator's neuropsychological deficits rendered him or her suggestible or controllable by adverse parties. There are many indicia for UI, which are discussed elsewhere in detail (Greiffenstein, 2003a). Antemortem assessment and postmortem inferential methods are offered by Heinik, Werner, and Lin (1999); Marson (2001); Marson, Annis, McInturff, Bartolucci, and Harrell (1999); Spar and Garb (1992); and Greiffenstein (1996, 2003a).

### **Criminal**

The government initiates a criminal proceeding when it charges a person with crime punishable by imprisonment

and/or fine (Denney, 2003). Because of strong liberty interests at stake (loss of life, freedom, or property), the evidentiary model for determining outcome is set high and the stages highly formalized. The burden of proof lies with the government prosecution, and the government must meet the familiar standard of "beyond a reasonable doubt," which to some is interpreted as 90% confidence that evidence shows guilt (Kagehiro, 1990).

Many legal decisions in criminal cases revolve around the cognitive, social, and behavioral capacities of the defendants. Competencies specific to criminal proceedings include competency to stand trial, confess, plead guilty, waive Miranda rights, waive right to counsel, receive a sentence, understand execution, and appreciate criminal responsibility (Grisso, 1986, 1988; Marson & Hebert, 2005). Neuropsychological testing can fulfill the law's needs by offering objective and quantified assessments that measure cognitive, social, and affective constructs linked to legal concepts of competence.

The most common criminal application for neuropsychologists addresses criminal responsibility. The most serious crimes require proof of concurrence between the mental element and the physical act of the crime. *Mens rea* is the mental capacity to plan a crime and foresee its consequences, and *actus reus*, is the physical criminal act itself. Concurrence requires that *actus reus* and *mens rea* occur at the same time. Persons pleading not guilty by reason of insanity (NGRI) seek acquittal, arguing they did not have the mental capacity to form intent. Neuropsychologists may determine that defendants' cognitive weaknesses do or don't relate to mental state at the time of the crime. Many courts may allow neuropsychologists to testify about criminal capacity, but a common complaint about forensic psychologists is that they do not understand the difference between legal insanity and clinical psychopathology. Not all states share the same legal definitions.

The earliest legal insanity test and one still used in nearly half the states is the *M'Naghten* (1843: 720) insanity test:

At the time of the act, the party accused was laboring under such a defect of reason from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong.

Often termed a "knowing right from wrong test" (Sullivan & Denney, 2003: 210), *M'Naghten* is a simple polythetic (either-or) definition that focuses strictly on general cognitive ability isolated from other elements of cognitive and psychological-emotional functioning. Some have argued the rule's general contour demands a *profound* general cognitive defect ("from *such* a defect"), implying only mental retardation fits the definition. Mapping this insanity test's terms onto neuropsychological concepts suggests the following. *Disease of the mind* refers to a recognized form of mental illness or organic brain disease. Not *knowing* the "quality or

nature of the act” and the word *wrong* appear to emphasize profound deficit in semantic memory and fund of general knowledge to the point the person did not know the behavior was unlawful even if they could appreciate the lethality of their actions. A more liberal interpretation of *M’Naghten* is the terms could also refer to a serious defect in any one of other cognitive systems, including poor executive-cognitive skills (unable to foresee the immediate outcome) and visual perception (did not know he or she had a weapon).

The *M’Naghten* test came under criticism from some legal scholars and psychiatrists in the late 1800s because the test appeared limited to profound cognitive defects, while ignoring less severe cognitive deficits and completely ignoring behavioral and affective/emotional problems. The “irresistible impulse” and *Durham* (1954) tests were a response to the perceived inadequacies of *M’Naghten’s* “knowing” test. The *Durham* (1954) test, authored by Judge Bazelon, states “An accused is not criminally responsible if his unlawful act was the product of mental disease or defect” (pp. 874–875).

Legal scholars refer to *Durham* (1954) as a “products test,” meaning the criminal act was a product of mental illness. This vague rule created many problems with unwelcome social outcomes. Unlike earlier or later insanity tests, the *Durham* test did not suggest a threshold for the magnitude of mental illness necessary for application. Hence, many health professionals assumed the mere existence of a diagnosable disorder was sufficient to support legal insanity. It was also easy to show that any criminal act would have some connection to mental illness (Shapiro, 1991). Worst of all, psychopathy had recently been recognized as a mental illness, making antisocial behavior easily excusable. In neuropsychological terms, even a mild impairment could support a NGRI defense under *Durham*.

The American Law Institute (ALI, 1962: 4) tried to resolve these problems by formulating a model insanity test that is now in use in most states.

A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality [wrongfulness] of his conduct or to conform his conduct to the requirements of the law. The term mental disease or defect does not include an abnormality manifested only by repeated criminal or otherwise antisocial conduct.

The ALI insanity test indicates the presence of a proven brain disorder or recognizable neurocognitive deficit as necessary but not sufficient to meet the test. This overcomes the wideness of the *Durham* test, which implied any mental disorder was sufficient. The exclusion of antisocial personality also defeated the efforts of psychopathic offenders to win NGRI cases. The ALI test replaces the *M’Naghten* rule’s “such a defect” language with *substantial incapacity* as the criterion.<sup>2</sup> The ALI definition does however move beyond *M’Naghten’s* purely cognitive insanity test and adds a

volitional prong by stressing inability to conform behavior to the law. This addition may be critical for neuropsychologists.

Neuropsychologists continue to make contributions to criminal courts, both as researchers and testifying experts (Denney & Wynkoop, 2000), and legal decisions stimulate their work. The volitional prong of the ALI definition implies executive-cognitive dysfunction. Persons with abnormal frontal lobe physiology, theoretically, could commit crimes because of inability to inhibit behavior (Damasio, Tranel, & Damasio, 1990). Neuropsychologists involvement in criminal matters also include classification of aggressive behavior into primary and secondary types (Houston, Stanford, Villemarette-Pittman, Conklin, & Helfritz, 2003), juvenile adjudicative competence (Wynkoop, 2003), malingering to evade criminal culpability (Wynkoop & Denney, 1999), and restoration to competence through use of medication (Stanford et al., 2005).

In 1984, Congress passed the Insanity Defense Reform Act (IDRA) after John Hinckley was found to be NGRI in his attempt to assassinate President Ronald Reagan (*United States v. Hinckley*, 1981). *Hinckley* was the first case to introduce neuroimages (computerized axial tomography [CAT] scans) as evidence of a psychiatric condition. Reaction to the verdict fueled the IDRA effort to narrow the circumstances when an “otherwise culpable defendant is excused for his conduct because of mental disease or defect” (18 U.S.C. § 17). Subsequent case law attempted to delineate the proper use of mental health evidence related to legal excuse and criminal culpability (*United States v. Cameron*, 1990).

*Cameron* explained how IDRA narrowed the use of mental health evidence in federal criminal trials:

- 1 Removing the volitional “diminished capacity” element of the insanity defense (§ 17(a)),
- 2 Ending all other affirmative defenses or excuses based on mental disease or defect (§ 17(a)),
- 3 Requiring defendants to show clear and convincing evidence of insanity (§ 17(b)),
- 4 Limiting expert psychological testimony regarding ultimate issues (FED. R. EVID. 704(b)), and
- 5 Linking a NGRI verdict directly to federal civil commitment proceedings (§ 4242(b)).

Notwithstanding the statutory language or congressional intent behind IDRA, federal courts have struggled with statutory interpretation and its application to criminal cases (*Cameron*, 1990, p. 1062).

When a defendant who is found competent to stand trial fails to show clear and convincing evidence of insanity, or cannot prove that diminished capacity negated the *mens rea* component of a crime, his or her mental condition may still be relevant in mitigating punishment. Consequently, when the battle of neuropsychologists experts does not yield a favorable verdict for the defendant, testimony used by the defense to argue incompetence, insanity, or diminished

capacity may be resurrected to reduce a sentence or avoid the death penalty. Testimony about brain damage may be an important factor mitigating against the death penalty for competent defendants found guilty of capital murder. Failure to call a neuropsychologist expert to present evidence of brain damage at trial has been the basis for ineffective assistance of counsel claims.

### Common Issues for Neuropsychological Analysis of Damage Claims

There is no known limit to the number of neurologic and pseudoneurologic conditions that neuropsychologists could address in forensic examinations, but there are a narrower set of damage and causation claims that neuropsychologists routinely encounter. Certain generalizations apply to all neurologic damages claims, but each claim has its own unique set of challenges, issues, and empirical bases.

#### *Head Injury and Postconcussion Syndrome*

A key element of a tort is proving the existence of damages. The most common damages issue encountered by neuropsychologists is the effects of remote head–neck injury (Ruff & Richardson, 1999). The specific issues are whether remote mTBI, adult common whiplash, or uncomplicated concussion can explain multiyear subjective disability or present cognitive profile (Alexander, 1998, 2003). Do late postconcussion syndrome (LPCS) claims represent a disorder of the “natural kind” (neurobiologically real, independent of culture; see McNally, 2005). mTBI is an objective, self-limiting, acute neurologic disease that resolves rapidly (Alexander, 1995; McCrea et al., 2003), hence a disorder of the natural kind. LPCS appears in part to be a social construction because of its historical association with compensability legislation and social upheavals (Erichsen, 1866). Boake et al. (2004) showed limited agreement on postconcussion incidence between the *Diagnostic and Statistical Manual of Mental Disorder*, fourth edition (DSM-IV) and *International Classification of Diseases* (ICD) definitions in persons with mTBI, although there was *no difference in neurocognitive or health outcome under either definition*. Failure of a subjective syndromal definition to predict some clinical endpoint means that definition is invalid as a disease concept.

In LPCS cases, the forensic neuropsychologist assists the trier of fact by (a) staging of initial injury severity based on objective indices, (b) background review of LPCS literature, and (c) assessment of the factors contributing to the plaintiff’s current neuropsychological presentation (Greiffenstein, 2000). The necessary first step is to stage initial head–neck injury severity with generally accepted criteria for objective injury, based on emergency room or paramedic records. Although published criteria for mTBI vary (Paniak, MacDonald, Toller-Lobe, Durand, & Nagy, 1998; Ruff & Richardson, 1999), the overlap of definitions allows a distillation

into a uniform set of core characteristics: mTBI is diagnosed when there is (a) *brief* loss of consciousness (LOC) or *brief* posttraumatic amnesia (PTA) (b) induced by rapid acceleration/deceleration of the head (c) after blunt force trauma (Shaw, 2002). Neurophysiologically, mTBI represents a transient disruption of intracellular and intercellular communication, not a structural lesion. There is no scientific dispute that these are sufficient conditions representing a fundamental definition of mTBI.

A good quantitative method that puts the testifying expert on solid scientific grounds is the core mTBI definition offered by the American Academy of Neurology (AAN) (1997). These graded criteria for sports concussion are both time and symptom weighted: Grade I concussion (no LOC with < 15 minutes PTA), Grade II (no LOC with one hour PTA), and Grade III (+LOC “seconds to minutes”). The AAN (1997) criteria deemphasize reliance on subjective mental changes although there is no way to eliminate all self-reports. The AAN criteria are also supported by the classical mTBI literature, which rely on participants with LOC duration of less than 30 minutes and PTA durations in the one-hour range (Gronwall & Wrightson, 1974; Gronwall, 1977; Newcombe, Rabbitt, & Briggs, 1994). The cognitive effects of mTBI are short-lasting, on the order of days to weeks (Dikmen, McLean, Temkin, & Wyler, 1986; McCrea et al., 2003; McCrea, Kelly, Randolph, Cisler, & Berger, 2002).

The second step is providing conceptual background for juries to understand the facts of a case should include well-established facts. One critical point is that LPCS symptoms are nonspecific. A reasonable distillation comprises nine proposed symptoms: headaches, dizziness, somatic preoccupation, memory loss, concentration lapses, irritability, mood disturbance, pain (excluding headaches), and sensory hyperacuity (Brown, Fann, & Grant, 1994). These symptoms’ nonspecificity is proven by their high frequency in personal injury litigants not claiming brain injury or in medical outpatients (Fox, Lees-Haley, Earnest, & Dolezal-Wood, 1995). LPCS does not demonstrate any objective neurologic findings (Alexander, 1995). It is associated with extremely elevated MMPI-2 profiles disproportionate to injury characteristics (Youngjohn, Davis, & Wolf, 1997), atypical motor findings on standardized neurocognitive measures (Greiffenstein, Baker & Gola, 1996a), higher symptom report than acute brain injury (Miller & Donders, 2001), and positive findings on symptom validity tests (Greiffenstein et al. 1994; Greiffenstein, Baker, & Gola, 1996b; Greiffenstein & Baker, 2006). LPCS patients are very similar to other persons with poorly defined, chronic complaints (viz., chronic fatigue syndrome, chronic insomnia) whose interpersonal style draws attention to their disability (Greiffenstein, 2000). Differences of opinion among some neuropsychologists yield different scholarly approaches regarding the scope (width) of the mTBI criteria. The scope of any definition is critical because it determines the mTBI prevalence rates (McCauley et al., 2005) and further unlocks access to financial benefits, treatment, and

social validation of disability. The well-grounded forensic neuropsychologist should emphasize mTBI and its variants *should not be diagnosed at random postinjury intervals on the basis of subjective symptom severity*. The American Congress of Rehabilitation (1993) criteria are problematic because of their overly broad scope: One criterion of this definition allows *any* “altered mental state” in the absence of blunt head trauma to qualify as brain injury, implying that any car accident involving a subjective state of being caught off-guard justifies diagnosing mTBI. Kibby and Long (1996) and Paniak et al. (1998) commented on the vagueness of the “altered mental status” feature and the false positive diagnoses it creates. When testifying in court on such matters, the forensic neuropsychologists may succinctly explain to the jury what false positive and negative errors are.

The third step, determination of causative factors, requires reasonable certainty of neurological, social, intellectual, and temperamental correlates of LPCS. There is no reasonable debate that initial head injury severity is the chief determinant of neurologic and neuropsychological outcome (Dikmen, Machamer, Winn, & Temkin, 1995; Rohling, Meyers, & Millis, 2003; Volbrecht, Meyers, & Kaster-Bundgaard, 2000), so persons with no emergency room evidence for amnesia, delirium, unresponsivity, or blunt head trauma are not likely to have acutely injured brains. The neuropsychologist may conclude by acknowledging there is no generally accepted single explanation for LPCS, but *it is generally accepted that LPCS is multifactorial and cannot be explained by a single discrete or systemic neurological problem* (Greiffenstein, 2000; Lishman, 1988; Luis, Vanderploeg, & Curtiss, 2003). LPCS likely represents the final common pathway of many preinjury and postinjury environmental, neurological, academic, social class, medical, and personality risk factors unrelated to traumatic brain (TBI) changes (Greiffenstein, 2000; Greiffenstein & Baker, 2003; Lishman, 1988; Ruff & Richardson, 1999). McCauley, Boake, Levin, Contant, & Song, (2001) showed LPCS correlates with gender, ethnicity, and social support networks. Clearly, social factors contribute heavily to the phenomenology of LPCS. Hence, the scientific literature justifies a greater focus on studying preinjury and postinjury social and situational factors in understanding current LPCS presentations. But one should always be open to new and objective case-specific information that may “trump” base rates and provide compelling contrary evidence for residual posttraumatic brain damage.

### **Neurotoxic Torts**

A steadily growing area of legal contention is the purported role of environmental toxins in central nervous dysfunction (Bolla, 2005). The issue of fact is whether plaintiffs’ brains were permanently damaged following exposure to various neurotoxins. The list includes organic solvents (e.g., Toluene, halides), organometals (e.g., lead, manganese), microorganisms (“black mold”; Lees-Haley, 2003), and even common

chemicals (“multiple chemical sensitivity”). Research into neuropsychological correlates of claimed and proven toxic exposure is growing. There have been investigations of neuropsychological correlates of exposure to neurotoxins such as manganese (Bowler, Mergler, Sassine, Larribe, & Hudnell, 1999; Deschamps, Guillaumot, & Raux, 2001), mercury (Meyer-Baron, Schaeper, Van Thriel, & Seeber, 2003), organic solvents (Albers & Berent, 2000; Colvin, Myers, Nell, Rees, & Cronje, 1993), and PCB (Jacobson & Jacobson, 2002, 2003; Schantz et al., 1996).

A special case of neurotoxic torts is lead poisoning in children and adolescents. Unlike toxic claims for which there is no reliable somatic marker, there are objective measures of body lead levels. Lead is easily absorbed by the body and is measured in micrograms per deciliter (mcg/dl). Per suggested guidelines by the Centers for Disease Control (CDC, 1991), < 10 mcg/dl is inconsequential, 10–19 mcg/del is of indeterminate medical meaning, > 20 requires a medical evaluation, and > 70 mcg/dl is a medical emergency. Empirically, Goldstein’s (1984) review of empirical literature suggested > 80 mcg/dl is associated with proven brain tissue damage. The forensic controversy centers on whether *low blood lead levels*, defined by the CDC (1991) as 10–20 mcg/dl, has any impact on general neuropsychological functioning. For example, the 14-month-old plaintiff in *Baxter v. Temple* (2008) had a lead level of 36 mcg/del, although the jury eventually found no evidence of damage caused by lead (*Baxter v. Temple*, 2012; see Chapter 36 in this volume for extended discussion). Proponents of a lead–cognition link argue that even low blood levels in the 10–20 mcg range have severe consequences for intellectual functioning (Needleman, 1979; Needleman & Leviton, 1979). More refined dose-response investigations showed lead–IQ effect sizes were small, with the best-designed studies showing group differences of three IQ points (Pocock, Smith, & Baghurst, 1994; Tong, Baghurst, McMichael, Sawyer, & Mudge, 1996), equivalent to a small effect size around 0.20.

Typically, these claims have a similar logical structure to LCPS, asserting that (a) exposure (trauma) levels below recognized disease-inducing thresholds causes occult brain damage not detectable through standard medical testing, (b) subjective disability and cognitive weakness are evidence for such brain damage, and (c) “syndromes” are defined by many nonspecific complaints. Circular reasoning problems endemic to many chronic low-dose claims remain a major methodological issue: “The exposure to solvents prove the plaintiff’s memory complaints are organic, but the memory complaints prove he or she must have had damaging solvent exposure.” Some neuropsychologists rely on this reasoning to support their arguments. For example, Bowler et al. (2003) judged manganese neurotoxicity to be present based on the plaintiff’s (a welder) 25-year retrospective recall of how often windows were open in the identified plants. Questionable reliance on post hoc evidence or the strongly held personal beliefs of litigants does not disprove manganese-cognition

claims; it only means such evidence is insufficient and potentially misleading.

The issue of fact that neuropsychologists cope with is which of multiple competing explanations best fits the facts of the individual case. Taking lead as an example, the modest associations between lead and cognition do not yet meet accepted standards of causality (Hill, 1965). Like other neurotoxic claims and LPCS, lead poisoning cases are confounded by powerful social comorbidities: Lead research studies and claims are strongly associated with covariate imbalances in socioeconomic status, parental cognitive aptitudes, and ethnic status. Hebben (2001) cited literature showing lead accounts for less intellectual variance than sociodemographic and other factors. In Kaufman's (2001) view, 26 of the best-designed lead-cognition studies still displayed marked shortcomings, including: uncontrolled variables clouding conclusion, insufficient assessment of parental IQ, failure to control for multiple comparisons, inappropriate comparison of extreme groups, and variable examiner characteristics. Most important, Kaufman's (2001) review failed to show any linear relationships between lead levels and IQ in the low range. Needleman and Bellinger's (2001) response to Kaufman (2001) offers a good example of unscholarly responses that testifying neuropsychologists should avoid: dismissal of any possible criticism, accusing critics of offering "weary" arguments, and joining "spokespersons for (fill in the blank) industry." Needleman went on to argue that even tiny effects could still have practical actuarial impact on intelligence levels depending on the population scale. But Needleman et al. (2002) later reported low lead levels caused executive-cognitive dysfunction in adjudicated delinquents, but no intellectual effects.

Needleman and Bellinger's (2001) visceral investment in lead-cognition effects aside, the challenge for the serious neuropsychologist in neurotoxic cases remains one of disentangling the brain effects of neurotoxins from the nonproximate, enduring, and situational characteristics of the person bringing a lead-cognition claim. This may be impossible in some cases and is certainly a difficulty in most. One should always recognize that lead can have a deleterious effect on brain tissue but the focus in the individual litigant should be on the reasonable impact of subclinical doses of lead.

### ***Suboptimal Effort and Malingering***

An important difference between clinical and forensic settings is the element of secondary gain. Secondary gain is defined as any external incentive for sustaining subjective disability inconsistent with the natural history of the claimed disorder. Secondary gain can take the form of positive reinforcements (compensation, attention, access to narcotics) or negative reinforcement (release from work obligations, inhibition of an abusive spouse). The mere existence of a lawsuit or compensable injury is insufficient to diagnose malingering, but it is sufficient grounds for justifying effort testing.

Rogers (1997) systematized forms of noncredible presentations. Invalidity may take the form of suboptimal effort (not trying hard enough), exaggeration of minor complaints (embellishment), dissimulation (exaggerating virtue and pre-accident adjustment), and effortful distortion of responses (malingering). As discussed earlier, diagnoses of malingering may not be allowed in some jurisdictions or by some judges, but acceptable alternate language is available, e.g., effort testing indicates scores not consistent with genuine brain injury (Ogloff, 1990; Tombaugh, 1995).

Traditional SVTs embedded in personality scales are insufficient for detecting malingered neurocognitive deficits. The Infrequency (F) scale of the MMPI-2 may capture simulation of psychotic syndromes, but it is insensitive to implausible pseudoneurologic histories (Greiffenstein et al., 2002), exaggerated cognitive deficit (Greiffenstein, Baker, & Gola, 1995; Larrabee, 2003c; Ross et al., 2004), exaggerated trauma syndromes (Greiffenstein, Baker, Axelrod, Peck, & Gervais, 2004) or exaggerated posttraumatic pain (Larrabee, 2003a, 2003b).

There are many methods for detecting response distortion, some grounded in logic and others in empirical findings. Sweet (1999b) classifies invalid neuropsychological performances into three basic types: (a) poor performance on specific validity tests; (b) atypical score patterns on genuine neuropsychological measures; and (c) poor ecological validity, which is defined as marked incongruence between scores and observed behavior. Use of specific validity tests is a purely objective approach and the other two a mixture of objective findings and clinical judgment.

### ***Specific Validity Tests***

Specific tests designed for detection of response bias were termed SVTs. More recently, Larrabee (2012c) distinguished performance validity tests (PVTs) as the validity of test performance from symptom validity as the validity of symptom report. PVTs typically target implausible memory and attention deficits, although any implausible performance from any neurobehavioral domain can be measured. The most effective PVTs are simple verbal or visual two-alternative recognition memory tests passed with ease by all but the most profoundly impaired neurological patients. Examples of two-choice verbal PVTs include the CARB (Allen, Iversen, & Green, 2002), the Word Memory Test (Green, Iverson, & Allen, 1999; Green, Lees-Haley, & Allen, 2002; Green, 2003), the Medical Symptom Validity Test (Green, 2004); the Non-Verbal Medical Symptom Validity Test (Green, 2008), and the Warrington Recognition Memory Test verbal condition (Millis, 2002). Examples of two-choice visual memory tests include the TOMM (Rees, Tombaugh, Gansler, & Moczynski, 1998; Tombaugh, 1995; Tombaugh, 2002) and the Warrington faces condition (Millis, 2002). Another validity determination method is a floor effects strategy, where the cutting score is based on a lower performance limit of clinical groups with

known brain disease (Frederick, 2003; Taylor, Kreutzer, & West, 2003; van Gorp et al., 1999). Minor injury litigants scoring “below” the floor of persons with substantial brain damage are probably putting forth insufficient effort. A good example of this is the Rey 15-Item Memory Test, a visual immediate recall task (Rey, cited in Lezak, 1995). Persons with moderate to severe closed head injury obtain a group mean of 12 items (four rows) with a lower limit of ten items; they rarely produce intrusion errors. Persons seeking compensation with a mean of 2.2 years postinjury often score < 10 (Greiffenstein et al., 1994; Greiffenstein et al., 1996b).

### *Atypical Patterns*

Pairs or groups of test scores inconsistent with neuropsychological or neuroanatomical first principles should be viewed with suspicion. Atypical patterns include (a) violations of test difficulty hierarchy, (b) extreme variability on tests measuring the same underlying cognitive processes, (c) incompatibility of test pairs, or (d) disease-deficit incompatibility (Larrabee, 2012b). A violation of the difficulty hierarchy means the claimant fails easy items but passes more difficult items in the same conceptual domain. Extreme variability refers to large discrepancies between test scores measuring the same underlying construct. Incompatibility of test pairs refers to tests with unidirectional relationship where the direction of dependence is violated. For example, recent memory depends on adequate attention, but attention does not depend on memory. Mittenberg, Azrin, Millsaps, and Heilbronner (1993) showed student simulators performed more poorly on the Attention/Concentration Index than the General Memory Index of the Wechsler Memory Scale–Revised, the opposite of genuine brain injury. Disease-deficit incompatibility means an abnormal score is not consistent with the claimed disease. For example, brief working memory tasks are not affected by non-dementing brain disorders with the exception of conduction aphasia. Persons feigning brain injury are not aware of this and perform poorly on digit span tasks (Mittenberg et al., 2001; Greiffenstein et al., 1994; Greve, Bianchini, Mathias, Houston, & Crouch, 2003). Another example is implausible motor dysfunction: Damage to motor control centers of the brain results in a gradient of increasing impairment as a function of task complexity (Haaland, Harrington, & Yeo, 1987; Haaland, Temkin, Randahl, & Dikmen, 1994), but Greiffenstein, Baker, and Gola (1996a) showed compensation seekers with minor traumas show the inverse pattern, with grip strength performance worst, finger tapping intermediate, and small parts dexterity best.

Lack of ecological validity is the neuropsychologist’s judgment that a respondent’s scores or history are not consistent with observable behavior (Larrabee, 1990; Sweet, 1999b). This is a subjective judgment that requires a comparison of the informal mental status evaluation (MSE) to the deficits implied by neurocognitive test scores. Persons with extremely

low cognitive scores should display obvious problems during an interview. For example, a person with genuine organic amnesia will exhibit considerable difficulty recalling postaccident information and a true aphasic will have great difficulty communicating thoughts. But persons feigning brain damage have to prove their claims through two clashing paradigms: (a) relying on intact cognitive processes to communicate disability beliefs during the interview but (b) proving cognitive defects by underperforming on neurocognitive measures. A good example of poor ecological validity is the person who performs < three standard deviations below expectations on memory and language tests, but who spontaneously and fluently verbalizes many symptoms during face-to-face interview. Greiffenstein et al. (1994) and Slick, Sherman, and Iverson (1999) offer behavioral criteria for judging unusual symptom reports. It has been empirically demonstrated that persons with genuine memory disorders report fewer complaints than normal controls (Feher, Larrabee, Sudilovsky, & Crook, 1994; Prigatano, Altman, & O’Brien, 1990). But neurologically normal persons with LPCS voice many complaints, and those who feign disability may offer dozens of symptoms. Such overreporting behavior is the opposite that expected in persons with genuine brain disease. Greiffenstein and Baker (2006) showed that malingering was more frequent in persons voicing the most LPCS complaints and nonexistent in those voicing the fewest.

### **The Process of Forensic Neuropsychological Assessment**

There are many phases to the neuropsychologist-attorney and neuropsychologist-court interaction. The assessment phase is the most crucial, because it is here that the bases for creating opinion are developed. Opinions and testimony develop easily if one has performed an adequate assessment.

### *General Contours of Assessment*

The neuropsychologist answers legal questions, not clinical ones. The assessment phase starts when the neuropsychologist begins collecting the data upon which answers to hypothetical questions (opinions) will be based. The evaluation of the neuropsychological injury claim requires selection of neurocognitive measures shaped by the legal context. The following principles constitute the structure of the forensic neuropsychological assessment. These principles are not independent, overlapping to some extent.

First, it is critical to recognize at the outset that *forensic neuropsychological assessment is a process*, of which formal test instruments are only one component. The entire process requires a multimethod, convergent evidence model. Neuropsychologists have no greater requirement to validate the entire process than physicians do to combining physical findings with “records and history.” Neuropsychology, like

medicine, is an inexact science that combines subjective art with objective measures.

Second, extratest data provide the enriched context for disentangling the many confounds present in individual brain damage claim cases, improving interpretation of nonspecific findings (Bolla, 2005; Guirguis, 1997; Matarazzo & Herman, 1985). In addition to neuropsychological test data, the three additional forms of extratest data constituting the entire assessment process are:

- Interview data (history, current self-reported symptoms, etc.)
- The MSE (Speech, affect, etc.)
- Collateral sources (medical records, neuroimaging studies, etc.)

Third, blind interpretation of isolated test scores is not a viable practice in neuropsychology. There is no such thing as a neuropsychological test with universal sensitivity and specificity across all possible pairings of target and control groups; reliability and validity of tests are *always contingent* and need to incorporate data on gender, ethnicity, demographics, and cultural factors (Hunsley & Mash, 2005). A convergent evidentiary model further recognizes there is no single, foolproof method or battery for differentiating organic posttraumatic changes from nonneurological factors (Pope, Butcher, & Seelen, 1993). A good example is the ubiquitous Performance IQ < Verbal IQ difference scores on Wechsler intelligence tests (Matarazzo & Herman, 1985). This pattern can be associated with acute right brain injury, but is also seen in persons with visual problems, motor deficits, low motivation, and preinjury developmental learning disabilities (Greiffenstein & Baker, 2002). There is always some potential nonneurological condition associated with low scores on a given measure.

Fourth, test selection for the assessment *relies on multiple standardized measures of effort and function that have (a) sound scientific and normative bases and (b) are relevant to the legal context*. Because the legal issues are broader than clinical ones, the legal contexts so variable, and the environment after various neurologic insults so much different, there is no legal (or scientific) requirement for a “fixed” or universal test battery.

### ***Extratest Elements of the Assessment Process***

#### *Interview*

The clinical interview and accompanying behavior observations usually take place before the administration of tests. Clinical history and MSE observations help provide a context that may substantially affect the interpretation of scores (Lezak, 1995; Vanderploeg, 1994). The history is divided into two groupings: presenting complaints and past personal histories. The history of presenting complaints pursues key case information regarding the date(s) of the incident, initial

injury severity; symptom mode of evolution (clinical course), present symptoms, claimant’s attribution of complaints, subjective functional status, and treatment related to the current problems. The past personal history gathers information extending into the past as far as necessary to consider *reasonable* nonincident-related explanations of a claimant’s current presentation (Melton et al., 1997). An intense analysis of dynamics in the family of origin is usually unnecessary in a neuropsychological context. This initial phase is critical in collecting demographic information that shapes performance expectations of the claimant. This is often termed the *estimation of premorbid cognitive levels* (Greiffenstein & Baker, 2003). Variables that help estimate premorbid functioning include years of education (Heaton, Grant, & Matthews, 1991), quality of educational attainment (Greiffenstein & Baker, 2003; Manly, Jacobs, Touradji, Small, & Stern, 2002), special education, age (Heaton, Ryan, Grant, & Matthews, 1996), gender (Dodrill, 1979), employment history (Heaton, Chelune, & Lehman, 1978), and intellectual level (Tremont, Hoffman, Scott, & Adams, 1998).

A symptom timeline documenting the appearance and disappearance of symptoms can be indispensable. Civil War neurologist Weir Mitchell noted, “Time is the great diagnostician!”<sup>3</sup> The symptom mode of evolution should follow a pattern generally consistent with the natural history of the claimed disease. mTBI typically resolves on the order of days to one week, reflecting restabilization of neuronal chemical processes (Guskiewicz et al., 2003; McCrea et al., 2003; McCrea et al., 2002). Factors that influence symptom evolution may also include symptom suggestion through Internet research, symptom suggestion by financially interested family members, changed socioeconomic circumstances, reinforcement of the illness role, and implantation of diagnoses by aggressive treaters. The neuropsychologist weighs what combination of psychogenic, reinforcement, and/or neurogenic factors best explains the symptom evolution.

There is no generally accepted history form, although forensic specialists should develop a standardized form to promote comparison across individuals within a specific legal context. The interview should balance open-ended and close-ended questions (Othmer & Othmer, 1989). The open-ended questions allow the claimant to prioritize their complaints and provide an injury narrative. Open-ended inquiry allows the neuropsychologist to make initial observations of the claimant’s memory function and discourse organization at a conversational level. The close-ended questions (“systems review”) provide opportunity to voice additional complaints. In this phase, the neuropsychologist may evaluate symptom suggestibility (false positive symptoms), assist patients who have genuine memory problems, or encourage productivity in minimally responsive persons. The neuropsychologist must ask follow-up questions about each complaint and never passively accept the claimant’s self-diagnoses. Lees-Haley (1995) noted there is a widespread tendency for clinicians to presume etiology or diagnosis based on lay patient’s conclusions

about these issues. For example, the complaint of “confusion” should not be interpreted as evidence for organic delirium. This complaint should be followed by questions. Good memory for one’s own confusion is likely nonorganic.

### *Mental Status Evaluation*

The MSE includes categorization of the claimant’s speech and language, affect, reported mood, motor behavior, cognitive organization, and speech content. Behavior observation provides another source of confirmatory (or refuting) evidence to correlate with test scores. The good historian who produces poor memory scores and the talkative patient who reports severe depression while smiling tentatively raises incongruence issues. However, some incongruities can be clinically meaningful: Schizophrenics may show incongruity between affect (laughing) and speech content (discussing a recent funeral), those with orbital-medial frontal damage appear unconcerned, and those with conversion features may appear bland while discussing their pseudoparesis. Again, such incongruities must never be viewed in isolation from other data.

### *Review of Records*

Medical records are critical in forming the extratest context that shapes neuropsychological test interpretations. For example, field, ambulance, and emergency department records allow reasonable estimates of initial severity. They may also provide the only objective evidence that a physical injury to the brain injury occurred, e.g., neuroimaging studies, observations of an exposed brain made by a neurosurgeon, coma status. A single negative neuroimaging study cannot rule out a closed head injury, but serial negative neurodiagnostic evaluations make brain injury less likely. Of the three methods, records are probably the most fallible because records are created by somebody else, and hence represent the perceptions, judgments, and interpretations of somebody who is not available for questioning. Cripe’s (2002) excellent critical review points out the limitations of analyzing records, which include unverifiable assumption of diagnostic accuracy. A preexisting diagnosis of anxiety disorder by a general practitioner may be insufficiently documented to support the conclusion. Conversely, the absence of medical records is not evidence for absence of mental illness. Persons with personality disorders are especially vulnerable to poor postaccident coping, but are also prone to misattribute long-standing coping difficulties to a single pivotal accident (Greiffenstein, 2002). One of the defining characteristics of persons with disordered personalities is poor insight and refusal to seek treatment.

### *Neuropsychological Test Selection*

The battery should contain core tests of functions and modalities in sensory, motor, and cognitive domains, with additional tests showing clear relevance to the legal issues at hand. A neuropsychological battery that is reliable, valid, standardized,

and well normed is not necessarily a logical choice in a given legal issue. The error of giving a fixed battery to all legal situations is easily evident: There would be no reason to give the Mattis Dementia Rating Scale (MDRS) in an mTBI tort, although the MDRS might be acceptable in a civil competence matter. The *Joiner* (1997) legal decision allows a trial judge to disqualify even sound methods if they have no lucid link to the case at hand. In general, a flexible test battery routinely administered to persons with the same claimed etiology or the same legal context is sufficient to draw defensible conclusions and gain admission to court. Single tests of “organicity,” although they may show modest sensitivity to some forms of cerebral dysfunction (Frankle, 1995; Lacks, 1982), are not likely to answer all questions before the court or may even miss severe neuropathology (Bigler & Ehrfurth, 1980).

The forensic neuropsychologist should always give symptom validity tests. Forensic settings contain strong incentives for distorting test scores or interview data. There is no legitimate reason for avoiding these measures in a forensic context. The base rate for invalid response styles in litigated brain damage claims is high, even when stringent criteria for malingering are applied.

The *Daubert* factors may be used as an aspirational guideline to assist in test selection. It is important to again emphasize that *Daubert* has a generally liberal thrust, and requires the existence of certain salutary scientific or logical characteristics. Again, *Daubert* addresses probative value for admissibility decisions. Hence, two measures with nonzero but different validities are both admissible. The *Daubert* criteria are assessed against individual tests, not batteries or groupings (see section of forensic neuropsychology myths, this chapter). The Halstead-Reitan Battery (HRB) and Luria-Nebraska Neuropsychological Battery (LNNB) are undoubtedly acceptable in court. They meet all criteria except for general acceptance, when this is defined in terms of community use. Per Sweet, Meyer, Nelson, and Moberg (2010), HRB and LNNB adherents are a shrinking minority (5%) of neuropsychology practitioners. Use by a minority does not make them poor measures; it only makes general acceptance difficult to prove.

### **Interpretation and Report Writing**

Virtually all cases referred by legal sources require a written report (Melton, Petrilla, Poythress, & Slobogin, 1997). Forensic neuropsychological reporting overlaps with written communication in clinical settings but distinguishes itself in a number of ways.

### *General Contours of the Interpretive Process*

First, the hypothetical legal question must be combined with what Larrabee (2012a) termed a *four-component consistency analysis*:

- 1 Are the data consistent within and between neuropsychological domains?

- 2 Is the score profile consistent with the claimed etiology?
- 3 Are the cognitive scores consistent with the documented injury severity?
- 4 Are the data consistent with behavioral presentation?

Scores are only initial data that need to be interpreted in light of other extratest data (Matarazzo & Hermann, 1985; Matarazzo, Bornstein, McDermott, & Noon, 1986). At best, neurocognitive measures give only an indirect picture of brain functioning.

Second, consider both nomothetic (general scientific laws) and idiographic (personal and context specific) factors. Much of the perceived conflict between academic and clinical neuropsychologists boils down to the tension between the nomothetic and idiographic approaches, also known as the *clinical versus actuarial controversy* (Meehl, 1954). The place of psychology in a nomothetic-idiographic dimension has been the cause of much controversy (Holt, 1998). However, these two methods have mistakenly been treated as irreconcilable and antithetical, when the fact is they are customarily integrated in everyday clinical sciences, such as forensic psychology (Slobogin, 2003). A good example of nomothetic considerations in neuropsychology is the *dose-response relationship* in head injury, the generalization that brain injury severity is the chief determinant of outcome in adults (Dikmen et al., 1995; Volbrecht et al., 2000) and children (Schwartz et al., 2003; Yeates et al., 2002). Another example of a nomothetic principle is the *inverse dose-response* relationship in litigated neurological damage claims: The more minor the remote injury in litigated cases, the greater the symptom production (Miller & Cartlidge, 1972). Inverse slopes were shown in protracted head injury litigation (Greiffenstein & Baker, 2006; Youngjohn et al., 1997), minor electrical injury (Pliskin et al., 1998), and organic solvent exposure (Albers & Berent, 2000). The dose-response generalization provides the crucial nexus when neuropsychologists correlate neuropsychological test scores, interval since injury, and present complaints. Idiographic considerations come into play when extratest data could substantially modify the interpretation. For example, in a two-year-old case of moderate-severe closed head injury, one would not expect poor Wisconsin Card Sorting Test (WCST) scores, but if one claimant shows encephalomalacia in the frontal lobes, this would be compelling evidence to ignore the outcome base rates and link poor WCST scores deficits to the accident. The maxim to be drawn is this: (a) Always consider base rates in forensic cases but do not let them rule you and (b) it takes powerful case-specific facts to ignore the base rates (Gouvier, 1998).

### **Crucial Elements of Forensic Neuropsychology Report**

The remainder of this section describes the crucial elements of the forensic neuropsychology report that differentiate it from the common clinical report.

The crucial elements are:

- Causation analysis through sound reasoning
- Functional analysis
- Accurate attribution of facts

### *Causal Reasoning*

The law is very concerned with antecedent causal connections that weigh which of several earlier conditions best account for the current state of affairs. The law recognizes two forms of causation: general causation (e.g., Could the accident cause cognitive problems?) and specific causation (e.g., Did this toxic exposure cause cognitive deficits?) (Sanders et al., 2002). The forensic specialist assesses the likelihood of neuropsychological damages acquired as a result of the legal cause of action. The law requires only reasonable likelihood, not experimental certainty of  $p < .05$  for every conclusion (Greiffenstein & Kaufmann, 2012). There is no formula or mathematical algorithm for drawing cause-effect conclusions; again, forensic neuropsychological analysis is an *entire assessment process* whose totality does not require sensitivity and specificity values. This reasoning process combines generally accepted principles and instruments (nomothetic, scientific knowledge) with idiographic data (case-specific facts). Hartman (1999) provides the most concise snapshot: The forensic reasoning process is *developing a chain of logical causation that considers the influence of a traumatic event or exposure in the context of a broad life history*.

There are three classes of variables that form this life history context: predisposing (risk), precipitating, and perpetuating variables (Greiffenstein, 2000). Put simply, the injury characteristics are weighed against nonproximate preinjury and postinjury variables as reasonable explanation for findings. Table 37.4 summarizes variables to consider within each of these three categories. Preinjury (risk) variables are nonneurological, sociodemographic, or other features of the individual that have proven association with cognition (Rankin & Adams, 1999). Large portions of neurocognitive score variance, sometimes up to 40%, can be explained by factors such as intelligence, education, grade point average, culture, age, and gender (Anger et al., 1997; Greiffenstein & Baker, 2003). In mTBI there is greater strength of association of scores with education than initial injury severity (Dikmen, Machamer, & Tempkin, 2001). Other preinjury variables that affect symptom reporting include premorbid personality style (Luis, Vanderploeg, & Curtiss, 2003; Ruff & Richardson, 1999), and premorbid body-oriented catastrophic thinking (Greiffenstein & Baker, 2001). Precipitating (periaccidental) factors include the severity of the brain trauma and any consequent medical complications influencing integrity of the central nervous system. Common symptom postaccident perpetuating factors suggestion, reinforcement of illness behaviors, and litigation.

Table 37.4 Tripartite list of moderator variables to consider in causation analysis of neuropsychological scores

*Preaccident (Predisposing)*

Congenital and/or experiential aptitude (IQ, academic achievement)  
 Demographics associated with neurocognitive patterns (e.g., age, gender, handedness)  
 Low education and poor academic achievement  
 Learning disability (dyslexia, nonverbal learning problems, perceptual-motor incoordination)  
 Nonneurological medical disorders with systemic effects (e.g., liver dysfunction)  
 Peripheral nervous system dysfunction (e.g., carpal tunnel syndrome)  
 Personality organization (e.g., dependent, histrionic, borderline, antisocial, narcissistic)  
 Vocational history (type of occupation, complexity, stability, downward drift)

*Periaccidental (Precipitating)*

Acute effects of medication (e.g., narcotics, mood stabilizers such as Depakote)  
 Neurological trauma severity (e.g., Glasgow Coma Scale (GCS); Grade I–III concussion, days to follow commands)  
 Electrodiagnostic findings (e.g., evoked potentials, EEG)  
 Internal distraction by pain (e.g., neuropathic pain, radiculopathy)  
 Posttraumatic psychiatric disorder (e.g., posttraumatic stress disorder, sleep adjustment disorder, acute stress)  
 Radiographic findings (e.g., CT/MRI, PET/SPECT imaging)  
 Topographic features of lesion (e.g., laterality, caudality, focal vs. diffuse)  
 Traumatic peripheral nervous system injury (e.g., neuropathic pain)

*Postaccident (Perpetuating)*

Acute + chronic effects of strong psychotropic and narcotic medication  
 Chronicity of brain lesion and complications (e.g., seizures, encephalomalacia)  
 Compensation and litigation  
 Negative reinforcement of illness behaviors (e.g., avoidance of unrewarding preinjury job)  
 Poor physical stamina (e.g., deconditioning, inactivity due to low postaccident expectations)  
 Positive reinforcement of illness behaviors (e.g., narcotic medications for pain, compensation)  
 Suboptimal motivation and deliberate feigning of deficits  
 Symptom suggestion (e.g., Internet, attorney, aggressive treater implanting diagnoses)

The process of weighing preaccident, periaccidental, and postaccident factors must be grounded in sound judgment. Hill (1965), writing in the context of epidemiological research, offered multifaceted causation analysis guidelines easily generalizable to the forensic setting. Table 37.5 summarizes Hill's (1965) factors used in support of causation judgments. "Plausibility" and "biological gradient" are the most pertinent factors for neuropsychologists to consider in judging the impact of periaccidental variables (e.g., brain injury severity). A documented history of mTBI with brief amnesia is not a plausible explanation for uniformly poor test scores one year later. The role of intervention (named "experimental evidence" by Hill, 1965) is useful in weighing causation factors: Posttreatment score improvements in severe brain injury adds weight to a neurogenic causation theory, but such causation is less likely in a person whose posttreatment scores show declines absent intervening neurological insult. The "coherence" factor refers to the consistency between a person's clinical course and the natural history of the claimed etiology (see also Larrabee, 1990).

Important caveats include never relying on post hoc symptoms alone to draw inferences about brain injury. One does not diagnose TBI on the basis of symptom severity at random intervals after accidents; it is determined by quantifiable variables closest to the injury date. Claims that individuals

can recall alterations in conscious more clearly after longer delay, assumes that retrospective recall is more accurate than in situ recall. This belief is unsupported nonsense best described as "junk science" (Worthington, Stallard, Price, & Goss, 2002). The dangers of post hoc reliance are shown by Varney, Kubu, and Morrow (1998), who used self-report alone to diagnose "intermediate" central nervous system damage after alleged organic solvent exposure. One needs a quantifiable somatic marker independent of self-report. In toxic cases where such markers are not readily apparent, Hartman (1999) recommends a minimum requirement of objective evidence for excessive toxins in a defined geographic area in the absence of evidence for somatic markers in a particular individual. Such conditions would fit a general causation model, but more is needed for a specific causation argument. In view of the *Joiner* (1997) decision, it is unclear whether Hartman's (1999) method is admissible.

*Functional Analysis*

The law concerns itself greatly with the functional capacities of individuals. Functional capacity refers to what activities a person can carry out in everyday life and what knowledge is necessary to accomplish such activities (Grisso, 1986). Legal decisions are based on the mental and social capacities of

Table 37.5 Sir Bradford Hill's (1965) nine factors for analyzing causal statements

Hill's Factors	Description in neuropsychological context
Specificity	Exposure associated with specific set of deficits not seen with other diseases or different chemical exposures. Is plaintiff's cognitive profile similar to profiles reported in good research papers?
Strength	Association so strong that competing factors are easily ruled out. Effect size calculations and correlation coefficients large. Example: Age and education no longer moderators in dementia patients (Tombaugh et al., 1996)
Consistency	Replication. Other researchers demonstrate same pattern of scores in similar disease group or similar litigating group. Example: Reliable Digit Span repeatedly shown sensitive and specific to feigned cognitive disorder
Temporality	A strong temporal link. Merely showing "B followed A" at a random time interval does not meet this criterion. Example: Plaintiff's memory complaints starting day after head injury versus six months later.
Biological gradient	Increased exposure correlates with deficit; identical to dose-response law. Example: Bullet wound to frontal lobe correlates with poor WCST score.
Plausibility	Is there a credible neurologic mechanism that explains associated deficit pattern? Example: A pattern of diffusely poor test scores is implausible in mTBI but more plausible in a dementia claim.
Coherence	Is deficit pattern consistent with natural history of disease? A major deviation from the expected course is evidence against coherence. Example: Worsening cognitive complaints not consistent with mTBI.
Experimental evidence	Does known intervention remediate deficits? Example: Neurocognitive scores worsening after "cognitive rehabilitation" is evidence against neurogenic causes in nondementing cases.
Analogy	Is there a similar exposure we can compare we can draw a relationship with? Example: Workers with organic solvent exposure in one industry (railroad) should look the same as similar exposure in a different industry (munitions).

individuals, and it is here that forensic neuropsychology can make its greatest contribution. A probate court may be interested whether an aged person can make a will, a civil court whether a plaintiff can work, and a criminal court whether a defendant could plan a crime.

A common mistake of psychologists in general is to equate neuropsychological diagnosis with functional disability. A remote diagnosis of mTBI does not automatically mean the person is not able to function, nor does a learning disability equate to legal insanity. The DSM-V (American Psychiatric Association, 2013) criteria require some evidence for functional problems in order to warrant a mental illness diagnosis, but some psychologists stop the inferential process after a patient fulfills symptom criteria. Similarly, neuropsychologists may find weakness, abnormalities, deficits, etc., on their tests then go on to conclude these findings imply inability to work, socially interact, or function around the house. The maxim should be *an abnormal test score is not the end of the diagnostic process but the beginning*. How exactly can "subtle" neurocognitive deficits (assuming they exist) impact driving or work? One must be careful to differentiate self-imposed disability from objectively manifested disability.

Empirically, the research suggests that pervasive cognitive impairments in combination with motor deficits are the only supportable grounds for finding functional disability. Dikmen, Temkin, Machamer, Holubkov, et al. (1994) attempted point predictions by calculating work return rates in a large sample of brain-injured persons. Relative to a preinjury employment base rate of 80%, the poorest return rates (46%) were only associated with Halstead Impairment Index scores of 0.80–1.0, meaning impairment on nearly all tests of the

HRB. The only single measure best associated with lower rates was dominant name-writing speed of > one minute. Searight et al. (1989) reported significant association between HRB scores and general competence in a geriatric sample, but poor prediction of individual living tasks as rated by caregivers of early dementia patients. LeBlanc, Hayden, and Paulman (2000) and Sbordone (2001) did not identify any single useful test in predicting in vivo situational behaviors, although general level of performance is useful.

#### *Attribution of Facts*

Clinical report writing is designed to achieve economy of expression. To achieve this, there is an assumption of veridical reporting by the patient. A patient states "I am supposed to get neuropsychological testing for my closed head injury" and the clinician writes, "Patient is 35 year old female currently 5 months status-post closed head injury." However, in forensic writing, source attribution is critical in separating fact from allegation. The forensic neuropsychologist should write "The claimant is a 35 year old female who (believes/states/represents) she sustained a closed head injury five months ago." In this manner, the neuropsychologist avoids basing test interpretations on a scaffold of uncritically accepted and possibly false allegations.

#### **Neuropsychological Testimony**

The neuropsychologist enters the testimony phase when he or she is asked to give opinions under oath in a number of response formats. These response formats include

interrogatories (written answers to questions), affidavits (sworn and signed declarations of opinions), discovery depositions (*duces tecum*), trial depositions (*bene esse*), or live testimony in front of the trier of fact.

Trial depositions and live testimony are the main vehicles for proffering neuropsychologist's opinions in court. A deposition is a pretrial procedure given under oath and used to (a) narrow legal disputes down to core ideas, (b) cement expert opinions, and (c) to discover whether the opposing expert is helpful to one's own client (Pope et al., 1993). Depositions are broken into two phases: direct examination by the retaining attorney and cross-examination by the opposing attorney. Both phases are different in character and purpose. The direct examination is conducted by the retaining attorney and consists of open-ended questions designed to establish the neuropsychologist's (a) credentials, (b) data collection methods, (c) case-specific findings, and (b) final opinion. Cross-examination is the questioning by opposing counsel about matters brought up during direct examination. The object of cross-examination is challenging the neuropsychologist's credibility, competency, and logical basis for opinions. There are a number of general principles for effective neuropsychological testimony and coping with cross-examination. The first, and overriding, principle is preparation: A good neuropsychological examination interpreted in the context of extratest information (demographics, medical records) and behavior observations helps adjustment to the most aggressive cross-examination. "Blind interpretation" of fixed batteries or brain damage diagnoses based on history alone are easily exploited and usually fatal. A second principle is acknowledging weaknesses in one's approach or conclusions when confronted with questions raising genuine issues. "Courtroom unfamiliar" (Brodsky, 1991) neuropsychologists view every question as a trap or contrivance; they strive to defend every statement in their report against every question, thereby eroding expert credibility. The third important principle is to always maintain the mental set that the neuropsychologist is there *to educate the jury* in general in principles of neuropsychology and the basis for one's opinion. This mental set fits the two prongs of FRE 702: providing background knowledge so the jury can understand evidence or providing a case-specific cognitive interpretation of evidence.

Not all cross-examination questions are genuine efforts to understand the neuropsychologist's position. Some questions are designed to undermine the neuropsychologist's credibility, others to manufacture pseudo-issues, blur important distinctions, or to create misimpressions. A general feature of cross-examinations is the use of ambiguity and imprecision present in all human discourse to parse opinions and impeach testimony. In depositions, most attorneys are interested in observing the expert's professional demeanor and poise when confronting subtle changes in wording of questions. One's prior testimony may be slightly paraphrased in such a way to convey meaning different than was originally intended. Coping with cross-examination requires (a) attentive listening for

imprecision/ambiguity, (b) calm professionalism, and (c) preparation for the most common approaches, termed *gambits*.

The most common gambit is the "learned treatise" (LT) approach; an effort to undermine the neuropsychologist's credibility by showing inconsistencies between the neuropsychologist's opinions from that held by the (purportedly) unimpeachable authority (Babitsky & Mangraviti, 1997). The LT is a completely legal construction that has no true parallel in science. It stems from the religious origins of the adversarial system: Religious canon was the foundation of all opinion and could not be questioned. Scientist-practitioners eschew attribution of perfection to any source. The gambit always begins by getting the witness to agree a certain person, text, excerpt, or pamphlet is a "reliable authority." The response is to deny any text the voice of *complete* authority (Brodsky, 1991). Instead, answers should qualify the limits of authority. For example, witness this interchange with a series of proposed answers:

- Q:* Isn't Muriel Lezak's book *Neuropsychological Assessment* a standard authority in your field?"
- A(1):* If you are asking if I agree with everything Dr. Lezak wrote in her book, no, but it is a useful resource.
- A(2):* Dr. Lezak's book is an excellent resource providing brief summaries of almost all neuropsychological tests, but I don't consider it the final word.
- A(3):* Some chapters and insights from the book are very reliable statements, but other chapters or insights are weaker. Which section did you have in mind?

A list of common cross-examination gambits is summarized in Table 37.6. A common gambit with many variants is "lumping." The questioner uses imprecise language to blur graded phenomena into a single category, implying the magnitude of a neurological condition is irrelevant. This method is often combined with the "yes-no" pigeonhole. A typical question may be, "Isn't head injury commonly associated with symptoms like (personality change/memory loss/attention deficits/headaches)?" The careful listener immediately notes imprecision as to (a) severity of the initial injury and (b) the postinjury interval at which the symptom is reported. The answer is quite different if you see an mTBI versus severe TBI patient within days postinjury versus years. When dealing with imprecise questions, the best strategy is *active answering*. This means you address both the surface and latent (unspoken) content. There is no statutory requirement or rule of court procedure that requires experts to limit answers to yes and no. The following interchange is an example of active answering:

- Q:* My client said she has terrible short-term memory. Isn't that complaint consistent with a head injury, yes or no, doctor?

Table 37.6 Common cross-examination gambits

Gambit	Description	Typical Question
Learned Treatise	Try to show neuropsychologist's conclusions differ from that of a famous neuropsychologist or key textbook.	"Would it change your opinion if Dr. Ima Legend published a position against the test you used?"
Isolate and Trap (The Hypothetical)	Takes one fact or finding out of context and asks the neuropsychologist to reformat his or her opinion. Tries to highlight isolated fact for jury as if critical/dispositive.	"Would it change your opinion if . . .?" or "Did you know . . .?"
Hired Gun	Proving the expert's opinion is offered on basis of money rather than objectivity.	"How much are you being paid for your testimony?"
General Pigeonhole	Witness is asked to place answers in overly simplified scheme. Witness forced into self-imposed halo effect when minor mistakes pointed out.	"Would you say you were X% accurate in your opinions offered today?" or "What letter grade would you assigned your practices, A? B? C?"
Yes-No Pigeonhole	Demands that answers be limited to Yes-No-I Don't Know; questioner implies this answer format is statutory.	"Head injury will cause headaches, yes or no, doctor?"
False Alternative Pigeonhole	A pigeonhole technique where neuropsychologist is asked to choose between two polar options.	"So if my client isn't faking, that leaves only brain damage?"
Subtle Restatement	Questioner paraphrases witness's earlier testimony in a subtle way. This is used to manufacture inconsistencies in testimony.	"Earlier you said that nearly all litigants are (malingerers/brain damaged)?"
Unreliable Examination	The attorney asks questions about the uncertainty of findings and opinions, often by exaggerating the virtues of any test <i>not</i> given by the witness.	"Doctor, isn't it true that only the complete Halstead-Reitan Battery shows excellent sensitivity and specificity?"
False Conceit Gambit	Attorney (typically for the plaintiff) portrays client as special/unique and hence not subject to general expectations of most persons with claimed etiology; this is often combined with the Unreliable Examination gambit to exaggerate virtues of opposing expert.	"My expert spent 25 hours testing my client, but you spent only five hours. Doesn't that make my expert's diagnosis of permanent brain damage more accurate?" (Context = three-year-old whiplash case)
Blurring	Questions blur important distinctions among graded phenomenon, leaving impression that "all injuries are the same."	"Head injuries can cause permanent memory problems?"

*A:* Memory deficits depend on the severity and the length of time since injury. In your client's case, a two-year-old head trauma without any immediate memory loss cannot explain her current belief in a memory disorder.

This answer addresses the imprecision of the question, educates the jury in dose-response thinking, stresses the subjectivity of memory complaints, and links a general principle (dose-response relations) to the instant case.

Brodsky (1991, 1999) provides generally useful techniques for resisting problematic gambits designed only to leave misimpressions. Two useful techniques include the Admit-Deny and Push-Pull tactics. With Admit-Deny, the neuropsychologist provides a two-clause answer; the first (dependent) clause acknowledges a kernel of truth to the question. The second clause, the "deny" step, strongly refutes the fact implied by the question. Note the following interchange between a plaintiff attorney and a neuropsychologist:

*Q:* Isn't it true that malingering measures are very controversial and not generally accepted?

*A:* Although there are some neuropsychologists who believe people never fake, considerable research has shown certain tests are very good at detecting persons not behaving like truly brain injured patients.

The dependent structure requires the questioner to wait for the full sentence. In this example, the dependent clause starts with "although," holding the listener in abeyance, making it difficult to interrupt.

Another form of cross-examination includes questions designed to put neuropsychologists on the defensive by inquiring into known weaknesses of the field. The "unreliable examination" gambit highlighted in Table 37.6 is very common and manifests in two variants: (a) questioning the status of the tests given by the witness, or (b) touting the superiority of tests not given. The latter variant is commonly seen when the cross-examiner retains a neuropsychologist using different tests. The witness should readily concede weaknesses and limitations without appearing defensive. The Push-Pull tactic helps the neuropsychologist take control of the issue that is raised. The technique works by not only conceding the point made, but also amplifying the allegation as if the witness owned the point. Witness the following exchanges:

*Q:* Isn't it true, Dr. Greiffenstein, that you did not give all the tests given by my expert?

*A:* You have no idea how many tests I could have given but did not. Judging the appropriateness of any test battery is always an issue neuropsychologists wrestle with.

*Q:* Wouldn't you agree the (clinical neuropsychological interview/records review) is subjective and

may vary from examiner to examiner? (Asked by both plaintiff and defense attorneys.)

A: The (interview/records review) is *very* subjective and the weakest part of the examination. That's why we give tests to correlate with the more subjective data to see if they match.

Q: Isn't it true that weak neuropsychological test scores can be due to things other than brain damage?

A: The list of explanations for abnormal test scores may be *very* long. No test score can tell you its own cause. I always aim to consider reasonable explanations.

### Ethical Issues in Forensic Practice

The courtroom setting brings an intense focus on ethical issues, as ethics and the law are tightly intertwined concepts that evolved together. Fair or unfair, it is inevitable that the testifying neuropsychologist will be confronted with the ethical ramifications of his or her practices. It is important to keep key ethical standards in mind, and know the ethical principles embedded in each phase of the forensic assessment. There are two main authorities for ethical conduct: the code of conduct for psychologists published in 1992 (American Psychological Association, 1992; hereinafter the 1992 Code) and the new conduct code (American Psychological Association, 2002; hereinafter the 2002 Code) as amended in 2010 and applicable to current practice. The 1992 Code is still of historical interest, and may continue to influence the thinking of some neuropsychologists. The 2002 Code includes modifications important for forensic neuropsychologists that reflect the evolving relations between psychology and the law (Fisher, 2003). The main change between 1992 and 2002 was the elimination of "specialty" language such as a separate section on forensic practices. The 2002 Code subsumes forensic considerations into more general standards. All subsequent discussion of ethical principles in this chapter will rely primarily on the 2002 Code.

Under Standard 2.01 (Boundaries of Competence), the 2002 Code requires that psychologists practice within areas in which they have appropriate experience and training. Most relevant: "when assuming forensic roles, psychologists are or become reasonably familiar with the judicial or administrative rules governing their roles" (Standard 2.01(f)). The reader may also appreciate the history of "aspirational" Specialty Guidelines for Forensic Psychologists (Committee on Ethical Guidelines for Forensic Psychologists, 1991). These are nonbinding on most neuropsychologists except those who are members of the American Board of Forensic Psychology, an ABPP specialty. Binder and Thompson (1995) proposed similar nonbinding guidelines specific to forensic neuropsychology. APA published updated Specialty Guidelines for Forensic Psychology (2013). These guidelines are

good sources for ideas in areas where the 2002 Code may be silent. For example, the 2002 APA Code is silent on the issue of liens and contingency fees for doing plaintiff's work, but the Specialty Guidelines strictly prohibit taking any financial interest in the outcome of a trial. The next section provides a partial listing of ethical guidelines associated with steps in the assessment process. The reader is referred to Grote and Pyykkonen (2012) for a comprehensive treatment of ethical issues in the forensic neuropsychology setting.

### Ethics of the Assessment Phase

Test selection is guided by a number of standards, foremost of which are 9.08 (Obsolete Tests and Outdated Test Results). *Obsolete* does not mean "old" tests; it means tests that are outdated for the current purpose. Older tests relying on very old normative tables should not be used. For example, some fixed battery proponents recommend using the old Wechsler-Bellevue and Wechsler Adult Intelligence Scale (WAIS) tests, but these tests rely on standardization samples that are more than 60 years old. Cohort effects can be important in neuropsychology, and a 48-year-old plaintiff should be compared to only persons who are currently 48, not those who were 48 years old in 1950.

There are legal circumstances when neuropsychologists may be asked to offer opinions based on records review only. For example, repeat neuropsychological testing may not be warranted because the claimant underwent numerous prior examinations. In other cases, an attorney may successfully block an examination or the discovery period may lapse. Basing one's opinions on records only is ethically allowable as indicated by 9.01 (Bases for Assessments). Subsections 9.01(b) and (c) require the testifying neuropsychologist to state the impact of limited information on the reliability and validity of his or her opinions and acknowledge records were the only basis for opinions. Further suggestions are provided in Specialty Guideline 9.03 (Opinions Regarding Persons Not Examined).

### Litigation Consultation

The trial consulting role poses special ethical risks. Typically, the consultant is anonymous. Anonymity may disinhibit aggressive behavior by removing typical consequences for inappropriate behavior. The absence of "moral hazard" can be an invitation to mischief. The 1992 Code did warn about situations where no "corrective mechanism" was in place (McSweeney, 1997). There are no specific guidelines addressing litigation consultation in the 2002 Code, but some ethical standards provide self-direction for anonymous experts. Standard 1.01 (Misuse of Psychologist's Work) recommends "correcting or minimizing misuse or misrepresentation" of psychologist's work. Further, Specialty Guideline 4.01 urges psychologists serving as litigation consultants to clarify role expectations and "any limitations to privacy, confidentiality,

or privilege” that may apply. Here, it may be important for the consultant to understand attorney work product rules in the jurisdiction in which the case is filed.

A good approach to behaving ethically in a background consultant role is to *raise only genuinely debatable issues*; see Specialty Guidelines 10.01 (Focus on Legally Relevant Factors). There are core positions within neuropsychology over which there is no reasonable debate. For example, it is undebatable that factors such as age, education, gender, social class, culture, and aptitude contribute to individual differences on neuropsychological measures (Greiffenstein & Baker, 2003; Heaton et al., 1991). Hence, telling the retaining attorney that age and education are inconsequential is unprofessional behavior. In contrast, a genuinely debatable issue in this situation might be the particular choice of normative table in the case of measures with multiple normative studies: for example, the choice of IQ-based normative table (Tremont et al., 1998) versus a strictly age-based table (Mitrushina, Boone, & D’Elia, 1999). Challenging these core positions is nothing more than nihilistic method skepticism. Similarly, the need for SVTs and PVTs in litigated contexts is beyond dispute. A genuinely debatable issue is the interpretation of SVTs and PVTs in a given case, or the strengths and weaknesses of a particular SVT or PVT.

#### **Discovery: Raw Data Disclosure**

A chronically contentious issue is the extent to which neuropsychological evidence is discoverable by opposing counsel. The 1992 Code (APA, 1992) contained conflicting imperatives. Neuropsychologists were required to provide documentation of their work for “reasonable scrutiny in an adjudicative forum” (per Standard 1.23 (b)), but also required avoidance of disseminating test data to “persons unqualified” (Standard 2.02 (b)). Historically, some neuropsychologists took an “exceptionalist” posture, emphasizing the public policy of test security and asserting that neuropsychological data were so unique they were not subject to the same scrutiny as any other legal evidence (Tranel, 1994). Others took what may be termed a “legal primacy” posture based on discovery rules, arguing that withholding raw test data violates due process rights, creates a special class of experts, protects psychologists from normal courtroom stresses, and allows neuropsychologists the de facto right to dictate cross-examination procedures (Lees-Haley & Courtney, 2000).

The 2002 Code (APA, 2002), however, eliminates forensic specialty guidelines and tries to resolve the 2002 Code’s ambiguities by dividing test material into two categories: (a) an individual respondent’s scored test protocols, commonly referred to as “raw data” (described in Standard 9.04); and (2) test instrumentation such as manuals and stimuli (described in 9.11, Maintaining Test Security). Test data can be disseminated to nonpsychologists under two clear conditions: a signed release from the patient (Standard 9.04(a)) or

requirements dictated by *local law* (Standard 9.04 (b)). To the extent that placing one’s neurocognitive status into legal contention via lawsuit voids the doctor–patient privilege, an implicit patient waiver is present in most lawsuits. Hence, one reasonable interpretation is that a valid subpoena is sufficient grounds for releasing raw data to an attorney.

Kaufmann (2009) outlined the public policy debate and detailed legal and other persuasive strategies to protect test security and prevent wrongful release of psychological test materials to nonpsychologists. Possible negative outcomes of breaching test security include infringement on the rights of companies that develop and sell the tests and facilitation of future coaching by attorneys. Standard 9.11 offers the exception for test instrumentation and stimuli. In this case, proliferation of test manuals are a realistic public threat and the neuropsychologist is required to take “reasonable steps” to protect these materials. Although no concrete examples are offered, a protective order limiting scrutiny of the test instrumentation is a reasonable interpretation of this standard. Professional psychology has not set forth a workable standard to resolve the raw data problem arising in forensic consultation. Both sides of an adversarial proceeding must and can have access while maintaining test security, and neuropsychologists should strive to balance this concern with the interests of test developers and users in preventing invalidation of tests. Greiffenstein and Kaufmann (2012) favor security of test manuals, stimuli, and items because it is consistent with law and best record-release in psychology practice. Some attorneys get court orders allowing videotaping of a neuropsychological evaluation. Depending upon jurisdictional law, the neuropsychologist should either refuse participation or petition the court to destroy or return all videotapes at the conclusion of litigation.

#### **Testimony Phase**

The testimony phase begins when the neuropsychologist is asked to offer opinions under oath. Opinions can be offered through discovery depositions, affidavits, interrogatories, *de bene esse* (trial) depositions, and live courtroom testimony. Testifying provides the only public face of forensic neuropsychology and is regulated by Standard 5.0 (Advertising and Other Public Statements), and Specialty Guidelines 2.05 (Knowledge of the Scientific Foundation for Opinions and Testimony) and 11.04 (Comprehensive and Accurate Presentation of Opinions in Reports and Testimony). Testimony usually begins with the neuropsychologist presenting her or his credentials qualifying her or him to testify as an expert. Accurate summaries of training, background, and research are required in legal proceedings and are required by Standard 5.01 (a) (Avoidance of False and Deceptive Statements) and Specialty Guideline 11.01 (Accuracy, Fairness, and Avoidance of Deception). Omission of crucial details gives a misleading picture of competence and training. Drawing on case files, a testifying neuropsychologist limited his description of

postdoctoral experience to include “University of Michigan 1980–1982.” But cross-examination uncovered mere attendance at irregular group supervision meetings with a retired professor in the Ann Arbor area. This willful omission on his *vitae* left the impression of two years of postdoctoral training in an organized health care setting.

After the credentials phase of testimony, neuropsychologists offer opinions on the meaning of their test results as they relate to the case. The ethical treatment of presentation and basis for opinions is described in Standard 9.10 (Explaining Assessment Results). Standard 2.04 (Bases for Scientific and Professional Judgments) further requires opinions to be grounded in both nomothetic psychological knowledge and customary practices (termed “professional knowledge”).

### **Responses to Ethical Issues**

Psychologists typically operate under an ethos of collegiality, conferring with each other to reach points of agreement. Nevertheless, colleagues may be asked to critique each other’s work in the forensic arena. This scrutiny of others’ work and professional behavior may uncover ethical lapses from time to time. Suggested responses to perceived ethical lapses by other psychologists are grouped under Ethical Standard 1.0 (Resolving Ethical Issues) and Specialty Guideline 7.03 (Resolving Ethical Issues with Fellow Professionals). Standard 1.05 (Reporting Ethical Violations) suggests a threshold for deciding whether to report behavior to an ethics board: evidence for past public harms or clear future prospects for such harm. Disagreements over ultimate opinions or test selection are common and do not constitute public harm. If there is a perceived lapse that does not rise to the level of harm, an informal resolution between neuropsychologists is recommended by Standard 1.04 (Informal Resolution). Brodsky and McKinzey (2002) provide guidance on raising and responding to ethical issues arising in the course of litigation consultation. They offer the following formula: (a) polite introductory language, (b) the specifics of the concern, and (c) polite concluding comments requesting some action. Nonetheless, some neuropsychologists take great offense to any criticism or disagreement. Plaintiff advocates may become enraged if the defense expert does not find the “catastrophic brain damage” they diagnosed, and some defense experts charge incompetence when another expert misdiagnoses somebody with TBI. Threatening to bring ethical charges against a disagreeing neuropsychologist is unethical behavior if the complainant makes allegations “with reckless disregard for or willful ignorance of facts that would disprove the allegation” (Standard 1.07, Improper Complaints). Some neuropsychologists acting as dual treater-experts may passive-aggressively vent their hostility by proxy, subtly manipulating their “patients” to file the ethics charge, but Standard 1.07 also bars “encouraging others” to file a complaint.

### **Myths of Forensic Neuropsychology**

Gaps between science and everyday practice are often filled by clinical myths (McNally, 2005). Myth-driven practices are defined as psychological or medical concepts that influence clinical decision making but for which there is little to no empirical support. Myths originate in face valid reasoning (“A memory complaint must mean there is brain damage”); overgeneralizations from a single anecdotal report (Paauw, 1999); unfalsifiable psychodynamic theories (“His malingering can only be unconscious”); uncritically accepted insights passed down from instructors to students; or illusory correlation based on cultural associations (Chapman and Chapman, 1969). Although forensic neuropsychology is relatively new, a set of myths is already emerging.

#### **Myth: “Only Fixed Battery Is Admissible Under Daubert”**

Some advocates for narrower sets of neurocognitive procedures interpret the *Daubert* ruling to support reliance on commercially available “fixed” test batteries such as the HRB (version unknown) or LNNB in courtroom settings. In this scheme, “flexible test batteries” are not or should not be admissible. A number of commentators expressed doubt that test groupings other than fixed batteries would be admissible under *Daubert* (Posthuma, Podrouzek, & Crisp, 2002; Reitan & Wolfson, 2002). The common source for this myth is a commentary article by Reed (1996), who cited the TBI case of *Chapple v. Ganger* (1998) to draw the following conclusion: “The *Daubert* standard was applied for the very first time to the use of fixed (standardized) versus flexible neuropsychological test batteries in the federal court” (p. 315). Reed understood the trial judge to bar admission of flexible test battery evidence because of “lack of medical and scientific evidence to support the conclusions” (p. 315) made from the flexible batteries.

Contrary to Reed’s (1996) characterization, even a cursory reading of the *Chapple* opinion reveals the following facts: There was *no* *Daubert* challenge to a “flexible” test battery; both the flexible test battery (plaintiff expert) and fixed battery data (defense expert) were admitted into evidence; and even testimony based on *partial* HRBs were admitted. Instead, the judge’s verdict was based on the *weight* of neuropsychological testimony: The court merely preferred the testimony of one “fixed battery” specialist because that expert integrated outside records into his opinion. Hence, it was the thoroughness of the reasoning process, not the type of test battery, that swayed the judge. Reed (1996) likely confused the different issues of *admissibility* versus the *weight* of evidence, not recognizing that *Daubert* goes only to admissibility.<sup>4</sup> In summary, the “*Daubert* requires fixed battery only” recommendation is a myth based on overgeneralization from a mischaracterized and unpublished (nonbinding) single case ruling.

As noted in the lengthy discussion of *Baxter v. Temple* (2008) in Sweet et al. (Chapter 36 in this volume), fixed battery superiority in forensic consulting is a myth that lives on in the minds of a few practitioners (Russell, 2012) as critiqued by Greiffenstein (2013).

**Myth: “Practice Effects Must Always Be Avoided”**

A recurring forensic issue is the impact of “practice effects” on cognitive scores. Practice effects (PEs) refer to gains in neurocognitive scores when a person is retested on the same instrument (Kaufman, 1994). PE issues are often raised in forensic cases, because parties undergo examination by two or more neuropsychologists retained by opposing sides. Some neuropsychologists assert a *blanket* prohibition against any repeat testing for a “protected” period after their own testing. Proponents for minimum test-retest intervals justify the prohibition by arguing that PEs may “mask” or “hide” underlying neurocognitive deficits they believe are present. It is difficult to identify any influential research citation for this belief, suggesting it rose *de novo* on a face valid basis. One psychologist’s website (United Psychological Services, www.brainevaluation.com, accessed on August 4, 2017) makes the assertion that the APA advises against retesting within a six-month interval. However, there is no such position statement during a restricted field search of the term <practice effects> at the APA website.

The “PE avoidance” belief can be labeled a myth for many reasons. First, and contrary to this belief, PEs provide much useful information to clinicians (Lezak, 1995; McCaffrey & Westervelt, 1995). PE is not methodological artifact from which no conclusions can be drawn. PEs are reliably *unidirectional* (better scores) in motivated subjects, meaning they cannot be error or random occurrence (Theisen, Rapport, Axelrod, & Brines, 1998), so they must represent the operation of memory retrieval.

The second objection is logical: The myth places its advocate in the contradictory position of claiming organic memory loss but refusing to consider score improvement as evidence for functional or improving memory systems. Third, stable and severe organic deficits do not improve with retesting (Shatz, 1981). Fourth, an examination of the review literature indicates no empirically mandated length of test-retest interval. Putnam, Adams, and Schneider (1992) found equivalent results with a one-day retest interval in an injured scuba diver, based on application of the standard error of measurement (SEM; standard deviation divided by the square root of *N*). Finally, a rich empirical literature on repeat testing strongly contradicts the blanket prohibition notion (Lezak, 1995). PEs depend on many factors, including demographics, the length of interval, baseline performance level, the severity of the brain disease in question, and the cognitive domain tested (McCaffrey & Westervelt, 1995). PEs are greater in younger participants than older ones (Horton, 1992), smaller in persons with severe baseline deficits (Shatz,

1981), and depend on the cognitive domain being tested (Mitrushina & Satz, 1991) and brain lesion severity (Shatz, 1981). For example, Dodrill and Troupin (1975) showed negligible PEs for most tests in the HRB except for the Category Test. Further, the absence of PEs where they are expected can sometimes be crucial evidence favoring a plaintiff’s position. Chelune et al. (1993) found small decrements in post-lobectomy memory scores compared to presurgical baseline; decrements on tasks with known high PE must represent substantial learning loss.

In conclusion, there is no authority for the view that retesting is harmful or artifactual (McCaffrey & Westervelt, 1995). The “meaning of PE depends solely on the generalization sought or needed” (Kaufman, 1994, p. 828). Neuropsychologists can offer opinions on any psychological phenomenon relevant to understanding an individual’s capacity for memory and new learning. Hence, the presence (or even absence) of PEs is just another important psychological datum that needs to be explained in the context of other case-specific knowledge. Lezak (1995) sagely advises a careful analytical approach to interpreting change (or its absence). Whether a robust PE represents intact memory or whether it represents recovery from a brain injury cannot be answered in isolation from extratest data (e.g., initial injury severity) and statistical considerations (SEM). More recently, the AACN (2010) provided guidance on repeat test administrations in clinical and forensic settings.

**Myth: Forewarning Improves Motivation and Validity of Deficits**

A universal procedural concern is obtaining maximal performance. Many manuals and texts offer general guidelines for encouraging best performances (Lezak, 1995), suggestions tempered by standardized administration rules. Most neuropsychologists try to find the balance between obtaining optimal performance and allowing deficits to emerge (Vanderploeg, 1994). Nevertheless, some neuropsychologists have drawn unsupportable conclusions from these guides, creating the following myth: Forewarning the respondent about specific effort tests safeguards the examination from insufficient effort or malingering. Put differently, warning otherwise deceptive persons guarantees effortful responding.

This belief achieves mythical status because there is no logical or empirical evidence that explicit forewarnings suppress response bias in persons otherwise intending to feign deficits. The “forewarning” myth is linked to a role-play simulation study by Johnson and Lesniak-Karpiak (1997), who compared undergraduate controls to student simulators asked to feign deficits for hypothetical compensation. Two groups of simulators were either forewarned about effort tests or not forewarned. Johnson and Lesniak-Karpiak reported an effect for warning: The warned group showed higher motor and memory scores than the naive simulation group on memory and motor tests, with 45% of the warned group

achieving classification as normal controls. Despite reporting that 55% of warned simulators still produced implausible scores, Johnson and Lesniak-Karpiak (1997: 321) made the blanket conclusion that “(the) results provide support for effectiveness of warning in reducing malingering behavior on selected measures.” Further, “use of a warning in cases of personal injury litigation will likely provide a more accurate cognitive profile” (p. 236). Youngjohn, Lees-Haley, and Binder (1999) criticized Johnson and Lesniak-Karpiak’s conclusions as unsupported by the data. Their reanalysis showed the coached group’s general level of performance was still well below that of a good effort control.

There is no empirical support for the forewarning myth: No study of coaching has *ever* demonstrated normalization of scores in all simulators with forewarning. Johnson was unable to replicate her initial findings in a study of feigned intellectual and memory deficits (Johnson, Bellah, Dodge, Kelley, & Livingston, 1998). Wong, Lerner-Poppen, and Durham (1998) were also unable to diminish exaggerated motor deficit with forewarnings. The work of Julie Suhr and her colleagues suggests forewarning changes only the style of malingering memory deficits (Suhr & Gunstad, 2000). Suhr (2002) further showed that naive and warned simulator groups still showed suspiciously low primacy scores on Rey’s Auditory Verbal Learning Test (RAVLT; Lezak, 1995), suggesting forewarning, fortunately, does not correct fakers’ erroneous internal stereotypes of brain-injured performance.

In conclusion, warning litigants about upcoming “specific malingering measures” is not an effective way of improving motivation in persons intending to feign deficits. Instead, the relevant body of research indicates “tipping off” changes only the preferred malingering style, making it less extreme (Storm & Graham, 2000).

## Summary Conclusions

Kaufmann and Greiffenstein (2013) note that neuropsychologists are becoming the preferred brain–mental state behavior experts in our courts, not just our medical clinics; the LEXIS database cases noted by Sweet et.al (Chapter 36 in this volume) clearly show that trend. Expert neuropsychologists who understand the principles and spirit of communicating in a legal setting are now positioned to make valuable contributions to our clients, our society, and the judicial system. Neuropsychology–law interactions are bidirectional. Our opinions can influence legal decisions and even public policy. Alternatively, legal considerations can stimulate neuropsychological research or improve ways to think about what we are doing. The evidentiary demands of the legal system can be similar to the rigors of science: Both are crucibles that separate workable from unworkable, bad from good ideas.

A distillation of this chapter’s main ideas is presented in Table 37.7. This table of “Rules of the Road” is presented in the style of the late Ted Blau (1998). A number of general themes are interwoven throughout this list. First, these

proposed rules treat the *Daubert* guidelines as an aspirational template, not a threat. The *Daubert* decision should be viewed as an ideal in conducting research and improving objective decision aids. All courts recognize that clinical inference (subjectivity) in the absence of an on-point study will always be part of every opinion. The threatened demise of psychology and neuropsychology after *Daubert* has yet to materialize. If anything, *Daubert* has strengthened the hand of scientist-practitioners: Neuropsychologists can more easily differentiate themselves from psychiatrists, counselors, and social workers who diagnose on the basis of history and intuitive impression (Lally, 2003). Unlike other mental health professionals, psychologists use objective psychological tests to refine clinical impressions when formulating working diagnoses, initial treatment plans, and expert opinions. Neuropsychology adds the brain–behavior knowledge base and incorporates neuroimaging, neurodiagnostic, and other neurologic findings to the history and clinical interview, thereby creating the unique practice of forensic neuropsychology consulting (Kaufmann, 2009). Kaufmann (2013) recently reviewed admissibility challenges to neuropsychologist testimony and called for greater interdisciplinary dialog among law, medicine, and psychology about neuropsychological evidence.

Another interwoven theme is principled forensic neuropsychology. This requires the integration of two attitudes: the ethical and the aspirational. Both are necessary conditions for the image of the profession and for personal development. The ethical attitude demands that forensic neuropsychologists always be aware of the multiple ethical issues embedded in every phase of neuropsychology-law interactions. The legal environment contains many pressures to deviate from both professional and societal codes of conduct. Being retained by one side rather than being hired by the court by itself creates a pull to affiliate with the retaining advocate. Seeing one’s courtroom role as the educator of the jury helps resist the pull of affiliation. It should be clear that morality, righteousness, and justness do not reside in a particular retaining side, be it plaintiff, defense, or prosecution. These characteristics reside in individuals, not situations. The posttrial phase of every examination requires some self-scrutiny. This process is similar to reviewing manuscripts submitted for publication: Questions such as “Have I (Has the author) considered statements (literature) at odds with my opinion (the mainstream literature) on this subject?” Sweet and Moulthrop (1999) provide a comprehensive program for self-scrutiny.

The aspirational arm of principled behavior means holding ideals that go beyond the individual legal case. One ideal is inductive: generalizing societal consequences from the individual case. Hess (1999) advises considering the wider ramifications in every single case one encounters. Opinions can have major consequences with effects that can persist after the jury verdict. This attitude is especially critical in legal cases where liberty interests are at stake, such as death

Table 37.7 Some rules of the road for forensic neuropsychologists

*Admissibility Issues*

- Keep up on admissibility developments in state and federal law.
- Use a flexible test battery organized around a core battery that is specific to legal issue.
- Select tests and procedures that meet general acceptance (*Frye*) rule + one other *Daubert* factor.
- Maintain a minimum document set to oppose the rare *Frye* or *Daubert* challenge.
- Be prepared for challenges to symptom and performance validity measures.

*Assessment/Data Collection*

- Remember that *Daubert* factors may be used as aspirational framework for choosing tests.
- Recognize and accept the nonspecificity problem for neuropsychological tests.
- Use converging evidence model based on three prongs: interview and mental status observations, neuropsychology test scores, key outside records.
- Use a multistrategy, multidomain approach to assess for validity of memory, somatic-motor and psychiatric malingering, consistent with the AACN Consensus Conference Statement.

*Interpretation Phase*

- An abnormal test score is the beginning, not the end of the inferential process. Respect that ecological validity and nonspecificity of neurocognitive measures is resolvable only with extratext data.
- Consider the influence of a traumatic event or exposure in the context of a broad life history.
- Be aware that neuropsychological interpretation works best on a nomothetic (lawful) foundation modified by idiographic (case-specific) data depending on the legal question. Nomothetic considerations include useful generalizations such as dose-response effects in brain injury; idiographic considerations may include an abnormal CT scan.
- Create a causal model that is plausible, coherent, fitted to a biological gradient, and consistent with postinjury interventions.

*Report Writing*

- Separate inferences and opinions from fact.
- Minimize clinical jargon and use plain language when offering testimony.
- Provide a logical link (nexus) between findings and opinions.
- Provide a functional analysis: Neuro- or psychodiagnosis does not automatically entail disability.

*Testimony Phase*

- Educate the jury on general background and the neuropsychologist's opinion.
- Refrain from giving opinions as to ultimate legal issues unless otherwise allowed by the court or statute.
- Apply a standard of reasonable probability to offered opinions.
- Use Push-Pull and Admit-Deny tactics selectively but do not overuse. It is more important to be genuine than clever.

*Post-Trial Phase*

- Conduct self-analysis of objectivity and ethics.
- Consider implications of individual opinions for profession, individuals, and society.
- Consider heuristic value of cases for generating research ideas.
- Actively combat "junk science" and misrepresentation of credentials.

penalty mitigation, legal insanity, and civil competence. If a neuropsychologist opines that "subtle" cognitive deficits either justify legal guardianship or support legal insanity, other individuals are made less safe from the government in the former and from amoral predators in the latter. Another facet of aspirational behavior is to combat "junk science." Junk science occurs when expert witnesses either employ questionable methodology to reach unsupported conclusions or present grossly fallacious interpretations of published data. Fox, Greiffenstein, and Lees-Haley (2005) showed how design and reasoning absurdities produce unsupportable conclusions about household mold and cognition. Finally, consider how a case may contain at least one heuristic issue stimulating future research (Greiffenstein, 2003b).

