Given that awareness syndromes are rooted in a reduced understanding of the illness, injury, impairments, functional implications, a multilevel approach should be undertaken to improve the level of awareness. The interplay between neuropathology and the experience and reaction of the individual to the resulting impairments cannot be teased apart easily and so interventions must include elements to address both underlying causes. A variety of approaches have been developed for addressing deficits in self-awareness, including feedback approaches (e.g., verbal, audiovisual, experiential), activity-based approaches, anticipation/predictive performance approaches, self-evaluation approaches, and adaptation/generalization approaches (for reviews, see Schrijnemaekers, Smeets, Ponds, van Heugten, & Rasquin, 2014; Tate et al., 2014). In addition to the approaches that are focused on improving the neurologically based impairments in awareness, there is the need to always keep in mind the more psychological coping aspects of awareness. Techniques should

be incorporated for developing a strong therapeutic alliance through a trusting therapeutic relationship with the individual who is supported in engaging fully in collaborative goal setting and selection of activities that are relevant and motivating (Lucas & Fleming, 2005). Additionally, there must be ongoing monitoring of the individual's emotional status so that interventions are guided by the individual's level of acceptance of current abilities (Lucas & Fleming, 2005). Finally, therapeutic tasks should be emotional neutral, nonthreatening, focused on the application of strategies, and allow for the demonstration of improvements (Lucas & Fleming, 2005).

This class of interventions is rooted in a set of theoretical models of self-awareness, including the *pyramid model of awareness*, the *self-determination approach to enhance self-awareness*, and the *Comprehensive Dynamic Interactional Model* of awareness (for a review of these models and discussion of awareness interventions in greater detail, see Fleming & Ownsworth, 2006). The key components (although somewhat different terminology is used among the three models; Crosson et al., 1989) are:

- *intellectual awareness*, in which the individual has a basic knowledge of the deficits and the implications;
- *emergent awareness*, in which the individual can recognize the impact of the deficits while performing a task; and
- *anticipatory awareness*, in which the individual is able to predict how she or he will perform on a particular task and/or whether a problem will occur given the deficits.

Interventional approaches target each of these three key components (see Table 15.5). Preliminary research suggests that interventions targeting all of these components within a comprehensive rehabilitation program that affords the individual to learn and practice skills within multiple contexts are effective (Goverover, Johnston, Toglia, & Deluca, 2007; Lundqvist, Linnros, Orlenius, & Samuelsson, 2010; Toglia, Johnston, Goverover, & Dain, 2010; Zlotnik, Sachs, Rosenblum, Shpasser, & Josman, 2009). Future research needs to expand upon these findings and replicate the results with larger sample sizes, but this line of research suggests that a multicontextual approach that targets the three components

Table 15.5 Key elements of awareness interventions

<i>Element</i>	<i>Target</i>	<i>Therapeutic Approach</i>
<b>Intellectual</b>	Educational	Aimed at patients learning about the types of deficits that they have following brain injury and how they impact daily life functioning. Assumed that the individual does not have information about themselves due to a lack of access and/or understanding of the problem.
<b>Emergent</b>	Feedback	Aimed at provision of cues and tangible feedback regarding performance on tasks (i.e., videotaped, observer feedback, self appraisal, timing feedback). Assumed that the individual cannot glean on his or her own the implications of the information about his or her deficits.
<b>Anticipatory</b>	Predictive	Aimed at the patient predicting his or her performance on a task taking into consideration all of his or her strengths and weaknesses. Assumed that individual bases prediction on past knowledge of self and so must “recalibrate” expectations and self-knowledge.

of complete awareness may offer a foundation for interventions for awareness syndromes.

### Final Thoughts About Neuropsychology’s Role in Understanding Consciousness

There is much work left to be done to understand consciousness, which is both incredibly exciting as well as daunting. We spent the time writing this chapter frequently thinking about our own thinking, pondering that our brains were grappling with understanding themselves, and relishing our conscious thoughts about consciousness. As neuropsychologists, we should never forget that we are explorers of the relationships between the physical (brain) and the manifestation of its functioning (behavior) and not become complaisant or resistant to exploring more complex, nebulous constructs, particularly to how these relate to our clinical work. The challenge at our feet as scientists and clinicians is to not avoid the uncharted territory, but to take one step at a time exploring the entire landscape of consciousness, developing tools and techniques to chart it, capture it, and do something about impairment: treat it. Although there are neuroscientists who are grappling with the underlying mechanisms of consciousness—comparing humans to animals in an attempt to understand whether humans’ conscious self is unique, and exploring how our brain *creates* consciousness—there is a relatively small number of scientists trying to apply what we know to the clinical realm. We need to continue our work towards understanding how impairments in the elements of consciousness affect our ability to be completely conscious human beings. What are the implications for impairments in consciousness for our ability to traverse the complex human relationships, plan for the future, understand the implication and consequences of our own behavior, and establish a goal and march out the steps accomplishing it? When we can unravel consciousness at these levels, then we will be better able to understand how injury to the brain can lead to criminal behavior, increased substance abuse, and failed intimate relationships in individuals who before injury had no history of social impropriety. Within the field of rehabilitation, we

are quite good at addressing the biomechanical impairments that arise with injury to the brain. However, the complex social, interpersonal, and self-defining implications of brain dysfunction are left unaddressed to a large extent. The field of clinical neuropsychology is well-poised to assist in better understanding the complexities of human consciousness and how to assess it most particularly. We should apply our expertise to better assessing the elements of consciousness with an eye towards the implications of the impairments on ability of the brain to have a concept of self, a personal past and future, and an awareness of one’s strengths and weaknesses. This knowledge will be foundational to further refining and developing new interventions to assist in the recovery from brain injury and the adaptation in the face of neurodevelopmental disorders that impact consciousness.

# 16 Cerebrovascular Disease

*C. Munro Cullum, Heidi C. Rossetti, Hunt Batjer, Joanne R. Festa, Kathleen Y. Haaland, and Laura H. Lacritz*

## Introduction

The acute and long-term clinical picture of cerebrovascular disease varies depending on underlying neuropathology, nature of onset, course, location, duration, and extent of lesion. These factors in turn contribute to differences in symptom presentation, intervention options, and prognosis. The intent of this chapter is to provide a resource for the clinical neuropsychologist on the diagnosis, evaluation, and management of stroke and related disorders. We will provide a review of relevant terminology, epidemiology, pathology and etiology, summarize current diagnostic work-up and treatment approaches, and discuss the current and future role of neuropsychology in relation to cerebrovascular disease.

## General Terminology

*Cerebrovascular disease* encompasses a wide array of neurologic conditions that compromise the function of brain blood vessels. Multiple pathophysiologic processes result in or contribute to cerebrovascular disease, including processes that are intrinsic to the vessel (e.g., atherosclerosis, inflammation, amyloid deposition, venous thrombosis), remote processes (e.g., embolism), inadequate blood flow (e.g., reduced perfusion or high blood viscosity), or vessel rupture. Each of these processes can result in a *stroke*, also known by the older term *cerebrovascular accident* (CVA). Stroke is typically defined as the abrupt onset of a focal neurologic deficit that is consistent with a vascular distribution and lasts more than 24 hours with or without positive imaging results or less than 24 hours with a positive imaging result. *Ischemia* refers to partially reduced blood supply that may lead to *infarction*, causing tissue death. A *lacune*, or *lacunar infarct*, is a small cavity caused by a stroke. A *transient ischemic attack* (TIA) is a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than one hour but as long as 24 hours and without evidence of tissue death. *Silent stroke* refers to the presence of vascular-related brain injury seen on neuroimaging without associated clinical symptoms. Consensus recommendation advocates the use of *brain attack/stroke* as the best umbrella term to raise public awareness of cerebrovascular disease, including TIA and stroke (Albers et al., 2002).

## Epidemiology of Cerebrovascular Disease

From 1999 to 2009, the actual number of stroke deaths declined by 23% (Go et al., 2013). However, stroke remains the most common serious neurologic problem in the world and continues to be a major cause of morbidity and mortality. In the United States, the lifetime risk of stroke for middle-aged and older individuals is one in six (Seshadri et al., 2006). Cognitive impairment is present in up to 64% of individuals with a history of stroke, and nearly one-third develop frank dementia (Jin, Di Legge, Ostbye, Feightner, & Hachinski, 2006). Stroke costs the nation nearly \$40 billion annually, including the cost of health care services, medications, and lost productivity (Heidenreich et al., 2011), in addition to the emotional costs and impact upon quality of life. Stroke is the fourth leading cause of death in the United States. On average, every 40 seconds, someone in the United States has a stroke, with resultant death approximately every four minutes. Each year, nearly 800,000 people experience a new or recurrent stroke. Approximately 610,000 of these are first attacks, and 185,000 are recurrent attacks. Although mortality due to stroke is on the decline, a 22% increase in stroke prevalence is expected by 2030 due to changing demographics such as the aging of the population and increased number of ethnic minorities (Go et al., 2013).

Stroke is more prevalent in older adults, African Americans, individuals with lower education, and in the southeastern United States (see Figure 16.1). In this “stroke belt” region, stroke mortality is approximately 20% higher than the rest of the nation (Go et al., 2013).

Women have lower stroke risk than men until late life, when that association reverses. Lifetime risk for incident stroke appears to be decreasing in Caucasians but similar declines have not been observed for African Americans, and among Mexican Americans rates may be increasing (Carandang et al., 2006; Kleindorfer et al., 2010; Morgenstern et al., 2004). Approximately 15% of all strokes are heralded by a TIA, the majority of which occurred within 30 days of the first stroke (Sacco, 2004). The estimated prevalence of self-reported physician-diagnosed TIA was 2.3% or approximately 5 million individuals (Johnston et al., 2003), and this is certainly an underestimate given that many TIAs go unreported. Of all strokes, 87% are ischemic, 10%

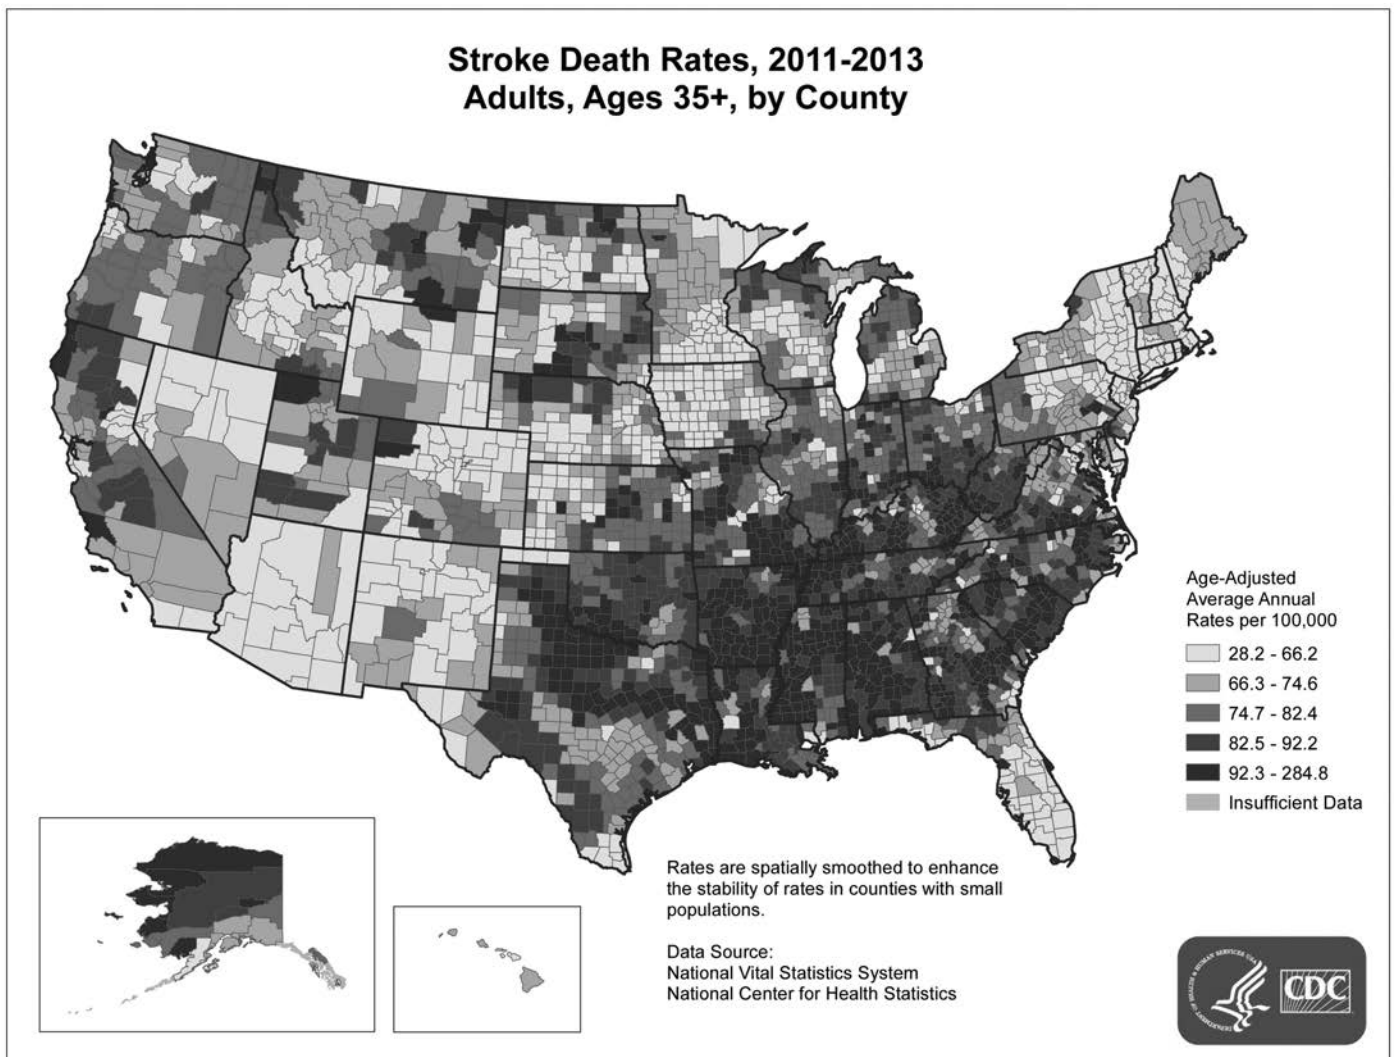

Figure 16.1 Centers of Disease Control stroke death rates, 2011–2013. A color version of this figure can be found in Plate section 2.

are intracerebral hemorrhagic, and 3% are subarachnoid hemorrhagic.

**Web Resource: CDC Interactive Atlas of Heart Disease and Stroke**

This application (available at [www.cdc.gov/dhdsp/maps/atlas/index.htm](http://www.cdc.gov/dhdsp/maps/atlas/index.htm)) allows users to view county-level maps of heart disease and stroke, along with maps of social environmental conditions and health services for the entire United States or for a chosen state or territory.

### Cerebral Vasculature

The arterial supply to the brain consists primarily of two pairs of arteries: the internal carotid arteries and the vertebral

arteries (see Figure 16.2). The internal carotid arteries give rise to the anterior circulation, and the vertebral arteries to the posterior circulation (see Figure 16.3). The vertebral arteries join to form the basilar artery, which converges with the two internal carotid arteries, thus forming the *circle of Willis*, a complete arterial ring at the base of the brain connecting the anterior and posterior circulation systems. The circle of Willis gives rise to all major cerebral blood vessels, including the three main arteries that supply the cerebral hemispheres: the anterior cerebral arteries (ACAs), the middle cerebral arteries (MCAs), and the posterior cerebral arteries (PCAs). The ACAs and MCAs are connected by the anterior communicating artery (ACom) and comprise the anterior circulation system, supplying most of the anterior medial cortex, from the frontal lobes to the anterior parietal lobes, as well as the majority of cortex along the dorsolateral convexity. The PCAs constitute the posterior circulation system and

Figure 16.2 Cerebral vasculature: major arteries

supply the inferior and medial temporal lobes and the medial occipital cortex. The anterior and posterior circulations are joined by the posterior communicating arteries (PCoM). The distinction between anterior and posterior circulation events is routinely made on clinical grounds during an initial emergency room evaluation for stroke. Aphasia, visual field cuts, hemi-neglect, and sensory-motor deficits typically suggest hemispheric regions; while vertigo, nausea and vomiting, and ataxia usually imply vertebrobasilar territory.

The venous system of the brain is essentially comprised of three groups of vessels that allow for drainage: the superficial cortical veins, the deep or central veins, and the venous sinuses in the dura. The cerebral cortex is primarily drained by the superficial cortical veins. Most cerebral venous blood eventually drains into the dural sinuses. With the exception of venous rupture leading to subdural hematoma, arterial disease has been considered more significant than venous disease.

### Hemodynamics

The brain accounts for a mere 2% of adult body weight but utilizes 20% of cardiac output and accounts for nearly 25% of resting total body oxygen consumption. Since the brain

### Cortical vascular territories

Figure 16.3 Vascular circulation territories. A color version of this figure can be found in Plate section 2.

does not store nutrients, it requires an uninterrupted supply of oxygen and glucose. The brain can function for only six to eight minutes if oxygen and glucose fall below critical levels, and complete blockage of blood flow will typically result in loss of consciousness within seconds. Physiologic mechanisms that regulate cerebral circulation are designed to meet metabolic demand in the face of disrupted supply. The delicate physiologic balance among cerebral blood flow (CBF), metabolism, and neuronal activity is governed by an array of functional mechanisms.

CBF is the volume of blood delivered to a defined mass of tissue per unit time, which under normal conditions is maintained at approximately 50 ml/100 g/minute. This consistent rate of blood flow is achieved by virtue of the process of autoregulation. The autoregulation of blood flow that is present in most vascular beds throughout the body is particularly well developed in the brain. Hemodynamic autoregulation involves changes in cerebral vascular resistance via vasodilation of cerebral arterioles when peripheral blood pressure is reduced or vasoconstriction when blood pressure is elevated. Metabolic autoregulation results in increased oxygen extraction fraction (OEF; the percentage of oxygen removed from blood as it passes through the capillary labyrinth), and as such is an additional mechanism that can increase the amount of oxygen extracted from blood (see Figure 16.4). The state of maximal arteriolar vasodilation is referred to as Stage I hemodynamic failure, which indicates that the brain is delivering all of the available oxygenated blood. Maximal vasodilation in addition to increased OEF is termed Stage II hemodynamic failure. Further loss of perfusion pressure and CBF falling below 15 to 20 ml/100 g/min will lead to ischemia and infarction, the hallmark of which is the combination of low flow with subnormal OEF, resulting in loss of functional tissue integrity due to cessation of electrical function and transfer of energy metabolism from aerobic to anaerobic glycolysis. Chronically suppressed global cerebral perfusion, as caused by underlying heart disease or carotid

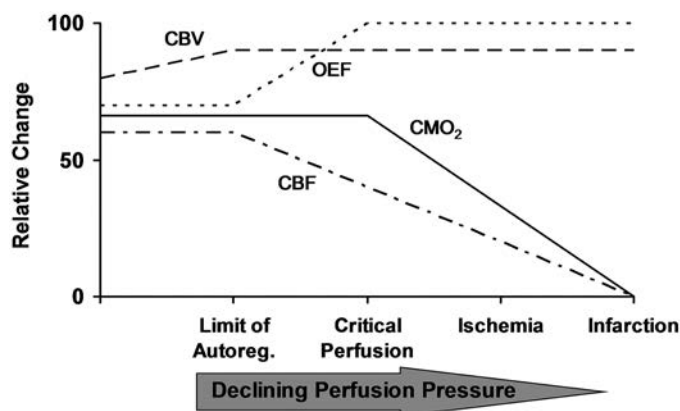

Figure 16.4 Cerebral response to hypoperfusion

Note. CBV= Cerebral Blood Volume; OEF= Oxygen Extraction Fraction; CMO<sub>2</sub>= Cerebral Metabolic Rate; CBF= Cerebral Blood Flow

artery stenosis, can impair cognitive function independent of infarction (Marshall, 2012).

In addition to autoregulation, collateral distribution is another mechanism for brain protection. It enables disruption of flow in one vessel to be compensated by distribution from an alternate supply. This built-in redundancy allows proper neuronal functioning to continue in face of a certain degree of vascular disruption. For example, an occluded carotid artery may have no measurable effect on distal cerebral perfusion if collateral flow through the circle of Willis is adequate. This is not true for the whole of brain vasculature, however, as small arteries and arterioles lack collateral mechanisms and have few interconnections. For example, the basal ganglia comprise an end-arterial region without extensive collateral circulation, which thus increases its vulnerability to ischemia and infarction.

Finally, the concept of *diaschisis* is relevant for understanding downstream effects of stroke pathology. Diaschisis refers to areas of reduced flow and metabolism at sites remote from the infarction site. This results from “stealing” of blood flow to distal brain regions. It is therefore possible to see clinical deficits corresponding to deafferentation of remote and/or ipsilateral cortical structures following a subcortical infarct. Accordingly, cognitive symptoms may also arise in functions not directly associated with the site of infarction. Because of the organization of cerebrovasculature and underlying cerebral organization, it is also important to keep in mind that small subcortical strokes may mimic cortical strokes in terms of clinical symptoms.

## Mechanisms and Pathology

### Ischemic Stroke

Ischemia, a reduction or loss of blood flow, can be focal or global. Global ischemia is the loss or reduction of blood flow to the entire brain, as seen in cardiac arrest. Focal ischemia refers to the loss of or reduction of blood flow to a specific vascular territory. Ischemic stroke results in two zones of injury known as the *core* and the *penumbra*. The core is the center of the infarct where blood flow is essentially absent, leading to tissue necrosis and the most severe area of damage. The area surrounding the core that has not yet been infarcted is the penumbra. The penumbra reflects the pathophysiologic state of viable brain tissue for which restored perfusion may restore both metabolism and function. The degree of tissue damage depends on a variety of factors, including the location and duration of ischemia, individual variations in vascular structure and collateral blood supply, edema of the surrounding tissue, and type and timing of therapeutic intervention. Secondary insults such as hypotension and hypoxia are devastating in this setting and usually result in a completed territorial infarction.

Ischemic stroke is the most common type of stroke, accounting for nearly 90% of cases (Go et al., 2013). Focal brain ischemia typically results from three primary

mechanisms: large vessel atherothrombosis, embolism, and small vessel disease. Small vessel disease is usually attributable to hypertension, which over time damages vessel walls and may lead to ischemia or infarction.

Thrombosis is an obstruction of blood flow due to a blood clot, which narrows or occludes the lumen of a vessel most commonly due to underlying atherosclerosis. Atherosclerosis involves the formation of fatty plaques along an arterial interior wall, which results in the deposition of fibrin, thrombin, and clots. Large vessels (e.g., middle cerebral artery) are particularly common sites for atherosclerosis, predisposing them to thrombotic infarcts. Other pathologies can lead to thrombosis as well, including hematologic conditions such as polycythemia or systemic hypercoagulable state. Obstruction of large vessels can also occur in vasculitis, arteritis, and fibromuscular dysplasia. Thrombotic infarcts often develop slowly and painlessly with a fluctuating course.

Embolism occurs when material from a distant site lodges in a cerebral vessel and occludes blood flow. Emboli are often fragments of a thrombus but could also be composed of fat, plaque, air, bacteria, tumor cells, or particles from an injection. Emboli most commonly originate from the heart, but may arise from the carotid or vertebral arteries, or from systemic veins, and typically cause the sudden onset of neurological symptoms (Caplan, 1993). Emboli may break up as they travel upstream and hit several areas of the brain, causing widespread and varying symptoms (known as *embolic shower*).

### *Clinical Presentation*

Symptom presentation of ischemic stroke varies by individual; however, there are classic syndromes that can be expected following occlusions within a specific vascular territory (see Table 16.1). In general, left hemisphere strokes are associated with aphasia and apraxia, while right hemisphere strokes are associated with neglect, constructional dyspraxia, and dysprosody. Motor and sensory impairments typically occur contralateral to the involved hemisphere though there is evidence of subtle ipsilateral deficits (Schaefer, Haaland, & Sainburg, 2009). This more detailed snapshot of clinical syndromes associated with specific territories is also useful (Haaland & Yeates, 2014)

Aphasia has received the greatest study, in part because few other higher cognitive functions demonstrate such predictable associations with underlying tissue damage, and aphasia syndromes are useful for localization. However, very few patients present with “classic” aphasia syndromes that fit neatly into the classification schemes that are studied by all neuropsychology and medical students. The nature and degree of language impairment will vary, for example, by lesion size, precise location, and tracts involved. As such, the neurobehavioral sequelae of the same injury may differ by individual, much like the anatomical organization of language and underlying brain topography varies. A summary

of aphasic syndromes is provided in Table 16.2 and we refer the reader to “Domains of Neuropsychological Function and Related Neurobehavioral Disorders” and “Aphasia: A Clinical Perspective” for a review of aphasia classification (Benson & Ardila, 1996; L. Schaefer & Hebben, 2014) as well as a proposed reinterpretation and reclassification of aphasic syndromes (Ardila, 2010).

### *Transient Ischemic Attack*

TIA has historically been defined as a sudden, focal neurologic deficit of presumed vascular origin lasting less than 24 hours. Until the 1970s, events lasting 24 hours to seven days were termed *reversible ischemic neurologic deficit* (RIND) and only symptoms lasting more than seven days were labeled “stroke.” However, present-day imaging techniques show that the majority of events between 24 hours and seven days in fact represent infarction. High-resolution computed tomography (CT) and diffusion-weighted magnetic resonance imaging (MRI) have demonstrated that the 24-hour duration criterion misclassified up to one-third of patients with actual infarction (Easton et al., 2009). Symptom duration does not appear to have a significant relationship to the 24-hour criterion, since 60% of classically labeled TIAs resolve within one hour, 70% in less than two hours, and only 14% last more than six hours (Shah, Kleckner, & Edlow, 2008). TIA has been reconceptualized as a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms lasting less than one hour, and without evidence of acute infarction on imaging (Albers et al., 2002). More recent consensus dropped the one-hour criterion in order to reflect that no single time threshold accurately distinguishes between patients with or without acute cerebral infarction, and to encourage tissue-based, rather than temporally based, definitions that serve to focus clinical attention on diagnosis and treatment of underlying pathology. The American Heart Association and the American Academy of Neurology now define TIA as a transient episode of neurologic dysfunction resulting from focal brain, spinal cord, or retinal ischemia, without acute infarction. The typical duration is less than one or two hours, but prolonged episodes may occur (Easton et al., 2009).

### *Diagnosis*

CT or MRI imaging was employed in more than 70% of emergency room TIA evaluations in 2001 (Edlow, Kim, Pelletier, & Camargo, 2006), and all TIA patients should undergo imaging studies as soon as possible. The preferred technique is MRI with diffusion-weighted imaging (DWI). Noninvasive vascular imaging (carotid ultrasound, transcranial doppler, magnetic resonance angiography, or CT angiography) to assess extracranial and intracranial circulation is also recommended. Finally, echocardiography is useful to rule out emboli of cardiac origin.