**Notes**

- 1 The use of the term *reliability* may be confusing to psychologists because they define it narrowly as referring to the consistency and stability of observation. The *Daubert* Court's uses of the term *reliability* is synonymous with the scientific term *reliability*.
- 2 This does not seem like much of an improvement, as both the ALI and *M'Naghten* rules imply a threshold set at severe defects.
- 3 Weir Mitchell was writing in the context of pseudocyesis (false pregnancies). He meant that women might initially convince earnest physicians they are truly pregnant. The progressive accumulation of irregularities eventually prompts skepticism, and the absence of a baby in the delivery room seals the diagnosis.
- 4 There was a *Daubert* challenge in this case, but it involved testimony from a vocational specialist who merely speculated about the future job prospects of the minor plaintiff. The judge excluded that intuitive testimony prior to trial.

# 38 Assessment of Incomplete Effort and Malingering in the Neuropsychological Examination

Scott R. Millis and Paul M. Kaufmann

*If it can't be expressed in figures, it is not science; it is opinion.*  
—Robert A. Heinlein (1907–1988)

Neuropsychological tests require the cooperation and effort of examinees to complete the tests to the best of their abilities. As Demakis, Sweet, Sawyer, Moulthrop, Nies, and Clingerman (2001) have observed, “If effort is fully applied throughout testing, the resulting test data can be considered valid, but if incompletely or insufficiently applied (whether because of psychopathology, malingering, or some other cause), test data may be invalid” (p. 240). One type of incomplete effort is malingering. Malingering has been defined as “the volitional exaggeration or fabrication of cognitive dysfunction for the purpose of obtaining substantial material gain, or avoiding for escaping formal duty or responsibility” (Slick, Sherman, & Iverson, 1999, p. 552). However, incomplete effort can occur in the absence of external incentives. Hence, the assessment of incomplete effort needs to be conducted within in the larger context of the differential diagnosis in which several diagnoses need to be considered. Therein lays the challenge. Malingering has no virus or bacteria associated with it. Its neuroimaging correlates are unknown. The behavior of malingering may be observed in other disorders as well. Although a veritable cottage industry has sprung up over the past decade offering a plethora of malingering tests, interest in this topic is quite old.

## Historical Context

In 1788, Samuel Farr’s *Elements of Medical Jurisprudence* was published in Great Britain, which dealt with the clinical detection of malingering (Geller, Erlen, Kaye, & Fisher, 1990). The 18th- and 19th-century papers that followed focused primarily on malingering of psychiatric disorders. A wide variety of methods were used to detect malingering such as flagellation, emetics, beef tea enemas, the “whirling chair,” and electrical shocks to the tongue from galvanic batteries (Geller et al., 1990). Although these methods have largely been abandoned, behavioral observation, clinical interview, and patient history are still central elements in assessing for malingering. Ray’s observation in 1838 remains relevant today, “In simulated madness, the

common error is to imagine that nothing must be remembered correctly, and that the more inconsistent and absurd the discourse, the better is the attempt at deception sustained” (Geller et al., 1990, p. 12).

Neuropsychology’s chief contribution in the assessment of malingering arguably has been the application of the psychometric and actuarial approach to diagnosis. This is not to imply that a single test in isolation should be used to diagnose a disorder. The perspective of this chapter is that the evaluation of malingering and incomplete effort will, by necessity, require the collection and integration of several types of information in addition to any test data obtained from the latest malingering test du jour. In addition, a bias of this chapter is that this diagnostic process should use quantitative actuarial formulas when available. Data can be systematically collected and integrated in a logically coherent and transparent fashion such that an external observer would be able to repeat the steps of the process. The external observer may disagree with the specific decision rules but will be in the position to empirically test any of the decision rules. This diagnostic process can be divided into several steps:

- 1 Assessing the role of external incentives;
- 2 Determining injury severity;
- 3 Evaluating the impact of psychosocial factors on patient behavior;
- 4 Using tests to refine diagnostic hypotheses;
- 5 Applying specialized tests;
- 6 Analyzing test performance patterns;
- 7 Integrating all sources of information; and
- 8 Applying new statistical methods to assist in decision making.

This chapter will consider the assessment of incomplete effort in the context of mild head injury (MHI). It is difficult to separate a discussion of malingering assessment from MHI. First, most effort tests and indices were developed from samples of persons with different severities of traumatic brain injury (TBI). Second, the incidence of mild and moderate brain injury is relatively high in the United States and most neuropsychologists will encounter head injury cases in the course of their practice. In an analysis of the National Health Interview Survey, Sosin, Sniezek, and Thurman (1996) estimated that

1.5 million U.S. civilians each year sustain a nonfatal brain injury that does not result in institutionalization. Third, litigation involving head injury claims is common, e.g., brain injury claims accounted for 7% of total plaintiff verdicts in vehicular accidents for the period between 1992 and 1998 (Jury Verdict Research, 2000). Fourth, neuropsychological data often play a central role in the litigated MHI case.

Taking these factors into consideration, it is likely that most neuropsychologists will confront the assessment of malingering and incomplete effort in context of the MHI case. However, the general guidelines and procedures presented in this chapter may be applicable in other diagnostic settings where malingering and cognitive impairment are at issue, e.g., toxic exposure, multiple chemical sensitivity, or electrical injuries. However, the generalizability of specific cutoff scores from effort measures to disorders other than those conditions from which they were derived remains an empirical question.

### The Role of External Incentives

By virtue of their training, neuropsychologists may tend to focus primarily on individual factors that influence behavior while ignoring environmental and situational factors. Yet, environmental contingencies have considerable impact on neuropsychological test performance. In a meta-analysis of 17 studies involving 2,353 participants, Binder and Rohling (1996) found a significant effect of financial incentives on disability and symptoms after head injury. A moderate overall effect size of 0.47 was reported. Persons with financial incentives showed greater *apparent* disability despite less severe injuries. Paniak, Reynolds, Toller-Lobe, Melnyk, Nagy, and Schmidt (2002) compared 50 persons with mild TBI without financial incentives with 18 who were seeking or receiving financial compensation at treatment intake, three months postinjury, and 12 months postinjury. The study participants volunteered to participate in a treatment study. The financial incentive group consistently reported a significantly higher number of symptoms (about one standard) and greater symptom severity at all intervals. There were no injury-related or demographic differences between the groups. Paniak et al. (2002) concluded that,

The correspondence between compensation status and symptoms level is suggestive of negative effects on functioning related to (though not necessarily caused by) aspects of the compensation process. This is the first time that this finding has been demonstrated in a 'treated' MTBI sample. It illustrates that even treatment that is highly rated by patients (Paniak, Toller-Lobe, et al., 1998) cannot overcome the strong relationship between compensation status and symptom report that has been previously reported in primarily 'untreated' MTBI samples (Binder & Rohling, 1996).  
(p. 192)

This is not to imply that all patients who are involved in litigation, receiving compensation, on disability, or seeking

compensation are malingering. However, the compensation process may be associated with an increased prevalence of malingering or symptoms endorsement. First, the litigation and disability proceedings can be protracted. In 1999, the median number of months from accident date to trial in vehicular liability cases in the United State was 37 months (Jury Verdict Research, 2000). During this period, plaintiffs will have undergone multiple medical examinations, recalled their accident and symptoms dozens of times, and undergone extensive treatment. This process may selectively reinforce attitudes and behaviors associated with a disability lifestyle. Second, the jury awards in brain injury litigation can be substantial. The median awards for mild TBI and moderate TBI were \$271,350 and \$1,375,000, respectively for the period of 1993–2001 (Kaiman, 2003). Third, state auto insurance systems offer different incentives for nonexistent or exaggerated claims. A study by the Rand Corporation (Abrahamse & Carroll, 1999) found that tort and dollar-threshold states have a higher frequency of excess soft-tissue injury claims than no-fault states. The study concluded that 42% of reported soft-injury claims in the tort and dollar-threshold states were for nonexistent or preexisting injuries.

These factors may differentially elicit and maintain illness behavior or malingering. As a starting point in the neuropsychological examination, it is essential for the neuropsychologist to determine whether external incentives for illness behavior exist for the persons they are evaluating. In addition, familiarity with one's state's automobile insurance and workers' compensation systems may help in assessing environmental contingencies that reinforce or discourage excess claims.

### Injury Severity in the Assessment of Effort

Having determined whether external incentives exist for illness behavior, knowledge of a patient's initial injury is the next essential step in the diagnostic process. Injury or illness severity can help in determining whether neuropsychological test scores "make sense." For example, there is a dose-response relationship between initial TBI injury severity and the degree of associated cognitive impairment (Dikmen, Machamer, Winn, & Temkin, 1995) that tends to be linear (Rohling, 2000). As severity of head injury increases, so do the extent and severity of neuropsychological impairment. Dikmen et al. (1995) found that "significant neuropsychological impairment due to a mild head injury is as unlikely as is escaping an impairment in the case of a very severe head injury" (p. 87).

Evidence from well-designed studies is quite compelling that the neuropsychological deficits from a single uncomplicated MHI are relatively subtle. Dikmen, Machamer, and Temkin (2001) examined a subgroup of persons with MHI from two earlier longitudinal studies of TBI. This subgroup met stringent criteria for MHI: posttraumatic amnesia of 24 hours or less, time to follow commands of less than one hour,

and no computed tomography (CT) abnormalities. This group was compared to a matched group of participants with injuries to other parts of the body (trauma control group) on the Selective Reminding Test, Seashore Rhythm Test, Trail Making Test B, and Wechsler Adult Intelligence Scale (WAIS) Performance IQ (PIQ). At one-month postinjury, there were no statistically significant differences between the MHI and trauma control (TC) groups on these measures. In fact, the MHI performed slightly better on three of the measures. On the Selective Reminding Test, the MHI group recalled about two fewer words on the sum of recall index, a difference that is associated with a small effect size (Hedges'  $g = 0.17$ ).

In an Australian study, Ponsford et al. (2000) also employed a trauma control group in comparison with consecutively enrolled patients with head injury. At one week postinjury, the mild TBI participants performed worse on complex attention tasks compared to trauma controls. At three months, there were no statistically significant differences between the groups on neuropsychological measures. Viewed from a broader perspective, Binder, Rohling, and Larrabee (1997) found a small effect size of mild TBI on cognitive functioning (Hedges's  $g = 0.07$ ) in a meta-analysis of 11 studies involving 622 subjects.

Neuropsychologists can establish initial brain injury severity with measures that assess alteration in consciousness, e.g., the Glasgow Coma Scale (GCS), Revised Trauma Score, time to follow commands (derived from the motor score on the GCS), or length of posttraumatic amnesia as determined by the Galveston Orientation and Amnesia Scale. These measures are commonly available from emergency department, acute hospitalization, or inpatient rehabilitation medical records. Estimates of initial injury severity can be compared with a given patient's neuropsychological test results to determine if the panel of results deviates significantly from expected patterns of neuropsychological test performance. Numerous studies are available that provide data on typical neuropsychological test performances of persons from different backgrounds with varying levels of TBI severity; see Dikmen et al. (1995); Kreutzer, Gordon, Rosenthal, and Marwitz (1993); Levin et al. (1987); Millis (2002); Millis et al. (2001) and Ponsford et al. (2000).

Excessively impaired neuropsychological test scores in MHI cases alone do not necessarily indicate malingering or incomplete effort. Conversely, reflexively attributing poor test scores to a MHI is also unwarranted. The diagnostic challenge is to detect the small neuropsychological effect of MHI in a sea of substantial variability in cognitive performance in the general population without acquired brain injury. In an analysis of their data, Dikmen et al. (2001) noted, "With this much variability, one would expect that 35% of those without brain injury would score at least as badly as the average person with stringently defined mild TBI 1 month after injury" (p. 736). Hence, the issue is much broader than malingering versus brain dysfunction cause

by MHI. In order to clarify the diagnosis, it is necessary to consider the individual differences that might account for the cognitive variability among examinees. In addition to external incentives, and initial injury severity characteristics, psychosocial factors provide important data regarding individual differences.

### Psychosocial Influences

Anxiety, dizziness, headache, memory and concentration problems, fatigue, irritability, depression, and noise sensitivity may occur following MHI (Alexander, 1995). Yet, these symptoms are not diagnostically specific for MHI. They are common in the general population and are also associated with other medical and psychological disorders (Fox, Lees-Haley, Earnest, & Dolezal-Wood, 1995; Gouvier, Uddo-Crane, & Brown, 1988; Lees-Haley & Brown, 1993; Lees-Haley, Fox, & Courtney, 2001; Sawchyn, Brulot, & Strauss, 1999; Suhr & Gunstad, 2002; Trahan, Ross, & Trahan, 2001). In one sample of healthy individuals, 90% reported various somatic symptoms during a one-week period (Kellner & Sheffield, 1973), such as headache, fatigue, muscle pain, and irritability. Fox et al. (1995) found the following rates of symptom endorsement in a sample of persons seeking outpatient psychotherapy: headache (52%), memory problems (31%), dizziness (30%), concentration problems (45%), fatigue (55%), and irritability (55%). Paniak, Reynolds, Phillips, Toller-Lobe, Melnyk, and Nagy (2002) compared symptom complaints of a patient with MHI within one month of injury with a matched control group of healthy participants. Interestingly, they found that subjective complaints did not adequately differentiate persons with MHI from the normal controls even soon after injury. Clearly, subjective complaints should not be used to diagnose head injury in the absence of other evidence.

In addition to the high prevalence of somatic and cognitive symptoms in normal and clinical groups, there appears to be an association between persisting symptoms following MHI and preexisting emotional distress and mental disorders, concurrent distress, and chronic social difficulties (Fenton, McClelland, Montgomery, MacFlynn & Rutherford, 1993; Klonoff & Lamb, 1998; Ponsford et al., 2000). Stogner (1999) administered a battery of personality tests to consecutively admitted patients with MHI at two hospital emergency departments within ten days of injury. Patients high on neuroticism at baseline were more likely to develop symptoms of postconcussive syndrome at three months postinjury. Greiffenstein and Baker (2001) examined premorbid and postinjury Minnesota Multiphasic Personality Inventory-2 (MMPI-2) profiles in a sample of compensation-seeking individuals with persistent concussion symptoms following MHI. The premorbid MMPI-2 modal profile indicated somatoform psychopathology. The postinjury MMPI-2 profiles also showed continued somatization but with a decrease in global psychopathology.

These findings suggest that the assessment of malingering should also involve determining whether psychopathology or situational stressors are present. The MHI cases that come to litigation are invariably persons with persistent symptoms. It is possible that an individual can have both a mental disorder and be malingering, a mental disorder alone, or be malingering. The prevalence of mental disorders in this country is high. The Epidemiologic Catchment Survey (ECA; Robins & Regier, 1991) and the National Comorbidity Survey (Kessler, 1994) estimated that about 20% of the people in the United States are affected by mental disorders during a given year, including anxiety, mood, somatoform, and schizophrenic disorders. It has also been estimated that up to three of every 50 patients seen by primary care providers may have somatoform disorder or a subsyndromal form of somatization (NIMH, 1990).

Screening for mental disorders is inadequate (Butler, Jenkins, & Braff, 1993). Taking a comprehensive history and using standardized personality assessment instruments like the MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989) or the Personality Assessment Inventory (Morey, 1991) can be recommended.

### Using Tests to Refine Diagnostic Hypotheses

Up to this point, the discussion has focused on obtaining a good history from the patient: i.e., presenting complaints, past medical and psychological history, and environmental factors. Consideration of malingering or incomplete effort occurs in this broader diagnostic process. The neuropsychologist develops diagnostic hypotheses based on this information, but substantial uncertainty may still exist without the use of tests.

Testing is used in the process of hypothesis refinement to help formulate a working diagnostic hypothesis, defined previously as one that is sufficiently unambiguous to set the stage for making decisions about further invasive testing, treatment, or judgments about prognosis.

(Kassirer & Kopelman, 1991, p. 17)

The fundamental diagnostic question is, "Given a positive test score, what is the probability that the patient has the disorder or condition?" This question is answered by combining test results with the information obtained in the history and related materials. Formally, this can be done by using the information from the patient's history to estimate the prior probability of the disorder. Prior probability is also known as *prevalence* or *base rate*. It can also be expressed as the pretest odds. A diagnostic test result can be summarized as a single number, the likelihood ratio (LR) (Sackett, Straus, Richardson, Rosenberg, & Haynes, 2000).

$$LR = \frac{\text{sensitivity}}{(1 - \text{specificity})}$$

The LR is the likelihood that a given test result would be expected in a person with the disorder compared to the likelihood that the same result would be expected in a person without the disorder (Greenhalgh, 1997). The LR is then multiplied by the pretest odds to obtain the posttest odds, i.e., the probability that the person has the disorder given a positive test result. The larger the LR, the greater the diagnostic power of the test.

To use an obvious case for an example, let's suppose that a 30-year-old man presents six months status-post-TBI with an initial GCS score of 5, 15 days to follow commands, and cranial CT within 48 hours of injury showing midline shift of 5.5 mm. When examined, the patient was not litigating. Given this presentation, most neuropsychologists would estimate the prior probability that this man's performance on cognitive testing would be consistent with a diagnosis of TBI would be high, say 0.75. This is equal to a pretest odds of  $0.75 / (1 - 0.75)$  or 3.0. To convert a probability to odds, we use the following formula:

$$\text{odds} = \frac{\text{probability}}{(1 - \text{probability})}$$

The patient was given the Halstead-Reitan Battery (HRB) and obtained an Average Impairment Rating (AIR) T score of 30, based on the Heaton, Grant, and Adams (1991) norms. The AIR has a sensitivity of 0.80 and a specificity of 0.88, when using a T-score cutoff of less than 40 to define impairment, which yields a LR of 6.7. Combining the pretest odds with the LR from the AIR, the posttest odds would be  $(3.0) * (6.7) = 20.1$  in favor of the diagnosis of brain injury. Converting odds to a posttest probability, we obtain a probability of 0.95 of a diagnosis of brain injury through the use of the following formula:

$$\text{probability} = \frac{\text{odds}}{(1 + \text{odds})}$$

This approach can also be applied in the assessment of malingering. Estimates of LRs for several response bias measures can be calculated from studies in the literature. Table 38.1 contains estimated LRs for several measures.

Table 38.1 Likelihood ratios for selected measures

Test or Index	Likelihood Ratio
Symptom Validity Tests (Portland Digit Recognition Test and Hiscock Forced-Choice Procedure)	15
Word Memory Test	4.6
Reliable Digit Span	19.5
Mittenberg WAIS-R Discriminant Function	5.8
California Verbal Learning Test (CVLT)	6.9
Discriminate Function	
CVLT Recognition Hits	8.6
Victoria Symptom Validity Test	7.4
Warrington Recognition Memory Test-Words	16.5

Several stipulations are in order: This is neither an exhaustive review of available response bias measures nor a meta-analysis of diagnostic efficiency statistics for selected measures. In addition, the measures were based on different samples and there is the possibility of spectrum bias. That is, a test will have a larger LR when extreme groups are studied (e.g., very ill vs. healthy controls). Hence, the LRs presented in this table cannot be used to determine which is the “best” effort test.

In a second example, let’s say that a 35-year-old woman is being evaluated who reported having sustained a MHI two years earlier. She reported no loss of consciousness and did not seek medical care following the motor vehicle accident. She saw her family physician a month later with complaints of headache, memory problems, language disturbance, and the inability to return to work as a cashier. She is receiving chiropractic care three days a week and is in civil litigation. Binder and Rohling (1996) estimated the prevalence of biased responding following mild TBI to be 0.26, based on a weighted mean effect size from a meta-analysis. This estimate yields a pretest odds of 0.35. Let’s suppose that this patient was given the WAIS-R. Mittenberg, Theroux-Fichera, Zielinski, and Heilbronner (1995) developed a seven-subtest WAIS-R discriminant function that was designed to detect incomplete effort. Based on several studies, the LR is estimated to be 5.76. Thus, if our hypothetical litigant’s score on the WAIS-R discriminant function was in the response bias range, the posttest odds would be 2.02 or 67% in favor of the diagnosis of biased responding.

Several issues arise when using this approach to weigh diagnostic evidence. First, it is based on the assumption that reasonably accurate estimates of prior probabilities of the target disorder are available. We would argue that any system of diagnosis, whether explicitly quantitative or not, depends on prevalence rates. It is inescapable. The accuracy of all diagnostic decisions depends on the estimates or assumptions that one makes about prevalence rates. When clinicians do not explicitly consider a disorder’s prior probability, they implicitly assume that the prevalence is 50%. This is often not the case. Consequently, the diagnostic value of the test result is overstated. This quantitative system simply forces the diagnostician to be explicit about the assumptions underlying the decision making process.

A second issue is the used of single cutoff scores for diagnosis and the derivation of LRs. Neuropsychologists are urged to abandon rigid diagnostic cutoff scores for any test. Diagnosis occurs in different contexts such that the relative costs of false positive and false negative errors will not be constant across situations. Raising or lowering a test’s cutoff score will increase or decrease the test’s sensitivity and specificity in an inverse fashion. In other words, when sensitivity is increased, specificity decreases. Hence, when a cutoff score yields high *sensitivity* and the test result is a *negative*, the disorder is more easily *ruled out*. Conversely, when a cutoff score yield high *specificity* and the test result is *positive*, the

disorder is more easily *ruled in*. Sackett et al. (2000) developed the mnemonics, SnOut (when a test has high **S**ensitivity, a **N**egative result rules **OUT** the disorder) and SpPin (when a test has high **S**pecificity, a **P**ositive result rule **IN** the disorder).

A third issue that is less easily resolved is the multiplicity problem. That is, we rarely use a single test to make a diagnosis. Moreover, there is no “gold standard” test for either brain dysfunction or response bias. If the tests were statistically independent, one could simply multiply the running product by the LR generated by each subsequent test. However, it is likely that there is some degree of collinearity among tests that preclude us from doing this. In later sections of this chapter, approaches to the multiplicity problem will be discussed. In the next section, the application of specialized tests to assess effort will be considered.

### Applying Specialized Tests

Forced-choice tests (FCTs), also known as *symptom validity tests*, are, by far, the most extensively studied and validated single measures designed to detect malingering or incomplete effort (Slick et al., 1999). In FCTs, target stimuli are presented, followed by a two-choice recognition task in which the target item is paired with a foil. Some FCTs present the recognition task immediately following each target item while other FCTs present an entire set of target items (e.g., 50 items) before the recognition trial. The examinee’s task is to identify the target item. Stimuli have included words, digits, photographs, and line drawings. The premise of FCTs is that examinees would score at chance level even if the test items were never seen. A performance that departs significantly below chance (e.g.,  $p < .05$ ) is considered to be a rare event that would be unlikely to have occurred by chance. It is inferred that the examinee was purposely choosing incorrect items, i.e., is malingering. The probability of obtaining a particular score can be calculated with the normal approximation to the binomial distribution (Altman, 1999), where  $x$  is the observed score and  $n$  is the total number of test items:

$$z = \frac{|x - (0.5 \times n)| - 0.5}{\sqrt{0.25 \times n}}$$

For example, the probability of obtaining score of less than 19 on a 50-item test is 0.03. In addition to determining the probability of chance level performance, most FCTs are extremely easy tasks. Even persons with significant cognitive impairment tend to score well above chance on FCTs.

Of the digit recognition FCTs, the 72-item Portland Digit Recognition Test (PDRT; Binder & Willis, 1991) is one of the best validated FCTs (Efcoff & Kampfer, 1996). Binder (2002) presents a current review of the PDRT. Depending on the cutoff score, sensitivity to incomplete effort can range from 39% to 77%. Using a cutoff of 39 for the total score, no patient with brain dysfunction was misclassified, i.e., 100%

specificity (Binder, 2002). In a sample of 120 persons with brain dysfunction, total scores below 46 occurred in 4% of the sample (Binder, 2002).

Other FCTs having empirical support include the Computerized Assessment of Response Bias (CARB; Conder, Allen, & Cox, 1992), the Test of Memory Malinger (TOMM; Tombaugh, 2002), the Victoria Symptom Validity Test (VSVT; Slick, Hopp, Strauss, & Thompson, 1997), and the Word Memory Test (WMT; see Green, Allen, & Astner, 1996). The CARB is a computerized version of the forced-choice digit recognition paradigm. A recent review of the CARB's psychometric and diagnostic properties was conducted by Allen, Iverson, and Green (2002). Various patient groups have been given the CARB and Allen et al. (2002) reported a combined total CARB score of 97.8% correct. Hence, it is an extremely easy test to perform. Although the probability of below chance performance can be calculated for performance scores on the CARB, cutoff scores above chance can be used to detect incomplete effort. The VSVT is also a computer-administered and scored, dichotomous, forced-choice digit recognition task. It has 48 items and response latency is considered along with the total number correct. Thompson (2002) provided a review of recent studies of the VSVT.

The TOMM is a FCT that uses 50 line-drawn pictures as stimuli (Tombaugh, 2002). Similar to the CARB and VSVT, the TOMM is an easy test and a criterion score above chance can be used to classify examinees with regard to effort. Very low failure rates have been observed for persons with TBI, dementia, aphasia, and depression (Tombaugh, 2002). The WMT employs a slightly different format in which the examinee is first presented with 20 pairs of words auditorily or on a computer screen. The examinee is asked to choose the correct words from target-foil pairs in both immediate and delayed recognition conditions. Again, the WMT is an easy task even for patients with pronounced cognitive dysfunction. Green, Lees-Haley, and Allen (2002) provided a comprehensive review of the WMT's psychometric and diagnostic properties.

Standard neuropsychological tests with a forced-choice recognition format have also been used to assess effort and motivation. The Recognition Memory Test's (RMT; Warrington, 1984) sensitivity to incomplete effort has been reported to range from 70% to 95% and specificity to TBI, 90% to 100%, for its Words subtest (Iverson & Franzen, 1994; Iverson & Franzen, 1998; Millis, 1992; Millis, 1994; Millis, 2002; Millis & Putnam, 1994). Similarly, the Seashore Rhythm Test, Speech-sounds Perception Test (SSPT) (Gfeller & Craddock, 1998; Goebel, 1983; Heaton, Smith, Lehman, & Vogt, 1978; Mittenberg, Rotholz, Russell, & Heilbronner, 1996; Millis, Putnam, & Adams, 1996; Trueblood & Schmidt, 1993), and Category Test (Sweet & King, 2002) can be used to assess effort.

It should be stressed, however, that these standard neuropsychological measures do differ from the CARB, PDRT,

TOMM, VSVT, and WMT in the sense that they are sensitive in varying degrees to cognitive impairment, i.e., persons with genuine impairment may, of course, perform poorly on the Category Test, RMT, Seashore Rhythm Test, or SSPT. Tests like the CARB are more resistant to the effects of brain dysfunction. Nonetheless, it is instructive to note that the mean performance on the RMT Words subtest was 40.8 out of 50 in a sample of *acute* rehabilitation inpatients with *severe* traumatic brain injuries (GCS 3 to 8) (Millis, 2002).

Although the MMPI-2 requires examinees to answer "true" or "false" to items, it is, of course, not a symptom validity test like the PDRT or TOMM. However, a rationally derived scale composed of 43 MMPI-2 items, the Fake Bad Scale (Lees-Haley, English, & Glenn, 1991), has been found to be superior to the standard MMPI-2 validity scales in characterizing symptom endorsement patterns associated with incomplete effort (Greiffenstein, Baker, Gola, Donders, & Miller, 2002; Larrabee, 1998; Martens, Donders, & Millis, 2001; Slick, Hopp, Strauss, & Spellacy, 1996). Scores in excess of 22 on the FBS may suggest response bias in litigated mild TBI cases.

FCTs represent a major advancement in the assessment of malingering and incomplete effort. Nonetheless, the majority of malingerers will not perform below chance. In a survey of studies, Hiscock, Branham, and Hiscock (1994) found that no greater than 34% of the cases performed below chance. As noted earlier, investigators using the CARB, PDRT, TOMM, VSVT, and WMT have derived cutoff scores that are above chance but still have acceptable diagnostic efficiency. In addition, there is the question whether FCTs they will "lose" their capacity over time to detect response bias as laypersons become more familiar with them. Some FCTs may be easily recognizable such that examinees can be warned to perform them to the best of their ability while performing other tests suboptimally.

A third issue is test redundancy. With the proliferation of effort measures and indices, how should the results be combined? Should some tests be given more weight? For example, Finger Tapping Test (FTT) has been found to be useful in detecting incomplete effort (e.g., Binder, 1990; Binder & Willis, 1991; Larrabee, 2002). A logistic regression model was fitted using the data set from Millis and Volinsky (2001) for participants having data for the FTT. Indeed, the FTT was a significant predictor of incomplete effort ( $p = 0.002$ ). It had high specificity (96% of the 93 persons with TBI were correctly classified) but low sensitivity (15% of the 44 litigants with MHI were correctly classified). Previous investigations have also identified Recognition Hits from the CLVT and digit span as sensitive to incomplete effort (e.g., Meyers & Volbrecht, 1998; Millis, Putnam, Adams, and Ricker, 1995). A second logistic regression model was fitted that included FTT, Recognition Hits, and forward digit span from the WAIS-R. Parameter estimates appear in Table 38.2. Now, FTT is no longer a significant predictor of incomplete effort in the presence of Hits and digits forward. Sensitivity to

Table 38.2 Logistic regression model parameter estimates

	<i>B</i>	<i>S.E.</i>	<i>Wald</i>	<i>df</i>	<i>Sig.</i>	<i>Odds Ratio</i>
FTT	-0.021	0.027	0.559	1	.455	.980
Digits Forward	-0.485	0.189	6.612	1	.010	.616
CVLT Hits	-0.803	0.219	13.498	1	.000	.448

incomplete effort increased to 75% and specificity to TBI was 95%. Although the development of better tests should not cease, there is a pressing need to determine how effort tests relate to each other and to standard cognitive measures in order to derive efficient diagnostic algorithms. The examination of performance patterns among several tests is one approach to this challenge.

### Analysis of Test Performance Patterns

Pattern analysis to detect incomplete effort is not new. In the late 1970s, Heaton et al. (1978) used discriminant function analysis with the HRB to differentiate persons with head injuries from people instructed to feign neuropsychological impairment. The study's findings were limited by a model that had too few subjects for the number of predictor variables. Nonetheless, the methodology inspired dozens of studies that followed.

Discriminant function analysis (DFA) and logistic regression have been the most commonly used statistical techniques for pattern analysis and group classification. For reasons unknown to us, DFA has been used more frequently in psychological research, yet logistic regression has clear advantages over DFA. Logistic regression has fewer restrictive assumptions, e.g., it does not require multivariate normality and homogeneous covariance matrices as does DFA (Long, 1997). In addition, interpretation of the relative importance of individual predictor variables is more straightforward. The logistic regression function can also be used to calculate the probability that an individual belong to one of the groups in the following manner. A linear composite known as the *logit* (also known as the *logged odds* or *linear predictor*) is calculated by multiplying each predictor variable's raw score by its respective coefficient (e.g.,  $\beta_1 x_1 + \beta_2 x_2$ ) and then a constant is added. The logit is exponentiated in the following manner to yield the probability of an individual belonging to one of two groups, based on the raw scores entered into this formula:

$$p = \frac{e^{\alpha + \beta_1 x_1 + \beta_2 x_2}}{1 + e^{\alpha + \beta_1 x_1 + \beta_2 x_2}}$$

Generally, the cutoff for  $p$  is 0.50, i.e., greater than 50% probability of membership in one of the two groups. However, the cutoff score can be adjusted in light of the relative costs of making either a false positive or false negative error.

Tests that have been used in subsequent pattern analysis of incomplete effort include the HRB, WAIS, and CVLT.

Extending the original work of Heaton et al. (1978), Mittenberg et al. (1996) used stepwise discriminant function analysis to differentiate persons with TBI from normal volunteers instructed to simulate cognitive impairment. The ten-variable HRB function correctly classified 89% of the cases. When applied to a sample of Veterans Administration patients with TBI, the discriminant function correctly classified 78% of the sample (McKinzey & Russell, 1997).

Mittenberg et al. (1995) also derived a seven-subtest WAIS-R discriminant function that accurately classified 79% persons with TBI and uninjured persons instructed to malingering. Millis, Ross and Ricker (1998) cross-validated the function: 92% of persons with moderate to severe TBI were correctly classified as were 88% of mild TBI litigants who had performed within chance on the RMT. Axelrod and Rawlings (1999) also applied this WAIS-R to a sample of persons with TBI who had received the WAIS-R two to four times over the course of one year postinjury. Rates of correct classification ranged from 76% to 93%. Mittenberg, Theroux, Aguila-Puentes, Bianchini, Greve, and Rayls (2001) applied the WAIS-R function on a new sample of persons given the WAIS-III. That is, a new function based on the WAIS-III was not derived. Rather, the original discriminant function derived from the WAIS-R was applied to WAIS-III data. This function and cutoff score accurately classified 83% of persons with TBI and 72% of persons simulating head injury. Mittenberg et al. (2001) provide alternative cutoff scores for the discriminant function that may improve diagnostic accuracy.

Several studies have used the CVLT (Delis, Kramer, Kaplan, & Ober, 1987) to examine incomplete effort. Millis et al. (1995) found that a three-variable CVLT discriminant function correctly classified 91% of persons with moderate to severe brain injuries and a groups of litigants with MHI who scored below chance on Warrington's RMT. Millis et al. (1995) also examined CVLT Recognition Hits as a single variable. Sensitivity to incomplete effort was 83% and specificity to TBI was 96%. Subsequent studies by Baker, Donders, and Thompson (2000), Coleman, Rapport, Millis, Ricker, and Farchione (1998), and Sweet et al. (2000) applied the original cutoff scores derived by Millis et al. (1995) to other groups of persons with TBI and to groups of analog and probable clinical malingerers. Sensitivity to response bias has been lower than the findings reported by Millis et al. (1995), e.g., 63% to 80% for Hits and 74% for the discriminant function, but specificity for TBI has remained high, e.g., 87% to 94% for Hits and 83% to 93% for the discriminant function. More broadly, biased responding appears to be associated with disproportionate impairment on recognition tasks in an absolute sense and in relationship to free recall performance on list learning tasks.

Although pattern analysis has made important contributions in the assessment of malingering, it is not without its limitations. It suffers from the same multiplicity problem as the single test approach. That is, how are tests selected

for inclusion in the logistic regression function? There are potentially dozens of effort tests and indices from which to choose. Yet, it is often not reasonable to include all potential measures because sample sizes may not be sufficiently large to avoid overfitting the model. Even when a moderate number of tests are chosen, the number of potential models is huge. For example, if one considers 15 different tests, there are 32,768 potential subsets of tests to evaluate (i.e.,  $2^{15}$ )! Moreover, theory and past research findings may not provide enough guidance for variable selection. We return to this issue with a discussion of approaches to this problem in “Challenge of Test Selection: New Statistical Methods.” In the next section, a strategy for combining data is covered.

### Integration of Information

Having completed the examination, the neuropsychologist will have information from the history and related sources along with test data. Slick et al. (1999) have developed a strategy for combining and interpreting these data. Acknowledging that there are various degrees of diagnostic certainty, the guidelines proposed by Slick et al. have specific criteria for *definite*, *probable*, and *possible* malingered neurocognitive disorder (MND). For example, if there are external incentives in a given case and the examinee performs below chance on an FCT, and there are no psychiatric or neurologic disorders to account for this performance, there is sufficient evidence for *definite* MND. As noted earlier, the majority of litigants will not score below chance on FCTs. Accordingly, these criteria do allow the use of other validated effort tests or indices along with an analysis of discrepancies between test results and patient behavior:

- “*Discrepancy between test data and known patterns of brain functioning*” (e.g., patient performs in the profoundly impaired range on measures of attention but within normal limits on memory measures).
- “*Discrepancy between test data and observed behavior*” (e.g., patient is unable to perform confrontation naming test but has no visuoperceptual deficits and spontaneous speech is fluent and without paraphasic errors).
- “*Discrepancy between test data and reliable collateral reports*” (e.g., patient handles financial affairs like balancing check book but is unable to perform simple arithmetic problems in the clinical examination).
- “*Discrepancy between test data and documented background history*” (e.g., patient with history of mild TBI who obtains memory test scores in the profoundly impaired range).

(Slick et al. 1999, pp. 553–554)

Two or more types of evidence from effort indices or test-behavior discrepancies would warrant a diagnosis of *probable* MNC, given the presence of external incentives and the

absence of psychiatric or neurologic disorders to account for this behavior.

The criteria also allow the use of patient self-report data in examining for discrepancies:

- “*Self-reported history is discrepant with documented history*” (e.g., patient reports an exaggerated length of loss of consciousness).
- “*Self-reported symptoms are discrepant with known patterns of brain functioning*” (e.g., patient claims inability to recall own birthdate and address following mild TBI).
- “*Self-reported symptoms are discrepant with behavioral observations*” (e.g., patient reports severe cognitive impairment yet lives independently, manages own financial affairs, and drove self to office).
- “*Self-reported symptoms are discrepant with information obtained from collateral informants*” (e.g., patient acts cognitively impaired but spouse or job supervisor report that patient experiences no functional difficulties).
- “*Evidence of exaggerated or fabricated psychological dysfunction*” (e.g., validity scales from the MMPI-2 or Personality Assessment Inventory indicate “fake bad” profile).

(Slick et al., 1999, p. 554)

A diagnosis of *probable* MND can also be made on the basis of one type of psychometric evidence and one type of self-report discrepancy. In the absence of psychometric evidence, one or more self-report discrepancies is sufficient for a diagnosis of *possible* MND.

### The Challenge of Test Selection: New Statistical Methods in Assist in Decision Making

It could be argued that there are now enough effort tests and indices to assess for malingering and incomplete effort. At this point, the next step in the evolution of malingering assessment is to determine which effort tests and indices should be combined and weighted to yield optimal diagnostic accuracy. Moreover, the task is broader in terms of possibly combining effort tests with standard neuropsychological measures to derive the actuarial diagnostic algorithms. In the past, stepwise regression methods have been used for selecting sets of tests for use in prediction. However, there are many problems with the stepwise method. Harrell (2001) has summarized the flaws: It yields inflated R-squared values; the F and chi-squared tests do not have the claimed distribution; it produces confidence intervals that are falsely narrow; it produces biased regression coefficients that need shrinkage; and it has severe problems in the presence of collinearity. Increasing the sample size does not overcome these problems. Fortunately, several new statistical methods are now available to assist in selecting sets of predictor variables.

### Bayesian Modeling Averaging

Bayesian model averaging (BMA; Hoeting, Madigan, Raftery, & Volinsky, 1999) approaches the problem of variable and model selection by averaging over the best models according to posterior probabilities. Unlike stepwise methods, BMA searches the entire model space and evaluates every possible model. Averaging over many models in this manner has been found to provide superior out-of-sample predictive performance compared to the typical approach of evaluating a single model (Madigan & Raftery, 1994). More detailed discussions of applied statistical and mathematical aspects of BMA can be found in Hoeting et al. (1999) and Millis and Volinsky (2001).

Millis and Volinsky (2001) used BMA to select and evaluate models composed of variables from the CVLT for the detection of incomplete effort. The BMA attempts to differentiate persons with documented moderate to severe TBIs from persons with mild injuries in litigation who show evidence of incomplete effort. The CVLT has over a dozen variables and, although previous studies identified CVLT variables that are sensitive to incomplete effort, an unresolved question was whether there are optimal sets of CVLT variables to predict incomplete effort. Millis and Volinsky's BMA identified four models with different combinations of CVLT variables that appeared optimal (Table 38.3). Bayesian modeling requires the specification of a reference set of prior probabilities, which are indexed by the  $\phi$  parameter. Different prior probabilities were selected to perform a sensitivity analysis. All models performed in a similar fashion under different prior probabilities. As can be observed in Table 38.3, Model 1 (SDFR, LDFR, Hits, and Bias) had the greatest support but there remained some degree of statistical uncertainty so that additional models were included. In terms of decision making, each model is used in a logistic regression model and its contribution is weighted according to its posterior probability. A spreadsheet that performs the mathematical calculations is available from the first author. If an examinee produced the following panel of results (Short Delay Free Recall, or SDFR = 3; Short Delay Cued Recall, or SDCR = 4; Long Delay Free Recall, or LDFR = 4; Primacy = 32; Hits = 5, False Positives = 1; and Bias =  $-.83$ ), the probability is incomplete effort is 99%, based on averaging over the four best models appearing in Table 38.3.

The computational and conceptual complexities of Bayesian modeling may dissuade some investigators from using it. There are additional approaches that can be used to select and simplify models.

### Stepdown Analysis

In stepdown analysis, a prognostic index is constructed, which is a linear combination of the variables in the model. It is used to determine what variables may be dropped from a model. The mathematical details can be found in Ambler, Brady, and Royston (2002). The same data used in the BMA study (Millis & Volinsky, 2001) were used in this stepdown analysis. Interestingly, the variables identified as important predictors of incomplete effort by the stepdown analysis were the same ones found to be important in the BMA except for False Positive errors (Table 38.4). This logistic regression prediction formula would need to be validated on independent samples before it should be used clinically. For each case, the CVLT raw scores for the respective variables would be multiplied by their respective coefficients to obtain the probability of incomplete effort, e.g., SDFR \* 0.404, etc. To illustrate with an example, let's say an examinee obtains the following scores on these CVLT variables: SDFR = 3; SDCR = 4; LDFR = 4; Primacy = 32; Hits = 5; and Bias =  $-.83$ ). The following linear composite (i.e., logit) is obtained:

$$(3) * (0.404) + (4) * (0.287) + (4) * (-0.502) + (32) * (-0.061) + (5) * (-1.05) + (-0.83) * (2.281) + 13.232 = 4.489$$

Hence, the probability of incomplete effort is  $[e^{4.489} / (1 + e^{4.489})] = 0.99$ . For greater ease of application of a logistic regression function, a nomogram (Figure 38.1) can be drawn that converts each CVLT variable in the model to a 0–100 scale that is proportional to the log odds (i.e., logit). One goes vertically from the variable to the top to the "Points" line. These points are added across the CVLT variables to calculate the Total Points. Going vertically from the "Total Points" line down to the "Linear Predictor," the total points are converted to the logit and then to the predicted probability. For example, an examinee gets about 7 points for recalling three words on SDFR, 7 points for recalling four words on SDCR, 35 point for recalling four words on LDFR, 14 points for a Primacy

Table 38.3 Logistic regression models and model posterior probabilities following BMA—CLVT \*

Model	Variables	Posterior Probabilities (%)		
		$f = 1.00$	$f = 1.65$	$f = 5.00$
1	SDFR, LDFR, Hits, Bias	42	43	44
2	SDFR, LDFR, Primacy, Hits	25	24	24
3	SDCR, LDFR, Hits, Bias	25	26	26
4	SDCR, LDFR, Hits, False Positives	7	7	6

\* SDFR = Short Delay Free Recall. SDCR = Short Delay Cued Recall. LDFR = Long Delay Free Recall. Hits = Recognition Hits. Bias = Response Bias.

Table 38.4 Stepdown analysis model—CLVT\*

Variables	Coef.	SE	Z	P
SDFR	0.404	0.187	2.17	.030
SDCR	0.287	0.848	1.55	.121
LDFR	-0.502	0.172	-2.92	.004
Primacy	-0.061	0.0318	-1.92	.055
Hits	-1.05	0.220	-4.77	.000
Bias	2.281	0.926	2.46	.014
Constant	13.232	2.647		

\* SDFR = Short Delay Free Recall. SDCR = Short Delay Cued Recall. LDFR = Long Delay Free Recall. Hits = Recognition Hits. Bias = Response Bias.

score of 32, 70 points for five Recognition Hits, and 1 point for a Response Bias score of -0.83. This total score of 134 points corresponds to a linear predictor score (i.e., logit) of approximately 4.8 and a probability of 0.99. These estimates are quite close to the formal calculation with the formula, which yielded a logit of 4.489 and a probability of 0.99. Once a model has been validated, nomograms provide a convenient tool for clinicians to apply complex algorithms in day-to-day practice. This nomogram was produced using a function in Harrell’s (2001) *Design* library that is available in S-Plus 6.1 (Insightful Corporation, 2002). Stepdown analysis can be performed with Stata Version 8.0 (Stata Corporation, 2003) and S-Plus Version 6.1 (Insightful Corporation, 2002) statistical software.

**Recursive Partitioning**

The methods described thus far are parametric methods. A nonparametric alternative is recursive partitioning (RP). RP can be particularly useful for examining relationships among variables in the absence of a well-developed model. In this approach, a “tree structure” is created by dividing the sample recursively into a number of subgroups. The divisions are selected so as to maximize the difference in the response variable in the resulting two groups. RP has additional advantages over parametric methods. Parametric methods are based on specific statistical assumptions. When they are violated, the parameter estimates may be inefficient or biased. Recursive partitioning has some advantages over parametric methods: (a) they may be easier to interpret when there is a mix of categorical and continuous predictors; (b) they are invariant to monotone re-expressions of predictor variables; and (c) they can handle missing values and nonadditive behavior (Chambers & Hastie, 1992).

RP was applied to the sample data from Millis and Volinsky (2001). For simplicity, three CVLT variables were selected: Recognition Hits, Long Delay Free Recall, and Short Delay Free Recall. A decision tree was derived (Figure 38.2). At the top of the tree, all 160 participants begin in one group. The statistic  $G^2$  refers to the LR chi-square, which is the criterion used to select variables. The “Level” column refers to the groups (0 = persons with TBI, 1 = persons showing

Figure 38.1 Nomogram to calculate probability of incomplete effort

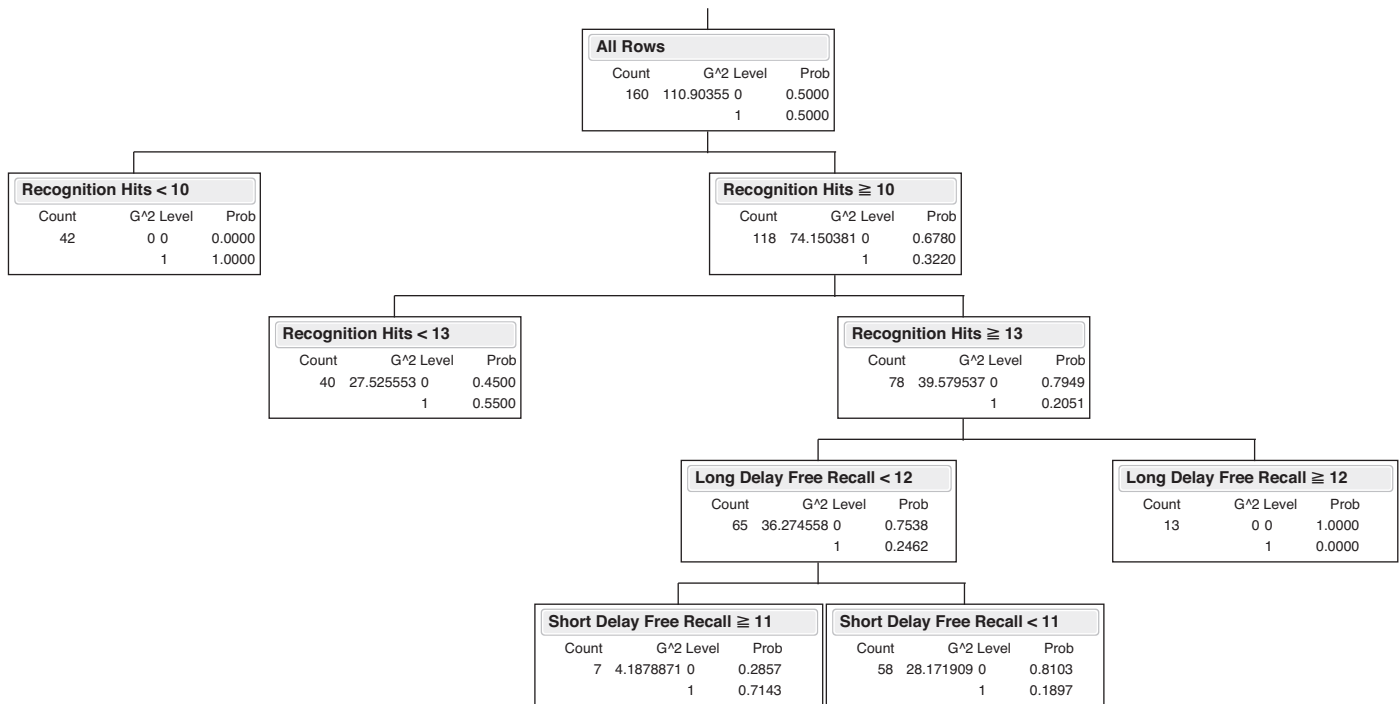

Figure 38.2 Recursive partitioning tree diagram—CLVT

incomplete effort). At the first split, Hits less than ten results in a subgroup of 42 persons showing incomplete effort (Effort). No persons with TBI are in that subgroup. All of the TBI participants and the remaining 38 from the Effort group are in the subgroup with Hits greater than or equal to 10. From this point, another advantage of RP becomes apparent (i.e., subtypes may be able to be identified). It appears that one type of incomplete effort is characterized primarily by atypically low recognition scores. Another possible subtype might be marked by mildly impaired or normal recognition in combination with SDFR performance being relatively better than LDFR. As with the stepdown derived-model, this RP model needs to be validated on independent samples before being used clinically. RP can be done with a number of statistical packages. JMP Version 5 (SAS Institute, 2002) was used for this example.

A variable can be useful for prediction in different ways. For example, further analysis of SDFR suggested that it may be a suppressor variable in that it suppresses variance that is actually irrelevant in the prediction of incomplete effort. In this case, it may be enhancing the effect of LDFR. Evidence pointing to SDFR being a suppressor variable is that its point biserial correlation with the grouping variable ( $-0.34$ ) and beta weight ( $0.46$ ) have opposite signs (Tabachnick & Fidell, 2001). In contrast, the correlations of Hits and LDFR with the grouping variable and regression coefficients are consistent in size and direction. When LDFR is dropped from the equation, SDFR is no longer a significant predictor of incomplete effort. This is not to imply SDFR

is unimportant but rather that its usefulness in predicting incomplete effort is indirect and emerges in combination with of LDFR.

### Legal Implications

Scientific innovation always precedes the law. No published legal cases have considered these statistical methods, nor base rates, nor LR<sub>s</sub>, as applied to malingering in forensic neuropsychological evaluations. Many judges would not recognize the relevance of these topics and would likely exclude such evidence out of fear that it would “confuse of the issues, or misleading the jury” (Fed. R. of Evid. 403). When there are no cases on point, legal scholars attempt to generalize by analogy to consider how courts may rule when an appropriate case or controversy is heard. Here, courts have considerable experience with the application of population frequency statistics to DNA evidence as first introduced in the 1987 rape convictions of Robert Melias (England) and Tommy Lee Andrews (Alabama) (Connors, Lundregan, Miller, & McEwen, 1996). Population frequency statistics used for DNA evidence are generally admissible and analogous to the base rate and LR<sub>s</sub>—the point of departure for the statistical methods described in this chapter.

This chapter sets forth, with mathematical precision, the scientific principles of assessment of incomplete effort and malingering in neuropsychological examination. It is only a matter of time until a defendant or plaintiff challenges the admissibility of the actuarial methods used, in part, to render

a malingering diagnosis. Although no neuropsychological evaluation was performed, *Berry v. CSX Transp., Inc.* (1998) addresses population frequency statistics and neuropsychological methods when rendering expert testimony about causation in a toxic tort case. No psychologist testified, even though a neuropsychiatrist found severe cognitive deficits that other physician experts attempted to link to the exposure to organic solvents trichloroethane (TCA), trichloroethylene (TCE), perchloroethylene (PCE), and mineral spirits. The *Berry* appellate panel found that the trial court erred when excluding population frequency statistics proposed to bolster epidemiological studies in support of the plaintiff's claim. Essentially, if an expert's opinion is well-founded and based upon generally accepted scientific principles and methodology, it will be admitted and weighed by a trier of fact, whether or not the expert's opinion is generally accepted. By analogy, this legal principle applies to neuropsychologists rendering expert opinions about response bias, suboptimal effort, or malingering.

This chapter considered such expert testimony in the context of MHI and highlighted the frequency of brain injury claims in civil litigation. Courts hear and consider expert opinions about malingering without necessarily appreciating the underlying probabilistic framework upon which such opinions are based. In *Reiner v. Warren Resort Hotels, Inc.* (2008), the plaintiff alleged a brain injury over two years after she slipped, fell, and struck her head while exiting the hotel hot tub. Preinjury medical and psychological history were complicated by preexisting conditions. Of particular interest was a preinjury neuropsychological evaluation in 1985 for complaints about memory and concentration. Reiner's injury occurred on May 1, 2005 and her occipital and basilar skull fractures were never in dispute. Moreover, there was no loss of consciousness, no amnesia, and no confusion. A CT scan was negative and magnetic resonance imaging (MRI) identified a preexisting 12 mm anomaly consistent with left posterior frontal meningioma. Neuropsychologists identified suboptimal effort on three measures—TOMM, CARB, and the MMPI-2 FBS—but expert opinions about effort diverged significantly. Among various motions *in limine*, the plaintiff moved to exclude FBS and a *Daubert* hearing ensued.

The plaintiff argued that FBS assigns malingering points to honest answers a subject provides, and this is especially true when the subject is a woman. Further, the defense neuropsychologist opined, "there is a lot of controversy surrounding the test." The plaintiff entered two articles highlighting the controversy over this method of testing for malingering. Defense countered that the plaintiff opened the door to this evidence by relying on a neuropsychologist who administered two tests for malingering and planned to use the test results to bolster the plaintiff's credibility with respect to her brain-injury claim. Moreover, the defense noted 11 articles recognizing FBS and several state and federal cases in which FBS results were admitted in evidence.

The defense in *Reiner* argued that the FBS is reliable enough, when considered together with other factors. This practice is consistent with the AACN Consensus Conference Statement (2009) encouraging practitioners to not rely on a single symptom validity test, but multiple measures administered throughout the assessment day(s). Further, neuropsychologists must be mindful of the important difference between scientifically based clinical decisions and legal adjudication, while showing respect to the laws and customs of the jurisdiction in which they practice when describing the behavioral presentation at issue. In the end, the *Reiner* judge admitted FBS and all other symptom and performance validity measures. Readers are directed to Kaufmann (2012, 2013) for more lengthy discussion of admissibility challenges to neuropsychological evidence of suboptimal effort. Most recently, challenges to symptom and performance validity measures are taking place in consultative examinations of Social Security litigation (*Bradley v. Astrue*, 2012; *Taylor v. Astrue*, 2012; *Pratt v. Astrue*, 2009).

### Closing Remarks

We rely on our clinical judgment to generate hypotheses. However, in an earlier discussion, Millis and Volinsky (2001) reflected on the limitations of clinical judgment in making accurate diagnoses:

As humans, we often have a low tolerance for ambiguity, which impels us to impose meaning on experience. This tendency carries over into the diagnostic realm. If we rely on our clinical judgment alone, our diagnostic accuracy can be abysmal. Humans tend to ignore prevalence rates, assign non-optimal weights to predictor variables, disregard regression toward the mean, improperly assess covariation, and over-weigh vivid data (Grove, Zald, Lebow, Snitz, & Nelson, 2000). Meehl (1954) was among the first to alert psychologists to the superiority of statistical prediction compared to clinical judgment. Little has changed in this regard over the last 46 years.

(p. 823)

Further advances in the assessment of malingering and incomplete effort will likely be fueled by human intuition and creativity and tempered by quantitative rigor.

## 39 Pediatric Forensic Neuropsychology

*Jacobus Donders, Brian L. Brooks, Elisabeth M. S. Sherman,  
and Michael W. Kirkwood*

The mainstay of the practice of most pediatric neuropsychologists (PNs) involves clinical evaluations of children who are referred by a physician, parent, or teacher, and with whom an advocating and/or treating clinician-patient relationship is established. This chapter, however, will deal with forensic contexts, where the client is an attorney representing a child, and which can range from personal injury litigation to disputes about eligibility for special education services to allegations about medical malpractice. We will review some of the variables that need to be considered routinely in the context of forensic neuropsychological evaluations of children. The term *forensic* is used here specifically as pertaining to a civic medicolegal or educational context and is not intended to apply to cases involving child custody or criminal responsibility. In addition, the term *child(ren)* is used with the understanding that this covers any person under the age of 18, unless the individual has become an emancipated minor. Throughout the chapter, the role of the PN will be assumed to be that of an independent expert, as opposed to some other potential role (e.g., litigation consultant to an attorney).

In this chapter, we will first review some basic aspects of legal procedures and contingencies that the PN needs to be familiar with before considering or performing a forensic evaluation. Next, we discuss several issues that are pertinent to the interpretation of assessment results, including definition of impairment and base rates of low scores. Specific attention will be paid to the evaluation of validity, as well as to malingered neuropsychological deficits and other conditions associated with under-performance or over-reporting of symptoms. Finally, some illustrative case examples will be provided with regard to options for documentation and sworn testimony.

### Forensic Context

Doing a forensic neuropsychological evaluation of a child is quite different from regular clinical practice, in a number of ways. Some of these differences are summarized in Table 39.1. It is important to have unequivocal common ground with the retaining attorney about these differences *before* agreeing to do the evaluation. At the time of the initial contact with the attorney, the PN also needs to have a good

understanding of the purpose of the evaluation. When considering a forensic referral, the PN must (a) only accept cases that are actually within his or her boundaries of professional competence (as is true with any referral), and (b) be reasonably familiar with judicial and administrative rules affecting local forensic work, as documented in standards 2.01(a) and 2.01(f) of the American Psychological Association (APA) Ethics code (2002). Therefore, a person with little or no continuing education in, or experience with, lead poisoning should most likely decline a request for an independent medicolegal evaluation of a child with such an alleged history. At the same time, a PN with considerable experience with the condition or area of interest should still make sure that he or she understands how the local legal system works.

Once the nature of the case has been established and it has been determined that it is within the boundaries of expertise of the PN, it needs to be ascertained that he or she can conduct an unbiased and objective examination, with access to relevant documents (including medical and school records) as well as the child. If the child has already undergone a prior neuropsychological or educational evaluation with a different provider, it is standard of care to request the associated report as well as the raw data. Fees and/or retainers for services should also be made explicit at the time of the initial contact with the attorney.

Any potential conflicts of interest dual-role situations should be ruled out prior to accepting a forensic case, as stated in Standard 3.05(a) of the APA ethics code (2002). For example, a PN who had at one time completed a clinical evaluation at the request of the child's pediatrician should definitely not later accept a referral from the attorney who represents the parents of the child in a personal injury lawsuit for another "expert" evaluation. As yet another example, if that same child had been clinically evaluated by PN A in the same department of which PN B was the director, it would most likely behoove PN B to decline doing an "independent" evaluation of that child.

Prior to the evaluation, it is advisable to obtain a specific set of questions from the retaining attorney to identify the main issues relevant to the case that need to be addressed. Sometimes, the PN will be asked to do a records review only. This is permissible as long as the limits this places on the ability to make specific diagnostic impressions are documented,

Table 39.1 Differences between clinical and forensic pediatric neuropsychology

<i>Neuropsychologist Variable</i>	<i>Clinical Evaluation</i>	<i>Forensic Evaluation</i>
Typical referral agent	Physician, parent, or teacher	Attorney
The client	Patient and parents/legal representative	Referring agent
Professional role with child	Treating clinician, patient advocate	Objective/independent expert
Relationship with other professionals	Collegial	Adversarial
Confidentiality	Maintained unless under extreme conditions (e.g., suspicion of child abuse)	Privilege has been waived; "private" information becomes a matter of public record
HIPAA/FERPA rules	Applicable	Superseded by discovery rules
Obtaining details about family medical and psychosocial history	Standard of care	Highly desirable but may be subject to legal/privacy objections
Necessity of performance/symptom validity testing	Recommended	Indispensable
Level of certainty required in interpretation of the data	Based on definition of impairment, base rates, and confidence intervals	More likely than not <i>or</i> with a reasonable degree of scientific certainty
Audience for the report	Treating professionals, school teachers	Attorneys, judges, and juries
Handling of raw data	Must attempt to maintain test security	Must often be made available in most states
Feedback to or follow-up with patient	Routine	Typically not allowed if retained by opposing counsel
Witness during deposition or trial	Fact witness	Expert witness

Note: Adapted (with permission) from Donders, J. (2012).

HIPAA = Health Insurance Portability and Accountability Act. FERPA = Family Educational Rights and Privacy Act.

consistent with standards 9.01(b) and 9.01(c) of the APA ethics code (2002). More commonly, the attorney will ask for an actual neuropsychological evaluation. Details of that process, including consideration of general psychometric issues and specific performance validity as well as symptom validity, will be discussed later, in the section on Identifying Cognitive Impairment. In general, though, it is important that the PN uses procedures that are ethical, widely accepted in the professional community, and grounded in psychometric and neurobehavioral science. This would also be an important proactive defense against any potential later challenges to the admissibility of the PN's report or sworn testimony.

When the parents or guardians bring a child in for a forensic evaluation, it is of utmost importance that the PN explains to them at the very beginning what the contingencies are and how these differ from a traditional clinical context. This starts with disclosing who retained the PN and what the nature and purpose of the evaluation are. Informed consent from the parent or guardian, as well as assent from the child, must be obtained in a language that they can understand, consistent with Standard 3.10(a–d) of the APA ethics code (2002). Sample consent forms are available from the website of the National Academy of Neuropsychology ([www.nanonline.org](http://www.nanonline.org)). Normally, the Health Insurance Portability and Accountability Act (HIPAA) would apply to a traditional health care environment, and the less-restrictive Family Educational Rights and Privacy Act (FERPA) to educational evaluations; in both cases, the child and parent are the client. Although the PN does not need to go into details about those laws, it needs to be made explicit to the

parents that the rights that these laws offer are not in effect during independent forensic evaluations. For example, they need to understand that the usual rules of confidentiality do not apply, that they may not have direct access to the report, and that follow-up is not routinely available. Nevertheless, the PN should conduct the evaluation in a respectful and evidence-based manner, with the goal of discerning information that will ultimately help the trier of fact (i.e., a judge or a jury).

It is distinctly not the role of the PN to try to "win the case" for either side in a pending legal dispute. During the entire forensic evaluation process, the PN should make every attempt at maintaining personal neutrality and scientific objectivity. Several authors have provided practical suggestions for self-screening by neuropsychologists for potential bias during the forensic evaluation process (Sweet & Moulthrop, 1999; Van Gorp & McMullen, 1997).

The reader is referred to Chapters 36 and 37 of this volume for a thorough review of all the legal terms, rules of evidence, and procedural issues that may arise in the context of a forensic neuropsychological evaluation. However, a few issues that arise commonly merit some further discussion. The first of these is that, at all times, the PN should aspire to the highest ethical, professional, and scientific standards, consistent with the ethics code of the APA (2002). At the same time, it needs to be realized that state or federal law may have different standards that will typically trump those of APA in case of conflict between them. For example, when faced with a subpoena for the raw data to be sent to the opposing attorney, the PN may and should express a preference

to send those data directly to another PN, citing issues of test security and the like; consistent with the standards of practice in the field. However, except in cases where state law prohibits such direct disclosure or when the PN can clearly demonstrate the likelihood of substantial harm to the child, a judge may ultimately order release of the raw data to the opposing attorney, anyway. In that case, the PN will most likely need to comply, or risk being held in contempt of court and face the legal consequences. The official joint position of various professional neuropsychological organizations with regard to test data disclosure has been described by Attix and colleagues (2007).

Another notable difference in standards between the traditional clinical environment and the forensic context pertains to the degree of certainty that is required for an opinion. The traditional  $p < 0.05$  criterion from the null hypothesis test context that is familiar to most PNs is typically not the evidentiary standard in a legal arena. In forensic cases, the PN may be asked whether something is "more likely than not," which essentially means anything that is  $> 51\%$  likely. A more stringent standard is applied if the PN is asked to offer an opinion with a "reasonable degree of scientific/neuropsychological certainty," in which case a 90% likelihood level may be assumed.

Regardless of the type of certainty that is asked for, it is typically a good idea for PNs to qualify their professional opinions with reference to a level of probability, or a degree to which the phenomenon deviates from expected patterns. For example, if it is known from independent empirical studies that test A has a specificity of 88% and test B a specificity of 86%, then "positive" findings on both tests in the same child would typically be expected less than 2% of the time  $([1 - 0.88] \times [1 - 0.86] = 0.0168)$  if the tests were largely uncorrelated. Phrasing this in the report or during testimony as something that would most likely occur in fewer than two out of every 100 patients would place the information in a context that is intelligible to those who are typically not experts in psychometrics, such as judges and juries.

It is also possible that PNs find themselves in a deposition or courtroom as a treating doctor who had originally seen the child for standard clinical reasons at the request of a physician, but is now asked to testify as part of legal procedures involving the same child. In such cases he or she will most likely be called as a fact witness, who can technically speak directly to the actual assessment findings only, whereas an independent expert witness has more leeway to offer professional opinions that include attribution of causality and discussion of the consensus in the literature. In reality, though, these lines are often blurred, and treating neuropsychologists are typically viewed as experts by most attorneys and judges. Requests from the opposing attorney for presence of a third-party observer during the evaluation present a unique challenge. Judges have leeway in the degree to which they may allow such presence but this varies considerably from state to state, which highlights the importance

of familiarity with local jurisdictions. With that reservation in mind, the PN should object to the presence of third-party observers during the actual psychometric assessment process, because of the deviation from standardized procedures and the likely confounding impact on the behavior of the examinee. Several professional organizations, including the National Academy of Clinical Neuropsychology (2000) and the American Academy of Clinical Neuropsychology (2001), have issued position papers on this matter, and there are also empirical studies that have documented the invalidating influences associated with third-party observers, even when the "observer" is a recording device (e.g., Constantinou, Ashendorf, & McCaffrey, 2005; Lynch, 2005). It is advisable to submit these references as part of a notarized affidavit. Most often, attorneys are agreeable to limiting the presence of a third person to the interview, but this is not universal. Howe and McCaffrey (2010) provide further suggestions about how to deal with third-party observer requests.

Some opposing attorneys may request, prior to the evaluation, a list of all the tests that the PN plans to administer. It is advisable to decline such a request on the grounds that (a) the choice of specific tests may not be made until after the completion of the interview and history, and (b) potentially providing the opportunity to review specific tests or items in advance would likely jeopardize the validity of the evaluation. Often, a reasonable compromise is that specific cognitive domains of assessment can be provided (i.e., memory, attention, etc.). Alternatively, a complete list of every possible test that is available in the PN's arsenal and that could reasonably be considered for a child of this specific age and background can be offered, with the understanding that not all those tests will be given but that selections will be made from them.

Another barrier that PNs may face when preparing for a forensic evaluation is that the opposing attorney may object to the inquiry about any kind of family medical history, even though this would be the standard of care in clinical practice. Families may consequently decline to answer such questions, or a judge may even prohibit such inquiry. Under such circumstances, the PN must (a) respect any boundaries imposed by a judge, (b) decide if he or she still wants to proceed or withdraw from the case, (c) if the choice is made to proceed, then clearly note the nature and extent of the imposed restrictions in the report, and (d) explain in the same report how those restrictions limit the scope of the conclusions that can be made.

After completion of the records review, interview, and testing, the PN will typically be expected to prepare a report. In some cases, the retaining attorney may request that this be deferred until he or she and the PN have verbally discussed the findings. This should be determined before commencing the actual evaluation. When a written report is desired, the PN usually sends this to the retaining attorney only, but it still needs to be understood that any written documentation of this kind is "discoverable" in a forensic context. In fact, the

PN's entire file may need to be made available for inspection by opposing counsel as part of a later deposition or trial process. This highlights the importance of making sure that the file is complete and that the report is evidence-based, and addresses in professional yet intelligible language if the child has any current neuropsychological deficits and to what degree those are related to a neurological condition of interest (e.g., traumatic brain injury; or TBI) or other factors. It is very important in this context that the PN offers only professional opinions that are based on his or her expertise and not engage in speculation. For example, in the case of an allegation of malpractice by an obstetrician during a pregnancy and/or delivery, the PN can most likely comment on the degree to which the child's current neurobehavioral functioning at the age of 4 years deviates from normal, and potentially even relate it causally to known brain damage that was visualized on neuroimaging, but comments about whether or not the obstetrician acted negligently during the perinatal process should be avoided.

At some point—which can occur weeks to months after the evaluation—the PN may be asked to provide some kind of sworn testimony about the case. This can be in the form of a deposition, where only attorneys from both sides of the case plus a court recorder are present, or an actual courtroom appearance during trial in front of a judge and/or jury. Some depositions are videotaped for later presentation at trial in lieu of live testimony. It is far more common for PNs to participate in depositions than testifying in court because many cases get settled out of court.

Prior to a deposition or trial testimony, the PN should confer with the retaining attorney about the procedures and the specific issues that may come up. New information that was not available previously (e.g., what another expert had testified to or new records that became available) may be provided. If this alters the PN's opinions or conclusions about the case in any way, this should be made explicit at that time. Subsequently, during the actual deposition or trial, it is important to understand that the PN is primarily there to assist the jury or judge, during both direct and cross examination. Attorneys are supposed to argue a case for their client in a vigorous manner. Therefore, tough or challenging questions are to be expected and should most often not be taken personally. The most effective report or testimony comes from PNs who are (a) thoroughly prepared, with recent review of their own case file as well as awareness of the current state of the scientific literature on the condition of interest, (b) capable of prompt and active answering in a way that is responsive to the question while also addressing ambiguities or possible misperceptions, (c) calm and professional without being completely devoid of emotion, and (d) familiar with common courtroom strategies or gambits (see the "Documentation and Testimony" section). Part of being thoroughly prepared includes a good understanding of psychometric issues when considering a group of neuropsychological test results. One common mistake is to overinterpret

isolated "abnormal" findings that would be commonly found in the general population. The next section will address these issues and related pitfalls.

### **Identifying Cognitive Impairment Using (Multiple) Neuropsychological Tests**

Neuropsychological assessment most often entails the administration of multiple tests, which shifts the interpretation of test scores from a Gaussian or univariate distribution (used for considering performance on a single test score in isolation) to a multivariate one (used for simultaneously considering performance on multiple test scores). The need for a multivariate interpretation of test scores has risen from the knowledge that obtaining some low scores on a neuropsychological assessment is common and expected in a substantial minority of healthy people (Binder, Iverson, & Brooks, 2009), which has been repeatedly demonstrated using neuropsychological measures with children (Brooks, 2010; Brooks et al., 2013b; Brooks, Iverson, Sherman, & Roberge, 2010a; Brooks, Iverson, Sherman, & Holdnack, 2009; Brooks & Sherman, 2012; Brooks, Sherman, & Iverson, 2010b; Crawford, Garthwaite, & Gault, 2007; Hurks, Hendriksen, Dek, & Kooij, 2013).

When interpreting multiple test scores, the PN needs to understand several key concepts that differ from interpreting a single score in isolation. Five key concepts of multivariate test interpretation are presented in the following sections (see also Brooks & Iverson, 2012 for a thorough review). Understanding and incorporating these concepts is beneficial for diagnostic judgment. Failing to appreciate or consider these five multivariate concepts may lead to increased chances of misdiagnosis of cognitive impairment.

#### ***Test-Score Variability (Scatter) Is Common***

There is classic thinking in the field of neuropsychology that a healthy brain has consistency across all cognitive domains, whereas an injured brain has variability. In contrast, existing research indicates that healthy children and adolescents commonly display variability (or "scatter") across their test scores and considerable differences between their highest and lowest scores. Indeed, it is actually uncommon to *not* have scatter among test scores. For example, having all ten primary subtests from the Wechsler Intelligence Scale for Children–IV (WISC-IV; see Wechsler, 2003) fall within one standard deviation (SD) is found in only 0.4% of healthy children from the standardization sample. Having at least a six-scaled-score spread (i.e.,  $\geq$  two SDs) is found in as much as 73.4% of healthy children from the WISC-IV standardization sample. Even a nine-scaled-score spread (i.e.,  $\geq$  three SDs) is found in 22.5% of this sample. Interestingly, the amount of scatter may increase with more tests being administered (see Figure 2 in Brooks & Iverson, 2012) and may differ based on demographic characteristics, with boys

and those with higher full-scale IQs having more intersubtest scatter than girls and those with lower full-scale IQs (Hurks et al., 2013).

**The Number of Low Scores Depends on Where a PN Sets the Cutoff**

There is no single universally accepted definition of what constitutes cognitive impairment on objective neuropsychological tests. Without clear direction on what is cognitive impairment or how to quantify it, PNs are left to arbitrarily determine and use various cutoff scores as interpretive guidelines for identifying a score that is in the "impaired" range. As might be expected, the more stringent a cutoff score (i.e., further from the mean in a negative direction), the less likely it is for an obtained score to be considered in the range of impairment. The same principle holds true for interpretation of multiple test scores: The prevalence of low scores on a battery of tests will depend on where the cutoff for "impairment" is set, with more stringent cutoffs resulting in fewer scores in the "impaired" range.

Figure 39.1 presents a simple example of the inverse relation between cutoff score and prevalence of healthy youth with low scores. When considering the ten primary subtests from the WISC-IV, 61% of children have two or more subtest scores  $\leq$  25th percentile. The prevalence rate drops as the cutoff is set further from the mean, with only about 8% having two or more scores  $\leq$  2nd percentile.

**The Number of Low Scores Depends on the Number of Tests Administered**

A simple principle exists for neuropsychologists in any setting: The more tests administered, the more likely one will obtain low scores. This does not argue against a thorough and lengthy assessment when warranted, but it does argue for the inclusion of multivariate base rates (whenever available) as part of the interpretation of the battery of tests.

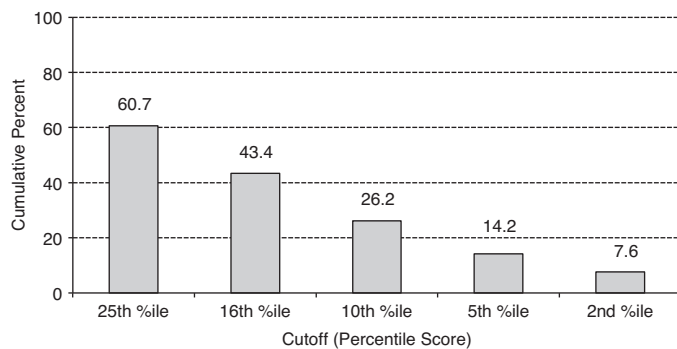

Figure 39.1 Percentage of healthy youth with two or more low WISC-IV subtest scores across various cutoffs

Note: Values were calculated from data provided in Table 1 in Brooks (2010)

Figure 39.2 Estimated percent of people with at least one low subtest score (< fifth percentile) when varying the length of a battery

Note: Percent of people with low scores was estimated using the Crawford et al. (2007) Monte Carlo program and an average intersubtest correlation of 0.3.

Figure 39.2 illustrates the prevalence of low scores across a battery with varying numbers of subtests, when considering all scores simultaneously. In this example, which was derived using a Monte Carlo estimation (Crawford et al., 2007) and an average intersubtest correlation of 0.3, having one or more scores below the fifth percentile is found in nearly 31% when considering ten subtests but only 9% when considering two subtests.

**The Number of Low Scores Varies by Examinee Characteristics**

Neuropsychological test performance relates to multiple examinee characteristics including age, gender, culture, language, and socioeconomic status. These relations partially form the basis for census-matched normative samples and demographic adjustments to standard scores. There are some factors, however, that are not accounted for in standard scores but can have an impact on the prevalence of low scores. For example, a child's level of intellectual functioning and a parent's level of education (which is related to a child's intelligence and socioeconomic status) can impact multivariate base rates.

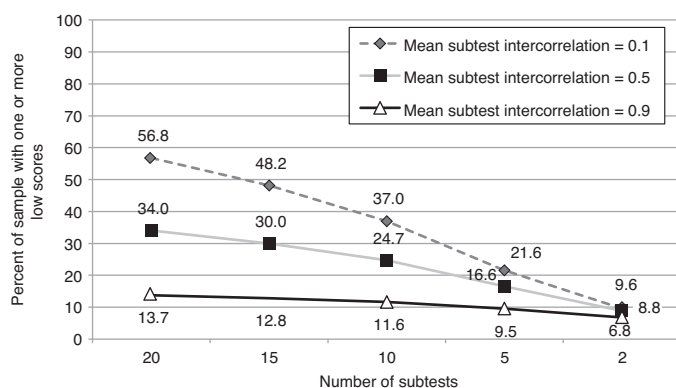

As noted previously, a study by Hurks and colleagues (Hurks et al., 2013) revealed that children with higher intelligence had more subtest variability or scatter on the Dutch Wechsler Preschool and Primary Scale of Intelligence—third edition (Wechsler, 2010) than children with lesser intelligence. However, children with lesser intelligence are expected to get more low scores than children with higher intelligence. For example, Brooks et al. (2009) showed that the prevalence of low memory scores increases as intellectual levels decrease. In those with below average intellectual scores, having one or more Children's Memory Scale (CMS; Cohen, 1997) index

score fall  $\leq$  fifth percentile is found in 33% of healthy youth. This is contrasted with only 3.5% of healthy youth with above average intellectual abilities having one or more CMS index scores  $\leq$  fifth percentile.

Parental education also has a relation with child neurocognitive functioning (e.g., Devlin, Daniels, & Roeder, 1997; Schoenberg, Lange, Brickell, & Saklofske, 2007; Schoenberg, Lange, & Saklofske, 2007; Thomas, Sukumaran, Lukose, George, & Sarma, 2007), which in turn has an impact on the prevalence of low scores found in youth. Brooks et al. (2010b) illustrated that 67.2% of 7–16-year-olds with parents having less than high school education had one or more low NEPSY-II scores ( $\leq$  fifth percentile) compared to 33.9% of those children with average parental education of at least an undergraduate degree. Similar findings with more low scores in those with lesser intellectual abilities were also reported for the WISC-IV (Brooks, 2010).

### Low Scores Are Common Across All Neuropsychological Tests

No neuropsychological test is immune to the presence of some low scores, even when administered to healthy children and adolescents. Several examples of multivariate base rates in pediatric neuropsychological batteries have been published (Brooks, 2010; Brooks et al., 2013b; Brooks et al., 2009; Brooks et al., 2010b; Crawford et al., 2007). Having some low scores is not an artifact of a specific standardization sample or a specific type of neurocognitive test. There are, however, differences in the prevalence rates of low scores depending on how strong the subtests are correlated. Figure 39.3 demonstrates an example of the percent of healthy people who would obtain one or more scores  $\leq$  fifth percentile if the mean intercorrelation ( $r$ ) was set at 0.1, = 0.5, or 0.9. When considering the multivariate base rates for 20 subtests, having one or more low scores is found in 57% when

**Figure 39.3** Estimated percent of healthy people who would obtain at least one low subtest score ( $<5$ th percentile) across different subtest intercorrelations

Note: Percent of people with low scores was estimated using the Crawford et al. (2007) Monte Carlo program

the mean  $r = 0.1$ , in 34% when the mean  $r = 0.5$ , and in 14% when the mean  $r = 0.9$ . Overall, the prevalence of low scores is higher when subtests have weaker intercorrelations, particularly when more tests are administered and interpreted (e.g., the prevalence rates start to converge with fewer subtests).

Currently, only a limited number of publications exist that can help the PN determine the multivariate base rates in a pediatric forensic assessment (Brooks, 2010; Brooks, Holdnack, & Iverson, 2011; Brooks, Iverson, & Holdnack, 2013a; Brooks et al., 2013b; Brooks et al., 2009; Brooks et al., 2010b). As such, the onus should be placed on test publishers to start producing this information as part of technical manuals and/or scoring programs. Some guidelines for the PN follow (Brooks & Iverson, 2012).

- The information on the prevalence of low scores is specific to the tests included in the analyses (i.e., one cannot substitute tests or index scores or apply a table to a different battery of tests) and to the number of tests included in the analyses (i.e., one cannot use the tables for more or fewer scores).
- When stratification by level of intelligence, parental education, or other demographic variable is not available, the PN may consider the prevalence of low scores in the entire sample. However, the PN needs to be aware that the prevalence rates are likely higher for lower functioning children and lower for higher functioning children.
- Some caution is warranted when interpreting the prevalence of low scores for a single battery or a single domain in isolation from the rest of the measures in a lengthy neuropsychological assessment (i.e., the base rates increase with more tests administered).
- Knowing the prevalence of low scores is designed to supplement, *not replace*, clinical judgment. Like any other psychometric information that is provided for test-score interpretation, the PN needs to make a determination based on all pieces of information and in the context of the specific details of the case.
- Having a common number of low scores does not mean that a low score cannot represent a relative weakness for a patient.

Consideration of these fundamental psychometric issues is not the only thing that is important in the interpretation of test results during a pediatric forensic neuropsychological evaluation. Consideration of validity issues is another crucial step.

### Validity Testing

Neuropsychological test interpretation rests upon the assumption that the examinee responded in an unbiased fashion during the exam. If a child provides noncredible effort during testing or overreports symptoms, the resulting

data will represent an inaccurate representation of the child's true abilities and/or difficulties. Reliance on such data can lead to a host of problems for the PN, including interpretive errors, inaccurate diagnostic and etiologic conclusions, mischaracterization of brain-behavior relationships, and possibly inappropriate recommendations. Thus, the incorporation of objective validity tests to detect invalid responding is crucial during all forensic evaluations. PNs should keep in mind, however, that the motivation to feign or exaggerate is typically complex in children, and failure on a validity test cannot be equated simplistically with "malingering." Motivations for invalid responding can be driven by both conscious and unconscious processes and include attempts to obtain external incentives and/or to fulfill internal psychological needs (Boone, 2007). In children, the motivations underlying noncredible performance are quite diverse, even in clinical populations (Kirkwood, Kirk, Blaha, & Wilson, 2010). In forensic settings, motivations are likely to be even more challenging to discern, with some children likely feigning in an attempt to seek indirect approval or attention from family members and others acting more directly to achieve an external incentive, either on their own accord or after explicit caregiver coaching or coercion (see section on Malingering, later in this chapter).

The frequency with which adults provide invalid test results during forensic evaluations is well studied, with rates as high as 40% across a variety of compensation-seeking contexts (Mittenberg, Patton, Canyock, & Condit, 2002). Relatively little attention was paid historically to how often noncredible presentations occurred during pediatric neuropsychological evaluations. However, over the last ten years, individual case reports and larger case series have documented clearly that children can, and do, underperform or even feign and/or exaggerate problems during both clinical and forensic neuropsychological evaluations.

In clinical settings, multiple case series across a host of populations have consistently found that a small percentage (~5%) of general pediatric outpatients perform suboptimally because of effort-related problems (Brooks, 2012; Carone, 2008; Donders, 2005; Kirk et al., 2011; MacAllister, Nakhutina, Bender, Karantzoulis, & Carlson, 2009). Certain pediatric clinical populations are apt to present in a noncredible fashion more frequently. For example, in a mild TBI case series consisting of children and adolescents referred exclusively for clinical evaluation, 17% of the sample failed an objective validity test, which was the same percentage estimated to have put forth noncredible effort more broadly across the exam once possible false positives and false negatives were taken into account (Kirkwood & Kirk, 2010).

In forensic settings, multiple authors have also presented individual cases of children providing noncredible effort, both when the child was likely acting independently and at the behest of a caregiver (Chafetz & Prentkowski, 2011; Flaro & Boone, 2009; Henry, 2005; Lu & Boone, 2002; McCaffrey & Lynch, 2009). No identified case series have

reported how often biased responding occurs in pediatric civil litigation contexts but a surprisingly high rate of validity test failure has been found in the only compensation seeking context that has been studied. During determination evaluations for U.S. Social Security Disability benefits, Chafetz and colleagues found that 28% to 37% of children failed objective validity tests (Chafetz, 2008; Chafetz, Abrahams, & Kohlmaier, 2007). Similarly, no identified studies have examined the base rate of response bias during pediatric independent educational evaluations. However, studies with university students seeking accommodations for learning disabilities or attention deficit/hyperactivity disorder (ADHD) raise serious questions for PNs conducting such evaluations, as the rate of invalid responding in these young adults has been found to be between 15% and 30% (Harrison, Rosenblum, & Currie, 2010; Suhr, Hammers, Dobbins-Buckland, Zimak, & Hughes, 2008; Suhr, Sullivan, & Rodriguez, 2011; Sullivan, May, & Galbally, 2007).

The incorporation of validity tests into neuropsychological evaluations has been endorsed strongly by various professional neuropsychological organizations (Bush et al., 2005; Heilbronner, Sweet, Morgan, Larrabee, & Millis, 2009), although an endorsement specifically for PNs has yet to be provided. Variance in pediatric neuropsychological ability-based test performance is also known to be accounted for to a considerable degree by validity test results. For example, in a pediatric mild TBI sample, validity test performance was correlated significantly with performance on all ability-based tests and explained more than a third (38%) of the variance on an ability-based test summary index (Kirkwood, Yeates, Randolph, & Kirk, 2012).

The two primary objective methods to evaluate the validity of an individual's neuropsychological data are (a) stand-alone or embedded performance validity tests (PVTs) that measure response validity using performance-based tests and (b) symptom validity tests (SVTs) that measure response validity during self-report instruments (Larrabee, 2012). Of course, responses from any validity test depend in part on the particular demands of the task and can vary for a multitude of reasons, including true cognitive impairment and temporary fluctuations in arousal, attention, emotional state, and effort. Determining whether a child is responding more broadly in an invalid fashion not only requires careful examination of validity test performance but also a solid understanding of the natural history of the presenting condition; scrutiny of the child's developmental, medical, educational, and environmental background; and thorough consideration of the consistency and neuropsychological plausibility of the behavioral, self-report, and test data.

### ***Performance Validity Tests***

A review of all PVTs that have been studied with children is beyond the scope of this chapter. However, as highlighted in Table 39.2, and discussed in more detail in Kirkwood (2012),

Table 39.2 Empirical evidence estimates for performance validity tests in pediatric populations

Test	Strength of Empirical Evidence in Various Pediatric Samples			
	Community samples	Clinical samples	Secondary gain samples	Simulation samples
Amsterdam Short-Term Memory Test (ASTM)	+	-	-	-
Automatized Sequencing Task	-	+	-	-
California Verbal Learning Test–Children’s Version	-	+	-	-
Computerized Assessment of Response Bias (CARB)	-	+	-	-
Fifteen Item Test (FIT)	+	+	-	-
Medical Symptom Validity Test (MSVT)	+	++	+	++
Nonverbal Medical Symptom Validity Test (NV-MSVT)	-	+	-	-
Test of Memory Malinger (TOMM)	++	++	+	+
Symptom Validity Scale for Low Functioning Individuals	-	-	+	-
Victoria Symptom Validity Test (VSVT)	-	+	-	-
Word Memory Test (WMT)	+	++	-	+

Note: ++ adequate evidence base;

+ modest evidence base;

- no or conflicting evidence

Adapted (with permission) from Kirkwood (2012).

at least two of them have received enough empirical attention in children that they could be justified for use by the PN during a forensic evaluation, at least with certain populations. Specifically, the Test of Memory Malinger (TOMM; Tombaugh, 1996) and the Medical Symptom Validity Test (MSVT; Green, 2004) have the most validation evidence for this specific purpose, at this time.

The TOMM has been investigated in child samples more than any other PVT including with community-based populations (Constantinou & McCaffrey, 2003; Rienstra, Spaan, & Schmand, 2010), a wide variety of clinical samples (Brooks, Sherman, & Krol, 2012; Donders, 2005; Gast & Hart, 2010; Kirk et al., 2011; MacAllister et al., 2009; Perna & Loughan, 2013), a secondary gain sample (Chafetz et al., 2007), and children asked to simulate impairment (Blaskewitz, Merten, & Kathmann, 2008; Gunn, Batchelor, & Jones, 2010; Nagle, Everhart, Durham, McCammon, & Walker, 2006). Collectively, these studies indicate that TOMM performance may be very modestly affected by age or IQ but that the vast majority of school-aged children can score above "adult" pass/fail cutoffs when providing adequate effort. Recent work indicates that administering only Trial 1 of the TOMM may be sufficient in certain clinical situations (Brooks et al., 2012; Perna & Loughan, 2013), although more work is probably needed in this regard before Trial 2 can be comfortably disregarded during forensic evaluations.

Several independent studies have also included the MSVT in pediatric samples. One focused on a clinical population of children with significant neurologic or developmental problems (Carone, 2008), several have been from an overlapping case series of patients with mild TBI (Kirkwood & Kirk, 2010; Kirkwood, Connery, Kirk, & Baker, 2014; Kirkwood,

Yeates, Randolph, & Kirk, 2012), one has included a secondary gain context (Chafetz et al., 2007), and one used a simulation design (Blaskewitz et al., 2008). One of the MSVT's clear strengths is its brief administration time, which makes it a good candidate for a screening validity test. Normative data and a growing body of independent work suggest that the vast majority of children who can read at a third-grade level or higher can pass using adult cutoffs. Some pediatric data (Blaskewitz et al., 2008; Nagle et al., 2006) indicate that it may be more sensitive than the TOMM. Further independent research will be necessary to examine specificity in pediatric patients with significant deficits and to establish the classification utility of profile analysis in child samples.

### Self-Report Validity Tests

Numerous pediatric self-report instruments include validity scales designed to detect symptom exaggeration. Commonly used measures in pediatric neuropsychological evaluations that contain a "fake bad" scale include general personality instruments such as the Minnesota Multiphasic Personality Inventory–Adolescent (MMPI-A, Infrequency scale), Personality Inventory for Youth (PIY; Dissimulation Scale), and Behavior Assessment System for Children–second edition (BASC-2, F Index), as well as domain- and disorder-specific scales such as the Behavior Rating Inventory of Executive Function–Self-Report (Negativity scale) and Trauma Symptom Checklist for Children (Hyperresponse scale). Each of these scales has solid normative data and at least adequate psychometric properties. Nevertheless, to date, very little to no independent research has focused on the utility of the validity indices in particular.

A few studies have provided initial support for the MMPI-A in identifying feigned psychopathology (Baer, Kroll, Rinaldo, & Ballenger, 1999; Lucio, Duran, Graham, & Ben-Porath, 2002; Rogers, Hinds, Sewell, 1996; Stein, Graham, & Williams, 1995). One study also provided support for the PIY Dissimulation Scale in identifying feigned emotional distress and psychosis (Wrobel, Lachar, Wrobel, Morgan, & Gruber, 1999). However, these studies have focused on simulators, so the value of the scales to detect exaggerated or feigned complaints in real-world examinees remains largely unknown. Moreover, none of the studies were conducted with individuals presenting for neuropsychological evaluation, so their applicability to children who may be more likely to present with physical or cognitive complaints, rather than psychiatric problems, is uncertain.

The only identified study that has focused on the value of an SVT in a neuropsychological setting examined the relationship between the BASC-2 Self-Report of Personality validity scales and the MSVT in a pediatric mild TBI sample (Kirk, Hutaff-Lee, Connery, Baker, & Kirkwood, 2014). Somewhat unexpectedly, no relationship was found between those children identified as responding invalidly via the BASC-2 and those failing the MSVT. The results of this pediatric study indicate that relying exclusively on the BASC-2 validity scales as an indication of the validity of the overall neuropsychological data will almost certainly significantly underestimate the percentage of patients providing invalid data during evaluation. Thus, the study reinforces the value of adding objective PVTs to the neuropsychological evaluation of school-age patients and also highlights the importance of future research into SVTs for nonpsychiatric pediatric populations. Unfortunately, at this point, PNs simply do not have any empirically backed SVTs to choose from when they want to detect the overreporting of health-related problems rather than psychiatric concerns.

In general, it is advisable to include both PVTs and SVTs during pediatric forensic neuropsychological evaluations. However, one of the most significant challenges that the PN may face pertains to the identification and reporting of deliberate poor performance, and the possibility of malingering.

## Malingering

Malingering is a behavior, not a clinical disorder. In *the Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; American Psychiatric Association, 2013), it can be found with other behaviors classified under “Non-adherence to Medical Treatment.” Conceptualizing malingering as a form of nonadherence to neuropsychological assessment is also a useful way of helping clinicians maintain a behavioral, nonjudgmental approach to detection and interpretation. DSM-5 notes that malingering can at times be an adaptive behavior; the reality is that examinees may malingering for a variety of reasons that may or may not be

available to the PN, whose job is to maintain professionalism and objectivity at all times.

Over the last two decades, various definitions and criteria for malingering of cognitive problems have been proposed for application in neuropsychology. However, the Slick, Sherman, and Iverson (1999) criteria continue to stand the test of time as the most commonly used definition, and the definition with the most empirical basis (e.g., Larrabee, 2012). In the Slick et al. framework, the term *malingered neuropsychological dysfunction* (MND) was defined as “the volitional exaggeration or fabrication of cognitive dysfunction for the purpose of obtaining substantial material gain, or avoiding or escaping formal duty or responsibility” (Slick et al., 1999, p. 552).

From a pediatric perspective, the Slick et al. (1999) criteria posed some problems. First, the criteria made only a cursory reference to situations involving malingering behavior in vulnerable examinees. Children or adolescents may exaggerate symptoms for material gain, but they do not necessarily have the ability to appreciate the consequences of their actions, whether a coercing adult is involved or not. On a more general level, the criteria were unclear regarding situations where malingering and bona fide impairment coexisted and whether the presence of another disorder would invalidate the presence of malingering. Finally, there was a need for more coverage regarding the diagnostic utility of self-reported symptoms and more explicit inclusion of compelling inconsistencies (Bianchini, Greve, & Glynn, 2005).

Slick and Sherman (2012) therefore proposed an update of these criteria (Table 39.3). The main changes were to divide malingering into three subcategories, namely, (a) *primary MND*, which essentially reflects the 1999 definition of MND; (b) *secondary MND*, for situations where MND is attributable to immaturity or developmental, neurological or psychiatric disorder; and (c) *MND by proxy*, where MND is attributable to the influence of another person on a vulnerable examinee, typically a child.

MND by proxy is poorly understood. To date, three cases of malingering of cognitive problems by proxy have been reported in the literature, two litigating and one seen as part of a Social Security Disability evaluation (Chafetz & Prentkowski, 2011; Lu & Boone, 2002; McCaffrey & Lynch, 2009). However, some settings may be associated with high rates. Chafetz and Prentkowski (2011) stressed that it is parents who arrange and carry out the plan to deceive in order to gain monetary awards on their children’s behalf, presumably by coaching children.

As in the earlier 1999 criteria, MND, secondary MND, and MND by proxy can be coded in terms of certainty, namely *definite*, *probable*, and *possible* MND. Definite MND is defined by the presence of either (a) below-chance performance on forced-choice measures, (b) high posterior probability ( $\geq 0.95$  that performance is substantially below actual ability level) on one or more well-validated psychometric indices, and (c) self-reported symptoms that are

Table 39.3 Proposed diagnostic criteria for malingered neuropsychological dysfunction, a revision and extension of the Slick et al. (1999) criteria for Malingered Neuropsychological Dysfunction

---

Primary MND

---

*Definite*

- 1 Presence of a substantial external incentive for exaggeration/fabrication of symptoms (Criterion 1)
- 2 One or more very strong indicators of exaggeration/fabrication of neuropsychological problems or deficits (one or more of Criteria 2.1–2.3)
- 3 Behaviors meeting necessary criteria are not substantially accounted for by psychiatric, neurological, or developmental factors

*Probable*

- 1 Presence of a substantial external incentive for exaggeration/fabrication of symptoms (medical-legal secondary gain)
- 2 Three or more indicators of possible exaggeration/fabrication of neuropsychological problems or deficits (three or more of Criteria 3.1–3.7)

*Secondary MND (Definite and Probable)*

Criteria for definite or probable malingered neuropsychological dysfunction (MND) are otherwise met, but there are compelling grounds to believe that at the time of assessment the examinee did not have the cognitive capacity to understand the moral/ethical/legal implications of his or her behavior, and/or was unable to control his or her behavior, secondary to immaturity (i.e., in childhood) or bona fide developmental, psychiatric, or neurological disorders or injuries of *at least* moderate severity. Secondary malingering cannot be diagnosed in persons with mild conditions such as mild TBI.

*MND by Proxy (Definite and Probable)*

Criteria for definite or probable MND are otherwise met, but there are compelling grounds to believe that a vulnerable examinee acted primarily under the guidance, direction, influence, or control of another individual. Examinees may be vulnerable to the influence of others by virtue of immaturity, neurodevelopmental and cognitive disabilities, and psychiatric illness, or by perceived inability to escape or avoid substantial coercion such as threats of physical harm for failure to behave as directed.

*Specific Criteria*

- 1 Presence of a substantial external incentive for exaggeration/fabrication of symptoms (medical-legal secondary gain)
  - 2 Very strong indicators of exaggeration/fabrication of neuropsychological problems or deficits
    - 2.1 Below chance performance ( $\leq 0.05$ ) on one or more forced choice measures
    - 2.2 High posterior probability ( $\geq 0.95$  that performance is substantially below actual ability level) on one or more well-validated psychometric indices
    - 2.3 Self-reported symptoms are unambiguously incompatible with or directly contradicted by directly observed behavior and/or test performance
  - 3 Possible indicators of exaggeration/fabrication of neuropsychological problems or deficits
    - 3.1 Data from one or more well-validated psychometric measures, while not sufficient to meet Criteria 2a or 2b, are on balance more consistent with non-compliance than compliance
    - 3.2 Marked and implausible discrepancy between test performance and level of function expected based on developmental and medical history
    - 3.3 Marked and implausible discrepancy between test performance and directly observed behavior and capabilities
    - 3.4 Marked and implausible discrepancy between test performance and reliable collateral reports concerning behavior and capabilities
    - 3.5 Marked and implausible discrepancy between self-reported and documented history, consistent with exaggeration of preinjury level of function and capabilities, minimization or preexisting injuries or neuropsychological problems, and/or exaggeration of the severity of new injuries
    - 3.6 Marked and implausible discrepancy between self-reported symptoms and level of function expected based on developmental and medical history
    - 3.7 Marked and implausible discrepancy between self-reported symptoms and information obtained from reliable collateral informants
- 

unambiguously incompatible or directly contradicted by directly observed behavior and/or test performance. In practical terms, this means that *definite malingering* can be defined only by below-chance performance on a PVT or observation of behaviors incompatible with reported symptoms (e.g., surveillance video of a child walking despite complaints of complete paralysis). Presumably an actual confession by the child would also be sufficient. The term can also be applied when a well-validated Bayesian model that uses multivariable input, such as scores from one or more tests that provide

positive predictive values of malingering, indicates that the positive predictive power for a given examinee is equal to or greater than 0.95. Any compelling evidence for malingering that falls short of these possibilities must therefore be termed *possible malingering*.

Importantly, avoiding false positives should be the goal in identifying cases of MND, as it should be when using PVTs and SVTs. In adults, failure on two PVTs is associated with exceedingly low rates of false positive errors, with failure on three PVTs associated with essentially nil chance

of a false positive identification of MND (Larrabee, 2012). In children, this has yet to be empirically determined. However, a good rule of thumb would be to identify MND only when at least two PVTs are failed, at minimum. Ideally, PNs would use measures with embedded validity indicators, in addition to stand-alone validity tests. In the end, the PN must identify a *reason* for the questionable or invalid test results. This is where the differentiation of MND from other conditions occurs. A number of different conditions should be considered before attributing underperformance to malingering.

### ***Conversion Disorder or Functional Neurological Symptom Disorder***

Conversion disorder, also known in DSM-5 as "Functional Neurological Symptom Disorder" and included under the broad category of "Somatic Symptom and Related Disorders," involves voluntary motor or sensory symptoms that are incompatible with recognized neurological or medical conditions, are not better explained by another condition, and cause impairment and distress. The earlier criterion from DSM-IV that symptoms not be feigned, or not intentionally produced, is no longer needed in DSM-5—likely because establishing causality and veracity was too fraught with difficulty. Children with conversion disorder will rarely be encountered in clinical practice by most PNs most of the time, unless they work in settings where unexplained medical symptoms are more common, such as movement disorder clinics or epilepsy-monitoring units, where a subgroup of children may present with unexplained paralysis or nonepileptic seizures. Most importantly, cognitive symptoms are *not* included under the diagnosis of conversion disorder, although some experts believe they should have been (Stone et al., 2011). Because of this, conversion disorder is no longer a condition that needs to be frequently considered in the differential diagnosis of feigned/implausible cognitive deficits or self-reported cognitive symptoms, although it can certainly co-occur with feigned or intentionally produced symptoms, according to the DSM-5 reformulation.

### ***Factitious Disorder Imposed on Self, and Factitious Disorder Imposed on Another***

Factitious disorder is the fabrication of physical or psychological symptoms, in order to deceive, without the necessary presence of external rewards. The DSM-5 formulation divides factitious disorder into two separate subcategories: *factitious disorder imposed on self*, and *factitious disorder imposed on another*. The latter replaces "factitious disorder by proxy." Of note, the presence of material gain or external incentives does not rule out factitious disorder, and so this may be a diagnosis to consider in cases where internal as well as external incentives are involved. Factitious disorder

should not be diagnosed in the presence of another mental disorder that better accounts for symptoms (e.g., delusional or psychotic disorders).

### ***Illness Anxiety Disorder***

Illness anxiety disorder bears considering here as well, even though it does not technically involve exaggerated or feigned cognitive problems. Instead, persons presenting with illness anxiety disorder have an intense fear about having a disorder. DSM-5 defines illness anxiety disorder as a preoccupation with having or acquiring a serious illness, without any physical symptoms, or else preoccupation in excess to symptoms. The main symptom is excessive preoccupation with health, not accounted for by other disorders such as generalized anxiety disorder or obsessive-compulsive disorder. For example, illness anxiety disorder may involve overreporting of cognitive symptoms due to overvigilance and anxiety, rather than deception or feigning, and therefore children with this condition may produce invalid or questionable results on SVTs due to excessive symptom reporting. Other reasons for overreporting of symptoms may involve attention seeking, hypervigilance, or catastrophizing of symptoms. The prevalence of illness anxiety disorder in children and adolescents is unknown.

Determination of whether or not the test data are valid, and whether or not the criteria are met for either malingered neuropsychological deficit or another condition associated with underperformance or overreporting of symptoms, is a key responsibility of the PN. The next step is to develop the ability to convey information about the validity and implications of the assessment findings in a report and during deposition or trial testimony.

### **Documentation and Testimony**

No deposition or trial is the same. However, we want to illustrate some common questions, tasks and scenarios that the PN often has to deal with when doing forensic work. As neuropsychologists, we do not presume to offer formal legal advice. In addition, our intent is not to provide tips for how to "win." Instead, we simply offer options for various strategies that respect the integrity of the legal process while also assuring that the judge or jury is presented with the most accurate and complete information. The following is not an exhaustive list of suggestions for dealing with every possible forensic deposition or courtroom strategy or dilemma that a PN may encounter. Only some of the most common ones that often arise in the context of civil litigation regarding personal injury, special education eligibility, and/or medical malpractice involving children are reviewed. For more specific suggestions about testifying during depositions or trials, the reader is referred to Greiffenstein and Kaufmann (2012), Tsushima and Anderson (1996) and the series of books by Brodsky (1991, 1999, 2004).

1 *Be clear about who, what, and when.*

A report should state who retained the PN and which side of the legal dispute this attorney represented. Sometimes listing all the records that were made available can be helpful, but at a minimum, specific records should be identified when information is included in the report (e.g., that the Glasgow Coma Scale score was mentioned in the emergency room report of a certain date). If potentially important information is not available (e.g., school records from before alleged mold exposure), it should be explained how this limits the ability to draw firm conclusions about the available data. If information becomes available at some later point and if that alters the PN's opinions (e.g., a novel record pertaining to a history of bacterial meningitis, well before any lead was detected in the blood of the child), this should be documented in an addendum to the report. Documentation of informed consent/assent should also be included at the beginning of the report.

2 *Keep written documentation objective.*

The PN should maintain a neutral tone in the report, avoiding "crusader" comments to bolster one side of the case, and also avoiding emotional overtones, particularly when expressing disagreement with the opinions of another expert, or when pointing out discrepancies between objective documents and observed examinee behaviors. For example, instead of saying:

"The mother denied any history of premorbid adjustment problems, which is a lie."

The PN would likely be better off stating that:

"John's mother reported no premorbid problems with John. However, this was inconsistent with the available school records, which documented a long history of detentions, preceding the motor vehicle accident in question by more than a year."

Similarly, instead of attacking another provider with pejorative remarks about his or her level of training, board certification status, or experience, the PN should, both in documentation and during sworn testimony, maintain the high road. For example, instead of saying:

"Dr. Jones was certified by a vanity board, plus I have ten more publications than he does about lead poisoning, so my opinion should weigh more."

a preferred approach might be:

"I will leave it up to the jury to decide about Dr. Jones' credentials, but I feel very confident about mine, as I do about my conclusions, which are simply based on the objective facts of the case."

3 *Keep the written documentation intelligible.*

A report should offer scientifically sound interpretations and conclusions, not speculation to favor one

side of the case. In addition, it should be phrased in a manner that is empirically accurate but clear to the judge or jury, who most likely do not have a background in clinical neuropsychology. For example, about an examinee who failed the MSVT, a PN who is used to communicating with other psychologists could write:

"The examinee's performance on a standardized forced-choice performance validity measure was not consistent with veracious effort because of the violation of empirical criteria and therefore indicative of a high probability of deliberate symptom magnification for secondary gain."

However, a more effective way of documenting this for a judge or jury might be:

"On a task where the chance of getting the right answer was equal to the flip of a coin, Jane answered correctly only 25% of the time. A person who had never seen the words on the computer screen, and just guessed, would most likely have done better than that. Therefore, I must conclude that Jane's test results do not show her true mental ability."

4 *Be well-prepared.*

One of the worst mistakes a PN can make with regard to sworn testimony is to not be intimately familiar with the facts of the case, the contents of his or her file, and the standard of care and consensus literature regarding the condition of interest. Particularly if the examination was done a considerable time in the past, the PN should again review relevant case information. Meeting with the retaining attorney prior to the deposition or trial is highly advisable. The PN should always make available a copy of his or her current CV. Particularly in federal cases, it is also advisable to have access to a list of all the depositions/trial testimonies that the PN has given over the past several years, along with a breakdown of plaintiff v. defense, when possible.

5 *Set limits.*

The time required for a deposition should be made clear in advance, in order not to jeopardize other professional activities that the PN has that day. It is perfectly reasonable for the PN to limit this to anywhere from 2 to 4 hours. When called to testify in court, it is the responsibility of the retaining attorney to make the time schedule as convenient as possible. It is also advisable to request a nonrefundable retainer fee before depositions, because sometimes these get cancelled on very short notice. During sworn testimony, the PN will be expected to answer any reasonable questions about the case at hand. However, in the rare event that questions are viewed as entirely irrelevant or objectionable (e.g., about the PN's private life), then the PN can ask for a decision

from the judge before answering. In court, this can be done by turning directly to the judge. During a deposition, the PN may decline to answer any further questions on the topic at hand until a ruling from the judge on the need to answer has been issued.

**6** *Understand that it is not about you.*

Although there is no universal agreement on courtroom dress code, standard business or business casual is typically advisable. The PN should realize that typically, he or she is only one of a number of experts to be called and that the deposition or trial is not for purposes of bringing attention to his or her appearance or for puffing up one's own ego but about helping the trier of fact. This may be particularly important when, at the beginning of the testimony, a review of the PN's credentials is sought. Although the entire 20+ page resume may be very interesting to the PN, the jury will likely only need to hear something like:

"I obtained my PhD from the University of X, did my internship at Y hospital, and my residency at Z medical center. I am licensed as a psychologist, and am board-certified in the specialty of clinical neuropsychology, which deals with brain-behavior relationships. TBI is an area of subspecialty for me because it is the condition I see relatively most often."

**7** *Don't come across as defensive.*

It is common to be asked in what percentage of cases the PN testifies for the defense or plaintiff. It is best to simply provide that breakdown, and not to elaborate too much about it. However, if forensic work is only a relatively small proportion of the PN's activity, this can be explained as well. It is a myth that only those who have a 50/50 balance in plaintiff *v.* defense work will be seen as believable. However, it may help to put the information in context. For example:

"More than 85% of all the clinical work that I do is based on referrals by doctors. Of the 15% of medicolegal work that I do, I am retained by the defense in the majority of cases."

Or:

"In all the depositions over the last three years, I testified as a treating doctor by plaintiff request ten times, and as an expert witness upon request by the defense 20 times. Keep in mind that when, as an expert witness, I arrive at an opinion that does not support their side, they often settle the case instead of having me testify."

When the PN does not know the answer to a question, it is best to simply acknowledge this. Long-winded, extemporaneous answers should be avoided. The PN may also be asked about fees. Again, it is simply best to provide those. However, if insinuations are made about objectivity, the PN should deal with

those while answering in a matter-of-fact manner. For example, assume a treating clinician/fact witness was asked: "You would say anything here to help your patient, right?" An unfortunate answer would be something like:

"I am her doctor and I have been taking care of her for years, so of course I want what's best for her!"

Instead, a more effective answer would be:

"I have sworn to tell the truth, and I take that oath seriously. I will answer any reasonable questions to the best of my ability. What specific question do you have for me about Jane?"

Similarly, assume an independent examiner/expert witness was asked: "You are being paid for your opinion here, today, right?" An unsatisfactory answer would be:

"Well, yeah, I guess—I mean, I hope so. And there's nothing wrong with charging more for depositions because everybody does that!"

In contrast, a more convincing answer would be:

"I expect to get paid today for my time. I have been hired for my expertise, not for a specific opinion."

**8** *Listen and answer actively.*

When attorneys pose questions or rephrase previous statements made, the PN should start by listening very carefully. If the question is not clear or too convoluted, ask that it be clarified. Any inaccuracies or mischaracterizations of previous testimony or about the consensus in the field should be immediately corrected, in a neutral voice. The PN should look at the attorney during the question but at the camera or jury when answering. The answer should be given with confidence, avoiding terms like "I believe" or "I suppose." Instead, calmly state one's objective, professional opinion. The latter should also be done succinctly. A common mistake for those PNs who are new to the process is that they talk too much, and lose the interest of the jury. Instead, they should just answer the question, elaborating only to make a crucial point of clarification. Referencing scientific literature can be helpful, as long as it is done objectively and not too broadly. For example, rather than stating that:

"The literature suggests that there are no long-term sequelae whatsoever of mild TBI."

It may be better to be more specific by saying:

"The most comprehensive, recent reviews in the literature, such as done by Babikian and colleagues out of UCLA, suggest that the vast majority of children with uncomplicated mild TBI do not have any long-term deficits, and that in those who do, there are almost always preexisting or other factors that are unrelated to the brain and that influenced recovery."

Humor can be used occasionally during answering questions but only very sparingly, and preferably not at the expense of the opposing attorney (i.e., no lawyer jokes) or anything that might be construed as derogative with regard to the child or parents. It is acceptable to repeat something to make a specific point, but again this should be done sparingly, in order to avoid coming across as argumentative or closed-minded. If opposing counsels argue amongst themselves about particular objections or other legal procedures, the PN should stay out of it and let them come to an agreement. In a courtroom, it is perfectly permissible to turn to the judge for guidance before answering a question.

**9** *Stay within your areas of expertise.*

If the PN is asked about data or records that are not within his or her area of expertise, this should be simply stated and further comment should be refused. For example, it is permissible to acknowledge that the child broke multiple bones in the accident but the PN should not offer expert opinions about measures of bone density or the surgical technique used to repair the fractures. Sometimes, peripherally related information may be introduced that has the potential to confuse or mislead the judge or jury. In that case, the PN should address this by bringing the focus back on topics related to neuropsychology. For example, pictures of the car may be shown in which the child sustained an uncomplicated TBI, along with close-ups of specific damage to the car, in an apparent attempt to suggest the presence of a more significant neurological injury. One proper way to address this would be:

“These pictures tell me a lot about that car; it looks pretty banged up and I doubt that it is still drivable. But then again, I am not an expert on cars. More importantly, these pictures tell me nothing about the child or how serious the injuries were that he sustained. For that, I have to rely on the emergency room records.”

**10** *Be aware of binary questions.*

It is not uncommon for a PN to be asked to answer a question with “yes” or “no.” If this can be done easily and unequivocally, then the requested type of answer should be provided. If not, then the PN should say so and express a need to elaborate briefly. In addition, a specific way of answering such questions in an active manner would be to use dependent clauses at the beginning of the answer, such as “although” or “whereas.” For example, let’s assume the question is phrased as: “Are there a lot of children who were never exposed to lead who have learning disabilities—yes or no?” A passive answer would be: “Yes.”

Instead, an active answer would be:

“Although it is indeed possible for children to have a learning disability in the absence of any lead poisoning, my review of John’s school records—both before and after the lead exposure—clearly suggests a significant drop in standardized test scores. Given the fact that there were no other complicating factors, I consider it most likely that the lead poisoning was responsible for that decline.”

This is what Brodsky (1991) calls the admit/deny technique. The first part of the answer specifically admits the true component of the question but the second part confidently denies any untrue implications that might result from a passive or binary answer. A related way of answering is what Brodsky calls the push/pull technique, which means that when the attorney pushes, the PN answers by pulling in the same direction while immediately providing important additional information. For example, the PN may be asked: “Did you even bother to talk to this child’s teacher, or to her coach, who will both be called to testify in this case? Did you?” A defensive and likely ineffective reaction would be:

“Well no, there really was not any time for that. I had a lot of tests to do.”

Instead, a more effective way of answering would be to “pull” the example in a more extreme direction and then to “push” back by qualifying the statement. Something like:

“Not only did I not talk to her teacher or her coach, I also did not call her grandmother or her parish priest. I talked to her, and to her parents, and I read her school and medical records, just like I would with any other child I saw in my office.”

**11** *Address successive yes/no questions.*

Sometimes, the PN may be asked a series of questions that may seem innocent and then get into a pattern of responding “yes” or “no” to each one. It remains important to listen carefully to each new alternative because it would not be unusual for one term or possibility to be thrown in that the PN would otherwise not agree with. In addition, it may be prudent to preface one’s answer by putting it in context. For example, if a PN were asked: “Can children with TBI have problems with amnesia? With intense headaches? With gross irritability? With . . . ?” it would be inadvisable to simply answer “Yes” to each item. Instead, a more active and effective way of answering might be:

“Let’s first be clear about what we’re talking about—severe TBI or mild TBI, which is what Jane had? And are we talking about right after injury or more than a year later, like we are now? I ask, because my answers would be different.”

**12** *Deal with the alleged superiority of the treating doctor.*

Sometimes, an independent expert PN for the defense may be challenged by plaintiff's counsel that "their" doctor has been seeing the child for medical care or psychotherapy on multiple occasions, instead of only a one-time evaluation by the PN. Again, the PN should not get defensive about this but simply restate the basis for his or her professional opinion. For example:

"I respectfully disagree that just because Dr. Jones has seen John more than once makes him a better judge of his current status. Two different radiologists have read John's CT and MRI scans as entirely unremarkable. That makes no difference, regardless of whether or not they knew John from before the accident. Furthermore, Dr. Jones did not perform the comprehensive assessment of John's mental abilities that I did. Those data were objectively compared to John's peers and they pretty much speak for themselves: They are all within normal limits."

**13** *Answer the question: "Is it authoritative?"*

A PN may be asked during cross-examination whether the work of a particular author is familiar and whether it would be considered "authoritative." Simply saying "yes" to that question can be misconstrued as deferring to any opinions that are stated in that particularly referenced work, with excerpts sometimes presented out of context. Instead, the author or the work can be acknowledged, while still making it clear that this does not mean that the PN simply defers to it. An effective answer might be:

"I have Dr. Jones' book in my office. I have even found it occasionally helpful, just like I rely on many other books and articles to stay informed about the field of lead poisoning, but that does not mean that I necessarily agree with everything Dr. Jones has written. Which particular part of her book do you want me to comment on? I would just need a minute to read that part again."

**14** *Answer the question: "Is it possible?"*

Another common scenario is that the PN is asked if it is "possible" that this particular child might have a certain symptom or condition. Simply acknowledging that something is "possible," without further qualification, may be perceived or misconstrued as supporting a position that may not actually be the PN's opinion. For example, in response to the question: "Isn't it possible, doctor, to have neuropsychological problems for several years after TBI?" the PN might answer:

"This would be common with severe TBI but not with uncomplicated mild TBI, which is what we are dealing with here. I cannot rule it out with

100% certainty but I would consider it extremely unlikely unless there were other factors, like prior behavioral problems or family stress, that could have hindered recovery."

**15** *Leave in a dignified manner.*

After conclusion of any deposition or trial testimony, the PN should leave the proceedings in a professional manner. Shaking hands, not only with the retaining attorney but also with the opposing attorney, would show courtesy at the end of a deposition. In a courtroom, the PN should wait until after having been excused by the judge, after which he or she may simply say "Thank you, Your Honor," briefly nod to the jury, and then walk out. The PN should not try to find out later who received a favorable verdict or how much money was awarded. That would have nothing to do with the business of evidence-based forensic work, and might cloud the PN's level of professional and scientific objectivity in future cases. If the retaining attorney is pleased with the PN's work, increased future referrals will likely result, anyway. For the novice PN who is deposed or appearing in court for the first time, however, it may be helpful to have the testimony observed by a senior colleague, to receive constructive performance feedback at some later point.

## Conclusion

PNs can make important contributions to the accurate evaluation of children in a forensic context, as long as they adhere to an ethical and scientifically defensible approach, without personalized investment in the outcome of the legal proceedings. It is important to be aware of not only the current state of the literature on the condition of interest but also of basic legal contingencies and proceedings as well as of general psychometric and specific performance/symptom validity issues. The PN who offers clear, intelligible, and evidence-based written and oral reports to the legal system serves not only the neuropsychological profession but also the public.

# 40 Clinical Neuropsychology in Criminal Forensics

*Robert L. Denney, Rachel L. Fazio, and Manfred F. Greiffenstein*

The inclusion of this chapter within the second edition of the *Textbook of Clinical Neuropsychology* reflects the increased awareness of neuropsychology's role and increasing presence within the criminal forensic setting. In the first book devoted solely to this subject, Kaufmann (2008) noted the 54% of published legal cases citing expert testimony from neuropsychologists over the preceding decade were criminal cases. This finding suggests neuropsychologists are, indeed, commonly involved in criminal matters. It should create no surprise then that neuropsychologists are involved in the assessment of criminal forensic issues as the demands placed on criminal defendants are largely cognitive. When liberty and due process interests are at stake, as is the case in criminal proceedings, the law demands a specific level of functional ability of defendants. They need to be able to understand their situation, their rights, and make knowing decisions for themselves. Neuropsychologists are positioned quite well to address these issues for the trier of fact, that is, either a judge or jury. Neuropsychologists are only helpful, however, when they understand the nature of the presented questions, which are rather unique in the criminal forensic setting.

The application of neuropsychological principles to criminal forensic issues requires knowledge outside the standard venue of clinical practice because issues before the trier of fact in the criminal setting generally have specific standards in law (Melton et al., 2007). Consequently, it is incumbent for neuropsychologists who choose to practice in this area to gain additional familiarity of the legal issues involved in order to practice competently (Sullivan & Denney, 2008). With that caveat in mind, this chapter will highlight the most common aspects of criminal forensics in which neuropsychologists become involved.

We will initially present the important theoretical and methodological differences between forensic neuropsychology compared to clinical neuropsychology, particularly as it relates to criminal matters, and touch on the assessment process. We will then review specific content areas and criminal legal standards. These topics include criminal competencies, criminal responsibility, diminished capacity and responsibility, dangerousness, and death penalty issues. We will then close by addressing common ethical concerns.

## **Theoretically Driven Practice of Criminal Forensic Neuropsychology**

There are striking differences inherent within the context of forensic psychology compared to clinical psychology. These differences are equally present when considering clinical neuropsychology and forensic neuropsychology. The goal in good clinical evaluation is most commonly the alleviation of human suffering through proper diagnosis and establishment of intervention plans. The goal in forensic assessment is most commonly whether or not an examinee's mental status meets a particular legal standard. It is not unusual for experts to provide information that may assist the court in obtaining proper treatment for the examinee; however, the end goal even in this situation is the improvement of the examinee's mental status in order for the defendant to complete a specific legal process or answer a legal question—*nothing more*. The issue is almost always about answering a specific question for the trier of fact. Forensic examinations are not primarily about helping the examinee, but rather, answering the question posed by the referral source. This different goal creates a different set of assumptions, roles, alliances, and methods.

### *Assumptions*

The assumption in clinical practice is that patients want to get better. They seek services from psychologists because they are having emotional hurt (symptoms) or functional impairment and want help in either dealing with them or making them go away. It is often presumed that they have a diagnosable condition because they would not have made the effort to seek help if the difficulty was not clinically significant. However, in criminal forensics, the defendants are not self-referred, or even voluntary in many instances. Additionally, the possibility of harsh criminal punishment creates a significant incentive for criminal defendants to manipulate the evaluator in order to alter the course of the adjudicative process. It is counterproductive to assume criminal defendants want to be freed from difficult symptoms or neurocognitive impairments; research suggests that many manipulate in order to improve their life situations (Ardolf, Denney, & Houston, 2007). The difference in assumptions between clinical and forensic assessment directly relates to different roles for neuropsychologists.

## Roles

The clinical evaluator seeks to maintain a helper role based on the assumption the patient is in distress and is seeking help. If fact, this is oftentimes the reason psychologists entered the mental health field in the first place, to serve in the role of patient-helper. In contrast, the forensic evaluator attempts to maintain a role consistent with a “seeker of truth” and educator to the trier of fact. As a seeker of truth, the evaluator cannot be biased by the desire to help the criminal defendant, but as a goal must maintain objectivity in seeking the truth in the situation (Saks, 1990). In many instances the findings of the neuropsychologist may not help the criminal defendant and indeed, the findings may actually do more “harm” to the defendant than good. In many instances the consequences are great as is demonstrated in the situation of evaluating a defendant facing a life sentence or even a potential death penalty. The roles can too easily become blurred when clinicians who are used to performing in the clinical setting enter the forensic setting; forensic evaluators must understand and remain true to the role for which they have been called (Bush, Connell, & Denney, 2006). The unique role of the forensic evaluator requires maintaining the proper alliance.

## Alliance

Although a therapeutic alliance is at the core of providing excellent clinical services, forensic neuropsychological examinations are not therapeutic endeavors. Hence, developing a therapeutic alliance is not appropriate during forensic examinations. The forensic examiner’s allegiance should remain with seeking the truth, not creating a therapeutic alliance with the defendant. On more than one occasion we have seen well-intended psychologists abandon the role of objective evaluator and act like the primary emotional support for the defendant—even having an arm around the defendant in an emotionally supportive manner during courtroom proceedings! Dispensing with the therapeutic alliance does not obviate the need to develop a working rapport with the defendant. Forensic examiners must develop and maintain a professional relationship with the defendant based upon dignity and respect. Rapport is needed in order to foster disclosure and help motivate the criminal defendant to perform his or her best during cognitive testing. It is possible to maintain the strict boundaries inherent in a forensic examination while at the same time maintaining a professional and ethical relationship with the criminal defendant.

## Methodology

The proper assumptions lead the way for a proper role and alliance, which set the stage for proper methodology. The common and acceptable practice in the clinical setting is rarely appropriate methodology within the criminal forensic setting. A clinical interview and testing is sufficient in many clinical settings, but such simple methods are ineffectual in a

setting where one cannot place the same weight of credibility on self-report. Those methods may be adequate to assist the patient, his or her caregivers, medical managers, and family in a timely fashion, but they do not correspond with the assumptions, roles, and goals inherent with forensic examinations. Clinical neuropsychologists who start to practice in the forensic setting must understand the differences between clinical practice and criminal forensic practice.

## Similarities and Differences Between Clinical and Criminal Forensic Practice

Some of the issues mentioned so far are likely not entirely novel to the clinical neuropsychologist; for example, variable effort or malingering is also present in other contexts. While clinical and criminal forensic practices have substantial overlap, there are also substantial differences. As illustrated in Table 40.1, the differences may be quite striking to those unfamiliar with criminal forensic work.

Table 40.1 Similarities and differences between clinical and criminal forensic practice

Similarities	Differences
Avoid conflicts of interest and dual relationships	<ul style="list-style-type: none"> <li>The individual being evaluated is typically not the client; there is no “feedback session.”</li> <li>Typically all communication is through the court or lawyers rather than with the individual being assessed.</li> <li>One should take care to avoid fee arrangements which could create bias towards one party.</li> </ul>
Appreciate individual and group differences	<ul style="list-style-type: none"> <li>A higher standard exists for test selection and administration in light of cultural issues given the weight of the matters involved.</li> </ul>
Evaluees must be notified of the nature and purpose of the evaluation, including limits to confidentiality	<ul style="list-style-type: none"> <li>Many evaluees are not voluntary, and they may not have to participate for the evaluation to proceed.</li> <li>There is limited confidentiality.</li> </ul>
The referral question should be answered	<ul style="list-style-type: none"> <li>Only the referral question should be addressed—to open other issues would be problematic both ethically and for the court.</li> <li>In clinical evaluations, there is a focus on diagnosis—in forensic evaluations, it may not be necessary to include a diagnosis in the report.</li> <li>The evaluator may or may not be allowed to answer the “ultimate issue” depending on what the issue is and the jurisdiction.</li> </ul>
Appropriate records should be maintained and only disclosed to appropriate parties	<ul style="list-style-type: none"> <li>It may be necessary to retain records for a much longer period of time for criminal forensic cases, as appeals can take decades.</li> <li>One must typically comply with subpoenas and other requests for information while ensuring it is used in the appropriate manner.</li> </ul>

### Forensic Evaluation Process

The practice of criminal forensic neuropsychology is particularly unique because it is not uncommon for experts to be asked to formulate an opinion that deals with a criminal defendant's past behavior. The most common of such instances is criminal responsibility (also known as an evaluation of sanity). Evaluations of past events can also include the ability to form prerequisite intent to perform the alleged criminal behavior and retrospective competencies, such as understanding *Miranda* warning, waiving the right to remain silent and confessing to a crime, and competency to stand trial, enter a guilty plea, or be sentenced. All of these particular evaluations require the examiner to understand a past mental state of the defendant.

Although we will discuss each of the specific legal criteria related to the evaluations described in the upcoming sections, each of them require the same methodological process to ensure a thorough examination and proper outcome. Figure 40.1 provides a graphic display of sources of information commonly needed to provide retrospective

forensic formulations. The model highlights the key issue that information should come from self-report and corroborative information specific to each period of time: present, historical, and at the time in question. The first two columns represent necessary information from both the defendant and corroborative sources. Each row represents a different period in time. Information from each box in a particular column should make some logical sense as far as consistency with information from other sources in other boxes within that column, just as each row should have some logical consistency from left to right. Self-report and corroborative information for the present should be reasonably consistent. Self-report and corroborative information for the defendant's past should be reasonably consistent. Self-report and corroborative information for the specific time in question should be reasonably consistent as well. The examiner can have significantly more confidence regarding the clinical opinion when both self-report and corroborative information coincides. For example when a defendant is behaving in a manner presently that suggests a severe mental illness such as

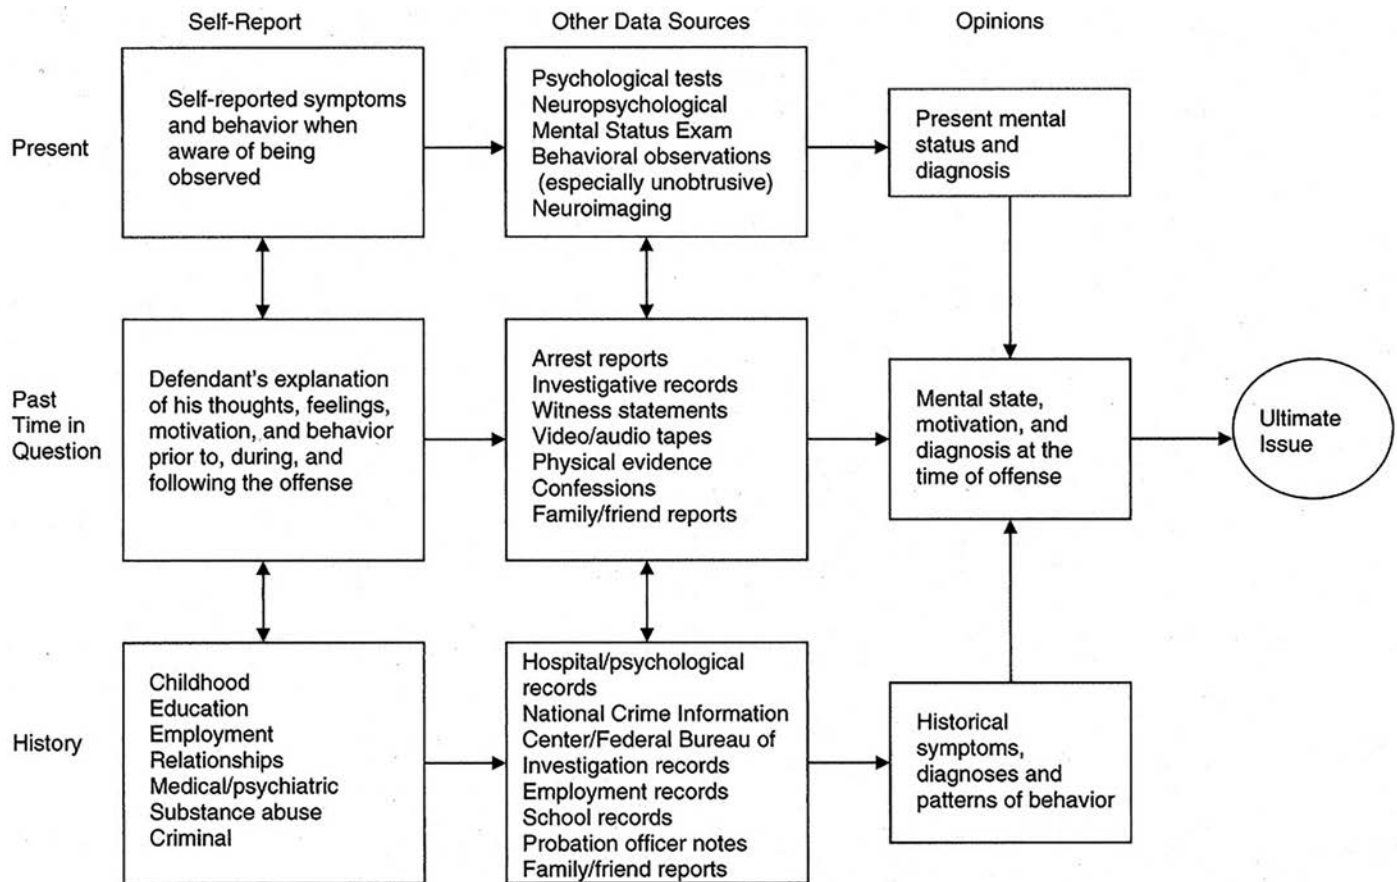

Figure 40.1 Multiple data source model for the assessment of past mental states. The left-hand column indicates period of time in question. Connecting lines represent avenues of expected consistency, with arrows leading toward opinions. The ultimate issue signifies the expert's opinion on the sanity (it could also represent an opinion on other *mens rea* defenses or retrospective competencies such as the *Miranda* waiver, competency to confess or stand trial). Reproduced with permission of David Mrad, PhD.

schizophrenia, the self-report and corroborative information regarding the defendant's history should be consistent with the proper age of onset for that condition. Those two specific rows then also support what the defendant's mental state was like at the time in question, such as during an alleged offense, but corroborative information regarding his or her behavior at that time in question must also be consistent with that clinical picture. The examiner can only provide a competent opinion regarding the ultimate issue after arriving at a clinical opinion pertaining to each of these three periods in time. This multiple data source model was originally conceptualized by Mrad (1996) then adapted to neuropsychology (Denney & Wynkoop, 2000) and personal injury assessment (McLearen, Pietz, & Denney, 2004). One of us (RLD) has also presented this model in the criminal arena elsewhere (Denney, 2005, 2012b; Yates & Denney, 2008).

### Criminal Competencies

Competency is the ability to understand and make reasonably knowledgeable decisions, and it is the question forensic neuropsychologists (FNs) will be asked to answer most often in the criminal setting. While those decisions do not necessarily need to reflect what one might consider the best judgment, they must reflect a knowing and intelligent choice among alternatives. The minimal level of understanding includes some sense of appreciation for the nature of the procedure, risks, a sense of likelihood of success, available alternatives, and the relative advantages and disadvantages of any available course of action (Denney, 2012a). It has been a long held requirement within the United States that criminal defendants must be competent to face criminal prosecution (Youtsey, 1899). In other words, defendants cannot progress through the criminal adjudication process unless they understand the nature of the proceedings and can assist in their own defense. The only exception to this rule is when the Court must stop the proceedings to determine competency and facilitate appropriate treatment to restore competency in the event the defendant is determined not competent to proceed.

The question of a defendant's competency to proceed can arise at any point in the adjudicative process from hearing a *Miranda* warning from a police officer, standing trial, waiving the appeals process, to even facing a lethal injection. Table 40.2 highlights common points when competency to proceed is often questioned as well as the general competency related principle in question for that period of time.

The reader may notice that "understand and appreciate" are the prevailing concepts pertaining to competency to proceed regardless of the specifics in question. These concepts derive, in large part, from the primary source of competency determination, *Dusky v. United States* (1960).

Table 40.2 Specific competencies in criminal adjudication

Competency To:	General Concept at Issue
Confess (or to Waive Rights at Pretrial Investigations)	Understanding and appreciation of rights to silence and legal counsel when the rights may be waived at the request of law enforcement investigators seeking a self-incriminating statement
Plead Guilty	Understanding and appreciating of above, and of the right to a jury trial, the right to confront one's accusers, and the consequences of a conviction
Waive Right to Counsel Stand Trial	Understanding and appreciation of the dangers of self-representation at trial Ability to assist an attorney in developing and presenting a defense, and to understand the nature of the trial and its potential consequences
Acting as One's Own Counsel During Trial	Understanding and appreciating of above, and ability to interact properly with courtroom participants, generally act with proper decorum in the courtroom while in front of a jury, and present a defense without assistance of counsel
Be Sentenced	Understanding and appreciation of nature of the sentence to be imposed (after trial has resulted in conviction or the entering of a guilty plea)
Waive Further Appeal (when Facing Execution)	Understanding and appreciation of right for additional appeal and potential consequences of waiving it
Be Executed	Understanding and appreciation of nature and purpose of the punishment, and ability to assist counsel in any available appeal

*Note:* The wording of these definitions does not conform to prevailing legal terminology. They are intended only to convey the general issues raised in each specific situation. Updated and adapted from *Competency to Stand Trial Evaluations*, by Grisso, 1988, p. 3. With permission of Professional Resource Press.

#### DUSKY V. UNITED STATES

Youtsey (1899) established that defendant competence was a U.S. Constitutional requirement in order for the government to prosecute someone; however, it did not spell out the difference between competence and incompetence. The Supreme Court of the United States established that standard in the 1960 ruling of *Dusky v. United States*.

Milton Dusky was arrested in 1958 for kidnapping a 15-year old girl, transporting her from Kansas to Missouri, and raping her. He received a mental health evaluation, and the psychiatrist testified before the presiding U.S. District Court judge that, as a result of severe mental illness, he was "unable to properly understand the proceedings against him and unable to adequately assist counsel in his defense" (Dusky, 1960: 402). The judge determined that he was competent to proceed, nonetheless, because he was oriented and had some recollection of the events in question. He was convicted of kidnapping. The defense appealed to the U.S.

Court of Appeals for the Eighth Circuit, but the conviction was upheld.

The U.S. Supreme Court reviewed the case and overturned the conviction, sending the case back to the trial judge for a new competency assessment, and making the point that the trial court's standard of competency was not adequate. The high court opinion indicated: "It is not enough for the district judge to find that the defendant is oriented to time and place and has some recollection of events" (p. 402). The trial court held a new hearing and found him competent under the new standard. The U.S. Supreme Court's decision has become known as the *Dusky standard* and is the primary rule of law for competency to proceed in all U.S. jurisdictions ever since. Although courts in the United States can provide additional safe guard pertaining to a defendant's competency to proceed, they cannot provide less than the *Dusky* standard: "[The] test must be whether he has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding—and whether he has a rational as well as factual understanding of the proceedings against him" (p. 402).

Several key points regarding this standard need highlighting. The decision makes it clear that competency is an issue of *current* ability, which is contrasted with formulations pertaining to mental state at the time of the crime. Occasionally, courts need to determine competency pertaining to a time in the past, such as during a past confession, trial, or guilty plea, but typically competency pertains to current mental state, and to some degree mental state in the foreseeable future (i.e., upcoming legal proceedings). The phrase "*ability to consult with his lawyer*" in the standard indicates *capacity* to cooperate rather than *desire* to cooperate. It is not uncommon for criminal defendants to choose to not cooperate with the proceedings, but improper motivation does not meet the standard unless it is considered caused by a severe mental illness (e.g., psychosis, as opposed to maladaptive personality disorder). Evaluators must also keep in mind that *ability to consult with* in no way means a "meaningful attorney-client relationship" (*Morris v. Slappy*, 1983). Additionally, the standard also includes the phrase "*reasonable level of understanding*"—that is, not necessarily a complete understanding. Criminal defendants are not expected to have a perfect understanding.

The core aspect of the *Dusky* standard can be reduced to "rational as well as factual understanding." *Factual* understanding is viewed as strict understanding, such as the ability to repeat information provided, paraphrasing it in the defendant's own words, and demonstrating the ability to put the understanding to use by making a decision. *Rational* understanding pertains to understanding that can be compromised by severe mental illness or defect. Although a person could understand the underlying facts of the case, such as expected roles of courtroom participants, the basic adjudication process, and the fact that he or she is a criminal defendant facing specific charges related to his or her alleged behavior, it is

possible that the person's rational understanding is compromised by psychotic mentation. The following case, evaluated by one of us (RLD) demonstrates this very issue.

Mr. Defendant was found standing next to FBI agents, dressed in a dark suit, when the FBI were acting security for Governor William Clinton, when he was in Little Rock, Arkansas. Governor Clinton was under federal protection because he had formally entered his run for U.S. president. When the FBI noticed one among them who did not belong, they began questioning him and searched his vehicle. They found a high powered rifle with a telescope sight attached resting in the trunk.

Mr. Defendant was referred for a competency to proceed mental health evaluation because of unusual ideas he voiced to his lawyer. During the evaluation, he voiced his belief that Governor Clinton ran a clandestine sex trade network focused on minors. He believed the only reason he was charged with his current offense was because he had special knowledge regarding Governor Clinton and was arrested and sent to a forensic hospital to keep him quiet and keep him from derailing the governor's bid for president.

The details of his beliefs and presentation indicated he held grandiose and paranoid delusional beliefs. He was diagnosed with Delusional Disorder. The evaluator considered him not competent to proceed not because of impaired factual understanding, but because of impaired rational understanding due to genuine psychotic delusional beliefs. He was able to describe adequately the roles of courtroom participants, the nature of his charges and their potential outcomes, and plea options available to him. Although he acknowledged those facts were supposed to be true for him, he believed that no matter what he did or said, he would be held in order to keep him quiet and away from the media because of his special knowledge. In essence, he did not believe he would get a fair and impartial trial, and that belief was due to a severe mental illness.

The case highlights the difference between a factual understanding and a rational understanding. I (RLD) have evaluated other cases where defendants believed the presiding judge on the case was not actually human but Satan in human form, a belief stemming from schizophrenia. Although individuals who have lost their rational ability to consider facts can sometimes still acknowledge those facts, it does not necessarily make them competent to the point that they have a rational as well as a factual understanding and can assist properly in their defense. Oftentimes, they are so focused on explaining their psychotic beliefs to the judge, jury, or media that they are not able to assist properly in their defense, even with a skilled lawyer. This case also demonstrates that the abnormal ideation or understanding must stem from severe mental illness. The *Dusky v. United States* case document does not make it clear that Milton Dusky's problem was due to psychosis, but he was in fact diagnosed with schizophrenia (Frederick, DeMier, & Towers, 2004). There can be cases where defendants are so incapacitated by physical disease that they become incompetent, but under

most circumstances the question of incompetency deals with mental illness. As is also true in most jurisdictions, the federal statute (Title 18, U.S.C., Section 4241a) makes this clear: "The defendant, as a result of mental disease or defect, is unable to understand the nature and consequences of the proceedings against him or assist properly in his defense." The federal statute also highlights an issue by substituting the word *consult* with the phrase *assist properly* in regarding working with a defense lawyer. There is no case law of which we are aware that spells out the exact meaning of "assisting properly." The level of assistance needed for a particular case depends on the specific situation. In this regard, there is a sense that competence is, to some degree, context based.

### *Competency in Context*

Grisso (1988) presented a theoretical structure for how we can consider criminal competence within a context. By this perspective the level of competence needed varies based on the demands required. There is clear U.S. Supreme Court guidance that the standard of competence does not vary between waiving one's right to a trial or to an attorney, as all competencies are benchmarked by *Dusky v. United States* (1960; see *Godinez v. Moran*, 1993); however, there is common sense and a practical aspect to how a judge determines competence to proceed as well. We will address this issue when we touch on the complicated matter of letting a criminal defendant act as his or her own lawyer during a trial before a jury shortly.

Grisso presented five areas of analysis that are helpful for the forensic evaluator: (a) functional description of specific abilities, (b) causal explanations for deficits in competency abilities, (c) interactive significance of deficits in competency ability, (d) conclusory opinions about legal competency, and (e) prescriptive remediation for deficits in competency abilities. Functional description of specific abilities in competency is the act of presenting defendant strengths and weaknesses as they relate to competency requirements. The causal explanation is the direct linking of those competency deficits to mental illness or defect. The facts of the case described earlier could be changed some to demonstrate this point. Rather than a psychotic-illness-based delusion, the defendant could have believed he would not be treated fairly because his past experience with the government had never turned out well for him, and he simply expected the same outcome. Such beliefs are common among repeat offenders, particularly if they have significant antisocial personality characteristics. The point of the causal link is for the evaluator to specifically address whether or not the presumed deficits in competency are directly related to a mental illness (which most jurisdictions require to be severe) rather than ignorance, culturally based beliefs that are not considered an indication of mental illness, or volitional behaviors from the defendant.

The interactive significance of the deficits forces the evaluator to make a judgment of the demands required of

the defendant by his or her specific situation. This focus of analysis is difficult for the clinician to fulfill because it takes competent understanding of the legal demands placed on a defendant, and the demands placed on the defendant could change depending on future decisions the defendant makes through the process. The best judge of the demands placed on a defendant at any specific time in the adjudicative process is the judge. Nonetheless, some jurisdictions (e.g., federal) require evaluators to provide an answer to the referral questions. In those instances, it is best for the evaluator to describe his or her reasoning related to perceived demands based on the nature of the criminal case (e.g., simple bank robbery or a multibank, multiaccount embezzlement scheme), what the defendant plans to do for a defense, and whether or not the defendant plans on utilizing the assistance of a lawyer.

The conclusory opinion about competency and prescriptive remediation often go hand in hand. The conclusory opinion is simply answering the ultimate issue question, in this case, competency to proceed. Some authors (Grisso, 1986, 1988; Grisso, Borum, Edens, Moye, & Otto, 2003) suggest it is more proper for the evaluator to not provide the answer to the ultimate issue. This view implies that a judge may be overly influenced by the testimony or report of an expert, a view that we have found unrealistic as related to competency. Typically, judges seek opinions when they want opinions and recognize them as opinions only. Evaluators are best served, however, to remember they are not generally experts in the law; they are simply consultants to the legal system, and the judge is in the best situation to take all facts into account when rendering a ruling on competency.

Prescriptive remediation for deficits in competency refers to providing education and guidance on the nature of the pathology involved and what it will specifically take from a treatment perspective to restore competency to proceed. Judges require this information to provide disposition for the defendant that will best serve the goal of the state as well as the defendant's U.S. Constitutional rights. If the condition is treatable, prescriptive recommendations can include such information as what treatment is needed, the likely duration of treatment, and local facilities that might be available to provide the treatment (Grisso, 1988).

As mentioned, different competency questions such as competency to stand trial, waive right to trial and plead guilty, waive rights to have assistance of counsel, and other nexus points in the process as listed in Table 40.2 are based on the same *Dusky v. United States* (1960) standard (*Godinez v. Moran*, 1993). Those issues are the most common types of questions asked regarding competency to proceed and generally have straightforward analyses as part of the conceptual formulation. For more detail regarding competency at those specific points in time, we recommend Grisso and colleagues (2003), Denney (2012a, 2012b), and of course, Melton and colleagues (2007). For now, we will turn briefly to two unique issues within the subject of competency to proceed and then

address death penalty related competency under the death penalty section.

### ***Miranda Warning and Competency to Confess***

The requirement for criminal defendants to be competent to proceed begins before they are actually criminal defendants. It certainly begins by the time law enforcement personnel provide a suspect with his or her *Miranda* warning (*Miranda v. Arizona*, 1966), a point where the suspect should be competent such that he or she can knowingly, intelligently, and voluntarily make the decision to remain silent or confess. FNs can become involved in evaluations related to past competence to waive the right to remain silent as well as whether or not a mental aberration existed at the time the suspect was questioned that might make plausible the possibility he or she provided a false or “involuntary” confession. Some mental abnormalities make it possible that a suspect might have been unduly influenced to confess, not because of overreaching police behavior during interrogation, but because of characteristics inherent within the suspect. Covering the nuances of these concerns from a practice standpoint is beyond the scope of this chapter. The area is relatively complicated, and there are specialized assessment tools clinicians can use to assess both *Miranda* comprehension as well as suspect susceptibility to influence and suggestion. We recommend Frumkin (2008) for a good primer to the area.

### ***A Unique Trial Competency***

We need to add an additional word regarding the contextual demands placed on a defendant as a result of an interesting U.S. Supreme Court decision. In *Indiana v. Edwards* (2008), the High Court chose to not maintain a single rule when comparing a defendant who is competent to proceed to trial with aid of counsel to a defendant proceeding to trial without the aid of counsel. Thus, the court has split the issue such that a criminal defendant could be found competent to proceed to trial with aid of counsel, but not competent to represent him- or herself without the aid of counsel. Consequently, FNs may find themselves in a situation where they are asked to opine on the issue of whether or not an otherwise competent defendant is also able to represent him- or herself during a trial without the assistance of counsel. For a more detailed discussion of this interesting case and the conceptual background for the U.S. Supreme Court’s conclusion, see Denney (2012a).

### **Competency-Related Measures**

Many competency questions can be assessed without any formal, structured instrument, and frequently are by seasoned evaluators. The competency-related measures discussed in this section are primarily structured interviews designed to help evaluators ensure they have covered the essential

features of competency rather than to produce a score that determines whether the defendant is competent. It should be noted that there are also instruments dedicated to assessing competency related to *Miranda* (Standardized Assessment of *Miranda* Abilities; Rogers, Sewell, Drogin, & Fiduccia, 2012), those with low intelligence and intellectual disability (Competency Assessment for Standing Trial for Defendants with Mental Retardation; Everington & Luckasson, 1992), and an instrument designed specifically to assess malingering of competency-related deficits (Inventory of Legal Knowledge; Otto, Musick, & Sherrod, 2010).

### ***Revised Competency Assessment Instrument***

The Competency Assessment Instrument (CAI) was originally developed by the Laboratory of Community Psychiatry in 1973 (McGarry, Lelos, & Lipsitt, 1973), and later revised (Riley, 1998). The Revised CAI (R-CAI) is an approximately 45-minute semistructured interview that should be administered in a flexible fashion, emphasizing questions that are relevant to the particular defendant.

### ***Georgia Court Competency Test—Mississippi State Hospital Revision***

Originally developed by Wildman et al. (1978) and consisting of 17 items, the most recent edition of the Georgia Court Competency Test (GCCT), the GCCT—Mississippi State Hospital Revision (GCCT-MSH) has 21 items. The test includes items asking the defendant to identify various figures in the courtroom using a line drawing of a courtroom, questions regarding the function of the various individuals in a courtroom, what charges the defendant is facing, and questions regarding the defendant’s relationship with his attorney. The GCCT-MSH’s strength is its use of a visual aide in the assessment of competency; its primary weakness is that it essentially assesses foundational competency only with little information gleaned about decisional competencies (Zapf, Roesch, & Pirelli, 2013).

### ***MacArthur Competency Assessment Tool—Criminal Adjudication***

The MacArthur Competency Assessment Tool—Criminal Adjudication (MacCAT-CA; Poythress et al., 1999) is the only instrument discussed here to use a hypothetical vignette in order to evaluate a defendant’s competency. This has the benefit of perhaps better being able to assess the competency of a cautious defendant who does not want to discuss his or her own case; alternately, this instrument requires a higher level of cognitive capacity for the defendant to be able to comprehend the story, remember the details, and then be able to apply legal knowledge to a case that is not his or her own.

The MacCAT-CA uses the vignette and the first eight items to assess the defendant’s understanding of the legal

system and process, and the vignette and an additional eight questions to assess his or her ability to reason. The final questions assess the defendant's knowledge of his or her own case and beliefs about how things will go as opposed to his or her more generalized knowledge and beliefs, hopefully allowing for any assessment of delusional belief systems.

### ***Evaluation of Competency to Stand Trial—Revised***

The Evaluation of Competency to Stand Trial—Revised (ECST-R; see Rogers, Tillbrook, & Sewell, 2004) was designed to assess domains of knowledge consistent with the *Dusky* standard. Specifically, its subscales consist of Consult with Counsel, Factual Understanding of the Courtroom Proceedings, and Rational Understanding of the Courtroom Proceedings. It is unique, however, in that it includes a scale (Atypical Presentation) that assesses response style; evaluators who have not administered this instrument before may want to practice reading these questions in a serious fashion prior to actual test administration as they are quite unusual. Items on the ECST-R are scored on a Likert scale and normative data is provided both in terms of T-scores as well as level of certainty (i.e., preponderance, probable, etc.).

Readers may wish to refer to Denney (2012a) as these competency related measures are reviewed in more detail and with a focus on their application to neurocognitive disorders. We will now turn to the unique situation where criminal defendants have self-reported amnesia for the alleged crime.

### **Competency and Amnesia**

The *Dusky* standard makes no reference to a defendant's memory capabilities directly. While anterograde amnesia would likely impair a defendant's current abilities to consult with counsel and understand the proceedings against him or her, retrograde amnesia for the time of the offense has *not* been considered a sufficient basis for a finding of incompetency in an otherwise competent defendant. Indeed, no court to date has found amnesia for the crime alone as a barrier to competency (Tysse, 2005). While a number of courts have stated, hypothetically, that amnesia alone could preclude competency in certain circumstances, no court has come upon such a set of hypothetical circumstances (*U.S. v. Andrews*, 2006).

### ***History of Competency and Amnesia***

This issue was examined by the DC Circuit Court in 1968, in *Wilson v. United States*. In this case, Robert Wilson was involved in a high speed chase in a stolen yellow Mustang that subsequently crashed into a tree, leading Mr. Wilson to incur a severe traumatic brain injury (TBI). This case was unique in that there was no argument to the fact that Mr. Wilson indeed had permanent retrograde amnesia for the events of that day due to his verified brain injury. While

initially found incompetent due to his amnesia impacting his ability to consult with counsel, this finding was eventually reversed. The reasoning was that, in this case, Mr. Wilson had sufficient *present* abilities to consult with counsel, as well as the

ability to construct a knowledge of what happened from other sources . . . a loss of memory should bar prosecution only when its presence would in fact be crucial to the construction and presentation of a defense and hence essential to the fairness and accuracy of proceedings.

(*Wilson v. United States*, 1968: 463)

On Mr. Wilson's later appeal, the appellate court essentially agreed, but also indicated that a posttrial review was necessary in order to determine if the defendant's amnesia did impact his competency as evidenced during the proceedings. In this review, it was stated that the court should consider how the defendant's amnesia affected his ability to assist his lawyer and testify on his own behalf, how well the evidence could be extrinsically reconstructed, how much the government assisted with that reconstruction, the strength of the prosecution's case, and any other circumstances which would indicate whether the defendant had a fair trial. If the trial was deemed to be unfair due to the defendant's amnesia, the court should vacate the conviction and a retrial may occur; after such retrial, if the trial remained unfair, the indictment should be dismissed.

### ***Other Findings Regarding Amnesia***

A more recent discussion of how retrograde amnesia may impact competency can be found in *U.S. v. Andrews* (2006). In this case, the court points out that only the DC Circuit Court has held that a posttrial review of competency is necessary when amnesia is an issue. In *Andrews*, the court instead indicated that, as in any case, the issue of competency can be raised *sua sponte* (at the judge's own accord) at any point throughout the proceedings; if this issue is not raised in the normal course of the trial by a concerned party, it is apparently not of sufficient concern to warrant a posttrial review specifically due to the issue of amnesia.

### ***Practical Considerations Regarding Competency and Amnesia***

As stated in *U.S. v. Swanson* (1978), the trier of fact "is in the best position to make a determination between allowing amnesia to become an unjustified safe haven for a defendant and, on the other hand, requiring an incompetent person to stand trial." Several of the issues outlined in *Wilson* (1968) and reaffirmed in *U.S. v. Rinchack* (1987) pertain to issues outside the expertise of mental health professionals, such as the extent the evidence can be extrinsically constructed including evidence of the crime itself and any potential

alibi as well as the overall strength of the prosecution's case against the defendant and "any other facts and circumstances" (p. 464) pertaining to the defendant getting a fair trial. See Denney (2012b) or more detail regarding this issue and also for methods to potentially determine when the claimed amnesia is feigned. Although amnesia for the crime can affect a defendant's competency to proceed, it has nothing to do with whether or not he or she is criminally responsible.

### Criminal Responsibility

Criminal responsibility has to do with one's mental state at the time of the offense, and is commonly known as "the insanity defense." The criminal court system has long recognized that individuals are not necessarily responsible for, and therefore should not be punished for, things done while they are not truly cognizant of what they are doing, and would not have done except for their mental state at the time of the offense. Given that two of the primary purposes of the criminal justice system are deterrence and retribution, what purpose would be served by punishing someone who was insane at the time of the offense? That is the key point—insanity has only to do with *mental state at the time of the offense*. This stands in contrast to issues of competency, which have nothing to do with mental state at the time of the offense, but pertain only to the defendant's current cognitive abilities and mental state.

A defendant can be sane at the time of the offense but yet not competent to stand trial. For example, if a man with a delusional belief system pertaining to the government happens to seriously injure another man in a bar fight over something said about his girlfriend, there is no evidence to believe he was not sane at the time of the offense. If, however, his delusional belief system regarding the government then hindered his ability to work with his court-appointed public defender, he may very well not be competent to stand trial. Alternately, many individuals who were psychotic at the time of the offense subsequently receive treatment with antipsychotic medication once they are arrested and otherwise involved with the legal system; while they may meet legal criteria for insanity at the time of the offense, once treated with antipsychotic medication, they will hopefully be restored to competency to stand trial. The ability to view these as two separate, often entirely unrelated issues is typically one of the most difficult concepts to grasp for those just entering the criminal forensic area.

### Brief History of the Insanity Defense

The criteria for the insanity defense have varied substantially over the years and continue to vary widely between jurisdictions. Historically, evidence of some form of an insanity defense can be found even in ancient Egyptian and Hebrew

civilizations, although most U.S. law has its roots in English case law (Melton et al., 2007). In the 1700s various definitions of insanity were used; perhaps the best known of these was put forth by Justice Tracy, who stated that to be insane, "a man must be totally deprived of his understanding and memory so as not to know what he is doing, no more than an infant, brute or a wild beast" (*Arnold's Case*, 1723). The definition then shifted, however, from an emphasis on lack of awareness to a more nuanced test, involving whether the defendant was able to distinguish right from wrong. This became known as the *M'Naghten test*. The ruling in this case (*Rex v. M'Naghten*, 1843) defined insanity as that, at the time of the offense, "the party accused was laboring under such a defect of reason . . . as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong."

The *M'Naghten* test held in the United States until 1887, at which point an additional facet was added—that of one's ability to control one's impulses (Melton et al., 2007). In *Parsons v. State*, the court concluded that a person was insane at the time of the offense if, due to mental disease, the defendant "had so far lost the power to choose between the right and wrong, and to avoid doing the act in question, as that his free agency was at the time destroyed" (*Parsons v. State*, 1887). The definition of insanity continued to evolve, later leading to various iterations such as the "product test" and a number of cases further defining those criteria (Melton et al., 2007).

The next major shift in the definition of insanity came when the American Law Institute (ALI) proposed a new rule. It read:

A person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the criminality [wrongfulness] of his conduct or to conform his conduct to the requirements of the law.

(ALI, 1955)

This definition also included a statement specifically prohibiting the inclusion of antisocial personality or psychopathy. The ALI rule was adopted by many jurisdictions from its proposal in 1955 (Melton et al., 2007) until the Insanity Defense Reform Act (IDRA) of 1984.

In 1984, John Hinckley, Jr., was found to be not guilty by reason of insanity (NGRI) in his assassination attempt of President Ronald Reagan. This verdict was not well received by the public, causing the IDRA to be enacted, substantially narrowing the legal definition of insanity. The current federal definition of insanity reads: "at the time of the commission of the acts constituting the offense, the defendant, as a result of a severe mental disease or defect, was unable to appreciate the nature and quality or the wrongfulness of his acts" (United States Code, Title 18, Section 17). The following case vignette highlights how a criminal defendant's beliefs

can meet the sanity standard for some aspects of a crime, but not necessarily all aspects of the crime:

A 53-year old man was pulled over at night by state police because his van tail light had burned out. The man acted oddly in the van, and the police called for backup. The man was asked to exit his van and speak with the police. After he exited the van he attempted to injure the police officer with his bare hands when the officer asked him for his identification. He was taken into custody. Found in the van were numerous wired contraptions that appeared to be booby traps for the van, and it was apparent he had been living in the van. Also found was a homemade white gas device that was classified as a bomb by the Bureau of Alcohol, Tobacco, Firearms, and Explosives, but which he later said was simply a homemade heater for his van. He was charged with possession of explosives and for assaulting an officer.

During his mental health evaluation, he disclosed his beliefs that the government could track people through their identification cards and that they were systematically collecting people's identification cards in order to control and kill them. His ideas became increasingly paranoid and psychotic. Information from his daughter verified that he had long held quite psychotic beliefs, lived in his van, and traveled the country, but had never been known to harm anyone.

One of us (RLD) evaluated this man and diagnosed him with schizophrenia. The report provided the opinion that the man's psychotic beliefs caused him to act in immediate self-defense when the officer asked him to hand over his identification card because he believed he was going to be killed. For this charge, he was considered insane because he did not appreciate the nature, quality, or wrongfulness of his act. Because the gas heater/bomb was not included in any psychotic thinking, he was not considered insane regarding possession of the device. He simply denied that it was a bomb, in what amounted to an "I did not do it" assertion.

### **Current State of the Defense**

As the U.S. Supreme Court presented in *Clark v. Arizona* (2006), states are not required under the U.S. constitution to offer an insanity defense in any form; despite this, most do. At that time, the federal government and 17 states defined insanity as some form of the *M'Naghten* test (both prongs), one only *M'Naghten's* cognitive test, and for ten, the moral test alone. Fourteen states were using the ALI rule or a variation thereof, and three a combination of *M'Naghten* plus volitional capacity. One state continued to use the "product test." Three states had no insanity defense, and one offered no insanity defense but the option of a "guilty but mentally ill" plea. A very nice table of the relevant statutes and information about the "variations" they contain is presented in Packer (2009).

### **Other Points Regarding Insanity**

The insanity defense is rarely used and even less often successful. When it is successful, however, acquittees are

typically remanded for evaluation of dangerousness, and if found dangerous, can be committed indefinitely for purposes of treatment. A number of defendants, if made aware of the ramifications of pleading NGRI, may opt not to use the defense, as they would rather have a defined sentence and release date, particularly if the sentence would not be overly lengthy. It should also be noted that a defendant is not eligible for the insanity defense (or at least would likely not be found NGRI) if his or her "insanity" at the time of the offense was due to substance abuse, as this is also specifically excluded in most definitions.

### **Diminished Capacity and Responsibility**

The issue of diminished capacity may arise when a defendant does not meet the jurisdiction's standards for a finding of NGRI, or when a jurisdiction lacks an insanity defense altogether. One scenario in which "diminished capacity" may occur is when the defendant committed a crime while under the substantial influence of drugs or alcohol. In this scenario, the issue is not the defendant's ultimate guilt, but rather that of which crime they are guilty. Put simply, due to their altered mental status, they may not have had the mental abilities to act with *malice aforethought*, which is a necessary precondition to be convicted of what are typically classified as first degree offenses, that is, those which are both deliberate and premeditated.

Alternately, diminished responsibility implies that the defendant is less culpable for a crime committed due to a mental abnormality, but does not imply that the defendant did not have the capacity to form the requisite intent (Clark, 2013). An example of a circumstance where the concept of diminished responsibility may be important is in a jurisdiction where there is no volitional prong to the insanity defense, and a deficit in cognitive, emotional, or behavioral control secondary to a neurological condition may be relevant, whether during trial or sentencing (Denney, 2012b). It should be noted, however, that while diminished responsibility is a formal legal concept in several European countries, there is currently no formally defined U.S. equivalent; in the United States, the concepts of diminished capacity and NGRI have frequently metamorphosed to include more or less of the concept of diminished responsibility over the past few decades (Clark, 2013). The IDRA essentially ended the concept of diminished responsibility in the United States with its statement that there shall be no affirmative defense other than insanity that relates to a mental disease or defect.

### **Mens Rea**

*Mens rea* is essentially the intent to commit a criminal act. Whereas a finding of NGRI absolves the defendant of responsibility entirely, diminished capacity does not negate all criminal responsibility, but is only a finding that the defendant was not capable of forming the *mens rea* for a specific

criminal charge (Clark, 2013). Therefore, the defendant may be convicted of a lesser offense amongst the original charges. As an example, say that a mother, while in a drunken stupor, beat her child to death. She may be charged with crimes such as first degree murder, second degree murder, and manslaughter. In this case, her capacity to form the intent and plan to murder her child was likely compromised due to her severe intoxication, making a conviction for first degree murder less likely should the defense present evidence relating to diminished capacity.

It should be noted that a string of cases in various jurisdictions have clarified the statement in the IDRA that short of insanity, “mental disease or defect does not otherwise constitute a defense.” While at first, this seems to eliminate the ability of a trier of fact to consider diminished capacity, all subsequent district and appellate cases have agreed that the purpose of the IDRA was not to prohibit the appropriate consideration of *mens rea* (Clark, 2013). As best summarized in *U.S. v. Pohlott* (1987), the phrasing of the IDRA was interpreted as leaving “no doubt that Congress intended . . . to bar only ‘affirmative defenses’ that ‘excuse’ misconduct but not evidence that disproves an element of the crime itself” (p. 897). Simply stated, demonstrating *mens rea* is essential for the prosecution to meet its burden of proof for all necessary elements of a crime (Clark, 2013), making diminished capacity a valid issue open for expert testimony.

### Assessment of Dangerousness

Neuropsychologists can be called upon to provide an assessment of the dangerousness of a defendant or inmate in a number of scenarios. For example, if a defendant is found noncompetent and nonrestorable, his or her dangerousness must be assessed; if he or she does not pose a serious risk of violence towards persons or property, the charges may be dropped. Alternately, if the defendant is dangerous due to mental disease or defect, he or she can be civilly committed, potentially indefinitely. This issue of dangerousness due to mental disease or defect is also relevant for those found NGRI and inmates at the end of their sentences if they are mentally ill or meet certain criteria regarding sexual offenses. While neuropsychologists may be able to provide special expertise in cases where dangerousness is an issue due to a neuropathological condition, they must also be familiar with the general principles of risk assessment as well as the broader static and dynamic risk factors.

### Methods of Risk Assessment

Just as in neuropsychology some clinicians prefer fixed batteries and some flexible, those performing risk assessments have a number of approaches from which to choose. The four most common are clinical judgment, structured professional judgment, actuarial, and adjusted actuarial. Clinical judgment is just that—based entirely on the clinician’s own

judgment and experience, which may or may not have any empirical underpinnings. Clinical judgment was essentially the only method of assessment until more scientific studies of risk assessment were performed and actuarial methods began to be produced. One early seminal study in risk assessment that used clinical judgment (Kozol, Boucher, & Garofalo, 1972) has been—somewhat erroneously—interpreted as resulting in the clinicians’ predictions being wrong two-thirds of the time, in other words, worse than chance (Douglas, Hart, Groscup, & Litwack, 2013). This method is not recommended as it is unlikely to meet legal standards regarding the scientific basis of expert testimony.

At the far end of the spectrum from clinical judgment would be actuarial assessment, which involves deriving a formula for considering and weighting risk factors from a known-groups population; this formula then allows the clinician to make a probabilistic prediction of the examinee’s future dangerousness. While the highly scientific appearance of actuarial instruments is attractive, they do have some weaknesses. Many actuarial instruments are not well cross-validated: Clinicians must keep in mind there may be “shrinkage” of classification accuracies when the instruments are used in different populations. For example, many of the popular actuarial instruments were designed in an incarcerated Canadian population, which may have very different sociodemographic characteristics than that of an urban metropolitan detention center or state prison.

Another critique of the actuarial risk assessment method is that it entirely disallows for clinical judgment, even in exceptional cases. So, for example, an inmate produces the highest score possible on an actuarial risk assessment method—but was seriously assaulted by another inmate while in prison and is now a quadriplegic. Regardless, this individual would be high risk using a strictly actuarial method. This is why some clinicians prefer an adjusted actuarial method, where they essentially administer and consider actuarial methods, but also use their own common sense and empirical knowledge of violence risk factors to sometimes modify the level of risk predicted by the actuarial instrument.

The previous example also illustrates a further limitation of the actuarial method; that is, actuarial methods rely largely on static as opposed to dynamic risk factors. Static risk factors are risk factors that are unmodifiable, such as the number of past victims and the examinee’s age. Alternately, dynamic risk factors are more fluid risk factors, which can also be targets for intervention to prevent future violence. These can include factors such as substance use, coping skills, education, employment, and a stable living situation. Clinicians’ desire to be able to account for both static and dynamic risk factors has led to increasing use of a *structured professional judgment* (SPJ) approach. This method is where clinicians base their assessment of an examinee’s dangerousness based upon the current empirical research and make their own judgment regarding overall level of risk. There are instruments that can guide the clinician’s SPJ as well,

Table 40.3 Common risk assessment tools

<i>Instrument</i>	<i>Type</i>	<i>Citation</i>
Classification of Violence Risk (COVR)	Violence–Actuarial	Monahan et al. (2005)
Violence Risk Appraisal Guide (VRAG)	Violence–Actuarial	Harris, Rice, and Quinsey (1993)
Violence Risk Scale (VRS)	Violence–Actuarial	Wong and Gordon (1999)
Sex Offender Risk Appraisal Guide (SORAG)	Sexual–Actuarial	Quinsey, Harris, Rice, and Cormier (2006)
Static-99	Sexual–Actuarial	Hanson and Thronton (1999)
Historical-Clinical-Risk Management (HCR-20; version 3)	Violence–SPJ	Douglas, Hart, Webster, and Belfrage (2013)
Risk for Sexual Violence Protocol (RSVP)	Sexual–SPJ	Hart et al. (2003)

although the final determination is still the clinician's own. See Table 40.3 for a list of some common risk assessment tools.

### ***Dangerousness and Neuropathology***

While the risk assessment tools in Table 40.3 will provide an adequate guide for those assessing dangerousness in a general sense, neuropsychologists may be called in when the standard methodology would not be entirely accurate due to issues involving neuropathology. For example, a convicted offender with known frontal lobe pathology may be at higher risk for affective or impulsive violence than one without. It is important to keep in mind that in this context civil commitment for dangerousness hinges upon dangerousness *due to a mental disease or defect*. What happens, for example, when an offender who was clearly already dangerous due to his past criminal history acquires neuropathology during the course of his detainment or incarceration? If a detainee is pending trial for a first degree murder charge, has a history of gang membership and similar charges, and then incurs a severe case of herpes simplex virus encephalitis during his detainment, does this now make him dangerous due to a mental disease or defect? How might his relatively dense amnesia increase or decrease his propensity for future acts of violence? These are cases that must be assessed cautiously when using standardized actuarial risk assessment instruments and empirically based SPJ measures, as neurocognitive and neuropathological features are simply not included in the extant instruments. For a detailed discussion of affective and predatory violence and the neurobiological underpinnings of such, which may be of relevance to neuropsychologists performing these assessments of dangerousness, see Fazio and Denney (2015).

### **Death-Penalty-Related Matters**

FNs are commonly utilized as experts in death penalty litigation. Because a human life is at stake in death penalty litigation, the process undergoes a higher level of scrutiny at every level than other more routine criminal adjudication. FNs participate in the same issues such as *Miranda* competency, competency to stand trial or enter a guilty plea, and be

sentenced; however, there are unique points of entry for FNs as well, such as the issue of potential intellectual disability at the early stage, mitigation at the sentencing phase, and competency to be executed at the late stage.

### ***Atkins v. Virginia (2002)***

The U.S. Supreme Court decision in *Atkins v. Virginia* (2002) is particularly significant for FNs involved in death penalty proceedings. Daryl Atkins and an accomplice abducted a man, robbed him, forced him to withdraw cash from an ATM, drove him to an isolated location, and then shot and killed him. Atkins was convicted of abduction, armed robbery, and capital murder. During the penalty phase, the defense-selected psychologist testified that Atkins achieved an IQ of 59, and concluded the defendant was mentally retarded. Rebuttal testimony by the government's psychiatrist painted a picture of psychopathic personality. The jury sentenced Atkins to death, the state supreme court affirmed the judgment, and the case was appealed to the U.S. Supreme Court.

The U.S. Supreme Court reviewed the various state standards across the union and determined that the number of states banning execution had increased substantially since the issue of executing the mentally retarded was last raised (*Penry v. Lynaugh*, 1989). This observed trend was a significant factor in the legal analysis. However, more significant for forensic neuropsychological analysis was the High Court's conclusion that developmental intellectual disability was associated with several cognitive limitations. They are detailed in Table 40.4.

Table 40.4 Cognitive domains relevant to mental retardation determination, per *Atkins v. Virginia* (2002)

- Comprehend information
- Process information
- Communicate
- Learn and remember
- Profit from mistakes and experience
- Engage in logical reasoning
- Control impulses
- Understand the reaction of others

The High Court also addressed the historical justification for the death penalty: retribution and deterrence of future capital crimes. It reached two conclusions: the diagnosis of retardation (now termed *intellectual disability*, or ID) implied both reduced culpability and lowered prospects for deterrence. In other words, persons with ID are less likely to understand and profit from an understanding of the deterrence value of the death penalty, and hence cannot control their conduct through the verbal mediation of a deterrence concept. Finally, the court expressed concern that offenders with ID may face an increased risk for wrongful execution because they may unwittingly provide false confessions. The idea is that those with ID are less able to resist persuasion and deceptive police tactics.

The *Atkins* decision had many ramifications, both positive and negative, for forensic examiners. The decision showed positive awareness of the unspoken criminal responsibility issue, as the court concluded that mental retardation did not necessarily eliminate a person's ability to appreciate right from wrong. Presciently, and of importance to FNs who also evaluate for feigned deficits, Justice Scalia writing the dissenting opinion in the *Atkins* case expressed concern that manipulative defendants would eagerly seek a mental retardation label long before a trial's penalty phase, to enhance chances of not only avoiding the ultimate penalty, but winning a legal insanity defense during the guilt phase.