Table 16.1 Major clinical syndromes of MCA, ACA, and PCA territories

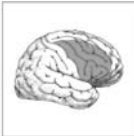

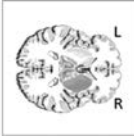

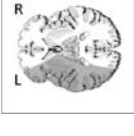

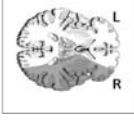

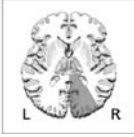

Nonfluent, or Broca's aphasia, and right face and arm weakness of the upper motor neuron type. In some cases there may also be some right face and arm cortical-type sensory loss.	Left MCA superior division			Right MCA superior division	Left face and arm weakness of the upper motor neuron type. Left hemineglect is present to a variable extent. In some cases there may also be some left face and arm cortical-type sensory loss.
Fluent, or Wernicke's, aphasia and a right visual field deficit. There may be some right face and arm cortical-type sensory loss. Motor findings are usually absent. Patients may initially seem confused or crazy, but otherwise intact, unless carefully examined. Some mild right-sided weakness may be present, especially at the onset of symptoms.	Left MCA inferior division			Right MCA inferior division	Profound left hemineglect. Left visual field and somatosensory deficits often present (these may be difficult to test due to neglect). Motor neglect with decreased voluntary or spontaneous initiation of movements on the left side can occur. Patients with left motor neglect usually have normal strength on the left side. Some mild right-sided weakness may be present. There is often a right gaze preference, especially at the onset.
Right pure motor hemiparesis of the upper motor neuron type. Larger infarcts may produce cortical deficits as well, such as aphasia.	Left MCA deep territory			Right MCA deep territory	Left pure motor hemiparesis of the upper motor neuron type. Larger infarcts may produce "cortical" deficits as well, such as left hemineglect.
Combination of the above, with right hemiplegia, right hemianesthesia, right homonymous hemianopia, and global aphasia. There is often a left gaze preference, especially at the onset, caused by damage to left hemisphere cortical areas important for driving the eyes to the right.	Left MCA stem			Right MCA stem	Combination of the above with left hemiplegia, left hemianesthesia, left homonymous hemianopia, and profound left hemineglect. There is usually a right gaze preference, especially at the onset, caused by damage to the right hemisphere cortical areas important.
Right leg weakness of the upper motor neuron type and right leg cortical-type sensory loss. Grasp reflex, frontal lobe behavioral abnormalities, and transcortical aphasia can also be seen. Larger infarcts may cause right hemiplegia.	Left ACA			Right ACA	Left leg weakness of the upper motor neuron type and left leg cortical-type sensory loss. Grasp reflex, frontal lobe behavioral abnormalities, and left hemineglect can also be seen. Larger infarcts may cause hemiplegia.
Right homonymous hemianopia. Extension to the splenium of the corpus collosum can cause alexia without agraphia. Larger infarcts including thalamus and internal capsule may cause aphasia, right hemisensory and right hemiparesis.	Left PCA			Right PCA	Left PCA Right PCA Left homonymous hemianopia. Larger infarcts including the thalamus and internal capsule may cause left hemisensory loss and left hemiparesis.

Table 16.2 Classic aphasia syndromes and associated language impairments

	<i>Broca's aphasia (motor)</i>	<i>Wernicke's aphasia (sensory)</i>	<i>Global aphasia</i>	<i>Conduction aphasia</i>	<i>TCMA</i>	<i>TCSA</i>	<i>MTCA</i>
<b>Fluency</b>	Impaired	Intact	Impaired	Intact	Dysfluent	Intact	Dysfluent
<b>Content</b>	Impaired	Impaired	Impaired	Mildly affected	Limited	Impaired, empty	Impaired
<b>Naming</b>	Impaired	Severely impaired	Severely impaired	Impaired	Impaired	Impaired	Impaired

<b>Writing</b>	Poor, grammatical errors	Impaired	Impaired	Intact	Impaired	Impaired	Impaired

Note. TCMA = transcortical motor aphasia; TCSA = transcortical sensory aphasia; MTCA = mixed transcortical aphasia.

### Treatment

Historically, TIAs were often considered relatively benign; however, with increased understanding of TIA and associated risks, there is greater emphasis on identifying TIAs and initiating treatment of the underlying cerebrovascular pathology (Rothwell et al., 2007). Given that between 10% and 50% of patients have a stroke within three months of TIA, with half of those occurring within 48 hours, there is great impetus for early evaluation and treatment. Early carotid endarterectomy following TIA has become an increasingly common means to decrease recurrence and risk of stroke with favorable cost-benefit outcomes (Ferrero et al., 2014). Fewer than one in six patients with symptom duration of at least one hour will demonstrate full resolution of symptoms by 24 hours (Levy, 1988), further highlighting the need for prompt stroke intervention, rather than a wait-and-see approach.

### Neuropsychological Implications

Aside from classic neuroanatomical correlates of TIA that can be seen with other focal lesion effects, relatively little is known about cognitive changes in the first few days following TIA or whether such symptoms have prognostic value. In patients who underwent brief cognitive screening with the Mini-mental State Exam (MMSE) either within one to seven days or after seven days following TIA or minor stroke (defined as a National Institutes of Health Stroke Scale  $\leq 3$ ), nearly 40% of the acute group (vs. 19% of the 7+ day group) showed “transient cognitive impairment” as defined by a baseline MMSE score  $\geq 2$  points lower than follow-up MMSE scores obtained one month later. These patients also demonstrated higher five-year risk of subsequent cognitive impairment, suggesting that even minor stroke can result in subtle cognitive changes and are a risk for further decline over time (Pendlebury, Wadling, Silver, Mehta, & Rothwell, 2011). This conclusion is supported by data from the Geographic and Racial Differences in Stroke (REGARDS) Study, which showed higher Framingham Stroke Risk Scores and greater risk (up to twofold) of cognitive impairment on a cognitive screening measure in those with history of stroke-like symptoms or TIA compared to those without such a history in an otherwise stroke-free sample (Kelley et al., 2013). Additionally, diffusion tensor imaging (DTI) has been shown to detect microstructural abnormalities that correlated with performance on the Montreal Cognitive Assessment (MoCA) in patients with TIA and carotid artery disease (Guo et al., 2014). Given that many of the large-scale studies in this area have tended to rely upon brief omnibus screening tests to assess cognitive outcome, it is likely that greater impairments would be detected through the use of more sensitive and detailed neuropsychological procedures.

### Hemorrhagic Stroke

Spontaneous intracerebral hemorrhage (ICH) is the second most common subtype of stroke and accounts for

Table 16.3 Causes of nontraumatic intracranial hemorrhage

Chronic hypertension
Vascular malformation
Arterial aneurysm
Hemorrhagic infarction (including venous sinus thrombosis)
Septic embolism, mycotic aneurysm
Brain tumor
Bleeding disorders, anticoagulants, thrombolytic therapy
Central nervous system infection (eg, herpes simplex encephalitis)
Moyamoya
Vasculitis
Drugs (cocaine, amphetamines)

approximately 10%–20% of all strokes (Ikram, Wieberdink, & Koudstaal, 2012). *Hemorrhage* is defined as the spontaneous bleeding within the brain or subarachnoid space as the result of vessel leakage or rupture. Primary brain damage from ICH occurs from interruption of blood supply, direct mechanical injury from the expanding clot, increased intracranial pressure (ICP), and/or herniation through the tentorium secondary to mass effect. In addition, the secondary effect of an ICH is a powerful inflammatory reaction triggered by toxic elements in the blood clot. Hemorrhagic stroke damage is manifested within the primary vascular territory affected by the disrupted perfusion, and also in overlapping or shared areas, referred to as watershed zones. There are numerous causes of intracranial hemorrhage (see Table 16.3). The majority of hemorrhagic strokes are attributable to hypertension, vascular malformations, and aneurysms.

The most common etiology of spontaneous ICH is the chronic effect of hypertension. Bleeding related to hypertension usually involves small penetrating vessels that branch directly off major intracerebral arteries at up to 90-degree angles. It is thought that penetrating arteries are more vulnerable to effects of hypertension because they are directly exposed to the larger vessel's pressure, which is ordinarily reduced by a gradual decrease in the size of other branching vessels. The territory of these vessels is the basal ganglia, thalamus, pons, and subcortical white matter. Many hypertensive hemorrhages begin as slow leaks, and in contrast to subarachnoid hemorrhage or embolic stroke, neurologic symptoms often do not begin abruptly and are not maximal at the onset. Rather, the major bleed may be preceded for weeks to months by fluctuating neurologic signs or seizure, and at onset, symptoms typically increase gradually over minutes or hours. Classic symptoms include severe headache, vomiting, decreased level of consciousness, oculomotor disturbance, and nuchal rigidity (neck stiffness). However, clinical signs will vary based on the size and location of the bleed (see Table 16.4).

Cerebrovascular malformations include congenital and acquired lesions and their rupture constitutes a major cause of devastating hemorrhagic stroke, particularly in young people. Arteriovenous malformations and cavernomas are

Table 16.4 Clinical presentation of intracranial hemorrhage by location

ICH Type	Site	Symptoms
<b>Lobar</b>	Most often affects the parietal and occipital lobes. Associated with a higher incidence of seizures.	Parietal: contralateral sensory impairment. Occipital: dense contralateral homonymous hemianopsia. Frontal: contralateral plegia or paresis of the leg with relative sparing of the arm.
<b>Putamenal</b>	Commonly occurs along white matter fiber tracts.	Hemiplegia, hemisensory loss, homonymous hemianopsia, gaze palsy, stupor, and coma.
<b>Cerebellar</b>	Originates in the dentate nucleus, extends into the hemisphere and fourth ventricle, and possibly into the pontine tegmentum.	Imbalance, vomiting, headache, neck stiffness, gaze palsy, and facial weakness. May become stuporous due to brain stem compression if the hemorrhage is unrecognized or untreated.
<b>Thalamic</b>	May extend in a transverse direction to the posterior limb of the internal capsule, downward to put pressure on the tectum of the midbrain, or may rupture into the third ventricle.	Hemiparesis, hemisensory loss, occasionally transient homonymous hemianopsia or quadrantanopsia. May be an upgaze palsy with miotic pupils that are unreactive, peering at the tip of the nose, skewed, or “wrong way eyes” toward the weak side. Aphasia if dominant hemisphere; neglect or anosognosia in nondominant hemisphere.
<b>Pontine</b>	Medial hematoma that extends into the base of the pons, disruption of the reticular activating system.	Deep coma within first few minutes, total paralysis, pinpoint pupils, absent horizontal eye movements, facial palsy, deafness, and/or dysarthria if awake.

common causes of ICH but conditions such as developmental venous anomalies, and capillary telangiectasias do not typically bleed.

### Arteriovenous Malformation

An arteriovenous malformation (AVM) is a tangle of blood vessels that form an abnormal connection between arteries and veins without an intervening capillary network (see Figure 16.5). AVMs have historically been considered congenital developmental vascular lesions because of their unusual angioarchitecture, but the pathogenesis is not well understood. It is likely that many are acquired during life, related to a two-hit hypothesis in which an inborn genetic mutation followed by a second mutation or another type of inflammatory insult results in the development of an AVM (Walker et al., 2011). They can vary in size from a few millimeters to several centimeters in diameter, and may grow over time (Soderman, Andersson, Karlsson, Wallace, & Edner, 2003). Increasing AVM mass can compress neighboring structures and result in the gradual onset of neurologic symptoms. Regional brain perfusion can be compromised due to the brain AVM “stealing” flow from normal surrounding tissue. Focal symptoms can occur if the AVM forms a pathway in which blood flows away from the site and causes hypoperfusion of brain tissue. AVMs are susceptible to spontaneous rupture because of their thin vessel walls. Supratentorial lesions account for 90% of AVMs; the remainder are in the posterior fossa. AVMs account for 1%–2% of all strokes, 3% of strokes in young adults, and 9% of subarachnoid hemorrhages, and

are responsible for 4% of ICH cases overall (Al-Shahi & Warlow, 2001). In addition to traditional angiography to assist in identification and illustration of AVMs and associated blood vessel involvement (see Figure 16.5), advances in neuroimaging and computer software now allow for sophisticated interface between structural and functional techniques (see Figure 16.6) to help plan and guide surgical treatments (see Figures 16.7 and 16.8).

### Clinical Presentation

Patients with AVMs may be asymptomatic until later in life, though symptom onset is often between the ages of 10 and 40. ICH is the most common clinical presentation (between 40% to 80% of AVM cases). Prior to rupture, headaches and seizures are common. The rate of hemorrhage in untreated cases is approximately 4% per year, with up to 2.4% causing sudden death (Huang & van Gelder, 2002). Over 90% of patients survive the initial hemorrhage and risk of recurrent bleeds is 1%–4% per year if untreated.

### Treatment

Mainstay treatment techniques for AVM include surgical excision, radiosurgery, or endovascular techniques. Stereotactic radiosurgery deploys high-energy beams to progressively destroy the AVM. The latency period (e.g., the time between treatment and obliteration) is typically one to three years. Once the lesion is completely obliterated, the hemorrhage risk is low. Complications after radiosurgery include radiation necrosis with new neurologic deficits and seizures. In contrast to standard cranial irradiation, radiosurgery may have a lesser impact on cognitive function, although comparative data are limited (Blonder, Hodes, Ranseen, & Schmitt, 1999). Endovascular embolization, often an adjunct to surgery, has relatively low risk of disabling complications.

Embolization prior to radiosurgery is employed to reduce size of large brain AVMs and to occlude vessels prior to surgical excision whose bleeding may be difficult to control during surgery. About 5%–10% of AVMs can be completely obliterated by endovascular methods (Yu, Chan, Lam, Tam, & Poon, 2004).

The long-term benefit of treatment for unruptured AVMs is unclear. A systematic review and meta-analysis of observational studies concluded that all available treatments were associated with considerable risks, including a 5%–7% median rate of permanent neurologic complications or death, and incomplete efficacy of 13%–96% (van Beijnum et al., 2011). The first multisite, randomized control trial comparing medical management to invasive treatments found the event rate in the intervention group was more than three times higher than in the medical management group after a mean follow-up of 33 months, suggesting that on average, medical management and careful monitoring are superior to intervention in patients with unruptured AVMs (Mohr et al., 2014). Extended follow-up is planned to determine whether the disparity in event rates will persist over time, however.

### Neuropsychological Implications

AVMs less consistently result in well-lateralized or focal neuropsychological impairments compared to ischemic

stroke. The variability in neuropsychological outcome may be due to AVM pathology resulting in differences in the development of cerebral (re-)organization, as well as variation in site and rate of expansion. When asymmetrical neuropsychological findings are present, the AVM laterality can be predicted as accurately as in embolic stroke. Interestingly, developmental learning disorders have been found in adults with AVMs at a rate four times that of the general population (Lazar et al., 1999). Neuropsychological functioning has been shown to improve postsurgery and may be attributable to the reduced mass effect of the AVM or surrounding edema. Alternatively, improvement may be related to eliminating the “steal effect” in which shunting through the AVM results in decreased cerebral perfusion in the surrounding area (Malik, Seyfried, & Morgan, 1996). Outcomes may also differ by age, given that executive dysfunction has been observed in adolescents, while performance on executive function tests improved in adults following AVM excision (Whigham & O’Toole, 2007). Understanding of cognitive deficit in AVM is commonly hampered by studies with comingled samples of unruptured and ruptured AVM, with incidence estimates of neuropsychological impairment ranging from 7% to 48% (Lantz & Meyers, 2008). It is possible that hemorrhage itself accounts for this wide difference among AVM patients, rather than the actual AVM, although combining patients with AVMs in various locations may also contribute to neuropsychological outcome heterogeneity.

### **Cavernous Malformation**

Cavernous malformations consist of a large vascular lumen with collagenous walls lined with a layer of endothelial cells and may vary in size from 2 mm to several centimeters. These vascular anomalies are typically sporadic though there are familial occurrences, particularly among individuals of Mexican descent (Morrison & Akers, 1993). In contrast to AVMs, cavernous malformations affect veins with trivial arterial connections. The majority of cavernous malformations are located in the supratentorial white matter. About a quarter of cases occur infratentorially, most often in the pons, followed by cerebellum, midbrain, and medulla. Rare cases of spinal cord cavernous malformations have been reported. Incidence estimates range from 0.02% to 0.9% in the general population, though this may be an underestimate, as many patients may remain asymptomatic throughout life. The risk of hemorrhage from a cavernous malformation may be comparable to AVMs, but most events tend to be small, clinically silent, and may not be detected on standard angiogram due to minimal blood flow through the lesion (Lobato, Perez, Rivas, & Cordobes, 1988). The MRI signature of a cavernoma is classic and is the ideal technique by which to follow patients over time (see Figure 16.9).

Figure 16.9 Classic MRI appearance of cavernoma with T2 (left) and Gradient (right) sequences

### *Clinical Presentation*

The mean age of symptom onset is 30–40. Cavernous malformations can be associated with headache, focal neurologic signs, and elevated ICP, though symptom manifestation varies greatly. Supratentorial lesions commonly present with hemorrhage, recurrent and intractable seizures, and progressive neurologic deficits. Seizure disorder is nearly twice as common in patients with cavernous malformations as AVM cases. The hemorrhage rate is estimated at 0.25%–1.1%. Infratentorial cavernous malformations commonly present with hemorrhage and progressive neurologic deficits. The annual bleeding rate for brain stem lesions is 2%–3% per year, with recurrent hemorrhage rates up to 20%. Brain stem lesions may produce a syndrome of waxing and waning neurologic symptoms (e.g., dysconjugate gaze, nystagmus, ataxia; see Vrethem, Thuomas, & Hillman, 1997).

### *Treatment*

Management of cavernous malformations may include routine clinical monitoring, antiepileptic medications, or surgical excision, the latter being most successful with superficial lesions. Stereotactic radiosurgery has not been shown to be beneficial. Regardless of location, asymptomatic lesions are typically closely monitored rather than treated. Expanding brain stem lesions may be treated if the malformation can be accessed without damaging critical tissue. Symptomatic cavernous malformations that are entirely surrounded by “eloquent” tissue (areas of cortex that if removed would result in loss of sensory processing, language or other cognitive abilities, or motor impairment, such as Rolandic cortex, brain stem, thalamus/basal ganglia) are usually untreated despite the poor prognosis of untreated brain stem and thalamic lesions. Stereotactic radiosurgery may be used for such surgically inaccessible lesions. However,

radiosurgery for deep lesions remains controversial due to high rates of radiation-related complications including posttreatment hemorrhage and the unclear impact on future hemorrhage risk.

### Neuropsychological Implications

Systematic studies of cavernous malformations are generally lacking, as these cases are often included with AVM and other focal lesion samples. As with AVMs, neuropsychological deficits typically are not as “focal” or lateralized as stroke, but often disrupt associated local systems and result in more generalized deficits, particularly when leading to hemorrhagic stroke. Persistent seizures associated with cavernous malformations can lead to additional cognitive morbidity. Case reports of cavernous malformations involving the thalamus have mentioned memory disturbance being common, but have lacked formal testing. A case study of cavernous malformation of the mammillary bodies reported preoperative learning and retention impairment on the Wechsler Memory Scale–Revised and Rey Auditory Verbal Learning Test (Loesch, Gilman, Del Dotto, & Rosenblum, 1995), suggesting that focal deficits may occur.

### Aneurysm

The most common cause of nontraumatic subarachnoid hemorrhage (SAH) is aneurysmal rupture. An aneurysm is a saccular outpouching of a blood vessel at a site of local weakness in the elastic membrane. There are three major types of aneurysm (see Table 16.5), the most common of which is round in shape and known as a *berry aneurysm* (see Figure 16.10). Saccular aneurysms tend to form at the bifurcation or branching of a vessel, and the majority (approximately 85%) develop within the anterior circulation at the ACom (30%) though other common sites include the PCom (25%), MCA (20%), and the vertebrobasilar apex (15%). Aneurysms range in size from 2 mm to 3 cm in diameter, with an average of 7 mm. Those larger than 2.5 cm are termed *giant aneurysms*

(see Figures 16.11–16.13). As an aneurysm grows, the vessel wall stretches, thins, and becomes increasingly vulnerable to rupture. For example, aneurysms < 7 mm in diameter have an annual rupture rate of 0.05%–2%, aneurysms > 12 mm and less than 25 mm have an annual rupture rate of 7%–10%, and aneurysms >25 mm have a five year mortality rate of

Figure 16.10 Small unruptured anterior communicating artery aneurysm

Figure 16.11 MRI of giant partially thrombotic middle cerebral artery aneurysm

Table 16.5 Types of aneurysms

Type	Description
Saccular	Berry-shaped with a narrow stem. Most commonly located in the anterior circulation.
Dissecting	Caused by a tear along the innermost layer of the vessel wall, with blood subsequently leaking in between layers of the wall. Often result of traumatic brain injury.
Fusiform	Bulges out on all sides (circumferentially), forming a dilated artery. Often associated with atherosclerosis.

Figure 16.12 Computed tomography angiography (CTA) appearance of aneurysm from Figure 16.11

Figure 16.13 Angiographic appearance of MCA giant aneurysm seen in Figures 16.11 and 16.12

Figure 16.14 CT without contrast demonstrating diffuse SAH and some intracerebral hemorrhage from ruptured anterior communicating artery aneurysm

80% if untreated (see Figure 16.14). In addition to size, risk of rupture and SAH is heightened by age, hypertension, atherosclerosis, alcohol use, and cigarette smoking, the latter of which has been shown to double the rate of SAH from aneurysms (Weir et al., 1998).

Aneurysms are typically considered a developmental or acquired vascular defect, though genetic factors may play a role. For example, individuals with two or more first- or second-degree relatives with a history of aneurysm or SAH (known as *familial intracranial aneurysm*) are up to four times

more likely to have an unruptured aneurysm compared to the general population (Ronkainen et al., 1998). Genetic diseases such as neurofibromatosis type I, Marfan's syndrome, Ehlers-Danlos Type IV, and autosomal dominant polycystic kidney disease carry higher risk of aneurysm and SAH but account for less than 5% of intracranial aneurysm cases (Gieteling & Rinkel, 2003).

### *Clinical Presentation*

Most aneurysms are asymptomatic; however, symptoms can manifest with localized head pain related to compression of cranial nerves or stretching of arteries, and transient symptoms of headache, speech disturbance, and unilateral weakness or numbness may be experienced. At the time of rupture, the classic symptom is the abrupt onset of sharp, excruciating headache often described as the "worst headache of my life" resulting from the sudden release of blood into the subarachnoid space and increased ICP. In awake and alert patients, severe headache at onset is nearly invariable, and vomiting is also a common symptom. Unlike intracerebral hemorrhage, SAH usually does not present with focal neurologic symptoms, although "suspicious" neurologic signs may occur, including Kernig's sign (inability to straighten the leg when the hip is flexed to 90 degrees due to severe hamstring pain), Brudzinkin's sign (neck flexion causes hip flexion), and oculomotor palsy (Blumenfeld, 2010). In contrast to vascular malformations, aneurysms are more likely to hemorrhage during exertion. SAH accounts for approximately 5% of all strokes. Approximately 10% of patients die prior to reaching the hospital, and mortality within the first 30 days approaches 50%, mostly due to the effects of initial and recurrent bleeding. Rebleeding is associated with an estimated 70% mortality.

### *Treatment*

The risk of rebleeding is high in aneurysmal SAH, with estimated rates of 3%–4% in the first 24 hours. Anticoagulants and antiplatelet agents are typically discontinued until the aneurysm is repaired. After SAH, treatment of the offending aneurysm is an immediate priority due to the high risk of early rebleeding, as well as the extreme risk of induced hypotension to manage vasospasm if the aneurysm has not been secured. Considerable progress has been made in the endovascular treatment of aneurysms in the past decade, including coiling, stent-assisted coiling, balloon remodeling of coil mass, and more recently, flow diversion. These treatments are subject to surgical risks just as is open craniotomy for aneurysm clip reconstruction. The decision to select either modality is best accomplished by experienced, multidisciplinary teams of neurosurgeons and neurointerventionists. The decisions are based on aneurysmal location and morphology, severity of neurological dysfunction, presence of vasospasm, patient age, and other factors. In general,

endovascular strategies are somewhat lower-risk on the day of treatment but pose a 10%–20% risk of recurrence that is not seen with clipping. Operative risks associated with aneurysm treatment include new or worsened neurologic deficits caused by brain retraction, temporary arterial occlusion, and intraoperative hemorrhage (Fridriksson et al., 2002). As might be expected, better outcomes are seen at specialized neurosurgical centers performing high volumes of cerebral aneurysm procedures compared with treatment at lower volume centers (Berman, Solomon, Mayer, Johnston, & Yung, 2003).

An alternative to surgical clipping is endovascular occlusion, in which a tiny platinum coil is inserted into the lumen of the aneurysm, forming a thrombus that then obliterates the aneurysmal sac. Endovascular techniques are generally safe and effective, although coil embolization is associated with high rate of recurrence (approximately 20% of patients). Attempts to combine endovascular treatment with gene therapies (to enhance aneurysm thrombosis) hold promise for improved outcomes (Ribourtout & Raymond, 2004).

### *Neuropsychological Implications*

Cognitive dysfunction is common after subarachnoid hemorrhage (Mayer et al., 2002). In a case study series of 217 patients treated for aneurysm rupture, 21.7% showed cognitive impairment on a telephone screening measure (von Vogelsang, Svensson, Wengstrom, & Forsberg, 2013). Neuropsychological deficits following hemorrhage are less focal or lateralized than following ischemic stroke, although the primary site of the bleed may lead to symptoms based upon associated functional brain regions. After SAH, patients may demonstrate a range of neuropsychological deficits that often do not correlate well with aneurysm location (Stabell, 1991). ACom aneurysms are often overrepresented in neuropsychological studies of aneurysm, and sequelae may manifest as broad cognitive decline, more prominent executive function deficit, an amnesic syndrome with associated frontal dysfunction, or no neuropsychological impairment (DeLuca & Diamond, 1995). Cognitive impairment ranging from mild to severe has been identified in several domains, including intellect, memory, visuospatial abilities, processing speed, and concept formation, even in patients with otherwise good surgical outcomes and up to several years after hemorrhage. Gross cognitive impairment, as measured by the MMSE, has been observed at one-year follow-up in patients who underwent aneurysm clipping (Gupta et al., 2014). In a study of patients who underwent surgery for aneurysm rupture and repair, 65% were impaired in at least one cognitive domain six months later, with 19% showing executive impairments alone, 14% showing memory impairments alone, and 32% showing deficits in both domains (Tidswell, Dias, Sagar, Mayes, & Battersby, 1995). Neuropsychological performance did not differ based on aneurysm location, but cognitive outcome was influenced by postoperative complications such as

vasospasm. The risk of cognitive impairment may be greater in those treated surgically versus endovascularly, though this issue remains unsettled, as both interventions carry risks. It is likely that neuropsychologic sequelae relate more to the site and volume of SAH rather than the mode of treatment. An increasing number of unruptured intracranial aneurysms are treated prophylactically, and a prospective comparison of patients who underwent surgical treatment of unruptured and ruptured MCA aneurysms found that 12 months after surgery, those treated for unruptured aneurysm performed at preoperative levels on a neuropsychological battery and those with ruptured aneurysms showed reduced verbal memory but otherwise mostly normal cognitive functions (Haug et al., 2009).

### *Cerebral Amyloid Angiopathy*

Cerebral amyloid angiopathy (CAA) refers to the deposition of the protein beta amyloid in small and mid-sized blood vessels of the brain and leptomeninges, weakening the vessel walls and making them vulnerable to rupture. CAA is an important cause of both large hemorrhages and microbleeds, typically in the cortex (Auriel & Greenberg, 2012). The incidence of CAA increases with age and is relatively uncommon before 60 years of age. The prevalence of CAA is estimated at 2.3% between the ages of 65 and 74, 8% between 75 and 84, and 12% over the age of 85 (Greenberg & Vonsattel, 1997). Unlike the much more common forms of intracerebral hemorrhage, CAA is not associated with hypertension. CAA is attributable to genetic mutations of amyloid precursor protein (APP), with heritable forms of the disease seen in specific Dutch, Iowan, Italian, and Arctic populations. Apolipoprotein (ApoE) is a protein that helps transport blood cholesterol and fat. The three common polymorphisms of the gene for this protein are ApoE2, ApoE3, and ApoE4. Individuals with ApoE2 or ApoE4 polymorphism appear to be at greater risk for CAA-related hemorrhage than those with the more common ApoE3 allele (Maxwell et al., 2011). Although ApoE4 is most strongly associated with a risk of Alzheimer's disease, it has been associated with other cognitive disorders as well. CAA is found in more than 90% of Alzheimer's disease cases but has also been observed in 20%–40% of elderly nondemented people (Charidimou, Gang, & Werring, 2012).

### *Clinical Presentation*

CAA is often asymptomatic but can occur in association with Alzheimer's disease, certain familial syndromes, or more rarely as transient neurologic symptoms. It is an important cause of spontaneous lobar hemorrhage in the elderly. Definitive CAA diagnosis relies on pathological examination, but probable clinical diagnosis may be made with MRI evidence of two or more hemorrhages or microhemorrhages in the cortex and sparing of sites typically affected

Figure 16.15 Classical CT example of a parietal-occipital hemorrhage from cerebral amyloid angiopathy

by hypertensive hemorrhage (basal ganglia, thalamus, and pons) (see Figure 16.15).

### *Treatment*

Acute treatment of CAA hemorrhage is the same as for other forms of hemorrhage. Surgical hematoma evacuation may be performed. CAA bleeds often recur and anticoagulant and antiplatelet agents are avoided. There is some evidence that rare inflammatory forms of CAA may be responsive to immunosuppressive therapy (Chung, Anderson, Hutchinson, Synek, & Barber, 2011).

### *Neuropsychological Implications*

Cognitive impairment has been observed in severe CAA independent of major hemorrhagic stroke and in the absence of extensive Alzheimer's disease pathology. The potential role of asymptomatic CAA in cognitive dysfunction has been highlighted by autopsy studies in which severe CAA yielded an elevated odds ratio for dementia of 7.7 (Neuropathology Group, Medical Research Council Cognitive & Aging, 2001).