More problematic for future examiners was poor guidance on defining retardation. The High Court neither dictated the exact manner in which ID was defined (thus leaving it up to the states), nor did it offer guidance on the severity of ID necessary to remove execution risk. All subsequent case law of which we are aware has settled on the conclusion that any level of ID will meet the *Atkins* standard.

We offer the following best practice. A reasonable interpretation of *Atkins* is that in order to be proven intellectually disabled, the FN should rely on the most contemporary *Diagnostic and Statistical Manual* (DSM). DSM-IV (American Psychiatric Association, 1994) was current at the time of *Atkins*, but was replaced by *DSM-5* in 2013 (American Psychiatric Association, 2013).

The defendant must show (a) subaverage intelligence during an individualized assessment, (b) impairment in daily adaptive functioning, and (c) evidence that the condition existed prior to the age of 18 years. Although some erroneously believe DSM-5 criteria no longer concerns itself with an IQ score (*Hall v. Florida*, 2014, Alito Dissenting), the preeminent criterion soundly remains in place. The authors simply removed the reference to an IQ score of 70 in Criterion A page, but retained it in the text:

Individuals with intellectual disability have scores of approximately two standard deviations or more below the population mean, including a margin for measurement error . . . On tests with a standard deviation of 15 and a mean of 100, this involves a score of 65–75 ( $70 \pm 5$ ).

(p. 37)

It must be noted, however, that this five-point confidence interval varies depending on the test, the IQ score, and the age of the individual. Adaptive functioning (solving everyday problems) was divided into 11 categories in DSM-IV, but reduced to three general categories in DSM-5, because of the clear influence from the American Association on Mental Retardation (AAMR), now called the American Association on Intellectual and Developmental Disabilities (AAIDD). Although not relevant to *Atkins* decisions because the litigation focuses on whether or not a defendant has ID, DSM-5 raised the significance of adaptive functioning within the diagnosis by using it to determine the difference between mild, moderate, severe, and profound ID, rather than the IQ score.

Since *Atkins*, courts and psychologist experts retained in the litigation continually struggle with four issues: the standard error of measurement (SEM), test-retest effects, whether IQ scores should be corrected for the so-called Flynn effect, and measurement of adaptive functioning.

### *Standard Error of Measurement*

Although the mental health field has long understood that IQ scores are estimates of intellectual ability in which inherent error is contained, the legal system has not always appreciated this reality. Recently, the U.S. Supreme Court overturned a Florida court's decision to limit intellectual disability for purposes of death penalty litigation to those individuals who score 70 or below on IQ testing irrespective of the test's SEM (*Hall v. Florida*, 2014). The High Court concluded that it was a violation of the Eighth Amendment against cruel and unusual punishment for trial courts to limit the consideration for intellectual disability to a strict 70 cut-off without considering the SEM.

When testifying about the confidence interval derived from the SEM, FNs need to remember that the confidence interval developed from the SEM does not remain a bell-shaped (Gaussian) curve once the score deviates significantly from the mean (Nunnally & Bernstein, 1994). In other words, the distribution becomes increasingly positively skewed as the score falls closer to 70 and below as a result of regression toward the mean. The practical ramification of this fact is that courts can have increased confidence that the true score is more likely to fall at the obtained score or higher in the confidence interval rather than the lower end of the interval. It is exceedingly unlikely that the true score would fall at the lowest point of the confidence interval.

### *Test-Retest Effects*

Criminal defendants progressing through death penalty litigation are likely to undergo multiple examinations regarding their intelligence. Additionally, they will likely have a history of previous intellectual assessment. When comparing results of multiple IQ tests, not only differences between

tests need consideration, but it is proper to consider potential test-retest effects as well. This issue almost always arises during an *Atkins* hearing. FNs need to be aware of how different versions of intelligence tests compare (if research of that comparison exists) and also how scores change with retesting using the same test. For the Wechsler Adult Intelligence Test, fourth edition (WAIS-IV), the technical manual (Wechsler, 2008) indicates the test was administered twice to the same healthy people, with retest intervals ranging from 8 to 82 days (mean = 22). Results indicated the Full Scale IQ increased by an average of 4.3 points over the entirety of the four age bands (ages 16–90 years). This sample was stratified by race/ethnicity, region of the country, and education (< 9 years to > 17 years). The greatest Index increase was 4.4 for Processing Speed, while Perceptual Reasoning was 3.9, Working Memory was 3.1, and Verbal Comprehension was 2.5. Overall, one should expect about a four-point increase in IQ with retesting if it was done within about three months of the initial testing. It is illogical to expect much greater differences as the delay interval increases beyond three months. Catron and Thompson (1979) administered the WAIS to college students on two occasions with intervals of one week, one month, two months, or four months. They found the average increase in FSIQ was 8.0, 5.7, 5.4, and 4.2 points for each interval, respectively. These findings support the belief that retest gains lessen as the interval increases, at least with college students.

Estevis, Basso, and Combs (2012), in contrast to the WAIS-IV validation study, highlighted the effects of IQ and education. They found an average increase in FSIQ on the WAIS-IV of seven points with healthy, educated ( $M = 14.9$ ,  $SD = 0.9$ ), young adults ( $M = 20.9$ ,  $SD = 2.5$ ) who were intellectually high average (FSIQ  $M = 111.6$ ,  $SD = 12.1$ ). There was no statistically significant difference between three-month and six-month intervals. Such a large increase was likely due to uniformly higher education and intellectual levels as well as smaller percentage of racial/ethnic minorities than that present in the WAIS-IV validation studies. Less extreme increases would be expected with individuals having lower IQs, particularly those falling in the range of intellectual disability. Rapport, Brines, Axelrod, and Theisen (1997) revealed this very finding that practice effects were smaller for those with IQs falling in the low-average range (80–90) than for those in the average (95–105) and high average (110–120) ranges when tested repeatedly with the WAIS-R (Wechsler, 1981) at two-week intervals. Results for the low-average IQ group more closely approximated findings from the WAIS-IV validation studies (i.e., FSIQ average increase of 5.6 points). We are not aware of any practice effect studies with individuals having intellectual disability.

One of us (RLD) has repeatedly faced cross-examination where the defense attorney presents a copied section out of Kaufman and Lichtenberger (2006) dealing with “progressive error” (p. 163). Progressive error refers to the compounding effect of test-retest error over the course of more than

two IQ test administrations. Kaufman and Lichtenberger cite Kausler’s (1982, 1991) work as the originator of the concept. They then highlight two longitudinal studies dealing with IQ testing among the elderly as examples of how this effect is revealed (Schmitz-Scherzer & Thomae, 1983; Siegler, 1983). The fact that performances did not decrease as expected during the studies was interpreted to indicate the age effects were being countered by the effect of progressive error. The answer to this interesting finding is presented by Kaufman and Lichtenberger on the pages following shortly thereafter. The section is called “Selective Attrition” and refers to the interesting finding that participants do not uniformly return for follow-up assessments during longitudinal studies. However, this attrition is not uniform across the IQ distribution. Interestingly, those who do return for follow-up assessments have, on average, higher IQs than those who do not return. The sum effect of this selective attrition is to increase the mean IQ scores during subsequent test administrations. In effect the follow-up groups are not the same as the initial group. Kaufman and Lichtenberger (2006) conclude, “Hence, generalizations from longitudinal studies must be made quite cautiously because of the considerable selective attrition factor” (p. 167).

Empirical data pertaining to multiple IQ administrations among those with very low IQs is lacking. Rawlings and Crewe (1992), in a retrospective study, compared repeated IQ test administrations among TBI survivors who were matched on variables thought to have “confounding influences” (p. 418). The “experimental” group of patients was tested at two-month, four-month, eight-month, and 12-month intervals. The other group of patients was tested at two and 12 months. Both groups were compared at 12 months to determine the effect of four multiple assessments over two assessments. The group that was administered four assessments increased the FSIQs an average of 2.97 points over and above the two assessment group at 12 months. Although the experimental group had a greater change effect size than the control group, these findings suggested the effect of an increased number of assessments over just two assessments was clinically negligible as scores fell well within the confidence interval. While progressive error is raised as a concern, empirical data to support the concept appears lacking. At this point, we consider selective attrition to be the more parsimonious explanation for so-called progressive error.

### *Flynn Effect: The Phenomenon*

The Flynn Effect (FE) refers to a large secular increase in aggregate intelligence scores since the 1930s, and it is a generally accepted phenomena (Neisser, 1998). The eponymic label became widespread because of political scientist James Flynn’s prolific writing on the topic (Flynn, 1984), although he was not the first to observe and theorize about the rise. Greiffenstein (2011) reviewed earlier literature that showed rising IQ scores since World War I.

The trend line across many studies suggests a rate of 0.3 IQ points per year (three per decade), if the baseline is set in the 1930s. The parameters of the rise include increases in many different industrialized countries and a greater rise in measures of “fluid intelligence” versus “crystallized,” with a more recent leveling off (possibly pausing) in IQ gains (Sundet, Barlaug, & Torjussen, 2004). The best evidence comes from national military records. Such samples are massive, and especially representative of the population in countries with conscription (Flynn, 1987a, 1987b).

### *Flynn Effect: Theory*

There is no widely accepted explanation of the intergenerational IQ trends. There are disagreements whether the increase represents actual changes in underlying *g* or ordinary facultative changes (learning and rote memorization); or whether methodological artifact (e.g., differences in recruitment bias between standardization cohorts), changes in subtest instructions and constructs (Kaufman, 2010), and/or if epigenetics (factors turning genes off/on) play roles (Greiffenstein, 2011). In 1998, the American Psychological Association published a monograph on the topic, with several authorities on intelligence weighing in with theories (Neisser, 1998).

There are single-process explanations of rising IQ. They include improved nutrition, learning to solve abstract problems without increased *g*, compulsory education since 1900, and increasing cultural complexity. However, the intermediate steps between the proposed single causes and rising IQs have not been specified in any concrete way. The short timescale of the massive secular IQ gains is inconsistent with positive selection of a recent gene mutation, but other genetic mechanisms are possible.

Greiffenstein (2011) theorized an epigenetic mechanism. He applied life-history theory as a conceptual tool, and argued that secular trends (primarily improved nutrition) changed the phenotypic expression of the genotype that controls the neurophysiology of problem solving. More resources (“energetics”) were committed to reasoning than other bodily functions, because the environment was more resource-rich and dependable. Essentially, Greiffenstein (2011) argued for earlier cognitive maturation than in prior generations, and mandatory education had a multiplier effect, increasing IQ scores.

### *Flynn Effect: Practical Considerations*

Moving from group to individual data, the FE is evident in everyday practice. Persons who take old IQ tests today score much higher than persons of the same age when that IQ test was first published, a fact reflected in data tables in some test manuals. The standardization group for the WAIS-R (Wechsler, 1981) also took the 1950 WAIS, and scored 11 points higher on average. Hence, the WAIS-R had to be recalibrated to a mean of 100. In death penalty venues, however,

standardized intelligence test administration, as memorialized in the test manuals, is considered inadequate by some forensic psychologists. These psychologists are proponents of making downward adjustments to current IQ scores, to “correct” for the age of the test norms, in criminal cases (Fletcher, Stuebing, & Hughes, 2010; Reynolds, Niland, Wright, & Rosenn, 2010). They typically subtract a fractional IQ unit from the current score to elucidate the “true” IQ score, arguing that this practice removes the test-age bias that is presumed to be systematic. As stated earlier, the rise has been a remarkably consistent 0.3/year when one smooths aggregated testing data bases that in some cases are separated by decades. This simple formula has been proposed:

$$\text{Adjusted IQ} = \text{Observed IQ} - [0.3 \times \text{years since test norming}]$$

Take, for example, a criminal defendant who is tested with the WAIS-R in 2000 and earns a Full Scale IQ of 75. Taking measurement error into account, the score is in a range consistent with V62.89, Borderline Intellectual Functioning per the DSM-IV-TR (APA, 2013). The WAIS-R was normed in 1980 (Wechsler, 1981). The forensic psychologist reports a “Flynn adjusted” score of 69, by subtracting 6 ( $0.3 \times 20$ ) from 75, and concludes that the defendant exhibits mild intellectual disability, rendering him ineligible for the death penalty.<sup>1</sup>

Proponents of “Flynn corrections” support their position with some reasonable arguments. The most compelling one is that the FE stands for increasing inaccuracy of Full Scale IQs as a function of test age. The older an IQ test is, the greater the upward bias in scoring error (i.e., IQ inflation). A psychologist needs to consider the alleged bias of an aging IQ test, because overestimating IQ has profound consequences. The death penalty is one of them, but outside of criminal law, special education services may be denied because “the IQ is too high.” Kanaya (2004) conducted a longitudinal test-retest study of children in special education and found large decreases in IQ when retested on new norms, when compared to old norms. Hence, children who may have qualified for special education services earlier may have been denied them because scores were inflated by the older first test.

Fletcher and colleagues (2010), proponents of applying FE, add that “correcting an IQ score is not a violation of test administration, rather it is selecting an appropriate normative comparison” (p. 4570). They give the example of a pediatrician relying on current national height/weight norms rather than old or foreign ones. Additionally, Fletcher et al. counter critics by making the aggressive argument that all practice standards should be ignored except for one: the manual published by the American Association of Intellectual and Developmental Disabilities, which advises correcting IQ scores in death penalty cases. Unfortunately, Fletcher et al. do not offer any norms for Flynn-corrected scores, or any data on the reliability and validity of adjusted scores.

Not all proponents are reasonable. The justification for making corrections is hotly debated, and sometimes

rancorously. For example, Reynolds and colleagues (2010) acknowledged that adherence to the test manual is “standard practice,” but threatened future charges of “malpractice” against those who do not make score adjustments that those authors demand.

Critics of making adjustments reasonably point out several problems with “Flynn” corrections. One problem is lack of general acceptance. The practice of adjustments is so far limited to a small cadre of psychologists who are usually hired by defense attorneys and specialize in pretrial evaluations in capital cases. Hagan, Drogin, and Guilmette (2008) used two methods to evaluate general acceptance: (a) a survey of doctoral training program directors and (b) a systematic review of relevant source material (test manuals, textbooks on IQ testing, and sources of legal/ethical guidance). Both survey and textual evidence demonstrated that IQ adjustments deviated markedly from the prevailing standards of psychological practice. Of further consequence to admissibility and ethics is the fact that downward corrections are never used in other contexts where IQ is critical, such as Social Security Disability evaluations.

The concern that aggregated cohort differences in IQ standardization causes inflated scores is valid. Nonetheless, there are serious logical problems with making adjustments in the *individual case*. It is unknown, for example, whether the 0.3/year increase applies universally to all examinees (Sternberg, 2010). More serious is the unproven assumption that increases are uniform across time and individuals. The annual 0.3 rate is just a convenient extrapolation from aggregated data separated by many years. In other words, it remains unknown whether the leap in IQ scores was densely clustered in a past generation followed by periods of dormancy (“lumpiness”), or if the trend was perfectly linear as implied by the FE correction formula. This question is not trivial, because if the IQ increase was both “lumpy” and remote in time (e.g., the 1930s to 1970s), then correcting more modern tests could distort scoring. There is, in fact, good evidence that the FE ended by the mid-1990s—interestingly, at the same time that height gains stopped (Sundet et al., 2004; also see Greiffenstein, 2011, regarding nutrition as a “prime mover” for FE). Equally unknown is the reliability and validity of Flynn-corrected scores, an issue ignored by corrections proponents. A Flynn correction is technically a change score, and change scores have more error than individual scores (Nunnally & Bernstein, 1994).

The hazards of applying corrections to the individual case are demonstrated in a critical study by Zhou, Zhu, and Weiss (2010). They administered pairs of old-new tests to large samples of children and adults. Their aggregate data showed the classic FE of 0.3/year, but the magnitude of the difference was not evenly distributed across ability level. Those with subaverage IQs (< 89) showed the largest mean inflation on the older test, but 40% still showed either a *decrease* (newer IQ score below older one) or little to no change. Applying a downward correction to a person’s subaverage IQ score

would be wrong at least 40% of the time, and of unknown exactitude in the other 60% percent. This adds even more error, beyond the SEM.

#### *Flynn Effect: Best Forensic Neuropsychology Practice*

We strongly recommend against making FE corrections. There are several reasons to avoid the practice. The reliability and validity of corrected scores is unknown and likely to contain more error; the contemporary (ongoing) existence of secular increases in IQ is scientifically disputable, because the trend may have ended decades ago; and it is unknown whether the corrections can universally be applied or whether further adjustments have to be made to the adjustment, based on the characteristics of examinees (race, age, gender); and Zhou et al. (2010) proved that the FE magnitude varies widely across and within ability levels. Finally, assigning a number in this fashion is pseudoscientific, because it gives the misleading impression of mathematical accuracy, when the assumption of underlying linearity is just speculative.

We recommend, however, including some consideration of the FE in the interpretive section of FN reports as mandatory practice. The FE is a real phenomenon, and the historical need to recalibrate IQ to center on 100 is all the proof needed to reflect that the “true” score could potentially deviate from an observed score with an aging test. We agree with Hagan et al. (2010) that, when there is legitimate concern about a difference in “true” versus observed scores on an intelligence test, psychologists are “justified in sharing this perspective in *narrative form*” (p. 475, emphasis added), not in pseudoscientific numerical form. Consider this excerpt from a FN report from one of us (MFG):

Defendant’s expert opined that the defendant should be viewed as mentally retarded, after ‘Flynn-effect correcting’ the 1980 WAIS and later 2010 WAIS-III scores, with a static formula. In my professional opinion, it is possible that the defendant’s true IQ is below the scores calculated according to older test manuals. Nonetheless, the size of the score inflation is unknown, even assuming that the FE ever touched this individual. For example, the Verbal IQ of 80 obtained with the Wechsler Adult Intelligence Scale in 1980, was based on persons who were defendant’s age in 1950. His old verbal IQ can reasonably be viewed as an over-estimate. However, no number reflective of his “true” verbal IQ can be calculated. The calculation formula is unreliable because it is based on unsupported premises, one falsifiable premise being that the Flynn Effect has been linear and uniform for everybody.

In summary of my professional opinion, defendant’s past IQ scores reasonably reflect *some* degree of overestimation. But IQ is not the sole basis for evaluating MR, and the totality of the evidence shows ordinary levels of adaptive function in several domains. His adaptive functioning skills appear more in line with the observed IQ scores, and not in line with the much lower “Flynn corrected IQ scores.” His

leadership qualities in running gangs inside and outside of prison are impressive, he taught himself to read, and there is no evidence that he was mentally retarded before age 18, except for his mother's belated insight that he was "retarded as a child" after the defendant was charged with a capital crime.

### **Measurement of Adaptive Function**

It is well understood that the assessment of adaptive function must be multidimensional. Olley and Cox (2008) provided this conclusion:

By using multiple sources of information and thoroughly understanding the nature of mental retardation, the expert can reach a conclusion that has consensual validity. Ideally, many sources of information are congruent and lead to a single conclusion . . . the expert who relies on multiple sources is better equipped to use his or her judgment to draw a valid conclusion.

(p. 387)

Use of a multidimensional model of adaptive functioning that incorporates multiple interviews as well as standardized scales is consistent with the Multi-Data Source Model (Denney, 2005, 2012b). The model is particularly relevant in *Atkins* litigation because the assessment of adaptive function should take into consideration adaptive function currently (or at the time of the crime) as well as retrospectively, to when the defendant was in the developmental period (defined as prior to 18 years of age). Added to the complexity is the need to consider atypical motivations not only for the defendant, but also for family members and spouses because of the forensic context. Examiners who use standardized scales such as the Vineland Adaptive Behavior Scales, third edition (Sparrow, Cicchetti, & Saulnier, 2016), and Adaptive Behavior Assessment System, third edition (Harrison & Oakland, 2015) to obtain information need to be aware that such scales have no validity scales within them and are relatively easy for examinees to manipulate (Doane & Salekin, 2009). An important issue to keep in mind in this regard is consistency across domains. It is clear that individuals with ID can have strengths and weakness, but adaptive function deficits that are significant will cut across multiple functional domains. The overall clinical picture must make sense with the facts of the person's life.

### **Mitigation Expertise at Sentencing**

Any and all mental-health-related issues can be presented to the jury at the sentencing phase providing they are considered relevant by the trial judge. FNs are often called upon to examine the defendant and testify to developmental issues, learning issues, current emotional and cognitive issues, and basically any relevant issue within the scope of practice for a neuropsychologist that might help a jury consider the

uniqueness of this particular defendant before determining whether or not to impose a death sentence. The U.S. Supreme Court has made it rather plainly clear that virtually any relevant individualized mitigating information pertaining to the convicted individual should be allowed (*Eddings v. Oklahoma*, 1982; *Lockett v. Ohio*, 1978; *Rompilla v. Beard*, 2005; *Skipper v. South Carolina*, 1986; *Wiggins v. Smith*, 2003). For a more detailed review of issues relevant for the FN and the evaluation process, see Heilbronner and Waller (2008) and Cunningham and Goldstein (2012).

### **Ethical Considerations**

When one enters the forensic arena, particularly the criminal forensic arena, where questions of loss of liberty or even life or death are at issue, one must be certain to practice with high ethical standards. Above all, psychologists will be held to the American Psychological Association's Ethical Code of Conduct for Psychologists (American Psychological Association, 2002), with which most clinical neuropsychologists should already be familiar. The code no longer includes a special section of forensics, but many standards continue to apply. For example, this ethics code mandates that one should not practice outside of their realm of competency. Entering the criminal forensic arena raises a number of clinical and ethical considerations with which most clinical neuropsychologists are *not* familiar, and can easily thrust them outside the realm in which they are competent and into the area of malpractice. As such, this decision should not be made lightly, and extensive training and supervision should be pursued. For example, when neuropsychologists enter this area of practice, they must always be aware of issues such as in which jurisdiction they are practicing, who is their client, and what is the actual legal standard or question that they are assessing. For many clinical neuropsychologists, this raises the unfortunate scenario of *professional anosognosia*—they are not even aware of what they do not know. To paraphrase a former defense secretary, novices can be hampered with too many "unknown unknowns."

Another important consideration is to determine one's temperament and adjustment capacity, when exposed to criminal forensic scenarios. Clinical neuropsychologists must ask themselves if they can cope with the emotional costs of giving important testimony in a death penalty case (e.g., insomnia), if they can remain an impartial evaluator after exposure to documented details of heinous crimes, and if they can maintain their composure when dealing with quite aggressive cross-examination. The next section offers aspirational guidelines for ideal professional behavior in the forensic arena.

### **Specialty Guidelines for Forensic Psychology**

Perhaps more so than in the civil area, the criminal forensic neuropsychologist should be familiar with the *Specialty*

*Guidelines for Forensic Psychology* (American Psychological Association, 2013). In addition to the aforementioned issues of competency and impartiality, these guidelines also emphasize issues such as having an adequate understanding of the scientific foundation of one's opinions and testimony, cultural sensitivity, and avoiding conflicts of interest and multiple relationships. For example, one should not perform a clinical evaluation for therapeutic purposes and then also serve as an expert witness in a criminal matter; one should only serve as a fact witness in this scenario.

### Conclusions Regarding Ethical Issues

It is appropriate that we conclude this chapter on the subject of ethics; it is undoubtedly one of the most important subjects for clinical neuropsychologists practicing in criminal forensics (Sullivan & Denney, 2008). One cannot obtain a level of advance professional competency in this arena without a willingness to maintain the highest level of integrity and remain fixed to the genuine conclusions raised by the facts of the case, regardless of whether or not those conclusions favor the neuropsychologist's referral source. Maintaining a higher standard for one's level of expertise regarding the tests and procedures used helps ensure the most accurate testimony possible for the trier of fact and readies the neuropsychologist to face the corresponding level of scrutiny seen in the courtroom.

### Note

- 1 Some argue that the calculation should not be based on the publication year of the manual, but should instead reflect the actual year of norming, which takes place in 1-2 years prior to official test publication and marketing.

# 41 Disability

*Michael Chafetz*

## Disability Terminology and Constructs

The term *disability* is defined in a broad way by advocacy and professional groups and typically has a distinct meaning from legal terminology one sees in public (Social Security) and private (insurance) disability evaluation settings. For example, the World Health Organization (WHO) World Health Report (2001) invokes *disability* to describe limitations from many different sources of impairment. WHO (2001) used a Global Burden of Disease (GBD) metric called the *disability-adjusted life year* (DALY). One DALY unit can be thought of as one lost year of healthy life due to premature death or disability. WHO (2001) reported that mental and neurological disorders accounted for 10.5% of the total DALYs lost due to all diseases and injuries. According to WHO (2001), the GBD 2000 estimates indicated that mental and neurological conditions account for 30.8% of all years lived with disability.

The American Psychological Association in its *Guidelines for Assessment of and Interventions With Persons With Disabilities* (2012) cited the U.S. Department of Health and Human Services (2005) construct that *disabilities* are physical, mental, and/or sensory characteristics that affect a person's ability to engage in activities of daily life. Similarly, in the Americans With Disabilities Act (ADA) Amendments Act of 2008, *disability* is defined as a physical or mental impairment that substantially limits a person's ability to engage in a life activity. These definitions are of great importance in both public and private evaluations for disability in which assessment of daily living activities takes on significance in the understanding of limitations caused by the impairments. WHO (2001) calls for a public health approach linking biological, psychological, and social factors to reduce the overall burden of mental disorders.

Rosa's Law (2010) amended all federal public laws that use *mental retardation* terminology, replacing the older term with *intellectual disability* (ID). The American Association on Intellectual and Developmental Disabilities (AAIDD), formerly the American Association on Mental Retardation (AAMR) has taken a disability-based environmental perspective in redefining *mental retardation*. AAIDD now states that the basis for helping and defining the levels of persons with ID is by the supports necessary to achieve optimal

functioning (Schalock, Borthwick-Duffy, Bradley, Buntinx, Coulter, et al., 2010). AAIDD promoted the adoption of Rosa's Law. According to AAIDD, the construct of *disability* has evolved from a *deficit*, which is person-centered, into a *human phenomenon* with origins that lie in organic and social factors. It is no longer an absolute and unvarying trait of a person, but now an interaction of a person and the environment. With appropriate personalized supports over a continuous and sustained period, the functioning of a person with ID will improve.

Under the Social Security definition of disability, the claimant must be unable to engage in any substantial gainful activity (SGA) because of a medically determinable physical or mental impairment. This impairment must last (or be expected to last) 12 months continuously or be expected to result in death (Social Security Administration [SSA], 2013a). Under this definition, the claimant must prove inability to work in any job for money; under the Supplemental Security Income (SSI) program, a means-tested program, the claimant must not be able to earn more than a legal limit (about \$1,000/month), which is the SGA amount (unless the claimant is blind). This is a strict legal definition of disability under which SSA determines whether an applicant is eligible for benefits. A claimant must meet the particular listing requirements from the Blue Book (SSA, 2013b) for benefits for any particular disability (e.g., mental disorders). For children, *disability* means that the child has a medically determinable physical or mental impairment that causes marked or severe functional limitations (Morton, 2010).

Under private disability contracts with a disability insurance carrier (e.g., Unum, Northwestern Mutual, Liberty Mutual), an individual may obtain disability benefits for partial or total disability, whereas Social Security has benefits for total disability only. Private disability carriers may also define contracts for short-term or long-term disability benefits. Some contracts may provide benefits if the individual is unable to work in his own occupation, while others are for any occupation for which the individual has training or skills (as with Social Security). As with Social Security, private disability carriers define the particular disabilities in specific terms, and are interested in how the impairments limit the person's activities, particularly work activities. Social Security benefits are funded by general tax revenues (SSI) or the

Federal Insurance Contributions Act (FICA) tax withdrawals from paychecks of workers for Social Security Disability Insurance (SSDI). Private disability premiums are paid for by the individual, the employer, or both.

The SSA has two basic disability programs: SSDI for workers and their dependents who have paid into the Social Security Trust Fund through the FICA tax; and SSI for disabled individuals and dependents with limited income and assets.

The Disability Determinations Services (DDSs) are state agencies funded by SSA that administer these disability programs. Through a professional liaison, the DDSs find and credential qualified psychologists. The schedulers arrange consultative examinations (CEs) with psychologists who have already been qualified, and the psychologists will then perform psychological consultative examinations (PCEs) for the referred cases. The DDSs will also obtain medical evidence about the claimant, attempting to catalogue impairments from claimed symptoms and the obtained evidence. As part of making a disability determination, the DDS personnel will have to look at all the evidence and determine whether the claim meets the legal definition of Disability according to the Blue Book listings for each mental impairment (SSA, 2008).

### Legislative History

On August 14, 1935, President Franklin Delano Roosevelt signed the Social Security Act into law, providing an old-age retirement pension (Old Age and Survivors Program) as income for those who were no longer working. This law saved millions from becoming impoverished when they were no longer able to work, thus setting the stage for the disability compensation laws in the 1950s. In 1954, amendments to the Social Security Act led to the Disability Insurance program, and in 1955 a “freeze” was placed on records during the periods a person was unable to work, which prevented the disability from reducing or eliminating retirement benefits (SSA, 2012). On August 1, 1956, President Dwight Eisenhower signed the new disability legislation, which delivered cash benefits to disabled workers aged 50–64 after a six-month waiting period.

Over the next four years, Congress broadened the scope of this new disability program, allowing benefits for dependents and for workers under the age of 50 who became disabled. The Civil Rights Act of 1964 protected women and minorities from discrimination in employment, and in the same period Congress passed legislation benefitting people with disabilities, including Medicare, the Elementary and Secondary Education Act, and the expansion of the Vocational Rehabilitation Act (Winegar, 2006). However, it was not until 1972 that President Richard Nixon signed into law the needs-based SSI program established to provide a true social safety net for disabled individuals who were never able to work, and for children with disabilities.

The next stage for disability legislation occurred with the ADA in 1990. The ADA was based on the Education for the Handicapped Act of 1975 (Colker, 2005; Chafetz, 2015), which in a newer version in 1997 was called the Individuals With Disabilities Education Act (IDEA, 1997). This law specified that in order to receive federal funds, states must develop and implement policies that ensure that all children with disabilities receive a free appropriate public education. The original act is known as Public Law 94–142. The Individuals With Disabilities Education Improvement Act (IDEIA) of 2004 provided additional procedural safeguards for students with disabilities.

The ADA (Title I) prohibited discrimination against a qualified individual with a disability concerning any aspect of the employment. Employers cannot discriminate against disabled individuals who, with appropriate accommodations, could perform the essential functions of their positions (Colker, 2001, 2005).

The ADA was heralded as becoming potentially one of the great civil rights laws for disabled individuals, but the next 15 years were seen as a time during which disabled plaintiffs frequently lost cases in favor of employer-defendants (Colker, 2001, 2005; Winegar, 2006). The ADA did not provide the intended relief during this period, and Colker (2001) has indicated that appellate litigation has not been an effective vehicle for ADA enforcement. Colker (2001) chided Shalit’s (1997) characterization (“buffet of perks”) as being inaccurate and misleading.

For a summary of various disability statutes and laws, including the Telecommunications Act, Fair Housing Act, Voting Accessibility for the Elderly and Handicapped Act, etc., see the U.S. Department of Justice Guide to Disability Rights ([www.ada.gov/cguide.htm#anchor64984](http://www.ada.gov/cguide.htm#anchor64984)).

### Social-Political Climate

It is interesting to note the political climate of the times. In 1972, the Democrat nominee for president, Senator George McGovern, had to replace Senator Thomas Eagleton (D-Mo) in the vice presidential slot on the ticket when it was disclosed that Senator Eagleton had been treated for depression, and there was a negative public reaction (Colker, 2005). In the 1988 presidential race between Michael Dukakis and the senior George Bush, there were rumors about mental illness flying when Governor Dukakis refused to disclose his medical records. When President Reagan, who was finishing his term and not running further for office, was asked about these rumors, he replied: “Look, I’m not going to pick on an invalid.”

However, at about the same time, in August 1988, Vice President Bush was urging Congress to enact the ADA, and bills were introduced in the Senate and House of Representatives. The Senate bill passed 76:8 in September 1989, and the House bill passed 403:20 in May 1990. George Bush’s son Neil had struggled with dyslexia. As president, George Bush

commanded Attorney General Dick Thornburgh, whose own son had experienced a traumatic brain injury (TBI) in a 1960 motor vehicle accident, to work with Congress on the legislation (Colker, 2005). As so often happens, the legislation was pushed by those who had directly experienced struggles with disabling conditions.

### A Medicolegal Arena: Ethics and Boundaries

Whether performing public or private disability evaluations, military compensation and pension, fitness-for-duty assessments, or for workers' compensation (WC), evaluators must understand that they are working in a medicolegal arena. Evaluations for accommodations for testing or for the schools fall under the same rubric, as the goal of the client is not necessarily to be helped clinically but to obtain a compensation or benefit under the law.

The typical training for a clinician involves developing knowledge of the consultation in which a patient comes to the clinician seeking help for a mental or cognitive condition. The psychologist's role in a clinical consultation is to offer assessment, diagnosis, recommendations, or forms of intervention and treatment. The client in this scenario is the patient, whether self-referred or referred by another provider. Payment in some form is usually expected, by the patient or from a third party (e.g., insurance company or parents), except when the psychologist accepts the case *pro bono* (work undertaken for the public good without charge). No matter what form or source of payment, however, the psychologist is expected to attempt to help the patient-client concerning the presenting condition. The psychologist has a fiduciary duty to this person (and/or parents or guardians). Privacy rights extend to this person under the relevant Health Insurance Portability and Accountability Act (HIPAA) of 1996 provisions. A treatment alliance is expected, and there exists a typical doctor-patient relationship, with appropriate clinical boundaries to avoid harm and exploitation of this relationship (American Psychological Association, 2002).

Concerning a medicolegal evaluation, the evaluator should fully understand that the motivations of claimants and patients are different (Greenberg & Shuman, 1997, 2007; Strasburger, Gutheil, & Brodsky, 1997). While the patient is seeking understanding and help regarding an uncomfortable condition, the claimant is seeking to have the disability or worker's compensation claim approved. These motivations are widely disparate, and frequently lead to different presentations. Claimants are often uncomfortable about doing anything that might lead to a denial of the claim. There may be an active attempt by the claimant to mislead the evaluator about the condition being claimed. The evaluator should not treat this behavior as a personal affront. It is always wise for the evaluator to be respectful toward the claimant, which may alleviate discomfort, but the evaluator is not expected to provide treatment or any intervention.

In a medicolegal workup for public disability (Social Security Disability), the client may be the local DDS, one of the state agencies funded by SSA to apply the rules and listings of disabilities to the determination of each claim. A Social Security private attorney may contract with the evaluator for a psychiatric, psychological, or neuropsychological examination. In this case, the claimant (through his or her attorney) is indeed the client. The motivation, however, is the same: That is, to prove to the DDS that the claimant has met the listing requirements to be awarded disability benefits. The evaluation is not about diagnosis or impairment *per se*, but about the claim for an inability to work (Puente, 1987).

These boundary conditions will also be seen in a WC setting. The evaluator may be seen at the request of the claimant (often through his or her attorney), or can be retained directly by the WC carrier. Again, the motivation by the claimant, no matter which "side" retaining the evaluator, is to obtain the legally appropriate benefits or compensation under the law. In WC cases, it is interesting that the payment to the evaluator usually comes from the WC carrier, no matter which "side" is consulting with the evaluator.

In both public and private disability cases, the evaluator is frequently asked to perform an IME, which can take the form of an independent psychological or neuropsychological evaluation. The term *independent* in these cases is taken to mean that the evaluator has not formed the doctor-patient relationship with the claimant, and is indeed *independent* of that relationship. As a practical matter, the evaluator who performs all, or predominantly, IMEs may be challenged as to "sidedness," with the criticism that the evaluator's opinions are shaped by the income coming largely from one "side."

This form of criticism, coming usually from lawyers, rests on the assumption that a 50-50 split of consultation from the plaintiff and defense (IME) sides would preclude bias, but this reasoning is faulty. For example, if the 50-50 evaluator always decides for the defense when the defense is paying, and always for the plaintiff when the plaintiff is paying, then the evaluator is perfectly biased toward where the money is coming from. This scenario presents the ultimate condition of bias.

The truly unbiased examiner should understand that integrity comes from the willingness (and actual behavior) to call the case exactly as the data findings show. When performing a disability IME, if the claimant is impaired and the scores are valid, then the conclusions and questions answered should accurately reflect the findings. If, in a plaintiff's case, the individual is found to be malingering, the examiner should inform the lawyer about the facts. While the retaining party may not be pleased, it is the duty of the examiner to follow the findings of the examination. Moreover, it is considered a myth that performing a defense-retained IME causes poor effort by the claimant (Greiffenstein, 2009). Indeed, the source of forensic referral (plaintiff vs. defense) does not affect any domain of neuropsychological test performance in those who pass validity tests or those who fail

validity tests (Meyers, Reinsch-Boothby, Miller, Rohling, & Axelrod, 2011).

In a PCE for the DDS, the DDS is the client of the psychologist/neuropsychologist. Indeed, the PCE can be considered as a psychological IME in which SSA is sending the claimant for an independent examination as part of the evidence gathering for a disability determination. The psychologist conducting the PCE neither works for the DDS nor for the claimant, and should fully embrace the independence. The job is to be objective and accurate, and to avoid bias in favor of the DDS or the claimant.

Concerning private disability evaluations, there is now a cottage industry of IME companies positioned between the disability insurance carrier and the evaluators. Typically, the IME companies have a number of examiners nationwide who have been vetted carefully and whose reports can be trusted to provide an accurate accounting of the findings and to answer the referral questions. Concerning the issue of bias, these IME companies provide a buffer between the disability carrier, who is paying the fee, and the examiner providing the IME service. In this way, the IME companies help ensure that the focus of the evaluation is on the accurate answering of the referral questions.

### Informed Consent

Under the American Psychological Association ethics code (3.10, 9.03), it is necessary for the psychologist to obtain informed consent for assessments except where testing is mandated by law. In criminal law (e.g., *Atkins* defense), when a defendant raises the defense of ID (formerly, *mental retardation*), the state has a right to its own examination of the individual. In litigation generally, as a practical matter, the lawyers (on both sides) will agree to the evaluation, and thus the plaintiff's attorney has already provided consent for the individual. When a claimant applies for Social Security Disability (SSD)<sup>1</sup>, the claimant agrees to be evaluated at the request of the DDS officials. Private disability contracts usually have a provision for evaluation at the request of the disability carrier. Nevertheless, under the American Psychological Association ethics code (3.10), at the time of assessment the evaluator should convey to the claimant in language that is reasonably understandable to that person the nature and boundaries of the evaluation.

The informed consent should contain information on the additional limits on confidentiality inherent in an IME, and may even restate the traditional limits on confidentiality under applicable state law (e.g., abuse of vulnerable persons). A statement that there is no doctor-patient relationship is important, and it is helpful to include that this examination does not replace psychiatric, psychological, or neuropsychological examination or treatment. A listing of points to include in a disability IME is shown on pp. 981 and 982.

A question often arises whether or what kind of warning about malingering should be provided in the informed

consent. When this writer was performing psychological CEs, the local DDS required the following warning: "Failure to do your best on these tests may result in an unfavorable decision on your claim." This warning is reportedly still being given. The debate about warnings concerns whether malingerers may attempt to cover their tracks when warned (Schenk & Sullivan, 2010; Boone, 2013).

As Boone (2013) has reviewed, there are studies showing reduced sensitivity of validity tests when a warning is given. Boone (2013) further argues that no warning is necessary when embedded validity indicators are administered, as these are an integral part of tests normally given in a neuropsychological evaluation. For example, the Minnesota Multi-phasic Personality Inventory-2 (MMPI-2 or MMPI-2F) has validity scales by which one can determine the validity of the examination, but there is no tradition of warning about specific scales on the MMPI.

#### Points to Include in Disability IME Informed Consent

- An insurance company is requesting an examination of you and will pay the fee.
- This insurance company is regarded as the client of the examiner.
- The examiner will prepare a written report that details the findings, and answers the questions asked by the insurance company.
- If you decide to withhold the report, you must send a request in writing to the examiner. This request will be effective only insofar as the examiner has not already relied upon this release of the report.
- The examiner cannot foresee the consequences of any decision not to participate in the examination or to withhold the report.
- Because of your relationship with the insurance company, any findings that you are entitled to [note: be sure to check your state's applicable law] should be obtained directly from the insurance company.
- The examiner is an independent practitioner who does not work for this insurance company and is not employed by them.
- The examiner does not participate in any decision concerning your claim.
- To maintain the integrity of the evaluation, the examiner does not permit any recording of the evaluation, either secretly or openly. By your signature, you agree not to record this evaluation yourself or permit this evaluation to be recorded by others.
- The examiner has [check applicable state law] a duty to warn anyone to whom you express a violent threat, which duty is discharged by calling the police. The examiner is also required by law to report abuse of vulnerable persons.
- This is an objective evaluation. You are warned to do your best on everything, and to provide accurate responding, as the examiner cannot foresee the consequences if there is any finding to the contrary.

- Please understand that you are not the examiner's patient, and the examiner cannot offer you treatment or advice. The examiner will certainly offer you respect for your dignity and person, but if you need treatment or advice you must obtain this from your own doctor(s).
- This examination does not replace regular psychological or neuropsychological examination or treatment.

Bush (2013), in discussing ethics in validity assessment, argued that justification for examiner deception in validity assessment can be found in the American Psychological Association ethics code (8.07) on "Deception in Research" in which deception is prohibited unless the techniques have a significant scientific, educational, or applied value and that effective nondeceptive procedures are not feasible. Indeed, providing claimants with accurate information that a particular test is not a real neuropsychological test but in fact measures their quality of effort would defeat the purpose of the test. Bush (2013) also argues that the other point that permits ethical use of deception is the informed consent process in which the examinees are told before the examination that measures to determine the validity of the examination (i.e., effort and accuracy of reporting) will be administered. Thus, warnings are ethically appropriate and even necessary in a general way at the outset of the examination.

### Concerns About Cheating

Stevens (1986) cited Rabbi Jerome Folkman's observation that in Judea in the middle of the second century B.C. rabbis discovered people taking advantage of relief programs of the era. According to Pratico (2001: 78), as the SSDI program was being debated in 1954, Elmer Hess, president of the American Medical Association (AMA) warned that "being on the federal dole would be crippling to the psyche of workers," that it was "tantamount to the government bribing them to stay out of the workforce," and that the program provided "an institutionalized reason to avoid vocational rehabilitation." Cyrus Anderson also warned that there would be doctors who would not be above certifying a dubious disability, and that there would be other doctors who lose patients because they refuse to cooperate with malingerers.

To be sure, the Office of the Inspector General (OIG) Fraud Unit for the SSA has traditionally been concerned with individuals who "purposely withhold, exaggerate, or fabricate work or medical information" (OIG, 2013) to collect disability benefits for which they are not eligible. The OIG's Cooperative Disability Investigations program and SSA's continuing disability reviews are noted to be highly effective in guarding against disability overpayments. However, in Congressional testimony dated March 20, 2013, OIG noted that increasing numbers of disability claims and beneficiaries have strained resources (OIG, 2013). In his own

investigation, Senator Tom Coburn (Social Security Benefits, 2013) uncovered numerous abuses in the system.

### The Issue of Malingering

The form of cheating to which disability evaluators will be most exposed is *malingering*, defined as the intentional production or exaggeration of false or misleading symptoms for compensation or the avoidance of punishment or duty (American Psychiatric Association; 2000; 2013). Malingering is also defined behaviorally as performance invalidity (Larrabee, 2012) in which an examinee intentionally underperforms on a cognitive test to demonstrate impaired memory processes, mental slowing, perceptual distortion, etc., for compensation or avoidance of punishment.

Malingering is widespread in medicolegal examinations. Summing more than 11 studies of base-rates of malingering, Larrabee (2003) showed an overall frequency of 548/1,363 subjects (40.2%), most claiming mild TBI, who were identified with performance deficits consistent with malingering. Appreciating the consistency in base-rate estimates of malingering in numerous studies over a wide review, Larrabee, Millis, and Meyers (2009) proposed a "new magic number" of  $40\% \pm 10\%$  to indicate the average base rate (prevalence) of malingering being about 30%–50% in individuals who have an external incentive.

Whether a claimant is malingering is an inference by the examiner based upon a probability analysis with strict knowledge of guidelines in the field. Generally accepted guidelines for malingered neurocognitive dysfunction were developed by Slick, Sherman, and Iverson (1999), and updated by Slick and Sherman (2013). The guidelines for probable malingered cognitive dysfunction require an external incentive (A), with two or more types of evidence from neuropsychological testing (B). The latter could include two failures on established validity tests (Larrabee, Greiffenstein, Greve, & Bianchini, 2007), or be a matter of atypical performance patterns on cognitive testing (Larrabee, 2003). The Slick et al. (1999) guidelines also include evidence from inconsistencies in self-report (C); probable malingering can also be defined with one inconsistency from testing (B) and one from self-report (C). In these guidelines, definite malingering is defined as involving clear and compelling evidence of volitional exaggeration or fabrication of cognitive dysfunction absent plausible alternative explanations, as when someone performs significantly below chance ( $p < 0.05$ ) on a test of validity. Significantly below chance performance on forced-choice validity testing has also been termed "the smoking gun of intent" (Pankratz & Erickson, 1990: 385). If the individual had been blindfolded, and thus unable to see the test stimuli, the performance would have been at chance levels, and therefore higher. In these guidelines, alternative explanations of test performance must be ruled out (D-criterion), as when developmental or neurological conditions would also cause the poor validity test performance. In these cases, the

conclusion of *probable* malingering would be mitigated to *possible* malingering.

Another area in which helpful guidelines have been proposed is malingered pain-related disability (MPRD; see Bianchini, Greve, & Glynn, 2005; Greve, Bianchini, & Brewer, 2013). In disability evaluations that involve pain conditions, malingering has been difficult to assess, largely because pain is multifaceted and appreciated mostly by self-report. Moreover, in disability evaluations, the pain is not the target of the assessment; it is about whether the pain is disabling, preventing the individual from working (Greve et al., 2013). While there are sometimes compelling inconsistencies that provide for straightforward assessment of malingering (e.g., as when someone with “debilitating lower back pain” is caught on surveillance performing a brake job for a neighbor), it has been difficult without guidelines to assess MPRD. Therefore, Bianchini et al. (2005), citing evidence from symptom and performance validity assessments of pain claimants, showed that in pain cases with significant external incentive (Criterion A), evidence from inconsistencies in the physical evaluation (B), and inconsistencies in cognitive-perceptual neuropsychological testing (C), along with evidence from inconsistencies in self-report (D) can be used to adduce the inference of malingering. Similar exclusion criteria (E) are used so that the inference points toward volitional evidence.

One readily sees the probabilities involved when multiple failure of validity tests is considered. The error term of special interest is the false-positive (FP) error rate (1-Specificity). If the appropriate classification accuracy study is performed, one can identify the specificity of any test, which is the probability of correct rejection of an individual who does not have the diagnosis of interest. For validity tests when malingering is the construct of interest, specificity is the probability of correctly identifying an honest claimant—one who is not malingering. For this particular test, the FP rate is the chance of misidentifying this individual as a malingerer (and the true positive [TP] rate is the chance of correctly identifying this person as a malingerer). As an examiner wishes not to harm the claimant by misidentifying the validity status, the examiner desires to have as low a FP rate as possible.

If multiple validity test failures are considered, one can show considerable diminishing of the FP rate. The pretest probability of malingering is the base rate (BR; Larrabee, 2008). The posttest, or posterior, probability when the validity test is positive depends upon the classification accuracy characteristics of the test. A likelihood ratio, dividing sensitivity by the FP rate, is multiplied by the pretest odds (formed from the pretest probability by dividing the BR by  $1 - BR$ ) to give the posttest odds, from which the posterior probability is calculated by  $Odds / Odds + 1$ . When a test is positive, the examiner can be more positive about the finding, as the probability (of malingering) rises from the base-rate level to a new higher level based upon the characteristics of the test.

Larrabee (2008) demonstrated that if two or more results from nonsignificantly correlated validity tests are chained by

taking the posterior odds from the first as the pretest odds for the second, the posterior probability for the second positive validity test then rises substantially. The posterior probabilities for three or more positive validity tests approach 1.0. This joint posterior probability is identical to the joint positive predictive value (PPV). Given that  $PPV = TP / (TP + FP)$ , one can easily see that as the joint posterior probability is approaching 1.00 with multiple validity test failure, the FP rate is approaching 0.0, leaving  $PPV = TP / (TP + \sim 0.0)$ . Thus, with two or more positive results on validity tests, the examiner can be more certain that there is no mislabeling of the claimant.

The same findings of joint high posterior probabilities of malingering can be shown whether one uses the calculated method (Larrabee, 2008), or by strictly empirical methods (Victor, Boone, Serpa, Buehler, & Ziegler, 2009) in which the joint classification accuracy statistics are simply derived from the data set. In a combined SSD data set, Chafetz (2011a) showed high and almost identical posterior probabilities for two or more embedded validity indicators, with occasional small differences. The posterior probabilities depend largely on the specificities of the individual test or embedded indicator, but rise to 0.99+ with three positive embedded indicators in this SSD data set (Chafetz, 2011a). Thus, with multiple validity test or embedded indicator failure, the evaluator can be more confident in the determination of malingering.

### *Expert Consensus on Malingering*

As expressed in the American Academy of Clinical Neuropsychology (AACN) Consensus Conference statement (Heilbronner et al., 2009), neuropsychologists are concerned with cognitive and emotional symptoms, and physical capacities. Examinees who are seeking compensation or avoiding punishment employ strategies that involve attempts to intentionally create the appearance of disability or dysfunction. They do so by exaggerating symptoms or intentionally reducing their abilities. This behavior is not simply a matter of poor effort. When an evaluator considers the diagnosis of malingering, there is an explicit determination of intent, and evaluators can use the current body of knowledge on validity testing to differentiate intentionally produced noncredible presentations (e.g., malingering and factitious disorder) from unintentional noncredible presentations (e.g., somatoform pain disorders or cogniform disorders). The AACN Conference statement recognized that malingering can be adaptive, and that the best way to assess intent was to rule out other conditions (e.g., psychological, neurological, developmental) that might better explain the noncredible presentation.

Before this consensus statement, the National Academy of Neuropsychology (NAN) Policy and Planning Committee had produced a position paper on symptom validity assessment (Bush et al., 2005). This policy paper noted that noncredible symptom exaggeration or production occurs in a large minority of neuropsychological examinees, with a

higher base rate in medicolegal or forensic contexts. They noted a number of terms in current use, including *symptom validity*, the accuracy or truthfulness of the symptom presentation; *response bias*, an attempt to mislead the examiner through the use of incomplete responses; *effort*, the investment in performing at capacity; *malingering*, the intentional production of false or exaggerated symptoms, motivated by external incentives; and *dissimulation*, the intentional misrepresentation or falsification of symptoms to appear dissimilar from one's true state. In this context, Larrabee (2012) has more recently distinguished between symptom validity tests (SVTs), which examine the validity of the claimant's symptom presentation, and performance validity tests (PVTs), which determine the validity of the claimant's behavioral performance on cognitive testing. The NAN policy paper asserts that validity testing is an essential part of a neuropsychological examination, and that the evaluator should be prepared to justify any decision *not* to use these tests.

### Base Rates of Malingering in Disability Examinations

More than 25 years ago, Puente (1987) considered the issue of malingering in the PCE for SSD, but the tools back then were limited mostly to an analysis of inconsistencies in the presentation and history. More recently, Chafetz (2008) showed widespread validity failure by adults and child claimants. In this study, the archived records of claimants were apportioned into separate graded effort groups. The Definite group was defined by most egregious validity test failure—significantly below chance performance (Slick et al., 1999). The next level was defined as Chance performance, which could as easily be obtained if the claimant had simply closed his or her eyes, not able to see any of the stimuli. This level of performance is obtained only by the most impaired of individuals—who cannot possibly track a conversation well enough to provide a history, or even make it to the evaluation without much help. As Chafetz (2008) discussed, Chance failure was the more egregious level of validity test failure, though not as bad as Below-Chance failure. The next level was Fail Two validity tests, which also satisfies the Slick et al. (1999) criteria for Probable malingering. The next graded level of effort was Fail One validity test; then there was Fail Indicators (embedded) without failing any one validity test; and then there were those who did Not Fail any test or embedded indicator.

Because of the absence of records and the overall unreliable nature of self-report in these examinations, Chafetz (2008) did not use the C criteria (self-report) from Slick et al. (1999). Moreover, because most of the Full Scale IQ scores were in the ID range, the question naturally arose whether these “developmental disabilities” mitigated Probable malingering to Possible malingering per Slick et al. (1999) guidelines. However, it was considered that if indeed these individuals were malingering, then the obtained IQ scores

Table 41.1 Rates of SSD validity failure and IQ levels from Chafetz (2008)

	TOMM		MSVT	
	<i>n</i> (% of <i>N</i> )	<i>FSIQ</i> <i>M</i> ( <i>SD</i> )	<i>n</i> (% of <i>N</i> )	<i>FSIQ</i> <i>M</i> ( <i>SD</i> )
<i>Definite</i>	16 (13.6%)	52.4 (4.4)	7 (12.3%)	50.7 (4.1)
<i>Chance</i>	27 (22.9%)	57.2 (8.0)	20 (35.1%)	59.9 (8.1)
<i>Fail 2</i>	11 (9.3%)	60.0 (3.8)	7 (12.3%)	62.1 (5.7)
<i>Fail 1</i>	26 (22%)	63.9 (6.1)	5 (8.8%)	64.6 (4.0)

Note: MSVT = Medical Symptom Validity Test; TOMM = Test of Memory Malingering.

would not be valid indicators of their true abilities. Thus, the D criteria were left as an open question, and indeed it was later discovered that low IQ itself was not a likely cause of validity failure in these examinations (Chafetz & Biondolillo, 2012; Chafetz, Prentkowsky, & Rao, 2011).

Table 41.1 shows the rates of validity failure in a SSD claimant sample using the Test of Memory Malingering (TOMM; Tombaugh, 1996) and a sample using Green's Medical Symptom Validity Test (MSVT; Green, 2004). In the archives for all SSD claimants, the total score from the Symptom Validity Scale (SVS) for low-functioning individuals (renamed from Chafetz, Abrahams, & Kohlmaier, 2007) was calculated.

We keep in mind that each graded level of validity failure is independent of the other. These rates of validity failure show that 45.8% of SSD claimants in the TOMM study fail two validity tests (TOMM and SVS) or worse, failing the TOMM at chance levels, or significantly below chance levels. In the MSVT study, 59.7% at least fail two validity tests (MSVT and SVS) or worse (chance or below chance). The difference lies largely in how many fail at chance levels of performance, as the rates of Definite (below-chance) failure (13.6% TOMM; and 12.3% MSVT) are about the same, and the rates of Fail Two tests (9.3% TOMM; 12.3% MSVT) are similar.

In both Adult samples (TOMM and MSVT samples), the correlation between the SVS total score (validity scale) and Full Scale IQ was  $r = -0.83$ , accounting for about 69% of the shared variance between invalidity and IQ. In both Child samples (TOMM and MSVT), the correlation between the SVS total score and Full Scale IQ was  $r = -0.75$ , accounting for about 56% of the shared variance between invalidity and IQ.

As can be seen in Table 41.1, mean IQ scores progress linearly from very low levels in the Definite group, to levels on the transition between Extremely Low and Borderline ranges in the Not Fail group. The interpretation of these groups is straightforward, graded from those who clearly have intent to fail testing up to those who do not fail validity testing. Thus, the interpretation of the corresponding IQ scores is that they are dependent on the validity levels, and not the other way around. In a later section on low IQ individuals, more data

will be shown illustrating that the failure of validity testing, particularly on the SVS, is not due to low IQ levels.

Data from other researchers show similar rates of validity failure in SSD samples. For example, Miller, Boyd, Cohn, Wilson, and McFarland (2006) showed 50+% validity test failure in an SSD sample in Georgia. Jason King also showed 50+% validity test failure in his sample (personal communication). Research presented at the 2012 NAN convention scientific session by Buddin, Schroeder, Teichner, and Waid (2012) showed that 35% of those applying for disability in South Carolina and 50% of those receiving disability failed the MSVT. Many consider that the turning point for the modern guidelines for the diagnosis of malingering occurred with the Slick et al. (1999) publication. Before these guidelines, Griffin, Normington, May, and Glassmire (1996) showed that 19% of DDS claimants had evidence of malingering when a Composite Disability Malingering Index was used. In this writer's invited address at the local state DDS (April 28, 2003), data were presented showing that before this writer used validity testing in DDS claimants, only 5% of DDS claimants were determined as having clear evidence of malingering, while 20% had some evidence. Clearly, without the use of validity testing, the DDSs have many false positives for disability benefits.

### **Costs of Malingered Disability**

Chafetz and Underhill (2013) have calculated the potentially staggering costs of SSA's failing to detect malingering. Considering the most widely accepted base rate of malingering in medicolegal cases of  $40\% \pm 10\%$  (Larrabee et al., 2009), the costs range from \$20 billion in one year considering mental disabilities alone up to \$180 billion in one year considering everything, including secondary costs (e.g., Medicare and Medicaid benefits) and all possible claim categories (Chafetz, 2011b).

### **Other Claimant-Centered Challenges to Validity**

When people have considerable internal distress or conflict, somatoform symptoms may be produced (American Psychiatric Association, 2000, 2013). Somatization disorder typically starts before age 30, has multiple symptoms, and involves a combination of pain, gastrointestinal, sexual, and pseudoneurological symptoms that are not fully explained by a general medical condition, effects of a substance, or by another mental disorder (American Psychiatric Association, 2000). Somatization disorder, which is more broadly called *Somatic Symptom Disorder* in DSM-5 (American Psychiatric Association, 2013), and requires only one or more somatic symptoms, is not typically considered volitional. It occurs when the person, not realizing the distress or admitting to the conflict, starts having stomachaches and headaches, and becomes "sick." The reader will recognize this presentation

in a child who knows he must take the math test but does not feel he has mastered the material and does not wish to let his parents down or invite their censure. Being "sick" is okay, and "resolves" the conflict. Conversion disorder describes the production of medically unexplained neurological (motor or sensory) symptoms such as numbness or paralysis, often out of guilt or conflict.

Delis and Wetter (2007) proposed a "cogniform disorder," which is the mental-cognitive equivalent. In a cogniform disorder, there is a production of medically unexplained cognitive problems (e.g., memory loss) when the person has unrealized internal distress or conflict. This writer once had a 74-year-old patient who was convinced she had Alzheimer's disease. When the examination revealed no neuropsychological problems, and feedback led to psychological therapy, it was discovered that she had boyfriend problems with a traveling salesman. Her "memory problems" arose from his unexpected arrivals or nonarrivals, prompting her to turn the anger on herself and complain of a memory disorder.

Boone (2009) analyzed the Delis and Wetter (2007) algorithm, suggesting that while it was a substantial advance in identifying individuals with noncredible cognitive symptoms and/or implausibly low cognitive scores, it did not distinguish between implausible cognitive complaints and implausibly low test scores. Boone (2009) presented the construct of neurocognitive hypochondriasis, which is a fixed belief in cognitive dysfunction despite normal cognitive test scores. It is likely that the example of the 74-year-old patient given earlier would fit neatly into this paradigm.

Factitious disorder is a volitional form of noncredible presentation in which the person plays a sick role, seeking treatment for medically unexplained symptoms to gain attention by doctors (American Psychiatric Association, 2000, 2013; Delis & Wetter, 2007). Factitious disorder has been called *Munchausen Syndrome* in the extreme case in which the individual begins introducing more harmful and invasive medical problems (American Psychiatric Association, 2000; but not 2013).

In this context of symptoms without a physical basis, one must consider "diagnosis threat" (Suhr & Gunstad, 2002), a form of self-fulfilling prophecy in which the individual "learns" that there is a disorder consistent with a diagnosis that has just been received. Consider, for example, the patient who comes to the emergency department of a major hospital with a "concussion." Despite that the head injury may not have been severe enough to cause damage, and there is no evidence of brain damage upon examination, hospital personnel will likely act in a conservative way, providing a warning sheet to be helpful to the patient. The warning sheet will discuss "management of your TBI," and may discuss legitimate signs of a TBI, including memory and concentration problems. A fixed belief may then develop concerning the effects of the TBI, and this belief may persist for long periods.

Chafetz (2011b) has discussed these problems in the context of a claimant who is seeking disability. Considering the

motivational differences in the Chafetz et al. (2011) study, in which disability claimants, compared to state rehabilitation or child protection claimants, were the only ones to show high rates of validity test failure, we have to view the possibility of other noncredible presentations in this context. In disability claims, these other nonvolitional forms of noncredible symptom presentation are not likely to be good explanations of the noncredible findings. Indeed, SSD claimants are aware of the burden of proving disability under the strict Social Security definition of disability. Having the burden of proving one's disability requires considerable deliberation and undergoing many hurdles, and indeed it is not unusual in a private disability examination to see letters from claimants to their doctors (while attempting to get SSD) asking for a doctor's note with specific disability language (e.g., "severe limitations" or "marked impairment"). This deliberation is clearly volitional. Moreover, the claim by Dan Allsup, communications director of Allsup, Inc., a company that helps disability applicants, that these hurdles help weed out malingerers (Ohlemacher, 2010) cannot possibly be true, as it is likely that these hurdles only increase the incentives to feign more believable symptomology.

### The Use of Validity Testing in Low-IQ Individuals

Validity testing in low IQ individuals has been criticized largely because of lower specificity, but also because validity tests had not traditionally been developed in low IQ samples (Salekin & Doane, 2009; Shandera, Berry, Clark, Schipper, Grau, & Harp, 2010; Smith et al., 2014; Victor & Boone, 2007).

Chafetz et al. (2011) conducted a study comparing individuals with low IQ in three groups with differing motivations for assessment. The SSD group were composed of individuals seeking monetary benefits for an inability to work; the state rehabilitation service (SRS) group were composed of individuals seeking to make money by going to work; and the child protection (CP) group were individuals seeking to have their children returned from state custody. In the CP group, these individuals were motivated to look good on testing, wanting to do everything in their power to have their children returned. IQ and validity test scores were obtained on all claimants. Individuals were defined as malingering if they failed the MSVT at significantly below chance levels, or if they failed the MSVT and the A-Test (Chafetz, 2012), which was developed on SSD claimants as a test of feigned auditory inattention. Profile analysis was used on the MSVT to remove individuals who were truly impaired (Howe & Loring, 2009).

Considering only the claimants who passed validity testing, the mean IQ scores of the SSD ( $67.5 \pm 6.0$ ), SRS ( $69.2 \pm 8.3$ ), and CP ( $71.7 \pm 7.7$ ) groups were not significantly different. However, 45.5% of the SSD group, 6.7% of the SRS group, and 0.0% of the CP group met criteria for

malingering. Thus, validity test failure in low-IQ individuals depended only upon the identified motivation of the group: Those seeking benefits for an inability to work showed a high rate of malingering (45.5%); those seeking to work for compensation showed a low rate (6.7%); and those seeking the return of their children from state custody showed no validity failure (0.0%). Moreover, concerning those few who failed validity testing in the SRS group, further investigation revealed that due to agency cooperation the local DDS office for Social Security had sent these claimants to the local state rehabilitation office to determine work status. It was therefore possible that these few individuals who failed validity testing when ostensibly seeking to work were indeed protecting disability status. After all, similarly low-IQ individuals motivated to look good to have their children returned showed no validity test failure.

In an extension of this study for other purposes, Chafetz and Biondolillo (2012) obtained a larger sample of CP claimants, all with  $IQ < 76$ . In all of these individuals, 35 of 37 (95%) passed Immediate Recognition (IR) of the MSVT, 34 of 37 (92%) passed Delayed Recognition (DR), and 35 of 37 (95%) passed Consistency (Cn). On the SVS, 94% passed at a more stringent cutoff ( $> 7$ ). On the A-Test (cutoff  $> 2$ ), 100% passed, and on Reliable Digit Span (RDS; Greiffenstein, Baker, & Gola, 1994), 32 of 35 (91%) passed a more stringent cutoff ( $< 6$ ). When considering only those CP claimants with  $IQ = 60-75$ , 100% passed all the MSVT effort variables, 100% passed the more stringent SVS cutoff ( $> 7$ ), 100% passed the A-Test, and 30 of 32 (94%) passed the more stringent RDS cutoff ( $< 6$ ). Thus,  $IQ < 60$  appears to be the tipping point for more validity failure, though in this well-motivated group there was no validity test failure above 10% (pass rates 90%+).

Considering the issue of validity tests designed for low-IQ functioning individuals, Shandera et al. (2010) and Musso, Barker, Jones, Roid, and Gouvier (2011) acknowledged the Symptom Validity Scale (SVS) for Low Functioning Individuals (renamed from Chafetz et al., 2007) as the first validity scale specifically designed for working with low-IQ individuals. The SVS was analyzed for use in disability examinees for Social Security. Most of these cases were from SSI referrals, mostly with low intellectual functioning. One of the advantages of using the SVS is that the examination can be done as it is usually done, and then the evidence from the examination can be entered into the scale afterwards; no additional testing is necessary. Embedded indicators such as coding errors or Ganser-like answers (where the numerical answer provided is immediately adjacent to the correct answer:  $2 + 3 = 6$ ;  $3 + 4 = 8$ ) are given score weights depending upon their value. As indicated in the Chafetz and Biondolillo (2012) study, a cutoff of  $> 7$  on the SVS has no false positives in well-motivated individuals with IQ between 60 and 75.

The A-Test (Chafetz, 2012) has been redesigned as a test of feigned auditory vigilance embedded within the mental-cognitive status examination (Strub & Black, 1993). It was

also developed in the SSD sample. As shown in Chafetz and Biondolillo (2012), it has a 100% pass rate (0% false positives) in a well-motivated sample of low-IQ individuals, even when IQ dips below 60. Chafetz (2008) showed that the mean scores follow the graded effort groups with good precision, accounting for 35% of the differences ( $\eta^2$ ) between the separate effort groups.

The Musso et al. (2011) work developed a Rarely Missed Index on the Stanford-Binet-5 with a high pass rate in the ID group of the standardization sample. They developed a “floor” of nonverbal items that are infrequently missed by identified ID subjects plus additional standardization sample subjects with IQ < 71. The sensitivity of this index was determined by using college students as simulators, which does not present an adequate real-life comparison. Thus, this index awaits validation in a criterion group of identified malingerers, preferably with low IQ. Also, no one in the standardization sample completed validity testing during the standardization process, and so it is unknown whether the “floor” might be lower than necessary and therefore less sensitive. Nevertheless, overall classification was 77.6% accurate, with 74.1% of analog malingerers and 83.9% of low-IQ individuals correctly identified with a logistics regression equation.

#### Principles for Validity Testing in Low-Functioning Individuals

- Below-chance performance is still definite malingering: Approximately 10%–13% of low-IQ individuals obtain significantly below-chance performance on validity testing (Chafetz, 2008), termed “the smoking gun of intent” (Pankrat & Erickson, 1990).
- Understand the difference between lower and higher IQ levels in ID: In well-motivated low-IQ individuals (IQ between 60 and 75), there is little failure on validity tests (Chafetz & Biondolillo, 2012).
- Account for motivation: Well-motivated low-IQ individuals (IQ 60–75) do not fail certain validity tests. There may be hidden secondary-gain issues in individuals who are apparently motivated to do well, including protection of disability benefits.
- Accommodate for executive dysfunction or reading difficulties: A combined computer–oral administration, with the examiner operating the mouse (or keys) removes errors due to executive dysfunction, leaving only the choices to be made.
- Use appropriate cutoff scores for validity tests that have an ability component: More stringent cutoffs are needed for low-ability individuals.
- Use appropriate test selection: People with particular impairments should not be tested on validity measures whose task demands require those abilities (e.g., a person with acalculia should not be tested on the Dot Counting Test, which requires multiplication).
- Where possible, use validity tests designed for low-IQ individuals: A few have been developed.

Chafetz and Biondolillo (2012) and Chafetz (2015) have proposed principles for dealing with validity issues in low-functioning individuals, including the necessity for understanding the level of impairment, the choice of tests, and the knowledge of studies showing pass rates in low-functioning individuals. It is also important to understand that the aggregation of three or more positive results can show high posterior probabilities for malingering in low-IQ individuals (Chafetz, 2011a).

#### Other Reasons for Poor Performance on Validity Tests?

It is natural to question whether other syndromes can cause validity test failure on their own. One might question, for example, whether people who are affected by pain might fail validity testing due to the distracting nature of pain. However, cold-pressor pain that produces considerable discomfort does not by itself reduce scores below cutoffs on validity tests (Etherton, Bianchini, Greve, & Ciota, 2005). Yanez, Fremouw, Tennant, Strunk, and Coker (2006) showed that severely depressed individuals did not significantly differ from controls on TOMM performance. Only one of 20 of these severely depressed individuals failed Trial 2 of the TOMM and only one failed the retention trial. Indeed, Rohling, Green, Allen, and Iverson (2002) showed that when highly depressed individuals pass validity testing, they do not score below controls on neurocognitive testing, indicating that the only reason for depressed individuals to have reduced scores on neurocognitive testing is because of poor quality of effort.

Performance validity accounts for the largest proportion of variance in a neurocognitive examination, even more than moderate to severe TBI (Green, Rohling, Lees-Haley, & Allen, 2001). Ord, Greve, Bianchini, and Aguerrevere (2010) also found that performance validity had a larger effect on neurocognitive measures than TBI severity.

#### Meeting the Requirements for Disability

In the box, the reader will see an example of the Social Security listing requirements for disability from a depressive disorder. For disability benefits from depression, a claimant must have five of the typical symptoms of depression (e.g., depressed mood, appetite disturbance, sleep disturbance, decreased energy, suicidal thoughts), resulting in extreme limitation of one or marked limitation of two of the following: (a) understanding, remembering, or applying information, (b) interacting with others, (c) concentrating, persisting, or maintaining pace, or (d) adapting or managing oneself; or the depressive disorder is serious and persistent (that is, the claimant has a medically documented history of the existence of the disorder over a period of at least two years, and there is evidence of both treatment, intervention, or supports that are ongoing and that diminish the signs and symptoms of the

disorder; and marginal adjustment, with minimal capacity to adapt to changes in the environment or to demands that are not already a part of daily life).

**Blue Book Listing 12.04 Depressive, Bipolar, and Related disorders**

- Meets listing with documented depression symptoms (at least five); AND extreme limitation in one or marked limitation in two of the following:
  - Understand, remember, or apply information;
  - Interact with others;
  - Concentrate, persist, or maintain pace;
  - Adapt or manage oneself.
- Or the depressive disorder is serious and persistent; that is, the claimant has a medically documented history of the existence of the disorder over a period of at least two years, and there is evidence of both:
  - Treatment, intervention, or supports that are ongoing and that diminish the signs and symptoms of the disorder; and
  - Marginal adjustment, with minimal capacity to adapt to changes in the environment or to demands that are not already a part of daily life.

Applicants for SSD may be turned down at any stage of the application process. They might have demonstrated SGA, making more money than allowed for SSI under the law. They might have gone through a consultative examination, and have not demonstrated sufficiently disabling problems to meet one of the listing requirements. Applicants who are denied may appeal by taking their own case further down the process, by hiring a disability attorney, or by seeking services through a disability company such as Allsup, Inc. Allsup Inc. boasts a 97% award rate compared to a 33% national average for those who apply without assistance (How It Works At Allsup, n.d.).

Appeals are handled through the Office of Disability Adjudication Review (ODAR) in hearings before an Administrative Law Judge (ALJ). The federal ALJs involved in these hearings are paid by the SSA. They must follow administrative law, which is public law that deals with the rules set forth by the administrative agency, in this case the SSA. The appeals hearing involves an ALJ and a court reporter. The ALJ is the fact-finder and decider. The claimant appears either alone or with representation (e.g., a disability attorney). There is no counsel to represent the people (government). ALJ decisions are public, and disability attorneys often display their decision records on the attorney website, thus telling the public to watch out about “certain judges.”

The ALJ obtains consultation by having medical experts present and sworn in. The expert can be present by phone. The medical expert is called according to the professional field involved in the claimed disability. For example, a psychologist might be called if the claim is for ID (listing 12.05). The ALJ typically asks the expert questions about

whether the evidence meets the listing requirements. It is incumbent upon the expert to have read the records and history supplied by the ODAR office. The expert may be cross-examined by the disability attorney, but there is no “direct” examination, as there is no government lawyer. Typically, what stands for the “direct” examination are the questions put forth by the ALJ.

### Military Disability Examinations

The Veterans Administration is composed of three organizations: (a) the Veterans Health Administration (VHA), which is one of the largest health care systems in the world; (b) the Veterans Benefits Administration (VBA), which manages compensation and vocational assistance to disabled veterans; and (c) the National Cemetery Administration (NCA), which honors veterans with a final resting place and memorials to commemorate their service. This chapter is especially concerned with the disability activities of the VBA, which also provides home loan guaranty, education, and insurance programs (for more information, visit the VBA website, [www.benefits.va.gov/BENEFITS/](http://www.benefits.va.gov/BENEFITS/)). The VBA has 57 regional offices in 50 states, Puerto Rico, and the Philippines.

According to the VBA, disability compensation is a tax-free monetary benefit paid to veterans with documented disabilities resulting from disease or injury while in active military service. The injury or illness may also have been aggravated during active military service. Even after discharge, compensation may be paid for disabilities considered related or secondary to those that occurred while in service. There is also payment for dependents of service members who die while on active duty. For specific disabilities (e.g., loss of use of a limb), there is special monthly compensation, including an additional higher rate for aid and attendance by another person. The VA also provides housing and insurance benefits to veterans with disabilities. Once a disability has been determined to be service connected, the veteran may also get access to programs for an automobile and clothing allowance, hospitalization, and convalescence.

The rating of the degree of disability is designed to compensate for the loss of working time from the disabling problem. Thus, as with any other disability program, the compensation is provided for an inability to work. The benefit amount is scaled in 10% increments from 10% to 100% according to the degree of the veteran’s disability. The VA will attempt to determine a service connection for all the claimed disabilities, and it is not uncommon to see a VA determination of service connection (or not) for posttraumatic stress disorder (PTSD), hypertension, sleep apnea, knee injury, liver disease, and TBI all in the same veteran. Service connection is granted for a disease or injury incurred during active military service or active duty for training. Service connection by law is also granted for conditions that existed before the veteran entered the service if the condition is shown to be aggravated by the service.

It is instructive to compare military compensation to SSD compensation. As Buddin and Kapur (2005) have indicated, the Code of Federal Regulations focuses the percentage rankings of VA disability compensation on the earnings loss of veterans who are disabled. These rankings are based on the average impairment in earning capacity. The analysis involves comparing what the veteran could have earned without the disability to the (reduced) earnings with the disability. Chafetz (2013) compared these rules to those in SSD, where disability is conditioned on the total inability to work. This is an extreme definition of disability that has been viewed as contrary to work motivation, as it disincentivizes those who might otherwise work part-time (see Chafetz, 2010). Indeed, this writer has been asked many times by claimants for other agencies (e.g., child protection, state vocational rehabilitation) not to mention to Social Security side income from hidden jobs. One claimant for state vocational rehabilitation mentioned that he worked at his uncle's business without pay to avoid interfering with his SSI, which of course belied his claim to Social Security that he could not work. Veterans do not have to claim "total disability." While this disincentive might not carry forward into the VA claim (Chafetz, 2013), veterans might see fabrication or exaggeration of symptoms as a pathway to a higher percentage rating. Thus, there is still an issue of the validity of the claim.

While private disability compensation (and to some extent SSDI) is tied to an individual's earnings, the rating in VBA compensation is based upon the disability. In Buddin and Kapur's (2005) example, a private and a major who both lose a foot are entitled to the same benefit, regardless of experience and earning potential. Moreover, earnings in civilian life do not affect disability compensation from the VA.

Psychologists who become involved with providing disability examinations for veterans frequently do so through IME companies (e.g., QTC or VES) who have contracts with the VA. The psychologist is instructed to fill out a Disability Benefits Questionnaire (DBQ) on (proprietary) software provided by the IME company. With experience, many examinations take approximately one hour, though some programs require more extensive detail and additional assessment, requiring at least two hours. With veterans who have combat experience, or who otherwise were stationed in a war zone, the consultation is frequently about PTSD or about TBI. However, any mental or cognitive problem may be the target of examination, or may be uncovered by the examination. The contract may be for examinations of veterans awaiting discharge, or for veterans who have already been discharged. Essentially, the VA wants to leave no veteran behind, and it is recognized that many older veterans (e.g., Vietnam era) had problems that went unrecognized during their service. This writer once evaluated a 92-year-old veteran of World War II whose job it was to retrieve the remains of the dead. Although he had a long and fruitful life, he still could not get the odor of decay and death out of his system. The odor was with him everywhere.

He was making a disability claim to be able to leave benefits for his family.

This method of using proprietary software does not permit thorough assessment of cognitive problems or of validity. For additional cognitive assessment, the psychologist may be asked to administer the Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975), the Montreal Cognitive Assessment (MoCA; Nasreddine et al., 2005), or the St. Louis University Mental Status (SLUMS) examination (Tariq, Tumosa, Chibnall, Perry, & Morley, 2006). None of these instruments is ideal for assessing the cognitive problems of veterans who have had a brain injury. For one, the MoCA, SLUMS, and the MMSE were developed in older individuals suspected of mild neurocognitive impairment or dementia; indeed, these are screening instruments for dementia. Thus, older veterans (who were involved in Vietnam or Korea) may score lower than expected, but the older veterans may also have complicating problems due to brain disease, poor health, or dementing illness that have nothing to do with a mild TBI suspected 45 years earlier. Ultimately, the evaluator may have to rely on an evaluation of the claimant's history as compared with the medical records provided, plus knowledge of the neuropsychological record on TBI (Iverson & Lange, 2011).

Moreover, the proprietary software is limited in guidance, frequently not distinguishing between problems associated with mild TBI versus moderate to severe TBI. The VA likely did not provide neuropsychological guidance to these IME companies. As Iverson, Langlois, McCrea, and Kelly (2009) have indicated, the VA has been deliberately overinclusive about TBI in postdeployment screenings, not wanting to miss any deserving case. Thus, the evaluator may see a case of TBI in the records, and the proprietary software will ask the evaluator to determine (many years after the event) if cognitive problems from this TBI have interfered with the veteran's social and occupational functioning. It is up to the evaluator to know the literature on TBI (Iverson & Lange, 2011; McCrea, 2008), be able to discriminate mild from moderate to severe TBI, and to determine whether it is possible that this particular injury left the residue of cognitive problems that are being claimed several years later.

The proprietary software does not ask the psychologist to determine the validity of these symptom reports. The style is medical: Self-reported symptoms are supposed to indicate to the clinician the nature and extent of the problems. In disability examinations, however, self-report is fraught with difficulty when it comes to determining the validity of the claims (Chafetz, 2010, 2011; Guilmette, 2013). With claims of psychiatric problems such as PTSD, it is up to the psychologist to carefully sort out the claim from the history. It is helpful to ask about the content of nightmares, comparing that with the history of involvement in combat-related activities. There is more veracity to the claim when the nightmares are about convoy explosions and the veteran was involved as a driver in convoys in Afghanistan or Iraq. If the veteran

was a driver, he or she may report being hypervigilant about objects in the road when he or she is driving at home. If the veteran was in the back of the truck, there may be no such avoidance. Alternatively, if the veteran did not experience combat first-hand, but only heard about others being killed, and dreams about problems at home that are unrelated to combat, the veracity of the PTSD claim is less likely.

To determine the validity of cognitive complaints, a similar analysis of potential inconsistencies in the history may be used. For example, recovery of function from an injury is the norm, and mild TBI without complication is known to show little or no significant clinical effect beyond three months after the injury (Iverson & Lange, 2011; McCrea, 2008). The claim that memory problems from an established mild TBI have been worsening yearly for the past five years to the point where the claimant can remember almost nothing lacks credibility. It is helpful for the examiner, at another point in the examination in which memory is not being discussed, to ask the veteran what he or she had for breakfast, for dinner the night before, and to tell the examiner what he or she has been most interested recently in the news. This information can be enlightening. The veteran who goes on at length concerning a recent news story about military policy is exhibiting intact recent memory, not worsening memory.

Concerning performance validity on the MoCA, the enterprising examiner will realize there are several opportunities for validity assessment. For one, there is a somewhat reduced A-Random Letter Test of Auditory Vigilance (Strub & Black, 1993), which has been shown to be an adequate measure of performance validity on SSD examinations (Chafetz, 2012). Given that veterans are typically higher functioning than Social Security claimants (Chafetz et al., 2007), and that the test on the MoCA has fewer items, it is likely that a cutoff of two or more errors on this reduced-item test would suffice to indicate validity problems. Moreover, the examiner could extend the testing of digit span to achieve a Reliable Digit Span (Greiffenstein et al., 1994), another well-known indicator of validity. The MoCA also has a multiple forced choice recognition trial as part of the delayed recall of five words, which may offer other clues as to the validity of the veteran's performance.

An excellent review of the compensation and pension (C&P) examinations for the VA and practical guide for psychologists can be found in Worthen and Moering (2011). These authors help psychologists understand the legal framework and roles involved in C&P examinations, detailing the specific language of the opinion. For example, if the examiner finds that the veteran is probably suffering from PTSD as a result of his traumatic experiences, the language of the opinion must include: "It is more likely than not that the veteran's PTSD was caused by the specific traumatic stressor." This language tells the VA that there is more than a 50% probability that the veteran has PTSD from the stated trauma. Worthen and Moering (2011) discuss the difficulties

involved in arriving at that opinion from using the DBQ, as outlined above. They also discuss the general rating formula for mental disorders, the way VA records are used, how the veterans statements are taken into account, and the difficulties involved with noncredible findings.

As with SSD (Chafetz & Underhill, 2013), it is instructive to calculate the costs of malingered disability in the VA system. According to Buddin and Kapur (2005), the total amount spent on all veterans receiving disability compensation in 2003 was \$19.536 billion. Using the same assumptions as in Chafetz and Underhill (2013), this would mean that \$7.81 billion was spent on malingered disability in the VA system in 2003.

If the psychologist can tolerate some uncertainty about the claim, and is content to work with proprietary software rather than using typical psychological or neuropsychological assessment tools, these examinations can provide considerable satisfaction. Veterans who have experienced combat have undergone extreme human conditions unlike that of most others psychologists will have the chance to work with. The contrast between the clarity of mission and purpose and the "tedium" of home life is something that is difficult for combat veterans to convey. This is a chance for the astute psychologist to provide insightful assessment and recommendations that can ultimately have an impact on the veteran's life and recovery. It is also a chance for the psychologist to learn about military technology, policy, and the human condition under extreme circumstances.

### **Private Disability Examinations**

Private disability carriers may offer disability policies tailored to the claimant's own work, or for any work for which the claimant is qualified by training or experience. There may be short-term or long-term policies. As with SSA, private disability carriers are interested in the claimant's residual strengths, as well as limitations in the abilities to perform tasks. Typically, the examiner is not being asked whether the claimant can perform a job, but whether there are limitations in job-related tasks: mental focus, understanding instructions, explaining things from different points of view, multitasking, influencing others, working alone, working with others, and remembering instructions or customer information. If the policy is specific for the claimant's line of work, there may be questions about limitations related to that line of work. For example, the examiner for a claimant who is a lawyer may be asked whether there are limitations on conceptualizing and writing. A thorough review of the examiner's role in handling a disability independent examination can be found in Oakes, Lovejoy, and Bush (2017).

Some disability carriers may ask about maximum medical improvement (MMI), inquiring whether the claimant's psychological or neuropsychological condition has become

stable such that further treatment will not improve the condition, or result in significant changes to the claimant's abilities for occupational functioning. There may be a question whether the condition permanently prevents the claimant from working.

The carrier is usually interested in different analyses of limitations, comparing self-reported limitations with those observed during the examination, indicated by cognitive testing, and documented by collateral interviews or in the medical record. Note that these limitations are not the same thing as psychological symptoms and problems, although knowledge and findings about these symptoms and problems can inform the analysis of limitations. For example, emotional lability and frequent crying may suggest social and emotional limitations that might carry over into the workplace. Moreover, limitations may indicate workplace restrictions; for example, fatigue that indicates limitations in the workplace may also indicate a restriction for not working more than four hours in a workday.

A thorough analysis of activities of daily living, both before and after the claimant stopped work, can be especially enlightening, as the examiner is frequently able to get information about social interactions and other abilities and limitations. For example, the parent who is not working but is very active in a child's schooling may demonstrate abilities to interact and influence others (e.g., teachers, child), handle phone calls, drive, remember and coordinate information, and understand spoken and written language. Alternatively, if there are documented memory problems (valid on neuropsychological testing), and the claimant requires others to handle these chores, the examiner may adduce evidence for limitations in remembering spoken instructions, and this finding may help elucidate the claim. The examiner might be directly asked whether there is psychologically or neuropsychologically based impairment in the claimant's abilities to carry out tasks.

Typically, the disability carrier is clear that these are independent examinations (independent of the claimant's own doctors). Whether the carrier uses an IME company or consults with the neuropsychologist (or psychologist) directly, there is an expressed need to assess the validity of the claims, and the consistency of the claimant's self-report. In this, the private disability claim evaluation stands apart from the public (SSD or VBA) disability. Indeed, the examiner will frequently get a written request to examine for "motivation," "secondary gain" issues, "insufficient effort," "symptom exaggeration," or to frankly determine whether there is malingering. The examiner might be asked whether the sources of information obtained are consistent or inconsistent with each other, recognizing that one of the time-honored methods of determining validity is an analysis of inconsistencies (Slick et al., 1999).

While there is a high base rate of malingering in medicolegal examinations (Larrabee et al., 2009), the examiner should be alert to other sources of noncredible complaints and

behavior. Diagnosis threat (Suhr & Gunstad, 2002) occurs when a claimant has been diagnosed with an impairing condition and begins acting consistently with the predicted outcomes of that condition. For example, the individual who is unwittingly (and inaccurately) told that she has a dementing condition, and then who looks up that condition on the Internet,<sup>2</sup> may be extremely scared to find that in a few short years she might need full supervised care. Her spouse will be appropriately concerned and engaged when they come in for the disability examination. If you, the examiner, find that no such condition exists, the claimant is then confronted with the potential denial of disability benefits and the uncomfortable feeling of having been misdiagnosed. Good reviews of other noncredible behaviors and problems can be found in Boone (2007, 2009, 2013).

Use of the MMPI-2 (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), or MMPI-2-RF (Ben-Porath & Tellegen, 2008/2011), or the Personality Assessment Inventory (PAI; Morey, 1991), will frequently be required in these examinations, whether neuropsychological or purely psychological. The validity scales on the MMPI-2 (or RF) have been well established. The Variable Response Inconsistency (VRIN) scale evaluates the consistency of responding. Random or otherwise inconsistent responding will produce an elevation on this scale, which will invalidate the other validity scales, as well as all the clinical scales. The True Response Inconsistency (TRIN) scale shows content-irrelevant true or false responding. TRIN thus evaluates whether the claimant tended to mostly respond true or most respond false regardless of what the items said. If TRIN is elevated in either direction (true or false), it also invalidates the validity scales and the clinical scales.

The F-Family scales (F, Fb, and Fp on the MMPI-2; F, Fp, and Fs on the RF) measure whether the claimant endorses items that people infrequently endorse. These scales provide an index of overreporting of psychopathology and of somatic symptoms (Fs). A symptom validity scale (the Fake Bad Scale [FBS]) was developed by Lees-Haley, English, and Glenn (1991) to assess noncredible neurocognitive and somatic complaints. The Response Bias Scale (RBS), developed by Gervais, Ben-Porath, Wygant, and Green (2007), utilized a series of multiple regression analyses to identify items that discriminate individuals passing and failing well-established freestanding validity tests. Both RBS and FBS discriminate well those who pass and those who fail validity tests (Gervais, Wygant, Sellbom, & Ben-Porath, 2011; Wygant et al., 2009).

In a study of non-head-injury disability claimants (Tarescavage, Wygant, Gervais, & Ben-Porath, 2013), higher scores on the MMPI-2-RF validity scales, especially the RBS, were associated with probable and definite malingered neurocognitive dysfunction (Slick et al., 1999). RBS was likely the best discriminator in this study, as it was originally defined by being able to discriminate those who passed and failed performance validity tests. In the Tarescavage et al. (2013)

study of disability claimants, the effect sizes for discriminating incentive only, suspect malingering, and probable malingering groups were greatest on clinical and content measures of reporting of cognitive complaints ( $d = 1.10$ ), low positive emotions ( $d = 0.86$ ), neurological complaints ( $d = 0.79$ ), and malaise ( $d = 0.78$ ).

In this writer's experience, the request by disability carriers for the use of the PAI has been diminishing, but it is still occasionally an option. The validity scales on the PAI include inconsistency (ICN), infrequency (INF), negative impression management (NIM), and positive impression management (PIM). The NIM scale was designed to indicate the probability that the test taker was portraying a more negative impression than was otherwise warranted. NIM items have low frequencies of endorsement in normal and clinical populations. Significant elevations on NIM are associated with higher reporting of pathology. Individuals with severe emotional problems will also get high NIM scores, as individuals with mental disorders frequently self-report more negative items. For example, a depressed person might report herself as worthless and incompetent, where others might see her as worthwhile and competent (Morey, 1991). While NIM is not to be interpreted in a straightforward manner as an indicator of malingering, Hopwood, Morey, Rogers, and Sewell (2007) provided evidence that the differences between actual and NIM-predicted clinical scales provides information about the type of symptoms being feigned (e.g., anxiety, depression, psychosis). Hammond (2006) showed that in SSD claimants, there was a 50% rate of claimants exceeding the cutoff on NIM. However, Sellbom and Bagby (2008) showed that NIM, the malingering index (MAL; Morey, 1991), and the Rogers Discriminant Function (RDF; Rogers, Sewell, Morey, & Ustad, 1996) had unacceptably high false-positive rates for the classification of malingering.

### Workers' Compensation

WC laws generally protect people who are injured on the job. Federal WC law (visit the Cornell Law School's Legal Information Institute website, [www.law.cornell.edu/uscode/text/5/8102](http://www.law.cornell.edu/uscode/text/5/8102)) specifies compensation for disability or death of an employee resulting from a personal injury while on duty. The U.S. Department of Labor, Office of Workers' Compensation lists four major disability compensation programs: (a) wage replacement benefits, (b) medical treatment, (c) vocational rehabilitation, and (d) other benefits (visit the U.S. Department of Labor Workers' Compensation website for more information: [www.dol.gov/dol/topic/workcomp/](http://www.dol.gov/dol/topic/workcomp/)). There are also other specific groups that provide compensation, including Energy Employees Occupational Illness Compensation, the Federal Employees Compensation program, the Longshore and Harbor Workers Compensation program, and the Black Lung Benefits Program.

The states have their own departments or commissions devoted to labor issues. For example, the North Carolina

Industrial Commission ([www.ic.nc.gov](http://www.ic.nc.gov)) provides steps for injured workers:

- 1 Report the injury to the employer and seek medical treatment.
- 2 Tell the medical provider that the injury is related to work, and have them bill WC for the service.
- 3 Tell the manager that you have initiated a work-related claim.
- 4 Provide written notice about the claim and describe the accident.
- 5 Follow the physician's instructions for medical treatment.

The state commission also provides advice to attorneys concerning a compromise settlement agreement. There is also advice to medical providers, and providers can also see a fee schedule.

As a practical matter, WC evaluations involve providing details about symptoms and problems that require appropriate treatment. There may be a determination of skills and capacities that underlie the ability to perform a job. There may also be a determination of whether the employee has reached MMI. This means that further treatment would not be expected to provide any further improvement in the employee's condition concerning his or her occupational abilities.

Thus, boundaries may be blurred. On one hand, this is inherently medicolegal work in which a hurt individual is seeking diagnosis and treatment for a disabling problem. On the other hand, the psychologist may be providing information about MMI and about the person's psychological abilities to perform their work.

However, psychologists may be retained directly by the WC carrier in which a typical IME is performed. Sometimes the Department of Labor may retain the psychologist for a second-opinion IME to decide on the differences found in the original WC evaluation versus the IME sought by the carrier.

Frequently, especially in industrial areas, the issues involve pain-related disability (Greve et al., 2013). As Greve et al. (2013) indicate, about one-third of all people will experience spinal pain in their lifetimes; half of these individuals will have chronic pain. In these cases, knowledge about how to evaluate pain looms large.

The Battery for Health Improvement-2 (Bruns & Disorbio, 2003) is a multiscale inventory that provides a validity assessment of whether the claimant is overdisclosing, and therefore inflating the self-report, or whether the claimant is responding defensively, and underdisclosing his or her conditions. Four scales are related to pain: Somatic Complaints, Pain Complaints, Functional Complaints, and Muscular Bracing. The Muscular Bracing scale indicates whether there is a high level of muscle tension in reaction to pain, which serves to increase the level of perceived pain. There are also scales of Depression, Anxiety, and Hostility. These, together with the

Table 41.2 Hypothetical example of CPCI findings

Scale	T-Score
<i>Illness Focused</i>	
<b>Guarding</b>	<b>70</b>
Resting	50
Asking for Assistance	37
<i>Wellness-Focused</i>	
Exercise/stretch	58
Relaxation	49
Task persistence	41
Coping self-statements	38
Pacing	49
Seeking social support	39

MMPI-2 (RF) and/or the PAI can be used to evaluate Axis I conditions that may be interfering with work. There are also scales of long-existing chronic maladjustment, and a Borderline scale that indicates personality characteristics showing emotionality that would interfere with work. There are also helpful practical scales of family dysfunction, survivor of violence, doctor dissatisfaction, and job dissatisfaction, all of which provide predictors about a claimant's interest in and problems in the workplace.

The Chronic Pain Coping Inventory (CPCI; Jensen, Turner, Romano, & Strom, 1995) is a 64-item questionnaire with nine scales divided into categories of Illness-Focused Coping (Guarding, Resting, and Asking for Assistance) and Wellness-Focused Coping (Exercise/Stretch, Relaxation, Task Persistence, Coping Self-Statements, Pacing, and Seeking Social Support). The CPCI emphasizes the importance of reducing maladaptive behaviors and increasing adaptive coping behaviors, and is therefore useful in a direct and practical way for treatment. An example of a CPCI result is given in Table 41.2, and an interpretation follows.

In this example, there is a significant level of guarding behavior, which is illness focused. The individual has fear that movement will lead to pain and further injury, and thus restricts or limits his or her movements. This can lead to deconditioning and further impairment. There is also a low level of coping self-statements. With improvement in these thoughts about pain and injury, the person can develop a more positive outlook. This individual is also rather isolated and is not seeking much social support. In this case, asking for assistance is also low. While the person is not facilitating disability by getting others to wait on him or her, this person is rather isolated and generally without much support.

## It's Also About Work

### *Fitness For Duty*

While this chapter is focused on disability, which involves the inability to work, it is important to contrast a disability examination with other types of assessment that are focused

on work. For example, a Fitness-For-Duty (FFD) examination involves an individual whose employer is concerned whether he or she can work. In these cases, the individual typically wants to be back at work, but there has been a problem: a threat, an altercation, an angry and inappropriate outburst, or an emotional setback. Sometimes there are cognitive problems. Frequently, management wants to know whether the person is a risk to him- or herself or others. While the concerns about a postal employee "going postal" have become a cliché, indeed the U.S. Postal Service is one of those employers who will want a FFD examination when a worker is displaying unstable or inappropriate behaviors. This writer was involved in a FFD evaluation in which a postal employee bought an AR-15 when many gun lovers were buying them right before the legislation banning assault rifles was voted on. The employee had bragged about his new purchase in the workplace, prompting a FFD evaluation.

In FFD examinations, it is frequently helpful for an IME company to arrange the evaluation, which facilitates a well-controlled environment. While a full interview will be conducted, and appropriate psychological testing will be administered, the employer should not see this information, as it could be prejudicial. Indeed, the employer should see only the answers to the referral questions, which involve whether there is any increased health or safety risk in the workplace, there is any potential risk, there are psychological problems that need treatment, the workplace environment needs to be changed to decrease any potential problems, accommodations are needed, the employee needs time off from work, and whether there are any suggestions for management. There are many cautions, as it is usually difficult to predict dangerousness or violence with any certainty. The reporting is typically short, as the employer should see only the assurances that the psychological or neuropsychological work was done, and then the answers to the questions (leaving out prejudicial background information and findings). For these examinations, collateral interviews with supervisors and managers are most helpful.

Examples of FFD evaluations include (in addition to the postal worker example) an individual with paranoid personality disorder who was blaming everyone in the workplace for his problems, a hospital concerned about an elderly surgeon blowing up at his nurse, management being concerned about an elderly financial manager's skills, a university concerned with an elderly professor who was noncompliant with his medications for bipolar disorder, a case in which suicidal ideation was expressed in the workplace, and the deterioration of an employee's safety-sensitive work in a high-stress job.

### *Regulatory Evaluations*

Regulatory agencies such as the Federal Aviation Administration (FAA) will have specific fitness for duty requirements

when a pilot or prospective pilot has used psychostimulants for attention deficit/hyperactivity disorder (ADHD), is using an antidepressant, has substance abuse problems, or has any form of cognitive problem needing assessment. The FAA will issue specification sheets for each of these types of evaluation. Frequently, there is a need for the use of Cogscreen Aeromedical Edition (Kay, 1995), a computer-based touch-screen evaluation of attention, problem solving, and processing speed that has been validated specifically for pilots. See Kay (2013) for a review of psychological and neuropsychological issues involved in aeromedical evaluations.

### Licensing Board Evaluations

Each licensing board has a mission of public trust to protect the public from licensees who may be doing a disservice from unscrupulous, ill-advised, illegal, or impaired practice. Psychologists and neuropsychologists may be asked to evaluate possibly impaired practitioners to help the board determine whether they are safe to practice in their specialties. For example, a neuropsychologist may be asked to evaluate an elderly physician to determine whether there is a dementing illness that is causing problems with practice of the specialty. Frequently, substance abuse is an issue in licensing board evaluations.

### State Vocational Rehabilitation

These are state agencies (e.g., Louisiana Rehabilitation services, [www.laworks.net/WorkforceDev/LRS/LRS\\_Main.asp](http://www.laworks.net/WorkforceDev/LRS/LRS_Main.asp)) to assist those with disabilities in their desire to obtain or maintain employment. Frequently, there is a goal for independence in the community, and the agency will help with independent living. Agencies will work cooperatively with businesses and other community resources to help an individual with employment. Psychologists and neuropsychologists may be asked to provide an evaluation focused on helping the individual with work in spite of a disability. Thus, as with disability evaluations, an analysis of strengths and limitations is useful. Compared with disability evaluations, however, the motivation of these claimants is to find or maintain work (Chafetz et al., 2011).

### Acknowledgments

The author would like to thank Paige Haley for her due diligence in helping with references, formatting, and APA style.

### Notes

- 1 In this chapter, SSD will be used to refer to both of the disability programs under Social Security: SSDI or SSI.
- 2 Alternatively, the examiner should be aware that it is easy to look up symptoms to provide an authentic-sounding case during the interview. For example, see the Centers for Disease Control's Traumatic Brain Injury Signs & Symptoms page (<https://www.cdc.gov/traumaticbraininjury/symptoms.html>).

## 42 Ethical Practice of Clinical Neuropsychology

*Shane S. Bush*

Do I need to use the most recent version of a test as soon as it is published? Do I allow family members to serve as interpreters for neuropsychological evaluations of patients who cannot speak English? Do I have to use performance validity measures in routine clinical evaluations? Is it best to use the normative data that comes with the test when it is published? Do I release raw test data to attorneys? Do I need to be board certified in neuropsychology? This brief series of questions reflects a sample of issues that lie at the intersection of ethics, laws, and clinical practice. Although these specific issues have been addressed in the neuropsychology literature, they nevertheless pose challenges for many practitioners. Even more complex issues with unique elements and no clear solution are routinely encountered in neuropsychological practice, requiring practitioners to be or become familiar with a variety of resources and a structured approach to ethical decision making.

It has been more than 20 years since the discussion of ethical issues in clinical neuropsychology began expanding from the classroom and clinic into the published literature (Binder & Thompson, 1995; Brittain, Francis, & Barth, 1995; Fowles & Fox, 1995). The initial articles specific to ethical issues in neuropsychology were published on the heels of early publications on policy and legal issues (Woody, 1989) and ethics in closely related specialties such as rehabilitation medicine (Ackerman & Banks, 1990; Banja, 1989; Banja & Johnston, 1994; Malec, 1993). These early neuropsychology ethics articles were immediately followed in the literature by additional application of professional ethics to various aspects of neuropsychological and neuro-rehabilitation research and practice (Anderson & Shields, 1998; Argarwal, Ferran, Ost, & Wilson, 1996; Artioli & Fortuny & Mullaney, 1998; Banja, 1996; Banja & Rosenthal, 1996; Banja, Adler, & Stringer, 1996; Guilmette & Hagan, 1997; Johnson-Greene, Hardy-Morais, Adams, Hardy, & Bergloff, 1997; Malec, 1996; Rosenthal, 1996; Rosenthal & Lourie, 1996; Sim, 1998; van Gorp & McMullen, 1997; Wong, 1998; Woody, 1997).

The period from the late 1980s to the turn of the century also brought publications on professional practice issues that have direct ethical implications involving professional competence; selection, use, and interpretation of tests; test security; and preservation of the examiner-examinee diad

(Binder & Johnson-Greene, 1995; Bornstein, 1991; DeLuca, 1989; Donders, 1999; Freides, 1993; Grote, Lewin, Sweet, & van Gorp, 2000; Macartney-Filgate & Snow, 2000; Martelli, Zasler, & Grayon, 1999; Matthews, Harley, & Malec, 1991; McCaffrey, Fisher, Gold, & Lynch, 1996; McSweeney, Becker, Naugle, Snow, Binder, & Thompson, 1998; van Gorp & McMullen, 1997; Youngjohn, Spector, & Mapou, 1998). Some publications during this time resulted in engaging commentary and discussion, which helped to refine the ethical and professional aspects of common practice issues (e.g., Barth, 2000; Freides, 1993, 1995; Lees-Haley, 1999; Lees-Haley & Courtney, 2000a, 2000b; Matarazzo, 1995; Naugle & McSweeney, 1995; Naugle & McSweeney, 1996; Sweet & Moulthrop, 1999a, 1999b; Tranel, 2000). These publications provided the foundation for the position papers from professional organizations such as the American Academy of Clinical Neuropsychology and the National Academy of Neuropsychology that began emerging in the late 1990s and early 21st century and help define standards of practice in clinical neuropsychology.

With these early articles, chapters, and position papers as the foundation, neuropsychology has seen steady growth in publications on ethical, legal, and professional aspects of practice. Edited books on ethical practice in neuropsychology provided coverage of ethical issues with various patient populations across multiple clinical settings (Bush, 2005a; Bush & Drexler, 2002). Subsequent publications have emphasized the importance of addressing ethical challenges with a structured decision-making model, pursuing high standards of ethical conduct beyond risk management, and striving to anticipate and avoid ethical challenges before they become dilemmas (e.g., Bush, 2007, 2009). Johnson-Greene and Nissley (2008) noted that knowledge of ethical standards and doctrine is not synonymous with sound ethical decision making; rather, knowledge of both ethical content and the decision-making process are essential for making good decisions in ethical matters.

The primary purpose of the present chapter is to provide an updated overview of ethical issues and decision making in clinical neuropsychology. Recently published ethical, legal, and professional resources are reviewed, an ethical decision-making model is presented, and the importance of a personal commitment to ethical practice is emphasized.

## Ethical Challenges and Ideals

If one were to consider complaints and notices filed with the American Psychological Association (APA) Ethics Committee when determining which ethical issues are most important for neuropsychologists and how seriously ethical issues should be taken, it would be easy to conclude that there is little to worry about as long as harmful dual relationships, particularly those of a sexual nature, are avoided. In 2011, complaints were filed with the APA Ethics Committee against 0.07% of the membership, and the Ethics Committee received notices of inappropriate behavior from licensing boards and other entities for 0.09% of the APA membership (APA Ethics Committee, 2012). Of the nine ethics cases that were opened in 2011, none came from complaints filed with the committee. The categories of ethics cases opened by the APA Ethics Committee in 2011 were as follows: Dual Relationship (Sexual Misconduct–Adult),  $N = 5$  (55.6% of cases); Dual Relationship (nonsexual),  $N = 2$  (22.2% of cases); Inappropriate Professional Practice (Insurance/Fee Problems),  $N = 1$  (11.1% of cases); and Inappropriate Research, Teaching, or Administrative Practice (Other),  $N = 1$  (11.1% of cases) (APA Ethics Committee, 2012).

Similar figures were reported for 2012 (APA Ethics Committee, 2013). That year, complaints were filed with the APA Ethics Committee against 0.08% of the membership, and the Ethics Committee received notices of inappropriate behavior from licensing boards and other entities for 0.05% of the APA membership. Just two (15.4%) of the 13 ethics cases that were opened in 2012 came from complaints filed with the committee. The categories of ethics cases opened by the APA Ethics Committee in 2012 were as follows: Dual Relationship (Sexual Misconduct–Adult),  $N = 5$  (38.5% of cases); Dual Relationship (Nonsexual),  $N = 2$  (15.4% of cases); Inappropriate Professional Practice (Child Custody),  $N = 3$  (23.1% of cases); and Inappropriate Professional Practice (Insurance/Fee Problems),  $N = 2$  (15.4% of cases) (APA Ethics Committee, 2013).

However, ethical practice in clinical neuropsychology extends well beyond the avoidance of complaints filed with the APA Ethics Committee. Psychological ethics, designed to prevent harm and to promote the well-being of consumers of psychological services, require practitioners to be aware of each aspect of their professional behavior and how those behaviors impact others, leading to choices that are consistent with the goals of professional ethics. While all ethical standards and principles are applicable to various neuropsychological activities, certain standards are more relevant than others for common neuropsychological practices (Brittain, Frances, & Barth, 1995; Bush, 2007; Bush, Grote, Johnson-Greene, & Macartney-Filgate, 2008). Based on a review of the literature and personal experience, 12 common sources of ethical conflict were identified, in the following order of importance: professional competence, roles and relationships (dual/multiple), test security and release of raw test data,

third-party observers, confidentiality, assessment, conflicts between ethics and laws, false or deceptive statements, objectivity, cooperation with other professionals, informed consent and third-party requests for services, and record keeping and fees (Bush, 2007). Practitioners working in various subspecialties within neuropsychology will place different degrees of emphasis on the various ethical standards depending on the needs of the patients or practice setting.

For each of these ethical standards, there are actions that can be taken to minimally satisfy the ethical requirement, and there are actions that can be taken that reflect the pursuit of higher standards of ethical practice. Aspiring to high ethical standards of professional behavior or ethical ideals, referred to as *positive ethics* (Knapp & VandeCreek, 2006), often requires more time and effort than is required to satisfy minimum requirements. Nevertheless, patients, other consumers of neuropsychological services, and the profession are typically better served by the practitioner's extra investment.

For example, regarding the first area of ethical importance (professional competence), obtaining board certification readily identifies a neuropsychologist to patients, the public, and others as meeting a certain level of professional competence. However, the board certification process can be time- and labor-intensive, as well as an added expense and source of stress in one's professional life. Some qualified clinicians choose not to undergo the examination process because of its challenges, time requirements, and expense, particularly given that it is not required for practice in most contexts; yet it can be difficult to distinguish those qualified clinicians from those not providing competent services.

To address the question "Do I need to be board certified in neuropsychology," the short answer, consistent with minimal ethical standards and legal requirements, is "no." However, at this point in the evolution of the profession, clinicians who perform neuropsychological services but have not obtained, or are not pursuing, board certification would be hard pressed to defend the decision to not demonstrate their knowledge and skills through formal peer review. Knapp, Younggren, VandeCreek, Harris, and Martin (2013) noted:

A continual danger is that psychologists' perceived personal skill inventory almost always will be greater than their actual skill inventory. Psychologists can reduce the gap between their perceived and actual skill inventories by ongoing contact and feedback with other mental health professionals.

(p. 13)

Board certification is ideal for determining whether one's actual skill inventory corresponds with one's perceived skill inventory and whether the actual skill inventory reflects competence in neuropsychology.

The value of board certification to the public, the profession, and practitioners has long been acknowledged and

repeatedly emphasized (e.g., Cox, 2010). Evidence indicates that board certification in neuropsychology is increasing (e.g., McCrea, 2011) and is achieving higher numbers than other specialties within psychology (Cox, 2010). Obtaining the highest credential offered in the specialty is consistent with the pursuit of the highest standards of ethical practice in the area of professional competence.

Similar examples can be provided for each of the 12 common sources of ethical conflict that were previously described. The important point is that there typically exists a range of ethically appropriate actions that practitioners can take when confronted with ethical issues and dilemmas, and the easiest option may not be the best option. A personal commitment to the pursuit of ethical ideals benefits patients and the profession.

### **Ethics Resources and Preparation**

Neuropsychologists practicing in the United States are aware of the APA ethics code (APA, 2010) and likely turn to the code first when confronting ethical questions or conflicts. In some circumstances, the code may not fully address the issue being confronted by the clinician. In other circumstances, the issue being addressed may be more of a legal, clinical, or risk management issue than an ethical issue per se (Behnke, 2014). Determining whether the issue of concern is an ethical, legal, professional, or risk management issue or some combination of these issues will dictate which resources will be useful for addressing the issue. Thus, familiarity with multiple resources can facilitate decision making when faced with challenging situations.

The following list provides some of the primary resources that can help neuropsychologists with ethical and legal decision making: (a) general bioethical principles; (b) ethics codes of organizations other than APA; (c) Code of Conduct of the Association of State and Provincial Psychology Boards; (d) jurisdictional laws; (e) position papers and practice guidelines from professional organizations; (f) scholarly publications such as books, articles, and chapters; (g) ethics committees; (h) professional liability insurance carriers; (i) institutional guidelines and resources; and (j) experienced and knowledgeable colleagues. These types of resources tend to provide more specific guidance than can typically be offered by a general ethics code.

Savvy practitioners do not wait until confronted with a challenging ethical matter before obtaining and familiarizing themselves with ethical and legal resources. They *anticipate* the types of issues and challenges that are most likely to be encountered in their practice and strive to *avoid* ethical dilemmas by reviewing relevant resources and establishing appropriate practices and routines. Although not all ethical challenges can be avoided, such practitioners are typically well prepared to *address* ethical challenges when they arise, taking the steps necessary as they *aspire* to the highest standards of ethical practice. These four words (anticipate,

avoid, address, and aspire), known as the *Four A's of ethical practice* (Bush, 2009), can cue practitioners to be mindful of the importance of regularly attending to ethical issues across the span of professional activities. Holding ethics rounds or seminars, or making a commitment to become familiar with one ethics resource per month, promotes the type of focus on professional behavior that is consistent with high standards of ethical practice.

Practitioners are also well served by understanding factors that tend to predispose them to, and protect them from, ethical misconduct (Johnson-Greene & Nissley, 2008; Knapp et al., 2013). Predisposing risk factors include (a) practicing in isolation where there tends to be little direct oversight of one's work and more limited availability of peer consultation; (b) practicing outside of one's boundaries of competence; (c) being an impaired provider, due to psychological, cognitive, or social problems; (d) working with certain patient populations (e.g., serious personality disorders, complex posttraumatic stress disorder) or in certain practice contexts (e.g., forensics); and (e) having limited awareness of, or corrective response to, personal and professional biases. Factors that help protect practitioners from ethical misconduct are essentially the opposite of predisposing factors and include (a) maintaining a system of protection, including membership in professional organizations and a network of colleagues for consultation when needed; (b) appreciating the limits of one's skill inventory and practicing within one's boundaries of competency; (c) establishing and maintaining familiarity with ethical issues, resources, and decision making; (d) engaging in self-examination so that maladaptive actions can be changed. Periodically reviewing these precipitating and protective factors with the goal of improving one's professional services reflects the pursuit of high standards of ethical practice.

### **Application of Resources to Ethical Challenges**

Familiarity with ethical and legal resources is usually necessary but not sufficient for addressing complex ethics questions. The information must be organized and applied in a manner that promotes sound decision making, with consideration of personal and situational factors and the dynamic nature of any complex decision making process. A structured ethical decision-making model can help in that regard. Such models help clarify the nature of the problem, identify requirements and guidelines from relevant resources, and generate possible solutions. Detailed models (e.g., Bush, 2007) break the process down into multiple steps, each of which can influence the decision making process and choices made.

Johnson-Greene and Nissley (2008) emphasized the importance of a process-oriented model in which

there is an appreciation for the dynamic nature of the model, acknowledgement of the multitude of predisposing

and protective factors, sources of ethical standards and variation in experiences and skills, and an understanding that all ethical issues start and end within the patient—provider relationship and the provider’s emphasis on the three ethical foundations of patient autonomy, beneficence, and nonmaleficence.

(p. 955)

Use of ethical decision-making models reduces the likelihood that complex ethical decisions are made on the basis of personal judgment alone.

To address the questions posed at the beginning of this chapter, neuropsychologists have considered the various possible solutions, often applying the decision-making model with a variety of resources, and arrived at the following conclusions.

- 1 Do I need to use the most recent version of a test as soon as it is published? No.

Determining whether or when to transition to a new version of a test can be particularly difficult for clinicians in psychological specialties because it can take years after publication of a revised test for research with special patient populations to be performed and published. As a result, different clinicians may adopt newer versions of tests at different times or elect not to use the newest version, depending on the specific patient population and referral questions. Decisions regarding transitioning to new test revisions should be based on the scientific merits of the tests, not on an arbitrarily defined time frame. Clinicians ultimately must use their judgment regarding which test version is best for a given patient at a given point in time.

(Bush, 2010, p. 7)

- 2 Do I allow family members to serve as interpreters for neuropsychological evaluations of patients who cannot speak English? Typically, no.

When providing service directly in the examinee’s preferred language is not feasible, neuropsychologists should make efforts to use professional interpreters and translators. . . . Whenever possible, neuropsychologists should avoid using family members, attorneys, and other persons known to the client as interpreters, unless circumstances dictate and permit such use.

(Judd et al., 2009, p. 131)

- 3 Do I need to use performance validity measures in routine clinical evaluations? Yes.

Adequate assessment of response validity is essential in order to maximize confidence in the results of neurocognitive and personality measures and in the diagnoses and recommendations that are based on the results. Symptom validity assessment may include specific tests, indices, and observations. The manner in which symptom validity is

assessed may vary depending on context but must include a thorough examination of cultural factors. Assessment of response validity, as a component of a medically necessary evaluation, is medically necessary.

(Bush et al., 2005, p. 419)

Additionally, a consensus conference on the neuropsychological assessment of effort, response bias, and malingering (Heilbronner et al., 2009) concluded, “Even in a routine clinical context the presence of problematic effort and response bias can potentially invalidate results. The assessment of effort and genuine reporting of symptoms is important in all evaluations” (p. 1121).

- 4 Is it best to use the normative data that comes with the test when it is published? The answer to this question depends entirely on the specific test and the patient being evaluated. For some new tests or new versions of older tests, the accompanying normative data is an improvement over that of preexisting tests for certain patient populations; however, the same data set may not be the most appropriate option for patients with certain disorders for whom a large body of published data exists for a prior test. Similarly, for older tests, research and normative data published subsequent to the publication of the tests are often preferred over the original normative data.
- 5 Do I release raw test data to attorneys? Typically this is not done as a first option and not without requesting safeguards. This question has been covered extensively in the neuropsychology literature (e.g., Bush & Martin, 2006; Bush, Rapp, & Ferber, 2010; Kaufmann, 2009) and by professional organizations (e.g., American Psychological Association & Committee on Legal Issues, 2006; Attix et al., 2007; National Academy of Neuropsychology, 2000, National Academy of Neuropsychology Policy and Planning Committee, 2003). Despite a lack of clear or rational guidance from the APA ethics code, multiple ethical and legal resources describe the potential problems associated with reproducing and releasing raw test data to nonpsychologists who do not have the education or training to understand and appropriately use and protect the materials. For example:

Threats to test security by release of test data to nonpsychologists are significant. . . . the National Academy of Neuropsychology fully endorses the need to maintain test security, views the duty to do so as a basic professional and ethical obligation, strongly discourages the release of materials when requests do not contain appropriate safeguards, and, when indicated, urges the neuropsychologist to take appropriate and reasonable steps to arrange conditions for release that ensure adequate safeguards.

(National Academy of Neuropsychology, 2000, pp. 383–384).

These questions reflect a very small sample of the types of questions that neuropsychologists have commonly found challenging over the years. More challenging for practitioners at this time are those that involve unique situations that have not yet received extensive attention by professional organizations or extensive coverage in the literature. It is in such situations that familiarity with a variety of resources, awareness of a decision-making model, and access to knowledgeable and experienced colleagues can be of greatest value.

### Changes Over Time and Future Directions

Since articles on ethical issues in neuropsychology began appearing the literature about 20 years ago, nearly every aspect of clinical practice and professional behavior has been dissected from the perspective of professional ethics and laws. Articles and book chapters on ethics pertaining to various subspecialties, patient populations, practice contexts, and emerging issues have been published, including, but not limited to, pediatrics, geriatrics, sport, forensics, military and veterans, and technology. Numerous resources that extend beyond the APA ethics code have been identified, decision-making models have been proposed, and professional organizations have taken positions on issues.

Despite these advances, unique situations continue to arise that challenge practitioners to make sound ethical decisions despite the absence of a clearly preferred course of action. It is in such situations that reliance on the core bioethical principles that have always been the foundation of good clinical practice can be of most value. A commitment to promoting understanding and welfare of patients, avoiding actions that are likely to be harmful to patients, respecting patient autonomy, and practicing in a manner that promotes fairness and justice can help practitioners maintain high standards of ethical practice, avoid ethical misconduct, and address dilemmas when they arise.

There seems to be little doubt that technology will continue to play an increasing role in neuropsychological practice, from electronic medical records to more extensive computer administration, scoring, and interpretation, to imaging, to telemedicine, and to options that practitioners have not yet considered. While some of these practices are already under way in some contexts, they are likely to be adopted more widely, and the range of activities will expand. In the rush to adopt new technologies and to apply technology to neuropsychology in new ways that can better serve patients and the profession, care must be taken to determine that quality is not lost and that patient care and the profession do not suffer. The following conclusion, drawn more than ten years ago, seems even more relevant today: “Neuropsychologists will minimize chances for ethical misconduct by increasing their sensitivity to the relevant ethical issues associated with ITT as well as by ensuring competence in those technologies used in clinical practice and/or research” (Bush, Naugle, & Johnson-Greene, 2002, p. 543; note: “ITT” is “information

technology and telecommunications”). When both technology-based and traditional options are available, informing patients and allowing them to choose reflects respect for patient autonomy.

A trend toward greater involvement in forensic cases has also been observed in recent years and is likely to continue (Kaufmann, 2009). With passage and recent implementation of the Patient Care and Affordable Care Act [P.L. 111–148] (ACA), some neuropsychologists are already experiencing an adverse impact on their hospital-based practices. Although the broader and longer-term impact of the ACA on neuropsychological practice remains unknown, and new opportunities are certain to arise for some clinicians, other clinicians may use this time of transition and uncertainty to begin or increase forensic work. Thus, the trend toward increased forensic work for neuropsychologists that was observed prior to implementation of the ACA may be further accelerated in the coming years, bringing to more practitioners the ethical issues and challenges encountered more commonly in forensic practice (e.g., Bush, 2005b).

As the practice of clinical neuropsychology continues to evolve, the application of professional ethics to clinical practice will need to keep pace. Maintaining open discussion of ethical questions, challenges, and solutions, and sharing experiences with colleagues, will promote ethical practice and be particularly valuable during times of transition. A personal commitment to the shared values of the profession, reflected in general bioethical principles and a variety of published resources, helps position neuropsychologists to understand ethical issues, anticipate and avoid ethical challenges, and successfully resolve ethical dilemmas when they arise. And, most importantly, those served by neuropsychologists benefit.

# 43 Evidence-Based Practice in Clinical Neuropsychology

*Jerry J. Sweet, Daniel J. Goldman, and Leslie M. Guidotti Breting*

## Introduction

Health care practice is constantly evolving. Although health care in the United States has a very long history of aspiring to have clinical science as its seminal basis, there have been numerous critics who have claimed that medical practice is not scientific enough (cf. Institute of Medicine, 2001). In fact, critics of nonscientific medical practice within organized medicine at an international level reacted by initiating a high level, explicit process of supporting assessment and treatment procedures that are *evidence-based* nearly 20 years ago. At the outset of this era, Sackett, Rosenberg, Gray, Haynes, and Richardson (1996) published a frequently cited article that described some essential features of evidence-based medicine (EBM). These authors noted that in fact EBM had been a “hot topic” for years, attributing the foundation to “ancient origins,” while also suggesting that the approach had been misunderstood and in their view had not reached the practice mainstream. A brief quote from Sackett et al. (1996) captures their view on the central thrust of EBM:

Evidence based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research.

(p. 71)

More recently, the Agency for Healthcare Research and Quality (AHRQ), which sponsors Evidence-Based Practice Centers (EPCs), has opined that a “quality gap” remains (i.e., a gap between best available clinical research evidence and practice; see Shojania, McDonald, Wachter, & Owens, 2004). In the words of Shojania et al. (2004), “Substantial evidence suggests that there is a wide gap between evidence-based best practices and those treatment practices actually used in day-to-day clinical medicine” (p. v).

In recent years, the visibility of EBM initiatives has been impressive. As of 2014, the *Journal of Evidence-Based Medicine* is in its seventh year of publication, the journal of *Evidence-Based Dental Practice* is in its 14th year of publication, and the journal of *Evidence-Based Mental Health* is in its 17th year of publication. The term itself, *evidence-based*,

has been applied to numerous specialties within medicine, as well as separate practice disciplines, such as social work, nursing, physical therapy, and psychology, to name but a few. Indeed, a search of documents within the website of the U.S. Department of Health and Human Services that houses AHRQ’s National Guidelines Clearinghouse returns approximately 1,700 documents that use the term *evidence-based*. Similarly, a search of the inventory of books listed on the Academic section of the Oxford University Press website (<http://global.oup.com/academic>) using the term *evidence-based* results in identification of dozens of books across multiple disciplines with the term in the title and a total of 11,720 books that apparently contain the term. Of this larger sum, surely some have mentioned the term only in passing, but the point is made that the term is now widely known and broadly applied across specialties and disciplines.

Over time, with such widespread application beyond the discipline of medicine, the more general term that has been applied across health care specialties and disciplines has been *evidence-based practice* (EBP), which will be used throughout the remainder of this chapter.

Similar to medicine, the history of aspiring to base practice on research evidence is not new to psychology. In fact, nearly 70 years ago the American Psychological Association (APA) recommended training guidelines specifying that the desired model for doctoral-level graduate training is the “scientist-practitioner” model (Shakow et al., 1947). Even with such a long history of emphasizing and promoting science as the basis for practice, it was not until 2006 that the APA published an official policy statement as an appendix to its 2005 Presidential Task Force on Evidence-Based Practice (American Psychological Association Presidential Task Force on Evidence-Based Practice, 2006). This evolution to more explicit commitment to practice based on best available research by organized psychology mirrors the evolution in the discipline of medicine; in fact, the official positions of these disciplines (n.b., medicine’s position has often been attributed to the 2001 Institute of Medicine report) are noted in APA’s document as quite similar. Relevant to promoting and disseminating relevant psychological research, billions of dollars have been made available for EBP psychological research funding, which will strongly promote a more complete shift to EBP in psychology (McHugh & Barlow, 2010).

Perhaps more so than any other psychology practice specialty, scientific research and empiricism have been the bedrock foundation of clinical neuropsychology. For many decades, clinical neuropsychologists have produced practice-specific assessment research demonstrating scientifically the clinical merit of its procedures. For the last three decades, such research has been published in journals devoted entirely to neuropsychological practice research (e.g., *Archives of Clinical Neuropsychology*, *The Clinical Neuropsychologist*). Authors have credited the subspecialty growth of forensic neuropsychology practice to the very fact that neuropsychological practice was scientifically based, and thus able to offer evidence for consideration in legal proceedings that is objective, rather than impressionistic or based solely on clinician opinion (Larrabee, 2012; Sweet, 1999; Sweet, Ecklund-Johnson, & Malina, 2008). In this sense, EBP is not a new concept for clinical neuropsychologists, but rather a movement well fitted to a preexisting philosophy and easily endorsed. However, as Chelune (2010) has pointed out, true outcomes-based research that demonstrates the economic value and value to society of neuropsychological consultation is only now emerging, with related advocacy regarding the import of decades of clinical research and service also in its infancy.

National policy has explicitly promoted EBP within the Patient Protection and Affordable Care Act (Public Law No: 111–148, Mar 23, 2010), which is known simply as the Affordable Care Act (ACA) and more colloquially as “Obamacare.” In a detailed discussion for psychology, Rozensky (2014) has noted the intent of the ACA to disseminate evidence-based health care research to practitioners and within the government’s own services to rely only on such information when determining payment coverage for health care services. Having become literally required by law, it seems clear that the EBP movement will continue. In sections that follow, more specific information will be provided and the “goodness of fit” with regard to neuropsychology practice will be explored.

## Overview of Evidence-Based Practice

In an influential 2001 report, the Institute of Medicine (IOM) identified six dimensions of ideal health care in the 21st century: safe, effective, patient-centered, timely, efficient, and equitable (IOM, 2001). In the subsequent recommendations regarding how present-day health care could be redesigned to fulfill this description, a central recommendation was the following: “*Evidence-based decision making*. Patients should receive care based on the best available scientific knowledge. Care should not vary illogically from clinician to clinician or from place to place” (IOM, 2001: 8).

In searching for information pertaining to EBP, one can quickly develop the impression that the term *evidence-based* is overused and may have lost some meaning. Among the numerous authors who have provided guidance, Sackett et al. (1996) plainly describe what it is and what it is *not*. The EBP approach takes into account that at times the best available

evidence is not the result of quintessential research methods, such as randomized clinical trials, when either none exist or the clinical problem at hand does not lend itself to such a research design. However, when high-quality clinical research evidence is available, clinicians are to rely on this information in applying related assessment and treatment procedures to individual patients. The EBP approach is not meant to represent a purely sterile, scientific approach; explicit consideration of the application of best available evidence involves consideration and respect of patient-specific values.

What then defines “best available scientific knowledge?” Research methodologists have described in detail the research methods and specific criteria for research publishing that can produce greater generalizability, replication studies, and clinical applications of research findings. The *APA Presidential Task Force on Evidence-Based Practice* report (2006) identified multiple types of research evidence that can be considered in determining EBP:

***Clinical observation (including individual case studies) and basic psychological science are valuable sources of innovations and hypotheses (the context of scientific discovery).***

***Qualitative research can be used to describe the subjective, lived experiences of people, including participants in psychotherapy.***

***Systematic case studies are particularly useful when aggregated—as in the form of practice research networks—for comparing individual patients with others with similar characteristics.***

***Single-case experimental designs are particularly useful for establishing causal relationships in the context of an individual.***

***Public health and ethnographic research are especially useful for tracking the availability, utilization, and acceptance of mental health treatments as well as suggesting ways of altering these treatments to maximize their utility in a given social context.***

***Process–outcome studies are especially valuable for identifying mechanisms of change.***

***Studies of interventions as these are delivered in naturalistic settings (effectiveness research) are well suited for assessing the ecological validity of treatments.***

***Randomized clinical trials and their logical equivalents (efficacy research) are the standard for drawing causal inferences about the effects of interventions (context of scientific verification).***

***Meta-analysis is a systematic means to synthesize results from multiple studies, test hypotheses, and quantitatively estimate the size of effects.***

(p. 274)

Efforts to improve the quality of published clinical research studies are ongoing. Various professional organizations, some of which are multidisciplinary and international, have

promulgated recommendations and guidelines that foster promotion and dissemination of high quality health care research. Generally referred to as journal *reporting guidelines*, a listing and brief description of current key guidelines are shown in Table 43.1. These efforts have become so prominent in academic health care that guidance on the development of guidelines has also been offered (Moher, Schulz, Simera, & Altman, 2010). Minimally, guidelines such as these are intended to facilitate critical analysis of the results during the prepublication peer-review process, and, in some instances, replication and extension (perhaps to different types of patients) after studies are published. Additionally, inclusion of key research methodology information and clinical sample characteristics allows practitioners, as consumers of the research studies, to determine with whom and under what conditions the study results may apply to their own patients.

Of the currently available reporting guidelines, one of the first was the Consolidated Standards of Reporting Trials (CONSORT), which first appeared in 1996 (Begg et al.) and is now in its third iteration (Schulz, Altman, Moher, & for the CONSORT Group, 2010). For a discussion of CONSORT as it pertains to neuropsychological research, see Miller, Schoenberg, and Bilder (2014). The acceptance and influence of such reporting guidelines is evident in the fact that with CONSORT alone there have been, to date, nine specialized versions of CONSORT for such specific clinical research applications as how to conduct clinical trials related to acupuncture, herbal treatments, and nonpharmacological interventions. Moreover, as of the writing of this manuscript, the EQUATOR (Enhancing the

Quality and Transparency Of health Research)-network website indicates that there are presently CONSORT extensions underway for social and psychological interventions, as well as for N-of-1 trials. In total, the EQUATOR-network website lists 21 new reporting guidelines currently in development. The net intended effect of the resources listed in Tables 43.2 and 43.3 is to improve the quality and specificity of clinical research, which is a key component of EBP.

To facilitate understanding and use of reporting guidelines by clinical researchers, a group of researchers founded the EQUATOR Network in 2006, which is self-described as “an international initiative that seeks to improve the reliability and value of published health research literature by promoting transparent and accurate reporting and wider use of robust reporting guidelines” (EQUATOR Network, 2006). This organization provides downloadable checklists that clinical researchers can use as a means of self-monitoring regarding study execution and manuscript preparation prior to submission to a peer-reviewed journal. In turn, peer-reviewed health care journals have gradually adopted one or more specific reporting guidelines. An international subset of journal editors themselves have organized to form the International Committee of Medical Journal Editors (ICMJE), which has created and, at intervals, updates recommendations regarding the means of conducting, reviewing, and publishing biomedical research that are viewed as increasing the likelihood of “accurate, clear, and unbiased” journal articles ([www.icmje.org](http://www.icmje.org)). More than 500 journals have endorsed and attested to following the ICMJE recommendations. In keeping with the EBP movement, these recommendations include

endorsement of reporting guidelines by journals, as well as transparency of author, peer review, and journal procedures and responsibility for the publication outcome, as well as sponsor involvement and inclusion of sufficient methods and sample information to allow replication and clear application of results in clinical settings. In similar fashion, the World Association of Medical Editors (WAME) has provided broad and detailed guidance for researchers and editors regarding honesty, transparency, and accuracy at all levels of the biomedical publishing enterprise (WAME, 2017).

### **Evidence-Based Practice in Mental Health**

As described earlier, EBP has a relatively long history in the field of medicine. Many of the principles described have been modified to apply specifically to the field of mental health. In 1998, one of the first major steps supportive of EBP within mental health was the establishment of the journal *Evidence-Based Mental Health*, which informs clinicians regarding important advances in treatment, diagnosis, etiology, prognosis, continuing education, economic evaluation, and qualitative research in mental health by selecting and summarizing high quality original and review articles from other peer-reviewed journals.

Importantly, the 1999 U.S. Department of Health and Human Services Surgeon General Report on mental health marks a turning point related to EBP in mental health. This report noted that “a variety of treatments of well-documented efficacy exist for the array of clearly defined mental and behavioral disorders that occur across the life span” and that the mental health field should make these EBPs available to all who seek treatment (U.S. Department of Health and Human Services, 1999: 3). A few years later, in 2003, President George W. Bush’s New Freedom Commission on Mental Health reported on the need to develop, implement, and expand EBPs; and it even formed a subcommittee to examine and offer policy recommendations on EBPs. Despite these efforts dating back to 1999 a gap continues to exist between the EBP research and clinical applications currently.

Oddly, despite clinical psychologists’ history of strong training in research and statistical methods, psychology was one of the last health care disciplines to formally adopt and support EBP. Due to the need to shift toward EBP, in 2005 the APA organized a Presidential Task Force on EBP and

in 2006 released a statement on EBP in Psychology. The 2006 report from this task force agreed upon a definition: “Evidence-based practice in psychology (EBPP) is the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences” (APA Presidential Task Force on EBP, 2006: 273). The Task Force also designated that: “The purpose of EBPP is to promote effective psychological practice and enhance public health by applying empirically supported principles of psychological assessment, case formulation, therapeutic relationship, and intervention.” (p. 273)

To continue these efforts, the APA later established a task force specifically related to EBP within the child and adolescent population (APA Task Force on EBP for Children and Adolescents, 2008). Even prior to the formation of this task force, psychologists had been examining EBP within children and adolescents to illustrate the challenges of implementation within this population (Kazdin, 2004; Kratochwill & Hoagwood, 2006).

Spring (2007) proposed a three-legged stool model for EBPs within the practice of psychology. This article is one of many cited within the present chapter that was a part of a special issue on Evidence-Based Practice in Clinical Psychology: Education and Training Issues within the *Journal of Clinical Psychology* in 2007. Spring’s model of EBP emphasizes:

- (a) the best available research evidence; (b) clinical expertise; and (c) patient values, preferences, characteristics, and circumstances. Evidence-based practice is the process of integrating the circles or tying together the three legs via a process of clinical decision-making.

(Spring, 2007, p. 613)

Rapp and Goscha (2005) describe six basic features that are common to EBP within psychology regardless of diagnosis, setting, or other factors. These six features include: (a) primary focus on recovery, (b) facilitating empowerment and choice, (c) recognizing the role of relationship, (d) importance of in-vivo service delivery, (e) utilization of the environment as a resource, and (f) primary focus on teamwork and integration of helping.

In a 2005 textbook, Azrin and Goldman stated that “evidence-based practice has emerged as the dominant

practice model for mental health care” (p. 67). The 21st century has seen a clear shift from systems and practices having been based on theory and clinical opinions to guidance from research on EBPs.

### *Challenges to Implementing Evidence-Based Practices in Psychology*

Many challenges currently exist when attempting to implement EBPs within the practice of psychology. There are too many challenges to list all of them in this chapter, but a few include resistance at the level of the psychologist or client; inconsistent construct definitions within the research; insufficient training; lack of infrastructure to support EBPs; complex presentations with comorbidities and social or family confounds; and even the complexities of designing, implementing, and testing EBPs. The majority of the evidence-based treatment models have been designed and researched for only a single diagnosis or similar symptom manifestations. As EBPs continue to be studied and implemented these challenges should continue to dissipate. Additionally, within a busy clinical practice it is difficult to find the time to keep up with the most recent EBPs, which is one of the reasons why continuing education for psychologists is required, and lifelong learning is so important.

Lilienfeld, Ritschel, Lynn, Cautin, and Lutzman (2013) discussed survey data on psychologists’ attitudes toward EBP, finding six sources underpinning the misunderstandings of those psychologists who are resistant:

- (a) naïve realism, which can lead clinicians to conclude erroneously that client change is due to an intervention itself rather than to a host of competing explanations;
- (b) deep-seated misconceptions regarding human nature (e.g., mistaken beliefs regarding the causal primacy of early experiences) that can hinder the adoption of evidence-based treatments;
- (c) statistical misunderstandings regarding the application of group probabilities to individuals;
- (d) erroneous apportioning of the burden of proof on skeptics rather than proponents of untested therapies;
- (e) widespread mischaracterizations of what EBP entails; and
- (f) pragmatic, educational, and attitudinal obstacles, such as the discomfort of many practitioners with evaluating the increasingly technical psychotherapy outcome literature.

(p. 883)

As mentioned earlier, some psychologists continue to be resistant to the idea of EBP. However, many studies have demonstrated that most mental health professionals hold reasonably positive views of EBP (Borntrager, Chorpita, Higa-McMillan, & Weisz, 2009; Sheldon & Chilvers, 2002). The varying levels of support and implementation of EBP in clinical practice have been discussed (Pagoto et al., 2007) and even those who support EBP may have hesitations or negative attitudes toward fully utilizing EBP. Lilienfeld and colleagues (2013) conclude that it is important for the field to advance educational proposals for articulating the importance of EBP to future clinical practitioners and researchers to assist with changing the current psychologists’ objections to EBP. The importance of

utilizing education to advance EBP within psychology has been described and this education should specifically recommend that educators “inject significant new content into research, design, and methodology courses and to further integrate research and practicum training” (Bauer, 2007: 685). Toward this effort by psychologists to better educate about EBP at the graduate level, several EBP textbooks were published between 2005 and 2008 (Drake, Lynde, & Merrens, 2005; Norcross, Hogan, & Koocher, 2008; Sturmey & Hersen, 2012).

Kazdin (2008) discussed some of the issues related to the gap between science and clinical practice within the field of mental health related to EBPs and made specific recommendations related to research and practice. Related to research, Kazdin proposed that

more work is needed on the mechanisms of change—not correlates of change alone but explanations of precisely how therapy works. . . . This is different from disseminating treatment manuals and prescribing specific interventions as our primary focus.

(p. 157)

Kazdin also recommended refocusing the emphases in clinical practice, which included monitoring treatment with systematic assessment and the important of integrating research and practice for clinical care, which would include assessment in the context of clinical care.

Despite the work toward using EBPs within the mental health field, research continues to demonstrate low rates of dissemination of these interventions within clinical practice (Stewart & Chambless, 2007) and at the training level within graduate and internship programs (Weissman et al., 2006). Responding to the similar status of a number of disciplines, the government has continued to allot funds toward better dissemination of EBPs within the mental health field. McHugh and Barlow (2010) have discussed the leading efforts at the national, state, and individual treatment developer levels to integrate psychology’s EBP into service delivery settings, as well as offer recommendations for future implementation strategies.

### *Evidence-Based Practice in Clinical Neuropsychology*

As described earlier, the field of clinical neuropsychology has been a relative latecomer to EBPs in the formal sense described previously in this chapter (i.e., Sackett et al., 1996). However, clinical neuropsychologists have always emphasized evidence-based approaches to clinical practice and research in less explicit ways, including through the use of empirically validated and standardized testing procedures, knowledge and application of psychometrics to test selection and interpretation, utilization of the best available normative data for each patient, and reporting of statistics such as sensitivity, specificity, positive predictive power, and negative predictive power in research findings. In an effort to guide the continuation of such EBPs, the American Academy of Clinical Neuropsychology (AACN) has published a number of relevant position papers

that are based on the most rigorous available research data, including on topics such as serial neuropsychological assessment (Heilbronner et al., 2010) and the assessment of effort, response bias, and malingering (Heilbronner et al., 2009). Related, clinical neuropsychology's evidence-based roots and high-quality research data clearly played crucial roles in the American Academy of Neurology's (AAN) practice guideline recommending the utilization of neuropsychological assessment for identifying patients with dementia (Peterson et al., 2001). This history, combined with training in the scientist-practitioner model, has positioned the specialty of clinical neuropsychology to effectively adopt the principles of EBP more formally in training, research, and clinical practice.

In keeping with the movement toward EBP in other health-related fields, there has been a recent push within clinical neuropsychology to adopt the principles of EBP (e.g., Bilder, 2011; Bowden, Harrison, & Loring, 2013; Chelune, 2010; Loring & Bowden, 2013). In fact, in 2014, a special issue entitled "Improving Neuropsychological Research Through Use of Reporting Guidelines" was published in *The Clinical Neuropsychologist*, the official journal of the American Academy of Clinical Neuropsychology (Schoenberg, 2014). Although there is no consensus definition for EBP of clinical neuropsychology (EBP-CN), Chelune (2010) proposed that the definition should include the integration of clinical expertise, best outcomes research, and the unique characteristics of the patient. Inclusion of these principles would keep the definition of EBP-CN consistent with the definition of EBM put forth by Sackett et al. (1996) and with the definition of EBP in psychology (EBPP) put forth by APA Presidential Task Force on EBP (2006). Additionally, given the consultative nature of clinical neuropsychology practice, the definition of EBP-CN must include consideration of the concerns and needs of the referral source. That is, determining the meaning of best practices with regard to each patient must involve being responsive to the specific referral question. In doing so, as Chelune (2010) has noted, the clinical neuropsychologist is required

to do only what is necessary to answer the specific questions asked while continuing to use their clinical judgment and expertise to know when to clarify or expand the referral question to explore alternative hypotheses and to meet the needs of the patient.

(p. 455)

Adopting a definition of EBP-CN that incorporates the principles addressed earlier will lead clinical neuropsychologists through essentially the same steps as those involved in evidence practice in other areas of health care. Adapting from Chelune (2010), the steps are as follows:

- 1 Generate answerable questions based on a careful evaluation of the presenting problems and complaints.
- 2 Gather relevant psychosocial and medical background information in order to integrate it with the best available outcomes research specific to the questions just formulated.

- 3 Obtain relevant data for the patient and specific questions by selecting germane test protocols.
- 4 Analyze the data with respect to the unique characteristics of the given patient.
- 5 Apply the results of this analysis to the patient in question, for example in making a diagnostic decision and formulating specific recommendations.
- 6 Objectively monitor the outcomes of the evaluation. It is important to note that in this context, outcomes refer to discrete, measurable events that impact a patient's condition, can be tracked at the individual and aggregate level, and are publicly verifiable (i.e., they are explicit in our reports).

Chelune (2010) further argues that the advancement of EBP-CN in both the clinical and research domains requires neuropsychologists to adopt two broad tenets. The first tenet is that "clinical outcomes are individual events characterized by a change in status, performance, or other objectively defined endpoint" (p. 456). The second tenet is that "to be useful in the care of patients, data from outcomes research must be analyzed and packaged in such a way that they can be directly evaluated and 'used' by the end-user, namely the clinician" (p. 456). Although the remainder of this chapter separates how EBP-CN can be achieved in the clinical and research domains, it is clear that the two are inseparably intertwined. In the tradition of the scientist-practitioner, clinical questions should inform outcomes research and outcomes research should guide best clinical practices.

### ***Research Applications of Evidence-Based Practice of Clinical Neuropsychology***

A key component of advancing outcomes research for EBP-CN is moving away from simple null-hypothesis significance testing of mean differences (e.g., Chelune, 2010; Bowden et al., 2013). These authors and many others have made the compelling case (which will not be detailed here) for adoption of more clinically applicable statistics, including effect sizes, positive/negative predictive power, base rates, and odds ratios. Briefly, such statistics allow for clinicians and other researchers to critically evaluate the *clinical* significance of findings beyond the fact that statistical significance has been observed with respect to the null hypothesis (for more regarding the difference between statistical and clinical significance, see Meehl, 1973).

Chelune (2010) outlines three specific steps for researchers that may increase the potential that their outcomes data will be more useful to clinical practice. First, neuropsychological outcomes should be defined in a manner that can be applied clinically. For example, by determining and reporting the magnitude of a difference on some measure(s) between individuals with and without a condition of interest. Reporting data in this way can also facilitate reporting of base rate information with regard to such outcomes. Second, researchers should report base rate information whenever possible

in order to calculate relevant statistics that will increase the accuracy of clinicians' inferences in a given case. Third, researchers should provide contingency table analyses that are supplemented with base rates. This will allow end-users (i.e., clinicians) to calculate and/or assess sensitivity, specificity, positive and negative predictive power, optimal cutoff scores, odds ratios, likelihood ratios, and pre- and posttest odds, all of which are critical to making optimal inferences regarding test results and are consistent with the superior methods of reporting results described above.

These goals can be more broadly achieved by adopting the appropriate research reporting guidelines (e.g., STROBE, CONSORT, and STARD) that have been established for EBP in neuropsychology's peer-reviewed literature. STROBE, for example, is particularly relevant for neuropsychology. Much of our literature is inherently biased because it consists of unfunded studies that rely on convenient patient populations and use quasi-experimental or observational study designs, and the STROBE reporting criteria explicitly improve transparency, which reduces the impact of such bias (Loring & Bowden, 2013). In addition, STROBE emphasizes reporting of effect sizes and practical implications (such as diagnostic accuracy classification statistics), rather than just statistical significance. For a detailed explanation of how each of the STROBE criteria apply to research in neuropsychology, which is beyond the scope of this chapter, see Loring and Bowden (2013).

In a related, but separate, endeavor, it has been proposed that researchers and/or clinicians create collaborative neuropsychological databases (e.g., Bilder, 2011). Given the relatively standardized data types and homogeneity of collected variables, neuropsychologists should be able to efficiently create such centralized resources using both individual case data and published group-level data. With shared access to data from a multitude of populations located across the country (or even the world), neuropsychologist researchers could generate substantially larger groups of participants in order to generate high-quality research related to a wider range of disorders, tests, and patient populations than is currently feasible. Additionally, normative data for commonly used tests could be dynamically updated for specific populations beyond the time-tables of test updates provided by publishers, possibly even in real time. In turn, such collaborative databases could facilitate the formulation of new research questions, data analyses, and, ultimately, clinical decision making to advance EBP-CN.

Consistent with such ideas, the National Academy of Neuropsychology (NAN) is developing the HONE-In (Health Outcomes and Neuropsychology Efficacy Initiative) project, with the goal of creating a centralized source of information regarding the utility and cost effectiveness of clinical neuropsychological services. The project was started in response to the ongoing need of clinical neuropsychologists to justify the effectiveness of neuropsychological services, often related to reimbursement challenges. The HONE-In team is compiling a listing of citations, including summaries of the articles and comments regarding outcome utilities of neuropsychological

services. These will address general utility, as well as specific patient populations, including brain injury, concussion, and rehabilitation; employment; multiple sclerosis; Parkinson's disease; pediatrics; primary care; and seizure disorders.

### ***Clinical Applications of Evidence-Based Practice in Clinical Neuropsychology***

Chelune (2010) offers three broad clinical practice guidelines that are incorporated into all EBP. First, referral questions must be converted into answerable questions, such as, Does this patient have attention and memory deficits after sustaining a moderate traumatic brain injury three months ago? To answer such a question, the neuropsychologist must know the specific characteristics of the patient as well as the relevant outcomes literature, including the best assessment tools for answering the question, and the test findings needed to make a positive versus negative determination. Second, clinicians should use base-rate information when describing test results in their reports. This includes describing base rates appropriately depending on whether the data from which they are derived are normally distributed and may include describing a patient's performances in terms of how far they deviate from expectations. And third, clinicians should incorporate and use the best available information, in the form of outcomes research, to guide assessments. This may be difficult, at times, given that there is no single repository for neuropsychological outcomes data and that it is rare to find relevant studies that sufficiently meet criteria of good quality research for EBP purposes (such as those defined by STROBE, CONSORT, or STARD). At present, the most useful data often comes from meta-analyses and review articles. In addition, clinicians can become outcomes researchers by monitoring and tracking outcomes within their own practices in order to improve the accuracy of test interpretation and diagnostic decision making.

To aid in the implementation of EBP, clinical neuropsychologists reading research articles and evaluating outcomes data can utilize Critically Appraised Topics (CAT) toolkits, which are available online through the Centre for Evidence Based Medicine ([www.cebm.net/critical-appraisal/](http://www.cebm.net/critical-appraisal/)). CATs have been developed as compliments to the major research reporting guidelines to assist in evaluating the quality of systematic review/meta-analytic, treatment, diagnostic, and prognostic studies. Bowden et al. (2013) argue that routine practice of critical appraisal gives clinicians the skills needed to "(1) evaluate the clinical relevance of new or unfamiliar research findings with a focus on patient benefit, (2) help focus on research quality, and (3) incorporate evaluation of clinical impact into educational and professional development activities" (p. 1). That is, employing the CAT method helps clinicians learn to routinely apply criteria for evaluating research evidence and to utilize such evidence in answering patient-specific questions, the latter of which is absent from the research guidelines. The techniques contained in the CAT process capitalize on the clinician's knowledge and expertise by guiding him or her to

a focused answer to a particular clinical question. While not necessarily needed for all cases, the approach can be particularly useful for unfamiliar areas and topics.

Given the nature of clinical neuropsychology practice, clinicians are likely to find the diagnostic CAT worksheet to be the most useful. Bowden et al. (2013) provide a detailed walkthrough of the use of the diagnostic CAT within clinical neuropsychology through a hypothetical example involving the use of a dementia-screening tool in making a diagnostic decision. With its emphasis on study design and accounting for base rates, the diagnostic CAT worksheet can be used as a framework for evaluating test utility and criterion-related validity, thereby making diagnostic decision processes more explicit. The worksheet is broken down into three parts, two of which contain subquestions to help focus critical appraisal of the research in question. Part 1 guides the clinician in determining whether the results of a diagnostic study are valid. Part 2 asks the clinician to then evaluate whether the results of the study are important (i.e., not just statistically significant). If the overall answers to Parts 1 and 2 are yes, Part 3 consists of a series of questions to help the clinician assess whether the evidence about the test in question can be directly applied to the patient the clinician is evaluating.

Of course, many specific clinical questions remain that cannot be clearly answered by applying EBP-CN principles, due to limited evidence or, at times, a lack of directly applicable evidence of sufficient quality. Such situations may be related to given neuropsychiatric conditions, patient characteristics, evaluation contexts, or other factors specific to individual patients. In such situations, APA Presidential Task Force on EBP (2006) broadly suggests that clinicians rely on clinical expertise in interpreting and applying the best available evidence, continually monitor patient progress, and adapt the assessment or intervention as appropriate. For EBP-CN, this requires (at a minimum) including appropriate caveats in the report about difficulties with test interpretation and, perhaps, uncertainty regarding diagnostic conclusions in certain cases in which the empirical support is sparse for the use and interpretation of our tests or normative data.

### ***Select Examples of Neuropsychology Research That Can Directly Influence EBP-CN***

The ability to engage in the EBP-CN continues to grow rapidly, as high-quality data that are readily applicable to specific clinical questions are more available than ever before. For example, evidence regarding the value of clinical neuropsychological test data as they relate to the diagnosis and treatment of mild cognitive impairment (MCI) and Alzheimer's dementia (AD) is increasingly strong. Bondi and Smith (2014) review the neuropsychological literature as it relates to the diagnosis of MCI and conclude that careful neuropsychological assessment improves the reliability of MCI diagnoses over and above commonly used screening measures, rating scales, and limited test batteries. When comprehensive

neuropsychological assessments are utilized, test results turn out to be strongly related to relevant biomarkers and can at times be shown to represent pathologies other than, or in addition to, AD. Additionally, neuropsychological research data demonstrate that mild, but identifiable, functional difficulties are present in individuals with MCI. Bondi and Smith (2014) conclude that neuropsychological tests should play a key diagnostic role in studies of MCI and clinical practice.

Related, Schmand et al. (2014) compared the effectiveness of various MRI measures and neuropsychological tests as outcome measures for intervention studies of AD and MCI at baseline and after two years. Results demonstrated that the sample sizes needed to detect a 50% reduction in the rate of change in the respective outcome measures were substantially larger using hippocampal atrophy ( $n = 131$ ) or cortical thickness ( $n = 488$ ) versus change scores on neuropsychological tests ( $n = 62$ ). The authors concluded that in memory clinic patients, neuropsychological assessment is more sensitive than MRI measures of brain atrophy for measuring disease progression. In a similar vein, Gomar, Bobes-Bascaran, Conejero-Goldberg, Davies, and Goldberg (2011) examined the effectiveness of various biomarkers and neuropsychological tests as predictors of conversion from MCI to AD over a two-year period. Effect size analyses demonstrated that neuropsychological tests and a rating scale assessing daily functioning were more robust predictors of conversion from MCI to AD than most biomarkers. In addition, declines in executive functioning and daily functioning appeared to drive conversion more than neurobiological changes, indicating that neuropsychological testing is best positioned to provide data that can predict conversion of MCI to AD. Studies such as these continue to support clinical neuropsychology's key role in the assessment and management of dementing conditions.

Similar evidence regarding the utility of neuropsychological assessment for other conditions is also increasingly available. For example, Williams, Rapport, Hanks, Millis, and Greene (2013) demonstrated that clinical neuropsychological assessment following mild complicated, moderate, and severe traumatic brain injury was uniquely predictive of functional disability two years postinjury, even after accounting for injury severity and demographic characteristics, including computed tomography (CT) scan data. As another example, neuropsychological assessment has also been shown to add uniquely to the treatment and behavioral management of attention deficit/hyperactivity disorder following diagnosis. Specifically, Pritchard, Koriakin, Jacobson, and Mahone (2014) found that in families whose children received neuropsychological assessment services, there was more behavior management training, special education services, and medication management of symptoms over the follow-up period. While unrelated, studies of these types continue to demonstrate the evidence-based added value of neuropsychological assessment for a variety of relevant conditions.

Beyond clinical practice, it is important to also acknowledge the rapidly growing, robust, high-quality evidence

regarding the practice of clinical neuropsychology in forensic, or medical-legal, settings. This is an area of research and practice that continues to grow rapidly, with neuropsychological evidence and neuropsychologist experts being widely accepted in legal proceedings (e.g., Sweet & Goldman, 2015). The concrete data neuropsychologists can provide regarding cognitive functioning has repeatedly proven to be valuable to the courts. For more information, also see Sweet, Kaufman, Ecklund-Johnson, and Malina (Chapter 36 in this volume).

### Future Directions

Kaufman, Boxer, and Bilder (2013) persuasively argued that clinical neuropsychology needs to continue to produce quality evidence to demonstrate the field's value in making differential diagnoses, predicting functional treatment outcomes, and measuring the effectiveness of various treatments. In order to do so, clinical neuropsychology must adopt higher standards for reporting research results in our journals, consistent with the various resources described earlier in this book, including STROBE, EQUATOR, and STARD.

Bilder (2011) and Kaufman, Boxer, & Bilder (2013) further argue that EBP-CN would be well served if researchers and clinicians shared group level and individual case data, respectively, in central databases, such as the one described above that is being considered by NAN or the one being proposed to Division 40 of the APA (Pliskin, personal communication). EBP is the other primary area for future growth within clinical neuropsychology. As the field pushes forward in adopting the principles of EBP, the teaching of EBP-CN must be incorporated into doctoral programs, internships, and postdoctoral training programs. Such training should encompass how to report research results consistent with the relevant guidelines, how to search out and critically appraise published evidence, and how to apply the principles of EBP as a graduate-level practicum student, intern, and postdoctoral resident. Of course, education in EBP should not end during formal training. Continuing education for licensed neuropsychologists should include refreshers in the basics and updates in EBP advances.

## 44 Medical and Psychological Iatrogenesis in Neuropsychological Assessment

*Dominic A. Carone*

*Today, we are frequently required to relieve our patients of their diagnoses so that the path is clear for them to understand and address their problems.*

—Martyn Patfield (2011)

Health care providers have long been familiar with the basic tenet of the Hippocratic Oath, which is to do no harm to patients. This tenet is expressed in the original language of the oath, which states: “And I will use regimens for the benefit of the ill in accordance with my ability and judgment, but from [what is] to their harm or injustice I will keep [them]” (Miles, 2005, p. xiii). A later section of the oath makes mention of not causing *intentional* harm and that is generally how the oath is conceptualized. However, despite the best of intentions, treatment and information provided to patients by their health care providers can sometimes prolong or worsen existing physical and/or mental health problems or cause new ones. When this happens it is known as *iatrogenesis*. The term has its roots in the Greek word *iatros* meaning “physician/healer” and the Greek word *genesis* meaning “origin,” meaning that the health care provider is the source of the creation of additional problems. The problem is so rampant in some medical settings (e.g., intensive care units, nursing homes) that it is referred to as “The I word” (Dunn & Murphy, 2010; Mitty, 2010).

In the most literal sense, *iatrogenesis* can be used to refer to any outcome (positive or negative) brought on by the health care provider although the term is mostly used to refer to negative outcomes, which has been criticized by some (Jacobs, Benavidez, Bacha, Walters, & Jacobs, 2008). For the purposes of this chapter, the term *iatrogenesis* is used to describe negative health outcomes caused by the health care provider.

There are two broad categories of iatrogenesis based on the underlying mechanism: medical and psychological. In psychological iatrogenesis, the patient develops new and/or worsening health problems due to negative expectations and beliefs that are either introduced or reinforced by the health care provider during the diagnostic and/or treatment process. In some cases, the information provided (e.g., prognosis, treatment needs) about the diagnosis may be incorrect and/or the actual diagnosis (or lack thereof) may be wrong.

There are three main types of iatrogenic diagnostic errors: (a) diagnosing the wrong condition when an actual condition exists, (b) diagnosing a condition when none actually exists, and (c) not providing a diagnosis when an actual condition exists. Each diagnostic error introduces the risk of adverse psychological and medical outcomes.

With the increasing availability of medical information to the layperson (e.g., Internet searches, TV shows, radio, print media), patients are increasingly comfortable with applying definitive diagnoses to themselves or family members that may or may not be accurate (Patfield, 2011), and pressuring their health care provider to agree. There can be various reasons such pressure is exerted, including the following: the patient or family is a known advocate for people with the condition; the diagnostic term is comforting for the patient in some way (e.g., providing an external locus of control and a feeling of validation); or the person needs the diagnosis for secondary gain purposes (e.g., disability application, litigation, obtaining prescription drugs for abusive purposes). In some cases, a provider may feel pressured *not* to provide the actual diagnosis because the patient or family member voices opposition to it—e.g., a parent stating that he or she does not believe attention deficit/hyperactivity disorder exists (ADHD). Sometimes, the pressure is self-exerted due to the provider’s belief systems (e.g., not wanting to provide a mental health diagnosis due to fearing that the patient may feel he or she is being blamed for his or her problems) as opposed to being based on anything the patient explicitly stated. These types of false positive and false negative diagnostic errors are likely to occur in situations in which diagnoses are based solely on subjective symptom reporting rather than objective data (e.g., biomarkers, test scores). This is particularly the case when the patient is evaluated by health care providers who see their role as a patient advocate first and as an objective scientist/practitioner second.

In medical iatrogenesis, the patient develops new and/or worsening health problems due to the physical effects of treatment. Examples include medication side effects, medication overdose, prescription errors, and adverse outcomes from surgical procedures. In many conditions, psychological and medical iatrogenesis co-occur. This chapter will focus on psychological and medical aspects of iatrogenesis, particularly as they relate to conditions that neuropsychologists

frequently encounter or need to rule out (although covering all such conditions is beyond the scope of this chapter). This is followed by a discussion on how to reduce iatrogenesis and address it once it is suspected or identified.

### Mild Traumatic Brain Injury and “Post Concussion Syndrome”

There is perhaps no condition where the risks of iatrogenesis are greater than during the assessment and management of patients with known or suspected mild traumatic brain injury (mTBI; also known as concussion). In a now-classic study, Mittenberg, DiGiulio, Perrin, and Bass (1992) showed how expectations about the effects of brain injury led a healthy control group to endorse virtually identical symptom rates compared to an mTBI group reporting persisting symptoms after being provided an imaginary vignette about suffering an mTBI. This led to the “expectations as etiology” hypothesis for chronic symptom reporting (e.g., three months or longer) after mTBI. Another interesting finding from the aforementioned study was that the mTBI group significantly underestimated the base rate of premorbid symptoms when compared to the control group. This is partly because people begin to focus more on symptoms once a salient negative event has occurred.

In mTBI and other medical conditions, psychological iatrogenesis can begin before the patient is evaluated by a health care provider, based on beliefs the patient has developed through sociocultural influences (e.g., movies, television shows, the media). A common example derived from the movies is the unrealistic portrayal of profound retrograde amnesia after head injury (Baxendale, 2004). Another example is the patient who suffered one concussion who then misapplies information (e.g., risk of prolonged symptoms) to him or herself from popular news stories about professional athletes suffering a career worth of multiple concussions. For a detailed review of the media’s influence on the course and prognosis of recovery after sports concussion, see Carone (2014).

With these beliefs established, mTBI patients experiencing either (a) normal symptoms during the acute phase of recovery and/or (b) normal everyday cognitive lapses and physical symptoms can begin to misinterpret normal everyday symptoms (e.g., forgetting keys in the car) as reflective of concussion or misinterpret genuine concussion symptoms as reflective of a more severe neurological condition. It is at this point where it is most helpful for health care providers to intervene by normalizing symptoms and providing patients with *proper* (e.g., nonalarmist) education about treatment, expected prognosis, and instructions on resuming premorbid activities. For example, Mittenberg et al. (1996) found that by doing the latter in an emergency room setting with mTBI patients as opposed to providing routine hospital discharge and treatment instructions (mTBI control group) that the experimental group experienced significantly shorter

symptom duration, fewer symptoms, and fewer symptomatic days. The results indicated that a brief, psychoeducational intervention could reduce the incidence of those reporting persisting symptoms after mTBI. These general findings have been extended and replicated by others (Miller & Mittenberg, 1998; Mittenberg, Canyock, Condit, & Patton, 2001; Ponsford et al., 2001; Ponsford et al., 2002).

Providing an early positive and normalizing message after mTBI helps to counter incorrect beliefs that a patient may have developed before interacting with a health care provider. However, logic dictates that a well-meaning but incorrect opposite message could increase the incidence of symptom persistence or worsen the presentations of those who are already reporting symptom persistence. A common example would be telling a patient with a single mTBI on the initial visit that he or she is expected to have a long and unpredictable recovery, that some symptoms may never improve, and/or that extensive rehabilitative efforts and medication treatment is needed. There are no evidence-based data to support such statements. In this sort of scenario, a patient’s incorrect beliefs may be unintentionally reinforced or created by the health care provider, sometimes causing significant distress in the process. While the health care provider may be attempting to be helpful by “validating” the patient’s subjective experiences, this validation can ultimately be counterproductive if not accompanied by accurate information.

Another commonly encountered iatrogenic cause of persisting problems in mTBI is the advice for excessive bed rest and withdrawal from all stimulating activities including school and work. While rest may be indicated for a very brief period (e.g., a few days) there is no evidence to support that chronic bed rest and excessive withdrawal from school and work is a helpful intervention. In fact, it is much more likely to be harmful due to facilitating the disability role, increasing feelings of depression, anxiety, frustration, and isolation (Allen, Glasziou, & Del Mar, 1999; Asher, 1947; de Kruijk, Leffers, Meerhoff, Rutten, & Twijnstra, 2002; Kouyanou, Pither, & Wessely, 1997a). Newer research has shown that making patients more physically active with controlled aerobic exercise soon after mTBI can be helpful in the recovery process (Leddy et al., 2012; Schneider et al., 2013), although the evidence base is sparse at this point. A similar iatrogenic problem emerges for mTBI patients advised to wear sunglasses chronically and most of the day due to reported photophobia. Wearing such glasses excessively has two main iatrogenic effects: it serves as a visual prop to reinforce disability beliefs, and it causes the eyes to be more sensitive to any incoming light (falsely reinforcing the concept that the glasses are still needed due to brain injury).

Neuropsychologists particularly need to be mindful of the effects that communications from themselves or others about a neuropsychological assessment can have on the evaluation results. For example, Suhr and Gunstad (Suhr & Gunstad, 2002, 2005) have documented the effects of “diagnosis threat” when neuropsychologically evaluating patients with mTBI.

Specifically, when mTBI patients were randomly assigned to the diagnosis threat group, attention was called to their head injury and they were informed that many patients with mTBI show evidence of cognitive deficits on neuropsychological testing. Those assigned to the neutral group did not have any attention brought to their head injury and no mention was made of cognitive deficits. They were essentially told that they would take cognitive tests of varying difficulty and to do their best. Both studies showed that the diagnosis threat group performed worse than the neutral group in various cognitive domains, and the 2005 study showed that these effects were not caused by differing levels of depression, anxiety, or effort between the two groups. The results served as an important reminder of the powerful effects that communications by health care providers have on the behaviors of their patients.

### Whiplash Injuries

Whiplash injuries are injuries to the neck caused by sudden acceleration of the trunk with abnormal extension and/or flexion of the neck, and are most often caused by motor vehicle accidents (Storaci et al., 2006). Because whiplash injuries often occur after such accidents and involve acceleration/deceleration forces, they often co-occur with mTBI. Much like research has shown with patients complaining of chronic postconcussive symptoms, subjective complaints in whiplash patients are associated with somatization and poor coping, especially in chronic cases (Guez, Brannstrom, Nyberg, Toolanen, & Hildingsson, 2005). Whiplash and mTBI also share many symptoms, making it possible that symptoms related to neck injury may be falsely attributed to brain injury by patients and their providers. No patho-anatomical foundation has been found for whiplash injury (Cote & Soklaridis, 2011) similar to many known or suspected mTBI patients who present with negative objective biomarkers.

Cote and Soklaridis (2011) found that overtreating patients during the early stages of recovery after whiplash can lead to iatrogenesis by promoting the development of chronic illness behaviors through emphasizing the use of passive coping behaviors. These authors also criticized whiplash becoming a medicalized concept, in which nonmedical problems or ordinary ailments are defined and treated as medical problems (e.g., diseases, disorders, illness), often resulting in mild symptoms being viewed as serious. Identical problems are known to occur in mTBI management.

### Multiple Chemical Sensitivities

Multiple chemical sensitivities (MCS), which is also known as *idiopathic environmental intolerance* is a set of nonspecific symptoms affecting many possible organ systems after low-level exposures to chemicals commonly found in the environment. The similarities between MCS and “postconcussion syndrome” are striking. First, both involve claims

of persisting nonspecific symptoms after exposure to a mild event that does not cause chronic problems in the vast majority of people. Second, many people claiming to be affected by these conditions report being chronically disabled. Third, many are pursuing some type of compensation such as medical disability and/or personal injury litigation (Binder, Storzbach, & Salinsky, 2006; Mittenberg, Patton, Canyock, & Condit, 2002; Staudenmayer & Phillips, 2007). Fourth, there are no proven reliable and valid objective biomarkers to confirm that the etiology of persisting symptoms is due to a prior concussion or mild chemical exposure (Baines, McKeown-Eyssen, Riley, Marshall, & Jazmaji, 2007). Fifth, both conditions are associated with a high degree of psychiatric comorbidity, neuroticism, and premorbid psychiatric problems (Black et al., 2000; Carone, 2008; Osterberg, Persson, Karlson, Carlsson Eek, & Orbaek, 2007; Reid et al., 2001) although patients may be more defensive about acknowledging this (Staudenmayer & Phillips, 2007). Sixth, both are typically reported in high levels in Western countries but are virtually unknown or rarely reported in other countries (e.g., Lithuania, Eastern Europe) (Bornschein, Forstl, & Zilker, 2001; Bornschein, Hausteiner, Zilker, & Forstl, 2002; Mickeviciene et al., 2002; Mickeviciene et al., 2004; Stovner, Schrader, Mickeviciene, Surkiene, & Sand, 2009), particularly if there are minimal opportunities for monetary compensation in the country. Seventh, both involve patients who are typically convinced that there is no other possible explanation for their symptoms besides the alleged triggering event (Staudenmayer, 2000). Eighth, both are associated with high levels of exaggerated responsiveness that can sometimes be caused by psychiatric factors (Leznoff, 1997) but sometimes can be caused by malingering (Mittenberg et al., 2002). Ninth, both conditions typically involve the use of lengthy and/or expensive treatments with a limited-to-nonexistent evidence base that rarely demonstrate effectiveness (Das-Munshi, Rubin, & Wessely, 2007), particularly in terms of meaningful outcome data (e.g., return to work, symptom reduction). Tenth, a cottage industry of self-proclaimed specialists have emerged to treat these conditions, claiming unique expertise outside of the scientific mainstream, which many patients tend to gravitate towards as they feel misunderstood by the mainstream medical community (Dumit, 2006; Lipson & Doiron, 2006). Eleventh, symptoms can be reduced in both conditions with psychoeducational approaches designed to minimize attributions to organic causes and by providing simple psychoeducational approaches designed to reassure patients (Herr et al., 2004; Miller & Mittenberg, 1998; Mittenberg et al., 2001; Mittenberg et al., 1996; Ponsford et al., 2001; Ponsford et al., 2002).

Given these common features, the risk of iatrogenesis in patients reporting MCS is particularly high, and health care providers need to be mindful of how the type of information they provide to their patients can affect them in undesirable ways. For example, Dalton (1999) found that telling patients that an odor to be presented is going to be harmful resulted

in them reporting significantly more symptoms and more intense irritation upon odor exposure compared to when patients were told that the identical odor will be neutral or healthful. The authors concluded that the actual odor exposure was not responsible for the reported health-related effects but was rather caused by the person's beliefs about the relationship between the environment and their health. Similarly, Leznoff (1997) showed dramatic and severe responses to nonchemicals when patients were led to believe they were real chemicals (cf., "expectations as etiology" in concussion described earlier). Another study found that painters reporting MCS actually reported more sensitivity to nonchemicals (i.e., coffee fumes) than chemicals (i.e., acetone), which the authors stated may be due to less familiarity with the former than the latter (Georgellis, Lindelof, Lundin, Arnetz, & Hillert, 2003). In these studies, patient beliefs—sometimes influenced by the examiner—caused more symptom reporting. However, negative belief systems can also be created and fostered by the media and lead to higher symptom reporting compared to patients who are not exposed to negative media reports (Winters et al., 2003). Thus, health care providers must be careful when discussing media stories (particularly those designed to raise awareness or to grab sensationalistic headlines) with patients because the message they send has the potential to contribute to iatrogenesis, negatively affecting patient outcomes (Carone, 2014).

Health care providers must also be aware that using unproven explanations for symptoms can sometimes lead to treatments with iatrogenic effects, some of which can be severe and can affect neuropsychological functioning. A good example is the case of a 39-year-old woman with multiple environmental sensitivities reported by Brusko and Marten (1991) who developed hepatic encephalopathy after being prescribed ketoconazole (an antifungal medication) by a "clinical ecologist" for systemic candidiasis (a type of fungal infection) despite no actual documentation of a fungal infection. Rather, it appears that the diagnosis (and subsequent treatment suggestions) was based purely on subjective reporting of symptom persistence for ten years. Liver function test results progressively worsened after treatment was initiated. She became extremely jaundiced, lethargic, slow to answer questions, developed worsening asterixis (hand tremor), and was transferred to a hospital for possible liver transplant. Although her reaction to the medication was rare and idiosyncratic, the case presentation suggests that it could have been avoided because she may not have had the treated condition to begin with. Making this case directly relevant to neuropsychology is the fact that hepatic encephalopathy is a well-known cause of cognitive impairment (Munoz, 2008).

As some have noted, patients with environmental sensitivities who feel abandoned and isolated by conventional medicine will likely turn to alternative/nonconventional treatments in a search for answers (Taylor, Krondl, Spidel, & Csima, 2002). However, it is important to note that many of these patients have not truly been abandoned by conventional

scientific approaches. Rather, some may be resisting what are indeed accurate findings and explanations (e.g., negative test findings, psychological etiology, medical comorbidities other than the one the patient is focused on). Anger and resistance towards conventional medicine can lead to further psychological distress and symptom exacerbation that perpetuates itself in a reciprocal feedback cycle along with exaggeration, assumption of a chronic disability role, and adherence to scientifically unproven nonconventional treatments. As Das-Munshi et al. (2007) noted, "Eventually, a protracted course of avoidance may lead to chronic disability, in part perpetuated by the iatrogenesis of unproven therapies which the sufferer may have sought from numerous 'experts'" (p. 277).

Although it is beyond the scope of this chapter to review all such conditions that can be caused by iatrogenesis, it should be noted that similar iatrogenic concerns are present for other conditions (e.g., fibromyalgia, chronic fatigue syndrome, sick building syndrome, Gulf war syndrome, electrical sensitivity) that are also poorly defined, controversial, and/or characterized by chronic nonspecific symptom reporting with few to no associated objective biomarkers. Other have found that patients with medically unexplained symptoms were more likely to experience higher frequencies of psychiatric morbidity and iatrogenesis than patients with medically explained symptoms (Kouyanou, Pither, Rabe-Hesketh, & Wessely, 1998).