Moderate-to-very severe CAA, but not mild CAA, was associated with lower perceptual speed and episodic memory but not semantic memory, working memory, or visuospatial skills in a sample of 400 individuals in the Religious Orders study (Arvanitakis et al., 2011). These effects were observed after controlling for age, sex, education, and autopsy findings

of Alzheimer's disease pathology, infarcts, and the presence of neocortical Lewy bodies.

### ***Cerebral Autosomal Dominant Arteriopathy With Subcortical Infarcts and Leukoencephalopathy***

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is an autosomal dominantly inherited angiopathy caused by mutations in the NOTCH3 gene on chromosome 19 (Joutel et al., 1996). Earlier terminology referring to CADASIL included familial subcortical dementia, hereditary multiinfarct dementia, and chronic familial vascular encephalopathy. The pathology of CADASIL involves amyloid-negative angiopathy involving small arteries and capillaries primarily in the brain, which result in loss of the periventricular subcortical white matter, lacunar infarcts in the basal ganglia, thalamus, and brain stem, and chronic ischemia (see Figure 16.16). CADASIL usually manifests in adulthood and is an important cause of stroke in the young (Chabriat, Joutel, Dichgans, Tournier-Lasserre, & Boussier, 2009). CADASIL has been reported to account for 2% of lacunar strokes with leukoaraiosis in patients younger than 65 years and for 11% of cases in those younger than 50 years (Dong et al., 2003). Ischemic stroke and TIA occur in approximately 85% of symptomatic individuals (Chabriat et al., 2009). In a large retrospective study, the age at onset for ischemic stroke ranged from 19 to 67 years, and the median age for ischemic stroke onset in men and women was 51 and 53 years, respectively (Opherk, Peters, Herzog, Luedtke, & Dichgans, 2004).

**Figure 16.16** Characteristic MRI of a patient with CADASIL; note extensive white matter injury

### ***Clinical Presentation***

CADASIL typically manifests with ischemic episodes, migraine with aura, cognitive impairment, or psychiatric disturbance. Ischemic episodes are nearly always subcortical with a classic lacunar syndrome presentation (pure motor stroke, ataxic-hemiparesis, dysarthria–clumsy hand syndrome, sensorimotor deficit). Strokes are often recurrent, leading to gait disturbance, urinary incontinence, and pseudobulbar palsy. Migraine with aura occurs in about 30% of CADASIL cases and is usually an early symptom (Liem, Oberstein, van der Grond, Ferrari, & Haan, 2010). The rate of migraine with aura is five times greater than in the general population, but rates of migraine without aura do not differ (Chabriat et al., 2009). The average age at onset of migraine with aura is approximately 30 years. Aura symptoms tend to involve the visual and sensory system. Some episodes involve hemiplegic migraine, basilar migraine, or prolonged aura, which may be difficult to differentiate from ischemic episodes. Less commonly, manifestations may include acute reversible encephalopathy or seizures.

### ***Treatment***

There is no specific disease-modifying treatment for CADASIL. Management is predominantly symptomatic, with a focus on controlling headache, depression, and urinary incontinence. Acute TIA and stroke in CADASIL patients is managed by general stroke guidelines. Secondary prevention involves basic risk reduction strategies (e.g., weight management, smoking cessation, etc.); treatment of hypertension may be of particular benefit in patients with CADASIL. Asymptomatic adult family members may undergo testing for the NOTCH3 mutation and possibly a skin biopsy for specific structural deposits within the small blood vessels.

### ***Neuropsychological Implications***

Cognitive impairment is a common clinical manifestation of CADASIL and approximately 75% of carriers eventually develop dementia (Opherk et al., 2004). Onset may be insidious and deficits may appear well before the first TIA or stroke. Cognitive decline tends to be slowly progressive with superimposed stepwise deterioration due to strokes. Predictors of cognitive impairment include older age, lesion location, lesion volume, and global brain atrophy on brain MRI. The cognitive syndrome typically involves deficits in multiple domains with early executive dysfunction and impaired processing speed. In a series of 42 patients between 35 and 73 years of age, executive impairment was present in all individuals, and attention and memory were also affected (Buffon et al., 2006). Verbal fluency, ideational praxis, and error monitoring have also been described (Peters et al., 2005). Recognition memory, verbal episodic memory, and visuospatial skills may be relatively spared and severe aphasia and

agnosia are rare, though the cognitive pattern becomes more homogeneous and diffuse late in the course of CADASIL. Major depression and apathy related to executive dysfunction occur in about 20%–30% of patients with CADASIL. Other manifestations include severe mood swings, panic disorder, visual hallucinations, and transient delusions. These episodes can precede other signs of CADASIL pathology or MRI findings. Overall, CADASIL cases may initially present with psychiatric dysfunction that is followed by pervasive cognitive impairment later in disease course (Harris & Filley, 2001).

### Moyamoya Disease

Moyamoya disease is most commonly reported in Japan and other Asian countries. It is a chronic progressive cerebrovascular disease characterized by bilateral stenosis or occlusion of the arteries around the circle of Willis with prominent arterial collateral circulation. *Moyamoya* is a Japanese word meaning *puffy*, *obscure*, or *hazy*—like a puff of smoke in the air. The term was applied to this condition to describe the smoky angiographic appearance of the vascular collateral network (see Figure 16.17). Moyamoya vessels can be seen in a number of other medical conditions; therefore, the term *moyamoya phenomenon* or *moyamoya syndrome* is used to differentiate from idiopathic moyamoya disease. Classic angiographic moyamoya findings without known risk factors are designated as moyamoya disease, while individuals with a recognized associated condition are classified as

Figure 16.17 The angiographic hallmark of Moyamoya includes proximal occlusive lesions as well as deep basal ganglial collateralization

having moyamoya syndrome (Roach et al., 2008). A few of the many conditions associated with moyamoya include sickle cell disease, Graves' disease, neurofibromatosis type 1, Down syndrome, and polycystic kidney disease. Estimated incidence in Japan is 0.35–0.94 per 100,000 (vs. 0.086 in the United States), with an approximate 1:2 male-to-female ratio and a family history found in 10%–15% of cases. Moyamoya disease can occur at any age and there may be a bimodal distribution with peaks during middle childhood and mid-adulthood (Duan et al., 2012).

### Clinical Presentation

The clinical manifestations of moyamoya can include TIA, ischemic stroke, hemorrhagic stroke, and epilepsy. Children present most commonly with TIA or infarction (up to 77% of cases) while hemorrhagic stroke (up to 70% of cases) is more common in adults with moyamoya. Hemorrhagic stroke in moyamoya disease often presents as intraventricular hemorrhage with or without intraparenchymal hemorrhage (Nah et al., 2012). The majority of these data come from Asian samples, and research in Caucasian populations suggests that clinical expression of idiopathic moyamoya disease may differ between Asians and Caucasians. For example, in a small German study ( $N = 21$ ) including 16 adults all cases presented with ischemic events (Kraemer, Heienbrok, & Berlit, 2008). The course of moyamoya may be different in North America, where moyamoya has a later onset and is less likely to involve hemorrhagic stroke. Common initial symptoms of moyamoya are motor disturbance, speech disturbance, migraine-like headache, seizures, and impaired consciousness. Uncommon presentations include dystonia, chorea, or dyskinesia (Baik & Lee, 2010). Ischemic episodes in children can be triggered by exercise, coughing, crying, fever, or hyperventilation (Hung, Tu, Su, Lin, & Shih, 1997). Epilepsy is also more frequent in children than in adults (25% vs. 5%).

### Treatment

Moyamoya is a progressive disease with no known cure. Stroke prevention typically involves surgical revascularization for moyamoya patients with progressive symptoms due to infarction or ischemia. Revascularization may include anastomosis of the superficial temporal artery to the middle cerebral artery, encephalomyosynangiosis, and encephaloduro-arteriosynangiosis, and as yet no one method of revascularization surgery has been shown to be more effective than another. Surgical revascularization for hemorrhagic moyamoya is controversial given concerns about increased risk of recurrent hemorrhage; however, one report found that the risk of rebleeding after seven years was lower in hemorrhagic patients treated with revascularization than those who received conservative therapy (7% vs. 43%) (Liu et al., 2013). The conceptual argument for direct or indirect revascularization in hemorrhagic moyamoya is that providing

augmentation of distal blood flow may reduce flow through the fragile deep collateral bed within the basal ganglia, which is the typical source of bleeding. There have been no randomized, controlled studies to determine the effectiveness of surgical revascularization treatment for moyamoya. A systematic review of retrospective case series and case reports identified 55 studies with data for 1,156 children (mainly from Japan) who underwent surgical revascularization (Fung, Thompson, & Ganesan, 2005). Over approximately five years, 87% of children had symptomatic benefit, defined as disappearance or reduction in symptomatic cerebral ischemia. Revascularization surgery may be more effective in children than in adults (Ueki, Meyer, & Mellinger, 1994), although treatment guidelines in the latter are lacking. Furthermore, there are no controlled studies directly comparing medical and surgical therapy for moyamoya, and antiplatelet therapy is generally contraindicated given the risk of hemorrhage.

Acute treatment is primarily symptomatic with the goal of reducing elevated ICP, improving CBF, and preventing seizures. Intraparenchymal hemorrhage may require ventricular drainage and/or hematoma removal. In children with moyamoya hospitalized for acute stroke, management includes precautions to minimize crying and hyperventilation as these can cause vasoconstriction and thus induce or worsen ischemia (Parray, Martin, & Siddiqui, 2011).

#### *Neuropsychological Implications*

Relatively little is known about the neuropsychology of moyamoya. The disease course tends to be progressive, with stepwise cognitive changes due to repeated ischemic stroke or hemorrhage. In studies with long-term follow-up of untreated patients, progressive neurologic deficits and poor outcome were reported in 50%–66%. Most research on cognitive effects of moyamoya has been limited to children in Japan, focused on intelligence, or conducted only postsurgically. In the first adult study, moyamoya disease had an impact on cognition, but it was not severe or pervasive (Karzmark et al., 2008). On measures of intelligence and other cognitive abilities, group performance was within normal limits. Cognitive impairment was present in approximately one-third of patients, and judged to be moderate to severe in only 11%. Executive functioning was the most common area of difficulty. These results contrast with typical pediatric findings of significant loss of intellectual capacity (Matsushima, Aoyagi, Masaoaka, Suzuki, & Ohno, 1990). More recently, a report of a moyamoya patients from three centers demonstrated at least moderate cognitive impairment (>2 SD beneath the mean) in two-thirds of the sample (Festa et al., 2010). The most common deficits were in delayed word list recall (31%), processing speed (29%), letter fluency (26%), and executive dysfunction (25%), in addition to significant decrements in grip strength and fine motor dexterity (36%–58%). Moderate to severe symptoms of depression were observed in 28% of cases, although depression was unrelated to cognitive impairment.

### **Vascular Cognitive Impairment and Vascular Dementia**

Broadly, dementias in which vascular mechanisms play a pathologic role are considered vascular dementias (VaD). VaD is thought to be responsible for at least 20% of cases of dementia, second only to Alzheimer's disease (Gorelick et al., 2011). Progress on VaD has been complicated by varying diagnostic principles and a lack of defined pathologic criteria, which have proved challenging given that cerebrovascular disease itself encompasses a wide variety of pathophysiologic mechanisms and clinical manifestations. Further, a diagnosis of VaD does not exclude the presence of Alzheimer pathology. In fact, the presence of vascular pathology increases the risk of Alzheimer's disease (Sahathevan, Brodtmann, & Donnan, 2012). This could be related to evidence that Alzheimer's disease and vascular dementia may share some of the same biological causes (Breteler, 2000) or to the fact that combined pathologies might increase dementia severity or clinical emergence. Furthermore, up to one-third of all-cause late-life dementia cases show significant vascular pathology at postmortem (Kalaria, 2002). Given that vascular risk factors are treatable, and thus VaD is theoretically preventable or modifiable, the development of satisfactory diagnostic standards is critical. The designation of VaD is perhaps currently best conceptualized as a heterogeneous syndrome rather than a distinct disorder.

#### *Diagnosis*

There are four widely used independent diagnostic criteria for VaD; the National Institute of Neurological Disorders and Stroke–Association International pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) for possible and probable VaD (Roman et al., 1993), the State of California Alzheimer Disease Diagnostic and Treatment Centers (ADDTC) criteria for possible and probable ischemic VaD (Chui et al., 1992), the *International Classification of Diseases*, tenth edition (ICD-10) criteria for VaD (WHO, 1993), and the *Diagnostic and Statistical Manual for Mental Disorders*, fifth edition (DSM-5) for major or mild vascular neurocognitive disorder (APA, 2013).

These four diagnostic approaches vary based on how dementia is defined, what types of cerebrovascular disease are included, what disorders must be specifically excluded, whether focal findings are required, whether the presence of vascular disease must be corroborated by neuroimaging, and whether a temporal relationship between stroke event and cognitive decline is required. The different criteria identify different patients and are not interchangeable, contributing to variations in epidemiologic estimates. For example, in a sample of 167 persons who met criteria for dementia, only five met criteria for VaD using all four classification systems (Wetterling, Kanitz, & Borgis, 1996). A thorough review of the various clinical diagnostic criteria for vascular dementia

highlighted the marked variability among reported sensitivities and specificities, incidence, and prevalence rates as well as substantial differences in the clinical classification of cases of dementia, and found that none of the available criteria distinguished mixed dementia from vascular dementia or recognized early vascular cognitive changes (Wiederkehr, Simard, Fortin, & van Reekum, 2008a, 2008b). More recently, a fifth approach was proposed by a joint American Heart Association and American Stroke Association statement that provided diagnostic criteria for probable and possible VaD, and probable, possible, and unstable vascular cognitive impairment (VCI) (Gorelick et al., 2011). VCI is presently conceptualized as “a syndrome with evidence of clinical stroke or subclinical vascular brain injury and cognitive impairment affecting at least one cognitive domain” (Gorelick et al., 2011: 2677).

The National Institute of Neurological Disorders and Stroke–Canadian Stroke Network Vascular Cognitive Impairment Harmonization Standards proposed a set of common data elements to help in common clinical practice or large research studies (Hachinski et al., 2006). This workgroup provided recommendations in several areas, including

neuropathology, imaging, and neuropsychology. For example, the Neuropsychological Working Group proposed three separate protocols for use of research investigations related to VCI (Table 16.6) with particular attention to tasks involving information processing speed, set-shifting, and working memory, based on the generally accepted notion that executive dysfunction is a key aspect of VCI.

### *Pathology*

At least three common pathologies contribute substantively to VaD. These include large artery infarctions, small artery subcortical infarctions or lacunes, and chronic subcortical ischemia (Kalaria, 2012). Lacunar infarctions and chronic ischemic changes in the white matter share a common primary vascular pathology—the lipohyalinosis or microatheroma of small penetrating arteries—and therefore tend to occur together and are particularly common in individuals with hypertension or diabetes and in the elderly. Other clinical manifestations attributed to small-artery disease and associated with VCI are retinopathy and the presence of cerebral microbleeds in the deep hemispheric and infratentorial

regions (Qiu et al., 2010). In contrast to cortical stroke, there is evidence of diffuse blood-brain barrier dysfunction throughout the white matter with lacunar infarction. Chronic subcortical microischemia can result in cognitive impairment even in the absence of ischemic lesions (Balestrini et al., 2013) and is a more frequent clinical-pathologic correlate of VCI and VaD than multiple large infarcts (Hulette et al., 1997; Jellinger, 2013). Deep white matter tracts are particularly susceptible to vascular pathology, in part because white matter is marginally perfused and particularly vulnerable to alterations in CBF and disruption of the blood-brain barrier, both of which contribute to oxidative stress, inflammation, and subsequent demyelination.

The role of vascular insults as initiator, stimulator, or additive contributor to VaD is significantly related to lesion volume, number, and location. Areas of strategic importance for deficits may be cortical (i.e., hippocampus, angular gyrus, frontal lobe) or subcortical (i.e., thalamus, caudate, genu of the internal capsule). Thalamic damage may be a particularly important contributor to cognitive impairment (Stebbins et al., 2008). Even a single stroke in so-called strategic areas can result in prominent cognitive impairment. This is sometimes referred to as “strategic infarct dementia,” though these cases generally have a static presentation rather than a degenerative course. Similarly, other vascular events may cause significant cognitive impairment (e.g., subarachnoid hemorrhage, impairment after cardiac bypass surgery, watershed infarction) but are not generally considered with VaD because of the lack of expected progression.

### *Neuropsychological Implications*

In contrast to the classic clinical picture of Alzheimer’s disease, which generally involves the insidious onset of cognitive impairments, vascular dementia classically is associated with an acute onset and fluctuating intensity of symptoms and a stepwise decline in cognitive functioning combined with evidence of cerebrovascular disease (e.g., focal neurological signs). However, the stepwise trajectory is typically expected with frank strokes rather than chronic microischemic insults that may have a more slowly progressive course. Alzheimer’s disease is typically associated with greater memory dysfunction and fewer executive deficits than VaD in early stages; however, the reverse is not always true (Reed et al., 2007). Despite extensive study, there remains no clear consensus of which cognitive functions or neuropsychological tests best discriminate between VaD and Alzheimer’s disease (Looi & Sachdev, 1999; Mathias & Burke, 2009). White matter pathology and subsequent disruption of fronto-subcortical networks, particularly associated with chronic subcortical microischemia, are thought to lead to slowed information processing speed, the neurocognitive symptom most commonly associated with VCI/VaD. In general, other symptoms associated with VaD include attention deficits, executive dysfunction, reduced phonemic verbal fluency, and impaired

motor programming. In terms of memory findings, relatively less prominent impairment is expected than in Alzheimer’s disease, and recognition memory performance tends to be better than free recall. However, the neuropsychological profile will depend on location and degree of the underlying cerebrovascular pathology. Gait disturbance, parkinsonism, urinary incontinence, and depression are more frequently implicated in VaD, relative to other dementias.

### **Mixed Dementia**

Mixed dementia, or Alzheimer’s disease with cerebrovascular disease, is recognized as a separate entity due to the common co-occurrence of Alzheimer’s disease and VaD pathology. Approximately 30% of patients with a clinical diagnosis of VaD demonstrate Alzheimer’s disease pathology at autopsy (Kalaria, 1993) and up to 50% of those with Alzheimer’s disease diagnoses will show vascular pathology at autopsy (Kalaria, 2012). Elderly patients with dementia may in fact be more likely to have mixed pathology (e.g., amyloid plaques, neurofibrillary tangles, and ischemic lesions) than Alzheimer’s disease or VaD alone (Launer, Petrovitch, Ross, Markesbery, & White, 2008) (Schneider, Arvanitakis, Bang, & Bennett, 2007). Furthermore, there is evidence that Alzheimer’s disease and VaD may have common etiologies and influence each other’s course. For example, after controlling for Alzheimer’s disease pathology in autopsied subjects (Schneider, 2007), cortical infarcts increased the odds of dementia fivefold. After subsequently controlling for the effect of cortical infarct, subcortical infarcts carried fourfold increased odds of dementia and were associated with lower performance on tasks of episodic, semantic, and working memory. Vascular risk factors such as hypertension, hyperlipidemia, diabetes, smoking, and coronary artery disease have been linked to both VaD and Alzheimer’s disease. The ApoE4 genotype has been associated with both Alzheimer’s disease and cardiovascular disease, though as with other central nervous system disorders, the association between ApoE4 and VaD remains unclear (Slooter et al., 2004). In part because of the common overlap of Alzheimer’s disease and VaD symptoms and shared risk factors, it has been posited that sporadic Alzheimer’s disease may in fact be a primary vascular disorder rather than a neurodegenerative disorder (de la Torre, 2002). Additional support for this view comes from studies showing the important role of cerebral perfusion in Alzheimer’s disease, including that Alzheimer’s disease risk factors reduce perfusion, medications employed in Alzheimer’s disease treatment improve cerebral perfusion, and neuroimaging evidence of regional cerebral hypoperfusion in preclinical Alzheimer’s disease. Alternatively, the hypoperfusion associated with cerebrovascular disease may impair beta-amyloid clearance. However, the interaction between cerebrovascular factors and Alzheimer’s disease remains poorly understood, as some studies find no relationship between Alzheimer’s disease pathology and infarctions

(Schneider, Wilson, Bienias, Evans, & Bennett, 2004). Alzheimer's disease pathology can overwhelm the impact of vascular or other forms of pathology (Chui et al., 2006), and cardiovascular risk profiles and white matter hyperintensities are not associated with Alzheimer's disease-specific pathology such as hippocampal atrophy and cerebrospinal fluid-derived biomarkers (Lo & Jagust, 2012).

## Cerebrovascular Risk Factors

### Web Resource

The National Stroke association offers an interactive guide ([www.stroke.org/site/PageServer?pagename=riskfactors](http://www.stroke.org/site/PageServer?pagename=riskfactors)) that explains 26 of the more common risk factors for stroke.

Cerebrovascular disease is typically due to a chronic, systemic process such as atherosclerosis or hypertension. Numerous risk factors exist and many individuals have more than one. Most risk factors have independent effects as well as interaction effects and may be more common in different disease processes. Prevention, identification, and treatment of risk factors are critical to decrease morbidity of these conditions.

### Hypertension

Hypertension is the single most important risk factor for both hemorrhagic and ischemic stroke, with approximately 77% of individuals presenting with first stroke having blood pressures higher than 140/90 (Go et al., 2013) and about 50% having a history of hypertension (Britton, Carlsson, & de Faire, 1986). Blood pressure ordinarily increases with age. Elevation of blood pressure above standard norms for age occurs in approximately a third of the general adult population and prevalence increases with age. High blood pressure places stress on blood vessel walls and subsequent morphologic changes result in cerebrovascular remodeling, impaired vasodilation and autoregulation, amyloid angiopathy, the accumulation of atherosclerotic plaque, white matter changes, and cognitive changes ranging from mild cognitive impairment to dementia (Faraco & Iadecola, 2013). There is compelling evidence that the control of high blood pressure contributes to the prevention of stroke. Numerous studies have found an association between antihypertensive drug treatment and lowered risk of dementia, presumably via the resulting reduction in subsequent major cardiovascular events and recurrent strokes (Furie et al., 2011).

### Diabetes

Diabetes mellitus, both Type I (absence of pancreatic insulin production) and Type II (insulin resistance; low production of insulin) cause elevation of blood sugar to above 100 mg/

dL, and cause microvascular (retinopathy, neuropathy) and macrovascular complications (peripheral, coronary, and cerebral atherothrombotic). Diabetes affects approximately 5% of the population, with Type II accounting for 85% of cases. Patients with diabetes have a threefold increase in risk for all cardiovascular diseases. Diabetes increases stroke risk in all ages, but particularly for African Americans younger than 55 years of age and Caucasians younger than 65 years (Go et al., 2013). This heightened risk relates to ischemic stroke while hemorrhagic stroke risk is comparable to those without diabetes (Bell, 1994). For those with a history of TIA, impaired glucose tolerance has been associated with twice the risk of stroke compared to those with normal blood glucose (Vermeer et al., 2006). Brain damage may be more severe and extensive if glucose is high at stroke onset because hyperglycemia is associated with increased edema and lesion size as well as decreased CBF (Capes, Hunt, Malmberg, Pathak, & Gerstein, 2001).

### Dyslipidemia

Three major classes of lipoproteins are found in the serum of fasting individuals: low density lipoproteins (LDL), high density lipoproteins (HDL), and very low density lipoproteins (VLDL), which together are referred to as total cholesterol. LDL augments plaque build-up and can raise the risk of ischemic stroke and TIA. HDL may reduce stroke risk. An estimated 100 million adults in the United States have total cholesterol values of 200 mg/dL and higher, and about a third of those have levels of 240 (< 200 is now established as the desirable level) or above. LDL cholesterol levels above 100 mg/dL appear to be atherogenic. The relationship between high cholesterol and neuropsychological function has been widely studied but remains inconsistent, with some studies showing a link between mid-life hypercholesterolemia and later dementia. The mechanisms underlying the relationship between cholesterol and cognitive decline remain to be clarified, though suggested processes include altered cholesterol metabolism in the brain (van den Kommer et al., 2009), increased beta amyloid production (Sparks et al., 1994), or blood-brain barrier compromise (Bjorkhem, Cedazo-Minguez, Leoni, & Meaney, 2009).

### Metabolic Syndrome

Metabolic syndrome is defined as the presence of  $\geq$  three of the following factors: (a) abdominal obesity as determined by waist circumference > 102 cm or > 40 inches for men and > 88 cm or > 35 inches for women; (b) triglycerides  $\geq$  150 mg/dL; (c) HDL cholesterol < 40 mg/dL for men and < 50 mg/dL for women; (d) blood pressure  $\geq$  130 /  $\geq$  85 mm Hg; and (e) fasting blood glucose  $\geq$  110 mg/dL (Goldstein et al., 2006). The World Health Organization modified the definition with the addition of hyperinsulinemia. Obesity, a sedentary lifestyle, and other factors seem to interact to

produce the metabolic syndrome. Metabolic syndrome may be an independent risk factor for ischemic stroke beyond the sum of its individual components. For example, in a prospective study of middle-aged subjects who were stroke-free at baseline, metabolic syndrome was present in 39% and a dose-response relationship was observed between the number of metabolic syndrome components and risk of ischemic stroke (Rodriguez-Colon et al., 2009). Elevated blood pressure and elevated fasting glucose were the two components that conveyed the highest risk. However, presence of metabolic syndrome may not be more effective for prediction of stroke than traditional assessments such as the Framingham Risk Score, a well-established algorithm used to estimate the ten-year stroke risk of an individual (Wannamethee, Shaper, Lennon, & Morris, 2005; Wolf, D'Agostino, Belanger, & Kannel, 1991).

### **Heart Disease**

Heart disease and impaired cardiac function are well-known precursors and comorbidities of stroke, including coronary artery disease, congestive heart failure, left ventricular hypertrophy, and atrial fibrillation (AF), which leads to the formation of intraventricular blood clots. AF is associated with nearly half of strokes with a cardiac origin (Force, 1989), and it increases stroke risk across the life span, with a nearly fivefold independent increase in risk. Given that AF is often clinically silent, this risk estimate may be underestimated (Elijovich, Josephson, Fung, & Smith, 2009).

### **Atherosclerosis**

Atherosclerosis, the principal cause of cardiovascular disease in adults, progresses over time and commonly manifests in mid-to-late life as heart attack or stroke. Atherosclerosis is thought to be related to chronic inflammation and subtle injury to artery walls from hypertension and high cholesterol. In response to the injured arterial wall, certain types of white blood cells migrate into the endothelium and are transformed into fat-laden foam cells that build up and form patchy deposits, or *plaques*, that are vulnerable to rupture into the arterial lumen. If a plaque ruptures, it initiates the clotting mechanism, which in turn leads to the formation of a thrombus and acute obstruction of the vessel.

### **ApoE4**

The epsilon4 allele of the apolipoprotein E gene (ApoE) is a risk factor for atherosclerosis, myocardial infarction, stroke, and Alzheimer's disease. ApoE4 polymorphism is linked to the development of small vessel pathology and enhances the extent of neuronal damage from cerebral ischemia. Amyloid beta peptide levels are associated with increased risk for lacunar stroke in carriers of the ApoE4 allele (van Dijk et al., 2004). Hypertensive ApoE4 carriers are at increased

risk for the development of subcortical white matter lesions (de Leeuw et al., 2004). The combined presence of ApoE4 and other cerebrovascular risk factors may diminish later-life cognitive performance significantly more than expected from the independent effects of ApoE4 or cerebrovascular disease alone.

### **Homocysteine**

Homocysteine is a sulfhydryl-containing amino acid derived from dietary methionine. Fasting plasma levels of homocysteine  $\geq 16 \mu\text{mol/L}$  indicate hyperhomocysteinemia. The exact mechanism of its atherogenic effect is unknown, but it is thought to contribute to endothelial damage, irregular vascular contraction, and coagulation abnormalities (Christopher, Nagaraja, & Shankar, 2007). Elevated total plasma homocysteine levels are related to several well-established stroke risk factors, including age, male sex, smoking, hypertension, and atherosclerosis. It also has an independent relationship with stroke incidence. High levels of homocysteine may increase stroke risk from 1.2 to 4.7 odds ratio. Vitamin B supplementation (folic acid, B<sub>12</sub>, and B<sub>6</sub>) lowers serum homocysteine levels and has been associated with a reduction in atherosclerotic plaque progression (Ji et al., 2013).