### Dissociative Identity Disorder

Another area in neuropsychology where the role of iatrogenesis is highly debated is dissociative identity disorder (DID; formerly known as *multiple personality disorder*). This is of interest to neuropsychologists who often work in forensic settings but also due to the differential diagnosis in clinical settings that sometimes needs to be made between DID, schizophrenia, epilepsy, and psychogenic nonepileptic seizures (Bowman & Coons, 2000; Foote & Park, 2008). DID is a highly controversial diagnosis, which some conceptualize as a psychological defense mechanism to avoid conscious processing of significantly traumatic memories (e.g., severe childhood physical, sexual, and/or emotional abuse) while others conceptualize it as a culture-bound phenomenon caused by treatment providers eliciting the personalities through suggestion, leading questions, and techniques (e.g., hypnosis, memory retrieval) geared towards suggestible individuals (Boysen, 2011; Piper & Merskey, 2004). These two etiologies are known as the *posttraumatic model* (PTM) and *sociocognitive model* (SCM), respectively.

There is no greater example to highlight the contrast between these two explanations of DID than *Sybil*, which was published in 1973 (selling more than 6 million copies) and made into a television movie in 1976. The public was fascinated by what was presented as a true story (PTM model), but recent documents have shown that *Sybil's* case was worsened significantly through iatrogenesis (SCM model). Since

Sybil is now the most well-known case of doctor-induced iatrogenesis, and it is described in more detail here, based on a summary of events detailed in Nathan (2012).

Sybil (real name = Shirley Mason) began treatment with a psychiatrist (Cornelia Wilbur) in 1954 for a multitude of problems that included “blackouts,” anorexia, anxiety, and depression. The treatment initially consisted of psychotherapy, but over time, personal and professional boundaries were crossed, which increased the risk of iatrogenesis. Examples include: (a) Sybil falling in love with Wilbur due to feeling that she understood her like no one else; (b) Wilbur over-indulging details about her own personal life to Sybil; (c) Wilbur offering to get Sybil a job as an art therapist, get her into classes at a college she taught in, get her into medical school, and to sell her paintings for her, later paying for her apartment and giving her numerous gifts; and (d) telling her that further therapy was needed so she (Sybil) could become a psychoanalyst.

Despite this “treatment,” Sybil reported worsening symptoms. Wilbur responded by prescribing medications in higher doses than were necessary. Sybil began reporting fugue states and multiple personalities (four). Wilbur diagnosed her with multiple personality disorder, which was met with relief by Sybil. Further treatments continued, which included electrical shocks and injections with “truth serums” such as sodium pentothal, which she became addicted to. Attempts to wean her from the drug resulted in aggressive and regressive behaviors.

After four years of “treatment,” Sybil had become much worse, developing new problems, worsening problems, and (reportedly) ten personalities. In 1958, Sybil wrote a letter to Wilbur stating that she had problems but that she did not actually have multiple personalities or fugue states, and that she had been lying for attention and excitement (i.e., factitious disorder). Sybil admitted that Wilbur’s unwavering devotion and belief in her stories led her to continue them and exaggerate them via sodium pentothal. Wilbur, who believed she had an important patient who could advance her career, refused to accept the recantation, labeling it a defense mechanism to avoid therapy. This created a non-scientific scenario, as there was no evidence that Wilbur would accept that would scientifically falsify the original claims. Sybil then wrote a new letter claiming that Wilbur knew better and that the person who confessed to lying was actually a new personality. Five new therapy sessions a week followed with additional sodium pentothal, fostering apparently false memories of abuse. Despite the additional treatment, she added six more personalities. Wilbur eventually proclaimed her as cured in 1965 and the two eventually moved in with one another.

Since the popularization of the Sybil story in the late 1970s, there was a significant rise in the number of people claiming to have this condition, including criminal defendants claiming that the condition rendered them not criminally responsible for their actions. Specifically, by 1980, 200

cases of DID were reported worldwide (Bliss, 1980), whereas only 14 cases were reported worldwide between 1944 and 1969 (Greaves, 1980). The cultural popularization of DID thus makes it ripe for malingering attempts as a way to avoid criminal responsibility or as a form of factitious disorder to gain attention (Coons, 1991).

For the purposes of this chapter, the more salient issue is whether the Sybil case not only reflected the effects of iatrogenesis upon Shirley Mason, but also whether popularization of the case in society, related media coverage, administration of self-report scales with dissociative content, and suggestions of dissociative symptoms by therapists and influential others have led vulnerable (e.g., suggestible, attention seeking, traumatized) individuals to present with multiple distinct fully elaborated personalities when they otherwise would not have (Merskey, 1992; Scropo, Drob, Weinberger, & Eagle, 1998; Weissberg, 1993). Of course, an iatrogenic explanation of some DID cases does not mean that the condition does not legitimately exist in some people, but only that some presentations may be caused or exacerbated by improper treatment. There has been long-standing continued controversy in the trauma literature as to the role (or extent of the role) that iatrogenesis has in DID, with some strongly making the case for the iatrogenic role (Lilienfeld et al., 1999; Merskey, 1992; Spanos, 1994) and others strongly refuting it (Greaves, 1996; Reinders, Willemsen, Vos, den Boer, & Nijenhuis, 2012; Scropo et al., 1998). More recently, a scientific review of the childhood DID literature supported the iatrogenic model more than the posttraumatic model because DID was found to be extremely rare outside of therapy, unevenly distributed across clinicians (with 65% of cases coming from four research groups), and mostly a Western phenomenon (Boysen, 2011).

### **Iatrogenesis From Medications and Medical Procedures**

Iatrogenesis resulting from inpatient hospital stays is a common problem, affecting between 3% and 20% of patients across the world (Baker et al., 2004; Brennan et al., 1991; Davis et al., 2002, 2003; Schimmel, 2003; Thomas et al., 2000; Wilson et al., 1995). In one study, up to half of the adverse events leading to hospital admissions were preventable and 7%–19% resulted in death. The problems in these studies were deemed to result from the health care management itself as opposed to the underlying disease process. Some problems in these studies are caused by medication iatrogenesis and/or iatrogenesis from medical procedures, some of which is classified as negligent.

In medication iatrogenesis, medications unintentionally exacerbate existing signs and symptoms, create new signs and symptoms (e.g., memory and concentration problems, weight changes), and/or can cause death (Dunn & Murphy, 2010; Ksouri et al., 2010; McAllister et al., 2009). Some refer to this as an adverse drug reaction (ADE) and it is the

most common form of medical iatrogenesis (Mitty, 2010). ADEs can be reactions to a normal medication dose but can also be the result of medical errors such as an incorrectly written prescription or a filling error at the pharmacy (e.g., wrong medications or higher-dose pills filled). Topiramate is an example of a medication neuropsychologists encounter frequently that is well-known to have particularly negative effects on cognition in its use in treating migraines, headaches, and seizures, particularly as the dose increases (Fritz et al., 2005; Loring, Williamson, Meador, Wiegand, & Hulihan, 2011). Psychiatric effects can occur as well such as psychosis (e.g., visual hallucinations) caused by medications to treat movement disorders such as Parkinson's disease (Friedman, 2002).

Medication iatrogenesis is particularly relevant for neuropsychologists to consider when assessing (a) the cause of chronic nonspecific symptoms such as headache (e.g., rebound headaches caused by excessive use of ibuprofen in a patient reporting chronic worsening headaches after concussion) (b) the cause of a new health conditions (e.g., neuroleptic malignant syndrome; delirium caused by excessive sedation on an inpatient unit, cancer treatment, immobilization, sleep deprivation, dehydration, and complications from indwelling catheters; see Inouye, Schlesinger, & Lydon, 1999; Jeste & Krull, 1990; van Steijn, Nieboer, Hospers, de Vries, & Mulder, 2001; Vasilevskis et al., 2010), and (c) the cause of poor neuropsychological test performance (e.g., cognitive impairment due to excessive chronic opioid use for low back pain; Pransky, Borkan, Young, & Cherkin, 2011; or from an incorrectly written prescription/pharmacy filling error resulting in an accidental overdose). Iatrogenesis is known to play a significant role in maintenance of chronic pain in subsets of patients through misdiagnosis, overinvestigation, overtreatment, inappropriate medication prescriptions, and conveying inappropriate information and advice to patients that legitimizes incorrect beliefs about the medical basis of symptoms (Kouyanou et al., 1998; Kouyanou et al., 1997a; Kouyanou, Pither, & Wessely, 1997b).

Lack of knowledge about iatrogenic treatment effects can lead to circular reasoning and persistent harmful treatment. An example would be a patient with chronic headaches 18 months postconcussion who is treated with high-dose topiramate. At the next visit, the patient reports continued headaches, "confusion," and other cognitive changes (e.g., attention and memory problems). Rather than recognizing this as a potential iatrogenic treatment effect, the provider attributes this change to concussion as well, increases the topiramate dose, and adds a neurostimulant, which then triggers significant weight loss and irritability. Thus, rather than tapering the patient off of the medication, the treatment is increased further. Despite the provider's good intentions, the patient worsens from the intervention.

Neuropsychologists also need to be mindful of iatrogenesis that can result from medical procedures that can impact neuropsychological functioning as they will sometimes

be asked to evaluate patients after this has occurred. One example is blood pressure changes leading to hypoxia/stroke during a surgical or diagnostic procedure either due to the effects of the surgery itself on the cardiovascular system and/or an adverse reaction to medications used at the time of surgery (including anesthesia). Other examples include delirium caused by hospital-acquired infection as well as severe impairments in speech and/or memory after an anterior lobectomy to treat intractable seizures. Another example is prion disease (e.g., Creutzfeldt-Jakob disease), which has been transmitted to more than 400 patients through the use of neurosurgical instruments, intracerebral EEG electrodes, human pituitary hormone, dura mater grafts, corneal transplants, and blood transfusions (Hamaguchi et al., 2009). Many patients who neurologists evaluate are being treated by chiropractors, and cervical manipulation can result in increased pain and headache in 30% of cases (Hurwitz, Morgenstern, Vassilaki, & Chiang, 2004). There is also controversy as to whether cervical chiropractic manipulation can lead to a vertebro-basilar stroke (Cassidy et al., 2008; Ernst, 2002).

Elderly patients ( $\geq$  age 65) are at high risk of iatrogenesis because they often require multiple treatments and have a higher incidence of cognitive difficulties (Fantino et al., 2006). In working with elderly patients, neuropsychologists and other health care providers must be aware of the potential for *cascade iatrogenesis*. Cascade iatrogenesis is the serial development of multiple medical complications triggered by an initial medical intervention and is associated with reduced mechanisms for coping with external stresses (Potts et al., 1993; Rothschild, Bates, & Leape, 2000). An example would be an elderly patient who is oversedated with analgesics for arthritis, falls due to imbalance, breaks a hip, becomes immobile, develops pneumonia, and experiences adverse medication reactions and side effects, followed by delirium. In cascade iatrogenesis, one adverse medical problem follows (cascades) from the other and is associated with decreased cognitive and/or physical reserve (e.g., less-effective kidney and liver functioning) (Rothschild et al., 2000). The elderly have a tenfold increase in falls (Rothschild et al., 2000) which increases their risk for traumatic brain injury (TBI). In fact, TBI hospital discharge rates for falls are highest for patients aged 65 and above (Langlois et al., 2003).

On the other end of the spectrum, medical iatrogenesis is common in neonatal intensive care units (NICUs). For example, Kugelman et al. (2008) found a 19% prevalence rate of iatrogenic events in NICUs, with 83% as preventable, 7.9% as life threatening, and 45.1% as harmful. They also found that the prevalence rate was much higher in younger infants (e.g., 57% for those at 24–27-week gestations compared to 3% born at term) and that the effects were more severe and harmful. Some of the iatrogenic effects have the potential to impact neuropsychological functioning such as hypoxia/anoxia from tracheal tube malpositioning, perforation of the inferior vena cava due to umbilical venous catheter use, and late-onset sepsis.

Finally, in some instances, it should be noted that determining whether certain medications patients are using have iatrogenic effects is controversial. Perhaps the best example is the controversy surrounding an alleged increased risk of suicidality when patients are treated with antidepressant medication. These concerns surfaced in 2004 when the U.S. Food and Drug Administration mandated strong “black box” suicide warnings on all antidepressant medications based on the antidepressant arm of randomized controlled studies with a placebo (Check, 2004). However, a subsequent comprehensive review showed that antidepressant medication actually serves to effectively treat and protect patients from suicide, especially if they follow up regularly with their providers (Rihmer & Akiskal, 2006).

### **E-Iatrogenesis (Technological Iatrogenesis)**

As technology has progressed and health care reform is implemented, more health care providers are being required to use electronic medical record (EMR) systems. Such programs are often integrated with computerized clinical decision support systems (CDSS) to improve compliance with best-practice guidelines (Seroussi, Falcoff, Sauquet, Julien, & Bouaud, 2010). While this technology certainly has benefits, it also creates the risk of what has been termed *e-iatrogenesis* (or *technological iatrogenesis*), which is when patient harm is caused at least in part by the use (or misuse) of health care information technology (Palmieri, Peterson, & Ford, 2007; Weiner, Kfuri, Chan, & Fowles, 2007). Such risk can be broadly divided into commission errors (e.g., false positive diagnosis; prescribing the wrong treatment; death) or omission errors (false negative diagnosis; not prescribing a needed treatment).

Health care providers should be aware that in some health care systems, EMR systems includes non-evidence-based clinical protocols and provider order sets in order to get as many clinicians to “buy in” to the system as possible (i.e., keep them happy) (Simpson, 2010). This is important to know because the use of non-evidence-based protocols and treatments increase the risk of iatrogenesis. In addition, EMR systems have been shown to decrease the efficiency of health care providers (Furukawa, Raghu, & Shao, 2010). This can lead to efforts to bypass time-consuming safety features and has even resulted in patient fatality (Smetzer, Baker, Byrne, & Cohen, 2010).

Computerized CDSS technology is also used in clinical neuropsychology in which automated interpretations are provided for some symptom validity, personality, and cognitive tests. This often results in diagnostic *possibilities* and treatment *considerations*. As with physicians, such technology has the capacity to both decrease and increase iatrogenesis in neuropsychological practice, depending on how the technology is used. Specifically, the risk of iatrogenesis will be increased with such technology when the data gathered is used in a rigid cookbook-like fashion without taking

other factors into consideration such as data from clinical interview/medical records review (e.g., history of treatment responses), medical comorbidities, behavioral observations, and convergence with published diagnostic criteria. Neuropsychologists should pay attention to disclaimer statements published in automated reports. For example, in the diagnostic possibilities section of the Personality Assessment Inventory–Adolescent (Morey, 2007) interpretive printout it states that “A diagnosis should be made only after careful examination of the specific DSM-IV diagnostic criteria and should be informed by clinical judgment.”

### **Preventing/Reducing and Addressing Iatrogenesis**

Some suggestions for preventing/reducing iatrogenesis were discussed in the preceding sections and are discussed more fully in this section.

#### ***Objective Corroboration of Subjective Reporting and Resisting Patient Pressure***

Health care providers must be especially cautious about the role and effects of iatrogenesis when assessing patients whose presentation is solely based on subjective symptom reporting. In such cases, the health care provider should seek objective information to corroborate the patient complaints (e.g., neuropsychological testing, objective biomarkers, physical exam findings that cannot be influenced by the patient) and should become increasingly concerned about the reliability and validity of these complaints (or at least their potential neurological basis) the more results come back as negative. Careful review of patient medical records should be used to verify patient reports (Doty & Crastnopol, 2010). The more discrepancy there is between self-report and statements in the medical record (pre- and postsymptom onset) the more that similar concerns should emerge (Slick et al., 1999). Health care providers should be especially cautious in such cases when diagnosing a neurological condition without converging objective evidence that the condition is actually present.

A significant cause of unnecessary medical procedures and inaccurate explanations that can cause patient harm is a response to significant pressure placed on treating providers by patients to agree with their conceptualization of the problem; to order requested procedures, therapies, and medications; and to write disability or out of school notes *ad infinitum*. In a desire to please the patient in a helping profession, along with a desire not to engender complaints, treating providers may sometimes go against their better judgment and write disability notes or order tests and treatments that are of no genuine benefit to the patient and may actually cause harm. Indeed, Little et al. (2004) found that doctors' perception of patient pressure was a strong predictor of prescribing, examinations, referrals, and examination, even in cases where there was slight to no actual medical need.

In order to prevent unnecessary utilization of health care resources and reduce iatrogenesis, the authors encouraged doctors to have a direct conversation with their patient about their expectations. As Kouyanou et al. (1997a) describe, the pressure that the doctor feels to help the desperate-appearing patient and search excessively for an organic cause when none likely exists can add to patient anxiety and impede the development of coping skills that could have helped resolve the problem.

### *Undiagnosis*

As discussed earlier, misdiagnosis is a common theme in many forms of iatrogenesis because it leads to incorrect treatment and can cause patients to develop a false belief system regarding their symptoms, each of which can lead to adverse outcomes. It has been argued recently that misdiagnosis has increased (Patfield, 2011), and this increase will likely continue as policy changes in the health care system (e.g., insurance companies, hospitals) and will lead to pressures to evaluate more patients in less time and with fewer resources. Since neuropsychologists have more time to interview patients/collaterals and review medical records to gather a proper history and integrate this information with objective test data, they are in a unique position to review the evidence in a comprehensive manner that should increase diagnostic accuracy. It is not uncommon for a neuropsychologist to conclude that the sum of the evidence indicates that the presumptive diagnosis is incorrect (referred to as “undiagnosis”; see Patfield, 2011). In some cases, the patient may be informed that a different diagnosis appears to be more appropriate or that no diagnosis is appropriate.

A common example of undiagnosis in neuropsychology would be informing a patient that the cause of his or her problems 18 months postinjury is not “postconcussion syndrome” as he or she has been told by numerous health care providers. In fact, the patient may also be told that he or she does not even meet liberal criteria (Mild Traumatic Brain Injury Committee of the Head Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine, 1993) for a diagnosis of a concussion because review of medical records and interview data does not indicate the presence of altered mental status or a focal neurological deficit. The patient may be informed that an undifferentiated somatoform disorder is a far more appropriate diagnosis and that treatment with cognitive behavioral therapy is indicated rather than chronic treatment with medications (some of which can cause cognitive dysfunction), physical therapy, occupational therapy, vision therapy, and/or chiropractic services.

While undiagnosis is a role that neuropsychologists are highly qualified to address, clinicians must be aware that it comes at the risk of upsetting a referral source (who may have made an incorrect diagnosis) or patient/family members (who may be psychologically invested in the diagnosis). To

mitigate this, it is important to use an informed consent form with patients before the evaluation informing them that a second opinion may result and by being careful in the report not to specifically attack other health care providers. Rather, it is best to simply provide a clearly stated independent opinion that is based on data, national practice standards, high-quality published research, and published diagnostic criteria. It is important to emphasize to patients how undiagnosis and a possible replacement diagnosis can lead to new and better treatment approaches (e.g., cognitive behavioral therapy) and a higher likelihood of functional improvement (e.g., return to work). In other cases it is helpful to explain to patients that there is “good news” that no underlying illness appears to be present and that the problems present are modifiable and not beyond their control to fix. Clinicians are urged not to provide a diagnosis merely because it provides patients relief that they have an answer for their problems, because that relief is often short-lived and can lead to adverse treatment effects if the diagnosis is incorrect (Patfield, 2011). However, clinicians must also be empathic and convey that they are trying to help people. Thus, it is best to avoid using terms that will alienate the patient such as that their symptoms are “imaginary” or “in your head” so that the patient does not attempt to prove the doctor wrong by producing more illness-behavior (Kouyanou et al., 1998). For more information on feedback approaches in such circumstances, see Carone, Bush, and Iverson (2013) and Carone, Iverson, and Bush (2010).

### *Use of Evidence-Based Treatments*

The use of evidence-based treatments needs to become more commonplace in health care. If health care providers do not voluntarily treat patients with such approaches, there will be increasing pressure (if not mandates) for them to do so based on modern-day health care reform. As a panel of international health care experts recently concluded, many countries (particularly the United States) have more of a medical industrial complex that is focused more on economics (e.g., billing for services) rather than actually improving health care (Pransky et al., 2011). Such approaches are ultimately more harmful to the patient, scientifically unjustifiable, and economically unsustainable. By using evidence-based treatment approaches, patients and providers can embark from the outset on clearly specified expectations, a clear understanding of risks and benefits, and a plan of action to change the treatment plan if it is not working by a certain time. Related to the latter, health care reimbursement will increasingly be tied to evidence that the patient is making improvements.

Measuring treatment effectiveness will require the use of outcome assessment measures during the course of treatment or before and after treatment. If a patient is not showing improvement in functioning (e.g., symptoms are the same or worsening, remains out of work) then the treatment is not working and should not be maintained indefinitely. It

is important to note that some health care providers may justify excessive treatments by pointing to times when the patient subjectively reported an improvement in symptoms across a few sessions. However, without objectively measuring such improvements, determining if the improvements are sustained, and simultaneously examining improvement in functional abilities (e.g., return to work, school, and/or driving), indefinite treatments are not well justified. Finally, as per Simpson's (2010) recommendation, EMR systems should not include protocols and order sets that are not evidence-based merely to please the health care provider.

### ***Reducing Medical Iatrogenesis***

Scott, Gray, Martin, and Mitchell (2012) proposed a ten-step model to minimize iatrogenesis related to inappropriate medication use. Of these, the step where neuropsychologists can have the greatest input is defining and confirming current indications for ongoing treatment. For example, if a patient had been using donepezil or memantine for presumed Alzheimer's disease but evaluation results revealed that the patient was actually cognitively normal (e.g., "worried well") or had mild cognitive declines related to poor effort in the context of major depressive disorder, these medications would no longer be indicated. Sometimes, these medications are also inappropriately used to treat persisting self-reported memory deficits after mild head injury/concussion even though no good scientific evidence exists to support this practice.

Another step where neuropsychologists can have partial input is estimating the magnitude of benefit versus harm in relation to each medication. Of course, neuropsychologists vary with regards to their expertise on certain medications and should modify their input accordingly, particularly focusing on medications that have known deleterious cognitive side effects. Thus, neuropsychologists may not be able to provide input on each medication depending on the number and type. In some cases, neuropsychologists may comment broadly on the cognitive effects of certain classes of medications (e.g., opioid analgesics) but in other cases may comment on the cognitive side effects of a particular medication (e.g., topiramate). See Stein and Strickland (1998) for a review of the cognitive effect of numerous prescription medications.

Neuropsychologists can provide input on another step, which is to review the relative utility of different medications. Again, input here will be limited to the neuropsychologist's experience, the type of medication(s) used, and the condition being treated. However, for many medications, neuropsychologists can usually provide some input. The last step of relevance to neuropsychologists is to implement and monitor a drug minimization plan (e.g., reducing polypharmacy when possible) with ongoing reappraisal of drug utility and patient adherence by a single nominated clinician. While neuropsychologists cannot implement and monitor such a plan or serve as the single nominated clinician, they are often in a position to strongly advocate that such a plan be put in place,

particularly in cases where it is evident that numerous health care providers are prescribing various medications without communicating with one another. This is most common in cases of polypharmacy in the elderly.

In inpatient settings, neuropsychologists may be able to provide input or advocate for fall prevention strategies that can cause or exacerbate a brain injury. An example would be recommending a sitter for an impulsive patient with a severe traumatic brain injury or an elderly patient with unstable gait. In such settings, neuropsychologists can also play a useful role in helping medical staff identify the early signs of hypoactive delirium so that it can be treated properly and not worsened by iatrogenic treatments. Neuropsychologists working in integrated care settings can also help facilitate communication among a patient's health care providers to reduce iatrogenic errors. They can also assist in routine cognitive screenings of elderly patients to detect acute changes suggestive of delirium.

While neuropsychologists can be helpful in reducing medical iatrogenesis, physicians and other health care providers will ultimately take the lead role in addressing factors contributing to it. Examples include utilizing evidence-based interventions to reduce the risk of preventable delirium (Bell, 2009; Inouye et al., 1999), improving the attitudes of health care staff towards the elderly to prevent delirium (Inouye et al., 1999), implementing fall prevention strategies (Reading, 2009), reducing delayed hospital discharges in the elderly after acute illness (Haack, 2009), adequate follow-up of abnormal physical findings and test results (Nemergut, 2009), more patient education on the effective and safe use of medication (Kouyanou et al., 1997b), implementing methods to reduce unnecessary transfer of patients from a nursing home to the hospital (Brooks, Warshaw, Hasse, & Kues, 1994), and reducing the risk of prion disease by using disposable instruments (Hamaguchi et al., 2009). In addition, the use of electronic prescribing can decrease some types of prescribing errors, and being familiar with drug formularies can decrease the chance of dosing errors when a provider must prescribe an alternative medication because the first choice is not covered by the insurance company (Olson-Garewal, 2001). Robinson and Weitzel (2009) discussed numerous ways to reduce cascade iatrogenesis in the elderly such as reviewing and minimizing the use of high-risk drugs, starting at the lowest reasonable medication dose and increasing the dose slowly as needed ("start low and go slow"), making sure they are wearing properly functioning sensory assistance devices (e.g., hearing aids), closely monitoring for pressure sores (which can lead to infection and altered cognitive functioning), and openly communicating with caregivers.

After finding far from optimal prescribing patterns towards the elderly among physicians, Fantino et al. (2006) also urged more cautious prescribing practices in the elderly to reduce iatrogenesis, which can further be accomplished by full access to the patient's medical history, obtaining therapeutic data and setting treatment goals, utilizing good

communication skills to decrease improper medication use, encouraging communication by the patient to the provider, and understanding the social and psychological status of their patients. The latter was noted by these authors to be an area that physicians appeared to have a general lack of interest in obtaining themselves, which makes it all the more important for neuropsychologists to bring significant psychosocial factors to their attention. An example would be depression or cognitive impairment interfering with the ability to understand medication directions.

In a study by Kugelman et al. (2008), NICU staff hired an iatrogenesis advocate who monitored and recorded iatrogenic events, and made the staff aware of them through open discussions but in an anonymous fashion to avoid individual blame. This intervention reduced the iatrogenic incidence rate slightly but not the prevalence rate. Government-sponsored initiatives (e.g., public ads, mandated continuing education on the topic) are another way to increase awareness on iatrogenesis among the public and health care providers. Also, as Johnson (2010) noted, devoting more time to quality assurance programs in hospitals is another way to try to reduce iatrogenesis. With regards to alternative and complementary therapies, Biley (2002) suggested developing an adverse events register to monitor for iatrogenic treatment effects.

## Summary and Conclusions

In summary, iatrogenesis is a serious problem that neuropsychologists will frequently encounter when working with patients. Iatrogenic effects are more likely to occur in cases where there is a lack of objective biomarkers and when patients are being treated by health care providers who view themselves and/or practice more as patient advocates than as scientific practitioners. However, psychological and medical iatrogenesis can theoretically present in any condition where a neuropsychologist evaluates and no health care provider is immune from causing iatrogenic effects. Although not all iatrogenic complications are avoidable and some are expected from standard therapies (e.g., neurological and neuropsychological impairments from cancer treatments such as radiation, chemotherapy, and other medication) many can be avoided by implementing some of the suggestions discussed in this chapter.

# 45 Complementary and Alternative Medicine for Children With Developmental Disabilities

*Karen E. Wills*

Adequate evidence is lacking for the efficacy of complementary and alternative medicine treatments (CAM) over placebo in children with developmental disabilities, for symptoms other than pain or insomnia (Golnik & Ireland, 2009; Harrington & Allen, 2014; Perrin et al., 2012). This has been the case for a century or more, during which the popularity of CAM has steadily grown, particularly for children with autism and attention deficit/hyperactivity disorder (ADHD), and increasingly for children with Down syndrome and other developmental disabilities (Kemper, Vohra, & Walls, 2008). Rather than redo existing comprehensive scientific reviews of CAM techniques and efficacy—an approach that clearly would conclude with the summary statement that this chapter begins with, as every other neutral review has done—the present chapter will address practical questions for pediatric neuropsychologists, specifically:

- What types of treatment are considered CAM?
- What problems does CAM offer to treat?
- Which patients and families are most likely to engage with CAM practitioners?
- Does any type of CAM work?
- What harm can scientifically unsupported CAM do? Can it do any good?
- Why are so many types of CAM popular if they don't work?
- What should neuropsychologists consider when discussing CAM?

## **What Types of Treatment Are Considered CAM?**

As shown in Table 45.1, allopathic (mainstream) medicine encompasses procedures of a nature similar to CAM procedures—the difference being an assumption that procedures should be subject to scientific validation of efficacy. That is not to say that in fact all of the procedures used in mainstream medicine have been validated, merely that it is assumed they ought to be, and that if scientifically unsupported, they should be discontinued.

Thus, CAM refers to a wide array of procedures usually defined by exclusion as being not subjected to scientific inquiry, “not scientifically proven,” or “not mainstream”

medicine or surgery. The most commonly used procedures including massage, breathing, relaxation exercises, yoga, and guided meditation. The more intrusive or elaborate CAM treatments are much less commonly used, although they get more press. Sometimes a treatment that starts out as CAM becomes validated and then may no longer be considered CAM—for example, the use of melatonin to enhance sleep onset has been excluded from CAM in some recent studies (Perrin et al., 2012).

What is considered CAM varies across studies and over time, which makes it hard to compare studies that reference CAM as an “umbrella” term for a range of procedures. For instance, massage therapy may be included as one type of CAM by one investigator, but as a mainstream palliative treatment by others. Whether or not an approach is CAM may depend, in part, on whether there is scientific support for its efficacy as a treatment for the particular symptom or outcome to which it is being applied—for example, massage as a treatment for pain or spasticity may be considered mainstream, whereas massage to enhance sustained attention among children with ADHD may be considered CAM. The list of CAM procedures changes over time, as well, because adverse events, changing fads, updated technology, or popularized research results may make particular techniques obsolete as new ones emerge.

CAM in some sense has existed for centuries but by definition could not exist without a formally established medical mainstream that endorses treatments based on scientific research with clinical trials. Since the 1930s, organized medicine dominated the available interventions, which were focused mostly on relief of life-threatening illnesses. Beginning in the 1970s, as many infectious diseases were nearly eradicated, there was increasing emphasis within the medical community on health and wellness, rather than illness. Benson (1975) in “The Relaxation Response” emphasized the use of breathing, meditation, and relaxation strategies to relieve pain, anxiety, insomnia, and hypertension. David Eisenberg (1993) learned Chinese medicine and helped popularize it within the United States. Subsequently, these strategies have been used to deal with anxiety, nausea, medical anorexia, pain, and insomnia, in adults and children with serious chronic illnesses such as cancer, heart disease, and arthritis. The idea that such treatments augmented

Table 45.1 Treatments for childhood behavioral or developmental problems

---

Dietary manipulations and supplements (efforts to eliminate perceived toxins, supplement perceived missing substances, or add perceived beneficial nutrients)	
Elimination (e.g., sugar-free, gluten-free, casein-free, preservative-free, food “allergies”)	
Supplements (e.g., herbs, vitamins, oils, minerals, enzymes, probiotics, antifungals)	
Special food preparation (e.g., raw foods, green smoothies)	
Homeopathic treatments, naturopathic treatments (Atwood, 2003)	
Melatonin (for sleep onset; see Bendz & Scates, 2010)	
Psychopharmacology (allopathic)	
Biomechanical (passive movement) therapies (touching, moving, piercing or adjusting the child’s body as an effort to improve motor function and response to physical sensation, or to ameliorate pain or physical discomfort)	
Massage therapies (Khilnani et al., 2003)	
Sensory integration therapy: compression, brushing	
Chiropractic (Synovitz & Larson, 2013)	
Acupuncture/acupressure	
Orthopedics (surgery, bracing, casting; allopathic)	
Mind/body, expressive, and active movement therapies (to improve mood, behavior, and well-being or ameliorate a broad spectrum of symptoms)	
Art, music, dance, movement therapies (e.g., Interactive Metronome)	
Sensory integration: gross motor/vestibular stimulation (swinging, spinning)	
Yoga, therapeutic horseback riding, martial arts, swimming, other exercise/sports	
Play therapy, sand play, other interpretive play techniques	
Psychotherapy (allopathic)	
Mind/body, relaxation and spiritual energy therapies (to improve mood, behavior, and well-being or ameliorate a broad spectrum of symptoms)	
Relaxation, eye muscle Desensitization with relaxation	
Hypnosis	
Meditation	
Biofeedback (muscle relaxation, galvanic skin response)	
EEG biofeedback (for concentration and/or memory and learning; Steiner et al. )	
Cranio-sacral healing (Gray et al., 2011), Qi Gong, therapeutic touch	
Prayer healing/faith healing/shaman ritual	
Listening/fostering the doctor–patient relationship (Allopathic)	
Physical/respiratory environment	
Hyperbaric oxygen chamber	
Salt caves	
Erlen lenses; colored overlays (effort to improve reading)	
Eliminate florescent lights; use broad-spectrum “natural” light	
Control acoustics (echo reduction) and light touch (soft clothing)	
Filter air and water (effort to remove perceived irritants or toxins)	
Aromatherapy (effort to combat nausea and pain of chemotherapy and other procedures)	
Chelation (allopathic to treat lead poisoning; otherwise, risky: Brown et al., 2006)	
Exposure to “green space” (spending time in nature; Kuo & Taylor,)	
Exposure to magnets or magnetic fields	
Sensory-motor training therapies	
Behavioral optometry (vision therapy; effort to improve functional vision for reading)	
Auditory Integration Therapy, Fast Forward, other “listening” therapies (effort to improve functional listening and communication skills, for speech and reading)	
Speech/language therapies (allopathic)	
Occupational therapies (allopathic when used to train specific skills)	

---

conventional medicine, rather than substituted for it, took hold as mainstream hospitals hired practitioners of “complementary” or “integrative” medicine. In 1992, an Office of Alternative Medicine was established at the National Institutes of Health. In 1999, the name was officially changed to The National Consortium on Complementary and

Alternative Medicine. A major conference on use of CAM with children took place in 2000. Going forward, the U.S. federal government may play an increasing role in regulating CAM, although the involvement of CAM practitioners in directing the NCCAM has been critically challenged (Atwood, 2003).

### What Problems Does CAM Offer to Treat?

Rather than objectively measurable signs of illness (such as fever), most symptoms and conditions addressed by CAM for adults and adolescents involve subjective distress, such as pain, malaise, nausea, fatigue, dizziness, anxiety, and depression. For children, including those with developmental disabilities, CAM is most commonly used to try to alleviate the following symptoms:

- Externalizing behavior problems such as irritability, aggression, impulsivity, and hyperactivity;
- Repetitive autistic-like behaviors such as self-injurious behavior, tics, stereotyped movements (“self-stimming”), and inflexible or perseverative behaviors;
- Anxious/agitated behavior such as agitation, anxiety, fearfulness, and “meltdowns”;
- Inattention, distractibility, and learning and memory problems;
- Insomnia, including settling to sleep and staying asleep through the night;
- GI symptoms such as cramps, gas, encopresis, diarrhea, and constipation;
- Pain such as headache, stomachache, cramps, and other aches and pains; and
- Seizures and staring spells.

Children with motor dyspraxias or cerebral palsy are subject to a range of interventions in an effort to improve their posture, gait, hand control, and speech that tend to be far more physically intrusive but no more effective than most of the common CAM treatments for autism and ADHD—for example, hyperbaric oxygen and stem cell injection—though the most common therapies are massage and hydrotherapy (Wray REF).

### Which Patients and Families Are Most Likely to Engage With CAM Practitioners?

CAM may be marketed or perceived as an alternative to mainstream treatments. It is viewed by some as avoiding adverse effects of medications or surgeries; offering a cure or symptom alleviation for problems when traditional medicine has proven insufficient or offers no recourse; sometimes providing less-expensive, more-comprehensive, or more-lasting treatment; emphasizing wellness and holistic health rather than mere symptom relief; providing more “natural” forms of intervention rather than synthetic chemical solutions; or as a more respectful “person-centered” approach rather than one that coerces or subjugates patients to a doctor’s authority.

While this “medicine avoidant” use of CAM might be more common among adults treating themselves, surveys consistently find that most parents who use CAM are not abjuring standard medical treatments for their children. For

children, CAM seems to be more often “complementary” than “alternative.” While for most studies this finding could result from an ascertainment bias (because parents often are interviewed in the waiting room of a clinic or hospital), the same pattern was found in a very large sample drawn from a national autism advocacy group (Perrin et al., 2012) and in a population-based Canadian survey (Adams et al., 2013). Most families who use CAM for children also are using traditional mainstream pediatric care, as well as educational interventions. It is less clear how often CAM is utilized in conjunction with scientifically tested psychological therapies for autism, ADHD, anxiety, and other behavior problems in children, although these are not intrinsically incompatible. CAM is seen by some medical providers as truly “complementary”—a useful adjunct to medication or standard physical or mental health care (Golnik & Ireland, 2009). In this context, it is used primarily for relaxation, distraction, desensitization, mindfulness, managing disruptive or risky behaviors, and lifestyle changes such as ceasing harmful habits or establishing health-promoting habits. CAM of this sort has been incorporated as a service or freestanding program into many major medical centers and is very popular with patients. It may be prescribed for children with cancer, diabetes, asthma, and other chronic illnesses. Hospital- and clinic-based CAM or Integrative Medicine services, and pediatric psychology services, may overlap, coexist, or sometimes conflict. Some hospital ethicists have cautioned that standards of informed consent, evidence-based treatment, and outcome evaluation of CAM do not equal those to which traditional medicine and psychological interventions are held (Ernst, 2009; Nissen, Weidenhammer, Schunder-Tatzber, & Johannessen, 2013).

Pediatricians at the Boston Children’s Hospital (Perrin et al., 2012) analyzed use of CAM by children with autism who were included in the Autism Speaks treatment network registry as of April 2011. The participants self-reported their choices of treatment in an organizational survey. This is one of few studies to date that avoided the problem of recruiting bias; that is, most studies estimate CAM use based on a sample of families who expressed interest in participating in a study about CAM and/or who were being treated already in a mainstream pediatric clinic—which may increase estimated prevalence of CAM use, and particularly increase the estimation of CAM use as a supplement rather than as an alternative to “standard” treatment. The psychometric properties of most surveys of CAM use, which are designed informally and unvalidated for the most part, also have been criticized (Toupin et al., 2012). Despite these problems and differences in study design, surveys of patterns of CAM utilization for children have yielded some remarkably consistent findings across countries (Adams et al., 2013; Akins et al., 2006; Akins, Krakowiak, Angkustsiri, Hertz-Picciotto, & Hansen, n.d.; Chugh, Erickson, & Fermin, 2006; Italia, Wolfenstetter, &

Teuner, 2014; Treat et al., 2014; Wray et al., 2014). CAM is used much more often for children with developmental disabilities (autism, ADHD, ID) than for other children. Parents who use CAM for children with developmental-behavioral disorders such as autism or ADHD tend to be more affluent, with higher educational attainment, than those who do not. Parents who use CAM themselves also are more likely to use it for their children. White families generally are more likely to use CAM than Latino or African American families (Akins, Krakowiak, Angkustsiri, Hertz-Picciotto, & Hansen, 2014; Perrin et al., 2012), although a Philadelphia survey of parents using CAM with newly diagnosed autistic children found an increased prevalence among Latino parents (Levy, Mandell, Merhar, Ittenbach, & Pinto-Martin, 2003). There may be some differences across ethnic or cultural groups in what kinds of CAM are most popular; for example, prayer was uncommon among Anglo American parents but a preferred approach for Latina mothers in New York (Chugh et al., 2006; Fortier et al., 2014) and Muslim mothers in Jordan (Aburahma, Khader, Alzoubi, & Sawalha, 2010).

The prevalence of CAM use and preferred types of CAM vary widely across regions of Canada or the United States, as well as across countries. Several large surveys have found more prevalent use of CAM for children with autism than for children with intellectual disabilities, attention deficit disorder, cerebral palsy, or behavioral disorders. More severe and persistent symptoms are associated with greater likelihood of CAM use. In Perrin's U.S. national sample of children with autism ( $N = 3,413$ ), 17% of the families reported use of special diets and 20% reported use of other CAM approaches (Perrin et al., 2012). That study did *not* include sensory integration therapy, massage, or melatonin in its definition of CAM treatments. Studies that do include those treatments in the definition of CAM yield much higher estimates of use, ranging to 90% of families affected by autism (Kemper et al., 2008). Use of CAM was associated with the presence of gastrointestinal symptoms, seizures, and clinically significant parent-rated behavior problems. Children who were using medications, and those with milder forms of autism (Asperger's disorder or pervasive developmental disorder), were less likely to be using CAM. Perrin and associates also reviewed previous work on CAM in children with autism, indicating that families report having tried an average of seven different types of CAM therapies, either sequentially or simultaneously. Dietary interventions were the most commonly tried. Valicenti-McDermott and colleagues (2014) also reported an association between use of CAM gastrointestinal, behavior, and sleep problems, as well as higher self-reported parental stress, among children with autism whose families were using CAM.

CAM treatments for ADHD are similar, and often the same, as for autism. Just as for children with autism, for the 50% or more of children with ADHD whose families use

CAM, the most common treatments are dietary changes or oral supplements (Chan, Rapoport, & Kemper, 2003). For example, the Feingold diet restricts synthetic coloring, flavoring, preservatives, and artificial sweeteners, as well as certain salicylate-containing fruits (apples, grapes). It does not involve restricting sugar. Repeated double-blind studies have shown no effect of sugar on children's behavior. Kemper (2015) cites some studies suggesting decreased hyperactivity or impulsivity among some children with ADHD treated by the Feingold diet, though changes tend to be minimal and impermanent. The Australian Guidelines report no benefit of the Feingold diet based on several well-controlled studies.

The findings that vitamin and mineral deficiencies were more common among children with ADHD than in the general population, and also that children with nutritional deficiencies are more restless and distractible than others, contributed to the idea that adding vitamin and mineral supplements might normalize behavior in children with nutritional deficiencies and ADHD. Megavitamin treatments have been shown to have significant negative side effects, as acknowledged in popular press and websites, and their use has diminished (Christison & Ivany, 2006). This shows that some scientific evidence does get shared in the popular press—particularly when children are made ill by a treatment. Several reviews have concluded that adding standard daily vitamin supplements to a standard balanced diet provides sufficient nutrients, vitamins and minerals, without need for additional supplementation. The strongest clinical evidence of benefit for any nutritional supplement is for zinc supplementation, which may potentiate the effect of methylphenidate treatment for ADHD (Rucklidge, Johnstone, Gorman, Boggis, & Frampton, 2014; Sarris, Kean, Schweitzer, & Lake, 2011; Searight, Robertson, Smith, Perkins, & Searight, 2012). Zinc deficiency contributes to problems of growth and development among malnourished children, although in infants with adequate general nutrition, zinc supplementation does not enhance their development (Gogia & Sachdev, 2012).

There are a few studies about the use of CAM within particular ethnic, cultural, or demographic groups, showing differences in the prevalence and preferences for children, as has been shown for adults (Hsiao et al., 2006). Chugh, Erickson, & Fermin (2005) reported an interview study of 101 low-income Hispanic mothers of general pediatric clinic patients in New York City. Those with higher education, and those who used CAM themselves, reported using CAM to treat their children. Childhood asthma was common, but not associated with any increased use of CAM treatments. Home remedies (30%), herbs (18%), and prayer (12%) were most commonly used. Other strategies were rare (including chiropractic, massage, acupuncture, naturopathy and spiritual healing). Immigration status and acculturation were not found to have an effect on CAM use in this sample.

## Why Are So Many Types of CAM Popular If They Don't Work?

### *CAM Is Big Business With Successful Marketing*

There has been significant increase in patient interest in CAM as the cost of traditional medical care has skyrocketed, so some have suggested that CAM is a less costly alternative to allopathic medicine. That might be true for strategies such as prayer or home remedies, but CAM for children doesn't typically save any expense for families of children with neurodevelopmental disorders such as autism or ADHD. Supplements and treatment procedures can be expensive. In 2009, \$34 billion was spent on CAM in the United States, including two-thirds for adult self-care and about one third for care of children (Briggs & Killen, 2013). With the exception of acupuncture, chiropractic, and massage therapy, CAM approaches rarely are covered by medical insurance. Moreover, as mentioned earlier, most parents use CAM to complement mainstream medical treatments for their children, not as an alternative.

In some communities, CAM providers advertise and market their services far more heavily and effectively than providers of scientifically supported treatments. Free-market traditions and concerns about restraint of trade make it difficult to inhibit any practice that stays outside of mainstream medicine and does not result in direct physical harm to the patient, even when substantial evidence shows the practice is ineffective. Miller, Shreck, Mulick, and Butter (2012) found that parents' choice of initial treatment for children with autism was heavily influenced by popular media, anecdotal stories of other parents, and nonmedical professionals (most often educators). Educators were somewhat more likely to recommend popular but unsupported treatments for autism (such as sensory integration therapy) than scientifically supported treatments (such as behavioral therapies). Stephenson, Carter, and Kemp (2012) reported that the major national autism websites—a major source of information for parents of newly diagnosed autism—listed 33 treatments, of which only three were scientifically supported. Descriptions of all treatments generally were positive and uncritical. Paradoxically, even negative information about a particular treatment may increase exposure, familiarity, and public awareness of that treatment, and thereby may increase parents' interest in trying it (Skurnik, Yoon, Park, & Schwarz, 2005).

### *CAM Often Is Marketed and Perceived as "The Natural Choice"*

CAM typically is perceived as more "natural," less physically invasive, and less likely to cause unwanted adverse effects, in contrast to allopathic medicine's use of synthetic chemicals or surgical procedures. Concern about adverse effects of environmental toxins and chemicals has extended to worries about vaccines and prescribed medications such as Ritalin, and to the notion that childhood conditions may be cured by

removing "bad" chemicals from the body, via dietary restriction, environmental accommodations (such as air filters or avoiding florescent lights), or chelation. Preference for a "natural therapy" differentiated CAM users from nonusers in a large sample of Boston parents of children with ADHD (Chan et al., 2003). Interest in CAM also has been fueled by public awareness that traditional medicine has flaws and limitations, may offer unnecessary invasive treatments or medications with adverse effects, and may sometimes be regulated for profit rather than for quality outcomes.

### *CAM Often Addresses Symptoms That Bother Parents*

The most popular CAM treatments for children address problems such as diarrhea, biting, and sleeplessness, which create tremendous stress for families but generally are not addressed by mainstream pediatric or psychological treatments. Pediatricians may class these as behavior problems rather than "health problems," and may not be aware of resources or strategies to address such issues. The promise of a cure or significant symptomatic improvement is bound to be highly attractive, particularly if it entails no direct adverse consequences.

### *CAM Often Offers a "Homey" Care Environment*

CAM practitioners may emphasize listening and establishing a personal relationship with patients who experience mainstream practitioners as too busy or indifferent to their specific concerns. Meeting in a more "homelike" setting, rather than having to deal with a large clinic or hospital staff, may appeal to some families. The social and physical context of a typical medical center visit—driving into a city, parking, taking elevators, sitting in a waiting room crowded with other children who have medical conditions, talking with a receptionist and nurse before visiting with a uniformed doctor for a strictly limited time period—often is stressful for parents and aversive to children with disabilities, no matter how good the quality of care provided. CAM may be perceived as more compatible with personal, cultural, religious, or spiritual values and beliefs, particularly when parents can select culturally congruent CAM providers.

### *Providers' Familiarity With Effective Treatment May Be Limited*

The popularity of scientifically unsupported CAM is partly due to parents and treating professionals (physicians and educators, in particular) having inadequate information about scientifically supported, effective treatment of autism and other developmental disabilities. Golnik and Ireland (2009) surveyed primary care physicians (each of whom treats, on average, ten children with autism; Dosreis et al., 2006). They found much uncertainty and willingness

to endorse whatever the parents already had initiated, as long as it was not directly harmful. Some physicians, educators, and parents may be unaware that there is good-quality evidence for improved function and reduced symptoms associated with mainstream medical and psychological treatment (e.g., Fein, 2011; Floet, Scheiner, & Grossman, 2010).

**Parents Face Systemic Obstacles to Choosing Optimal Treatment**

Even when providers are well informed, the structure of a typical pediatric practice may not allow adequate time or resources for parent guidance and care coordination. Children with autism are somewhat more likely to find a “medical home” than those with other conditions, and those who do find care coordination tend to do better, but such wrap-around care is not routine (Golnik, Scal,

Wey, & Gaillard, 2012; Kogan et al., 2009). Parents are largely on their own to identify, evaluate, access, and coordinate providers and care options for children with developmental disabilities and special health care needs. “Gabe’s Care Map” (Figure 45.1) illustrates the caregivers coordinated by one mother of a child with autism (Antonelli & Lind, 2012; this figure is available online at [www.childrenshospital.org/care-coordination-curriculum/care-mapping](http://www.childrenshospital.org/care-coordination-curriculum/care-mapping)).

Finally, for many children, availability of effective treatment may be limited by financial costs, lack of transportation, and poor interface among the administrative systems of medical care, social services, and special education. For example, early intensive behavioral intervention has been shown to benefit children with autism (Peters-Scheffer, Did-den, Korzilius, & Sturmey, 2011) but access to such services varies greatly with income, place of residence, and type of health insurance (Liptak et al., 2008).

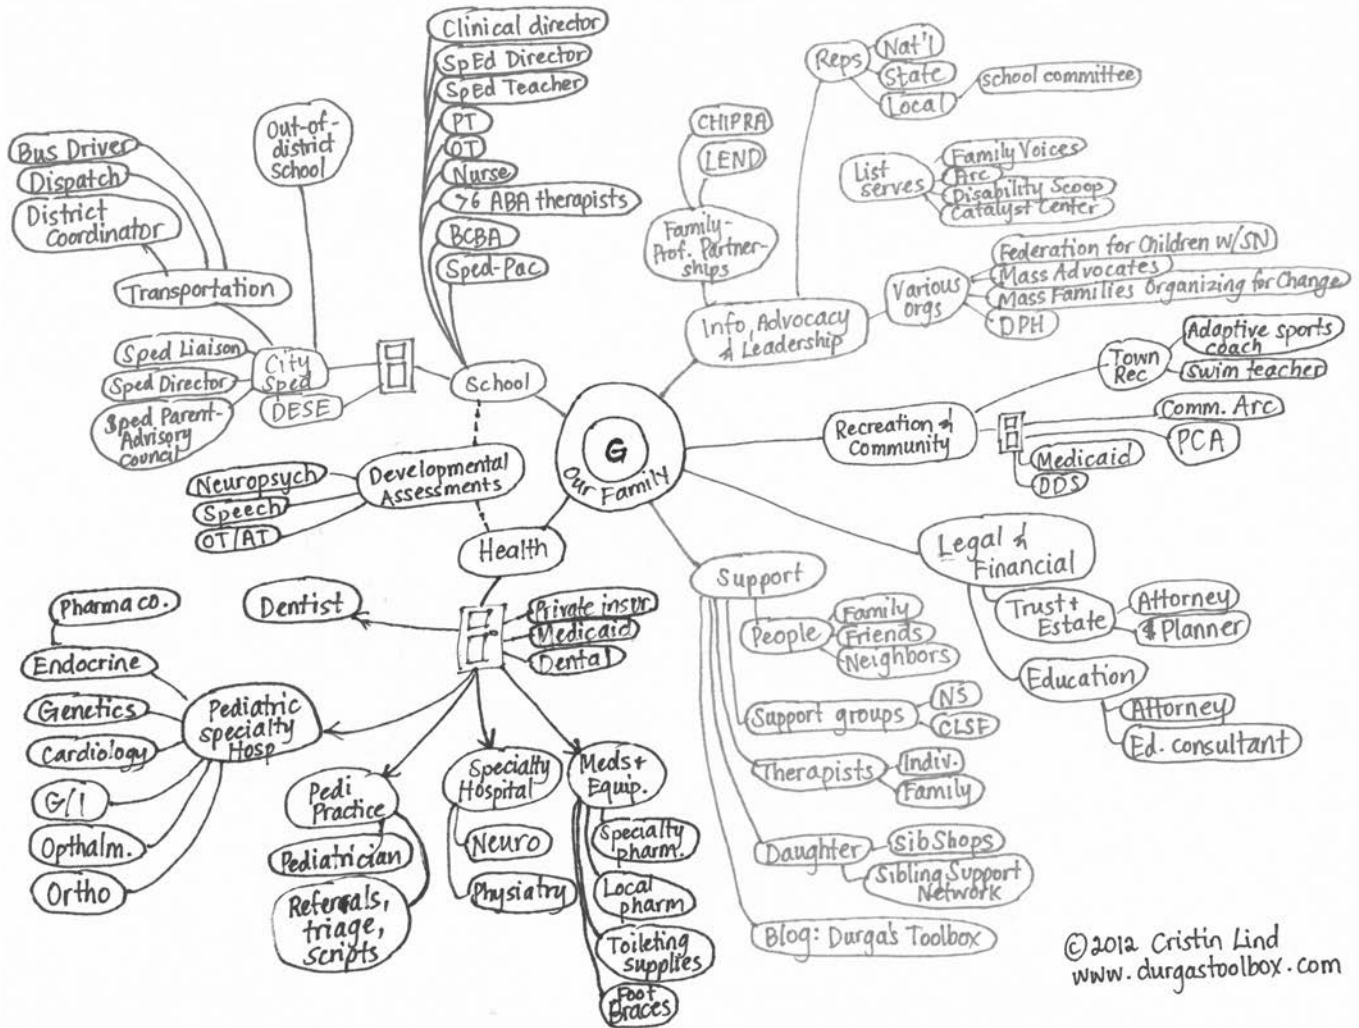

Figure 45.1 Care mapping for a child with autism

## Does CAM Work?

As with any heterogeneous group of treatments, a better question is: which, if any, type of CAM works for which problems in which children? Unfortunately, with the exceptions of treating pain and insomnia, there is no consistent evidence of a lasting, substantial, positive effect of any sort of CAM for behavioral or developmental problems in children of any age with any diagnosis. Several studies report a positive effect of melatonin to help regulate sleep onset (Bendz & Scates, 2010; Levy & Hyman, 2002). Relaxation, hypnosis, and massage are effective in managing pain, at least in the short term (see, for example, Rutten, Kortering, Venmans, Benninga, & Tabbers, 2015), but have not been shown to reduce hyperactivity or autistic symptoms in controlled trials. Zinc supplementation, which is better researched than most other oral supplements, may augment the effects of methylphenidate and help sustain concentration, particularly if children are zinc-deficient (Arnold et al., 2011).

The majority of studies of CAM are so poorly designed as to be uninterpretable. A Cochrane review of effects of acupuncture for children with ADHD concludes the following:

Further well-designed trials are required to confirm or refute its efficacy. Future trials should avoid methodological limitations. In particular, they should include enough participants to detect at least a modest effect; they should ensure adequate concealment of allocation and blinding of participants and outcome assessors; objective and quantifiable tools should be used to assess the short-term outcomes; and participants should be followed up for at least six months to assess the clinically important outcomes.

These conclusions apply to the majority of studies of CAM approaches.

In addition, studies of CAM should specify and measure behavioral targets of intervention more precisely. Recent studies of ADHD treatment outcomes in response to medication and behavioral therapy concluded that changes in symptoms were related to functional, adaptive improvements, but some children showed improved function despite little or no change in clinical symptoms (Karpenko, Owens, Evangelista, & Dodds, 2009).

One of the most interesting things about CAM is that despite widespread negative results and generally discouraging advice from professionals, many parents who use CAM tend to express satisfaction, believe it is helpful, and tell other parents to try it. Perhaps CAM does not actually change the child, but does change the parent, in some meaningful way. Professionals tend to assume that parents simply see what they hope to see, rating improvement unrealistically in its absence. Alternatively, perhaps the perception of “being in treatment” changes parents’ levels of intrusiveness or disengagement, frustration versus patience, anxiety versus acceptance, such that the child

does respond positively to momentary changes in parental behavior, but doesn’t show measureable changes in symptoms or function when observed alone or in school settings, or rated on global measures. If that were true, then there should be observable changes in parent and/or child dyadic interactions when the parent thinks that an effective CAM (or other) treatment has been given, versus when the parent believes the child has had only placebo. This type of study was done using methylphenidate, showing that changes in the child’s impulsivity decreased command/control utterances by the mother, but this sort of approach has not yet been used to study how CAM treatments affect parent-child behavioral interactions.

## What Harm Does CAM Do?

The financial cost of CAM, which can be high, generally is out-of-pocket because few procedures are covered by medical insurance. Therefore, CAM treatments most commonly are accessed by higher income, higher educated families whose children have conditions that are chronic but not life-threatening. Though many people are very credulous about CAM, many also are skeptical about its efficacy, and well aware there is limited evidence of positive outcomes. Some procedures clearly entailed significant risk of harm, which has been publicized in public media. For example, chelation therapy, wrapping or extreme compression of children with autism, “regression therapy,” and use of high-dose megavitamins, have caused serious illness or even death in children and therefore are widely discredited. Some herbal products may be teratogens; may affect breastfeeding infants; or may potentiate, diminish, or conflict with effects of prescribed medications (Buehler, 2007). The consistency, purity, potency, and safety of nutritional supplements, vitamins, and minerals vary and are not regulated (Chan, 2002).

Harm has gradations, however, including costs of time, money, and energy invested in therapies of questionable value, and lost in pursuit of treatments that have a greater likelihood of success. Some treatments (e.g., ABA therapy for autism) may be maximally effective within a particular time window and less effective once that “sensitive period” has passed. Spending hours on scientifically unsupported treatment, such as Sensory Integration Therapy’s “sensory diet” (e.g., joint compression, brushing, swinging, and spinning) may block or restrict the onset, duration, frequency, or intensity of more effective treatments (American Academy of Pediatrics, 2012; Hoehn & Baumeister, 1994; Stephenson & Carter, 2009).

From a public health perspective, an ethical response to the proliferation of CAM providers would include building parents’ health literacy, skills for critical thinking about treatment options, and support for choosing and coordinating care, as well as regulating the quality and safety of CAM options in the same way that mainstream medical options are regulated (Kennedy, Mercer, Mohr, & Huffine, 2002; Nissen et al., 2013).

### What Should Neuropsychologists Consider When Discussing CAM?

Gupta (2010) advises that physicians' communication styles affect parents' trust and willingness to be guided by medical advice about autism treatment:

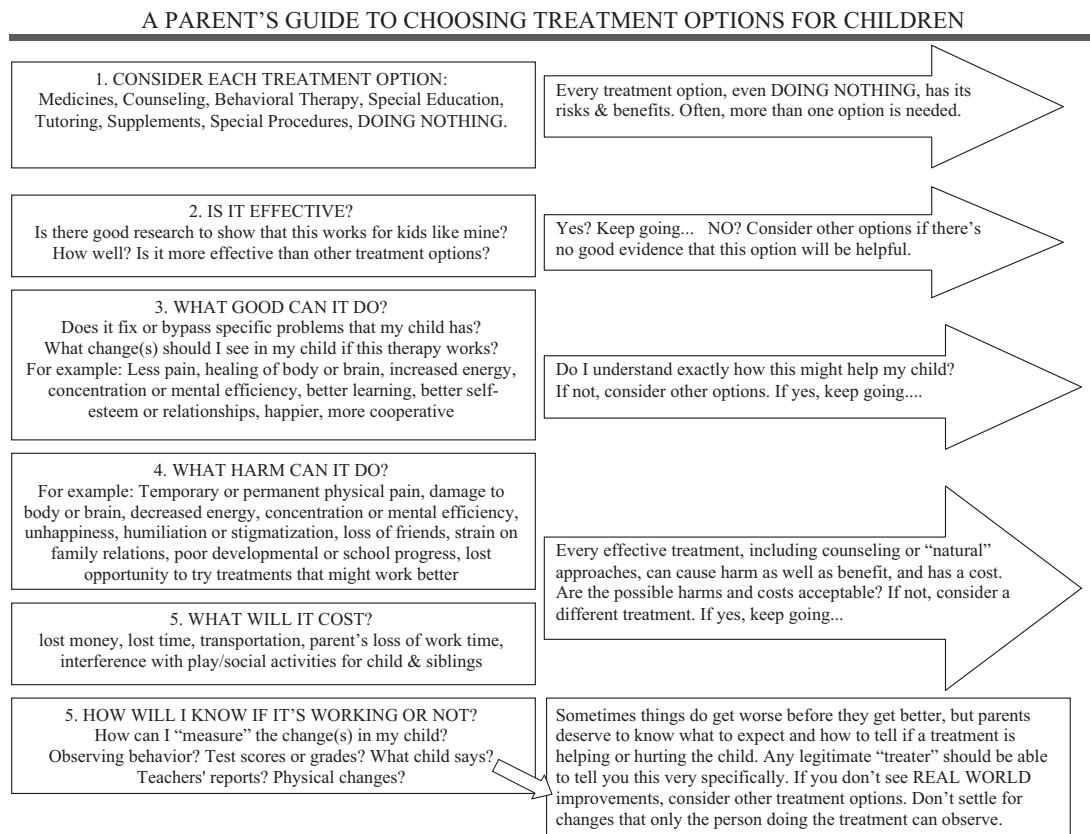

The American Academy on Physician and Patient suggests a mnemonic, PEARLS, for this relationship building: partnership, empathy, apology, respect, legitimization, and support. Acknowledging that you will ride with the family in their predicament, supporting and respecting their views and decisions even if they are at variance with your opinions and suggestions as long they do not harm the child; acknowledging the scientific uncertainty about the cause, management, and outcome of autism; asking parents about their view of their child's condition and their expectations; respecting the parents' view of their child's symptoms and causation, acknowledging their suffering, anger, and frustration and assuring them that you will not abandon them even as they seek solutions that you do not agree with, as long as they do not harm the child. Words should be matched by appropriate nonverbal behavior.

(p. 344)

Pappas and Perlman (2002) suggested those exploring parents' reasons for seeking CAM treatments might help to identify concerns about standard treatments that, once aired,

could be addressed and resolved. Continuing to monitor the child's response to treatment may provide later opportunities to revisit the decision to pursue an unsupported therapy (Bell, Wallace, Chouinard, Shevel, & Racine, 2011).

Advising families about treatment options for behavioral and developmental problems may involve a pediatric psychologist or neuropsychologist in consultation with the child's primary care provider, other specialists, and educators. How can we help parents make an informed choice? Researchers in education and library science have tested different strategies for teaching people how to critically evaluate what they glean from the Internet or television. One approach involves providing a "checklist" of attributes, typically referencing authoritative sources. To review current knowledge about particular CAM approaches, some resources include: The Physician's Desk Reference for Herbal Medications, the National Center for Complementary and Integrative Health (<https://nccam.nih.gov>), Quackwatch ([www.quackwatch.org](http://www.quackwatch.org)), and ConsumerLab.com ([www.consumerlab.com](http://www.consumerlab.com)) (Buehler, 2007). However, "checking the data" may be insufficient to help with health care decision making, since approximately two-thirds of patients find the scientific data irrelevant, as stated in the May issue of *Mayo Clinic Proceedings* (Bardia, 2007). Another approach to assessing media claims is "contextual" (Meola, 2004)—weighing one source of information against others to seek corroboration or disconfirmation. Figure 45.2 outlines an approach that

by Karen E. Wills, Ph.D., Children's Hospitals and Clinics of Minnesota

Figure 45.2 A parents' guide to choosing treatments

may be useful in assisting parents to critically evaluate CAM treatments, by providing them with a set of questions that can be used to evaluate any treatment—including those of mainstream medicine. This approach honors the autonomy of parents to select their own strategies, while responsibly offering information about the risks and benefits of different treatment options.

Rather than evaluating one particular treatment, parents are encouraged to “chuck the checklist” (Meola, 2004) and consider their various options—conventional and CAM treatments—with regard to relative efficacy, benefit, harm, costs (in money, time, effort, and lost opportunities), desired effects, and measured outcomes. Processing this information with a parent may fulfill some functions that may make CAM attractive, namely, listening to and identifying what is bothering the parent, defining specific targets of intervention according to the family’s needs as well as the child’s condition, and considering emotional well-being and functional capabilities as well as clinical symptoms and disabilities (Karpenko et al., 2009; Pappas & Perlman, 2002).

# 46 Psychotherapy and the Practice of Clinical Neuropsychology

George P. Prigatano

## Introduction

In the first edition of this book, this chapter focused on neuropsychological rehabilitation and the role psychodynamic psychotherapy can play in facilitating a positive rehabilitation outcome (Prigatano, 2008). Since that time, several other clinical neuropsychologists have discussed the role of psychotherapy in the care of brain-dysfunctional patients (e.g., Klonoff, 2010; Laaksonen & Ranta, 2013; Ruff & Chester, 2014). Providing effective psychotherapeutic interventions for patients is an important clinical skill that will help maintain the viability of our profession in the present health care marketplace (Prigatano & Morrone-Strupinsky, 2010). Approximately three-fourths of practicing clinical neuropsychologists have their doctorate degree in clinical psychology (Sweet, Meyer, Nelson, & Moberg, 2011) and therefore are indeed in a unique position to provide such services. This chapter attempts to broaden the discussion of the role that psychotherapy may play in the general practice of clinical neuropsychology, where the emphasis is primarily on neuropsychological assessment and secondarily on providing individual psychotherapy for patients who might benefit from such services. It reviews empirical findings and presents case vignettes that illustrate the potential value of psychotherapy (in its different formats) to help reduce depression after stroke as well as to lessen anxiety and depression in patients with multiple sclerosis (MS). It also discusses common issues encountered when attempting to provide psychotherapy for patients who have a reduced awareness of their neuropsychological disturbances following severe traumatic brain injury (TBI). This chapter does not provide an extensive review of the literature on psychotherapy with brain dysfunctional patients or their family members.

## A Definition of Psychotherapy

Psychotherapy is an intensely personal dialogue between two individuals that results in a working (or therapeutic) relationship in which one person (the therapist) attempts to help another (the patient or client) cope with a personal problem or problems the latter individual seems to have difficulty managing on his or her own. The personal problem(s)

may clearly vary, but often centers on some type of emotional disturbance or severe dissatisfaction with life. Coetzer (2007) has emphasized that many patients with a brain disorder struggle with feelings of loss and grief. Klonoff (2010) has emphasized the need of patients to be realistic about their neuropsychological disturbance and acceptant of those changes. Salas, Vaughan, Shanker, and Turnbull (2013) point out there is a complicated interaction between the cognitive and emotional deficits/changes that a patient experiences. This issue has to be addressed when working with brain dysfunctional patients from a psychotherapeutic perspective. Judd and Wilson (2005) have made a similar point when using the term *neuropsychotherapy* for brain dysfunctional patients (also see the work of Laaksonen & Ranta, 2013). Whatever the personal struggles are for a given patient, ultimately his or her emotional/motivational disturbance frequently interfere with establishing and maintaining mutually satisfying interpersonal relationships. They also can affect multiple domains of functioning include sleep, appetite, automatic control of bodily functions (such as the ability to maintain consciousness in patients with psychogenic seizures or involuntary movements in patients with psychogenic motor disorders), sexual activity, socially appropriate management of angry or aggressive feelings, and the capacity to remain productive (e.g., work) at a level appropriate to the person's abilities throughout the life cycle. They disrupt the person's sense of meaning to his or her life and deprive the person of an inner peace and sense of joy from living (Prigatano, 1991).

For psychotherapeutic dialogue to be successful, the therapist needs professional training in understanding the nature of the patient's personal struggles as well as his or her neuropsychological strengths and limitations. The therapist must have the capacity to form a therapeutic relationship and skill at guiding this learning process. Finally, the therapist must have the time and willingness to help the patient. The patient (or client) needs the financial resources to pay for this service, adequate cognitive and emotional/motivational skills to learn from the dialogue, and the willingness to "face the truths" in his or her life.

This learning process can be approached in different ways. Helping patients understand how certain thoughts and feelings aid or hinder their adjustment to their personal

problems is crucial. Thus, different forms or approaches to psychotherapy have appeared over the years.

### **Data on the Efficacy of Psychotherapy for Persons Without Brain Disorders**

Before attempting a discussion of whether or not psychotherapy can help brain dysfunctional patients, the broader question of whether psychotherapy can help non-brain-dysfunctional individuals' needs to be considered. Several review papers have documented the potential value of cognitive behavioral therapy (CBT) for treatment of a depression and anxiety in non-brain-dysfunctional patients (Beltman, Oude Voshaar, & Speckens, 2010; Covin, Ouimet, Seeds, & Dozois, 2008; Gould, Coulson, & Howard, 2012; Hofmann & Smits, 2008; Jakobsen, Hansen, Storebo, Simonsen, & Glud, 2011; Mitte, 2005; Spek et al., 2007; Stewart & Chambless, 2009). This form of psychotherapy is presently quite popular and has been applied to various patient groups. Psychodynamic psychotherapy is often seen as less effective and clearly not cost-effective. There is a common misconception that there is a lack of empirical support for this form of psychotherapy.

In an extremely useful and frequently cited review paper, Shedler (2010) presents convincing evidence for the efficacy of psychodynamic psychotherapy. He notes that many of the features of CBT are actually based on psychodynamic approaches to psychotherapy. This may contribute to both forms of psychological treatment being useful in reducing anxiety and depression in non-brain-dysfunctional individuals. They include the establishment of a good working or therapeutic alliance and having the patient experience how emotions can influence the thinking process and vice versa. Both forms of therapy note that the patient's enhanced awareness of how implicit feelings and beliefs (i.e., meanings) greatly influence behavior and mood can contribute to a good treatment outcome.

An important observation of Shedler (2010) that is relevant to the psychological care of brain-dysfunctional individuals is that: "The goals of psychodynamic therapy include, but extend beyond, symptom remission. Successful treatment should not only relieve symptoms (i.e., get rid of something), but also foster the positive presence of psychological capacities and resources" (p.100). This is often the goal when helping individuals adjust to the permanent effects of brain disorder.

Shedler's (2010) meta-analytic review notes a consistent trend in which psychodynamic therapy with non-brain-dysfunctional patients leads to continue improved psychological adjustment after therapy has ended. Under what conditions this may be accomplished when working with patients with brain disorders is an important question that clinical neuropsychologists, who are trained in psychodynamic psychotherapy, may well help to answer in the future.

Finally, Shedler (2010) notes that various meta-analyses reveal that the overall effect sizes of psychotherapy for treating depression can be substantial. It is not uncommon to demonstrate a size effect of 0.73 (see Robinson, Berman, & Neimeyer, 1990). In contrast, "the overall mean effect size for antidepressant medications approved by the FDA between 1987 and 2004 was 0.31" (Turner, Matthews, Linardatos, Tell, and Rosenthal, 2008, p. 100). These observations should help clinical neuropsychologists who want evidence-based treatments to seriously consider the potential role of psychodynamic psychotherapy, as well as CBTs when helping their patients with symptom relief and improving their long-term adjustment to neuropsychological consequences of their brain disorder.

### **Neuropsychological Assessment and the Beginnings of a Psychotherapeutic Dialogue**

In the course of interviewing patients and conducting clinical neuropsychological examinations, patients often reveal their personal concerns and emotional reactions to their neuropsychological disturbances. If the examining clinical neuropsychologist shows an interest in them and not just the patient's test scores, the professional relationship is enhanced (Prigatano, 1999a). Within the confines of that relationship, the patient and/or family may directly or indirectly express a need for psychotherapeutic consultation to help them deal with the neuropsychological disturbances in everyday life.

Repeatedly, patients report increased irritability, anxiety, and depression as they attempt to cope with their cognitive limitations (e.g., Sherer & Sander, 2014). After the neuropsychological examination is completed, it is not uncommon for patients (or family members) to ask what can be done to improve their cognitive status and reduce emotional distress. Depending on the extent of their cognitive impairments and degree of impaired "executive functions or ego functions," different forms of psychological interventions may be attempted (Prigatano, 2016). If a patient has adequate impulsive control and a basic capacity and willingness to observe and understand his or her own cognitions, feelings, and behavior, then psychotherapy should be attempted by the clinical neuropsychologist, who understands the patient's brain-behavior difficulties and has a willingness and professional training to help the patient improve his or her psychological adjustment to the effects of the brain disorder. This requires time, patience, and clinical skill on the part of the clinical neuropsychologist.

### **Depression and Psychotherapy After Cerebral Vascular Accident (or Stroke)**

Clinically defined depression is common after stroke (Robinson, 2003). Prevalence rates vary depending on the measurement techniques and the time of assessment following stroke.

Estimates of major depressive disorder are in the range of 20%, while estimates of minor depression range from 9% to 18%. During the acute phases following stroke (i.e., one to two months), left frontal and left basal ganglia lesions are frequently observed in severely depressed individuals (Starkstein & Robinson, 1993) Prolonged depression, several months or years poststroke, is associated with multiple factors. They include a history of previous psychiatric disorder as well as dependence in activities of daily living (Robertson, 1997).

Literature reviews (e.g., Eldred & Sykes, 2008) frequently report that various forms of psychosocial support for the patient with a stroke and family caregivers helps improve psychological health, which includes reducing depression. The nature of “effective interventions,” however, is often not clearly specified, which is understandable giving this diverse patient population.

The most recent Cochrane review on “Interventions for treating depression after stroke” (Hackett, Anderson, House, & Xia, 2008) concluded:

There was some evidence of benefit of pharmacotherapy in terms of complete remission of depression and a reduction (improvement) in scores on depression rating scales, but there was also evidence of an associated increase in adverse events. There was no evidence of benefit of psychotherapy.

(p.1)

The last conclusion was rather surprising in light of the clinical experience of psychotherapists that depression can be reduced via psychotherapy (e.g., Robinson et al., 1990). A close reading of this Cochrane review highlights some important methodological limitations that can be easily glossed over if one is not an experienced psychotherapist.

Hackett et al. (2008) limited their review to randomized controlled trials only (RCTs) and had rather strict exclusion criteria. Consequently, only three clinical trials were evaluated regarding the impact of psychotherapy on depression. Four studies, however, were reviewed. While the sample size of 445 patients was relatively impressive, the studies that Hackett and colleagues cite were not. One study was described as offering a counseling approach to problem solving conducted by social workers. A second study was described as a structured CBT program offered by nurses. A third study was on motivational interviewing that was “delivered by nurses and non-clinical psychologists” (p. 8). The fourth study was described as “a supportive psychological intervention including education delivery by special personnel” (p. 8).

Most experienced psychotherapists would hardly consider this a test of the efficacy of psychotherapy for depression after stroke. Too often such reviews (which can be quite influential from an academic and insurance coverage point of view) focus on strict methodology, without fully understanding the

phenomena that is being studied or reported to being studied (see Prigatano, 1999b). Consequently, erroneous conclusions can be put forward which are damaging to patient care.

What is actually involved in the psychotherapy of patients who suffer some form of intracranial hemorrhage? First, a careful assessment of lesion type, location, and resultant neurocognitive and neuroaffective disorders is necessary. Second, the acuteness of the patient's clinical condition is considered before deciding on whether some form of psychotherapy is warrant. Acute and severely aphasic patients following left hemisphere stroke or acute confusional patients with hemineglect or anosognosia following right hemisphere (AHP) stroke should be made comfortable, but attempts at psychotherapeutic interventions would seem premature. As patients recover and start to communicate about their clinical condition, depression can then be assessed. This can be done through an interview or having the patient complete various brief questionnaires concerning behavior, mood, and thought patterns.

Dialogue with the patient and the family is aimed at providing supportive diagnostic and at times prognostic information in the hopes of developing a therapeutic or working alliance. Once a trusting relationship is established, then gentle probes regarding how one might best help the person (and family members) fully engage rehabilitation activities and reduce the potential adverse effects of severe depression on recovery and social interactions are considered. This is a highly individual process that keeps in mind the patient's age, educational level, occupational history, psychiatric history, gender, cultural and religious values, aspirations in life, and traditional methods of coping with loss or tragedy in life. While these are variables that any experienced psychotherapist would consider, other important variables need to be assessed and worked into a treatment plan.

An understanding of the direct and indirect effects of a brain disorder for a given patient is crucial (Goldstein, 1952; Prigatano, 1999a). Helping the patient make adaptive choices in face of permanent neuropsychological deficits is perhaps one of the most useful services that a clinical neuropsychologist can provide, especially during the postacute and chronic phases following a brain disorder (as Goldstein, 1952 noted several years ago). Educating the patient regarding the effects of a stroke on certain higher integrative brain functions is crucial in this regard. If the patient does not know “what is wrong,” he or she cannot take steps to cope with impairments. Likewise, the clinical neuropsychologist, if properly trained in psychotherapy, can help patients made adaptive choices that restore, in part, their sense of dignity as they relate to key family members (see Prigatano, 2011a). Finally, the treating psychotherapist needs to be clinically sensible, as well as clinically sensitive (see Prigatano, 1999a). Considerations as to where in life a patient is, what his or her psychosocial situation consists of, what his or her premorbid psychological adjustment history was like, and the extent of

present neuropsychological strengths and limitations, must guide any attempt at psychotherapeutic interventions. There is no easy formula for guiding the psychotherapy process with different patients. The first goal, of course, is to do no harm to patients, followed by the goal of helping them cope with the effects of a brain injury in light of the variables noted above. The clinical neuropsychologist must be able to draw on large bodies of knowledge found in clinical psychology and psychiatry when attempting this work (Prigatano, 2011b).

Research on psychotherapy for depression after right and left hemisphere stroke should continue to clarify how to best describe the specific and general effects of such lesions on the patient's mood, behavior and cognitive capacities. Such studies are needed before global studies on its effectiveness of psychotherapy can be meaningfully assessed. Specific case examples provide clues on how to best treat these patients from a psychotherapeutic perspective.

Pinhasi-Vittorio (2007) eloquently describes work with an aphasic patient that reflects the confusion and frustration of many aphasic individuals. When the patient came to the point of wanting to give up on a therapeutic exercise because he felt so incompetent, the therapist recalled Luria's (1972) book, *Man with a Shattered World*. She asked the patient to write ten to 20 minutes each day because writing consisted of "kinetic melodies" that may facilitate the recovery of certain aspects of language. The patient did this and it was a "turning point" in helping him. He now wrote poetry that conveyed his authentic experiences (not just a boring speech and language exercise). As a result, he became more "proactive in his healing process" (Pinhasi-Vittorio, 2007, p. 118). This is a realistic description of how a psychotherapeutic experience (provided by linguist/therapist) with an aphasic patient makes a real difference in that patient's life.

Patients with right hemisphere lesions often have adequate language function, but can suffer with ill-defined visual spatial deficits that impact their lives in unpredictable fashions and can lead to significant depression. Several years ago, a 33-year-old woman was referred to me for treatment of depression. She was approximately three years post a ruptured arteriovenous malformation (AVM) involving the right parietal lobe. To my surprise, she was a physician, but she did not refer to herself as a doctor. She stopped using the MD initials after her name and now worked as a statistician in a hospital.

She never received a neuropsychological examination after surgical resection of her AVM. She attempted to return to her residency program in radiology after she made an apparently good neurological recovery. She was not knowledgeable about why she had difficulty perceiving different "shadows" on the imaging films and consequently left her residency program because she could not meet academic requirements.

She was understandably very depressed because her one aspiration in life was to be a doctor.

Her psychotherapy brought to light the importance of Freudian and Jungian ideas when helping brain dysfunctional patients cope with their personal losses (e.g., the phenomena of transference, the relationship between anger and depression, and the underlying and at times unconscious motivations to pursue certain careers). Moreover, her dreams and poetry revealed all of the frustrations and psychodynamics of not living up to one's personal aspirations in life. In the context of dealing with her anger toward life and resultant depression, a therapeutic "turning point" also occurred for her. I want to emphasize this turning point occurred only after a strong therapeutic alliance was established as a result of intensive discussions regarding multiple feelings she had toward me, her husband, and her parents. The patient struggled about whether she should return to some practice of medicine or not, given that she could not be a radiologist.

In the course of psychotherapeutic dialogue, it came up that the patient loved golf. I asked the patient the following question: Suppose you were playing professional golf and found that after attempting to hit the ball, you miss it after several swings. This occurred daily after your intracranial hemorrhage and your doctor's release to go back to playing. Angered and embarrassed you are faced with an existential question: Should you leave the game (i.e., the aspiration to be a radiologist) or play miniature golf on the weekends with friends (be a doctor in a substantially reduced capacity) since you love the "game" so much.

She chose to work for an insurance company conducting histories and physicals. She enjoyed patient care (it gave her a sense of meaning in life) and as a consequence her depression slowly resolved into predictable human sadness over a major loss in life. Her neuropsychological rehabilitation was successful in large part due to the impact of psychotherapy.

These two case vignettes highlight the notion that understanding the patients' cognitive deficits (the direct effect of a brain injury) and their personality prior to their brain disorder can substantially help reduce their reactionary depression (an indirect effect of a brain lesion). Note these patients had posterior brain lesions not directly affecting frontal mediated cognitive processes.

### **Multiple Sclerosis, Anxiety, and Depression**

MS is a common neurological disorder that results in demyelination of axons and the formulation of sclerotic plaques. The neurocognitive impairments include decreased speed of information processing and problem solving, impaired verbal and visuospatial learning, and a reduction in working

memory (Thornton & DeFreitas, 2009). Emotional disturbances are also common, especially depression. Feinstein (2011) suggests that significant depression can affect up to 50% of patients with MS. Anxiety is also very common in depressed MS patients (Burns, Siddique, Fokuo, & Mohr, 2010).

A Cochrane review (Thomas, Thomas, Hillier, Galvin, & Baker, 2006) cautiously recommended that various sources of psychological interventions potentially could help MS patients with their anxiety and depression. They specially noted that the variable and unpredictable nature of symptoms could certainly increase the psychological distress level of patients.

Brief relaxation training has been showed to reduce anxiety in MS patients (Artemiadis et al., 2012). Small group exercises to help MS patients maintain an active life style also appear to be of help (Nordin & Rorsman, 2012). Grossman et al. (2010), in a randomized trial, demonstrated that mindfulness-based intervention improved not only the quality of life of MS patients, but resulted in substantial declines in depression, anxiety, and fatigue.

In a recent randomized trial, MS patients were taught behavioral stress management therapies to improve their coping skills (Mohr et al., 2012). Participants who received such training not only reported a reduction in their stress levels, but also their magnetic resonance imaging (MRI) scans of the brain revealed fewer new gadolinium-enhancing lesions. The effect was present only when actually receiving the therapies. While the effect did not sustain itself after the therapies were concluded, the findings suggest a very interesting possibility. Not only do the patients feel better during their time of their psychological treatment, but fewer lesions develop during this time. Sustained efforts at treatment may prove clinically helpful for some individuals.

While sustained efforts at cognitive behavioral strategies may be very helpful, also helping the individuals understand how their approach to life (i.e., their basic psychodynamics) may aid or hinder their adjustment to MS should be seriously considered. For example, a 32-year-old professional man who was diagnosed as having MS was constantly fatigued. His wife had very unrealistic expectations of what she considered he should do at home despite his MS and associated fatigue. Given his dependence on maternal approval (which was only partly recognized by him), it was very difficult for him to set appropriate boundaries with his wife. His fatigue worsened as did his depression. These realities are seldom discussed when evaluating the effectiveness of psychotherapy in helping MS patients. Individual psychodynamic insights do not lend themselves to randomized control studies. Yet, they may be crucial ingredients to the effectiveness of psychotherapeutic interventions.

In the early 1970s, I was asked to examine a 50-year-old male who had been diagnosed as having MS for at least ten

years. He was now complaining of memory difficulties. At that time, many neurologists did not believe that MS patients should have memory difficulties. Using the old Wechsler Memory Scale, I demonstrated to the patient and his neurologist that he indeed had memory difficulties relative to his intelligence. Also, during that time in my career, I administered the Rorschach. When I got to Card VIII, he refused to offer any response to this card. He turned it over and asked to see the next card.

After the neurologist got my neuropsychological report, he acknowledged to the patient that indeed the patient did have memory difficulties. The patient felt vindicated in his complaints and asked to see me again. He wanted to know if I could help him with his depression and anger over having MS. We begin talking in weekly psychotherapy sessions about his life. He told me some general facts about his childhood and why he choose to be an engineer. With time he also spoke about how he often was uncomfortable with women, but eventually married his wife of some 30 years.

In conjoint sessions with his wife, she talked about her husband getting very angry, very quickly over what appeared to be slight frustrations in life. After several other individual sessions with this patient, he asked me to pull out the Rorschach cards and specially show him Card VIII. He then gave me his perceptions of what the card looked like to him and stated that when he looked at this card he was reminded of his mother. As an adolescent boy his mother would approach him in a negligee and ask him to rub her back. He was both sexually excited and scared by these repeated experiences. This always occurred when his father was not home. He did not want to be alone with his mother (and now knew why he probably was uncomfortable as a man when being alone with women). This is a prime example frequently observed in psychodynamic psychotherapy. The goal is not to simply focus on the past, but to understand how the past sheds light on current psychological difficulties (see Shedler, 2010).

With the help of psychotherapy, he began to be less angry and less frightened about his disease. He accepted his wife's help with his physical limitations and could also accept he could no longer function as an engineer in light of his memory difficulties. He experienced a certain internal peace of mind and his anger was substantially reduced.

While both of these MS patients had diffuse white matter lesions, their "executive" or "ego" functions remained intact. Clinically, this seemed to help them reflect on the psychotherapeutic dialogue and benefit from discussions about how previous relationships, recurring themes in their life, and how powerful emotions that they did not seem to fully understand influenced their behavior in a maladaptive fashion. These are key topics frequently discussed in psychodynamic psychotherapy (Shedler, 2010).

## Denial/Unawareness of Impaired Neuropsychological Functioning after Severe Traumatic Brain Injury

Early efforts at neuropsychological rehabilitation of patients with moderate to severe TBI noted the importance of impaired self-awareness (ISA) as a deterrent to successful outcomes, particularly the ability to maintain gainful employment (Prigatano et al., 1984). Subsequent and recent reviews have also identified ISA in TBI patients as an important predictor of rehabilitation outcome (see Sherer & Sander, 2014). Sherer and Fleming (2014) provide a comprehensive review of various treatment approaches to improve self-awareness after TBI. Psychotherapy is considered as one possible alternative, and they provide a case example of how it might be approached.