### **Inflammatory Biomarkers**

C-reactive protein (CRP) is an acute phase-reactant that increases in response to inflammatory stimuli and is a known mediator of adhesion molecule production and thrombogenic factor release. Elevated CRP levels have been associated with both cardiovascular and cerebrovascular events. CRP elevations confer a two- and threefold increase in stroke risk in healthy men and women, respectively. Risk of ischemic stroke is significantly increased at CRP levels of  $> 4.19 \text{ mg/L}$ . Numerous other inflammatory markers are emerging as identifiable factors associated with atherosclerotic plaque instability. For example, the CD40/CD40 ligand system plays a role in the activation of inflammatory mediators. CD40L was significantly elevated in patients with noncardioembolic stroke and remained elevated in both stroke and TIA after three months. Interleukin-18 (IL-18), a cytokine with proatherogenic properties, and monocyte chemoattractant protein-1 (MCP-1), are among other proinflammatory markers of interest. The impact on stroke of inflammatory markers such as CRP is not yet clear, and these biomarkers have not yet been recommended for routine clinical use.

### **Smoking**

Cigarette smoking increases heart rate and blood pressure, and decreases arterial distensibility. Individuals who smoke cigarettes have two to four times the risk of stroke compared to nonsmokers, and risk increases with the number of cigarettes smoked per day (Go et al., 2013). Smoking is linked

to both ischemic and hemorrhagic stroke. Exposure to environmental tobacco smoke is also a substantial stroke risk factor. Second-hand smoke has been shown to compromise endothelial function in healthy young people in a manner indistinguishable from that of active smokers and has been associated with increased inflammatory markers including CRP protein and homocysteine (Panagiotakos et al., 2004). Fortunately, smoking cessation results in reduced stroke risk across demographic groups: Within five years, stroke risk is no greater than in those who never smoked.

### **Obstructive Sleep Apnea**

Obstructive sleep apnea (OSA) is a treatable form of disordered breathing characterized by the intermittent cessation or reduction of airflow during sleep due to complete or partial upper airway obstruction. OSA prevalence among patients with stroke exceeds 60%, compared with 4% in the middle-aged adult population. OSA is intertwined with many cardiovascular burdens, but is also an independent risk factor for stroke, nearly doubling its risk (Redline et al., 2010). There is also a dose-response effect: Individuals with severe OSA have three to four times increased risk (Yaggi et al., 2005). Proposed mechanisms include acute hemodynamic changes during episodes of OSA, decreased CBF, hypercoagulability, and hypoxia. The main medical therapy for OSA is airway pressurization, which has been shown to reverse hemodynamic changes and even reduce the risk of cardiovascular events.

### **Obesity**

Obesity is associated with an array of atherogenic risk factors, including sleep apnea, hypertension, and diabetes, and it is also an independent stroke risk factor. The pattern of fat deposition appears meaningful. Abdominal deposition of fat has been linked to atherosclerotic disease, but not weight carried in the hips and thighs. Abdominal obesity is defined by a waist circumference > 102 cm (40 in) in men and 88 cm (35 in) in women. It is a stronger risk factor for vascular and metabolic disease than total body obesity, even for individuals who are not overweight, perhaps due to greater metabolic activity in visceral adiposity. Abdominal obesity has implications for cognitive dysfunction, as obesity in midlife has been associated with a threefold increased risk of dementia, independent of diabetes and cardiovascular comorbidities (Whitmer et al., 2008).

### **Psychiatric Considerations in Cerebrovascular Disease**

Depression is the most common psychiatric sequela of stroke. One-third of all stroke survivors develop poststroke depression at some point during recovery. Depression is significantly more likely after stroke than other illnesses with

comparable disability and cannot be accounted for by the existence or extent of physical symptoms. Following a stroke, individuals have approximately a sixfold higher risk of developing depression even two or more years after the stroke event, compared to age-matched controls (Whyte, Mulsant, Vanderbilt, Dodge, & Ganguli, 2004). Major depression is particularly common in individuals with left frontal or left basal ganglia lesions. Importantly, poststroke depression can adversely affect recovery and rehabilitation. At two years follow-up, depressed poststroke patients showed less recovery of physical and language functions than comparably treated nondepressed patients (Parikh et al., 1990). Furthermore, patients with poststroke depression show greater cognitive impairment even after controlling for age, education, and lesion size and location (Starkstein, Robinson, & Price, 1988). A number of psychosocial risk factors appear to increase the likelihood of developing poststroke depression. These include premorbid major depression and poststroke social isolation. Other variables—including degree of cognitive impairment, age, and gender—have not been consistently associated with the development of poststroke depression, although the presence of depression may complicate and delay cognitive recovery. Last, risk of death is three times higher over the next decade in depressed stroke survivors compared to survivors without depression, further underscoring the importance of depression screening in this population.

The clinical manifestation of poststroke depression varies, and some symptoms overlap with cognitive sequelae (e.g., anhedonia, loss of initiative). It can also be overlooked in the presence of physical symptoms such as limb paralysis, but as noted, it occurs irrespective of physical disability. Acute symptoms are often characterized by sad or apathetic mood, tearfulness, feelings of guilt, poor appetite and sleep, and pessimism about the future. Effective treatment of poststroke depression can be accomplished using conventional psychopharmacologic and/or psychotherapeutic interventions (Broomfield et al., 2011; Mikami et al., 2013; Robinson et al., 2008).

Anxiety following stroke is also common, but is assessed and reported less frequently than depression. Approximately one-fourth of poststroke patients meet criteria (except for the duration criterion) for generalized anxiety disorder at some point during recovery. As with depression, poststroke anxiety is also associated with poorer or delayed functional recovery, which can persist for years after stroke. Patients with generalized anxiety in the acute poststroke period have also been noted to show a decreased ability to perform activities of daily living (ADLs) when compared to poststroke patients without anxiety (Astrom, 1996).

Less common than depression and anxiety, psychotic symptoms may occur following stroke. Visual hallucinations are most common in poststroke delirium, but may occur later as well. Factors predisposing to hallucinations include

lesions of the right temporo-parieto-occipital area, seizures, and subcortical atrophy. Visual hallucinations have also been associated with auditory hallucinations, delusions, and depression, all more common after right-hemisphere lesions.

Pseudobulbar affect, a clinical syndrome involving frequent and easily provoked emotion (typically manifested by involuntary laughing and/or crying unrelated to mood), is seen in approximately 10%–15% of poststroke patients. Poststroke mania occurs in less than 1% of patients, although hypomanic, “euphoric,” or indifferent reactions and symptoms are more frequent in patients with right-hemisphere stroke.

## **Structural, Metabolic, and Functional Neuroimaging**

### *Computed Tomography*

CT is widely available, inexpensive, and remains the most commonly used imaging method in the initial evaluation of stroke. CT effectively detects acute bleeds and excludes many other processes such as neoplasm. CT signs of acute stroke include edema, loss of gray–white matter distinction, and blurring of the internal capsule and insular cortex. These changes result from cellular injury due to fluid influx; however, they are often subtle, and up to 60% of CT scans are normal in the first hours after insult (Mehta, 1997). After the acute period, most large vessel infarcts manifest on CT as wedge-shaped areas of attenuation, with increasing mass effect up to a few days after insult. Edema can cause midline shift, effacement of ventricles and sulci, ventriculomegaly, and transtentorial herniation. Later stages of stroke will manifest on CT generally at three to four weeks with shrunken gyri, glial scars, resolved edema, regional or global ventricular dilation, and reabsorption of necrotic tissue.

### *Magnetic Resonance Imaging*

MRI has greater sensitivity and specificity than CT for ischemic lesions. In contrast to CT, more than 80% of magnetic resonance scans are sensitive to acute infarcts within the first 24 hours (Bryan et al., 1991). DWI images are more precise for ischemic damage detection than standard CT or MRI (Easton et al., 2009). MRI with diffusion sequences is now considered superior to noncontrast CT and a preferred diagnostic technique for acute stroke or suspected TIA (Schellinger et al., 2010). DWI may also be useful for predicting late clinical outcome. Early MRI changes in stroke include gray matter swelling and increased signal intensity. With use of contrast agents, early enhancement surrounding the lesion (due to slow flow) and meningeal enhancement (due to irritation of overlying meninges) may be seen. Contrast MRI also helps differentiate strokes of indeterminate age, with subacute lesions showing enhancement that is often ring-like that typically resolves by eight weeks (up to three

months) and meningeal enhancement resolving within two to four days. In later stages, enhancement and mass effect tend to abate. Subacute MRI changes become more prominent with time due to edema and mass effect, and enlargement of T2 hyperintensities, though this can also reflect late effects of regional atrophy and/or ventricular dilation. Other MRI-based techniques include DTI, which can depict abnormalities of white matter tracts. Functional MRI (fMRI) allows for analysis of small blood flow changes in response to cognitive challenge tasks. Resting-state fMRI examines spontaneous synchronous activation of various brain regions and circuits. These latter techniques remain largely investigative at this point, but show promise in terms of depicting structural and functional brain changes following stroke. Because it involves a strong magnetic field, MRI is not possible in patients with pacemakers and internal defibrillators.

### *Cerebral Angiography*

Cerebral angiography is the technique to measure intracranial vascular disease (Citron et al., 2003). It involves the insertion of a catheter into an artery in the arm or thigh, which is then threaded through the circulatory system to the carotid artery where a contrast agent is injected. A series of radiographs are taken as the contrast agent spreads through the brain’s arterial system, and a second series as it reaches the venous system. Cerebral angiography provides information about collateral flow and perfusion status, determines degree of arterial stenosis, and detects dissection, or lesions such as vascular malformations. Conventional angiography carries a low risk of stroke (0.14%–1%), transient ischemia (0.4%–3%), and clinically silent embolism (up to 25%). The procedure has been made safer and easier with advances in catheter technology, nonionic contrast media, and digital image three-dimensional reconstruction. This technique remains more sensitive than noninvasive methods in cases of suspected large-vessel occlusion though continued advances in noninvasive neuroimaging techniques may eventually replace cerebral angiography. Conventional angiography is also utilized for planning neurosurgical and endovascular interventions.

### *Magnetic Resonance Angiography*

Magnetic resonance angiography (MRA) is a noninvasive technique for assessing vascular flow. MRA sensitivity and specificity for detection and degree of stenosis is 80%–95%, with 5% of exams being nondiagnostic due to patient motion artifact (Mehta, 1997). Contrast-enhanced MRA may be more accurate than standard time-of-flight studies and has replaced the use of catheter angiography in some areas (Phan, Huston, Bernstein, Riederer, & Brown, 2001). An initial screen of the carotid bifurcation is performed with ultrasound, MRA, or CTA, and if the study is abnormal a second noninvasive test or catheter angiography is conducted prior

to endarterectomy. Prompt testing in symptomatic persons is critical in order to quickly identify patients with severe disease for whom endarterectomy would be beneficial.

### **Magnetic Resonance Spectroscopy**

Magnetic resonance spectroscopy (MRS) is a complement to MRI as a noninvasive method for chemical tissue characterization. In contrast to MRI, which uses hydrogen protons to form anatomic images, MRS determines the concentration of brain metabolites such as choline, creatine, and lactate. MRS allows for in vivo localized measurements of selected metabolite levels from focal lesions deep within the brain. Its utility in the evaluation of cerebrovascular disease has been limited by long scan times and limited spatial resolution, but faster imaging sequences have been developed. The earliest spectroscopic abnormality in stroke is an increase in lactate (Gujar, Maheshwari, Bjorkman-Burtscher, & Sundgren, 2005).

### **Positron Emission Tomography**

PET is a functional imaging test that measures CBF and local metabolism using a radioactive tracer. The method is based on the assumption that CBF directly reflects neuronal activity. PET scans obtained in acute stroke have been shown to help predict prognosis at two months (Marchal et al., 1993). PET may prove particularly useful in monitoring therapeutic interventions aimed at improving cerebral oxygenation and blood flow in acute stroke, as it is currently the only accurate method for assessing regional CBF and oxygen levels.

### **Single Photon Emission Computed Tomography**

Single photon emission computed tomography (SPECT) utilizes cerebral blood flow measurement, which can be used to detect and characterize remaining viable tissue, and demonstrate reperfusion. SPECT is similar to PET in its use of radioactive tracer material and detection of gamma ray, but uses radioisotopes that are longer-lived and more easily obtainable. It is therefore less expensive, though it offers lower resolution than PET. SPECT scans show the entire low-flow area, including the ischemic core and surrounding penumbra, and unlike CT, occlusive damage is visible on SPECT immediately. Lesions in the cortex are more easily identified by SPECT than are deep lesions. SPECT is inexpensive, repeatable, and typically safe, though there are concerns about exposure to the ionizing radiation. However, SPECT does not assess cerebral metabolism. Other limitations of SPECT include limited image resolution compared to MRI or CT, variable inter-rater reliability, and the lack of standardized SPECT acquisition/analysis protocols, which make it difficult to compare results from different centers.

### **Transcranial Doppler Sonography**

Transcranial Doppler sonography (TCD) is a noninvasive bedside technique that uses a pulsed Doppler transducer to measure CBF velocity. It is used to detect gross abnormalities in intracranial cerebral hemodynamics and is relatively quick and inexpensive. TCD can help diagnosis emboli and vasospasm, detect severe stenosis, assess extent of collateral circulation, evaluate suspected brain death, and assist in the diagnosis of AVM. TCD can detect recanalization following thrombolytic therapy and may guide treatment following tPA intervention.

#### **Web Resource**

Transcranial Doppler Simulator Educational Software ([www.transcranial.com/edu/index.html](http://www.transcranial.com/edu/index.html)) introduces the transcranial Doppler investigation technique, includes a tour of the cerebral arteries with a three-dimensional simulation of the ultrasound approaches used in the clinical setting, and includes simulation of compression maneuvers to observe the activation of collateral flow.

### **Acute Management and Treatment**

The primary goals of initial stroke management are to diagnose the likely cause and extent of stroke, quickly initiate treatment, identify other potential contributing factors, and anticipate and prevent potential complications. Immediate focus is on ensuring medical stability, with particular attention to airway, breathing, and circulation, and determining if patients with acute ischemic stroke are candidates for thrombolytic therapy. The importance of immediate assessment of patient eligibility for thrombolytics or other treatment cannot be overstated, given that for each minute in which a large vessel ischemic stroke is untreated, an estimated 1.9 million neurons, 13.8 billion synapses, and seven miles of axonal fibers are lost, and for each hour the brain experiences a neuronal loss equivalent to approximately three years of normal aging (Saver, 2006).

A general overview of an initial stroke work-up is provided in Table 16.7. All patients with a possible TIA or stroke should undergo neuroimaging. Routine blood tests include a complete blood count, chemistry panel, and basic blood coagulation studies (e.g., prothrombin time), and specialized coagulation tests for young, healthy individuals. Cardiac and vascular imaging tests will be ordered based on brain imaging results. Noninvasive tests such as ultrasound or MRA usually precede catheter angiography, which is done when a lesion is suspected but not otherwise evident in prior testing. Cardiac studies, including electrocardiogram and chest x-ray, are a routine part of the workup and useful for detecting a heart or aortic source of embolization or comorbid coronary artery disease. Other key acute management issues that arise

Table 16.7 Initial stroke workup

---

Laboratory Studies
Hematology: CBC, Platelet Count, Prothrombin Time, Partial Thromboplastin Time
Chemistry: Electrolytes, BUN, Creatinine, Glucose
Toxicology Screen (suspected drug abuse)
Arterial Blood Gas (suspected hypoxia)
Electrocardiogram
Chest x-ray
Neuroimaging/Neurophysiologic Studies
CT, MRI, Transcranial Doppler, SPECT, PET, angiography, EEG
Lumbar Puncture (if CT negative and SAH suspected)

---

include blood pressure control, swallowing assessment, management of abnormal blood glucose levels, and treatment of fever and infection.

Most strokes are caused by intra-arterial occlusion from clots. Timely restoration of blood flow using thrombolytic therapy is the most effective means of salvaging ischemic brain tissue that is not already infarcted. The efficacy of intravenous tissue plasminogen activator (tPA or alteplase) therapy is well established for reducing neurologic damage in selected patients with acute ischemic stroke. Once it has been determined that the patient has an acute ischemic stroke and hemorrhagic stroke has been ruled out, consideration should be given to the use of thrombolysis. However, eligible patients may be treated with intravenous thrombolysis if neurovascular imaging is not readily available or if obtaining imaging would significantly delay therapy. There is a narrow window during which this can be accomplished, and the sooner tPA is administered, the greater the efficacy (Hacke et al., 2004). The conventional accepted treatment time window for administration of tPA is within 3 to 4.5 hours after clearly defined symptom onset and potentially between 3 and 6 hours. Symptomatic intracranial hemorrhage is the most important complication of thrombolytic therapy. Other interventions for ischemic stroke associated with better outcomes include antithrombotic therapy initiated within 48 hours of stroke onset, prophylaxis for deep venous thrombosis and pulmonary embolism, antithrombotic therapy at discharge, and initiation of lipid-lowering therapy. In addition to thrombolysis, two major classes of antithrombotic drugs—antiplatelet agents and anticoagulants—can be used to treat acute ischemic stroke. In terms of prophylaxis, low-dose aspirin (81 mg) is the most commonly used antiplatelet agent and has proven value as a risk reducer of stroke and stroke mortality.

Acute treatment of hemorrhagic stroke involves a combination of medical and surgical interventions, the latter depending on the site of the bleed. Surgical removal of blood clots is particularly indicated in patients with cerebellar hemorrhages, brain stem compression, and/or hydrocephalus due to ventricular obstruction, typically via posterior fossa decompression. Surgical hematoma evacuation for

supratentorial ICH is controversial, and suggested primarily for large bleeds that are near the surface. Other features that increase the likelihood of surgical intervention include clinical deterioration, stuporous arousal, and involvement of the nondominant hemisphere. Open craniotomy is the most common technique for supratentorial ICH; other methods include endoscopic hemorrhage aspiration, use of fibrinolytic therapy to dissolve the clot followed by aspiration, and CT-guided stereotactic aspiration. Ventriculostomy can be used in the setting of ventricular enlargement, particularly of the third and fourth ventricles. Balloon angioplasty may be used in the management of vasospasm after subarachnoid hemorrhage.

### Telestroke

There are various important developments in modern technology utilization for stroke management. Although a full review is beyond the scope of this chapter, telemedicine applications to stroke are increasingly commonplace. In fact, the implementation and evaluation of mobile telemedicine systems in emergency medical services has been recommended by the American Heart Association. Only a small fraction (< 1.5% nationally) of acute stroke victims receives thrombolytic intervention and few benefit from the expertise and experience of dedicated stroke units. Telemedicine technology for stroke management, or *telestroke*, has the potential to greatly reduce geographic disparities in stroke care and rapidly link underserved areas to stroke expertise anywhere in the country or across the world.

Telestroke programs are typically employed for emergency department consultation, patient triage, and inpatient consultation. The American Heart Association and American Stroke Association (AHA/ASA) support the use of telemedicine in the acute stroke setting when local stroke expertise is not available. Quality videoconferencing systems are useful for patient evaluation, review of neuroimaging results, and thrombolysis decision making. The utility of telemedicine for remote intravenous tPA treatment decisions before transfer to a stroke unit is a subject of ongoing debate. The use of telemedicine-equipped ambulances has been explored as a means of providing advance patient information and improving time management, referral of patients to specialized hospitals, and identification of patients eligible for thrombolysis (Liman et al., 2012). Data to suggest that telemedicine is cost-effective for acute stroke care are accumulating, particularly given that telestroke costs are short-lived and improved stroke care has lifelong benefits (Nelson, Saltzman, Skalabrin, Demaerschalk, & Majersik, 2011). Important barriers to program growth include lack of program funds, low insurance reimbursement rates, high equipment costs, liability, and credentialing in out-of-state situations. Teleneuropsychology is an emerging area with demonstrated feasibility in areas such as dementia assessment (Cullum, Weiner, Gehrman, & Hynan, 2006) and clear potential utility for

subacute stroke evaluation. Preliminary practical and ethical considerations for neuropsychologists are provided by Grosch, Gottlieb, and Cullum (2011).

## Complications

Preventing medical complications is an important aspect of stroke management. These include hypoxemia, metabolic acidosis, and hyperglycemia. Other complications that may develop in the acute or subacute phase of stroke include heart failure, dysphagia, aspiration pneumonia, deep vein thrombosis, pulmonary embolism, and urinary tract infection. Common complications are discussed in detail in this section.

### Edema and Increased Intracranial Pressure

Life-threatening complications of edema and ICP may occur in as many as 10% of all strokes. Large supratentorial infarcts are particularly associated with edema. Early clinical signs include decreased level of consciousness, asymmetric pupils, and changes in breathing pattern. Edema associated with infratentorial stroke, particularly cerebellar hemorrhage, can result in hydrocephalus, brain stem compression, and death. Mortality rates rise to more than 50% once there is elevated ICP and significant mass effect. Surgical interventions to improve the chance of survival include infarct resection or hemicraniectomy. Resection of edematous tissue typically employs temporal and frontal lobectomies of the right hemisphere. In hemicraniectomy, a large bone flap is removed and the dura is opened to allow the brain to expand, with a cranioplasty performed at a later date.

### Vasospasm

Clinically significant vasospasm occurs in approximately 20%–30% of patients with aneurysmal SAH, and is the leading cause of death and disability after aneurysm rupture. Vasospasm may occur because nearby vessels are irritated by the blood from the ruptured aneurysm, which generates spasmogenic substances during the lysis (breakdown) of the clots. It typically presents around day five after hemorrhage and peaks at days seven to eight. Vasospasm manifests with a decline in neurologic status including the onset of focal neurologic abnormalities. Vasospasm can sometimes be visualized on MRI or MRA, though treatment can be difficult.

### Hydrocephalus

Hydrocephalus (i.e., expansion of the cerebral ventricles) is a common complication of SAH, occurring in up to 20% of cases. Ventricular drainage via shunt placement is considered for patients who develop hydrocephalus and experience a deteriorating level of consciousness and for those in whom

no improvement in hydrocephalus occurs within 24 hours. Delayed enlargement of the ventricles can also occur.

### Hemorrhagic Conversion and Cerebral Hyperperfusion Syndrome

Hemorrhagic conversion or transformation (secondary bleeding) is a potential complication of ischemic infarction that occurs in approximately 10% of cases and is usually asymptomatic. The current classification of hemorrhagic transformation encompasses a broad spectrum of secondary bleeding, ranging from small areas of petechial hemorrhage to large space-occupying hematomas. The former often appear as patchy areas of bleeding with indistinct margins within the vascular territory of the infarction, representing movement of blood cells through capillaries without frank vessel rupture. Parenchymal hematomas are discrete, dense collections of blood that may exert mass effects associated with rupture of an ischemic vessel that has been subject to reperfusion pressures. This hemorrhagic conversion is also known as *cerebral hyperperfusion syndrome*. Though relatively uncommon, this is a well-described complication of revascularization surgery. Revascularization restores blood flow to a normal or elevated pressure in the area that was previously hypoperfused with compensatory dilation of cerebral vessels. These vessels are unable to vasoconstrict quickly, causing breakthrough perfusion pressure. Cerebral hyperperfusion syndrome may manifest with headache, seizures, reversible focal neurologic deficits, cerebral edema, and rarely intracerebral hemorrhage.

### Seizures

Seizures are a relatively common complication of hemorrhagic stroke, occurring in 4%–29% of patients with acute spontaneous ICH and more commonly in lobar bleeds than in deep hemorrhage. Antiepileptic drugs (AEDs) are usually continued for approximately six months in patients who experience an acute seizure (i.e., within seven days) following SAH, although there are no strict guidelines. The most commonly used agents include phenytoin and carbamazepine. The use of AEDs to prevent seizures in patients with SAH has been widely debated (Naval, Stevens, Mirski, & Bhardwaj, 2006). Many experts favor seizure prophylaxis in the setting of an unsecured aneurysm because of the relatively low risk of AEDs compared to the potential damage from seizures in a compromised brain. However, AED exposure may be associated with worse neurologic and cognitive outcome after SAH, and current guidelines indicate that AEDs for seizure prophylaxis after SAH should be minimized. The incidence of late epilepsy (more than two weeks after surgery) is unclear. In a retrospective report of 472 patients with aneurysmal SAH who underwent surgical clipping and were followed for at least 12 months, late epilepsy occurred in only 5% (Buczacki, Kirkpatrick, Seeley, & Hutchinson, 2004).

### Cognitive Impairment

Cognitive impairment is a very common outcome of stroke that often is unrecognized or underappreciated by clinicians and patients. In contrast to the routine inclusion of screening measures of quality of life, large randomized stroke-treatment trials traditionally have unfortunately failed to include neuropsychological measures of stroke morbidity. A systematic review of 51 randomized studies of acute stroke drug intervention studies involving more than 50,000 participants (Duncan, Jorgensen, & Wade, 2000) found only two that measured cognitive deficit—both using the MMSE, which is insensitive to many cognitive deficits and provides only cursory insight into cognitive status. Furthermore, only one study reviewed used a brief neuropsychological battery that included measures of aphasia, perceptual discrimination, sustained concentration, and processing speed (Duncan et al., 2000). A more recent review of 190 acute stroke treatment trials found similarly poor examination of neuropsychological outcomes, with only three studies incorporating specific measures of cognitive function, specifically the Trail Making Test, Boston Naming Test, Visual Form Discrimination Test, and Line Cancellation Test (Anderson, Arciniegas, & Filley, 2005). The MoCA, another global cognitive screening tool that is slightly more sensitive than the MMSE in some populations, was included as a three-month outcome measure in a multicenter trial of earlier and more frequent mobilization after stroke, and preliminary results indicated the feasibility of the MoCA in stroke trials as a complement to existing efficacy outcomes (Cumming, Bernhardt, & Linden, 2011). Future studies of stroke treatment and outcome should address the dearth of more sensitive and detailed neuropsychological outcome data.

### Rehabilitation

Stroke is a leading cause of disability in the United States (Centers for Disease and Prevention, 2009). Among Medicare patients with stroke, 45% are discharged home (32% of these utilize home health care services), 24% enter inpatient rehabilitation facilities, and 31% go to skilled nursing facilities (Buntin, Colla, Deb, Sood, & Escarce, 2010). In the Framingham Heart Study, the following disabilities were observed after six months in ischemic stroke survivors over age 65: 50% had some hemiparesis, 46% had cognitive deficits, 35% had depressive symptoms, 19% had aphasia, and 26% were institutionalized (Kelly Hayes et al., 2003).

Neurologic recovery is most rapid during the first three months and tends to plateau around 6–12 months poststroke, though continued improvements can continue over the coming months and even years following stroke. Stroke rehabilitation efforts should begin immediately. The overall goal of stroke rehabilitation is to help patients regain and relearn the skills of everyday living, adapt to new limitations, prevent secondary complications, and educate the patient and family

members in appropriate supports. Rehabilitation programs are generally directed toward improving motor function, speech, and performance of daily activities. A rehabilitation team is typically multidisciplinary and often includes physiatrists, neuropsychologists, speech and language therapists, physical therapists, occupational therapists, and social workers. Interventions may include physical therapy to address strength and ambulation, occupational therapy to increase functional independence, speech therapy to improve dysphasia and dysphagia, and group or individual psychotherapy to combat discouragement, manage mood symptoms, and help patients to develop realistic expectations. As noted earlier, it is particularly important to identify mood disorders, as they can complicate and protract cognitive and functional recovery. Although large-scale studies are limited, cognitive rehabilitation programs have shown efficacy in enhancing neurobehavioral function and quality of life (Cumming, Marshall, & Lazar, 2013).

Cerebral plasticity, important in the developing nervous system, persists to some degree throughout life and is a fundamental factor in stroke recovery. Neuroimaging studies in stroke patients indicate altered poststroke activation patterns, which suggest some functional reorganization. Many of these changes may be explained by the well-established compensatory process known as *functional reorganization* or *functional adaptation*; however, modern views acknowledge that recovery of function may also be accounted for by partial restitution of the impaired neuropsychological processes themselves via experience-dependent brain plasticity (Robertson & Murre, 1999; Rossini et al., 2007). Enhanced understanding of brain plasticity will likely improve stroke rehabilitation efforts, particularly as targeted therapies are developed.

### Innovative Technologies

Although specific technologies are beyond the scope of this chapter, we want to mention several technologic innovations that have implications for stroke rehabilitation. The use of virtual reality and video games is being explored as a means of promoting exercise, social interaction, and rehabilitation (Laver, George, Thomas, Deutsch, & Crotty, 2015). This type of therapy uses computer-based programs designed to simulate real-life objects and events and may be more motivating for patients (see Figure 16.18). Transcranial magnetic stimulation (TMS) and transcranial direct-current stimulation are noninvasive methods that can improve motor and language function (Naeser et al., 2012). TMS instruments consist of a high-voltage capacitor that can be discharged through an insulated coil of wires and the magnetic field passes through the skull and induces an electrical current in brain tissue. In healthy individuals, TMS can produce a contralateral evoked response in the muscle and a movement when the coil is placed on the scalp over the motor cortex. Such stimulation over the damaged motor cortex may be used

Tsoupikova, Electronic Visualization Laboratory. *A color version of this figure can be found in Plate section 2.*

to increase poststroke motor-evoked potentials with associated functional improvements (Dimyan & Cohen, 2010). Brainwave technology known as brain–computer interfaces (BCI) and brain–machine interfaces (BMI) stimulate cortical activity at the level of neuronal action potentials and may facilitate recovery by normalizing neurophysiologic activity (Wang et al., 2010). These brain training devices facilitate motor relearning to help patients control external devices (such as a computer cursor or arm prosthesis) and move paretic limbs (Meng et al., 2009). Other promising noninvasive rehabilitation methods include robotic therapies, such as robot-assisted physical therapy with robotic manipulation of impaired limbs. Home telerehabilitation programs will also likely play an important future role in stroke treatment (Chumbler et al., 2012; McCue, Fairman, & Pramuka, 2010).

### Prevention

Secondary stroke prevention interventions include anticoagulants, platelet inhibitors, carotid endarterectomy, and stenting. Carotid endarterectomy, the removal of plaque to

correct stenosis, is the most frequently performed surgical procedure to prevent stroke, with about 100,000 inpatient procedures performed in the United States in 2010 (Go et al., 2013). Carotid artery stenting is a relatively newer and less-invasive procedure that involves threading a stent and expanding a small protective device in the artery to widen the blocked area and capture any dislodged plaque. A large randomized stroke prevention trial over nine years found that safety and effectiveness between carotid endarterectomy and carotid stenting were generally equal, with stenting being slightly better in younger patients (Timaran et al., 2013).

Advances in acute stroke therapy will continue; however, primary prevention will remain the most important and effective strategy for reducing mortality and morbidity from stroke. Primary prevention includes both education and management of risk profiles. In 2009, 51% of a sample of approximately 20,000 individuals was aware of five stroke warning symptoms and would call 911 if they thought someone was having a stroke. This awareness was higher among Caucasians, women, and individuals with higher education (Go et al., 2013). In a study of individuals with a history of

stroke, only 55% were able to identify one stroke symptom. The median time from symptom onset to emergency room admission was 16 hours, and only 32% entered an emergency room in less than two hours (Zerwic, Hwang, & Tucco, 2007). In a UK study of TIA, approximately 70% of patients did not correctly recognize their TIA or minor stroke; 30% delayed seeking medical attention for > 24 hours, regardless of age, sex, social class, or educational level; and approximately 30% of early recurrent strokes occurred prior to receiving medical attention (Chandratheva, Lasserson, Geraghty, & Rothwell, 2010). It is helpful for the public to develop heart-healthy habits and estimate stroke risk. Risk-assessment tools can be used to identify persons at elevated risk and to guide appropriate use of further diagnostic testing. Public awareness campaigns with phrases such as “F.A.S.T.” (face, arms, speech, and time) and “Time Is Brain” seek to emphasize that brain tissue is rapidly lost as a stroke progresses and that rapid treatment is urgently needed.

Most strokes are the outcome of pathologic processes, such as atherosclerosis, that are typically set into motion many years prior and are preceded by a number of risk factors that are common across all stroke types. Preventive care should include reduction of individual risk factors, such as the components of the metabolic syndrome. Preventive care for vascular risk reduction should include lifestyle modification (diet, exercise, smoking cessation, and avoiding weight gain). Regular physical activity has well-established benefits for reducing the risk of premature death and cardiovascular disease (Nelson et al., 2007; Sattelmair et al., 2011). At least 30 minutes of moderate intensity exercise, defined as vigorous activity sufficient to break a sweat or noticeably raise the heart rate (e.g., walking briskly, riding a bicycle or exercise bicycle) one to three times a week may significantly reduce risk factors and comorbid conditions associated with an increased likelihood of recurrent stroke. There are no data to confirm that weight reduction directly reduces the risk of recurrent stroke for overweight persons; however, weight loss is beneficial for improved control of other important parameters, including blood pressure, glucose, and lipid levels. Current guidelines for stroke prevention include intake of folic acid (400 µg/d), B<sub>6</sub> (1.7 mg/d), and B<sub>12</sub> (2.4 µg/d) either by supplementation or by dietary means (Furie et al., 2011).

For examples of patient educational tools, please refer to the National Stroke Association's website ([www.stroke.org/site/DocServer/Scorecard.Q\\_08.pdf?docID=601](http://www.stroke.org/site/DocServer/Scorecard.Q_08.pdf?docID=601)).

#### Conclusion

Cerebrovascular disease represents an array of related disorders and pathophysiologic processes that often result in neuropsychological and functional morbidities. The focal lesion model provided by patients with strokes and related disorders

helped propel the field of neuropsychological assessment forward. These patients can sometimes be extremely challenging to evaluate because of deficits, such as aphasia, which can confound the accurate characterization of other neuropsychological deficits. Although stroke research often includes only brief indices of global cognitive function, there is growing recognition of the importance of neuropsychological outcomes in clinical trials, patient recovery, and quality of life in patients with cerebrovascular disorders. Because significant cognitive and mood disorders may go undetected or underappreciated in standard clinical settings, there is a need for routine and efficient neuropsychological assessment procedures in such populations in clinical and research settings. Furthermore, the residual neuropsychological sequelae of cerebrovascular disease can vary greatly by individual, and as such, there is more to be learned about clinical phenotypes and multimodal prediction models of outcome that incorporate neuropsychologic, neuroimaging, clinical, and biomarker measurement techniques.

# 17 Moderate and Severe Traumatic Brain Injury

*Tresa Roebuck-Spencer and Mark Sherer*

Traumatic brain injury (TBI) has been defined by the Centers for Disease Control and Prevention (CDC) as an injury to the head that involves at least one of the following: (a) decreased level of consciousness, (b) amnesia, (c) skull fracture, or (d) objective neurological or neuropsychological abnormality or diagnosed intracranial lesion (Marr & Coronado, 2004). TBI severity is classified on a continuum from mild to moderate to severe, with treatment, recovery course, and ultimate outcome varying widely across these groups. Neuropsychological assessment and intervention are frequently requested for patients with TBI at all levels of injury severity and across multiple time points in the treatment and recovery course.

Individuals with moderate to severe TBI often have persisting impairments that impact their ability to return to their previous level of functioning. These patients are much more likely than patients with mild injuries to require inpatient or postacute rehabilitation and subsequently may be followed for ongoing outpatient care related to their injuries (Harrison-Felix, Newton, Hall, & Kreutzer, 1996; Malec & Moessner, 2000). Neuropsychologists in both inpatient and outpatient settings may be asked to evaluate and treat patients with moderate and severe TBI to address referral questions including, but not limited to, stage of recovery, supervision/guardianship needs, ability to return to work or school, and effectiveness of psychotropic medication or other interventions.

This chapter will provide a review of neuropsychological issues relevant to moderate and severe TBI. Specifically, this chapter will cover (a) incidence/prevalence and risk factors, (b) classification of TBI severity, (c) neuroanatomical effects of TBI, (d) course of recovery, (e) neuropsychological and neurobehavioral effects of TBI, (f) neuropsychological assessment, and (g) outcome following moderate and severe TBI.

## **Incidence/Prevalence and Risk Factors for TBI**

TBI is a serious public health issue that affects all ages, genders, and ethnicities. In its most recent report on TBI in the United States spanning the years 2002–2006, the CDC reported an estimated 1,691,481 people (576.8 per 1000,000) sustain a TBI annually (Faul, Xu, Wald, & Coronado, 2010). Of this number, nearly 80% are treated in the emergency

department (ED) and released, with approximately 275,000 individuals hospitalized for further care. In addition, 52,000 individuals are reported to die as a result of their injuries with TBI identified as a contributing factor in a third of all injury-related deaths.

Comparison of incidence rates over time revealed increases in TBI-related ED visits and hospitalizations (Faul et al., 2010; Langlois, Rutland-Brown, & Thomas, 2006), particularly in children and older adults (Faul et al., 2010), likely due to increases in population and increases in falls. However, this increase may also represent increased public awareness of TBI. TBI-related deaths decreased as much as 8.2% over time (Coronado et al., 2011; Faul et al., 2010; Langlois et al., 2006), potentially related to increased preventive measures such as seat belt and helmet use (Braver, Ferguson, Greene, & Lund, 1997; Thompson, Rivara, & Thompson, 1989) and better overall treatment for severe TBI (Faul, Wald, Rutland-Brown, Sullivent, & Sattin, 2007).

Incidence of new-onset disability from TBI has been estimated to be 80,000 to 90,000 new cases each year (Thurman, Alverson, Dunn, Guerrero, & Sniezek, 1999) and more than a million Americans live with disability due to TBI (Thurman, 1999). A more recent projected estimate indicated that incidence of new onset disability may actually be higher, at the rate of more than 124,626 new cases per year, or 43.3% of all hospitalized TBI survivors (Selassie et al., 2008).

Regarding severity, CDC estimates from the year 2000 documented that, of patients hospitalized due to TBI, more than 50% had mild injuries, 21% had moderate injuries, and 19% had severe injuries (Thurman & Guerrero, 1999). Other estimates indicate that mild TBI makes up 75% of the TBIs in the United States each year (National Center for Injury Prevention and Control, 2003). The actual incidence of mild TBI in the United States is difficult to determine because many individuals with mild TBI do not seek treatment or are not hospitalized for their injuries. Further, CDC estimates of TBI incidence are limited because they do not include individuals treated in outpatient settings or who do not present for treatment at all (Coronado et al., 2011) with estimates that up to one-fourth of all persons who sustain a TBI do not seek medical care (Sosin, Sniezek, & Thurman, 1996). Further, incidence varies widely across studies from 92 cases per 100,000 persons (Thurman & Guerrero, 1999) to 618 per

100,000 (Sosin et al., 1996) most likely due to methodological differences such as populations sampled and case definitions of TBI used. Additionally, the most recent CDC data do not include military personnel who sustained a TBI abroad or who received care for TBI in federal, military, or Veterans Administration hospitals (Faul et al., 2010).

The leading causes of TBI in the U.S. civilian population are falls (35.2%), followed by motor-vehicle-related injuries (17.3%), a strike or blow to the head from or against objects (16.5%), assaults (10%), and other or unknown causes (21%) (Faul et al., 2010). Fall-related TBIs are greatest at the extremes of the life span (i.e., children less than 4 and adults over 75 years), and motor-vehicle-related injuries are the leading cause of TBIs in late adolescence (ages 15–19) and early adulthood (ages 20–24). Assault-related TBIs are also highly represented in the 20–24 year age group (Faul et al., 2010; Rutland-Brown, Langlois, Thomas, & Xi, 2006).

Risk factors for TBI vary greatly, with some specific groups at higher risk than others. Age is a risk factor, with children under 4, adolescents between the ages of 15 and 19, and adults over 65 years of age showing the highest rates of brain injury (Faul et al., 2010). A disproportionate number of elderly individuals sustained brain injuries as a result of falls and there is evidence that elderly individuals are at risk for worse outcome from TBI than younger individuals (Howard, Gross, Dacey, & Winn, 1989; Rothweiler, Temkin, & Dikmen, 1998). Additionally, probability of TBI-related long-term disability has been shown to increase with age (Selassie et al., 2008). Sex also represents a risk factor for TBI, with males accounting for approximately 59% of all TBI cases in the United States (Faul et al., 2010). Probability of long-term disability following TBI is significantly higher for females (49.5% compared to 39.9%) (Selassie et al., 2008), whereas death rates from TBI are three times higher among males (Coronado et al., 2011). Alcohol use and intoxication have long been documented as risk factors for TBI, with 23% to 56% of individuals sustaining TBIs documented as intoxicated at injury (Cherner, Temkin, Machamer, & Dikmen, 2001; Dikmen, Machamer, Donovan, Winn, & Temkin, 1995; Parry-Jones, Vaughan, & Miles Cox, 2006). Further, a preinjury history of alcohol and substance abuse has been shown to increase risk for TBI and negative outcome across a variety of domains (Corrigan, 1995; Corrigan, Bogner, & Holloman, 2012; Graham & Cardon, 2008; Parry-Jones et al., 2006; Taylor, Kreutzer, Demm, & Meade, 2003). Prior brain injury poses a separate risk for TBI (Salcido & Costich, 1992; Saunders et al., 2009), with the risk of a second TBI for those with past injuries being approximately three times that of the general noninjured population. Rates for a third injury given two prior injuries increase even further (Annegers, Grabow, Kurland, & Laws, 1980). A recent study found that 20% of patients in the TBI Model Systems database had a prior TBI, with 80% of these prior injuries being the mild range and 40% occurring prior to the age of 16 (Corrigan et al., 2013). Finally, there is evidence that lower socioeconomic status and

inclusion in a minority racial/ethnic group may increase risk for TBI and poorer overall psychosocial and functional outcome following TBI (Arango-Lasprilla et al., 2011; Arango-Lasprilla & Kreutzer, 2010; Cooper et al., 1983; Kraus, Fife, Ramstein, Conroy, & Cox, 1986; Langlois et al., 2006; Sosin et al., 1996; Whitman, Coonley-Hoganson, & Desai, 1984; Williams, Arango-Lasprilla, & Stevens, 2009).

### **Classification of TBI Severity**

Initial presentation of TBI varies greatly across patients and has significant implications for ultimate outcome. Thus, classification of injury severity has become one of the most important predictors for immediate and long-term outcome. Severity of TBI can be measured in a variety of ways, but is generally determined by depth of coma, duration of coma or unconsciousness, and duration of acute confusion following injury.

The most commonly used index of injury severity is the Glasgow Coma Scale (GCS; see Teasdale & Jennett, 1974), which measures depth of coma by determining a patient's responsiveness level in eye opening, motor movement, and verbal communication. Scores range from 3 to 15, with higher scores indicating more intact functioning. Patients with postresuscitation GCS scores of 3 to 8 are classified as having had severe TBI and those with scores from 9 to 12 are classified as having had moderate injuries (Clifton, Hayes, Levin, Michel, & Choi, 1992; Hannay & Sherer, 1996; Levin & Eisenberg, 1991). Some researchers further divide the severe group into severe (GCS 6 to 8) and very severe (GCS 3 to 5) (Zhang, Jiang, Zhong, Yu, & Zhu, 2001). Patients with GCS scores between 13 and 15 are classified as having had mild injuries. Outcomes of these patients can differ drastically depending on the presence or absence of findings on the initial neuroimaging and, thus, they are often subdivided into complicated and uncomplicated mild TBI. Patients with GCS scores between 13 and 15 with no intracranial abnormalities on neuroimaging (uncomplicated mild TBI) typically have very favorable outcomes with resolution of clinical symptoms within three months (Belanger, Curtiss, Demery, Lebowitz, & Vanderploeg, 2005; Belanger, Spiegel, & Vanderploeg, 2010; Dikmen, Machamer, Powell, & Temkin, 2003; Rohling et al., 2011; Schretlen & Shapiro, 2003; Williams, Levin, & Eisenberg, 1990). In contrast, patients with initial GCS scores between 13 and 15 who also demonstrate depressed skull fractures or other intracranial abnormalities (complicated mild TBI) have outcomes more similar to patients with moderate TBI (Dikmen et al., 2003; Kashluba, Hanks, Casey, & Millis, 2008; Williams et al., 1990). See Table 17.1 for the association between GCS scores and injury severity.

The advantages of using GCS scores to classify injury severity are that these scores can be determined in the first 24 hours and are predictive of early important outcomes, such as survival (Wardlaw, Easton, & Statham, 2002), and later

functional outcomes, such as employment (Dikmen et al., 1994). However, there is disagreement about which time point GCS should be collected (Marion & Carlier, 1994). Many use GCS scores obtained immediately postresuscitation or at admission to the ED for classification of TBI severity, whereas others suggest that the best or worst GCS within the first 24 hours of injury are better options. GCS scores at early time points may underestimate severity for patients whose responsiveness deteriorates due to intracranial hematomas or other complications within the first 24 hours. In contrast, GCS taken at early time points may overestimate severity level for patients who are under the influence of alcohol or other substances at the time of injury. GCS scores may also be affected by early management such as intubation or sedating and paralyzing medications, and the use of GCS scores is limited in patients with aphasia or facial injuries that limit eye opening or verbalization.

A recent study by Barker and colleagues (2014) examined the impact of changes in emergency management from 1987 to 2012 on the relationship between GCS scores and functional outcome, and found that the predictive utility of GCS did not decline over time. Rates of intubation did not change over time, whereas the use of chemical paralytics or heavy sedatives increased. Paralyzed and sedated patients performed slightly better on average than those with severe TBI, raising the possibility that the paralyzed group may contain people with less-severe brain injuries. Thus, caution should be taken when interpreting studies that classify all medically sedated patients as having severe TBI.

Injury severity can also be determined by the length of time it takes an individual to return to a conscious or responsive state, which is most often indicated by the ability to follow simple commands, indicate yes/no responses reliably through words or gestures, give intelligible verbalizations, or other purposeful behaviors (Giacino et al., 2002). Studies typically use time to follow commands as the indicator for when a patient has returned to a conscious state, but others have specifically used spontaneous eye opening (Ariza et al., 2004; Eisenberg & Weiner, 1987) or withdrawal from a painful stimulus (Levin, 1995; Whyte, Cifu, Dikmen, &

Temkin, 2001). Thus, it is important to specifically determine the criteria used for duration of unconsciousness before comparing results across studies. The interval from injury to recovery of ability to follow commands, corresponding to a GCS motor score of 6, has proven to be a more useful index in determining injury severity when compared to the interval between injury and time to motor localization (GCS motor score of 5) (Whyte et al., 2001). Some authors substitute the term *duration of unconsciousness*, *coma duration*, or *length of coma* for this variable. A classification scheme for this index reported by Lezak and colleagues (Lezak, 1995; Lezak, Howieson, Loring, Hannay, & Fischer, 2004) classified an interval of < 20 minutes coma duration as a mild injury, an interval of < six hours as a moderate injury, and > six hours as a severe injury. (See Table 17.1); however, it should be noted that across studies authors tend to use different cut points for this variable when assigning severity levels. Importantly, time to follow commands has been shown to be predictive of global outcome, neuropsychological functioning, personal independence, and employment outcome after TBI (Dikmen & Machamer, 1995; Dikmen, McLean, Temkin, & Wyler, 1986; Dikmen et al., 1994; Dikmen, Ross, Machamer, & Temkin, 1995).

Advantages of using time to follow commands for determining injury severity are that this index takes into account early complications and can be obtained during relatively early stages of recovery. However, this interval can be affected by early sedation and the patient must be closely monitored for an extended period of time. This index is also limited by difficult to interpret behaviors and fluctuations in patient's mental status. Further, this index is not immediately available for early prediction of outcome, there is no commonly agreed upon classification scheme, and it is often not available to later treating clinicians because of lack of availability of initial medical records.

The duration of posttraumatic amnesia (PTA) has also commonly been used to classify TBI severity. PTA refers to the phase of recovery following TBI during which the patient is responsive, but acutely confused, disoriented and unable to form and retain new memories (Russell, 1932; Symonds,

Table 17.1 Comparison of different methods of injury severity classification

Injury Severity	Classification Method			
	Glasgow Coma Scale (GCS) <sup>1</sup>	Time to Follow Commands <sup>2</sup>	Posttraumatic Amnesia (PTA) <sup>3</sup>	Mississippi PTA Classification Scheme <sup>4</sup>
Mild	13–15	< 20 minutes	< 1 hour	
Moderate	9–12	< 6 hours	1 to 24 hours	0–14 days
Moderate Severe				15–28 days
Severe	6–8	> 6 hours	1–7 days	29–70 days
Very Severe	3–5		> 7 days	> 70 days

<sup>1</sup>(Clifton et al., 1992; Hannay & Sherer, 1996; Levin & Eisenberg, 1991)

<sup>2</sup>(Lezak, 1995; Lezak et al., 2004)

<sup>3</sup>(Russell & Smith, 1961)

<sup>4</sup>(Nakase-Richardson et al., 2009; Nakase-Richardson et al., 2011)

1937). Duration of PTA can be assessed retrospectively by waiting until the patient is no longer confused and asking him or her to report the first memory that he or she can recall following brain injury (Symonds & Russell, 1943). More commonly, duration of PTA is determined prospectively by serial assessment of the patient's degree of disorientation using measures such as the Galveston Orientation and Amnesia Scale (GOAT) (Levin, O'Donnell, & Grossman, 1979), the Orientation Log (Jackson, Novack, & Dowler, 1998), the Oxford Scale (Fortuny, Briggs, Newcombe, Ratcliff, & Thomas, 1980), and the Westmead Scale (Shores, Marosszeky, Sandanam, & Batchelor, 1986).

While disorientation and memory disturbance are hallmarks of this phase of recovery, recent researchers have noted the similarity of this state to delirium and have recommended use of the term Posttraumatic Confusional State (PTCS) (Nakase-Thompson, Sherer, Yablon, Nick, & Trzepacz, 2004; Sherer, Nakase-Thompson, Yablon, & Gontkovsky, 2005; Stuss et al., 1999). As with time to follow commands, the usefulness of duration of PTA as an index of TBI severity is limited by the lack of commonly agreed-upon criteria for intervals indicating severe, moderate, and mild injuries. One of the most commonly used criteria, developed by Russell and Smith (1961), classifies patients with PTA < one hour as having had slight concussion, patients with PTA of one to 24 hours as having had moderate concussion, patients with PTA of one to seven days as having had severe concussion, and patients with PTA of greater than seven days as having had very severe concussion (see Table 17.1). Numerous studies have shown that duration of PTA is predictive of various aspects of outcome after TBI including neuropsychological outcome, independent living status, and return to work (Dikmen et al., 1994; Ellenberg, Levin, & Saydjari, 1996; Sherer et al., 2002). However, this measure is limited in that it may not be available for an extended period of time following injury; requires close monitoring of the patient over time; and is affected by fluctuations in behavior, aphasia, intubation, and other issues preventing effective communication.

It is not uncommon for patients in rehabilitation settings to have PTA durations well beyond one week postinjury. Thus, PTA as a classification system reaches ceiling levels for patients at the more severe end of the severity spectrum, resulting in decreased prognostic value for this index as defined by Russell and Smith (1961). Newer classification systems for PTA duration have been proposed, demonstrating that PTA durations of four and eight weeks are better threshold points for predicting functional outcome (Walker et al., 2010). Likewise, a new Mississippi PTA classification scheme examined and validated by Nakase-Richardson and colleagues (Nakase-Richardson et al., 2009; Nakase-Richardson et al., 2011) shows improved prediction of later outcome compared with the original Russell classification system.

There are clear pros and cons of using each of these indices to determine injury severity. Further complicating the issue is

that classification using these indices independently does not always correspond to the same injury severity level within a given patient. Thus, a given patient's injury can be assigned different severity levels depending on which of these indices is considered. To illustrate this point, Sherer, Struchen, Nakase-Thompson, and Yablon (2005) compared these three indices of TBI severity in a sample of 259 consecutive admissions to an acute rehabilitation setting and found significant discrepancies in classification depending on which index was used. When GCS scores were used, 63% of patients were classified as severe, 19% of patients were classified as moderate, and 18% of patients were classified as mild. Of note, 88% of "mild" patients had pathology on initial CT. Using GCS as the standard, the time to follow commands criteria reported by Lezak and colleagues (Lezak, 1995; Lezak et al., 2004) misclassified as severe 84% of patients with a moderate level of injury and 72% of patients with a mild level of injury. Russell and Smith's PTA criteria (1961) misclassified as severe 100% of patients with a moderate level of injury and 87% of patients with a mild level of injury. Thus, studies using a combination of these indices to assign subjects to severity levels should be interpreted with caution. Additional caution should be taken when relying on a patient's self-report of duration of coma and PTA to estimate severity of injury, given recent findings that individuals with a history of TBI consistently overestimate coma duration by approximately ten days (Sherer Sander, Maestas, Pastorek, Nick & Li, 2015).

### Neuroanatomical Findings Following TBI

Although the circumstances under which the brain can be injured are diverse, two principal mechanisms have been described. First, contact injuries occur either when an object strikes the head or when the brain comes into contact with the skull. Second, acceleration/deceleration injuries result from unrestricted movement of the head resulting in shear, tensile, and compressive strain on brain tissues (Gennarelli & Graham, 2005). Similarly, categorization of injury can be described as focal, affecting a circumscribed region(s) of the brain, or diffuse, affecting the brain in a widespread pattern (Graham, Gennarelli, & McIntosh, 2002).

Mechanism of injury determines to a large extent the nature of the resulting pathology to the brain. That is, the pathology resulting from a contact injury tends to be focal in nature and may include injury to the scalp, skull fracture, surface contusions, and associated intracerebral hematomas. Pathology resulting from acceleration/deceleration injuries often includes tearing of bridging veins, subdural hematomas, diffuse axonal injury, and diffuse vascular injury (Gennarelli & Graham, 2005). In addition to the primary brain changes that occur as a direct result of the injury itself, secondary or delayed complications can also occur, leading to further neuropathologic damage. Secondary factors can include swelling/edema, hypoxia/ischemia, raised intracranial pressure, associated vascular changes, meningitis,

and abscess (Gennarelli & Graham, 2005). Secondary factors—particularly raised intracranial pressure, hypoxia, and hypotensive events—have been found to be predictive of later outcome (Andrews et al., 2002; Jiang, Gao, Li, Yu, & Zhu, 2002; King, Carlier, & Marion, 2005).

Lesions of the scalp, skull, and dura provide a clue to the site and nature of the injury. For instance, bruising at the back of the head is often associated with severe frontal contusions as a result of coup contra coup injuries (Gennarelli & Graham, 2005). Whereas the presence of a skull fracture does not necessarily indicate underlying brain damage (Williams et al., 1990), the absence of skull fracture does not mean that the brain has not been injured. In fact 20% of fatal cases do not have skull fracture (Jennett & Teasdale, 1981). There is a strong association, however, between the presence of a skull fracture and development of an intracranial hematoma (Mendelow et al., 1983).

Contusions have been considered the hallmark of brain damage following TBI, with a characteristic distribution involving the frontal and temporal poles, the lateral and inferior aspects of the frontal and temporal lobes, and less commonly the inferior aspects of the cerebellum (Adams, Graham, Scott, Parker, & Doyle, 1980; Gennarelli & Graham, 2005; Holbourn, 1943; Levin, Amparo, et al., 1987; Levin, Williams, Eisenberg, High, & Guinto, 1992). This pattern of findings is most likely due to friction caused between the brain and the bony ridges on the surface of the skull in these areas (Ommaya & Gennarelli, 1974). These parenchymal contusions often result in focal signs and symptoms and have been blamed in some studies for the frontal executive behavioral deficits following TBI (Levin, Amparo, et al., 1987; Levin et al., 1993). However, other studies have found no differences in neuropsychological functioning between groups of TBI patients with and without lesions confined to the frontal lobes on tests of executive functioning (Anderson, Bigler, & Blatter, 1995).

Intracranial hematomas are commonly seen following TBI and are the most common cause of serious clinical deterioration in patients who initially present well (Reilly, Graham, Adams, & Jennett, 1975; Rockswold, Leonard, & Nagib, 1987). Subarachnoid hemorrhage is frequent in moderate to severe TBI and typically occurs in conjunction with surface contusions. When present, subarachnoid hemorrhage is related to worse outcome at time of discharge from acute hospitalization and worse neuropsychological and vocational outcome at one year postinjury (Hanlon, Demery, Kuczen, & Kelly, 2005). An epidural hematoma consists of a convex-shaped collection of clotted blood between the skull and the dura. Most commonly, this type of hematoma results from temporal bone fracture and tearing of the middle meningeal artery, but it can also occur in relation to the frontal or parietal aspects of the brain. Because the source of bleeding is arterial, the hematoma develops rapidly, causing mass effect. If they are not treated quickly, epidural hematomas can be life-threatening, but in

many cases there is little associated underlying brain damage (Gennarelli & Graham, 2005).