A key issue when providing psychotherapy for patients with moderate or severe TBI who show poor self-awareness of their residual neuropsychological disturbances, is obtaining a realistic understanding of what is causing their apparent lack of awareness. In some instances, significant frontal contusions in the presence of diffuse axonal injury seem to underlie the disturbances. These patients often show many neuropsychological signs of severe executive dysfunction. In other instances, the picture is more complex. The patient may show not only signs of “organically” based ISA, but behave in a manner suggestive of denial of disability (see Prigatano & Klonoff, 1997; Prigatano, 2014). The psychotherapeutic approach to patients with these two conditions can be different.

In the former case in which significant executive dysfunction is present, traditional forms of psychodynamic therapy may not be especially helpful, as noted in our early work (Prigatano, Fordyce, Roueche, Pepping, & Wood, 1986) and as recently emphasized by Ben-Yishay and Diller (2016). These patients present with significant disturbances in what psychodynamic therapists refer to as “ego-functions” and what Goldstein (1952) referred to as disturbance in the “abstract attitude.” These patients may have a difficult time introspecting and understanding how past relationships with significant others may influence their behavior in the present. More importantly, their behavioral and associated emotional and motivation

reactions may be a direct effect of severe bilateral frontal-temporal lobe damage (not psychodynamic conflicts). Thus, their behavioral and personal adjustment issues may be best treated by providing them carefully constructed feedback concerning their behaviors (particularly within the context of a milieu rehabilitation program) in a manner they can “concretely” understand (see Ben-Yishay & Diller, 2016). Within the context of a therapeutic environment, they can be taught specific methods of copy that result in improved social integration and adjustment. They do require, however, a therapist who can deal with the broader issues of establishing meaning in life despite their severe cognitive impairments (see Prigatano, 1999a). Table 46.1 summarizes key components when attempting psychotherapy with this group of patients.

Patients with less severe brain injuries and more intact ego-functions, however, potentially may benefit from traditional forms of psychotherapy, including psychodynamic-oriented psychotherapy. This appears to be especially true when the problem is mediated more by psychological denial than severe ISA. One example is that of a young man who had a moderate TBI and who refused to admit to any substantial cognitive difficulties. He was frequently belligerent and argued that whatever difficulties he had performing neuropsychological tests were irrelevant or existed prior to his injury. He showed many of the behaviors that Klonoff and Lage (1991) described as “narcissistic injuries.” Helping him face his tendency for risk taking and propensity to engage in addictive behaviors slowly resulted in his acknowledging that his memory was indeed compromised. After several years of psychotherapy, he began to make more adaptive choices regarding work and interpersonal relationships. These types of patients are perhaps the most difficult to treat, but helping them understand the psychological basis of their denial is crucial for a successful outcome. Working closely with a psychiatrist who can provide psychotropic mediations as needed is also very important when working with these individuals.

Table 46.2 provides some guidelines when attempting psychodynamic psychotherapy with brain-dysfunctional patients who have relatively intact ego or executive functions.

*Table 46.1* Suggestions for conducting psychotherapy after brain injury when there has been significant disruption of higher integrative brain functions and patient requires a holistic, milieu-oriented neuropsychological rehabilitation program (adapted from Prigatano et al., 1986)

- 1 Provide a model or models that help the patient understand what has happened to him or her.
- 2 Help the patient deal with the meaning of the brain injury in his or her life.
- 3 Help the patient achieve a sense of self-acceptance and forgiveness for himself or herself and others who may have caused the accident.
- 4 Help the patient make realistic commitments to work and interpersonal relations.
- 5 Teach the patient how to behave in different social situations (to improve competence).
- 6 Provide specific behavioral strategies for compensating for neuropsychological deficits.
- 7 Foster a sense of realistic hope.

Table 46.2 General considerations relevant to successful psychotherapy with persons who have a brain injury, but relatively preserved executive or ego functions

- 1 The psychotherapist should help the patient understand “basic facts” about all human beings and how they apply their particular background and psychodynamics (Prigatano, 2011b) (e.g., the role of sex and aggression in animal and human behavior; the struggle to find meaning in life; parental influences in forming social attitudes and choices of a partner and work preferences, etc.)
- 2 The psychotherapist must understand the nature of the patient’s neuropsychological strengths and limitations and focus the psychotherapeutic dialogue in a manner that is understandable to him or her (Prigatano, 2012).
- 3 The patient’s life history should be explored and the psychotherapist should encourage introspection on the patient’s part as to what has most influenced his or her behavior, thought processes, decisions in life, and methods of coping with adversity.
- 4 The psychotherapist should gently point out or make explicit how recurring themes/perceptions in the patient’s life have helped him or her to adapt to certain situations or conversely resulted in repeated poor adaptations with increased anxiety, depression, and/or anger. This should be done in an empathetic, nonjudgmental fashion.
- 5 The psychotherapist should listen carefully to what the patient says about him- or herself and restate it back in a manner that allows them “to hear” what exactly he or she is saying (i.e., experiencing) (Rogers, 1961; Prigatano, 2011b). This often helps the patient consciously experience ambivalent or even contradictory subjective feeling states.
- 6 The psychotherapist must understand the important symbols that guide a given patient’s life before and after brain injury and use those symbols (including metaphors) to help the patient cope with his or her daily problems and adjust to the long-term effects of the brain injuries (Prigatano, 1999a, 2012).
- 7 The psychotherapist should encourage the patient to discuss dreams that come up at certain points in the psychotherapy and what they may mean as he or she faces different issues/problems in the “here and now.”
- 8 The psychotherapist should encourage the patient to use various art forms (writing poetry, storytelling, painting, drawings, etc.) to help clarify his or her subjective experience. The patient’s favorite songs and fairy tales provide rich insights into core features of the patient’s personality that the patient may not be able to verbally identify.
- 9 The psychotherapist should encourage the patient to view anxiety and depression as behavioral reactions to life’s problems. Since life always presents problems, anxiety and depression will never go away, but they can be reduced as the patient better understands themselves and what is the best plan of action for them when dealing with their struggles in life.
- 10 The psychotherapist should help the patient remain as productive as possible and work at establishing and maintaining love relationships. This has to be done with a full recognition of the individuality of the patient and his or her long-term struggle to deal with their sense of “lost normality” (Prigatano, 1991, 1999a).

### The Strength and Limitation of the Therapeutic Alliance in Psychotherapy

While the therapeutic alliance is clearly an important component to various forms of psychotherapy, it is crucial to recognize it is often not a sufficient condition to produce meaningful change in the patient’s life. This error is frequently made and is reflected in the title of Schofield’s (1964) book: *Psychotherapy: The Purchase of Friendship*. For example, a strong therapeutic alliance does relate to work productivity after neuropsychological rehabilitation (Prigatano et al., 1994; Klonoff, Lamb, & Henderson, 2001), but not necessarily to job satisfaction (Lustig, Strauser, Weems, Donnell, & Smith, 2003). Job and interpersonal satisfaction often requires the patient to have greater insight into his or her motivations, past and present.

Martin, Garske, and Davis (2000) define the therapeutic alliance “as the collaborative and affective bond between therapist and patient” (p. 438). Their meta-analytic review on the role of the therapeutic alliance on treatment outcome is informative. First, there are many scales for measuring the therapeutic alliance, and the reliability of these scales is good (average reliability was 0.79 based on 93 reliability indices). It is a “real” phenomenon that can be consistently measured. Second, and most importantly, Martin et al. (2000) reports a conservative estimate of the effect size on psychotherapeutic outcome to be 0.22 when reviewing 79 studies. They

emphasize that this is a conservative estimate because of the heterogeneity of the study samples. They conclude that the therapeutic alliance has moderate—not mild or minor—effect on treatment outcome. This has been my clinical experience as well. The therapeutic alliance is a necessary, but not sufficient condition for successful psychotherapy outcomes in many patient groups, including those with brain disorders. Successful psychotherapy with brain-dysfunctional patients requires a broad knowledge of learning theory and practices, the biological basis of behavior (and cognition), psychodynamic theory in its psychoanalytic and analytic forms (Prigatano, 2012), and an appreciation of how a particular patient’s developmental and cultural history influences his or her view of life and what makes it meaningful or meaningless (Prigatano, 2011a). Insight—yoked with practical suggestions for behavioral changes—is often necessary for meaningful emotional/motivational change. In this latter regard, patients must have the desire, and the cognitive and behavioral skills, to implement change given the support and the relationship they experience with their psychotherapist.

### Summary Observations and Conclusions

Clinical neuropsychologists, who have expert knowledge regarding brain-behavior relationships, are in a unique position to provide psychotherapy services for some of their assessment patients. The neuropsychological examination

provides a unique opportunity to provide feedback to patients (and their family members) that helps clarify the cognitive, behavioral, and affective disturbances that are directly or indirectly related to a known or suspected underlying brain disorder. This process fosters an initial sense of trust and understanding that is crucial to begin psychotherapeutic dialogue. This chapter attempts to highlight how this may proceed when working with the problems of depression after stroke; the depression and anxiety associated with MS; and the complex disturbances of ISA and denial of disability often encountered in persons who have a history of severe TBI. There are also many other brain-dysfunctional patient groups that could also benefit from psychotherapy that are not considered in this chapter. The major point of this chapter, however, is that if the clinical neuropsychologist has training in various forms of psychotherapy, and the time and patience to work with these patients, the process of providing psychotherapy for brain-dysfunctional patients can be an extremely important and rewarding professional activity (Klonoff, 2010; Laaksonen & Ranta, 2013; Ruff & Chester, 2014). It requires, however, that the clinical neuropsychologist has adequate skill and knowledge to understand the patient's subjective experiences that fuel anxiety and depression. It also requires the clinical neuropsychologist to understand how patients' psychological development and present neuropsychological status must be considered when talking to them and guiding them when dealing with their life's problems and decisions.

# 47 Mindfulness-Based Interventions in Neuropsychology

*Patricia M. Arenth*

## Introduction

The aim of this chapter is to discuss the developing literature regarding mindfulness meditation as it relates to the field of neuropsychology. The research literature in the field of mindfulness study has grown exponentially in the past 20 years. In fact, based on citations in a recently formed database of the published literature (Black, 2010; American Mindfulness Research Association, <https://goamra.org/>), after the first listed publication of mindfulness meditation in 1966, 17 additional publications are recorded during the 1970s, with increased rates of publications beginning in the 1980s and continued acceleration to the present. Currently, updates to the database are occurring monthly at a rate of approximately 50 new studies per month. As a result of the breadth and high volume, a full review of the mindfulness literature is beyond the scope of this chapter. It should be noted, however, that in comparison to other fields of study, the scientific study of mindfulness is still relatively young. That stated, the emerging findings suggest that mindfulness-based interventions (MBIs) have the potential to positively impact multiple aspects of emotional, behavioral, biological, and neuropsychological functioning in ways that may be of benefit to individuals with many of the diagnoses discussed in the other chapters of this book. As a result, the review and discussion in this chapter will focus on the potential utility of these types of practices for the rehabilitation and training of individuals with neurologically based injuries and illnesses. While globally, the literature in this area should be considered preliminary, with more rigorous study needed, the employment of mindfulness training with clinical groups may prove to offer neuropsychologists tools with which to train patients and clients in methods with broad, as well as targeted benefits, which are nonpharmaceutical, and which can be taught at relatively low cost in a group setting. Most importantly, these skills, once learned, can potentially be used by patients and clients for positive self-care in the long-term.

## Defining Meditation

In the broad sense, meditation has been present, in many forms and across world cultures and religions, for thousands of years. While meditation is most commonly associated

with Eastern cultures, it could be asserted that even some denominations of Western Christianity include meditation practices in certain forms of contemplative prayer. As a result of this broad use of the term *meditation*, there have been challenges in attaining a consensus definition for the purposes of scientific study. In an effort to do so, the Agency for Healthcare Research and Quality ([www.ahrq.gov](http://www.ahrq.gov)) proposed a definition that includes three essential principles (Ospina et al., 2008): (a) a defined technique allowing for a describable set of instructions for practice; (b) an element described as “logic relaxation,” meaning that there is a lack of intent to make judgments, create expectations, or analyze the practice itself; and (c) a self-induced state or mode, indicating that a person is not under the direct instruction of another person (i.e., as in hypnosis). This definition was later modified further (Goyal et al., 2014) to differentiate forms of meditation during which one remains stationary (i.e., transcendental meditation or other sitting practices) from forms of meditation that involve awareness during meditative movement (i.e., yoga, Tai Chi).

## Mindfulness Meditation

Mindfulness is a specific form of meditation with basic philosophical foundations in Asian Buddhist practices, although ascribing to a specific cultural or religious belief system is not required. In fact, it has been argued that the basic tenets of mindfulness are anchored in universal principles rather than specific religious or cultural ideas (Kabat-Zinn, 2003). Many traditions and practices are often included under the umbrella of mindfulness meditation; some familiar traditions may include Zen, Hatha yoga, and Insight meditation. Clinical training and treatments using mindfulness approaches or mixing various practices are often included in a general category of MBIs in the literature. The differences in specific training and traditions pose some challenges in the study of mindfulness, and it has been suggested that different approaches may impact various psychological, cognitive, and brain changes in different manners, as will be discussed later in the chapter (i.e., Fox et al., 2014). All forms of mindfulness meditation do share some basic tenets, as suggested by this straight-forward definition of mindfulness offered by Jon Kabat-Zinn (1994), the founder of the Mindfulness-Based

Stress Reduction (MBSR) program: “Mindfulness means paying attention in a particular way: on purpose, in the present moment, and non-judgmentally.” This simple definition meets the formal criteria set forth by the Agency for Healthcare Research and Quality, and can be engaged in during both sitting and active movement practices. At the most basic levels of training, mindfulness involves focus on the breath and other bodily sensations, as well as any thoughts and emotions that may arise during a practice session. The aim is to attend without judgment, but with simple awareness. Through practicing this form of meditation, and observing thoughts, feelings, and emotions as they occur in the moment, practitioners may gain greater awareness of how they are interacting, and may choose to mentally position themselves differently in relation or response. In addition, as will be described later in this chapter, positive changes in emotional, cognitive and physiological health appear to be by-products of even relatively brief periods of practice.

To some degree, mindfulness practice is deceptively easy. In its basic form, it is concrete, simple, and focused on the present moment. The initial attention to the physical awareness of the breath and bodily sensations allows for disengagement from the higher level processing of emotions and thoughts, with a focus only on experiencing, rather than judging, analyzing, or responding. There is scientific evidence that this initial focus on the body may neurologically precede changes in emotion and cognition (i.e., Kerr et al., 2013). This simplicity and “unplugging” from all but the basic sensations may at least partially account for the increased interest and popularity of mindfulness in Western cultures, where stress related to the intensity of fast-paced jobs, activities, and lifestyles, as well as “information overload” from electronic media and devices is becoming a common complaint (i.e., Ludwig & Kabat-Zinn, 2008). In fact, the term *mindfulness* has become much more a part of the popular literature in recent years. Just as yoga has become more widely accepted, so the ideas of meditation, and in particular, mindful forms of practice, have become much more widely available and accepted. In fact, mindfulness has graced the cover of major magazines (for examples, see [www.scientificamerican.com/article/neuroscience-reveals-the-secrets-of-meditation-s-benefits/](http://www.scientificamerican.com/article/neuroscience-reveals-the-secrets-of-meditation-s-benefits/) and <http://time.com/1556/the-mindful-revolution/>), has been a topic on popular talk shows such as Oprah Winfrey's *SuperSoul Sunday* (watch “The Difference Between Mindfulness and Meditation?” at [www.youtube.com/watch?v=Nigoy8rIuT4](http://www.youtube.com/watch?v=Nigoy8rIuT4)) and trainings have been offered to executives and employees of major U.S. corporations (see the Visionary Insights website at <https://visionaryinsights.wordpress.com/category/popular-culture/> and [www.huffingtonpost.com/2014/01/02/will-2014-be-the-year-of-\\_0\\_n\\_4523975.html](http://www.huffingtonpost.com/2014/01/02/will-2014-be-the-year-of-_0_n_4523975.html)).

Just as yoga that has become “Westernized” as a form of exercise, some would argue that the philosophical underpinnings of mindfulness are in danger of being diluted

or lost completely (for example, see Rapgay & Bystrisky, 2009), as mindfulness training has been touted as a potential method for gaining an “edge” or improving productivity in our competitive American culture, or as a “quick fix” for the stress of our hectic lifestyles (i.e., [www.theatlantic.com/business/archive/2015/03/corporations-newest-productivity-hack-meditation/387286/](http://www.theatlantic.com/business/archive/2015/03/corporations-newest-productivity-hack-meditation/387286/)). Indeed, although it is sometimes misunderstood, the goal of mindfulness meditation is not to shut the world out, or to gain a competitive edge, but rather, through slowing down to focus on the moment, the aim is to experience the moment clearly, with the opportunity to respond deliberately, rather than reactively via the increased awareness gained over slow and deliberate daily practice.

One significant positive impact of the increased interest and acceptance of mindfulness in the United States and other Western countries is that this has produced a surge in science and research in this area. In addition, clinical adaptations and protocol programs have created unique opportunities in psychology, medicine, and education. There has been a growing acceptance of the teaching of mindfulness to many groups, and it has been employed with reportedly positive results in the treatment of a wide range of problems and diverse treatment groups—from incarcerated individuals (i.e., Leonard et al., 2013; Barnert et al., 2014; Samuelson et al., 2007), to schoolchildren (i.e., Napoli, Krech, & Holley, 2005; Wisner, Jones, & Gwin, 2010), soldiers and veterans (i.e., Trousselard et al., 2012; Serpa, Taylor, & Tillisch, 2014; Serpa, 2014), professionals (i.e., Galantino et al., 2005; Kelley & Lambert, 2012), and to individuals with chronic health conditions and diseases (i.e., Baer, Carmondy, & Hunsinger, 2012). While the current “hype” around mindfulness in the popular media will certainly wane with time, in the area of neuropsychology, the ideas of mindfulness practice, in both theory and philosophy, fit well with the focus of rehabilitation and provide skills training that research suggests may positively impact cognition and emotion. In addition to behavioral studies, more recent neuroimaging research has suggested that brief periods of mindfulness training have the potential to physically alter brain function and structure in ways which positively impact attention, memory, and frontal lobe functioning, as well as improve emotional regulation (i.e., Tang et al., 2015).

The remainder of this chapter will be focused on elucidating the current state of the literature related to mindfulness and MBIs, with particular attention paid to the multifaceted ways in which this form of practice has the potential to benefit individuals who have sustained neurological injuries and diseases. Given the preliminary nature of the overall literature in this area, an exhaustive review of the literature will not be undertaken; however key exemplars and reviews will be utilized in order to elucidate, along with discussion of our aims in the field of rehabilitation with the goal of highlighting the potential opportunities for additional study and clinical exploration within our field.

### Mindfulness-Based Stress Reduction

Although there are many forms of mindfulness meditation, MBSR is a program that is particularly notable in the sense that, from the time of its founding, the primary focus has been on providing mindfulness training and interventions to individuals with health issues in a medical setting. For example, the first studies on MBSR indicated positive results for use with individuals diagnosed with chronic pain (Kabat-Zinn et al., 1985, 1987), increased response to light therapy for patients with psoriasis (Kabat-Zinn et al., 1998), and improvements for individuals with anxiety (Kabat-Zinn, 1992). In addition to the focus on medically related issues, over time the program has been protocolized in a manner that has made it useful for study via research paradigms.

MBSR was formulated by Jon Kabat-Zinn in 1979 as a program for a newly formed outpatient stress reduction clinic at the University of Massachusetts Medical Center (Kabat-Zinn, 1982). The program began as a consult service to assist patients in managing symptoms associated with chronic pain and various medical diagnoses, as well as other life stressors. The intention of the program from the onset was to complement medical care, not to replace it. Over time, MBSR has evolved into the current design, in which the intervention is administered as an eight-week group program (for a full description of the program, refer to the book entitled *Full Catastrophe Living: Using the Wisdom of Your Body and Mind to Face Stress, Pain, and Illness*, by Jon Kabat-Zinn, 1991). Individuals in the program are required to participate in group education and practice for two-hour sessions weekly, and are asked to engage in individual practice at home on a daily basis.

The initial components of this program are focused on body awareness, which is practiced through sitting and supine mindfulness meditation practices involving focusing on the breath, and engaging in the “Body Scan,” which entails bringing awareness to successive body areas in a sequential manner with the aim of focused attention and awareness of sensations occurring with each body area. As the eight-week course progresses, sessions include didactic presentations, movement (mindful Hatha yoga and mindful walking), as well as specific exercises in mindful eating and observation of positive and negative thoughts. An all-day silent retreat is part of the program as well. It should be noted that, from its inception, while MBSR practices are derived from Eastern traditions of meditation and yoga, Kabat-Zinn intentionally removed specific cultural or philosophical language from the program in a concerted effort to make it universally accessible to clinical patients of all backgrounds (i.e., Kabat-Zinn, 2003). This program has grown exponentially in recent years and is now known as the Center for Mindfulness in Medicine, Healthcare, and Society. Kabat-Zinn and colleagues have now trained practitioners worldwide to teach the eight-week course, with more than 20,000 individuals participating up to this point (for information about the program and

training, visit the Center for Mindfulness website at: [www.umassmed.edu/cfm/](http://www.umassmed.edu/cfm/)).

Over the course of the MBSR course, weekly themes are introduced that are incorporated into didactic presentations and group discussions. Although meditation practices are conducted with a focus on attentional awareness without judgment or response, the weekly themes provide a context with which to consider the information gained through observation during practice. Weekly themes build over the course of the program and are designed to provide information about how stress impacts health and the body, as well as to assist participants in gaining insight and perspective regarding choices available to them in responding to pain, illness, and chronic life stressors.

It is worth noting that, with the increasing popularity of mindfulness research, there are efforts to differentiate and identify types of practices studied in an effort to clarify how the use of different practices or methods may lead to distinct findings in the literature. For example, there has become a growing interest in adapting the eight-week MBSR protocol to meet the needs of various groups and programs. In an effort to preserve the authenticity of the program and clarity in research literature, an effort has been made in the literature to designate that only programs and studies implementing the full eight-week course with trained instructors and the protocolized format should be described as MBSR. Any changes in characteristics, such as variations in the number of weeks, length of sessions, themes, or practices, are designated as various MBIs in order to differentiate and evaluate emerging studies. It should be noted that MBIs are not considered to be inferior to MBSR, but are valid and important tools that can be quite useful and studied in their own right. The differentiation is made merely for clarity in the literature. An example of a specific MBI, which will be discussed at a later point in this chapter, is Mindfulness-Based Cognitive Therapy (MBCT; see Teasdale, Segal, & Williams, 1995). Other examples include the alteration of the MBSR program in the length of sessions for number of sessions to accommodate individuals with chronic illness who may fatigue easily or require additional time and repetition due to cognitive limitations. As the scientific study of mindfulness has continued to grow, additional efforts in the larger literature have also been made to more clearly define which types of meditation practices are being used across various studies, due to increased awareness that different types of meditation may produce distinct findings due to variations in active processes across types. Higher-level studies of individual practices and traditions may allow for increased clarity regarding the key components of activation. For example, as we explore MBSR in the next section, efforts to evaluate the active components involve study of the order in which changes occur through practice, behavioral considerations, as well as various brain structures and functions may be altered via participation in MBSR. It should be noted that there some (i.e., Rapgay & Bystrisky, 2009) who argue that, despite its higher level

of protocolization as compared to some paradigms, there still may be too many “moving parts” in MBSR due to the mixed forms of practice (i.e., sitting, yoga, breath awareness, body scan). These authors assert that research may be better served by studying more classic mindfulness paradigms.

Following are some examples of studies evaluating outcomes from MBSR programs on physical and mental health in individuals with stress and chronic medical issues.

Early in the development of MBSR, Kabat-Zinn and colleagues (1985) used a ten-week course of mindfulness meditation to train 90 individuals with chronic pain, compared to a group of pain patients receiving traditional treatment protocols. Measures evaluating self-report of present-moment pain, negative body image, inhibition of activity due to pain, symptoms, mood disturbance and psychological symptoms, including those related to anxiety and depression symptoms were measured. The utilization of pain medications, activity levels and self-esteem reports were also monitored over the course of treatment. Results indicated statistically significant positive changes in all measures, including physical and emotional symptoms and pain-related behaviors when pre- and posttreatment assessments were compared. In addition, utilization of pain-related medications was significantly decreased. Results indicated that findings of improvement appeared to be independent of gender, referral source, and type of pain. In comparison, participants in the traditional treatment protocols did not show significant improvement on the same measures. Follow-up indicated that improvements for those receiving mindfulness training persisted up to 15 months after participation in the program for all measures, except present-moment pain. In addition, the majority of participants in mindfulness training reported continued to use mindfulness practice in daily life.

From the behavioral perspective, a study by Baer, Carmody, and Hunsinger (2012) evaluated the weekly changes in self-reported mindfulness and perceived stress in a group of 87 adults with chronic illness, pain, and life stressors who were engaged in an MBSR program. The aims of the study were not only to evaluate changes occurring overall between pre- and post-MBSR participation, but also to look at patterns for the development of change. Via evaluation of weekly questionnaires, significant increases in the acquisition of mindfulness skills, as well as significantly decreased reports of perceived stress were reported from pretreatment to posttreatment overall. Regarding timing and patterns of change, however, subjects reported significant changes in mindfulness occurring by the second week of the program, where significant decreases in perceived stress were not noted until the fourth week. Additional evaluation of these differences indicated that the extent of change in mindfulness skills during the first three weeks of the program was predictive of the extent of perceived stress reduction over the course of the intervention. Conclusions of this study were that the improvement of mindfulness skills may predict and

mediate the effects of mindfulness training on positive outcomes reported as stress reduction.

In 2010, Merkes conducted a review article of 15 studies reporting outcomes of MBSR programs for adults with chronic diseases. Outcomes reported in these studies were regarding physical and mental health, well-being, and quality of life. The articles evaluated used both self-report and physiological outcome measures. Clinical diagnoses included chronic pain, rheumatoid arthritis, Type 2 Diabetes, chronic fatigue syndrome, multiple chemical sensitivity, cardiovascular diagnoses and fibromyalgia. Due to the inclusion of multiple and variable measures, specific outcomes of studies were difficult to compare, however, improvements were reported in all 15 studies, with no negative changes reported in any study between baseline and follow-up.

In additional study of individuals with chronic pain and a diagnosis of “Failed Back Surgery Syndrome,” Esmer and colleagues (2010) completed a randomized, single-blind, parallel-group clinical trial in which 25 participants were randomly assigned to MBSR therapy plus traditional therapy or traditional therapy alone. Final analysis was completed at the time of a 12-week follow up. Results indicated that the addition of MBSR to traditional treatment produced statistically and clinically significant increases in measures of pain acceptance and quality of life, decreases in functional limitations, decreased visual analog pain scale reports, and reduced frequency of use and potency of pain medications, as well as resulting in improvements on a self-reported measure of sleep quality.

Taken together, these studies suggest that participation in MBSR is unlikely to be associated with negative outcomes, and that positive outcomes such as improved coping, well-being, and quality of life are likely to be reported by individuals with chronic health issues who participate in MBSR groups. As we consider the populations who are followed in our inpatient and outpatient rehabilitation settings, many individuals are working to manage with chronic disability, health issues, and often pain. At this very basic level, as we work to provide treatments that are cost-effective and efficacious in training patients and clients to engage in self-care for the purposes of managing current health issues and perhaps reducing exacerbation or future issues, MBSR or related mindfulness practices—which can be presented relatively inexpensively as a nonpharmacological group treatment—may be worth consideration.

### ***Frequency and Length of Practice: Impact on Brain and Behavior***

Neuroimaging studies of Buddhist monks and other master practitioners of meditation have shown significantly altered brain structure and function. For example, in a structural neuroimaging study of 22 long-term meditators as compared to 22 nonexperienced control participants using voxel-based morphometry, Luders and colleagues (2009) found gray

matter volumes to be significantly larger in the right orbito-frontal cortex and the right hippocampus for meditators as compared to controls. The authors stated that both areas were associated with response control and emotional regulation. Of note is that this was a study of practitioners of various forms of meditation, as compared to other studies focusing on one method of practice. The authors assert that these findings may be representative of overall changes related to meditation in general, while variations in practice types may have additional specific regional findings not supported by this less specific, yet broader study.

Clearly, in studies of long-term practitioners, the question arises about what other sorts of personality and lifestyle factors may play a role in these alterations as compared to nonpractitioners. In addition, the question of how long one has to practice in order to achieve noticeable changes is a consideration for training individuals who are patients and clients. Of interest is the fact that several studies have now been conducted with results suggesting that novice practitioners of mindful practice may show positive functional and structural changes in the brain after just eight weeks of mindfulness training. For example, Hölzel and colleagues (2011) completed a study in which changes in gray matter concentrations were investigated using voxel-based morphometry and compared with a wait list control group. Sixteen healthy participants who were naive to meditation and 17 wait list controls completed neuroimaging before and after the eight-week period during which the treatment group participated in MBSR. Findings indicated increases in gray matter concentration within the left hippocampus (the *a priori* region of interest). Whole-brain analysis identified increases in the posterior cingulate cortex, the temporo-parietal junction, and the cerebellum. The authors note that these findings represent gray matter regions involved in learning and memory processing, emotional regulation, self-referential processing and perspective taking.

Hölzel and colleagues (2010) also completed an additional longitudinal evaluation of the relationship between changes in amygdala gray matter density following an eight-week MBSR intervention. The aim of this study was to evaluate if a psychological variable (perceived stress) may be associated with changes in the brain following mindfulness practice. The amygdala was chosen as the brain structure of interest, as it is known to be involved in the response to stress, and previous studies had reported increases in activity during functional studies of stress conditions. Following the intervention, participants in this study reported significant reductions in perceived stress and these reductions correlated positively with decreases in the right basolateral amygdala gray matter density.

Kilpatrick et al. (2011) applied functional magnetic resonance imaging (fMRI) to evaluate whether participation in MBSR was associated with alternations in intrinsic connectivity networks. Healthy female subjects were randomly assigned to participation in either MBSR or a wait-list

control group. After eight weeks, fMRI data were acquired while subjects rested with eyes closed and were instructed to attend to the sounds of the scanner environment. Results indicated that, as compared to controls, individuals participating in MBSR showed increased functional connectivity within auditory and visual networks, and increased functional connectivity between the auditory cortex and areas associated with attentional and self-referential processes. Stronger anticorrelations between auditory and visual cortex, and between visual cortex and areas associated with attentional and self-referential processes were also noted. The conclusion of this study was that eight weeks of participation in mindful meditation training alters intrinsic functional connectivity in ways that may reflect a more consistent attentional focus, enhanced sensory processing, and reflective awareness of sensory experience.

In all, at least 21 studies have been conducted to examine structural changes related to mindfulness meditation. It should be noted, however, that various traditions of mindfulness meditation were included, and designs and measures differ across studies, precluding the full comparison across all studies. In addition, the majority of these studies have had small sample sizes and many have employed post-hoc explorations of changes, which reflects the “young” nature of this literature. As a result, many studies in these areas should be considered preliminary, although these early findings have implications that are potentially quite interesting for clinical practice. For example, such studies have indicated changes in cortical thickness (i.e., Lazar et al., 2005; Grant et al., 2010), gray matter volume and density (i.e., Vestergaard-Poulsen et al., 2009; Hozel et al., 2011), and white matter changes (Tang et al., 2010; Tang et al., 2012). In at least some of these studies, structural changes in the brain have been associated with psychological variables, such as self-reports of stress reduction (Hölzel et al., 2011), emotional regulation (i.e., Tang et al., 2012), or an increased sense of well-being (Singleton et al., 2014). In a recent review of the neuroscience findings associated with mindfulness, Tang, Hölzel, and Posner (2015) conclude that there is “emerging evidence” of neuroplasticity in brain structure and functional regions associated with emotion, self-awareness, and attention regulation; however, they indicate the need for additional rigorous research with larger sample sizes for further scientific study. In addition, Fox and colleagues (2014) concluded conservatively that the results most concurrent across studies of morphological differences associated with meditation indicated positive changes in the left rostrolateral prefrontal cortex, the anterior/mid-cingulate cortex, the anterior insula, primary/secondary somatomotor cortices, left inferior temporal gyrus, and the hippocampus.

Given these findings, further studies and consideration of correlations between structural and functional brain changes associated with mindful practices, along with evaluations of how these alterations may impact areas such as memory, attention, executive functioning, as well as emotional

response will be of interest, as these areas have the potential to significantly impact outcomes for individuals in our clinical rehabilitation populations with neurologically based illnesses or injuries.

### ***Biophysiological Functioning***

In addition to brain-based alterations, significant changes in immune function, inflammatory markers and physical health have been reported with MBSR and other mindfulness training. For example, Davidson and colleagues (2003) conducted a randomized controlled trial of MBSR to evaluate how reported changes in mental and physical health reported with mindfulness training may be associated with biological changes. This group measured electrical activity in the brain prior to participation in an eight-week MBSR course, immediately following completion of the course, and at a follow up session four months after completion of the program. Twenty-five subjects completed the MBSR arm of the study, while 16 subjects in a wait-list control group were assessed at the same time points as the MBSR group. At the end of the eight-week MBSR versus wait-list control period, individuals in both groups were given an influenza vaccine. Results of the study indicated that individuals participating in the MBSR arm, as compared to controls, displayed an increase in electrical activation of the left-sided anterior areas of the brain, a pattern previously shown to be associated with positive affect. Subjects in the MBSR group also were found to have significant increases in antibody titers to the influenza vaccine as compared to nonmeditators. In addition, the magnitude of increases in brain activation associated with positive affect predicted the magnitude of antibody titer rise in response to the vaccine.

Studies have also been conducted to look at how participation in mindfulness practice might modulate neurogenic inflammation. In one study (Rosenkranz et al., 2013), evaluated MBSR compared to the Health Enhancement Program (HEP), a recently validated active control intervention (MacCoon et al., 2012). Stress response was measured using a paradigm in which participants engaged in a standardized socially stressful situation (a five-minute speech and mental arithmetic—a modified version of the Trier Social Stress Test, or TSST; see Kirschbaum et al., 1993) and a local neurogenic inflammatory response (capsaicin cream topically applied to the forearm), after which baseline self-report, saliva cortisol, and molecular (blister fluid cytokines—TNF- $\alpha$ ), and skin inflammatory (flare) measures collected. Subjects then participated in one of the two groups for eight weeks, after which the experimental stress paradigm was repeated. Findings indicated that both groups had equivalently reduced reports of psychological distress and physical symptoms and comparable stress-evoked cortisol levels. Despite similar levels of stress hormones (cortisol), however, individuals in the MBSR group did have significantly smaller inflammatory response at postintervention testing as compared to HEP.

The main difference between MBSR and HEP is that MBSR focuses on reducing emotional reactivity as compared to HEP, which has a focus on well-being-promoting activities. The authors suggest that reduced emotional reactivity may be the active ingredient of MBSR associated with reduced inflammatory response to stress. In an additional study of elderly individuals, Creswell and colleagues (2012) noted that older adults who are lonely have been shown to have an increase in expression of proinflammatory genes, as well as an increased risk for morbidity and mortality. They assessed whether participation in an MBSR program might impact these factors. They compared 40 older adults (aged 55–85) who were randomly assigned to MBSR or a wait-list control group. Participants were asked to complete measures including a loneliness scale and also provided a blood sample at baseline and after the end of the eight-week period. Findings indicated significantly decreased reports of loneliness in the MBSR group as compared to the control group, as well as a down-regulation of the specific proinflammatory gene expression profile.

In an additional study of psychological and physiological outcomes with a clinical group, breast and prostate cancer patients, Carlson and colleagues (2007) completed baseline and follow-up measures immediately postparticipation, and again at six and 12 months after completion. Measures of quality of life, mood, stress symptoms, salivary cortisol levels, immune cell counts, intracellular cytokine production, blood pressure, and heart rate were included. Results indicated that improvements in stress maintained over the follow-up period. In addition, decreased cortisol levels, continued reduction of proinflammatory cytokines, and systolic blood pressure decreased from baseline to post-group. Heart rate was also positively associated with self-reported symptoms of stress.

### **Mindfulness and Cognition**

In the American Mindfulness Research Association database, there are listed 177 citations for publications related to attention and meditation. This level of scientific inquiry in the literature is not surprising as the focus of attention is one of the hallmark components of definitions of various forms of meditation practice. Although the literature in this area is fairly sizable, it should be noted that findings related to attention remain somewhat mixed. While the general consensus is that mindfulness practice does seem to have a positive impact on performance on some attentional tasks, and brain areas associated with regulation of attention do seem to be impacted by participation in mindfulness-based practice, there is not yet scientific evidence to definitively conclude that alterations in attention are responsible for the changes observed (i.e., for a review, see Tang Hölzel & Posner, 2015). In part, this is due to the fact that there are multiple types of attention, and multiple types of training that may impact attention differently, as well as other

confounding factors making it difficult to tease out causation and effect. Further studies are needed in this area to more fully elucidate the relationship between mindfulness and attentional functioning. Of potential significant interest to rehabilitation practitioners, a study by Kerr and colleagues (2013) provides a theoretical framework suggesting that the initial weeks of standardized practices of focusing on the sensory experiences of the breath and learning to control the focus of attention on various parts of the body in a systematic way through the body scan provide training in sensory attention that leads to later positive changes in seemingly unrelated cognitive and affective measures (i.e., mood, rumination, working memory, and pain-related distress). This framework lays out a predictable sensory-cognitive sequence of practice-related gains whereby localized attention to body sensations enables subsequent gains in emotional and cognitive regulation by enhancing sensory information processing in the brain.

As with attention, the literature related to the associations memory functioning and mindfulness training are not entirely clear. This is also in part due to the fact that there are multiple types of memory and multiple ways in which memory may be targeted. Available studies do suggest positive associations between mindfulness training and working memory capacity (Mrazek et al., 2015; Jha et al., 2010). Of particular interest for the current discussion is a systematic review of meditation associations with age-related decline (Gard, Hölzel, & Lazar, 2014) that indicated preliminary findings of positive effects of mindfulness on general cognition, including attention, memory, executive functioning, and processing speed in relation to aging and cognitive decline. An additional study (Marciniak et al., 2014) evaluated mindfulness in the context of neurodegenerative disease and aging. Seven studies were analyzed and also suggested positive effects of mindfulness on cognition, in particular in the areas of attention, memory, verbal fluency, and cognitive flexibility. Of note, however, is that both studies included in the analysis utilized various forms of meditation, and the authors concluded that further longitudinal and stringent designs were needed for results to be declared more than preliminary.

A thorough review of 23 studies of mindfulness-based practices and cognitive functioning (Chiesa, Calati, & Serretti, 2011)—including attention, memory, executive functioning, and other cognitive measures—suggested that practices of mindfulness training (often early in training) in which the aim is to build focused attention may have a positive impact on selective and executive attention, where open monitoring practices focusing on internal and external stimuli may be positively associated with unfocused sustained attention. Participation in mindfulness-based practices was also associated with improvements in working memory and some executive functions such as improved verbal fluency and reduced cognitive proponent responses on set tasks. As with other reviews of the literature, this group cautioned that

further higher quality studies were needed for scientific validation of these preliminary findings.

### **Mindfulness and Affective Disorders**

In a recent review article evaluating the potential effects of meditation for the treatment of affective dysregulation, Leung, Lo, and Lee (2014) asserted that affective dysregulation is the root cause of emotional illness, including poor response to stress, as well as anxiety and depression. The authors reviewed the empirical evidence for the neural impact of mindfulness meditation and compassion meditation. These two forms of meditation were chosen as the authors assert that each form of meditation engages different cognitive processes, and are therefore interesting to compare from a neuroscience standpoint. Mindfulness meditation focuses on engaging and practicing attention for the purpose of nonjudgmental monitoring of present-moment thoughts and sensations. In comparison, compassion meditation engages the emotional regulation and response system in the brain. The authors of this review conclude that both mindfulness meditation and compassion meditation have a positive impact on attention and emotional regulation, and that practice in these forms of meditation can produce lasting morphological changes in the corresponding neural regions—specifically the prefrontal regions and amygdala. They assert that healthy regulation of affect requires top-down cognitive control in which the prefrontal regions modulate the bottom-up processing of the subcortical regions, and that mood disorders result from the weakening of cognitive control due to activation of the limbic system over the prefrontal control system, thus allowing for heightened response to emotional stimuli and creating vulnerability to mood disorder. They suggest that mindfulness meditation can be considered as an exercise that may have potential for both prevention of and intervention in mood and affective disorders. They state that further study is needed to evaluate the use of meditation in general as a clinical treatment.

Jain, Walsh, Eisendrath, Christensen, and Cahn (2015) conducted a clinical review of 18 studies of meditation trials for depression. The studies reviewed included a mix of meditation modalities. The authors' overall conclusion was that the use of meditation interventions in the clinical setting as a primary or adjunct treatment for depression appears to be promising, especially as there is little risk of negative side effects and potential benefits that far outweigh any risks. While pointing out significant limitations in the literature, the authors indicated that data from randomized controlled trials suggest that meditation-based meditative interventions may have substantial effects on depressive symptoms in patients with clinically diagnosed depressive disorders, including both patients with major depressive disorder as well as those in partial remission. Variations among sub-components of different types of meditation therapies did not allow for derivation of a common effect size—although,

overall, data from the reviewed studies suggest that meditative interventions may have substantial effects on depressive symptoms in patients with clinically diagnosed depressive disorders, including those having diagnoses of acute major depressive disorder, as well as those in partial remission. Variations among subcomponents of different types of meditation therapies did not allow for derivation of a common effect size. The authors made specific recommendations for further carefully designed studies, including differentiating groups with various distinct levels of affective disorders. Additionally they recommended the inclusion of individuals with significant medical comorbidities, as the benefits of efficacious, yet nonpharmacological interventions for depression may be of even greater benefit to individuals at higher risk for negative side effects or polypharmacy interactions.

### **Mindfulness-Based Cognitive Therapy**

One MBI of particular interest in the treatment of affective disorders is MBCT (Teasdale, Segal, & Williams, 1995). This intervention was specifically designed as a clinical treatment for depression and anxiety. Both MBCT and MBSR employ a standardized protocol for practice, including an almost identical eight-week instructional format that involves three somatically focused meditative techniques (body scan, sitting meditation, mindful yoga), however MBCT modifies traditional MBSR to incorporate components of cognitive behavioral therapy (CBT), which is widely accepted as an efficacious treatment for anxiety and mood disorders.

Maj van der Velden and colleagues (2015) reviewed 23 studies evaluating the mechanisms of change in MBCT in the treatment of major depressive disorder. Of the studies included in their analysis, the authors report that 12 studies found alterations in mindfulness, rumination, worry, compassion or meta-awareness that were associated with, predicted, or mediated MBCT's effect on treatment outcome. In addition, preliminary studies indicated that alterations in attention, memory specificity, self-discrepancy, emotional reactivity, and momentary positive and negative affect might play a role in how MBCT exerts its clinical effects. The authors called for more rigorous designs to assess greater levels of causal specificity.

### **Neuropsychology and Rehabilitation**

Chapters in this book provide examples of the many sorts of diagnoses for which clinical neuropsychologists are often asked to provide evaluations. Neuropsychological deficits may be the result of newly acquired injuries or medical events, gradual declines in function associated with chronic conditions or aging, or other disease processes that impact neurological functioning. The ultimate aim of neuropsychological assessment in rehabilitation is to evaluate which areas of limitation may be amenable to therapeutic interactions for improvement, to identify the types of cues and methods that might be most helpful in providing treatments, and to

determine how the areas of remaining strength may be used to assist in restoration of function or accommodation. The overarching aim of the rehabilitation process is to ultimately allow each individual to attain and maintain the highest degree of function and independence possible. In addition to evaluating and treating physical, cognitive, and sensory processes, neuropsychologists also often evaluate and treat emotional and behavioral issues, some of which may be the direct result of neurological injury or disease process, and some of which may be due to challenges with adjustment to disability, and, including significant anxiety and depression.

### ***Where Neuropsychology, Rehabilitation and Mindfulness Meet***

Following acute injury or a sudden decline in neurological status, simple movements that were once conducted with little thought, such as standing, walking, and grooming, may require conscious effort. In rehabilitation, we are often helping patients to “relearn” these previously automatic tasks. Many patients in the early stages of recovery report that significant cognitive, emotional energy, and physical energy is expended to produce even small coordinated movements, or to sequence or place limbs properly for activity. In order to work most effectively within therapy sessions, patients are truly asked to ascribe to the basic definition of mindfulness put forward by Jon Kabat-Zinn: “Paying attention in a particular way: on purpose, in the present moment, and non-judgmentally” (Kabat-Zinn, 1994). In working with our patients on these therapeutic tasks, we are asking them to bring new awareness to their bodies in ways that are consistent with the focus on body sensation, movement, balance, and proprioception practiced in mindful meditation practices. Working with them to engage in these therapeutic tasks mindfully and assisting them with suspending judgment fits naturally with our daily work in rehabilitation.

In addition, neuropsychologists are often working with individuals with neurological illnesses or injuries impacting brain functioning and causing significant deficits in attention, memory, and executive functioning. Our role as neuropsychologists is often to work to find methods of remediation or compensation for cognitive disability. As we have discussed in this chapter, it appears that engaging in MBIs may be associated with structural and functional changes in the brain and with positive general changes in attention, memory, and executive functioning. As practitioners, it seems possible that any small positive changes in brain structure associated with some of the very cognitive components most often impacted by neurological issues has the potential for real functional changes in cognition. As a clinical example, it is well known that after traumatic brain injury (TBI) attentional, memory, and executive functioning are commonly impaired. Based on this, as well as the literature previously discussed, it is likely that an individual with TBI may require some alterations in a traditional MBSR program (for example extra repetition,

shorter sessions to manage attention and fatigue, extra practice, and additional cues). As will be elucidated in the following section, the literature suggests that, with some small changes, individuals with TBI are able to learn and benefit from MBIs. If, for example, key components of attention are shown to improve with mindfulness training, it is possible that increased attention could significantly impact encoding and memory, leading to significant improvements in cognitive functioning and, ultimately, to improved outcomes for individuals with cognitive issues associated with TBI.

From an emotional standpoint, in rehabilitation, we are often asking patients to simultaneously participate fully in therapies designed to optimize their recovery during relatively brief inpatient rehabilitation stays or a set number of outpatient therapy sessions, while also asking them to adjust to significant changes in health and function. Patients and families are often dealing with stress related to multiple—potentially overwhelming—factors, including acute and chronic disability, acute and chronic pain, cognitive limitations associated with injury, illness, emotional adjustment, anxiety, depression, potential changes in roles at work and home, financial security, and often likely permanent changes in independence, mobility and lifestyle. Ultimately, we work with individuals to assist them in positively adjusting to new changes in function and ability. As part of this process, mindfulness-based practices are based in themes that resonate with positive emotional adjustment. For example, for positive adjustment to occur, it is necessary for individuals with newly acquired disability to overcome the tendency to focus on the way things were before injury, and to move towards living and finding meaning in the present life as it is. The mindful approach of focusing on and accepting the present moment, as well as the didactic themes that are part of MBSR programs, including discussion about accepting ourselves as “whole” as we are in the present moment, may be very powerful and meaningful to individuals working to adapt to new life circumstances. In addition, the aim of experiencing and examining the present moment, and making choices about relating to the present in order to move towards future choices, also fits well with the immediate needs of individuals after injury or illness, as life plans and goals must often be altered based on the new circumstances presented to the patient in the form of new disability.

From a long-term perspective, it is also worth noting that individuals with significant neurological illnesses or injuries often follow up with their rehabilitation physicians and team for many years after injury. Given the chronic health and disability issues of many of our rehabilitation populations, therapeutic interventions that can be employed efficiently and have lasting effects are of significant interest. In addition, our goal is for individuals to attain the highest level of recovery and independence as possible. Based on these factors, there are a number of potential advantages of teaching mindfulness to patients and clients: We are empowering patients to participate in the management of their own physical, emotional, and cognitive

symptoms. Skills can be taught efficiently in a group program. Once learned, skills can be practiced anywhere and employed over a lifetime, making the teaching of these skills both efficient and cost effective. In addition, due to the increased awareness of bodily sensations and functioning that may be associated with mindfulness practice, patients may have an improved ability to recognize and report new symptoms and changes to their medical team. Ultimately, this may enhance self-management and increase appropriate use of medical services, potentially reducing complications or other additional medical problems. In a sense, mindfulness practice has the potential to empower patients and clients to more fully engage in a partnership with health care providers as they participate in their own care.

Finally, for consideration, following TBI—as well as other diseases impacting frontal lobe functioning in particular—impulsive behaviors and difficulty with controlling emotional responses such as anger are sometimes concerns and can have a significant impact on outcome, as “frontal lobe symptoms” may cause significant difficulties in interpersonal relationships and in work and community re-entry. Training individuals with frontal behaviors to focus on triggers and to learn to recognize increases in anxiety or irritation prior to explosive behaviors occurring is part of the efforts that are often employed in treatment. Based on the available literature as presented in this chapter, it is possible that mindfulness-based interactions may assist individuals with frontal lobe symptoms to more readily engage in “top-down” management of emotions as suggested by Leung et al. (2014).

As an example of a mindfulness-based approach, let’s consider the management of chronic pain related to illness or injury: Mindfulness practice can be used to assist with pain management by teaching patients to pay attention to the present moment in order to manage or work through pain. For example, patients may learn to experience the thoughts that accompany pain, so that they can later determine the veracity of those thoughts or make conscious efforts to evaluate and change them. Patients can be taught to breathe through painful moments, and to learn more about their pain through observation (i.e., attention to the sensations of pain in detail may allow an individual to notice that the pain is not actually constant, but may come in waves or wax and wane with various circumstances or timing). This observation of and facing of the pain directly rather than avoidance can assist patients in changing their relationship with the pain and ultimately in managing pain more effectively while regaining an increased sense of control and self-efficacy. Breathing techniques, use of the body scan, and evaluation of the thoughts and emotions associated with the pain can be associated with significant gains in pain management.

### *Traumatic Brain Injury*

Efforts have been made to create programs tailored to individuals with specific limitations. For example, an earlier randomized controlled trial of the use of a brief mindfulness

training paradigm with individuals with TBI (McMillan et al., 2002) did not result in positive findings. The authors indicated that the brevity of training may have been a factor. In contrast, a later pilot of an MBI for individuals with mild TBI was conducted by Azulay and colleagues (2012) in which a traditional MBSR course was modified with recognition that individuals with brain injury may require additional considerations for training due to limitations in attention and memory, mental fatigue, and other cognitive issues. Modifications included a ten-week rather than eight-week course with weekly two-hour sessions. Main outcome measures included the Perceived Quality of Life Scale, the Perceived Self-Efficacy Scale, and the Neurobehavioral Symptom Inventory. Secondary measures included neuropsychological testing results and self-report measures of mindfulness and problem solving. Although this was a pilot study, the results indicated that it is possible to adapt the MBSR program for the inclusion of individuals with mild TBI. Clinically relevant improvements in measures of quality of life and perceived self-efficacy were reported, with smaller (but still significant) effects on measures of the central executive aspects of working memory and the regulation of attention. The authors concluded that additional comparative effectiveness research is warranted regarding the use of MBIs with this population.

In another pilot study with individuals with TBI, Bédard and colleagues (2003) 12 weekly sessions, which included a form of mindfulness-based meditation called Insight Meditation, breathing exercises, guided visualization, and group discussion focusing on altering perceptions of disability, increasing acceptance, and moving beyond limiting beliefs. Subjects were ten individuals with mild to moderate TBI who were at least one year postinjury. Findings of this pilot indicated improvements in self-reports of quality of life and on the cognitive-affective domain of the Beck Depression Inventory II (BDI II). Changes in the overall BDI II and positive symptom distress inventory of the SCL-90R approached significance. The authors concluded that the intervention was simple and had improved quality of life after other treatment options were exhausted.

Bédard and colleagues (2012) evaluated the use of MBCT in a group of 20 individuals with diagnosed clinical depression after TBI. Subjects participated in an eight-week course of 90-minute weekly MBCT sessions using materials that combined MBCT and MBSR manualized programs. Measures of depression, pain frequency and intensity, energy levels, health status, and function were collected pre- and postparticipation. Findings indicated that participation in the intervention significantly reduced depressive symptoms on all scales. Medium to large effect sizes for each depression measure were indicated. Significant reductions in pain intensity and significant increases in energy levels were also reported. No significant changes were reported in anxiety symptoms, pain frequency, or level of functioning. The authors concluded that MBCT was efficacious in decreasing

depression symptomology after TBI, and that further studies with more robust designs were warranted.

Individuals with a history of TBI often report ongoing issues with focused and/or sustained attention. McHugh and Wood (2013) reported positive findings in a study in which they completed in which 24 individuals with ongoing issues with focused or sustained attention were divided between a mindfulness intervention and control (no treatment) group. Individuals in both groups were asked to participate in a task designed to measure stimulus overselectivity (i.e., paying attention to one environmental stimulus disproportionately to other salient stimuli, suggesting difficulties with attentional control). Per the results of this study, stimulus overselectivity was indicated in individuals with TBI participating in the study at baseline, however, this was significantly reduced after mindfulness training as compared to those who participated in the no-intervention control group.

One group has produced multiple studies of the utilization of mindfulness-based practices with individuals with a history of TBI, with results indicating significant benefits for reducing self-reported symptoms of depression (Bédard et al., 2003) and depression and anxiety (Bédard et al., 2014) after TBI via treatment with MBCT. An additional study by the same group indicated reductions in self-reported symptoms of depression, with maintenance of improvement at the time of a three-month follow-up (Bédard et al., 2014).

### *Stroke*

Lawrence and colleagues (2013) conducted a review of four studies of the use of MBIs with individuals with a history of stroke. In total, 160 participants were involved across the four studies. Three interventions were delivered via a group format and one was delivered one-to-one. The authors report a positive trend in findings, suggesting benefits ranging across multiple psychological and physiological outcomes, including depression, fatigue, blood pressure, perceived health, anxiety, and quality of life. They concluded, however, that further study is needed with enhanced scientific methodology in order to validate results. An additional review article (Lazaridou, Philbrook, & Tzika, 2013) evaluated the use of yoga and mindfulness in stroke rehabilitation. The review evaluated five clinical trials, four case studies, and one qualitative design. Again citing the need for additional research, the authors indicated preliminary findings suggesting improvements in cognition, mood stress reduction, and balance associated with the therapeutic use of MBIs after stroke.

Johansson, Bjuhr, and Rönnbäck, conducted a series of studies regarding mental fatigue following acquired brain injury. In the first study, (2012), 18 individuals with stroke and 11 with TBI, who had no residual significant physical or cognitive impairments aside from mental fatigue, were randomized to a MBSR course or a wait-list control group. Results indicated that statistically significant positive changes in self-assessments of mental fatigue were reported

by individuals engaged in MBSR. Secondly, improvements were noted on neuropsychological tests (digit symbol-coding, and the Trail Making Test). Conclusions of the study were that MBSR may be a promising nonpharmacological treatment for mental fatigue after stroke or TBI. Johansson and colleagues were also able to obtain positive outcomes in an additional advanced mindfulness program with the same population (2015) and in delivering an online MBSR program to individuals with ongoing issues of fatigue after stroke or TBI in a live and interactive format to enhance care and participation (2015).

These findings showcase just a few of the studies suggesting benefits of MBIs for populations with diagnoses that are commonly followed by neuropsychologists engaged in the rehabilitative evaluation and treatment of individuals with neurologically based injuries or illnesses. It is worth noting that, in addition to stroke and TBI, studies have indicated benefits associated with the use of mindfulness for emotional adjustment and coping associated with diagnostic groups including of Parkinson's disease (i.e., Advocat et al., 2013; Pickuta et al., 2013), multiple sclerosis (Agha-Bagheri et al., 2013; Pakenham et al., 2013; Simpson et al., 2014; Senders et al., 2014), and other chronic and disabling diagnoses, including a fairly large literature on fibromyalgia (see, for example: Henke & Chur-Hansen (2014) and cancer (see, for example: Zainal, Booth, & Huppert, 2013).

### **Methodological Considerations: Summary and Recommendations for Future Study**

In most available reviews of the mindfulness literature, authors have continually asserted that additional scientific study of mindfulness is warranted and necessary. Most recently, Tang, Hölzel, and Posner (2015), in a review of the neuroscience literature, summed up nicely what has been repeatedly stated. In discussing the current challenges, the authors caution readers to be vigilant of the fact that research in this field, although promising, is relatively preliminary. They note that further replication and validation are needed via studies that are larger and more stringent in methodology. We are reminded that mindfulness research, in general, is a relatively young field. While findings in the past 20 years have been supportive of the beneficial effects of mindfulness on physical and emotional health, as well as on improved cognition, the neuroscience findings are more recent. In general, neuroimaging studies and neurobiological studies have had relatively small sample sizes, with few longitudinal studies. The authors point out the limitations of cross-sectional designs comparing individuals or groups with various experience in meditation to control groups with no exposure or practice. In some cases, long-term meditators have been compared to individuals with no experience (i.e., Luders et al., 2011), while other studies have compared novices who undergo training for variable periods of time to wait-list control groups (i.e., Hölzel et al., 2011; Kilpatrick

et al., 2011). Although behavioral as well as structural and functional changes in the brain have been reported in many of the early studies reviewed, Tang and colleagues (2015) point out that it is possible that there are other factors outside of the meditation experience that may play a role in the findings observed. For example, it is possible that other personality or lifestyle characteristics may make it more likely for an individual to practice or persist in meditation. In addition, the authors point out that it may be necessary to control for other factors that may be active ingredients in the changes noted, such as dietary changes made during the practice period due to greater awareness of or desire to make healthy lifestyle changes, or other factors associated with social participation in a group. Tang and colleagues (2015) also assert that control conditions within neuroimaging sessions may be difficult to control for, as it may not always be possible to monitor true resting-state periods in individuals who may be practiced meditators and may naturally fall into a meditative state during rest periods. Active distraction, however, may be hard to differentiate from brain activity due to target tasks. Overall, the authors conclude that evidence from these early studies suggests that mindfulness meditation may cause structural and functional changes in the brain. The current evidence indicates changes in specific areas associated with regulation of attention, self-awareness, and emotion. The authors assert that further, more rigorously controlled, studies with larger sample sizes are necessary for further validation of the current findings.

### **A Few Final Considerations**

Modern medicine and modern society often focus on “cures” and “quick fixes” that are often desired to alleviate pain and medical issues. As the landscape of medicine and health care continue to shift towards increased focus on patient satisfaction and outcomes after injury or illness, it becomes even more important for professionals working with individuals with chronic health conditions to seek interventions with the potential for significant potency and long-term impact. Individuals who are often seen in rehabilitation settings due to neurological injuries, illnesses, or diseases often present with a complex constellation of challenges and needs. In our work with them, it is likely that physical, cognitive, and emotional aspects of care will be important to consider. The research reviewed in this chapter suggests that the literature regarding MBSR and other MBIs requires additional scientific validation. That said, the interventions available via mindfulness-based programs have the potential to address patient and client concerns in a multifaceted fashion, and to have a positive impact on areas of significant concern for our clinical populations. As a result, mindfulness appears to be a field worth following, with an awareness that as neuropsychologists we may be in a unique position to further study and apply mindfulness techniques and practices in our work in the rehabilitation of individuals with neurologically based injuries or illnesses.

# 48 Collaborative Therapeutic Neuropsychological Assessment

*Tad T. Gorske*

Collaborative Therapeutic Neuropsychological Assessment (CTNA) is a method for giving feedback from neuropsychological test results that is based on client-centered principles (Gorske & Smith, 2009). This chapter will provide an overview of CTNA principles and methods as well as developments in collaborative neuropsychology, and will describe two cases where CTNA feedback methods were used.

## **Roots of Collaborative Therapeutic Neuropsychological Assessment**

CTNA's roots are most directly tied to Finn's Therapeutic Assessment (TA) and Fischer's Collaborative Individualized Assessment (Gorske & Smith, 2009). However, the history of psychological testing as a therapeutic intervention can be traced to the late 1940s and 1950s, when practitioners used performance-based tests as precursors to psychotherapy and, in some cases, as part of the therapy encounter (Aronow & Reznikoff, 1971; Bellack, Pasquarelli, & Braverman, 1949; Berg, 1985; Harrower, 1956; Luborsky, 1953; Mosak & Gushurst, 1972). Fischer developed these approaches further into Collaborative Individualized Assessment (CIA). CIA reflected a "human-science" assessment process that emphasized humanistic and existential principles of psychological assessment into a collaborative "man-as-co-constitutor" experience (Fischer, 1970, 1994). Beginning in the 1990s, Finn used the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) and other performance-based tests as therapeutic interventions and developed guidelines for conducting a TA (Finn, 1996a, 1996b, Finn, 2007). Over time TA and CIA mutually influenced each other. Since the initial publications, TA has developed increasing empirical support (Finn, Fischer, & Handler, 2012). TA and CIA methods traditionally employ personality-assessment measures and occasionally intelligence and cognitive tests; however, there has been little application of TA and CIA in neuropsychology (Finn, 1996a, 2003).

## **Feedback in Neuropsychology**

There is limited empirical literature about neuropsychological assessment feedback methods. Gass and Brown (1992) were the first authors to emphasize the importance of

feedback in neuropsychological assessment and to provide a framework for conducting a feedback session. Prior to their 1992 article there was almost no information on a neuropsychological feedback process or its value in patient care. Luria's Neuropsychological Investigation (LNI) emphasized a phenomenological analysis of the patients' cognitive life and a qualitative analysis of patient functioning (Christensen & Caetano, 1996). The preliminary conversation in Luria's method emphasized a positive therapeutic atmosphere with a flexible and interactive examination that included a feedback process (Christensen & Caetano, 1999; Christensen, Goldberg, & Bougakov, 2009). However, LNI in and of itself was not a formal feedback method.

Following Gass and Brown's article, authors wrote about the utility of neuropsychological test feedback and emphasized its importance, but no formal studies or methods were offered (Armengol, Kaplan, & Moes, 2001; Bennett-Levy, Klein-Boonschate, Batchelor, McCarter, & Walton, 1994; Malla et al., 1997). In 2005 Pegg and colleagues published what could arguably be the first article looking at the utility of providing medical and neuropsychological information to traumatic brain injury (TBI) patients (Pegg, Auerback, Seel, Buenaver, Kiesler, and Plybon, 2005). The results indicate that patients who received feedback about their medical and neuropsychological information in a person-centered style of interaction were more empowered and informed consumers of a TBI rehabilitation program (Pegg et al., 2005). Pegg noted that patients who received this information tended to be more assertive and inquisitive about their condition and treatments (Pegg, P., personal communication, 2004).

## **Development of Collaborative Therapeutic Neuropsychological Assessment**

CTNA developed from the work of the present author and Steven Smith from the University of California, Santa Barbara, along with guidance and mentoring from Finn, Fischer, and Diane Engelmann. The present author had been working in an extended joint postdoctoral placement in addiction medicine and clinical neuropsychology, under the mentorship of Christopher Ryan, at Western Psychiatric Institute and Clinic in Pittsburgh, Pennsylvania. At the time, this author was working with patients diagnosed

with substance abuse and psychiatric disorders (dual disorders) in a specialized Dual Diagnosis Clinic. This author and Ryan developed a method for giving patients feedback from neuropsychological test results. Initially the feedback method was based on the Motivational Interviewing Personal Feedback Report and adapted to include neuropsychological assessment results only (Gorske & Smith, 2009; Miller, Zweben, DiClemente, & Rychtarik, 1999). Positive feedback was received from patients about the neuropsychological feedback sessions and the utility of the method was explored more formally. Following collection of pilot data, a Career Development Award Grant through the National Institute on Drug Abuse was awarded in 2004 (NIDA-DA017273-01). It was during that time that the author had formal contact with Finn, Fischer, Smith, and Engelman during the Spring 2006 annual convention at the Society for Personality Assessment, where methods were presented. Smith had been developing Collaborative Neuropsychological Assessment (CNA) with adolescents and their families at UC Santa Barbara. Eventually methods were combined into a CTNA model that was presented at the National Academy of Neuropsychology in 2006. The model was continually developed and refined and led to the Gorske and Smith publication in 2009.

### **Collaborative Therapeutic Neuropsychological Assessment Model**

CTNA begins with seven basic assumptions, which will be summarized here (Gorske & Smith, 2009). These assumptions guide the CTNA process and provide a conceptual framework for which a clinician approaches the feedback process.

- 1 The patient/caregiver/referral source has noticed a change in the patient's cognitive and/or behavioral functioning and would like a professional to determine if there is a true change.
- 2 The patient/family members are distressed because of a change in the patient's cognitive/behavioral functioning.
- 3 Patients would like to learn potential ameliorative strategies so that they are able to perform better in school, work, and social spheres.
- 4 Patients want to be respected and empowered as active and autonomous participants in treatment and decision making.
- 5 Neuropsychological tests provide objective, concrete information about patients' cognitive and behavioral functioning as it applies to their daily life and problems they may be experiencing.
- 6 Feedback from neuropsychological tests can help answer questions regarding changes in cognitive and behavioral functioning, provide hypotheses as to causes of change, and give direction for treatment.

- 7 Feedback presented in a patient-centered manner can enlist the patient as an active collaborator, empower the individual in the treatment and decision making process, and lower resistance to hearing difficult or discrepant information. This will motivate the patient to work more closely with professionals to alleviate his or her problems and distress.

### **The Initial Interview: Collaborative Information Gathering**

Collaborative information gathering is an interviewing style that emphasizes listening to the patient's story in addition to collecting important clinical information necessary for understanding what will later be called the patient's *Central Cognitive-Emotional Complaint* (Gorske & Smith, 2009). Collaborative information gathering emphasizes a directive-nondirective approach similar to that found in Motivational Interviewing methods (Miller & Rollnick, 1991/2002). The clinician uses person-centered skills such as empathy, summarization, open-ended questions, and skilled reflections to elicit and elaborate upon the patient's story. Throughout this process the clinician is also guiding the interview in a direction that helps clarify the nature of the patient's cognitive and functional difficulties. This style is especially helpful when the patient is scared, confused, or unclear as to the nature of the problem. Skilled empathic direction and elaboration can help to crystallize the problem more succinctly. This is a skill I emphasize when working with neuropsychology students. I encourage students to learn a person centered-directive style of interviewing versus following a checklist approach. By modeling this in actual patient interviews, one hopes to show how this style can elicit more information about a patient's clinical history and cognitive difficulties that will ultimately help with the neuropsychological interpretation after testing.

In conducting a collaborative interview, there are five phases (Gorske & Smith, 2009). The first, Understanding the Problem, is a gathering of background information while seeking to understand symptoms and problem in context of day-to-day life. Second, Understanding the Emotional Experience of the Problem is when the clinician seeks to understand his or her patients' emotional experience of the problem and its effect on their experience of themselves, their life, relationships, and future. Third is the identification of the Central Cognitive-Emotional Complaint (CCEC). Based on Lester Luborsky's (1984) model, this is a conceptual framework in which the clinician seeks to understand (a) the patients' wish or desire for themselves and their lives, (b) a behavioral or cognitive reaction, (c) an emotional response to that difficulty. Fourth is an understanding of the patient's wishes for the assessment, results, and outcomes. This helps to guide the testing and subsequent feedback process. Finally, the fifth phase is a summarization of topics discussed in order to set the stage for the upcoming tasks of assessment and

consequent feedback. The neuropsychological testing session then proceeds in the standard manner based on whatever procedure(s) and battery the clinician chooses. The hope is that by fully elucidating the concerns of patients (and family members), CCEC, wishes and hopes for the future through an open ended/directive collaborative style, the clinician feels he or she has a roadmap for the best way to proceed with testing in order to answer the questions as fully as possible.

### **Collaborative Therapeutic Neuropsychological Assessment Feedback Session**

CTNA is based on three primary approaches: therapeutic/individualized models of psychological assessment; recommendations from previous authors on the provision of neuropsychological test feedback; and Motivational Interviewing principles as reflected in the format for providing information and advice, which is termed "elicit-provide-elicited" (Miller & Rollnick, 1991/2002).

The first step of the CTNA feedback session is Setting the Agenda and Introducing the Feedback Report. This is where the clinician sets the agenda with the patient/family members by outlining the goals and structure of the feedback session. This is followed by a "check in" where the clinician assesses how the patient's life has been since the initial assessment and testing. Part of the check in is to remind the patient of the CCEC as in order to establish a focus for the feedback. The second step is to develop Life Implication Questions, which is where the clinician guides the patient in developing well-formed and specific questions that guide the CTNA feedback session. The third step is the determination of a Personal Skill Profile. This is where the clinician describes to the patient how different cognitive skills are rated and determined to be normal, above normal, or below normal. Essentially, the clinician is describing in lay terms how norm-based scores are obtained. The fourth step is the provision of individual test results. At this stage the clinician revisits the tests given and the skills assessed, and then provides information and feedback in the "elicit-provide-elicited" format. The clinician summarizes a patient's strengths and weaknesses, all the while eliciting patient thoughts, reactions, and understanding of the information provided. Throughout this process the clinician is continually interacting with the patient in a person-centered manner using skills reflected in the acronym "OARS," which stands for "open-ended questions, affirmation, reflections, and summaries." The clinician is always aware of times when resistance may occur in response to the information given. Consistent with Motivational Interviewing principles, the clinician deals with resistance with understanding, empathy, and inviting the patient to consider alternative viewpoints (Miller & Rollnick, 1991/2002). The fifth step is the summarization of the information provided and the relationship between the results and the patient's questions and life goals. Essentially, this step is the bridge between the assessment and the patient's concerns for the

future. During this stage the clinician provides a general summary of information provided, gives information and advice, and elicits the patient's thoughts on how he or she would like to use the information for his or her benefit. This stage leads to the final phase of the CTNA session, which is the development of recommendations and a change plan. Here the clinician and patient further develop their partnership in the CTNA process by negotiating and developing concrete change plans. Part of this process is assessing the patient's level of readiness to follow through with change plan recommendations.

At this point the CTNA session focuses on change planning and the implementation of goals and recommendations. Clinical experience suggests that patients who undergo a neuropsychological test feedback session have greater levels of satisfaction with the services provided and are more likely to follow through with goals and recommendations. From a research perspective there is limited information on the effectiveness of feedback on outcomes and goal attainment. The pilot study conducted with dual diagnosis clients at the University of Pittsburgh, Western Psychiatric Institute and Clinic, demonstrated the effectiveness of the Neuropsychological Assessment Feedback Intervention (NAFI) in increasing patients' compliance with a partial hospital group program (Gorske & Smith, 2009). Other research has examined both clinician and patient perceptions of a neuropsychological feedback process with generally positive results (Bennett-Levy et al., 1994; Donofrio, Piatt, Whelihan, & DiCarlo, 1999; Smith, Wiggins, & Gorske, 2007). To date, no formal study has utilized the CTNA approach to assess clinical outcomes. However, there have been further developments in collaborative neuropsychology feedback methods.

### **Contemporary Developments and Adaptations**

Since CTNA was published in 2009, other authors have developed guidelines about the neuropsychological feedback process in clinical situations. However, this line is increasingly blurred when patients referred by a physician for a clinical evaluation often have current or pending litigation, disability, or workman's compensation claims. Carone, Iverson, and Bush (2010) provide guidelines on the provision of feedback to patients in clinical settings when there is evidence of suboptimal effort and response bias. This issue is important given the increased use of symptom validity testing in clinical settings. Carone and colleagues reiterate the widely held belief that it is not advisable, and in fact discouraged, to give patients feedback in forensic settings because the typical doctor-patient relationship does not exist in these circumstances. While a clinical question may be at the forefront of the referral, there will likely be an underlying forensic matter that will surface immediately or in the near future. Carone and colleagues provide sound suggestions on ways to address evidence of suboptimal effort and response bias with patients in a way that maintains a positive therapeutic relationship.

They propose a three-phase model. The first phase involves building rapport and obtaining informed consent. Here the clinician sets the tone and ground rules for the clinical interaction by laying expectations on the table and making sure a client is fully informed, and all the while establishing and maintaining an effective working relationship. The second phase involves completing the evaluation and laying the groundwork for an open discussion of results. If there is sufficient evidence of invalid performance, the authors suggest exploring the patients' willingness to acknowledge poor or variable effort. The authors appropriately caution on the language used to describe suboptimal effort in patients (i.e., framing poor effort as "not fully invested" vs. "lying"). The third and final phase is the feedback session. Carone and colleagues emphasize many sound clinical skills such as maintaining objectivity and professionalism while framing results in terms of strengths and weaknesses. The authors recommend comparing the performance of "poor effort" patients to known clinical groups for comparison. This avoids judgment and labeling and simply points out a discrepancy for patients to consider. The article goes on to address other clinical issues that may be present with patients who give suboptimal effort such as identification of specific effort tests, caution on using terms such as exaggeration and malingering, managing resistance, whether or not to provide a report copy, and handling complaints by patients (Carone et al., 2010; Carone & Bush, 2013). The authors' model contains methods and principles highly consistent with the CTNA approach and is an excellent guideline for providing difficult feedback to patients about effort and motivation in the neuropsychological testing process.

More recently, Postal and Armstrong published *Feedback that Sticks: The Art of Effectively Communicating Neuropsychological Assessment Results* (Postal & Armstrong, 2013). They interviewed 85 neuropsychologists to learn ways these clinicians communicate results from neuropsychological tests in ways that "stick" with patients. The authors identified "pearls" of communicative wisdom from each clinician. The pearls were "ways of explaining clinical phenomenon and findings that engage patients in ways that can alter their lives" (c.f. Postal & Armstrong, 2013: xxxi). The first part of the book discusses what feedback is and what makes it effective and memorable. They also discuss feedback protocols and theoretical issues, concluding with specifics about how feedback is presented. The second part reviews the way feedback is utilized in various clinical populations. Each chapter reviews issues that may arise during a feedback session with different clinical groups. The authors then illustrate examples of feedback that clinicians have given patients in ways that help them understand and learn complex neuropsychological phenomenon. For example, in explaining mild cognitive impairment (MCI; see Postal & Armstrong, 2013, p. 92), Postal and Armstrong provide examples of how clinicians have used down-to-earth and simple language and metaphors to describe the concept of MCI and its relationship

to dementia (pp. 92–94). The goal of the book is to provide readers examples of how to give feedback to patients in ways that facilitates learning and understanding. The third and final section of the book is about communicating information beyond the feedback session to other professionals and in report writing (Postal & Armstrong, 2013). The book is an excellent contribution in the effort to help make neuropsychological test feedback meaningful and applicable to the daily lives of patients.

Since the publication of CTNA in 2009, its methods have been recommended by authors for different clinical situations and populations. Pachana, Squelch, and Paton (2010) described the application of CTNA, more specifically Therapeutic Neuropsychological Assessment (TNA) and CNA, which are precursors to CTNA, in giving feedback to older adults in a collaborative and therapeutic manner. In Schoenberg and Scott (2011), *The Little Black Book of Neuropsychology: A Syndrome Based Approach*, Suarez discusses the application of Motivational Interviewing in neuropsychology in the rehabilitation process (Suarez, 2011). An interesting article by Lucas in the *African Journal of Psychiatry* discusses the possible role of CTNA approaches in situations where intervention is required for patients with deteriorating decision-making processes (Lucas, 2010).

Since 2009, very few studies have examined the effects of neuropsychological test feedback on clinical outcomes. Tharinger and Pilgrim (2012) investigated the effects of receiving neuropsychological assessment findings in the form of therapeutic "fables" on clinical outcomes with children and their families. A "fable" is an individualized story developed for a child based on guidelines from Tharinger et al. (2008). The results were that children who received the experimental neuropsychological feedback intervention reported a greater sense of having learned new things about themselves and perceived their parents as understanding their problems better. Both children and parents in the experimental group reported a significantly more positive relationship with the assessor, a greater sense of collaboration with the assessment process, and greater overall satisfaction with the clinical service.

Longley, Tate, and Brown (2012) investigated the psychological benefit of neuropsychological test feedback to patients with multiple sclerosis while looking at the type of patients who benefitted most from feedback. The intervention was described as a semistructured, collaborative, and interactive feedback session based on Gorske (2008); Gass and Brown (1992); and Pachana et al. (2010). They measured treatment fidelity with audio recordings and a feedback checklist reviewed by a blind observer. They examined a number of outcomes, including improvements in client knowledge and use of adaptive strategies, improved caregiver knowledge and decreased burden, improvement in various *patient* psycho-emotional factors and relationship quality, and improvement in *caregiver* psycho-emotional status and relationship quality. The paper concluded that the study design was realistic and feasible, with results

pending at the time of its publication (Longley et al., 2012). Since this initial paper, the authors have conducted a randomized controlled trial of neuropsychological assessment with feedback as a therapeutic intervention to improve psychological well-being in patients with multiple sclerosis. Preliminary results showed that patients who received the intervention had reduced levels of distress, increased social confidence, and a high level of satisfaction with the neuropsychological assessment process. Caregiver satisfaction with the assessment process was also high. Caregivers also reported a reduced need to provide psychological support to patients (implying the issue of caregiver burnout) (Longley, Tate, Brown, & Contini, 2013).

In reviewing the developments discussed in this section, there appears to be a burgeoning interest in a collaborative neuropsychology approach among clinicians who wish to blend the scientific discipline of neuropsychology with patient-centered and collaborative methods designed to enhance the working alliance with patients seeking guidance and answers about various neuropsychological conditions. The challenge will be to find the best practice model for the CTNA approach. Neuropsychological practitioners will need to ask the same questions that psychotherapists have asked in regard to the efficacy and effectiveness of psychotherapy interventions: "What treatment, by whom, is most effective for this individual with that specific problem, and under which set of circumstances?" (Paul, 1967: 111). The outcome studies mentioned in this chapter may provide some preliminary information as to how CTNA approaches are best utilized from a research perspective. The case studies presented in the next section will provide examples of how CTNA may be used clinically.

### Case Examples

The two cases presented in this section provide contrasting examples of how CTNA may be used. The first is a deidentified TBI case where CTNA was used with a gentleman who suffered a TBI, and had made a reasonably good recovery by the time he was seen for neuropsychological assessment, but continued to experience various deficits including anosognosia and a need to get back to his former life as quickly as possible. However, his intense desire to "be cured" was actually moving his TBI recovery backward. The CTNA session was able to disrupt his regression and help him get his recovery back on track. The second is a continuation of a case presented in Gorske (2008) on "Amy," a young woman diagnosed with a grade IV glioblastoma in the right temporal lobe and her struggle to retain her sense of identity in the face of brain cancer and physically taxing treatments. The case not only shows the importance of goal development in the CTNA approach, but also the ways in which highly motivated patients can use the assessment and feedback process for their benefit. In these situations it is important for the clinician to listen to patients and follow their lead as they

struggle on a journey of healing and wholeness in the face of fear and uncertainty.

### *Case 1: Traumatic Brain Injury Recovery*

The first case is a Caucasian gentleman in his late 40s who was an avid bicyclist and was struck by an automobile while riding in the streets. He had no memory for the events and local bystanders contacted Emergency Medical Services (EMS) who took him to the emergency room. He had a Glasgow Coma Score of 8, and exams revealed right frontal, subdural, subarachnoid, and intraparenchymal hemorrhaging. He required a posterior craniectomy due to developing hydrocephalus and a compressive cerebellar hematoma. His course was also complicated by seizure activity. He was eventually stabilized and transferred to inpatient brain injury rehabilitation. When inpatient neuropsychology saw him, he was determined to be just emerging from the posttraumatic amnesia phase (the period of confusion and inability to form new memories after sustaining a brain injury) of recovery about 20 days post injury. Due to ongoing symptoms and recurring hydrocephalus he required a ventriculoperitoneal shunt, which allowed symptoms to resolve. He was eventually discharged about 50 days postinjury. He had to go back to the emergency room within a month after hospital discharge due to a reoccurrence of symptoms, also suffering a seizure and shunt malfunction. This was successfully treated and he was discharged home. He was followed up by outpatient brain injury psychiatrists, neurosurgery, and rehabilitation specialists with reported good progress.

I saw the patient for an outpatient neuropsychological assessment about seven months postinjury. By all accounts he was doing reasonably well and had "graduated" from outpatient physical, occupational, and speech therapies. He was continuing to struggle with nausea and occasional dizziness that seemed to improve with rest. Cognitively the most notable differences were difficulty sustaining attention without becoming distracted and becoming overwhelmed with large amounts of stimulation, such as a busy shopping area, driving in traffic, or being around people where there are multiple simultaneous conversations. Another issue was that the patient was very anxious to get back to his normal activities, particularly exercising. He was an avid bicyclist and loved to exercise. Both the patient and his spouse admitted a tendency toward impatience, particularly when doctors set limits on his activities. He stated that he was trying to take walks and use a stationary bike but found these to be unfulfilling compared to his previous level of activity.

From a neuropsychological perspective, the patient demonstrated average intellectual functioning and was performing normally on tests of attention, working memory, visuomotor tracking, verbal learning and immediate recall, retention, and recognition. He also performed normally on tests of visual recognition, expressive language, and response inhibition. Thus, he had likely made a reasonably good cognitive

recovery at the time. He was demonstrating moderate deficits in psychomotor speed, mild deficits in verbal encoding and delayed verbal memory, significant visuoconstructional deficits with low average visual free recall, moderately impaired cognitive flexibility, mildly impaired higher level executive functions, and mildly impaired processing speed.

I met with the patient and his wife about a month later to review the neuropsychological test results and discuss recommendations. Following the introduction and overview of the feedback process, the patient's individual test results were discussed. Although the patient had made a reasonably good cognitive recovery at the time of the assessment, he continued to have deficits and became easily overwhelmed with large amounts of stimulation, a common impairment seen in TBI patients. Therefore, it was important to present the information in small chunks and use strategies to ensure understanding. Fortunately, his wife was present for the feedback—which would help should they decide to review information from our session at a later time. An example of the dialogue is as follows:

GORSKE: “Do you remember the test that required you to draw a line connecting numbers and letters? Like 1-A, 2-B, etc.?”

PATIENT: “Oh yes, I remember that. I think I started off OK but then I got lost?”

GORSKE: “That’s right, you started off pretty well but then lost track about half way through. Do you remember what it was like to do that test?”

PATIENT: “I’m not entirely sure. I think I remember just saying it in my head (1-A, 2-B, 3-C) but then at some point I kind of blanked and forgot what I was doing. I’m not sure I can explain it any better.” (The patient’s wife is sitting behind him and nodding vigorously).

GORSKE: “So it seems like when it comes to activities where you have to move your attention from one thing to another as quick as you can, you might do OK for a while but then find yourself lost. It looks like you wife has something to add to this.”

PATIENT’S WIFE: “Yes, this is what happens throughout the day. He tries very hard to help out around the house, which is fine if I give him one thing to do and he sticks with it, but then he tries to do more than one thing at a time; he starts out OK but then there are times I’ll see him just standing there looking lost.”

GORSKE: (To patient) “Did what she said make sense and have you noticed this yourself?”

PATIENT: “I don’t really notice when I *blank* out until someone sort of *wakes me up*. Then I realize that I haven’t done what I set out to do. It’s frustrating because I’m really trying to get better. It’s been what, eight months now? I feel like I should be back to normal now and that’s what gets me more depressed than anything. I’m not depressed like sleeping all day or want to kill myself, I just get impatient and down.”

PATIENT’S WIFE: “Honestly, you’re trying too hard I think.”

This interaction brought up some important issues for the patient’s recovery. One of the issues he struggled with was multitasking, which was reflected in his reduced executive functioning scores in addition to lower processing speed. This is a common cognitive deficit following a TBI, and ways were discussed to help the patient identify situations he is most likely to try and multitask, learn to slow down and break tasks into smaller and more manageable “chunks,” and ways his wife could remind him to follow this plan so he doesn’t try to manage too much at one time. However the larger issue was the patient’s frustration and impatience with his perceived lack of progress and intense desire to “get better” and get back to normal activities. This tendency was consistent with his personality. Prior to the TBI he was very active—almost obsessive—about exercising and working, and easily managed multiple tasks at one time. The patient tended to minimize the intensity with which he approached activities, but his wife stated that he would often work himself to exhaustion in an effort to convince himself and others that he was back to normal. As a result he would be exhausted and nonfunctional the next day. In fact, through further exploration it was discovered that the day before he suffered the seizure he had been extremely active on a stationary bike, and doing activities in and outside the house, and likely did not drink enough fluids. From this conversation a plan was developed that included (a) frequent planned rest breaks throughout the day, (b) counseling with a rehabilitation psychologist on learning the physiological and mental signs that he may be pushing himself too hard and needs to stop and rest, (c) general brain injury recovery education about timelines and reasonable expectations for progress. The patient’s psychiatrist and neurosurgeon reinforced these suggestions, and over time plans were developed for gradual supervised re-entry into activities such as bill paying and other household activities. Counseling helped him cope with his frustrations and impatience.

This case illustrates some of the ways CTNA can be used in neurological disorder cases.

- 1 Awareness and insight: In this patient’s case, there was evidence of anosognosia that was keeping him from being fully aware of his cognitive and functional deficits. However, there was also an element of emotional denial given his premorbid personality was one of very high activity that was almost obsessive in nature yet functional. Now that same premorbid tendency was a detriment to recovery because the patient became overwhelmed easily and his insistence on pushing through actually caused him to regress. The objective data, combined with an empathic and inquisitive approach presented in small and understandable points, allowed the patient to gradually integrate the information and, with the help of his spouse, use the information to enhance his recovery.