Subdural hematoma (SDH) results from rupture to bridging veins between the upper surface of the brain to the sagittal sinus (Gennarelli & Thibault, 1982). Because this blood can spread freely throughout the subdural space, SDHs tend to cover a large area and often appear crescent-shaped on neuroimaging. SDHs are often large enough to act as significant mass lesions and have been reported in between 26% to 63% of blunt head injuries (Freytag, 1963; Maloney & Whatmore, 1969). The incidence of SDH may be higher in patients sustaining fall injuries than other types of injuries (Gennarelli & Thibault, 1982). While in a small percentage of cases (8%–13%) these hematomas are not associated with other brain damage, most are associated with considerable brain damage, resulting in relatively greater mortality and morbidity compared with epidural hematomas (Gennarelli & Graham, 2005). Although early reports describe overall mortality rates from acute subdural hematomas ranging from 40% to 90%, with poor outcomes observed in all age groups, more recent studies indicate mortality rates are more than four times higher in older patients than in younger ones (74% vs. 18%) despite similar treatment (Howard et al., 1989). SDH may take longer to cause a marked decrease in level of consciousness in older adults as compared to younger adults due to a greater amount of cortical atrophy and slower time to midline shift, thus initial GCS may be a less-sensitive indicator in older adults (Rothweiler et al., 1998).

In acceleration/deceleration injuries, the brain is at particular risk for diffuse axonal injury (DAI) (Gennarelli, 1983; Gennarelli & Graham, 2005). DAI refers to a number of pathologies including hemorrhages and tissue tears seen throughout the brain. The cerebral commissures and other white matter tracts of the brain stem are vulnerable to stretching and shearing as a result of mechanical forces (Gennarelli, 1983). The extent of DAI may be the principal pathological substrate responsible for the range of neurological deficit from mild to severe brain injury (Gennarelli et al., 1982). For instance, DAI was determined to be the cause of death in a group of individuals with fatal TBI without associated intracranial mass lesion (Gennarelli, 1983). Evidence from animal models suggests that extensive DAI in the brain stem may play a contributory role in posttraumatic coma (Gennarelli, 1994). Further, clusters of microglia have been found even in patients with mild brain injury who died of unrelated causes (Oppenheimer, 1968).

DAI is generally not readily apparent on traditional MRI scans but can be seen microscopically with the histological appearance depending on the length of survival after injury. Diffusion tensor imaging (DTI), which allows visualization of disruptions in white matter pathways, has been proposed to indicate DAI in acute recovery from mild TBI (Arfanakis et al., 2002; Inglese et al., 2005; Wilde et al., 2008; Yal-lampalli et al., 2013). Although some studies demonstrate relationships between abnormal DTI findings and severity

of postconcussion symptoms and cognitive functioning in acute mild TBI (Wilde et al., 2008; Yallampalli et al., 2013), other studies have not replicated these findings (Lange, Iversen, Brubacher, Madler, & Heran, 2012; Waljas et al., 2014). DTI abnormalities have also been proposed as a marker for chronic white matter changes years after injury in individuals with moderate to severe TBI (Kennedy et al., 2009; Kraus et al., 2007; Wilde et al., 2006) with abnormal DTI findings showing relationships with impaired cognitive functioning (Kraus et al., 2007). White matter changes seen on DTI in chronic TBI samples may represent multiple injury processes including direct primary mechanisms such as DAI shearing, hemorrhages, and contusions; secondary mechanisms such as swelling; and tissue atrophy from Wallerian degeneration (Kennedy et al., 2009).

DTI studies to date demonstrate evidence that white matter changes exist on a continuum corresponding to severity of injury with greater white matter abnormality seen in more severe TBI and related to greater cognitive deficits (Kraus et al., 2007). Other studies have shown that DTI shows promise in tracking recovery in patients with severe TBI, with improved DTI indices related to more favorable outcome over time (Sidaros et al., 2008). Although further study is warranted to improve specificity, particularly with mild TBI, this technology is showing promise in detecting DAI and may ultimately become an early prognostic indicator in patients with TBI.

### Course of Recovery from TBI

Individuals who sustain a moderate to severe brain injury typically pass through a series of predictable stages as they recover from injury to the brain. Almost all patients will pass through at least one of the stages described below. See Figure 17.1 for stages of recovery. While progression through these stages is fairly constant, specific stages and length of time spent in each varies significantly from patient to patient.

Impaired consciousness has been described as the hallmark of severe TBI, with coma representing the most extreme end of the spectrum (Levin, 1992; Ommaya & Gennarelli, 1974). Coma is a temporary nonresponsive state in which the patient has closed eyes, follows no instructions, gives no communication, and shows no purposeful movements (Teasdale & Jennett, 1974). Patients with severe injuries are often

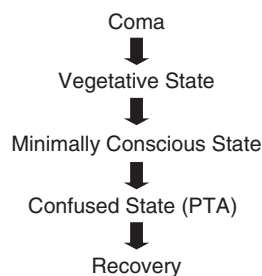

Figure 17.1 Stages of recovery

in coma for some period of time immediately following their injury. While 23%–49% of patients in coma do not recover from this state, those that do survive almost always recover to a more responsive state (Lippert-Gruner, Wedekind, & Klug, 2003; Murray et al., 1999; Zhang et al., 2001).

Following resolution of coma, a small percentage of surviving patients remain in a nonresponsive vegetative state (Lippert-Gruner et al., 2003; Murray et al., 1999), characterized by a complete absence of behavioral evidence for self or environmental awareness. These patients demonstrate recovery of some brain stem functioning and have return of sleep/wake cycles with periods of eye opening. Only a few patients remain in the vegetative state as their ultimate outcome. At three months postinjury, less than 10% of patients are in a vegetative state (Choi & Barnes, 1996; Choi et al., 1994) and by six months, only 4% remain vegetative (Murray et al., 1999). Of those who are vegetative at three months, 50% improve, 25% expire, and 25% remain in a vegetative state so that, by one year postinjury, the incidence of vegetative state ranges from less than 1% (Jiang et al., 2002) to 2% or 3% (Choi & Barnes, 1996; Choi et al., 1994) of severe TBI survivors.

Surviving, nonvegetative patients who go on to recover a limited degree of responsiveness to the environment may be classified as being in a minimally conscious state. Patients in this state show minimal, but definite, evidence of awareness of self or the environment, such as localized motor responses to noxious stimuli or sounds, sustained visual fixation, vocalization in response to a stimulus, smiling or crying in response to a stimulus, and inconsistent command following (Giacino et al., 2002). Resolution of the minimally conscious state is indicated by consistent command following, verbal or gestural yes/no responding, intelligible verbalization, or some other evidence of consistent purposeful behavior such as functional use of objects. This state is generally temporary but may be permanent in a small subset of patients.

In many cases, resolution of coma is followed by a responsive, but markedly confused state (bypassing vegetative and minimally conscious states). Likewise, patients with moderate TBI who have lost consciousness at the time of injury typically evolve directly into a responsive but confused state once consciousness is regained. This confused phase of recovery manifests in a variety of neurobehavioral impairments that were described by early writers (Russell, 1932; Symonds, 1937) as deficits in arousal, memory, orientation, attention, language, behavior, mood, and perception. This stage is generally referred to as PTA, but it has also been referred to as *acute traumatic psychosis*, *after effects of concussion*, *traumatic confusion*, and *delirium*.

The term *posttraumatic amnesia* is reflective of the fact that early investigations of this period of confusion after TBI primarily focused on disorientation and poor memory encoding (Russell, 1932; Symonds, 1937). These authors described PTA as the period of time between onset of injury and return of a patient's orientation and ability to encode

and retain memories from day to day. High, Levin, and Gary (1990) confirmed the high rate of disorientation following TBI and found that orientation after TBI recovers sequentially with initial recovery of orientation to person followed by orientation to place and time. Memory disturbance after head trauma is characterized by some loss of ability to recall events immediately preceding injury (retrograde amnesia) as well as a period of inability to encode and later recall new memories (anterograde amnesia) (Levin, 1992). Complicating the concept of PTA is the presence of islands of intact memory within an otherwise amnesic period, a lucid interval with delayed amnesia, and progressive shrinkage in the temporal extent of retrograde amnesia (Russell, 1971).

While disorientation and memory disturbance are hallmarks of this phase of recovery, recent researchers have noted the similarity of this state to delirium rather than an amnesic state (Nakase-Thompson et al., 2004; Sherer, Nakase-Thompson, et al., 2005; Stuss et al., 1999). Specifically, Stuss and colleagues (1999) argued that attentional disturbance is a key aspect of impaired consciousness after TBI, with recovery of attention happening in an orderly manner prior to resolution of PTA based on GOAT scores. These authors noted the similarity of this state to delirium and proposed the term “posttraumatic confusional state” (PTCS) to replace the more commonly used PTA.

Providing further support of this conceptualization, Nakase-Thompson, Sherer, Yablon, and colleagues (2004) found that 59 (69%) of 85 consecutive TBI patients admitted for inpatient rehabilitation met diagnostic criteria for delirium (American Psychiatric Association, 1994) at some point during their hospitalizations, and the presence of delirium was associated with poorer functional outcome at discharge from inpatient rehabilitation (Nakase-Thompson, Sherer, Yablon, Kennedy, & Nick, 2002). Sherer and colleagues (Sherer, Yablon, & Nick, 2014) found that seven key symptoms characterize the confused state after TBI, including (a) disorientation, (b) impaired cognition, (c) restlessness, (d) fluctuation of symptom presentation, (e) sleep disturbance, (f) decreased daytime level of arousal, and (g) psychotic-type symptoms. PTA (or PTCS) presents in a heterogeneous fashion but has been shown to have a predictable pattern of symptom resolution, such that psychotic-type symptoms, decreased daytime arousal, and nighttime sleep disturbance resolve the earliest and fluctuation and cognitive impairment remain the most persistent (Sherer, Yablon, & Nakase-Richardson, 2009). Sherer, Yablon, Nakase-Richardson, and Nick (2008) showed that presence of psychotic-type symptoms (e.g., hallucinations or delusions) during inpatient rehabilitation was associated with poorer long-term outcome, even though all patients showed resolution of these symptoms and none showed new onset of a persistent psychotic disorder. In a follow-up study, shorter time postinjury, more severe cognitive impairment, and presence of sleep disturbance were associated with a greater likelihood for psychotic-type symptoms with the presence of psychotic-type symptoms early in

recovery from TBI serving as a negative prognostic indicator (Sherer, Yablon, & Nick, 2014).

For some, recovery may be compromised by late (greater than two weeks postinjury) complications such as posttraumatic seizures or posttraumatic hydrocephalus. The incidence of late seizures is lower in survivors of nonpenetrating TBI (4%–7%), compared to survivors of penetrating TBI (up to 50%) (Annegers, Hauser, Coan, & Rocca, 1998; Yablon, 1996). The incidence of posttraumatic hydrocephalus is less well known due to variation in the degree of monitoring for this condition. One prospective series in which all patients with moderate or severe TBI admitted for inpatient rehabilitation received head CT scans found an incidence of hydrocephalus of 13% (Yu, Yablon, Ivanhoe, & Boake, 1995).

After resolution of PTA, patients continue to show progressive resolution of physical, cognitive, and behavioral impairments. Impaired performances are consistently seen soon after injury on tests of reasoning, concept formation, cognitive flexibility, and psychomotor speed, and are inconsistently seen on tests of attention, concentration, and incidental memory (Dikmen, Reitan, & Temkin, 1983). Improvement over time appears to be the rule, with general agreement that recovery continues for up to 18–24 months after moderate or severe TBI (Dikmen et al., 1983; Finnanger et al., 2013; Levin, 1995; Tabaddor, Mattis, & Zazula, 1984). There is evidence that some cognitive functions may continue to recover beyond this time frame (Millis et al., 2001; van Zomeren & Deelman, 1978).

Persistent motor impairments, including spasticity, dysphagia (impaired swallowing), dysarthria, balance disturbances, or hemiparesis, may be present in TBI patients with large focal hemispheric lesions or certain subcortical, brain stem, or cerebellar lesions (Bontke, Zasler, & Boake, 1996; Horn & Sherer, 1999). Most patients with moderate or severe TBI, however, show good resolution of motor impairments and (when present) motor impairments are less likely than cognitive and emotional impairments to interfere with return to independent functioning and productive activity (Brooks, McKinlay, Symington, Beattie, & Campsie, 1987).

When considering very long-term outcome, the link between moderate to severe TBI and risk for dementia later in life has been repeatedly established (Fleminger, Oliver, Lovestone, Rabe-Hesketh, & Giora, 2003; Guo et al., 2000; Jellinger, Paulus, Wrocklage, & Litvan, 2001; Lee et al., 2013; Lye & Shores, 2000; Mortimer et al., 1991; Plassman et al., 2000; Rasmusson, Brandt, Martin, & Folstein, 1995; Salib & Hillier, 1997; Schofield et al., 1997; Starkstein & Jorge, 2005; van Duijn et al., 1992; Wang et al., 2012). Systematic reviews (Bazarian, Cernak, Noble-Haeusslein, Potolicchio, & Temkin, 2009; Institute of Medicine, 2009) conclude an increased risk of dementia in individuals with a previous history of at least one moderate to severe TBI compared to those with no TBI history. Some studies provide evidence that history of TBI accelerates dementia onset by a few years (Gedye, Beattie, Tuokko, Horton, & Korsarek, 1989; Nemetz et al.,

1999; Schofield et al., 1997) and that risk for developing dementia increases with increasing severity of TBI (Guo et al., 2000; Plassman et al., 2000). Explanations for the risk of dementia following TBI focus on a presumed neuropathological trigger at the time of injury that persists and evolves over time, ultimately resulting in progression to dementia. Both human studies and animal models have convincingly demonstrated that multiple proteins associated with neurodegenerative disorders accumulate as a result of TBI (Uryu et al., 2007) particularly within axons damaged by trauma (Johnson, Stewart, & Smith, 2010).

### **Neuropsychological and Neurobehavioral Functioning After Moderate and Severe TBI**

The magnitude and pattern of cognitive and neurobehavioral impairments resulting from moderate and severe TBI vary widely across patients. This heterogeneity in outcome is caused by many factors, including patient variables such as premorbid level of functioning, type and severity of injury, and representativeness of the sample being studied. Risk for persistent cognitive impairment is related to initial injury severity as indicated by postresuscitation GCS score or time to follow commands, with more significant cognitive impairment seen in those with the most severe initial injuries (Dikmen & Machamer, 1995; Tabaddor et al., 1984). Furthermore, the extent and pattern of cognitive impairment depends to a great extent on severity of injury and timing of the assessment relative to injury, with recovery seen across almost all areas of cognitive functioning (Dikmen et al., 1983; Finnanger et al., 2013; Millis et al., 2001).

At one month postinjury, Dikmen and colleagues (1986) found that brain injury resulted in deficits on almost all measures of neuropsychological functioning included in a comprehensive battery of tests when compared to a matched control group. Specifically, these authors found that the degree of neuropsychologic impairment depended on the severity of head injury, with those with the most severe injuries showing impairments on most measures including motor speed, attention, cognitive flexibility, processing speed, memory, and reasoning skills. Impairments in less severely injured groups (time to follow commands between one and 24 hours) were more selective, occurring most frequently on tests of memory, cognitive flexibility, and psychomotor speed.

Lasting cognitive impairment is not uncommon in patients with moderate to severe TBI, with those with the most severe injuries demonstrating the widest range of cognitive impairment. At one year postinjury, all patients with very severe TBI (time to follow commands > 14 days) have residual cognitive impairments, while more than one half of those with time to follow commands between one hour and 13 days have residual deficits (Dikmen & Machamer, 1995). This pattern remains in more recent studies,

showing executive functioning deficits in patients with moderate and severe TBI, whereas patients with severe TBI demonstrated a much broader range of cognitive deficits in areas of motor function, processing speed, and memory (Finnanger et al., 2013).

Improvement is the general rule, with evidence of improved cognitive functioning from three to 12 months across multiple cognitive domains for both moderate and severe TBI (Finnanger et al., 2013). Continuing improvements are seen for 12–24 months postinjury (Dikmen, Machamer, Temkin, & McLean, 1990; Dikmen et al., 1983; Tabaddor et al., 1984). Tasks requiring more complex functions, such as problem solving and complex attention, appear to recover more slowly than tests with more simple cognitive demands (Dikmen et al., 1983). Although a subgroup of patients shows improvement beyond the typically reported 18–24 month follow-up (Millis et al., 2001), there is limited evidence that another subgroup of patients may show late decline (Millis et al., 2001; Ruff et al., 1991). Age at time of injury appears to be a risk factor for late decline, with older age at time of injury indicating greater risk for late decline.

Overall, the typical pattern of impairments after blunt head trauma includes slowed fine motor movements, decreased attention, decreased cognitive speed, memory impairment, impaired complex language skills and discourse, and impaired executive functions. Severe persistent aphasia or visual perceptual impairment are uncommon after diffuse injuries but may occur in patients with focal injuries (Levin, 1993). Tate and colleagues (1991) followed a consecutive series of 100 patients with severe blunt head injuries for up to six years after trauma to examine potential patterns of cognitive impairment. Principal component analyses were applied to 85 of these patients to examine the incidence of impairment in specific neuropsychological domains, including classical neuropsychological syndromes, learning and memory, rate of information processing, and personality change. Seventy percent of patients showed cognitive impairment, and isolated cognitive findings were common. Although no single functional area was consistently impaired, the most frequent area of impairment was learning and memory, occurring in 56.5% of patients. When premorbid functioning is accounted for using tests of reading recognition, patients with TBI show the greatest decline in performance on tests of information processing speed and cognitive flexibility, followed by less significant declines on tests of immediate and delayed memory. Overall intellectual level is only minimally affected (Johnstone, Hexum, & Ashkanazi, 1995).

Although discrete cognitive findings may be seen in patients with focal injuries, these are generally superimposed on global cognitive dysfunction resulting from diffuse injury. While there is great variability in the pattern of cognitive dysfunction in individual patients with moderate to severe TBI, the most commonly affected areas of cognition include attention, memory, language and communication, and executive functioning.

### **Attention**

Impaired attentional processes and information processing speed are prevalent after TBI across all levels of injury severity. Specifically, patients with TBI consistently demonstrate impairments on tests of simple and choice reaction-time, color naming and word reading, symbol digit coding, and divided attention (Finnanger et al., 2013; Ponsford & Kinsella, 1992; Stuss, Stethem, Hugenholtz, et al., 1989; Stuss, Stethem, Picton, Leech, & Pelchat, 1989). Even patients with supposed good recovery continue to show impairments on tests of complex attention and higher level reasoning skills (Stuss et al., 1985). While many studies have described a primary deficit in attention, others have suggested that deficits in information processing speed underlie these attentional impairments (Ponsford & Kinsella, 1992).

### **Memory**

Memory dysfunction is also common after TBI, even in postacute phases, with a dose–response relationship such that greater impairments in memory are seen with increasing levels of injury severity (Carlozzi, Grech, & Tulsky, 2013). In patients with moderate to severe TBI, dysfunction in memory often persists even after normalization of other areas of cognition (Ruff et al., 1991). Investigators report that memory problems occur across different aspects of memory processing including encoding, consolidation, and retrieval (Curtiss, Vanderploeg, Spencer, & Salazar, 2001; Wright & Schmitter-Edgecombe, 2011) while others suggest that patients with TBI have specific problems in the consolidation of newly learned information leading to poor recall of information over time (Vanderploeg, Crowell, & Curtiss, 2001; Vanderploeg, Donnell, Belanger, & Curtiss, 2014). While memory performance tends to improve in most TBI patients over time (Finnanger et al., 2013), a select group fails to show improvement or may even show decline. It has been speculated that the presence of injury-related factors such as hypoxia may contribute to a failure for performance to improve over time, and patient-related factors such as depression may contribute to declines in performance (Ruff et al., 1991). Further research is needed to better understand this observed heterogeneity of performance on memory measures and to determine if distinct memory problems characterize subgroups of patients. Specific deficits have also been noted on tasks of prospective memory, or the ability to remember one's future intentions (Huang et al., 2014; Kinsella et al., 1996; Mathias & Mansfield, 2005), episodic and autobiographical memory (Rasmussen & Berntsen, 2014), and meta-memory or the awareness of memory efficiency (Kennedy & Yorkston, 2000).

### **Language and communication**

Although persisting classic aphasia syndromes are rare following TBI, impairments in language are common, including

deficits in naming, verbal fluency, and comprehension of complex commands (Levin, Grossman, & Kelly, 1976; Sarno, Buonaguro, & Levita, 1986). Traditional neuropsychological tests may be insensitive to language and communication problems observed in patients with TBI, especially at post-acute stages. For instance, studies of naturalistic language have shown that patients with TBI demonstrate less productive speech, convey less content with longer utterances, and have generally more fragmented language than their peers (Hartley & Jensen, 1991). Difficulties in pragmatic language have also been reported in patients with TBI, including problems initiating and maintaining a conversation and interpreting indirect communication (Snow & Douglas, 2000). Similarly, deficits in social cognition (emotion recognition, theory of mind, empathy) have been specifically reported following TBI (Spikman, Timmerman, Milders, Veenstra, & van der Naalt, 2012). These problems in language functioning and social cognition likely contribute to impairments in psychosocial functioning.

### **Executive function**

Executive dysfunction is common following TBI and may be one of the critical cognitive determinants of independent functioning and return to occupational functioning (Creppeau & Scherzer, 1993; Finnanger et al., 2013; Hart et al., 2003; Sherer, Nick, Millis, & Novack, 2003). Patients with moderate to severe TBI show a wide range of executive function deficits, with reported impairments on tests of verbal and design fluency (Millis et al., 2001; Ruff, Evans, & Marshall, 1986), conceptual reasoning/flexibility (Millis et al., 2001; Sherer, Nick, Millis, et al., 2003; Stuss et al., 1985), working memory (Stuss et al., 1985; Stuss, Stethem, Hugenholtz, et al., 1989), response inhibition (Rochat, Beni, Annoni, Vuadens, & Van der Linden, 2013), application of clustering strategies on verbal memory testing (Levin & Goldstein, 1986), time discrimination (Mioni, Stablum, & Cantagallo, 2013), and planning (Leon-Carrion et al., 1998). However, performance on formal neuropsychological tasks may fail to capture the executive-based neurobehavioral deficits seen in social functioning and self-regulation frequently seen in patients with TBI (Levine, Dawson, Boutet, Schwartz, & Stuss, 2000).

Persistent neurobehavioral impairments and impaired psychosocial functioning are common in patients with TBI. Specifically, patients are noted to have increased irritability, headache, anxiety and depression, difficulty concentrating, fatigue, restlessness, and impulsivity/aggression (Bhalerao et al., 2013; O'Dell, Barr, Spanier, & Warnick, 1998; Satz et al., 1998). Patients and family members are more distressed by these neurobehavioral impairments, particularly personality change and threats of violence, than either cognitive or physical impairments (Brooks, Campsie, Symington, Beattie, & McKinlay, 1986; Kaitaro, Koskinen, & Kaipio, 1995; Lezak, 1987, 1988). There is some evidence that family

member report of these symptoms may actually increase with the passage of time (Brooks et al., 1986), but it is unclear whether this is due to an actual increase in behavioral problems or to greater sensitivity to these problems.

Limited awareness of cognitive and psychosocial problems is common after TBI and may play a role in family member stress associated with residual neurobehavioral impairments (Prigatano, Altman, & O'Brien, 1990; Sherer, Boake, et al., 1998). Impaired self-awareness is common after moderate and severe TBI both in the acute (Sherer, Hart, et al., 2003) and the postacute periods (Sherer, Bergloff, et al., 1998; Vanderploeg, Belanger, Duchnick, & Curtiss, 2007). Although self-awareness improves over time, impairments in self-awareness have been shown to persist five years or more following injury (Kelley et al., 2014). Self-awareness of cognitive impairment is related to employability and employment outcomes (Sherer, Bergloff, et al., 1998; Sherer, Hart, et al., 2003), presumably because awareness of cognitive impairments is needed in order for an individual to appreciate the need for and learn compensatory strategies needed to maintain employment (Kelley et al., 2014). Patients with poor self-awareness have poor motivation to change, as they do not perceive the need to change. Some authors have suggested the decreased ability to recognize and acknowledge changes in one's functioning may be related to impaired executive functions and abstract reasoning (Malec & Moessner, 2000). Life satisfaction has been shown to be higher for individuals who *perceive* higher levels of neurological impairment, even when this perception is discrepant from that reported by their significant others (Kelley et al., 2014). In return, there is evidence that distress and symptoms of depression increase with increasing self-awareness (Godfrey, Partridge, Knight, & Bishara, 1993).

### **Neuropsychological Assessment of Patients with Moderate and Severe TBI**

Given the range of cognitive and neurobehavioral impairments resulting from TBI and their impact on functional outcome, psychosocial functioning, and family functioning, neuropsychologists are poised to make significant contributions to the care of persons with moderate and severe TBI. Evaluations of neuropsychological functioning can provide documentation of cognitive, behavioral, and emotional status that may ultimately assist with determination of patients' ability to function independently (Sherer & Novack, 2003). Specifically, neuropsychologists are asked to determine functional abilities, such as decision-making capacity, capacity for safe and independent home functioning, driving capacity, and ability to return to work. Additionally, documentation of neuropsychological functioning is useful to provide feedback to family members, improve patient self-awareness, guide treatment efforts, assess the effectiveness of medication trials, and assist with discharge planning.

The focus of neuropsychological assessment is determined both by the goals of the assessment and the stage of recovery

of the patient. Early neuropsychological assessment may focus on determining level of responsiveness and documenting changes in level of responsiveness in minimally conscious patients. Measures such as the Coma Recovery Scale-Revised (Giacino, Kalmar, & Whyte, 2004) assess arousal and attention, auditory perception, visual perception, motor function, oromotor ability, communication, and initiation, and provide a structured repeatable protocol for assessing low-level patients. With responsive but confused patients, assessment focuses on orientation, attentional skills, ability to form new memories, and level of agitation. Measures such as the GOAT (Levin et al., 1979) or Orientation Log (Jackson et al., 1998) are well suited to assess orientation, while the Toronto Test of Acute Recovery After TBI (Stuss et al., 1999) includes simple measures of attentional skills and the ability to form and retain new memories. The Agitated Behavior Scale (Corrigan, 1989) is the most commonly used measure of agitation after TBI. The Confusion Assessment Protocol (Sherer, Nakase-Thompson, et al., 2005) includes elements of all these areas, and findings indicate that it may be useful in assessing a wide range of symptoms of confusion after TBI.

There is some disagreement about when to first administer traditional neuropsychological tests. Some recommend delaying administration of formal neuropsychological tests until the patient has emerged from PTA (Clifton et al., 1992), due to the assumption that confused, disoriented patients will perform poorly on all tests resulting in limited information regarding profile of cognitive strengths and weaknesses. In contrast, there is evidence that administration of selected neuropsychological measures to patients still in PTA is feasible (Kalmar et al., 2008) and can result in useful data that are predictive of later functional status (Hannay & Sherer, 1996; Pastorek, Hannay, & Contant, 2004). In an attempt to provide some guidance regarding timing of neuropsychological evaluations for patients with TBI, Sherer and Novack (2003) conducted a survey of neuropsychologists who were selected based on board certification, extensive clinical experience with TBI, published research on TBI, and current participation in TBI research. Guidelines for timing of assessments based on this survey were contingent on severity of injury and period of time since injury. For instance, respondents recommended preliminary testing at resolution of PTA for all levels of TBI severity. Early testing between one week and one month postinjury was recommended for patients with mild TBI with repeat assessment at one year. In contrast, respondents recommended that the initial follow up testing not occur until three months for patients with moderate to severe injury, with subsequent repeat assessments as needed at six months, one year, and two years postinjury. Importantly, these guidelines provide general suggestions only, and timing of testing for any specific patient should be determined by clinician judgment based on factors unique to that patient.

Although several different neuropsychological batteries have been used in the literature to assess the cognitive effects of TBI, no specific battery of tests for TBI has been

proposed or widely accepted. However, batteries such as the NIH Toolbox (Weintraub et al., 2013), a computerized battery of cognitive tests designed for longitudinal cognitive assessment, are being used in large-scale longitudinal studies of TBI and may show promise as an effective TBI outcome measure in the future. There is also emerging evidence supporting the use of the Neuropsychological Assessment Battery (NAB) for assessment of cognitive impairment following TBI (Donders & Levitt, 2012). Regardless of battery chosen, neuropsychological evaluations of persons with moderate or severe TBI should assess a wide range of cognitive abilities including orientation, fine motor skills, divided and sustained attention, cognitive speed, learning and memory, language skills, visual-perceptual skills, and executive functions (Hannay & Sherer, 1996). Despite the presence of clear-cut evidence that a patient has sustained a brain injury (i.e., neuroimaging reports, medical documentation of loss of consciousness or coma, and operative reports), some patients may either consciously or unconsciously exaggerate symptoms when seen for follow-up evaluations. This possibility is even stronger for those engaged in litigation or with other secondary gain issues. Consequently, symptom validity measures should be included in assessment batteries when appropriate. Further, comparison of current performance with past neuropsychological reports may be helpful to document expected trajectory of recovery over time. With no other intervening factors, it would be unusual and unexpected for neuropsychological performance to decline significantly over time.

In addition to cognition, neurobehavioral problems such as mental flexibility, planning, unusual thought content, agitation, disinhibition, emotional withdrawal, hostility, depression, anxiety, and motor slowing should also be assessed (McCauley et al., 2001). Such neurobehavioral impairments are frequently assessed with measures such as the Neurobehavioral Rating Scale (Levin, High, et al., 1987) and the Neurobehavioral Functioning Inventory (Kreutzer, Marwitz, Seel, & Serio, 1996).

Functional status is a separate but important factor to consider in a neuropsychological evaluation. Thus, it is often beneficial to assess functional status separately from traditional neuropsychological measures. There are

a number of instruments that can be used to directly rate a given patient's functional status. The Disability Rating Scale (DRS) (Rappaport, Hall, Hopkins, Belleza, & Cope, 1982) was developed to track patient progress after TBI from coma to return to community activities (Gouvier, Blanton, LaPorte, & Nepomuceno, 1987; Rappaport et al., 1982). It has been shown to be sensitive to improvements in functioning between two and six months postinjury, as well as between six months and one year (Hall, Cope, & Rappaport, 1985). The Supervision Rating Scale (SRS) (Boake, 1996) can be used to quantify the level of personal independence. SRS scores are related to patient living arrangement and to skills in activities of daily living. Additionally, assessment of participation in community activities and societal roles is crucial to understanding the long-term impact of TBI. The Community Integration Questionnaire (CIQ) (Willer, Rosenthal, Kreutzer, Gordon, & Rempel, 1993) was developed to assess degree of community integration after TBI across three areas, including home integration, social integration, and productive activity. More recently, items from previously validated measures of participation were combined to create the Participation Assessment with Recombined Tools—Objective (PART-O). The PART-O measures important aspects of participation such as involvement in productive activities, degree of social integration, and community involvement (Bogner, Bellon, Kolakowsky-Hayner, & Whiteneck, 2013; Whiteneck et al., 2011).

### Outcome After Moderate and Severe TBI

Outcome after moderate and severe TBI can be assessed in many ways and at many time points postinjury. Neurosurgical studies generally focus on early survival, with the Glasgow Outcome Scale (GOS; see Jennett & Bond, 1975) being the most commonly used measure of overall outcome after TBI. Table 17.2 presents a breakdown of the five different GOS categories. Table 17.3 provides a summary of global outcome for patients with moderate and severe TBI over time intervals ranging from three months to one year using the GOS as an outcome variable. As expected, global outcome varies significantly depending on the time point examined

Table 17.2 Description of individual categories for the Glasgow Outcome Scale (GOS)

<i>GOS Category</i>	<i>Description</i>
Death	
Vegetative State	Unable to follow commands or communicate.
Severe Disability	Conscious but requiring assistance to meet basic physical and cognitive needs such as feeding, toileting, grooming, or personal safety.
Moderate Disability	Able to meet basic physical and cognitive needs and use public transportation and work in a sheltered workshop, but unable to return to nonsheltered work or resume other major societal roles.
Good Recovery	Able to return to nonsheltered work though perhaps in a decreased capacity and resume social roles, though some neurologic or psychologic impairments may remain.

Table 17.3 Global outcome based on the Glasgow Outcome Scale for TBI Patients with Severe and Moderate Injuries. Numbers represent percentage of TBI patients in each category.

	<i>Severe TBI</i>			<i>Moderate TBI</i>
	3 months postinjury	6 months postinjury	1 year postinjury	6 months postinjury
<b>Death</b>	23%–50% <sup>1,2,3,4,5</sup>			< 10% <sup>3,8</sup>
<b>Vegetative State</b>	< 10% <sup>6,7</sup>	4% <sup>3</sup>	< 1% <sup>5</sup> –3% <sup>6,7</sup>	
<b>Severe Disability</b>	31%–32% <sup>6,7</sup>	22% <sup>3,6,7</sup>	17% <sup>6,7</sup>	0% <sup>8</sup> –14% <sup>3,9</sup>
<b>Moderate Disability</b>	30% <sup>3,6,7</sup>	30% <sup>3,6,7</sup>	17%–22% <sup>4,6</sup>	25% <sup>8,9,10</sup>
<b>Good Recovery</b>	22% <sup>6,7</sup>	35% <sup>3,6</sup>	46%–54% <sup>4,6</sup>	53% <sup>9</sup> –73% <sup>10</sup>

postinjury with a general trend toward better outcome with passing time.

Death is a relatively common outcome for patients sustaining a severe TBI, occurring in approximately 40% of hospitalized patients. Specific death rates range from 23% to 50% (Braakman et al., 1980; Jiang et al., 2002; Marion, 1996; Murray et al., 1999; Zhang et al., 2001). Causes of early death after severe TBI include brain swelling, diffuse axonal injury, increased intracranial pressure, and intracranial hematomas (Graham, Adams, & Gennarelli, 1993; Marion, 1996). In contrast, death is a rare outcome after moderate TBI, occurring in fewer than 10% of cases (Murray et al., 1999; Stein, 1996). When death does occur, it is likely to be due to associated trauma or medical complications (Signorini, Andrews, Jones, Wardlaw, & Miller, 1999).

Factors most predictive of death after TBI are those that directly indicate neurologic and physiologic status early after injury. Such factors include: (a) level of responsiveness as indicated by admission GCS score (Eisenberg & Weiner, 1987; Mosenthal et al., 2002), (b) pupillary responses (Andrews et al., 2002; Jiang et al., 2002; Wardlaw et al., 2002), (c) initial CT scan findings (particularly presence of subarachnoid blood or mass lesion such as subdural hematoma) (Eisenberg & Weiner, 1987; Mataro et al., 2001; Wardlaw et al., 2002), (d) elevated temperature (Andrews et al., 2002; Jiang et al., 2002), (e) electrophysiologic findings (Claassen & Hansen, 2001; Vespa et al., 2002), (f) elevated intracranial pressure (Eisenberg & Weiner, 1987; Jiang et al., 2002), and (g) hypoxia (Andrews et al., 2002; Eisenberg & Weiner, 1987; Jiang et al., 2002). Of demographic variables, age is most predictive of death, with older age being associated with greater risk of death (Jiang et al., 2002; Mosenthal et al., 2002; Susman et al., 2002). Early neurosurgical management also affects death rates. Centers that managed patients aggressively, as indicated by intracranial monitor placement,

had 40% lower mortality rates than centers with less aggressive management (Bulger et al., 2002).

Vegetative state is a rare outcome after severe and moderate TBI, with between 1% and 3% of severe TBI patients remaining in this state at one year and reports of no cases in patients with moderate TBI in large trauma series (Murray et al., 1999). Approximately 31%–32% of surviving patients initially hospitalized with severe TBI were categorized as having Severe Disability (Choi & Barnes, 1996; Choi et al., 1994) at three months postinjury, compared with 30% of patients categorized as having Moderate Disability (Choi & Barnes, 1996; Choi et al., 1994; Murray et al., 1999) and 22% with Good Recovery (Choi & Barnes, 1996; Choi et al., 1994). Percentages of individuals with Severe Disability tend to decrease over time (Choi & Barnes, 1996; Choi et al., 1994; Murray et al., 1999) in conjunction with these patients progressing to higher levels of functioning. Improved functioning for those patients categorized in the Moderate Disability range at three months was masked by the fact that some patients progressed to Good Recovery while patients with Severe Disability improved to the Moderate Disability range. Thus, an overall trend is seen in which patients with severe TBI show gains in general functioning over time, evidenced by increases in the percentage of individuals categorized as having Good Recovery at six months and at one year (Choi et al., 1994; Zhang et al., 2001). However, it is important to note that these patients may remain with significant cognitive or neurobehavioral problems even though they have recovered well enough to return to work.

For patients with moderate TBI, few patients remain in Severe Disability at six months (Murray et al., 1999; Stein, 1996; Williams et al., 1990) and only 25% of patients remained in Moderate Disability at six months postinjury (Jain et al., 2000; Stein, 1996; Williams et al., 1990). Good Recovery is by far the most common outcome for patients

with moderate TBI with 53% (Murray et al., 1999) to 73% (Williams et al., 1990) of cases showing Good Recovery by six months postinjury. As with severe TBI patients, Good Recovery cannot be taken to mean the absence of lasting impairments or functional disability.

The outcome studies discussed so far focus on survival and global disability but do not provide specific information about functional status, such as whether a patient will return to work, community activities, and/or independent living. In fact, it is this functional information that is often of most concern to clinicians, families, and patients, particularly in the inpatient rehabilitation setting where neuropsychologists are most likely to encounter these patients.

Disorders of consciousness (DOC)—including coma, vegetative state, and minimally conscious state—following TBI have gained increasing attention in the literature. While many individuals with DOC recover quickly, others remain with impaired consciousness for prolonged periods or even permanently. A recent large longitudinal study by Nakase-Richardson and colleagues (2012) examined the recovery course of patients who were admitted to acute inpatient rehabilitation with DOC. During inpatient rehabilitation, 68% regained consciousness and 23% emerged from PTA. Outcome was assessed at one, two, and five years postinjury and found that 8% had died within an average of two years after discharge. Of survivors, 21% improved to the point of living without in-house supervision, and 20% improved to the point of having employment potential based on the Disability Rating Scale. Importantly, despite a perception that patients with posttraumatic DOC have a poor prognosis regarding functional outcome, this study demonstrated substantial recovery among patients with DOC relatively early following injury with continuing recovery for two to five years postinjury.

There is a large body of literature examining employment outcomes and prediction of employment in patients with moderate and severe TBI with reported return to work rates ranging from 22% to 66% (Sander, Kreutzer, Rosenthal, Delmonico, & Young, 1996). The wide range of rates is contributed to by interstudy differences in injury classification, populations sampled, time from injury to follow-up, and definition of employment. An early study by Brooks and colleagues (1987) reported on a series of patients with severe TBI seen on an acute neurosurgical service with follow-up evaluations ranging from two to seven years postinjury. The employment rate dropped from 86% before injury to 29% after injury. Younger patients and those with technical/managerial jobs before injury were more likely to return to work than those over 45 years of age or in unskilled occupations. Physical deficits were less related to return to work than was the presence of cognitive, behavioral, and personal changes.

In their seminal study, Dikmen and colleagues (1994) reported on a series of 366 previously employed patients with TBI who were admitted to a trauma center. At one year

postinjury, 26% of patients with severe injuries had returned to work and 56% of patients with moderate injuries had returned to work. By two years postinjury, 37% of patients with severe injuries were working while 64% of patients with moderate injuries were working. Age, education, stability of preinjury work history, and injury severity were all strongly related to the amount of time it took patients to return to work. Specifically, individuals over the age of 50, those with less than high school education, and those with an unstable preinjury work history were less likely to return to work and took longer to go back to work than those in other groups. Further, individuals with milder injuries went back to work more frequently and sooner than those with more severe injuries. Only 8% of those in the most severely injured group (time to follow commands > 29 days) returned to work by two years and those with the best neuropsychological abilities at one month postinjury had the highest return to work rates (96% by one year).

Doctor and colleagues (2005) examined unemployment rates among individuals with TBI one year postinjury after adjusting for risk of unemployment in the general population. This study found that 42% of individuals with TBI were unemployed at one year compared with a 9% expected unemployment rate based on demographically similar persons in the general population. Relative risk for unemployment was higher for males, those with higher levels of education, those with more severe injuries, and those with greater impairment on early neuropsychological and functional status. Specifically, greater risk for unemployment at one year was associated with poor performance on Trailmaking Test Part B, Performance IQ, and the Digit Symbol subtest of the Wechsler Adult Intelligence Scale administered at one month. Those that were unable to complete testing at one month showed the greatest risk of unemployment.

The studies just reviewed focused on consecutive cases seen at trauma centers. In contrast, many other studies of outcome focus on patients recruited from inpatient rehabilitation settings. While both populations are important to study, results from one population cannot necessarily be generalized to the other. Specifically, patients admitted for inpatient rehabilitation may exclude those with very poor outcomes such as vegetative patients or very good outcomes that might preclude them from entering inpatient rehabilitation programs. Such samples may be most representative of patients evaluated by neuropsychologists. One such study conducted by Sherer, Nick, Sander, and colleagues (2003) reported on 1615 patients with TBI who were admitted to 17 TBI Model Systems sites for inpatient rehabilitation. Of this population, 72% were employed at time of injury. Of the 1,083 patients with employment data available at one year, 63% had severe injuries, 16% had moderate injuries, and 20% had complicated mild injuries. The postinjury employment rate for these patients combined was 35%. However, patients available at follow-up had a higher preinjury employment

rate (76%) than those lost to follow-up (68%). Thus, this postinjury employment rate is likely an overestimate.

Independent living outcomes have been studied less often than employment outcome, perhaps because of the greater difficulty in characterizing personal independence compared to employment status. Hart and colleagues (2003) examined predictors of supervision level using a series of 563 patients with TBI who were seen for inpatient rehabilitation. Patients who could not complete a neuropsychological evaluation during inpatient rehabilitation were excluded from study, meaning that patients with more severe injuries might be underrepresented in the study sample. Sixty-nine percent of this sample received no supervision at one-year follow-up, 24% received varying degrees of part-time supervision, and 7% received full-time supervision. Amount of supervision received at follow-up was generally related to initial injury severity as determined by GCS rating, such that individuals with more impaired GCS ratings received more supervision at follow-up. However, initial GCS scores ranged from 3 to 15 for those who were independent as well as for those receiving the highest levels of supervision at follow-up. Furthermore, in an analysis of a subgroup of patients who were able to complete neuropsychological testing, supervision at

one year was predicted by educational level and scores on the Trail Making Test Part B and Digit Span Backward from the Wechsler Memory Scale–Revised.

Factors predictive of functional outcome (return to work and independent living) can be categorized as preinjury factors (preinjury employment status and demographic variables), injury severity variables, cognitive and neurobehavioral impairments, and environmental supports. As time from injury to outcome becomes greater, injury characteristics become less important and other factors such as premorbid functioning and environmental supports become more important. Interpretation of the literature predicting outcome following TBI is complicated by the wide variety of populations sampled, time frames of outcomes, potential predictors selected, and outcomes studied. Factors predictive of a given outcome in a particular population over a specified time frame may not be at all predictive of apparently related outcomes in a different population over a different time frame. This is particularly the case for subpopulations that are highly selected (e.g., patients admitted for postacute rehabilitation services). A review of studies using these variables to predict functional outcome is presented in Table 17.4.

Determination of prognosis for favorable outcomes and potential ability to return to previous activities is a common referral question for neuropsychologists being asked to evaluate an individual with a history of TBI. In a review, Sherer and Novack (2003) reported that results from neuropsychological evaluations are generally predictive of personal safety, independent living, driving safety, and return to work. Neuropsychological testing has been shown to be predictive of later productivity even when controlling for demographic and injury severity variables (Sherer et al., 2002). There is also evidence that a brief battery of neuropsychological tests administered early in the recovery course is predictive of handicap, functional outcome, supervision needs, and employability at one year (Hanks et al., 2008). This battery was able to predict functional outcome at one year above and beyond functional and injury severity variables, providing strong support for the incremental validity of neuropsychological testing in moderate to severe TBI. A recent study found that early evaluation of neuropsychological functioning was predictive of long-term functional disability at one to two years postinjury even after considering demographic variables, injury severity, and CT findings. Both CT findings and neuropsychological evaluations were predictive of return to work at two years (Williams, Rapport, Hanks, Millis, & Greene, 2013). Regarding specific areas of functioning, there is evidence that measures of attention and executive functioning are predictive of independent living and employment status at one year (Finnanger et al., 2013).

While individual factors may be independently related to outcome after TBI, more recent research indicates the importance of considering multifactorial models of outcome. Bush and colleagues (2003) used structural equation modeling to validate a model using premorbid variables, injury severity indices, cognitive abilities, and functional status to predict functional outcome as measured by the CIQ and DRS at one year postinjury, and then cross-validated their findings on a larger national prospectively collected sample. Both samples were followed longitudinally from injury through acute rehabilitation to one year postinjury. Results generally replicated an earlier path analysis study (Novack, Bush, Meythaler, & Canupp, 2001) showing that premorbid characteristics and cognitive and functional status were better predictors of outcome at one year than were injury severity variables. Results further indicated that although injury severity indices had a significant causal impact on functional skills and cognitive status, they did not independently influence one-year outcome. Premorbid status (particularly preinjury employment) had a positive influence on functional skills, cognition, and outcome. Further, both cognitive and functional status strongly influenced outcome. These findings indicate that understanding recovery requires consideration of multiple factors and cannot be achieved by evaluating injury severity alone. Based on these results, Novack and colleagues (2001) assert that interventions to improve outcome after TBI must

continue to focus on rehabilitation of cognitive and functional skills in combination with amelioration of the effects of premorbid factors on postinjury functional and cognitive status.

In closing, this chapter illustrates that mortality and morbidity due to TBI are major public health problems in the United States. Although a large percentage of individuals with moderate and severe TBI have lasting physical, cognitive, and neurobehavioral impairments, the course of recovery, pattern of resulting impairments, and ultimate functional outcome of these individuals is highly variable and dependent on a combination of potential predictive factors that often differ across populations studied. When encountering these patients, the neuropsychologist is challenged with the task of not only evaluating current cognitive and neurobehavioral functioning but also making recommendations regarding expectations of ultimate outcome. Thus, neuropsychologists are well poised to help patients and their families understand and adjust to injury-related cognitive and emotional changes while helping them to make realistic plans for the future. Finally, future research is needed determine which specific rehabilitation and neuropsychological interventions are most beneficial in helping patients with moderate to severe TBI reach their optimal recovery potential.

### Acknowledgments

Completion of this chapter was partially supported by U.S. Department of Education National Institute on Disability and Rehabilitation Research (NIDRR) Grant #H133A120020.

# 18 Concussion and Mild Traumatic Brain Injury

*Heather G. Belanger, David F. Tate, and Rodney D. Vanderploeg*

## Definition of Mild TBI

Mild traumatic brain injury (or mild TBI) is typically defined as disrupted brain functioning from any force to the head as evidenced by altered or lost consciousness that is of shorter duration than more severe TBI. There are somewhat divergent diagnostic criteria, which will be briefly discussed in the next section, that detail the specifics of the duration of the altered state of consciousness. Some diagnostic criteria allow for diagnosis of mild TBI or “possible” mild TBI with the mere presence of symptoms post-event and do not require altered or lost consciousness (Malec et al., 2007; Smits et al., 2007). The term *concussion*, is sometimes used to refer to a milder subcategory of mild TBI (McCrorry et al., 2013), but is more typically used synonymously with mild TBI (and will be in this chapter).

## Pathophysiology of Mild TBI

Mechanical forces cause injury to the brain in two phases: an immediate phase in which damage occurs as a direct result of the mechanical impact, and a later phase of altered biochemical events that may result in delayed tissue damage. While posttraumatic increases in cellular calcium do not inevitably lead to cell death, cell death can occur due to a variety of mechanisms (see Giza & Hovda, 2001) that lead to free-radical overproduction, cytoskeletal reorganization, and activation of apoptotic genetic signals.

Axons in the brain may stretch and twist due to mild TBI. The resulting damage should be considered a “process rather than an event” (Gennarelli & Graham, 1998: 163; see also Gaetz, 2004). Following a head insult in animal models of mild TBI, scattered axons swell slightly and become misaligned, but unlike moderate TBI, there is no altered axolemmal permeability (Pettus, Christman, Giebel, & Povlishock, 1994). Contrary to the widely held “shearing hypothesis,” in which axonal injury was thought to be the result of axons being disconnected at the time of impact (i.e., primary axotomy), there is no physical tearing or shearing of the axon cylinder (Gaetz, 2004). Several terms are used to describe the secondary axonal injury resulting from closed head injury, including *traumatic axonal injury* (TAI), *diffuse axonal injury* (DAI), or *multifocal axonal injury*. In most cases, TAI is

most accurately understood as a relatively short-duration event in which axonal alterations evolve through a complex cytochemical cascade which can lead to axonal disconnection. Importantly, disconnection does not necessarily lead to rapid cell death (Singleton, Zhu, Stone, & Povlishock, 2002). Due to mild TBI, scattered axons may swell and disconnect, while others remain intact (Greer, Povlishock, & Jacobs, 2012). Animal models show that mild TBI uncomplicated by contusion can cause perturbation with electrophysiological changes, in the form of increased excitability, even in some intact neurons, that return largely to normal within a day or two (Greer, et al., 2012). Disconnection can be followed by various processes that lead to atrophy in some neurons and neuroinflammation, as has been demonstrated one month postinjury in moderate TBI animal models (Kelley, Lifshitz, & Povlishock, 2007; Lifshitz, Witgen, & Grady, 2007).

By definition, there is disruption to the functioning of the brain with mild TBI. Some structural injury may also occur. Borg et al. (2004) reported on the prevalence of abnormalities on computed tomography (CT) scans, for those who go to the hospital following mild TBI, as follows: 5% for those with a Glasgow Coma Score (GCS) of 15, 20% with GCS score of 14, and 30% with GCS score of 13. Clearly, when abnormalities are present on neuroimaging, cellular damage is present. Indeed, this is corroborated by studies demonstrating metabolic changes in the vicinity of brain injury seen on scans (Govindaraju et al., 2004; Son et al., 2000).

However, the vast majority of mild TBI cases are normal on clinical neuroimaging (i.e., CT and structural magnetic resonance imaging, or MRI). Indeed some clinical diagnostic criteria require normal acute neuroimaging (e.g., U.S. Department of Defense and Veterans Administration [VA] criteria). The question then becomes whether “invisible” persistent structural injury is present. An autopsy study of five people with history of mild TBI with loss of consciousness (LOC), who died of other causes 2 to 99 days postinjury, revealed evidence of axonal injury in all cases, particularly in the corpus callosum and fornices (Blumbers et al., 1994). Recent studies using more advanced imaging methods—i.e., susceptibility weighted imaging (SWI) and diffusion tensor imaging (DTI)—have also begun to demonstrate imaging abnormalities previously unseen in mild TBI patients (see “Current Clinical Imaging Findings” section later in this

chapter). SWI has been shown to be up to six times more sensitive than other more traditional MRI modalities (i.e., T2, fluid attenuated inversion recovery, or FLAIR) commonly employed in TBI to detect small lesions and discrete vascular changes (Tong et al., 2003). In our own sample of mild TBI patients ( $N = 74$ ), 13.6% have SWI abnormalities while other imaging modalities appear to demonstrate no abnormalities (Tate, Gusman, Kini, et al., 2013). These findings are similar to reports from other groups (Haacke, Raza, Bo, & Kou, 2013). These studies may indicate pathology previously undetected and may have relatively unexplored clinical implications.

### Epidemiology of Mild TBI

TBI is a leading cause of death and disability in the United States. Data from emergency room visits, hospitalizations, and deaths suggest that 1.7 million TBIs occur each year (Faul, Xu, Wald, & Coronado, 2010). It is estimated that approximately 70%–90% of all TBIs are mild in severity. While the incidence of TBI-related hospital admissions decreased between 1993/1994 and 2006/2007, most hospitalized adult TBI patients were classified as mild in both time periods (Farhad et al., 2013). Some individuals who sustained a mild TBI may not have that diagnosis recorded in their list of ER discharge diagnoses, thereby resulting in under-estimates of incidence (Powell, Ferraro, Dikmen, Temkin, & Bell, 2008; Puljula et al., 2012). Extrapolating from the 1.7 million estimated annual TBIs, and assuming that 80%–90% of those are mild, we can conclude that about 1.36 million of annual TBIs are mild. However, this is likely an underestimate, as these were hospital data and many people likely seek no treatment at all, or consult their primary care physician or some other provider (e.g., military health care system). Methodological limitations in estimating the incidence and prevalence of mild TBI also include variability in definition/diagnostic criteria and ascertainment methods (i.e., self-report, discharge diagnoses based on medical records/billing, emergency medical records, survey, etc.). These limitations must be considered when examining epidemiological studies, as well as variances based on context (i.e., sports vs. military vs. general population).

### Diagnosis and Diagnostic Criteria

There is disagreement about what criteria should be used to identify mild TBI, and it is important to realize that different criteria have been used in research studies of mild TBI. The most common diagnostic criteria utilized are those proposed by the American Congress of Rehabilitation Medicine (1993). These criteria are delineated in Table 18.1.

Severity of TBI is determined at the time of injury, and not by level of functioning at some later point in time. Though severity level has prognostic value, it does not necessarily predict a patient's likelihood of functional recovery. Severity of TBI is a continuum and the particular classification used to designate a patient as having mild, moderate, or severe injury is somewhat arbitrary.

Table 18.1 American Congress of Rehabilitation Medicine criteria for mild TBI

#### Diagnostic Criteria for Mild Traumatic Brain Injury

- I. Traumatically induced physiologic disruption of brain function as indicated by at least one of the following:
  - A. Any loss of consciousness
  - B. Any loss of memory for events immediately before or after the accident
  - C. Any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused)
  - D. Focal neurologic deficit(s) that may or may not be transient
- II. Severity of the injury does not exceed:
  - A. Loss of consciousness (LOC) of 30 minutes or less
  - B. After 30 minutes, an initial Glasgow Coma Scale (GCS) score of 13–15
  - C. Posttraumatic amnesia (PTA) not greater than 24 hours

Source: American Congress of Rehabilitation Medicine(1993)

In 2004 the World Health Organization published a review paper on the various diagnostic criteria for mild TBI and concluded that the degree of variance was impeding progress in the field (Carroll, Cassidy, Holm, Kraus, & Coronado, 2004). So, for example, some research studies on mild TBI included participants with a GCS score between 13 and 15, while others included only those with GCS of 14 or 15. The authors proposed a set of diagnostic criteria that they acknowledged was based largely on the ACRM criteria but allowed for later assessment of GCS (“upon presentation for healthcare”), eliminated the word “dazed” from description of altered consciousness, and noted “transient neurological abnormalities such as focal signs, seizure, and intracranial lesion not requiring surgery” (p. 115) may be present.

Because knowing whether or not a person has sustained a mild TBI is in some cases impossible, some argue that broad and inclusive criteria should be used to identify those at greater risk, to ensure proper evaluation and treatment (e.g., McCrory, et al., 2013; Scholten, Cernich, Hurley, & Helmick, 2013). For example, a recently published consensus statement on concussion in the sports arena encourages assessment and management of athletes showing “features” of concussion, which includes symptoms such as headache and emotional lability, and sleep disturbance (McCrory, et al., 2013). However, inclusion of possible mild TBI would not suffice in a legal setting where injury and attribution of symptoms to a particular etiology is part and parcel of what cases are about.

Unlike moderate to severe TBI, diagnosis of mild TBI often cannot be corroborated with objective diagnostic tools or medical personnel. First, not all traumatic injurious events are witnessed and often there is no documentation or corroboration of the person's immediate status following the injurious event. Any period of disturbed consciousness may resolve before it can be assessed and documented by medical personnel. Second, a person may mildly injure his or her brain and not report it or seek medical care. Because of

reliance on self-report and because emergency and other personnel may not ask (Powell, et al., 2008), mild TBI is likely under- or overdiagnosed, depending on the setting.