- 2 Providing information about cognition that is applicable and relevant: In order to make the cognitive information understandable and relevant, a continual give and take occurred between the neuropsychologist, patient, and family member about what skills the tests are assessing and how those skills apply to the patients' daily life. One method for this is using plain and simple language. A second method is finding an example in the patient's daily life that he or she can relate to and use that situation to illustrate a cognitive skill. Another method is the use of story or metaphor, as illustrated in Postal and Armstrong (2013). For this patient, biking was used to explain the concept of cognitive set shifting: "Do you remember a time when you would be riding on a road behind a car and the car would come to a sudden stop? What kind of things did you have to do to avoid hitting the car? First, you had to sense that the car had abruptly stopped and judge your distance from the car; second, you had to apply the brakes; third, you had to shift your body weight back so you wouldn't fly over the handlebars; fourth, you had to unclip your feet so you could put them on the ground so you wouldn't fall. Those four basic things used to be automatic and your brain easily shifted from one task to another rapidly and almost effortlessly. However, now the brain becomes confused and it doesn't send messages as quickly. It's as if your brain needs to relearn how to do this."
- 3 Developing recovery plans: From one test (Trail Making B) two important recovery issues were identified, including (a) the need to break up multitasking activities into smaller parts, and (b) the need to increase rest breaks and learn to listen to his mind and body to avoid exhausting himself and compromising his health and recovery.

This case illustrates ways to develop goals and objectives that can guide TBI rehabilitation and assess progress at a later date. The next case shows how a young woman used the neuropsychological assessment experience to help her cope with an existential crisis in her fight with brain cancer. This case shows how the CTNA approach can go beyond educating patients about cognitive functioning for goal development and delve more deeply into their daily struggles and life stories (Finn, 2003).

### *Case 2: The Case of Amy, Continued*

In 2008, I wrote an article that was published in the *Journal of Humanistic Psychology*, "Therapeutic Neuropsychological Assessment: A Humanistic Model and Case Example" (Gorske, 2008). This article introduced "The Case of Amy" (p. 327). Amy was a young woman diagnosed with brain cancer who underwent neuropsychological testing and feedback in July 2006. Meetings together illustrated the spirit of CTNA, which is the use of neuropsychological test results as a tool to

understand and form a patient's "life story" to promote healing and growth. Amy's real name, published here with permission from her estate, was Marisa Muscarella, and sadly she died on April 2, 2012 after becoming sick and suffering a seizure presumptively related to her brain cancer. This case study conveys more of Marisa's life story following the initial meeting in 2006.<sup>1</sup>

Marisa was born in 1976 to a Sicilian father and a mother from the island of Malta. Marisa was described as a very intelligent, passionate, and strong-willed young woman who had an intense zest for life and was not afraid to express her opinions to others. She described herself as someone who "loved to wake up in the morning" (Gorske, 2008, p. 329) and her family described her as the "go-to" person when it came to knowing the latest activities and events around the city. She was especially passionate about good food and restaurants in Pittsburgh, Pennsylvania, and had high standards as to how food should be cooked, served, and savored. She earned a Master's Degree in Social Work in 2001 and was working with children in the Pittsburgh public schools. She brought the same passion and zest for life to her work and it was said that she treated the children she worked with as if they were her own.

Marisa was diagnosed with brain cancer in April 2006. The details of her diagnosis and treatment are in Gorske (2008) but will be briefly summarized. She experienced her first symptoms around April 26, 2006 when she became ill and suffered a grand mal seizure. Following treatments and evaluations she was initially diagnosed with a grade I pilocytic astrocytoma in the right temporal lobe and underwent surgery on May 23, 2006, which was by all accounts successful at the time. However, later testing revealed that she actually had a grade IV glioblastoma and she began radiation and chemotherapy. I first met Marisa on July 15, 2006 for neuropsychological testing, which was broken up over two days with a feedback session a few weeks after. The details of the testing and feedback session can be found in Gorske (2008). The predominant theme that arose from the meetings and feedback session was Marisa's strong and intense desire to hold onto her sense of self, which she felt was being robbed of by the tumor and consequent treatments. Her neuropsychological test results revealed some expected, mostly mild, deficits consistent with the location of the tumor in her brain and compounded by the effects from chemotherapy and radiation treatments. What was most impressive was how the neuropsychological tests became a "battleground" for Marisa where she was going to prove to herself and others that she would reclaim the life that the cancer was trying to take from her. This was most evident on the Digit Span Subtest of the Wechsler Adult Intelligence Scale, third edition (WAIS-III) where despite her obvious exhaustion she managed to perform in the 96th percentile for Digits Forward and the 92nd percentile for Digits Backward (Gorske, 2008). Another theme that emerged was the need for Marisa to create balance in her life. Although her desire to "beat"

the cancer energized her and pushed her to heal herself, this also took an immense toll on her in that she was frequently exhausted and could not be at her best. This was illustrated by her performance on the Rey Complex Figure Test. On this test she was so intent on performing “perfectly” that she was tense, anxious, and not processing the information efficiently. The fact that she experienced peripheral vision loss made it even more difficult. Her experience of that subtlety became a teaching moment when I encouraged her to relax, breathe, and just try to “soak in” the whole picture without trying to be perfect. This “perfectionistic tendency” became a second theme wherein Marisa needed to find a balance between fighting and giving herself permission to rest and heal (Gorske, 2008). The recommendations generated from the CTNA feedback session reflected these two themes: (a) Marisa was going to continually search for ways to battle the cancer and reclaim her sense of herself; and (b) that she would learn to listen to her mind and body, and give herself permission to rest and to heal so she can re-energize and be at her best to continue the battle.

Once the diagnosis of brain cancer became a reality, Marisa experienced sadness, depression, and grief, but in the same turn her family described her as being happier with the simple things in life. Her basic personality remained the same. She was still passionate, strong willed, and had an intense zest for life—but her focus changed. Her family described it as changing from focusing on worldly things to simpler things. She became stronger in her faith and found comfort in Bible passages such as Philippians 4:11–13: “I am not saying this because I am in need, for I have learned to be content whatever the circumstances. I know what it is to be in need, and I know what it is to have plenty. I have learned the secret of being content in any and every situation, whether *well fed or hungry, whether living in plenty or in want. I can do all this through him who gives me strength.*” She joined a brain cancer survivors group and support group, which would go on trips—including a rock climbing excursion (being a brain injury specialist, I was a bit concerned about this, but she was adamant). She became involved with Gilda’s Club in Pittsburgh; she took college classes and was working on a Master’s Degree in Food Studies; she took both Salsa and Belly Dancing lessons; and she learned Italian at The Chautauqua Institute in addition to many other new endeavors. She was “in her glory” when she visited Sicily with her father, Giovanni Muscarella, because she was very proud of her heritage. Sadly, her father died in November 2009. Most of all, her family described Marisa as someone who wanted to be around others. She would confide in and talk with someone whenever she could and was always ready to express her thoughts, her fears, and her hopes.

I met with Marisa two other times, in May 2007 and September 2010. She shared many of the things described earlier. She talked about all the activities she was involved in, how her treatments were progressing, and how she felt on a day-to-day basis. She shared all the positive things that were happening,

but also the painful things such as the physical toll, relationship challenges, and fears about the future. After testing, there were feedback sessions that always revisited the themes developed in the first meeting. Marisa admitted that she often struggled with the “resting” part, but was getting better at listening to her body and knowing when it was time to stop, regroup, rest, and heal. She also had a black Labrador Retriever mix who was a source of love and comfort for her and was described as a dog who would “take Marisa for a walk.”

Marisa was stable and doing well even up through January 2012. She was among the few people who had survived more than five years having been diagnosed with a grade IV glioblastoma. She continued to follow up with neurology and Duke University Medical Center in addition to all her other activities. In March 2012 she had been experiencing migraine headaches and nausea. On April 1, 2012 she experienced severe bouts of headache, nausea, and vomiting and was taken to the emergency room in Pittsburgh. Her computed tomography (CT) scans were essentially unchanged at the time. She was admitted to the hospital and during the night was found on the floor of her room unresponsive. Attempts to revive her were unsuccessful and her time of death was recorded 5:15 am on April 2, 2012, at age 36. A later autopsy would reveal the cause to be a seizure leading to unexpected death.

During the time before her death her family described her as suffering but compassionate. She was described as kind and sweet to everyone, and appreciative of all they had done and continued to do for her. In the last few weeks and months before her death she was also described as frequently disoriented, fatigued, and nauseous. Despite these symptoms she continued to try to do things for her family in an effort to feel normal, such as help with the laundry and drive her mother places, even though they would plead for her to rest. The day before she became very sick and had to go to the emergency room, her mother was sitting on a chair, exhausted from caregiving. Her mother thought to herself out loud, “I wish someone would make me a cup of tea.” Marisa did just that. This reminded her mother of when Marisa was a little girl, she would do things like put a blanket on her mother when she was lying or sitting on the couch. Even up to the very end, Marisa was doing things that were true to her sense of self.

After Marisa’s death and funeral there were many changes in her family. Her mother moved from Jamestown, New York to live closer to her family in Pittsburgh. Her mother, sister, and other family members became more involved in the church Marisa had been attending. Marisa’s mother became involved in a church ministry to women in prison. In doing so she reached out to a particularly troubled woman by giving her a bible that had belonged to Marisa. It was somewhat worn with writing and highlights throughout the book. This gesture was a transformational experience in her mother’s relationship with this woman, and her mother stated that she felt Marisa’s presence during the encounter. Marisa’s sister made some bold changes of her own. One in particular

involved a plot of land that Marisa had wanted her sister to have for a garden. Sometime after her death, Marisa's brother-in-law created "Marisa's Garden" where they grow herbs and vegetables that they use to feed and share with others. Marisa's family says that people come up to them almost every day and tell stories of how Marisa touched their lives. One time Marisa's mother recalled the movie *The Blue Butterfly*, which was the story of a terminally ill boy who travels with an entomologist to South America to find and catch an elusive and mythic blue butterfly. During a time when Marisa's mother was grieving and holding a picture of Marisa, she saw a butterfly near the house and felt Marisa's presence—Marisa also loved butterflies. Even after her death, Marisa's sense of self was inspiring, moving her family to take risks, make changes, and connect with something larger than themselves.

My last meeting with Marisa was September 27, 2010. Her family stated that Marisa spoke of the neuropsychological testing and feedback sessions, saying that they were very positive points in her life, and that she used them to prove that she would not be affected by the tumor, chemo, and radiation treatments. Of course, I have no misconceptions that the testing and feedback sessions were *pivotal points* for Marisa that were dramatically life altering. What I would like to believe is that these meetings were brief *pit stops* where Marisa could see how she was doing from a cognitive and emotional perspective in terms of the goals and themes developed from the initial meeting in July 2006. Marisa had always feared losing her sense of herself as a person and that the tumor and treatments had somehow changed who she was. One would like to think that the neuropsychological assessments and feedback sessions were small microcosms of her greater struggle that allowed her to gauge where she stood in her fight against cancer to reclaim her sense of self and make any needed changes from discussing the results and the implications for her life. Based on everything observed and heard from her family, Marisa's personality and sense of self were never lost, but instead redirected and refocused to where she touched people's lives in a deeper and more meaningful way than even she may have imagined. Not only was her sense of self retained, but it actually grew and flourished to where Marisa became even more like the person she wanted to be. She always remained energetic, a "type A go-getter," passionate, and strong willed. This was who she was before the cancer, during her fight against the cancer, and even beyond death when she continued to touch the lives of others and most importantly her family. Given that Marisa's goal was to claim her sense of self in her fight with cancer, one thing is clear: She won.

## Note

- 1 The author would like to thank Michelle Ulrich, the executor of Marisa Muscarella's estate, for giving express written permission to use Marisa's name and other identifying medical information in the writing of this chapter.

# 49 Empirically Based Rehabilitation of Neurocognitive Disorder

Anthony Y. Stringer

*I am convinced that considerable results can be obtained with restoring to aphémiques the part of their intellect that perished with a part of their brain.*

—Paul Broca

## A Short History of Cognitive Rehabilitation

In his seminal 1865 paper, Paul Broca (transl. Berker, Berker, & Smith, 1986) not only solidified a new era in our understanding of aphasia, but he also introduced the idea that, with training, aphasic patients could regain aspects of their compromised oral and written language ability. Arguably, cognitive rehabilitation therapy (CRT) has been practiced since at least this early observation. The large number of World War I and II soldiers who, thanks to medical and surgical advances, survived what formerly were fatal penetrating missile wounds to the brain, gave further impetus to this burgeoning field and expanded its reach beyond language disorder (Prigatano, 2009). In the 1940s, Aleksandr Luria, then a member of the Russian National Volunteer Corps, organized a hospital in the Southern Urals dedicated to the rehabilitation of recovering soldiers (Homskey, 2001). Luria's wide-ranging clinical investigations encompassed pharmacological and rehabilitative interventions for both motor and cognitive disorders. Always an integrative thinker, Luria postulated that these interventions worked by: (a) releasing a temporarily inhibited function, (b) recruiting the participation of the spared hemisphere in task performance, and (c) reorganizing functional systems in the brain. Not surprisingly, given the scope of Luria's insights, this early rubric encapsulates most contemporary CRT approaches.

More recent growth in CRT practice is due more to carnage on the roadway than the battlefield. The postwar era brought vehicle ownership, longer driving distances from home to work, and more opportunities for vehicular injury. The 1970s and 1980s saw an expansion of CRT for traumatic brain injury (TBI), often with little demonstrated empirical support. CRT became standard care in rehabilitation hospitals throughout the United States and Europe, before outcome studies were performed. With clinical need driving this expansion, clinical science did its best to catch up. Several hundred CRT outcome studies have been completed since the 1980s. While methodological rigor has varied across

these studies, sufficient data have been collected, analyzed, and meta-analyzed to permit the establishment of practice standards and guidelines (see Cicerone et al., 2000, 2005, 2011; Rohling, Faust, Beverly, & Demakis, 2008).

The field of cognitive rehabilitation is no longer in its infancy. Since Broca's early musings about aphasia rehabilitation, CRT has matured into a multidisciplinary field grounded in the science of neuroplasticity and the art of clinical rehabilitation. This chapter provides a short overview of the practice of CRT, characterizes the various approaches utilized to rehabilitate patients with neurocognitive impairment, and summarizes the evidence on CRT outcome. The chapter closes with some projections on what this now mature field will accomplish in the decades ahead.

## Definition and Overview of Cognitive Rehabilitation Therapy Practice

The American Congress of Rehabilitation Medicine Brain Injury Special Interest Group (Harley et al., 1992) broadly defines CRT as "systematic, functionally oriented . . . therapeutic cognitive activities, based on an assessment and understanding of the person's brain-behavior deficits" (p. 62). This definition encompasses *remediation techniques* intended to restore a damaged cognitive ability, as well as *compensatory techniques* that aim to maximize functioning irrespective of whether a cognitive deficit remains. Remediation techniques generally employ a rehearsal or "mental exercise" approach to rehabilitation. They treat the brain as if it were a muscle that can be strengthened through the exercise of weakened cognitive abilities. Compensatory approaches are largely agnostic with regards to what happens to underlying cognitive abilities. Their goal is to improve functioning using any technique that allows a patient to circumvent cognitive limitations. Such techniques may be internal, as when patients are taught a mnemonic strategy to aid recall of information, or external as when patients use a notebook or calendar to store information they would otherwise forget. Rehearsal and practice remain an important aspect of compensatory CRT, but the goal of rehearsal is to make patients proficient in the use of a strategy rather than to restore a cognitive ability.

Surveys of cognitive rehabilitation practice patterns are few and far between. Unfortunately the most recent surveys are more than a decade old. Blundon and Smits (2000) surveyed Canadian occupational therapists at 27 nonrandomly selected sites to identify therapeutic modalities used to treat brain injury survivors. With a 74% response rate, these investigators reported memory impairment was the most common cognitive domain treated. Interventions included both compensatory and remediation approaches.

Stringer (2003) sent surveys to 270 randomly selected rehabilitation hospitals and programs within all nine American Hospital Association regions (covering the United States, Puerto Rico, and Canada), yielding a 45% response rate. Cognitive compensation approaches were being utilized only slightly more often than rehearsal approaches. The most common areas of cognition addressed (in order of highest to lowest frequency) were attention, memory, reasoning/executive function, and visual perception. Rehearsal techniques utilized (again in order of frequency) included practice of activities of daily living, paper-and-pencil exercises, practice of vocational tasks, board games that involved cognitive skill, computerized cognitive exercises, and computer games. The most common compensatory strategies in rank order were written aids, problem-solving strategies, mnemonics, and electronic aids.

Patients with strokes or traumatic brain injuries were the most common patients being treated in the Stringer survey, but CRT was also attempted with patients diagnosed with brain tumors, dementia, anoxic brain damage, demyelinating diseases, and cerebral infection. The CRT field was truly interdisciplinary, with (in order of frequency of involvement) speech therapists, occupational therapists, neuropsychologists, recreation therapists, physical therapists, and nurses all delivering care. The overwhelming majority of patients in the programs responding to this survey were in individual CRT, with group sessions rarely utilized. Most patients were in therapy from one to six months, with relatively few programs reporting patients finishing therapy in less or more than this period of time.

Much has doubtlessly changed in the years since these surveys were collected. Lumosity, the leader in Internet-based computer games intended to improve cognitive function, reports on its website ([www.lumosity.com/](http://www.lumosity.com/)) having 50 million users from 182 countries. While the vast majority of these are healthy individuals with no discernable cognitive impairment, the 50 million users doubtlessly include people with neurocognitive impairment who are attempting to improve their abilities independently or with the guidance of a therapist. Even more striking, since smartphones were first marketed in 1996, users have grown to 1 billion worldwide (Business Wire, 2012). With their ease of use and countless applications that store information, remind users of appointments and tasks, and provide organizational tools, these almost ubiquitous devices cannot help but find use as compensatory aids for cognitively impaired patients. A

contemporary survey would likely find a very different profile of remediation and compensatory-based rehabilitation strategies in use in North America.

## Cognitive Rehabilitation Therapy Approaches

Both remedial and compensatory CRT approaches are available for the three most commonly treated cognitive domains of attention, memory, and executive function/problem solving. Before turning to the outcome research, I'll briefly illustrate each approach with respect to these three cognitive domains.

### Attention

Attention Process Training (APT) (Sohlberg & Mateer, 1989) attempts to remediate deficits in sustained attention, working memory, selective attention, suppression of response to competing inputs, and alternating attention through the use of progressively more difficult cognitive exercises. The earliest version of APT utilized paper-and-pencil exercises; however, the latest version uses computer administration with the assistance of a therapist. The patient moves from relatively easy exercises to more complex tasks as performance improves. Both visual and auditory stimuli are incorporated, although most of the activities are fairly artificial and would not be encountered in everyday life. The therapist plays a vital role in treatment, and the program is not intended for unaided patient use.

Lumosity and PositScience Brain HQ are more recent Internet-based examples of the remedial approach to attention; however, these programs also target the much larger healthy population by promulgating the idea that neurologically healthy people need to exercise their brains. PositScience ([www.positscience.com/why-brainhq](http://www.positscience.com/why-brainhq)), for example, draws a direct analogy to the "revolution" in physical fitness that took place in the 1980s and 1990s when more people began going to the gym. "Brain fitness" is supposedly the "next step in that revolution." Physical fitness, however, became a contemporary priority in the United States as a consequence of increasingly sedentary work, high-calorie fast-food diets, and a growing rate of obesity. In contrast to this physically sedentary lifestyle, contemporary life does provide ample cognitive exercise for neurological healthy people, leaving little need for a "brain workout."

While not well-researched in adults, excessive time spent playing computer games is associated with eye strain (Gillespie, 2002) and obesity (Carvalho, Padez, Moreira, & Rosado, 2006) in nonclinical pediatric samples, and may provoke seizures in pediatric epilepsy patients (Shoja et al., 2007). Hence, it is a bit ironic to posit that computerized games can lead to fitness of any kind in presumably healthy individuals.

These Internet-based approaches to attention make little use of a therapist. This may arise from the fact that their

primary market is comprised of healthy individuals. Active involvement of an actual therapist may be critical to the success of cognitive rehabilitation. This may give APT an advantage over most of the Internet programs. However, it should be noted that one such program—Scientific Brain Training Pro (SBTP; at [www.scientificbraintestingpro.com](http://www.scientificbraintestingpro.com))—does incorporate a therapist and allows the therapist to select exercises, monitor performance, and guide participation even when the patient is playing the games on a home computer.

Compensatory approaches to attention are largely absent from the clinical and research literature, however, in our clinic (Stringer, Denham, & White, in press) we utilize a technique called DIRECT. This approach teaches a patient to “direct” attention by manipulating the environment. DIRECT is an acronym that cues the patient to manipulate six factors in the environment in order to compensate for attention impairment. These six factors are (a) *Distractions* and (b) *Interruptions* (both of which the patient should eliminate), (c) *Rate of performance* (which the patient increases or decreases to maximize attention), (d) *Earnings* (which the patient tries to increase, as we tend to pay more attention when there is a tangible and immediate payoff), (e) *Complexity* (which the patient tries to decrease as attention wanes when tasks are too complex), and (f) *Tiredness* (which the patient uses as a cue to take a break as attention tends to wane with fatigue). The intent of therapy is to give the patient tools that can be used in everyday home and work settings to maximize attention. The techniques are intended to improve performance in attentionally demanding situations, without necessarily improving actual attention abilities. What hopefully does improve is the patient’s ability to recognize what in the environment can be changed to facilitate attentiveness.

### Memory

Lumosity, PositScience, and SBTP also include Internet-based games to improve memory. Lumosity, for example, includes games that require the recall of spatial positions, associations between stimuli, and associations between names and faces. In contrast, the BrainTrain program ([www.braintrain.com/](http://www.braintrain.com/)), provides cognitive remediation software that runs on a desktop computer or network, with optional cloud data storage for remote access. BrainTrain, one of the earliest exemplars of the mental exercise remedial approach, has been continuously updated since 1989 to now include hundreds of exercises in its “Memory Gym.” The program also incorporates EEG monitoring and brainwave feedback to develop what the program refers to as “CHARM”—a calm, happy, alert, and relaxed mental state. Regardless of whether the approach is Internet or desktop-based, the basic premise continues to be that an impaired mental ability can be repaired through exercise and practice. BrainTrain and SBTP incorporate a therapist, while as already noted, Lumosity and PositScience do not. All programs target both

the cognitively impaired and the cognitively healthy who want to improve functioning from a current baseline.

Compensatory approaches to memory provide internal mnemonic aids or external means of storing and retrieving information with the intent of improving memory performance, if not actual memory ability. Mnemonic strategies are as old as ancient Greece. Cicero (Sutton & Rackham, 1942) relates the legend of Simonides (circa 556–468 B.C.), a Greek poet who narrowly escaped the collapse of a banquet hall roof and subsequently discovered he could identify the physically unrecognizable corpses of the diners by recalling where they were positioned around the banquet table. From this experience came the “method of loci,” a strategy for mentally associating an image of something to be recalled with a location along an already known path. Once the association is learned, the information is recalled by taking a mental “walk” along the path to see what image has been placed in each location.

These and other mnemonic techniques were originally intended to enhance the performance of healthy individuals whose work demanded a prodigious memory. Clinicians have adapted them for use by patients with memory impairment. The “peg system,” another imagery mnemonic, makes use of high-imagery words that rhyme with numbers 1–12 (systems developed for healthy individuals expand the number of peg words well into the hundreds, but clinicians typically make use of only 10–12 peg words). The rhyme makes it easy for even people with memory impairment to learn the number-word association (e.g., “one-bun,” “two-shoe,” “three-tree”). Once the association is learned, an image of the peg word can serve as a substitute for the associated number. Chains of such images provide a means of learning a series of digits such as a phone number or address. These imagery chains are often humorous or bizarre, which enhances their memorability. A patient who recalls the image chain can back-translate it to retrieve the desired number.

While many mnemonics are imagery based, verbal strategies are also common. In an acronym, each letter of a word represents a piece of information to be remembered. Similarly, in an acrostic, the first letter of each word of a sentence represents the target information. Such techniques rely on the memorability of the word or sentence, which then cues recall of the embedded information. Beginning piano students, for example, learn to associate notes with the lines and spaces of a musical staff using such acrostics as “Every good band draws fans,” with the first letter of each word (“E,” “G,” “B,” etc.) representing a musical note.

Some verbal mnemonics enhance depth of information processing, rather than providing a means of storing and retrieving information. “PQRST,” a strategy for learning narrative information, guides the reader to first preview text, develop questions about the content, read the text to answer the questions, study the questions and answers to memorize the content, and test memory by attempting to recall the answers to the questions. PQRST fosters a deeper

engagement and depth of processing of the narrative in order to facilitate retention of content. While not providing a specific mnemonic strategy, it uses an acronym to help the reader remember the steps in the process.

External memory aids attempt to put information at a patient's fingertips in an easy to retrieve format. Low-technology examples include memory notebooks and appointment calendars. The advent of personal digital assistants and wearable technology has made available many new ways of storing and retrieving information. A smartphone can provide a calendar of appointments and scheduled activities, an alarm to cue a patient to keep the appointment or perform the activity, multiple applications for storing information that might be needed at home or in the community, a global positioning system application and maps to assist with navigation to a destination, applications for storing information (including a photograph) about people, and a means of summoning help via text or voice when all else fails. Smartphones and portable tablet computers are, in essence, all-purpose external memory aids for both the cognitively well and the cognitively impaired.

Even people with intact memories struggle to retain all the information that comes at them in the course of a day and utilize a combination of internal and external memory aids. Consequently, it makes sense to incorporate both types of aids in working with memory-impaired patients. One difficulty, however, is that patients often mix up which aids to use with which type of information. The Ecologically Oriented Neurorehabilitation of Memory (EON-Mem) program (Stringer, 2007) makes use of both internal and external memory aids, and attempts to reduce patient confusion by using the same four-step method (Write-Organize-Picture-Rehearse) for all types of memory content.

A final compensatory approach to memory should be included here, known as "domain-specific learning" (DSL; see Schacter & Glisky, 1986). This approach, developed for severely amnesic patients, utilizes memory strategies without *explicitly* teaching them to the patients. Instead, often severely amnesic patients, are taught specific content utilizing *implicit* memory strategies. For example, the DSL approach may use "errorless learning," in which maximum cues are provided on every trial so that the patient never makes a mistake during the acquisition of a skill or information. Cues are gradually faded, but never so rapidly as to produce a performance error, until the patient has mastered the skill or acquired the information. Incorrect responses are thought to compete in one's memory with correct responses, hence by avoiding errors, learning is enhanced even in an amnesic patient. Another common strategy utilizes "spaced retrieval," in which the time between study and recall is systematically increased, but again at a rate at which recall accuracy is maintained. Using these and other implicit strategies, even amnesic patients can learn complex skills, despite having no recollection of ever undergoing training (Glisky &

Schacter, 1987; Glisky, Schacter, & Tulving, 1986a, 1986b; Schacter, Rich, & Stamp, 1985).

DSL is compensatory in the sense that it attempts to enhance performance through a learning strategy, but it does not attempt to improve memory ability. It has some unique limitations. Human beings seem to naturally learn through trial and error, and it can be a challenge to design a rehabilitation intervention in which errors are eliminated. As patients are taught specific content, rather than a strategy they can independently use across content, the technique may not generalize to new content and the patient may never be independent in use of the technique. In addition, learning can be hyperspecific. In amnesic patients, even a minor change (e.g., switching keyboards when patients were being taught to operate a computer) is sufficient to eliminate the benefits of training (Glisky et al., 1986a). Despite these limitations, DSL can improve performance in amnesic patients who do not respond to any other remedial or compensatory approach.

### ***Problem Solving***

To varying degrees, the Internet and desktop computer remediation programs already discussed include exercises that target problem solving, reasoning, and related abilities. PositScience has fewer exercises in this area. It includes what it refers to as "Intelligence Exercises," but these consist primarily of variations on the "n-back" task in which a player tries to determine whether a current stimulus matches a previous stimulus presented a specified number of trials back. Lumosity, in contrast, makes use of a number of arithmetic games to provide practice in problem solving. SBTP uses "Tower of Hanoi" games in which patients must follow preset rules for moving stimuli from one location to another, word puzzles (e.g., cracking a code in order to decipher a famous quotation in which letters have been replaced by coded symbols), and sequencing exercises. These are all computerized versions of an earlier generation of paper-and-pencil "brain teaser" games in which people attempt to solve riddles. Often the solution involves paying attention to the wording of the riddle in order to discover a clever resolution.

The compensatory approach typically utilizes a problem-solving algorithm that can be applied across different problems. These algorithms variously emphasize slowing down decision making, thinking flexibly, brainstorming, and being systematic. Goal Management Training™ (GMT) teaches five problem-solving steps: Stop (become aware of the problem situation), Define (set a goal), List (divide the problem solving task into substeps), Learn (remember the steps for completing the task), and Check (compare the result to the goal). In our clinic, we employ the Ecologically Oriented Neurorehabilitation Executive (EON-Exec; see Stringer et al., in press) program, which makes use of the acronym "GO-AS" to teach four problem solving steps: setting a Goal, developing Options for achieving the goal, Anticipating and

rating the outcomes associated with each of these options, and selecting the option that leads to the best anticipated outcomes. We have also adapted GO-AS for modern times by developing a “smart form” version that runs on tablet computers. In contrast, GMT is designed to run on a desktop computer system only. Both programs utilize a variety of problem scenarios to train patients in use of the respective algorithms.

### **Cognitive Rehabilitation Therapy Outcome Studies**

Having characterized remedial and compensatory approaches to attention, memory, and problem solving impairment, in this section I will review evidence on the outcome of cognitive rehabilitation. Specifically, the following three questions will be addressed: (a) For what neurological conditions is CRT effective? (b) For which cognitive domains is it effective? (c) Is there an outcome difference for remediation versus compensatory CRT approaches? In answering these three questions, we will consider the results of available evidence-based reviews and meta-analytic studies, updated with more recently published studies not included in these reviews.

#### ***For What Neurological Conditions Is Cognitive Rehabilitation Therapy Effective?***

The overwhelming majority of research on CRT outcome has been in patients with stroke or TBI. For these two patient populations, the evidence for CRT effectiveness is quite strong. Cicerone and colleagues (Cicerone et al., 2000, 2005, 2011) on the Brain Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine have reviewed a combined 60 prospective, randomized controlled trials (RCT) and an additional five quasi-randomized studies of cognitive rehabilitation in stroke or TBI. Across these studies, CRT was found to improve cognitive performance in stroke and TBI. The European Federation of Neurological Societies Task Force on Cognitive Rehabilitation came to a similar conclusion (Cappa et al., 2005) as the Cicerone group with regards to the benefits of CRT in stroke and TBI.

Rohling et al. (2008), however, came to more tempered conclusions about CRT outcome in TBI and stroke after conducting a meta-analysis of the RCTs, nonrandomized control group studies, and single group pre- and posttreatment comparisons included in the first two of the Cicerone et al. (2000, 2005) reviews. Many of the studies included in the Rohling et al. meta-analysis were also included in the Cappa et al. (2005) paper, so their less sanguine conclusions apply to the European review as well. Rohling and his colleagues found that effect sizes tended to be small in true RCTs. Effect sizes were larger in single group, pretreatment, and posttreatment comparison studies. These larger effect sizes

in single-group designs were thought to be due to practice effects from repeated test administration.

Stringer (2011) directly compared CRT outcome across stroke, TBI, and a mixed neurological group in a nonrandomized clinical trial and found all three groups showed comparable improvements in memory performance with a strategy training program. Effect sizes were 0.65, 0.73, and 0.89 respectively for stroke, TBI, and the mixed neurological groups. Importantly, this study controlled for practice effects in many of the pre- and posttreatment comparisons by utilizing alternate test forms when available. Effect sizes remained high even when practice effects were controlled in this manner, and the average effect size across patient groups did not differ significantly when the same (effect size of 0.75) or an alternate (effect size of 0.72) form was used.

Stringer's (2011) mixed neurological group was too small for findings to be considered robust, but it included patients diagnosed with epilepsy, brain neoplasm, or cerebral infection. The fact that the effect size was highest in this group suggests that CRT may be effective in patients with neurological diagnoses beyond stroke and TBI. Though fewer studies have been conducted in patient populations other than TBI and stroke, results have generally supported CRT effectiveness.

Given their often prominent anterograde memory impairment, temporal lobe epilepsy (TLE) surgery patients have been the target of several CRT studies. In one of the earliest studies of CRT in this population, Jones (1974) reported improved verbal memory performance when left temporal lobectomy patients used an imagery mnemonic. Engelberts et al. (2002) contrasted patients randomly assigned to compensatory training, remediation, and a wait-list control group. Both CRT groups showed improved performance on neuropsychological tests, decreased cognitive complaints, and higher quality of life scores after treatment and at a six-month follow-up. However, the patients undergoing compensatory training improved more in word memory, while patients undergoing the remediation approach showed increased response rates.

Helmstaedter et al. (2008) compared treatment and no treatment control patients (matched on demographic and seizure-related variables), in a nonrandomized clinical trial. Postsurgical CRT was multifactorial and included computer exercises, group interventions, and occupational therapy. CRT resulted in better verbal learning (with less impact on retention). Visuospatial memory did not show improvement and attention improved in all patients regardless of whether they received CRT.

A weakness of both wait-list and no-treatment control studies is that the control group gets less attention and has fewer opportunities to interact with a therapist, so that treatment effects could result simply from greater contact. It is reasonable to expect these nonspecific factors to impact all cognitive functions equally. The differential effect of CRT on verbal versus visuospatial memory in the Helmstaedter et al.

(2008) study and the different effects of remediation versus compensatory training in the Engelberts et al. (2002) study support, but do not prove, the hypothesis that the effects were due to the interventions rather than the greater attention that treated patients receive.

Taking a somewhat different approach, Koorenhof, Baxendale, Smith, and Thompson (2011) compared pre and postsurgical CRT in TLE patients. Presurgical CRT did not lead to a better outcome than did postsurgical CRT and improvements on outcome measures were associated with improved mood. While not providing strong support for CRT in TLE, the study highlights the importance of considering the impact of affective status in CRT outcome research.

Butler and Copeland (2002) combined elements of the APT remediation program for attention (described on p. 1074), strategy training, and cognitive behavior therapy and found better attention performance in a group of treated brain tumor patients ( $n = 21$ ) compared to wait-list controls ( $n = 10$ ). In a larger, multicenter study, Butler et al. (2008) randomly assigned brain tumor patients to the treatment combination described earlier ( $n = 108$ ) or to a wait-list condition ( $n = 53$ ). Outcomes were evaluated by examiners blind to treatment condition at multiple time points from six weeks to six months after study enrollment. This study found significantly better performance on academic measures and better observer ratings of attention in the treated patients. Despite Butler's inclusion of a number of methodological controls in the second study (i.e., random assignment, multicenter recruitment, blind evaluation, and outcome assessment at multiple time points), the combination treatment used in both studies does not allow us to determine what led to improved cognitive performance. This problem is again compounded by the use of a wait-list control.

Poppelreuter, Weis, Mumm, Orth, and Bartsch, (2008) randomly assigned cancer patients ( $n = 157$ ) undergoing stem cell transplant to two groups receiving compensatory attention and memory training, or computerized attention and memory remediation. A third, nonrandomized no-treatment control group was subsequently recruited for comparison. All three groups improved significantly in outcome performance, but did not differ from one another. While studying a different cancer population than Butler and colleagues (2008) and utilizing less rigorous methodological control, these findings raise further questions about the efficacy of CRT in cancer patients with cognitive dysfunction.

A small number of studies have explored CRT in various other medical populations, also with mixed results. Hypoxic patients did not improve significantly when given CRT compared to a control group (Incalzi et al., 2008). Similarly, toxic encephalopathy patients showed no statistically significant improvement in memory performance in a study that compared training in compensatory memory strategies and psychosocial treatment (control condition) in a study using a counterbalanced crossover design (van Hout, Wekking, Berg, & Deelman, 2008). In contrast, Parkinson's disease patients

receiving practice-based remediation showed better executive functioning compared to controls receiving standard medical care only (Sammer, Reuter, Hullman, Kaps, & Vaitl, 2006); however, both groups included only 13 subjects.

As is the case with CRT research in other patient populations, attempts to demonstrate an impact in patients with early dementia or mild cognitive impairment (MCI) have struggled to show improvement in treated patients beyond what occurs in active control interventions (Martin, Clare, Altgassen, Cameron, & Zehnder, 2011). Recently, I have collaborated on a series of studies exploring CRT in patients diagnosed with amnesic MCI (aMCI). While sample sizes have been small, these studies have incorporated randomization to treatment versus active control conditions, posttreatment follow-up assessment, cognitive outcome measures, and both structural and functional magnetic resonance imaging (fMRI).

The first in this series of studies (Hampstead, Sathian, Moore, Nalisnick, & Stringer, 2008) was a pilot investigation that attempted to see whether memory strategy training was even feasible with an aMCI sample ( $N = 8$ ) given the expectation that many would progress towards dementia. Patients attempted to learn 90 face-name pairs, during three 1-hour long training sessions. Gender-appropriate names were randomly paired with the faces. The 90 training stimuli were divided into two sets of 45 face-name pairs, with each set of faces matched for gender, race, and age, and each set of names matched for length and popularity of the name. For half the pairs we trained patients to associate the sound of the name with a distinctive facial feature (i.e., the memory strategy condition). Patients rehearsed the other 45 face-name pairs without benefit of a strategy (the control condition). No differences in recognition accuracy for the two sets of face-name pairs was present before training. At the end of training and at one-month follow-up, recognition accuracy was significantly higher and response latencies were shorter for face-name pairs in the strategy training condition compared to the control condition. Patients also showed greater left temporal, parietal, anterior cingulate, insular and frontal opercular cortex activation to strategy trained stimuli, with the differences in activation magnitude for trained and untrained stimuli significantly correlated with recognition accuracy (Hampstead et al., 2011).

The second of these studies (Hampstead, Sathian, et al., 2012) randomly assigned healthy controls ( $n = 21$ ) and aMCI patients ( $n = 28$ ) to mnemonic strategy training to learn object locations within a pictured room or a control condition involving matched exposure to the object location training stimuli. While controls were always superior to aMCI patients, for both groups, strategy training led to better retention of object locations than matched exposure, a difference that persisted at one month follow-up. The ability to benefit from strategy training was positively correlated with baseline memory and executive function test performance, suggesting that the patients who benefitted the most had less

initial impairment. Structural imaging results also supported this conclusion as greater inferior lateral ventricular volume (an index of hippocampal atrophy) was negatively correlated with improvement after strategy training.

We also obtained fMRI in healthy elderly and aMCI patients undergoing strategy training or matched exposure to learn object locations (Hampstead, Stringer, Stilla, Giddens, & Sathian, 2012). Prior to training, aMCI patients showed reduced hippocampal activity during both encoding and retrieval of object locations relative to healthy controls. After strategy training, hippocampal activation increased in the aMCI strategy training group during encoding and retrieval of object locations, partially reversing the initial hypoactivation. Statistically greater activation was seen in the aMCI patients who received strategy training compared to those given matched exposure to object locations. This difference was especially evident in the right hippocampus during retrieval of object locations from memory.

Consistent with these investigations, there is an emerging consensus that CRT can improve functioning in MCI in the short term (Belleville, 2008; Cotelli, Menenti, Zanetti, & Miniussi, 2012; Jean, Bergeron, Thivierge, & Simard, 2010; Li et al., 2011; Rejinders, van Heugten, & van Boxtel, 2013; Simon, Yokomizo, & Bottino, 2012). To date, there is no evidence that CRT significantly impacts the progression of MCI patients towards dementia, although it may be neuroprotective in the healthy elderly.

A longitudinal study of cognitive training in a cohort of 2,832 older, independent, community-dwelling adults showed that groups who received training functioned better at ten-year follow-up compared to no-contact controls in the areas of reasoning and processing speed, but not memory (Rebok et al., 2014). While this project has the weakness of using a no-contact control, it remains impressive that ten initial and four booster sessions of cognitive training yields benefits evident a decade later. It is hard to attribute such a difference to treatment group contact with the experimenters in this community dwelling cohort. This project suggests there may be value in studying further the long-term effects of CRT in MCI.

Broadly speaking, the strongest evidence is for the efficacy of CRT following TBI and stroke, and indeed it is now standard of care in these patients, particularly when they have vocational and community reentry goals that require a level of independent functioning. Evidence for CRT efficacy in other diagnostic conditions is emerging, though further research is required. For example, there is beginning support for CRT in epilepsy surgery, brain tumor, Parkinson's disease, and MCI patients. While perhaps not at the point where CRT is standard care in conditions beyond TBI and stroke, the accumulating evidence makes it a reasonable intervention to attempt with any patient whose cognitive impairment is stable over at least the short term and whose quality of life may be enhanced through cognitive intervention. The decision to initiate CRT, therefore, should be focused less

on etiological diagnosis, and more on other factors that may determine treatment outcome. Such factors will be highlighted in the remainder of this chapter.

### ***For Which Cognitive Domains Is Cognitive Rehabilitation Therapy Effective and Is There a Difference Between Remediation and Compensation Approaches?***

Cognitive domain is an obvious factor that could influence CRT outcome. Is CRT effective for all or only some cognitive domains? Similarly, it is obvious to ask whether both remedial and compensatory approaches are equally effective across cognitive domains. To avoid confounding the effects of etiology and cognitive domain, in answering these questions about factors moderating outcome, it is necessary to hold etiology constant. As CRT outcome has been most thoroughly researched in TBI and stroke, we will look to research in these populations to address these questions about what moderates outcome.

RCTs and other (including nonrandomized) control group investigations in TBI and stroke have demonstrated improved memory following CRT using compensatory training (Kaschel et al., 2002; Ownsworth & McFarland, 1999; Schmitter-Edgecombe, Fahy, Whelan, & Long, 1995). Studies incorporating a direct comparison have shown compensatory training to be more effective than remedial approaches to memory (Berg, Konning-Haanstra, & Deelman, 1991; Doornhein & de Haan, 1998; Fish, Manly, Emslie, Evans, & Wilson, 2008; Kalla, Downes, & van den Broek, 2001; Wilson, Emslie, Quirk, & Evans, 2001; Wilson, Emslie, Quirk, Evans, & Watson, 2005), with the exception of one early study that failed to find a difference in the two approaches (Ryan & Ruff, 1988). Similarly, various domain-specific learning strategies appear to improve performance more than trial-and-error learning/rote rehearsal or no treatment control conditions (Baddeley & Wilson, 1994; Dou, Man, Ou, Zheng, & Tam, 2006; Hunkin, Squires, Parkin, & Tidy, 1998; Squires, Hunkin, & Parkin, 1997).

CRT therefore has yielded positive results for TBI and stroke patients with memory impairment. Memory compensation and domain-specific learning appear to be the better approaches to memory rehabilitation following TBI or stroke, a conclusion also supported by evidence-based reviews that included studies lacking adequate control groups in addition to the RCTs reviewed here (Cicerone et al., 2000, 2005, 2011). The Rohling et al. (2008) meta-analysis, however, found only a moderate (though statistically significant) effect size for memory rehabilitation in TBI, and the effect size became even weaker, and statistically nonsignificant, when the meta-analysis included only studies employing independent group pre- and posttest designs.

Rohling et al. (2008) found more support in their meta-analysis for an impact of CRT on attention. Attention training produced medium range, statistically significant

effect sizes across RCTs and single group research designs. Specifically, computer-aided compensatory strategy training has produced greater and more stable improvements in TBI and stroke patients compared to control interventions (Gray, Robertson, Pentland, & Anderson, 1992; Niemann, Ruff, & Baser, 1990). As expected with a computerized program, the interventions also incorporated considerable practice of attention skills. Hence, while they involved compensatory training, they may also have had a remedial effect on attention. Accordingly, automated computerized attention remediation programs requiring little therapist contact, and therapist-intensive programs like the APT remedial program, both improve attention performance compared to control conditions (Sohlberg, McLaughlin, Pavese, Heidrich, & Posner, 2000; Westerberg et al., 2007). Some studies, however, combine these remedial approaches with strategy training (Tiersky et al., 2005), again obscuring the active therapeutic ingredient. Direct comparison of compensatory and remedial approaches to attention, however, do appear to favor compensatory CRT (Fasotti, Kovacs, Eling, & Brouwer, 2000).

In summary, there is evidence for positive effects of both compensatory and remedial approaches to CRT for attention. Direct comparisons of the two approaches are limited, but appear to favor compensation. Typically the two approaches are combined when treating attention, so that it remains unclear whether one is truly more effective than the other. The effectiveness of attention training survives even the Rohling et al. (2008) meta-analysis, with the one notable study that failed to show a difference between attention training and a control intervention confounded by spontaneous recovery in an acute TBI sample (Novak, Caldwell, Duke, & Berquist, 1996).

Strategy training, including the GMT program described on p. 1076, improved problem-solving performance compared to control conditions in two TBI and stroke clinical trials (Levine et al., 2000; von Cramen, Mathes-von Cramen, & Mai, 1991). Hewitt, Evans, and Dritschel (2006) used an interesting combination of memory and problem solving training in an additional clinical trial. Patients were taught to use autobiographical memory (i.e., examples from their past experience) to guide them in a new planning task. This approach improved planning performance compared to a group that did not receive training in the autobiographical memory strategy.

A final study combined training in problem solving and emotional self-regulation strategies and found that, compared to “standard” neuropsychological rehabilitation, this experimental group intervention improved performance more on executive function tests, problem-solving self-ratings, and observer ratings of problem solving during role-play situations (Rath, Simon, Langenbahn, Sherr, & Diller, 2003). Interestingly, patients who processed information the slowest at baseline showed the most benefit from the experimental treatment. They did not improve on timed attention tests,

despite showing improved performance after treatment and at follow-up. The authors interpreted this as reflecting the patients’ successful use of compensatory strategies despite having ongoing executive dysfunction.

As reviewed in this section, research on problem-solving CRT is quite limited. Strategy training has been tested alone, or in combination with other strategies, and has consistently resulted in improved problem solving. Despite the number of available computerized remedial approaches that provide practice of executive functions, there is little well-designed research on the effectiveness of this approach.

### **The Future of a Now-Mature Field**

Given the amount of research conducted across multiple cognitive domains and diagnostic etiologies, CRT is arguably now a mature field of practice and research. Compensatory approaches to CRT have been shown to be effective in addressing attention, memory, and problem solving though the size and robustness of the effect varies by cognitive domain. Practice-based remedial approaches also are of benefit in treating attention and memory deficits, but have not been well-studied in the problem solving domain. In most direct comparisons, the compensatory approach appears to have an edge over the remedial approach, but in reality strategy training never occurs in isolation. Compensatory treatments always involve rehearsal of cognitive skills, and part of their effectiveness may derive from this remedial aspect of the intervention.

Given the state of the research, questions about CRT effectiveness seem less urgent than they were even a decade ago. While the most solid data on efficacy and effectiveness comes from studies of TBI and stroke patients, CRT is being used and is producing positive outcomes with a widening spectrum of medical conditions (Langenbahn, Ashman, Cantor, & Trott, 2013). CRT is standard care in the treatment of TBI and stroke, and when cognition is a factor in the patient’s quality of life, CRT is becoming standard care regardless of etiology.

Some questions, however, remain perpetual in the field of CRT. Since its inception, CRT has fallen short in proving the generalization of its benefits beyond the clinic and laboratory. This is less the fault of CRT itself, than a limitation of assessment methodologies. With neuropsychological testing itself not always able to demonstrate its ecological validity (Spooner & Pachana, 2006), it is not surprising that CRT would have a similar weakness. Given the limited ability of neuropsychological tests to predict everyday functioning, they are not the best outcome measures for a treatment study. Alternative measures include self and observer rating scales, but these are heavily influenced by rater biases. One promising approach is to use simulations of everyday cognitive activities or role-play scenarios that can be administered in the clinic (Rath et al., 2003; Stringer, 2007), but such procedures are few and far between. The best approach may be to

use a combination of neuropsychological tests, rating scales, and simulated everyday activities to evaluate CRT effectiveness, both in the clinic and the research laboratory. Without such a combined assessment strategy, generalization of training will remain an uncertain proposition.

Technology has played and will continue to play an important role in CRT. The cost of technology decreases as it pervades the societal landscape. The cognitive rehabilitation field can be expected to make increasing use of smartphones, tablet computers, and all manner of wearable technologies (Gillespie, Best, & O'Neill, 2012). The risk will be that the hype of technological innovation will exceed the substance. Commercialization of cognitive games via the Internet is a good example of this problem of exaggerated results (Owen et al., 2010), and the best antidote is the insistence on randomized control group investigations to support all claims of effectiveness. While one cannot prevent a commercial entity from making claims that outstrip the science, clinicians should insist upon a higher standard of evidence before they prescribe and use such interventions.

None of this is intended to stifle innovation and creativity. While there is little evidence supporting entire suites of cognitive exercises, there is support for the potential of specific computerized exercises to improve selected aspects of cognition (Glass, Maddox, & Love, 2013). While innovation is important, new CRT programs should minimally be based upon the science of CRT and should limit their claims to what the science actually supports. Available therapies should follow the evidence, rather than the evidence perpetually having to catch up with the available therapies.

Finally, almost no work has been done combining CRT with interventions that more directly impact brain physiology and function. Psychiatric disorders such as depression and anxiety often respond best to the combination of pharmacologic and psychotherapeutic interventions. The synergistic effect of CRT and pharmacotherapy remains unexplored, even in populations such as Alzheimer's disease where a number of drugs are available, but with only limited, short-duration benefit. It should be a priority to change this state of affairs, particularly within the drug companies that fund the majority of research in this area. Likewise, Transcranial Direct Current Stimulation, a recent innovation that alters cortical excitability by passing a current between electrodes placed on the scalp, may have a future role in rehabilitation by inducing neuroplasticity (Halko et al., 2011). Unknown is whether such techniques might also work synergistically with CRT in improving cognitive function.

Mature fields of research can stagnate if new directions of research and practice do not continuously evolve from existing protocols. While arguably mature, the field of CRT is far from stagnant. There is far more work to be done in the future than has been done up to the present. One could not ask for better future prospects for cognitive rehabilitation.

# 50 Clinical Psychopharmacology

*Samuel Alperin and Lenard A. Adler*

This chapter will provide an overview of major psychiatric disorders, including presenting symptoms, pathophysiology, and treatment options. Given space limitations, the discussion is not meant to be exhaustive or complete, but rather to provide a background for the reader that may be helpful in understanding other chapters. The treatment recommendations are not meant to be specific to any patient and treatment decisions must be tailored for each individual patient by the providers.

## Schizophrenia

Schizophrenia spectrum disorders are defined by abnormalities in at least one of the five domains: delusions, hallucinations, disorganized thinking (speech), grossly disorganized or abnormal motor behavior (including catatonia), and negative symptoms (American Psychiatric Association, 2013). Negative symptoms include the absence of normal behavior as seen with flattened affect, alogia, apathy, avolition and social withdrawal (American Psychiatric Association, 2013). According to DSM-5, schizophrenia is diagnosed by the presence of the following (American Psychiatric Association, 2013):

- Criterion A: At least two of the previous five domains (one of which must be either delusions, hallucinations, or disorganized speech)
- Criterion B: Impairment for a significant portion of time in a major area of functioning
- Criterion C: Signs of the disturbance continuously for at least six months
- Criterion D: Schizoaffective, depressive, or bipolar disorder with psychotic features have been ruled out
- Criterion E: The symptoms are not attributed to the effects of some substance (medications) or medical condition
- Criterion F: There is no history of autism spectrum disorder or a communication disorder during childhood

There are five types of schizophrenia: paranoid, disorganized, catatonic, undifferentiated, and residual. The majority of individuals manifest with symptoms in their 20s (American Psychiatric Association, 2013; Davis, Charney, Coyle, &

Nemeroff, 2002; Schultz, North, & Shields, 2007). Risk factors include family history of psychoses, older age of father, autoimmune disorders, and viral infections during the first or second trimester (Schultz et al., 2007). The worldwide prevalence of schizophrenia is about 1%, and is equally prevalent amongst men and women, although men usually present slightly earlier than women (American Psychiatric Association, 2013; Schultz et al., 2007). Furthermore, most patients go through a prodromal phase, where there is a slow onset of developing symptoms, including social withdrawal, worsening of hygiene and grooming, unusual behaviors like outburst of anger, and deterioration and loss of interest in school or work (American Psychiatric Association, 2013; Davis et al., 2002).

Cognitive impairments in schizophrenic patients include deficits in memory, abstraction, and attention. With impaired activation of the prefrontal cortex (PFC), they generally have reduced intelligence measures along with delays in early developmental milestones. Unlike many of the other major psychiatric disorders, schizophrenia generally presents with “global” cognitive impairments that include difficulty with everything from attention, to memory, to fluency, executive function, and verbal ability (Lepage, Bodnar, & Bowie, 2014; Millan et al., 2012; Schaefer, Giangrande, Weinberger, & Dickinson, 2013). Nonetheless, schizophrenia commonly leads to an especially significant decline in processing speed and episodic memory. Furthermore, the impairment in verbal memory has been posited as a strong marker of outcome of schizophrenic symptoms (Lepage et al., 2014).

Although the pathophysiology of the disorder is not fully established, it is believed that symptoms of schizophrenia are attributable to dysregulation within the dopaminergic tracts of the brain. There are four main tracts, namely the mesolimbic, mesocortical, nigrostriatal, and tuberoinfundibular (Purves et al., 2007). It is hypothesized that there is excess dopaminergic activity within the mesolimbic pathway leading to the positive symptoms, with a simultaneous reduced dopaminergic activity in the mesocortical pathway, resulting in the negative symptoms (Davis et al., 2002; Miyamoto, Miyake, Jarskog, Fleischhacker, & Lieberman, 2012). The mesolimbic dopaminergic pathway includes the connections between the ventral tegmental area (VTA) and the nucleus accumbens and mostly the D1 and D2 receptors. The

mesocortical pathway includes connections from the VTA to the temporal cortex, frontal cortex, and PFC, and mostly D1 receptors with some presence of D2 and D5 receptors (Purves et al., 2007). The last two dopaminergic pathways consist of connections from the substantia nigra to the corpus striatum (the nigrostriatal) and from the hypothalamus to the anterior pituitary (the tuberoinfundibular) (Purves et al., 2007).

There are two main categories of antipsychotics: first generation (FGA, also known as the *typical*) and second generation (SGA, also known as the *atypical*) (Davis et al., 2002; Ellenbroek, 2012; Golan, Tashjian, Armstrong, & Armstrong, 2011). It is believed that FGAs, like chlorpromazine and haloperidol, have high affinity for dopamine receptors, specifically the D2, especially within the mesolimbic pathway, thereby decreasing the presence of positive symptoms (Ellenbroek, 2012; Golan et al., 2011; Miyamoto et al., 2012). Conversely, SGAs (like clozapine, risperidone, olanzapine, quetiapine, and aripiprazole) have slightly decreased affinity for the D2 receptors, but are believed to have some serotonin antagonism (Ellenbroek, 2012; Golan et al., 2011; Miyamoto et al., 2012). Furthermore, SGAs have an increased dissociation constant than dopamine (Golan et al., 2011).

The main side effects from FGAs include extrapyramidal side effects (EPS) from acute use and tardive dyskinesia (TD) from more chronic use (Davis et al., 2002; Ellenbroek, 2012; Schultz et al., 2007). EPS is defined as parkinsonism (rigidity, bradykinesia, shuffling gait, tremor), dystonia (fixed upper gaze, neck twisting, facial muscle spasms), and akathisia (inability to sit still, restlessness, tapping of feet). Studies have shown that while about 65%–70% receptor occupancy of D2 allow for the antipsychotic effects of the FGAs, above 80% occupancy leads to the increased risk of EPS (Davis et al., 2002; Golan et al., 2011; Miyamoto et al., 2012). It is believed that it is D2 inhibition within the basal ganglia that leads to EPS, as is similar to Parkinson's disease (Golan et al., 2011). EPS is mostly treated with anticholinergic drugs, although some studies have shown that these may lead to further cognitive impairment (e.g., verbal memory or confusion; see Golan et al., 2011). Akathisia has been shown to be responsive to low doses of beta blockers (Adler, Angrist, Reiter, & Rotrosen, 1989). Furthermore, it is important to keep in mind that while decreasing the dose of FGAs helps to decrease EPS, lower doses have increased probability of relapse (Golan et al., 2011). TD is defined as involuntary movements, especially of the lower face. One proposed etiology of TD is an adaptive hypersensitivity of D2 receptors in the striatum.

The main benefit of SGAs over the FGAs is their decreased risk of EPS and TD (Davis et al., 2002; Golan et al., 2011). Decreased presence of these side effects is believed to be a result of the increased serotonergic inhibition (Miyamoto et al., 2012) of a relatively lower level of dopaminergic blockade. Nonetheless, SGAs come along with their own set of side effects, including sedation, weight gain, and diabetes

mellitus type II (DMII; this risk is separate from the weight gain) (Davis et al., 2002; Schultz et al., 2007).

## Depression

Depression, as defined in the DSM-5 (American Psychiatric Association, 2013), consists of a pervasive feeling of sadness or irritability that results in significant disturbances in energy, sleep, appetite, sexual drive, weight, or the ability to express or seek pleasure. Major depressive disorder (MDD) is defined as depression that lasts for at least a two-week period, with symptoms that cause clinically significant impairment at work, with the family, or in other important areas. There are three types of MDD: typical (melancholic), atypical, and psychotic (American Psychiatric Association, 2013). MDD can present at any age, but has an increased likelihood during puberty (Kessler et al., 2003). Furthermore, the 12-month prevalence of MDD in the United States is about 7% (about 4.7% worldwide; see Ferrari, 2013), with a prevalence of twice as much in women than in men (Kupfer, Frank, & Phillips, 2012). MDD is also highly associated with many other health issues, including coronary artery disease, metabolic syndrome, diabetes, and other chronic illness (American Psychiatric Association, 2013; Kupfer et al., 2012). MDD also shows some heritability, of about 40% (American Psychiatric Association, 2013; Belmaker & Agam, 2008).

While depression usually leads to overall poor performance on cognitive tests (Millan et al., 2012), studies have found specific deficits in some areas. In one meta-analysis of those presenting with their first episode of MDD, significant impairment was found in psychomotor speed, attention, and visual learning and memory (Lee, Hermens, Porter, & Redoblado-Hodge, 2012). Furthermore, executive dysfunction was specific to attentional switching, verbal fluency performance, and cognitive flexibility (Lee et al., 2012). When considering lifetime impairment from MDD, significant impairment was found in executive function, processing speed, and episodic memory (Trivedi & Greer, 2014). Furthermore, these impairments have been found to persist even after symptoms have remitted (McIntyre, Cha, Soczynska, et al., 2013).

The main theory of depression is known as the “monoamine” theory, which postulates that depression is due to decreased serotonergic and/or noradrenergic neurotransmission within the brain (Belmaker & Agam, 2008; Golan et al., 2011; Krishnan & Nestler, 2008). Norepinephrine, on the one hand, is a molecule mostly produced in the locus ceruleus (LC) and is involved in vigilance, stress response, neuroendocrine function, pain control, and the sympathetic nervous system (Golan et al., 2011). Serotonin, on the other hand, is produced within the raphe nucleus, and is involved in modulation of mood, the sleep–wake cycle, motivation and reward, cognition function, and pain perception, as well as neuroendocrine function (Golan et al., 2011). After being released into the synaptic cleft, these molecules are then transported back through a nonspecific transporter, vesicular monoamine

transporter (VMAT), or through specific serotonin transporter (SERT) and norepinephrine transporters (NET). Both of these molecules then get degraded intracellularly by an enzyme called *monoamine oxidase* (MAO), of which there are two types: MAO-A degrades serotonin, norepinephrine, and dopamine, while MAO-B degrades dopamine only. Another enzyme, catechol-O-methyltransferase (COMT), is involved in monoamine degradation extracellularly, but is only found more peripherally outside the brain (Purves et al., 2007).

The norepinephrine from the LC innervates a wide variety of structures throughout the brain, including the amygdala, the hippocampus, prefrontal and frontal cortices, and the raphe nuclei and VTA (thereby, controlling the release of 5-HT and DA, respectively). The dopamine release from the VTA helps to modulate the reward network of the ventral striatum, orbitofrontal cortex, and the medial PFC, while the serotonin helps to modulate the limbic or emotional system of the amygdala, medial PFC, and anterior cingulate cortex (Krishnan & Nestler, 2008; Davis et al., 2002). Some studies have shown that those with depression have increased activity in the amygdala, ventral striatum, and medial PFC in reaction to negative emotion, while decreased activity in the ventral striatum in response to positive emotions and reward (Kupfer et al., 2012). The theory is, therefore, that those who are depressed have an increased emotional reaction (as seen with increased activity in the amygdala and medial PFC), with decreased voluntary control over the emotion (as seen with activity in the dorsolateral PFC; see Kupfer et al., 2012). Studies have shown that there is decreased gray matter volume and glial density in the PFC and hippocampus in those with diagnosed MDD, while imaging studies have shown increased activity on fMRI and PET in the amygdala and subgenual cingulate cortex (a small portion of the PFC) (Krishnan & Nestler, 2008).

There are three main types of medications that treat depression: the classical MAO inhibitors, reuptake inhibitors, and the atypicals (Golan et al., 2011). Reuptake inhibitors fall into four categories: tricyclic antagonists (TCAs), selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), and heterocyclics.

MAO inhibitors (MAO-Is) inhibit the breakdown of the monoamines once they have been taken back up by the pre-synaptic cell, thereby increasing their availability for release back into the synapse. The irreversible MAO-Is include iproniazid, phenylzine, and isocarboxazid (Davis et al., 2002; Golan et al., 2011). The newer MAO-Is are reversible and also selective for MAO-A (which degrades all three, 5-HT, NE, and DA), and includes moclobemide, biefloxatone, and brofaromine (Davis et al., 2002; Golan et al., 2011). The older, irreversible MAO-Is have a higher risk of tyramine toxicity (tyramine comes from products like wine and cheese and is also metabolized by the liver version of MAO), leading to sympathomimetic side effects like hypertension, headache, tachycardia, nausea, cardiac arrhythmias, and stroke (Golan et al., 2011). The newer MAO-Is are easily replaced

by tyramine, and therefore have a decreased risk of this toxicity; however, nonetheless the risk of this toxicity has limited the clinical utility of all MAO-Is.

TCAs are broken up into secondary amines and tertiary amines. The former is more selective for NE and the latter for 5-HT (Davis et al., 2002; Golan et al., 2011). Nonetheless, TCAs block SERT, NET, and dopamine active transporter (DAT), resulting in increased levels of 5-HT, NE and DA in the synaptic cleft, respectively. The list of TCAs includes imipramine, desipramine, clomipramine, amitriptyline, and nortriptyline, among others (Davis et al., 2002; Golan et al., 2011). Common side effects of TCAs include their anticholinergic effects of nausea, vomiting, orthostatic hypotension, anorexia, dry mouth, blurred vision, confusion, constipation, tachycardia, and urinary retention (Golan et al., 2011). The potential for orthostatic hypotension is important to consider when using TCAs in the elderly as it may increase the risk for serious falls (Glassman, 1984). Furthermore, TCAs also have some antihistaminergic effects of sedation, weight gain, and confusion in the elderly (Golan et al., 2011). Finally, TCAs have some antiadrenergic effects such as reflex tachycardia, drowsiness, and dizziness (Golan et al., 2011). The pharmacologic class has also shown to have some Type I antiarrhythmic effects that can predispose to cardiac conduction problems, especially in patients with underlying cardiovascular disease (Glassman & Bigger, 1981). SSRIs have more selectivity for the SERT receptors and therefore are associated with less adverse events (compared to TCAs), and are therefore generally considered the first-line medications for MDD (with specifically increased effectiveness for typical, melancholic-type depression) (Golan et al., 2011; Timonen & Liukkonen, 2008). In addition to treatment of MDD, SSRIs are also used to treat panic syndrome, obsessive-compulsive disorder (OCD), premature ejaculation, and PTSD (Golan et al., 2011). Their major limiting factor is dosage: while increased dose shows increased effect, it also shows increased binding to NET receptors. Major side effects of SSRIs include sexual dysfunction and gastrointestinal (GI) problems. The list of SSRIs includes fluoxetine, citalopram, fluvoxamine, paroxetine, sertraline, and escitalopram. Although the evidence has been debated, there is some that shows there is an increased risk of suicide with SSRI treatment, warranting clinicians to be watchful (Golan et al., 2011; Kupfer et al., 2012). There are specific warnings regarding the risk of new onset suicidal ideation in children, adolescents, and young adults (Hetrick, McKenzie, Cox, Simmons, & Merry, 2012).

Unlike TCAs, SNRIs inhibit only SERT and NET, thereby decreasing the reuptake of serotonin and norepinephrine (Davis et al., 2002; Golan et al., 2011). SNRIs are generally considered second-line after SSRIs, due to their more limited receptor selectivity than TCAs (Golan et al., 2011). The list of SNRIs includes venlafaxine, desvenlafaxine (a metabolite of venlafaxine), and duloxetine. Side effects of SNRIs include hypertension, sweating, weight loss, GI distress,

blurred vision, nervousness, and sexual dysfunction (Golan et al., 2011).

The last class of antidepressants is the atypicals, which includes bupropion, mirtazapine, and trazodone (Davis et al., 2002; Golan et al., 2011; Kupfer et al., 2012). Bupropion increases the levels of serotonin and dopamine in the synaptic cleft (in a similar manner to the amphetamines; see Golan et al., 2011) and is a modest dopamine and norepinephrine reuptake inhibitor (Carroll et al., 2014). Side effects include seizures (generally thought to occur in doses > 450 mg/day), insomnia, and electrolyte abnormalities (and there is a noted contraindication in patients with eating disorders). Bupropion has also been shown to be helpful in smoking cessation (Cahill, Stevens, Perera, & Lancaster, 2013). Mirtazapine blocks the postsynaptic serotonin receptors, as well as the  $\alpha_2$ -adrenergic autoreceptors, thereby decreasing serotonin neurotransmission (Golan et al., 2011). Due to its appetite-stimulating effects (possibly from its antihistaminic properties), mirtazapine is particularly effective for elderly patients suffering from weight loss and eating problems. Trazodone is thought to exert its mechanism of action through effects on serotonin; the most common adverse events noted are sedation, headache, and dizziness (Fagiolini, Comandini, Catena Dell'Osso, & Kasper, 2012). The sedative properties of trazodone have led to its off-label use as a hypnotic in a variety of conditions, including antidepressant-associated insomnia (Nierenberg, Adler, Peselow, Zornberg, & Rosenthal, 1994).

Drugs within the SSRI category usually do not show any effect for about two to three weeks. These effects take a while to take hold due to the fact that they are due to more chronic changes at the synaptic level, which are secondary to the increase in monoamines in the cleft (Davis et al., 2002; Golan et al., 2011; Krishnan & Nestler, 2008). Finally, it is important that a misdiagnosis of MDD, with an underlying bipolar disorder (BPD), and treatment with MAO-Is, SSRIs, and TCAs (and some heterocyclics) can precipitate manic and hypomanic symptoms (Golan et al., 2011).

## Bipolar Disorder

BPD is characterized by three stages: periods of mania that percolate periods of depression, surrounded by periods of euthymia (mood defined as neither depressed nor excessively elevated). Mania is defined in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) by elevated levels of euphoria or mood and energy that last at least one week (American Psychiatric Association, 2013). These periods of mania are characterized with an inflated self-esteem, little need for sleep, inability to stop talking, racing thoughts, distractibility, involvement in dangerous or negative activities, and an increase in goal-directed activity. BPD requires that these manic periods cause impairment in social and occupational realms. BPD is most frequently diagnosed prior to the age of 30, usually around 18 years old, and most patients present during periods of depression, and

so it is important to probe for previous manic or hypomanic episodes (American Psychiatric Association, 2013; Connolly & Thase, 2011). This disorder has a lifetime prevalence of about 1%–2% worldwide (American Psychiatric Association, 2013; Geddes & Miklowitz, 2013). Those with BPD have some residual depressive symptoms that present for about one-third of their life (Geddes & Miklowitz, 2013).

Cognitive impairments of BPD depend on the specific stage. The manic and depressed stages are associated with moderate deficits in executive function, memory, and attention (Malhi et al., 2007; Miklowitz, 2011). The depressive stage is further associated with impairment in fine motor skills. Some studies have also found deficits in verbal learning and processing speed (Miklowitz, 2011). As has been seen with MDD, absence of symptoms does not lead to improvement in impairment. Memory deficits, especially those with verbal recall, have been observed in euthymic bipolar subjects (Malhi et al., 2007).

The neurobiology of BPD centers around the limbic system and especially the amygdala. A model recently put forth by a consensus group shows that it is most likely a dysregulation of two networks that results in the symptoms seen with BPD (Strakowski et al., 2012). The first network, the so-called *external emotional control* network arises from the ventrolateral PFC. This external control includes functions such as understanding facial emotion. The second network originates in the orbitofrontal cortex and is called the *internal emotional control* network, as it is more involved in the emotional response to certain cues. Both of these networks are connected with the limbic system, which involves the hippocampus, thalamus, cingulate gyrus, limbic cortex, and hypothalamus. It is believed, therefore, that there is impaired regulation of the amygdala from both networks, allowing overactivation of the amygdala and its control over the limbic system (Blond, Fredericks, & Blumberg, 2012; Strakowski et al., 2012). This increased amygdala activity is usually only seen during manic episodes, and disappears when anticonvulsants are used (Blond et al., 2012).

Historically, the most common medication used for treatment of mania associated with BPD has been lithium carbonate. Lithium is believed to block regeneration of PIP<sub>2</sub>, a second messenger that is involved in the intracellular signaling initiated by neurotransmitters within the adrenergic, muscarinic and serotonergic systems (Davis et al., 2002; Golan et al., 2011; Oruch, Elderbi, Khattab, Pryme, & Lund, 2014). Other mechanisms thought to be involved in lithium's actions include affecting the synthesis and degradation of dopamine and norepinephrine, affecting glutamate neurotransmission, and increasing serotonin release from the raphe nucleus (Oruch et al., 2014). The dosing of lithium is titrating according to blood levels, which should be maintained within a therapeutic range. While lithium has been shown to be effective for acute mania, psychotic symptoms associated with BPD, and even perhaps maintenance therapy (it helps to decrease manic and depressive relapse

between 28% and 38%, (Geddes & Miklowitz, 2013), it has been shown to have less of an effect with bipolar depressive symptoms (Davis et al., 2002). Lithium is associated with adverse events, including dangerous effects on the thyroid, cardiac abnormalities, and GI dysfunction, along with many others (Golan et al., 2011; Oruch et al., 2014). Furthermore, hyponatremia and concomitant treatment with NSAIDs can lead to acute lithium toxicity, which includes symptoms of tremor, ataxia, dysarthria, renal insufficiency, confusion, delirium, neuromuscular dysfunction, and seizures (Golan et al., 2011; Oruch et al., 2014).

Another effective treatment has been valproate or divalproex, which was initially marketed as an antiepileptic. Divalproex acts to slow down sodium channel recovery from an inactivated state after an action potential as well as to limit activity of T-type calcium channels. Finally, divalproex has been shown to increase availability of GABA within neurons, both through decreased degradation and increased synthesis (Golan et al., 2011). Divalproex has been shown to be effective for acute manic and psychotic symptoms of bipolar and may be more effective for depressive symptoms than lithium (Davis et al., 2002).

The third major drug used in treatment of bipolar is carbamazepine, another antiepileptic that also slows sodium channel recovery from an inactive state. Carbamazepine has been shown to be more effective than placebo and about as effective as lithium. Lamotrigine is another antiepileptic that has similar mechanism of action as carbamazepine, but there is little evidence of its efficacy in acute mania (Geddes & Miklowitz, 2013); lamotrigine is more commonly used in maintenance therapy of BPD with prominent depressive symptoms (Reid, Gitlin, & Altshuler, 2013). It is believed that antiepileptics (divalproex, carbamazepine and lamotrigine) may help restore the balance between glutamate and GABA inputs, thereby decreasing the postulated overactivity in the amygdala (Blond et al., 2012).

Recently, there has been evidence that antipsychotics, both FGAs and SGAs, have also been effective in treatment of acute mania (Geddes & Miklowitz, 2013; Golan et al., 2011; Oruch et al., 2014). Specifically, the FGAs most frequently used have been chlorpromazine and haloperidol, and olanzapine, risperidone, and quetiapine have been the effective SGAs used. Antipsychotics have been shown to have more frequent and more severe side effects in the long run, but have a faster onset of action, and therefore may have greater efficacy in acute mania, while lithium and other mainstay treatments take time to take effect (Geddes & Miklowitz, 2013; Golan et al., 2011).

In bipolar depression, the symptoms have been shown to be different from those seen in unipolar depression (like in MDD). This conclusion comes from the fact that antidepressants used to treat MDD have not been as effective, although there is definite heterogeneity (Geddes & Miklowitz, 2013). Combination treatments of antidepressant and antipsychotic (e.g., fluoxetine and olanzapine) have shown

some positive effects (Geddes & Miklowitz, 2013). Recently, SGAs like quetiapine and lurasidone have been used with some positive benefits for bipolar depression (McIntyre, Cha, Kim, & Mansur, 2013). Lurasidone can be used in addition to the treatment of the manic symptoms (i.e., lithium or divalproex). Some of the drawbacks of these medications are the potential for weight gain and metabolic disruption (McIntyre, Cha, Kim, et al., 2013). Lamotrigine is also FDA approved for the treatment of bipolar depression (Vasquez, Holtzman, Tondo, & Baldessarini, 2015).

## Anxiety Disorders

Anxiety disorders are mental disorders that are characterized by anxiety and fear. Anxiety is defined as the fearful behavioral response to a potential future threat and the uncertainty of the effects of the threat, whereas fear is related to the emotional response to current events. Anxiety disorders can be broken up into about six different major sub-categories; namely, panic disorders (PD), generalized anxiety disorders (GAD), social anxiety disorder (SAD), PTSD, OCD, and specific phobias. The 12-month prevalence of anxiety disorders in the United States is around 18%, with 12-month prevalence of each of the anxiety disorders as follows: PD (2.4%), GAD (2.0%), SAD (7.4%), PTSD (3.7%), OCD (1.2%), and specific phobias (12.1%) (Kessler, Chiu, Demler, Merikangas, & Walters, 2005; Kessler, Petukhova, Sampson, Zaslavsky, & Wittchen, 2012). Most of the anxiety disorders can present at childhood and continue to present into adulthood (American Psychiatric Association, 2013). Females are twice as likely to have anxiety disorders than males (American Psychiatric Association, 2013).

Each anxiety disorder presents with its own unique list of cognitive impairments, but overall, the anxiety disorders present with impairments in executive function and verbal episodic memory (although GAD usually presents with very little overall impairment; see Millan et al., 2012). OCD mostly presents with executive dysfunction but also impairments in long- and short-term visual memory, and processing speed (Castaneda, Tuulio-Henriksson, Marttunen, Suvisaari, & Lonnqvist; Millan et al., 2012). Similarly, PTSD presents with short- and long-term verbal and visual memory impairment and executive dysfunction. However, PD, while presenting with processing speed impairment, executive dysfunction, and issues with divided attention (but not selective attention), only presents with short-term verbal memory impairment, and without any visual memory impairment (Castaneda et al., 2008). It is interesting to note that most of the anxiety disorders (i.e., PTSD, OCD, and PD) actually have improvement in attention, mostly due to their increased vigilance (Millan et al., 2012).

While each of the individual anxiety disorders have their own unique neural correlates, most of them center around the amygdala-PFC circuitry (Martin, Ressler, Binder, & Nemeroff, 2009; Mohler, 2012). While the amygdala is associated

with detection of threat and gives rise to the emotion of fear, the PFC controls the amygdala in top-down manner. Most studies of anxiety have shown that there is hyperreactivity in the amygdala to stimuli and hypoactivity in the PFC. Specifically within the PFC, the orbitofrontal cortex and the medial PFC have been associated with the assessment and integration of stimuli (Mohler, 2012). Unlike MDD, where there is also hyperactivity of the amygdala, this increased activity results only when provoked by environmental stimuli that are considered neutral by those not suffering from the anxiety disorders (Martin et al., 2009).

The hyperactivity in the amygdala and hypoactivity in the PFC are most likely due to decreased inhibition of the fear circuitry due to dysfunction of the GABAergic system. GABA ( $\gamma$ -aminobutyric acid) is the main inhibitory neurotransmitter in the central nervous system (CNS). There are two types of GABA receptors: Type A and Type C, both of which are ligand-gated ion channel (although GABA<sub>A</sub> is the main one found in the CNS), and Type B, a metabotropic G-protein coupled receptor. Deficits in the number of GABA<sub>A</sub> receptors have been found in various anxiety disorders such as PTSD, and have been correlated with anxiety symptoms (Mohler, 2012).

One main class of medications used to treat this impaired inhibition of the fear circuitry has been the benzodiazepines, which act to enhance the GABA transmission in the CNS (Davis et al., 2002; Golan et al., 2011; Griebel & Holmes, 2013; Mohler, 2012). Benzodiazepines—such as diazepam, alprazolam, lorazepam, and clorazepate—have mainly anxiolytic, sedative, hypnotic, amnesic, and muscle-relaxant effects. Their main mechanism of action is to bind to GABA<sub>A</sub> receptors and to increase the chance of the channel being open at low GABA concentrations as well as slowing down the receptor deactivation (Golan et al., 2011). There is also evidence that benzodiazepines increase the affinity of GABA to the receptor. Benzodiazepines range in their duration of action from short-acting (e.g., three to eight hours for clorazepate) to long-acting (e.g., one to three days for diazepam). Nonetheless, while benzodiazepines are effective in the treatment of anxiety, they are limited by their potential for tolerance, dependence, and addiction, and are therefore best used intermittently (Golan et al., 2011; Griebel & Holmes, 2013; Mohler, 2012). The tolerance is believed to be either due to decreased expression of the GABA<sub>A</sub> receptor at the synapse or due to the uncoupling of the binding site of the benzodiazepines from the GABA site (Golan et al., 2011). Furthermore, they should not be used concomitantly with other sedatives like alcohol, CNS depressants, opioid analgesics, and TCAs, due to the possible synergistic effect on the GABA<sub>A</sub> receptor (Golan et al., 2011). Benzodiazepines should be tapered slowly due to potential for a withdrawal syndrome that includes symptoms of confusion, seizures, anxiety, agitation, and insomnia (Davis et al., 2002; Golan et al., 2011).

SSRIs like sertraline, paroxetine, and fluvoxamine have also been shown to be efficacious in treating anxiety disorders. See

the "Depression" section for a description of SSRIs. SSRIs have been prescribed more for long-term treatment as their initial anxiogenic effects can be somewhat problematic, while their long-term adverse effects are more tolerable than other classes (although they include sexual dysfunction and weight gain; see Davis et al., 2002). Serotonergic fibers from the raphe nucleus are believed to modulate both the GABA interneurons that modulate the fear circuitry and the neurons within the lateral amygdala.

Tricyclic antidepressants like imipramine and clomipramine have also been shown to be effective, most likely due to their serotonergic effects, although they have the same list of adverse events as discussed with MDD. Similarly, MAO inhibitors like moclobemide have similar effects but are only used after other classes are found to be ineffective due to MAO-I's poor drug–drug and food interactions.

Buspirone is a nonbenzodiazepine anxiolytic that is an agonist at the 5-HT<sub>1A</sub> receptor and has nonaddictive and nonsedative properties that make it more attractive than benzodiazepines (Golan et al., 2011). Buspirone, however, has been found to be most useful for GAD and not as helpful for other anxiety disorders like PD and OCD (Griebel & Holmes, 2013).

Glutamatergic signaling has also been implicated in various anxiety disorders. Glutamate, another amino acid neurotransmitter (like GABA), is critical in associative learning as seen with the hippocampus and amygdala association during fear learning (Griebel & Holmes, 2013; Martin et al., 2009; Mathew, Price, & Charney, 2008). As with GABA, there are ionotropic and metabotropic glutamate receptors. Ionotropic receptors include AMPA, NMDA, and kainate, the first two of which are implicated in associative learning during long-term potentiation and long-term depression (Davis et al., 2002; Purves et al., 2007). It has been hypothesized that there is elevated glutamatergic signaling, allowing for easier association of anxious and fearful response to neutral stimuli (Davis et al., 2002; Martin et al., 2009; Mathew et al., 2008).

Finally, other drugs used to treat disorders like bipolar and depression, including pregabalin and gabapentin, have found some off-label use in treatment of some of the anxiety disorders (see previous sections on BPD and MDD for descriptions) (Frampton, 2014).

### Attention Deficit/Hyperactivity Disorder

Attention deficit/hyperactivity disorder (ADHD) is characterized by symptoms of poor impulse control, impaired attention regulation, excessive motor activity, and restlessness. The DSM-5 lists nine symptoms of inattention and nine symptoms of hyperactivity/impulsivity. It divides ADHD into three Presentations: Predominantly Inattentive (those with at least six of the former group of symptoms), Predominantly Hyperactive/Impulsive (those with at least six of the latter group of symptoms), and Combined

(with at least six in both groups of symptoms for patients under the age of 17 years; the required symptom threshold is five and not six symptoms for patients 17 and older; see the American Psychiatric Association, 2013). ADHD is considered a childhood and adult disorder, though at least some of the symptoms must present by the age of 12. Significant impairment must be noted in two out of three domains (work/school, home, and/or social). Additionally, the childhood symptoms must be multidimensional and the symptoms and impairments must be from ADHD and not another mental health disorder (Adler & Alperin, 2014). Studies have shown that as many as 60% of adolescents continue to have symptoms of ADHD into their adulthood (Floet, Scheiner, & Grossman, 2010). Prevalence of the disorder range from about 6%–9% in childhood to about 4.4% in adults (Faraone, Sergeant, Billberg, & Biederman, 2003; Kessler et al., 2003). While boys are much more likely to have the disorder during childhood, the ratios even out within the adult population (Floet, Scheiner, & Grossman 2010; Kessler et al., 2003). ADHD commonly presents comorbidly with other disorders including conduct disorder, BPD, anxiety disorders, and depression.

Cognitive impairments in ADHD are not limited to issues with attention. ADHD also leads to impairment in working memory and processing speed (Millan et al., 2012). ADHD commonly cotravels with deficits in executive function and with difficulties in organization, planning, initiating, and completing tasks, shifting tasks, self-monitoring and self-inhibition (Barkley & Murphy, 2010; Brown, 2013).

The PFC is involved in regulation of attention and thought, and is therefore implicated in ADHD. Specifically, the dorsal and lateral PFC help to monitor attention and activity; while the ventral (orbital) and medial structures monitor emotion (Arnsten & Berridge, 2014). Furthermore, the PFC has many connections with the temporal and parietal cortices and therefore is involved in behaviors initiated in those loci (Arnsten & Berridge, 2014). The PFC has also been implicated in inhibition of inappropriate behaviors, and especially in the right hemisphere (Arnsten & Berridge, 2014). There are two neurotransmitters that play an important role in the PFC: the adrenergic and the dopaminergic system (Arnsten & Berridge, 2014; Golan et al., 2011). Of note, all marketed medications for ADHD have been shown to mediate their effects through these two neurotransmitters. Within the PFC, norepinephrine has a high affinity for the  $\alpha_2$  receptors, and dopamine binds to the two main receptors found in the PFC, D1, and D5 (Arnsten & Berridge, 2014). The dopaminergic system is believed to be involved in weakening and suppressing irrelevant signals, while the adrenergic system may help enhance and strengthen behaviorally appropriate systems. Not only have studies shown that the PFC in ADHD subjects is reduced, but also that it has reduced functional activity, most likely due to decreased signaling from these two systems (Arnsten & Berridge, 2014; Davis et al., 2002).

Therefore, pharmacological treatment of ADHD generally aims to enhance or mimic catecholaminergic signaling, specifically within the PFC. The medications fall into three categories: stimulants, nonstimulants, and atypical. The stimulants can be further broken into two main groups: methylphenidate and amphetamine. Stimulants block dopamine and norepinephrine reuptake into presynaptic neurons (Arnsten & Berridge, 2014; Davis et al., 2002; Golan et al., 2011). Unlike amphetamine, methylphenidate increases the release of dopamine (and norepinephrine at higher doses) from the presynaptic neuron (Arnsten & Berridge, 2014; Davis et al., 2002; Prince, Morrison, & Wilens, 2014). Although some stimulants also have an inhibitory effect on serotonin reuptake, this is not thought to play a major role mediating their therapeutic effect (Arnsten & Berridge, 2014; Prince et al., 2014). Furthermore, the effect on symptoms is generally thought to be a result of stimulant effect on catecholamines, specifically within the PFC and not outside the PFC (Arnsten & Berridge, 2014; Prince et al., 2014). Stimulants come in a variety of different formulations, from immediate-release to sustained and extended-release. There are four extended release stimulants that are FDA approved for adults with ADHD: two methylphenidate (dexamethylphenidate XR, OROS methylphenidate) and two amphetamine (mixed amphetamine salts XR and lisdexamfetamine) preparations. Potential side effects include nausea, difficulty falling asleep, anorexia, obsessiveness, headaches, dry mouth, rebound phenomena, anxiety, nightmares, dizziness, irritability, dysphoria, and weight loss (Prince et al., 2014). There is also misuse and diversion of stimulants, which appears to be greater with the immediate-release preparations (Prince et al., 2014), further highlighting the preference for treatment with extended-release preparations.

The main nonstimulant medication is atomoxetine, which acts as a selective norepinephrine reuptake inhibitor. Although it has no direct effect on dopamine transporters, it is believed that there is some effect on dopamine concentration within the synapse, since NET channels have increased affinity for dopamine, especially in the PFC, which has limited density of DAT channels (Arnsten & Berridge, 2014; Swanson et al., 2006). Atomoxetine may be particularly useful with adults with substance abuse issues (a common comorbid disorder) due to its lack of abuse liability (Prince et al., 2014). The overall magnitude of effect of atomoxetine is less than seen with stimulants (Prince et al., 2014). Both stimulants and atomoxetine can have cardiovascular effects, with modest elevations of blood pressure and pulse, suggesting the need to monitor these measures during treatment.

Other categories of effective medications that have been shown to be effective in off-label studies in adults with ADHD (and generally have not been extensively studied, as stimulants or atomoxetine) include antidepressants (specifically TCAs and bupropion) and the adrenergic agonists (specifically  $\alpha_2$ ) (Davis et al., 2002).