When neuroimaging findings or positive signs on an acute neurological examination are present following what otherwise would be classified as a mild TBI, the classification changes to “complicated mild TBI.” Complicated mild TBIs have a six-month outcome more similar to moderate TBI than to an uncomplicated mild TBI (Borgaro, Prigatano, Kwasnica, & Rexer, 2003; Goldstein & Levin, 2001; Kashluba, Hanks, Casey, & Millis, 2008; Williams, Levin, & Eisenberg, 1990). Although several studies have failed to demonstrate this difference in outcome (see bolded studies in Table 18.2), as can be seen in Table 18.2, these studies utilized less-sensitive outcome measures (i.e., not cognitive performance) or

involved chronic, clinical samples that likely do not represent the mild TBI population at large (i.e., sample bias). Of note, in some diagnostic criteria, abnormal imaging that is attributed to the injury (i.e., typically, in the acute phase) results in the patient being considered to have greater than mild injury. (Department of Veterans Affairs and Department of Defense, April, 2009)

To complicate matters, the term *concussion* is sometimes used synonymously with mild TBI but may also be used to denote a less serious injury. The term *concussion* tends to be used in the sports arena, while the term *mild TBI* tends to be used more in medical settings. It has been suggested that the term *concussion* should be used, rather than *mild TBI*, due to the potentially iatrogenic effects of being told one has a “brain injury” (Hoge, Goldberg, & Castro, 2009). Indeed,

Table 18.2 Mild TBI outcomes in adults in relation to neuroimaging findings

Study	Mild TBI Participants	Mild TBI criteria	Time Since Injury	Outcome Measure(s)	Performance Validity Assessed?	Caveats	Did CT/ MRI+ Have Worse Outcome?
Borgaro et al. 2003	28 patients recruited in emergency room	GCS	13 days	Cognitive performance	No	No differences based on affective disturbance	Yes
<b>de Guise et al. (2010)</b>	<b>167 symptomatic outpatient clinic referrals</b>	<b>ACRM</b>	<b>3 weeks</b>	<b>Cognitive performance PCS GOS-R Mood</b>	<b>No</b>	<b>No data on % involved in litigation</b>	<b>No</b>

Yuh et al. (2013)	Consecutive patients to emergency room	GCS	3 months	GOSE	No	No data on % involved in litigation or other variables	Yes

*Note:* Studies with null findings are in bold. CT/MRI+ = abnormalities seen on CT and/or MRI images; LOC = loss of consciousness; PTA = posttraumatic amnesia; ACRM = American Congress of Rehabilitation Medicine criteria (1993) such that LOC < 30 minutes, PTA < 24 hours and GCS 13–15; GOSE = Glasgow Outcome Scale–Extended (Wilson, Pettigrew, & Teasdale, 1998); FIM = Functional Independence Measure; DOS = Differential Outcome Scale (van der Naalt et al., 1999); GCS = diagnosis of mild TBI based only on Glasgow Coma Scale

\*Groups did not differ on severity of postconcussion symptoms (PCS) or return to work at 6 months.

\*\*Group with +MRI/CT did have better return to work outcome.

\*\*\*No differences only once those with positive medical histories (e.g., prior TBI, drug use, etc.) and incomplete data removed.

\*\*\*\*It's unclear how many patients had neuroimaging findings—only a nonsignificant chi-square is reported suggesting no relationship between disability grouping and neuroimaging findings.

\*\*\*\*\*No difference between the groups acutely on cognitive performance, just on chronic PCS.

there is empirical evidence to suggest that poorer outcomes and greater symptoms of posttraumatic stress disorder (PTSD) are expected following “mild TBI” as opposed to “concussion” when these labels are used to describe the same injury (Dematteo et al., 2010; Sullivan, Edmed, & Kempe, 2014; Weber & Edwards, 2010). Within the sports literature, diagnosis and management of concussion is typically multidimensional and includes assessment of signs and symptoms, as well as objective assessment of cognitive functioning, balance and other functional capacities. (McCrea & Guskiewicz, 2014). Please see Chapter 27 for more details about mild TBI sustained in sports.

## Outcomes

The lay public and sometimes even the “experts” have a tendency to lump any type of TBI together, as though all TBIs are the same. As the recovery trajectories can vary widely depending on severity (as well as other factors), it is important to differentiate between mild and more severe forms of TBI. Likewise, when discussing outcomes, it is important to specify what type of outcome. As people recover from injuries (of any kind), they do so in different domains, at different rates, and at different rates based on the domain. Outcomes of interest may include the experience of unpleasant or

debilitating postconcussive symptoms (PCS) such as headaches, fatigue, and dizziness; psychiatric sequelae; cognitive performance; utilization of health care services; or return to work or other activities. These different outcomes may or may not be correlated with one another, hence the need to consider the particular outcome of interest. So, for example, subjective experience of cognitive impairment is typically not correlated with objective performance on cognitive tests (Drag, Spencer, Walker, Pangilinan, & Bieliauskas, 2012; Spencer, Drag, Walker, & Bieliauskas, 2010).

### Cognitive Outcomes

Many individuals with mild TBI experience cognitive decline immediately after injury (Landre, Poppe, Davis, Schmaus, & Hobbs, 2006). In population-based studies of mild TBI, there are acute/subacute cognitive difficulties in virtually all aspects of neuropsychological functioning. Individuals with mild TBI perform about half a standard deviation ( $d = 0.57$ ) more poorly than demographic-matched controls in the initial weeks following a mild TBI (Belanger, Curtiss, Demery, Lebowitz, & Vanderploeg, 2005). For the overwhelming majority of individuals, several independent meta-analytic studies suggest a favorable prognosis, with recovery of function over the course of several days to no more than a few months (Belanger, et al., 2005; Binder, Rohling, & Larrabee, 1997; Frencham, Fox, & Maybery, 2005; Rohling et al., 2011; Schretlen & Shapiro, 2003). Indeed, the effect size associated with mild TBI becomes essentially zero by one to three months postinjury (Belanger et al., 2005; Schretlen & Shapiro, 2003). Similar to the studies in meta-analytic reviews, Himanen et al. (2006) found no evidence of cognitive decline in those with mild to moderate TBI, relative to controls, an average of 30 years postinjury. Likewise, Hessen et al. (2007) found neuropsychological test scores in the average range in those with mild TBI sustained 23 years prior.

In contrast to this typical pattern of excellent recovery following mild TBI in the population at large (i.e., prospective or population-based studies), individuals with mild TBI who present to clinics in the chronic phase for medical or neuropsychological evaluation or who are in litigation (i.e., groups composed of individuals reporting ongoing symptoms and problems) represent a different subsample of patients. At least a portion of these individuals perform more poorly on neuropsychological measures, but in a manner not associated with any specific pattern. In contrast to the expected recovery, worse neuropsychological performance is seen across time (Belanger et al., 2005). See Table 18.3 for the effect sizes associated with different samples.

It may be that typical neuropsychological batteries are not sensitive to subtle, long-term impact of mild TBI, or it may be that there generally is no long-term impact on cognitive performance measures. A few studies have demonstrated differences between those with a history of mild TBI and controls on experimental tasks. Table 18.4 summarizes

Table 18.3 Time since injury by cognitive domain by participant selection context

	<i>Litigation-Based</i>	<i>Clinic-Based</i>	<i>Population-Based</i>
<i>Cognitive Domain</i>	<i>Studies</i>	<i>Studies</i>	<i>Studies</i>

<b>Averaged Across Domains</b>			
< 90 Days	0.52* (2)	No Studies	0.63* (23)
≥ 90 Days	0.78* (6)	0.74* (11)	0.04 (8)

Note: These are meta-analytic results from Belanger et al. (2005). *d* is the effect size; *k* is the number of studies that contributed to the effect size.

\* indicates significant at  $p < .05$ .

those nonclinical studies (e.g., studies using population-based recruiting such as from introductory psychology courses, veterans of the Vietnam War, etc.) that have found differences between mild TBI participants and controls at long-term follow-up. These studies have the advantage of a relative lack of diagnosis threat (though see caveats noted in Table 18.4) and relative lack of external incentives to perform poorly. One common denominator between the studies in Table 18.4 is that the tasks that elicit differences tend to be “experimental” and/or the differences occur on portions of standard tests not typically examined. Given that impairments tend not to occur on standard neuropsychological batteries, the question becomes one of ecological validity. That is, are these subtle differences (found in some studies but not others) meaningful in the real world? Might they account for subjective complaints many months after injury in a small subset of patients? Given the limitations of these studies (e.g., sample selection issues, the role of expectation due to diagnosis threat, etc.) and the potentially futile philosophical arguments about “importance,” it is impossible to answer these questions. Perhaps a next step is correlating these subtle “impairments” with functional limitations and/or psychological distress. Vanderploeg and colleagues (2007) attempted to do that and found that of those with a mild TBI and subtle neuropsychological attention problems, 40% reported a complex of postconcussion symptoms. Of patients with mild TBI and major depression, 69% had the postconcussion complex of symptoms. In contrast, PCS was unlikely to predict other adverse outcomes.

### Structural/Functional Outcomes

In recent years, there has been a growing interest in mild TBI neuroimaging research, summarized in detail elsewhere (Koerte et al., 2015; Lin et al., 2012; McDonald, Saykin, & McAllister, 2012; Shenton et al., 2012; Wilde et al., 2015). Findings can be summarized into two major categories:

Table 18.4 Studies using nonclinical samples demonstrating some decline in mild TBI participants at long-term follow-up

Study	Time Post Injury	Sample Size	Main Finding	Caveats
Bernstein 2002	8 years	13 mild TBI 10 controls	No differences on standard battery except Digit Symbol; mild TBI worse on dual task of visual and tone discrimination	<ul style="list-style-type: none"> <li>• 7/13 had &gt; 1 mild TBI</li> <li>• Diagnosis based on self-report</li> </ul>
Ozen 2012	6.8 years	26 mild TBI 31 controls	No differences on standard battery; mild TBI slower despite comparable or superior accuracy on working memory	<ul style="list-style-type: none"> <li>• All mild TBI had LOC</li> <li>• Mild TBI group more anxious</li> <li>• Unknown if more than one mild TBI</li> </ul>
Segalowitz, Bernstein, and Lawson, 2001	6.4 years	10 mild TBI 12 controls	No differences on standard battery; mild TBI worse only on most difficult experimental sustained attention task	<ul style="list-style-type: none"> <li>• Diagnosis Threat</li> <li>• 7/10 had &gt; 1 mild TBI</li> <li>• 3/10 had been hospitalized</li> <li>• 8/10 had LOC</li> </ul>
Sterr, Herron, Hayward, and Montaldi, 2006	6.8 years	11 mild TBI + PCS 27 mild TBI – PCS 38 controls	Poorer performance by mild TBI + PCS but not mild TBI – PCS on some but not all measures of attention and working memory	<ul style="list-style-type: none"> <li>• Diagnosis Threat</li> <li>• Diagnosis based on self-report</li> </ul>
Vanderploeg, Curtiss, and Belanger, 2005	8 years	254 mild TBI 539 MVA controls 3,214 controls	No differences on standard battery; Mild TBI greater proactive interference and discontinuation on PASAT	<ul style="list-style-type: none"> <li>• Mild TBI severity inferred</li> <li>• Unknown if more than one mild TBI</li> </ul>

Note: LOC = loss of consciousness; PCS = postconcussive symptoms; diagnosis threat possible based on either recruitment method or instructions/tasks; MVA = motor vehicle accident.

current clinical imaging findings and advanced experimental imaging findings.

### Current Clinical Imaging Findings

Since the advent of in vivo imaging methods, clinicians and researchers have examined patients with TBI. In the case of mild TBI, there is limited utility in acquiring imaging, as it is often found to be negative. This is especially true of CT imaging, which is extremely useful in detecting lesions or bleeds that might require neurosurgical interventions but poor at imaging soft tissue, uses radiation, and offers limited contrast between tissue types (e.g., gray and white matter). For these reasons, there are guidelines that govern the use of CT in emergency room settings (Haydel et al., 2000; Papa et al., 2012; Stiell et al., 2001). In the absence of clinical red flags (i.e., progressive declining level of consciousness, worsening neurologic exam, focal neurologic deficit, disorientation, etc.), no medical imaging is recommended by most criteria.

In contrast, there are a growing number of structural MRI research studies examining the effects of mild TBI. MRI has several advantages over CT imaging, including improved contrast between tissue types, submillimeter resolution, and no radiation exposure. It is sensitive to small contusions and white matter damage when examining mild TBI patients. In fact, direct comparison of CT and MRI findings in mild TBI demonstrates that as many as 30% of the mild TBI patients with a negative CT scan will have hemorrhagic and non-hemorrhagic diffuse axonal abnormalities on MRI (Mittl & Yousem, 1994). However, these imaging abnormalities are

not always related to functional changes in mild TBI patients (Slobounov, Gay, Johnson, & Zhang, 2012). To date, the majority of quantitative structural MRI studies in TBI have included mixed samples of patients across the range of severity, vary in chronicity of injury, are cross-sectional in nature, and have limited evidence of relationships between imaging and functional outcomes.

Regardless, there are a few important conclusions that can be gleaned from structural MRI studies to date. First, it is clear from studies that include the full range of severity that several regions of the brain tend to be more vulnerable to the effects of TBI, including the frontal and temporal poles, medial temporal lobe structures (including the hippocampus), and inferior frontal gyri (Bigler & Tate, 2001; Levin et al., 2004). In addition, overall brain volume loss seems to be a common finding in TBI patients, with the moderate and severe TBI patients experiencing the most volume loss (Bigler et al., 2013; Gale, Baxter, Roundy, & Johnson, 2005). However, mild TBI patients also demonstrate volume loss compared to healthy controls that may become evident only when examined in a prospective fashion (Levine et al., 2008; MacKenzie et al., 2002). More sophisticated postprocessing methods of structural MRI (e.g., cortical thickness, hippocampal shape, etc.) demonstrate diffuse abnormalities in TBI (Bigler, et al., 2013; Merkley et al., 2008; Tate et al., 2013) though many of these studies often include a range in injury severity, making it more difficult to know what types of atrophy may occur in mild TBI. Only a few studies have demonstrated relationships between structural imaging abnormalities and cognitive outcomes (Bergeson et al., 2004;

Monti et al., 2013; Wilde et al., 2011) and once again often include a range of injury severity before any relationship is noted. Thus, the clinical utility of structural imaging studies has been limited when trying to understand the clinical significance of any abnormalities that might be observed in mild TBI patients.

### *Advanced Experimental Imaging Findings*

In contrast to standard clinical imaging, recent advances in experimental neuroimaging techniques promise new insights into the diagnosis, functional outcomes, and treatment of mild TBI patients. Advances include new techniques for acquiring MRI data (i.e., DTI, SWI), and new postprocessing analytic methods/statistics (i.e., machine learning, finite-element models, etc.). Current research is also emphasizing prospective MRI data to begin tracking the evolution and progression of changes resulting from mild TBI. Though these advanced MRI methods require additional research before the pathological and functional relevance of findings are fully understood, there is accumulating evidence that these methods have additional sensitivity in detecting important features associated with injury.

DTI has been touted by many as an imaging method that could provide unique pathological and functional insight into the changes associated with mild TBI. DTI differs from conventional structural MRI in that it is sensitive to the microstructural changes in white matter that may be the primary locus of injury in mild TBI (Basser, Mattiello, & LeBihan, 1994; Pierpaoli & Basser, 1996). Because this sequence is tuned to the orientation and degree of water movement in living tissue, the local changes in these measurements can provide important information regarding microstructure of the underlying tissue. In healthy brain parenchyma, white matter is highly organized (often linear), making tracking of white matter pathways easier and improving the sensitivity of this measure to white matter injury across a variety of neurologic disorders.

In mild TBI, there is growing evidence of compromised DTI metrics—e.g., mean diffusivity (MD), fractional anisotropy (FA), etc.—when comparing controls (typically orthopedic-injured controls) and mild TBI patients. These differences have been noted across several brain regions, including the corpus callosum (Matsushita, Hosoda, Naitoh, Yamashita, & Kohmura, 2011; Mayer et al., 2010), internal capsule (Grossman et al., 2012), cerebellar peduncles (Mac Donald et al., 2011), corona radiata (Matthews et al., 2011), forceps major/minor (Messe et al., 2011), and several major white matter pathways including the inferior longitudinal fasciculus, cingulum bundle, and corticospinal tracts (Messe et al., 2011; Smits et al., 2011; Wilde et al., 2012; Wu et al., 2010). Importantly, there are also studies that do not demonstrate differences in DTI metrics between mild TBI patients and controls (Arfanakis et al., 2002; Lange, Iverson, Brubacher, Madler, & Heran, 2012) though there are often methodological differences between these studies including

sample differences (i.e., time since injury), scanner differences, and/or analysis methods (i.e., voxel wise, tract based, region of interest) that require further examination before these disparate results can be better understood.

Critically, DTI metrics appear to explain additional functional variance in mild TBI patients compared to volumetric MRI studies. For example, several studies have demonstrated significant relationships between DTI metrics in the white matter and subtle changes in cognitive function including reaction time deficits (Arenth, Russell, Scanlon, Kessler, & Ricker, 2013; Niogi et al., 2008; Wu et al., 2010), executive functions (Hartikainen et al., 2010), attention (Kraus et al., 2007), memory (Tate et al., 2013), and measures of global cognitive function (Lipton et al., 2008). In addition, mild TBI patients who report postconcussive symptoms six months postinjury also demonstrate significantly worse (i.e., reduced FA) global DTI metric differences compared to mild TBI patients not reporting postconcussive symptoms (Messe et al., 2012). Combined, these studies appear to demonstrate the utility of DTI findings as a potential biomarker for functional deficits in mild TBI subjects. However, it is clear that additional research is needed to fully understand the pathological underpinnings of these findings (Bigler & Maxwell, 2012) and/or the complex evolution and progression of the metrics over time (Lipton et al., 2008; Rosenbaum & Lipton, 2012; Wilde et al., 2012).

Recent DTI efforts appear to be focused on developing methods to examine the individual mild TBI patient (Bouix et al., 2013; Lipton et al., 2008; Shenton et al., 2012). Conceptually, this may prove to be a huge advantage both pathologically and functionally. Due to spatial variation in injury location across patients, group analyses may obscure potential findings, especially in mild TBI patients (Shenton et al., 2012). For example, Bouix and colleagues (2013) demonstrated unique subject-specific abnormal DTI profiles in mild TBI patients experiencing persistent postconcussive symptoms in spite of nonsignificant group difference findings. Identifying these unique spatial locations of injury in individual patients may not only improve diagnosis, but also provide unique insights into patient-specific functional changes leading to improved prognostication and treatment recommendations not available currently.

SWI has also demonstrated additional sensitivity to injury in mild TBI patients not available in conventional MRI techniques. One of the main clinical applications of SWI to date is the detection of micro-hemorrhages, shearing, and DAI in TBI (Haacke, Tang, Neelavalli, & Cheng, 2010). In fact, SWI is extremely sensitive (up to six times more sensitive) to injury after TBI, detecting subtle lesions (i.e., small punctate lesions typically located at the gray/white matter boundaries) and venous changes (i.e., venous undulations/bulbs) previously unobserved using conventional MRI technique. In our own sample of mild TBI patients, SWI detects previously unobserved lesions in 22% of mild TBI patients with persistent cognitive symptoms. Importantly, there is a clear relationship

between the number/volume of SWI lesions and functional outcomes of TBI patients (Beauchamp et al., 2013; Spitz et al., 2013; Tong et al., 2004). More specifically, an increase in the number and/or volume of SWI lesions is related to worse functional outcomes in these patients, including clinical measures such as GCS, length of hospital stay, and intellectual function (Tong et al., 2004).

In summary, CT and structural MR imaging have broadened our understanding of mild TBI in important ways, though these methods leave many unanswered questions. Currently, CT remains the clinical standard, though in the case of mild TBI or concussion, CT has very little benefit and, if indeed imaging is required, MRI should be considered given its markedly improved sensitivity. Determining the imaging biomarkers that are predictive of long-term outcome in mild TBI will be an important emphasis in future clinical and academic research as accurate identification of these markers will improve our ability to differentially diagnose (i.e., PTSD vs. TBI), treat, and prognosticate (i.e., why some mild TBI patients experience persistent symptoms), as well as evaluate and develop new treatment options.

### ***Psychological Outcomes/Mood Disorders***

Prevalence of a psychiatric disorder in the first year following a mild TBI is elevated compared to the general population (Fann et al., 2004). Those with prior psychiatric history are at greater risk. Depression is the most common psychiatric diagnosis following TBI of any severity. The prevalence of depression following mild TBI (as opposed to moderate to severe TBI) has not been as well studied. Nonetheless, those who sustain a mild TBI are at greater risk of depression than noninjured controls but not injured controls (Levin et al., 2001; McCauley, Boake, Levin, Contant, & Song, 2001; Vanderploeg, Curtiss, Luis, and Salazar, 2007). Indeed, depression is relatively common following mild TBI, with a prevalence of 14%–35% (Busch & Alpern, 1998; McCauley et al., 2001; Rao et al., 2010; Rapoport, McCullagh, Streiner, & Feinstein, 2003). Older age and abnormal neuroimaging are predictors of new-onset depression following mild TBI (Levin et al., 2005; Rao et al., 2010). It is unclear whether the new onset depression following mild TBI is due to psychological reaction to the injury or brain dysfunction due to neurotransmitter dysfunction. It is clear that those who develop depression have poorer outcomes than those who do not (Mooney et al., 2005; Rapoport et al., 2003; Silver, McAllister, & Arciniegas, 2009).

There is notably less research on the prevalence of anxiety disorders and mild TBI, with the possible exception of PTSD with the recent wars (see Chapter 32 for a discussion of PTSD and mild TBI). The estimated prevalence of new-onset anxiety disorders is approximately 24%–33% in mild TBI patients (Mooney & Speed, 2001). Significantly higher percentages of psychiatric inpatients have a reported history of mild TBI than the 13%–19% in a nonpsychiatric comparison group

(McGuire, Burright, Williams, & Donovick, 1998). The prevalence of acute stress disorder is roughly 15% in those with a history of mild TBI (Harvey & Bryant, 1998), while the prevalence of generalized anxiety disorder is 16% (Vanderploeg et al., 2007). Once psychiatric and demographic comparisons are made, these rates are likely not elevated compared to non-TBI controls (Vanderploeg et al., 2007). The prevalence of PTSD among noncombat mild TBI patients ranges from 12% to 24% (Bryant & Harvey, 1999; Levin et al., 2001; McCauley et al., 2001; Vanderploeg et al., 2007), again not elevated relative to trauma controls. The rate of PTSD tends to hold steady when reassessed two years later (Harvey & Bryant, 1998).

A few important caveats are in order when considering new-onset psychiatric disorders following mild TBI. The first is that patients may experience symptoms of a disorder without meeting full diagnostic criteria. So, for example, depressed mood is a frequently cited postconcussive symptom that may interfere with cognitive functioning. Depressed mood may or may not be indicative of a depressive disorder. Second, it is of course also important to realize that depression and anxiety often co-occur. For example, one small study of a mixed TBI sample found that every TBI patient diagnosed with generalized anxiety disorder also had clinical depression (Jorge et al., 2004). Another small sample found that 18% of mild TBI patients had both PTSD and depression (Levin et al., 2001). Finally, for the most part, it is currently unclear to what extent a mild TBI affects the prevalence of specific psychiatric disorders. However, prevalence of any psychiatric disorder in the first year following a mild TBI is elevated compared to the general population, with those with prior psychiatric history at greatest risk.

### ***Symptom-Related Outcomes***

Postconcussive Syndrome refers to a set of symptoms that can arise after mild TBI, consisting of physical/somatic (e.g., headache, dizziness, photophobia, fatigue), cognitive (e.g., impaired memory, decreased concentration), and emotional (e.g., depression, irritability) symptoms (Hall & Chapman, 2005). In the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV; American Psychiatric Association, 1994) postconcussional disorder (PCD) is listed as a proposed diagnostic criteria for investigation, whereas Postconcussive Syndrome is listed as an actual diagnosis in the *International Statistical Classification of Disease and Related Health Problems*, tenth edition (ICD-10; World Health Organization, 1992). Criteria differed between the DSM-IV and ICD-10 in that only the DSM-IV requires neuropsychological evidence of attention or memory difficulty and only the ICD-10 indicates that Postconcussive Syndrome may be accompanied by hypochondriacal preoccupation. The ICD-10 lack of requirement for evidence of neuropsychological impairment results in a sixfold increase in the prevalence of a Postconcussive Syndrome diagnosis over the DSM-IV

PCD diagnosis (ICD-10 = 64% vs. DSM-IV = 11%) at three months postinjury in one study (Boake et al., 2005). PCD has been eliminated altogether in the recent *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-V). Indeed, prospective studies of symptom complexes have cast doubt on the clinical utility of Postconcussive Syndrome (Arciniegas, Anderson, Topkoff, & McAllister, 2005; Ettenhofer & Barry, 2012). By definition, a syndrome constitutes a compilation of symptoms that tend to occur together and/or resolve together over time. This has not been the case with Postconcussive Syndrome symptoms. Studies of Postconcussive Syndrome symptom trajectories over time do not support the syndrome construct.

By definition, mild TBI results in some initial brief loss or alteration of consciousness. Shortly after a concussion, several symptoms tend to predominate. The initial alteration of consciousness is experienced as confusion and some disorientation to one's immediate environment. Individuals may describe feeling "confused," "fuzzy," or "slowed down." Although a variety of other symptoms can be associated with TBI, they are not part of the definition of TBI, and other than loss or clear alteration of consciousness (i.e., immediate confusion and disorientation), there are no pathognomonic symptoms or signs. Symptoms should not be attributed to the mild TBI if they are better explained by preexisting conditions or other medical, neurological, or psychological causes—except in cases of an immediate postinjury exacerbation of a preexisting condition (Department of Veterans Affairs and Department of Defense, April, 2009). Within days of injury, patients with mild TBI do not differ from controls in their report of postconcussion-like symptoms (Landre et al., 2006; McCrea et al., 2003). See Figure 18.1 for symptom recovery in college football players.

When patients are initially examined in the emergency room after a mild TBI, one study found the most commonly reported symptoms to be headaches (61%), nausea (27%), dizziness (18%), and vomiting (6%) (De Kruijk et al., 2002). However, as with acute onset cognitive impairments described earlier, these initial symptoms resolve quickly in most individuals. In the sports concussion literature, both cognitive problems and symptom reports resolve in parallel over seven days (McCrea et al., 2003).

In another study, the most frequently reported symptoms within the first 14 days were fatigue (45%), insomnia (32%), headaches (28%), dizziness (24%), and irritability (24%) (Meares et al., 2011). However, the frequency and severity of these symptoms did not differ between a mild TBI and a trauma control group, either during the initial 14 days or at three-month follow-up. Similarly, using a criteria of three or more postconcussive-like symptoms to define Postconcussive Syndrome, the mild TBI and trauma control groups had comparable findings during the first 14 days (mild TBI = 40.3% vs. trauma controls = 50.0%) and again at three-month follow-up (mild TBI = 46.8% vs. trauma controls = 48.3%). These findings replicated an earlier study in which mild TBI

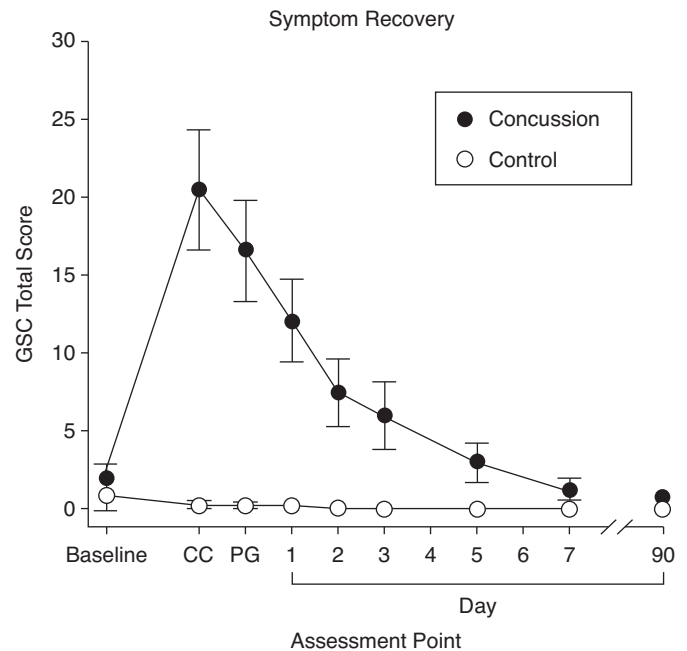

Figure 18.1 Symptom recovery in college football players

Note: CC = time of concussion. PG = postgame/postpractice. GCS = Graded Symptom Checklist; higher scores on the GCS indicate more severe symptoms. Error bars represent the 95% confidence interval. Baseline is preinjury. Figure reproduced with permission, McCrea, Iverson, McAllister, Hammeke, Powell, Barr, & Kelly (2009).

(43.3%) and trauma control (43.5%) groups did not differ in the frequency of PCS at five days postinjury (Meares et al., 2008). However, findings in prospective studies have not been entirely consistent. Although Boake and colleagues (2005) found comparable rates for DSM-IV PCD at three-months postinjury for a mild TBI (11%) and an extracranial control group (7%), they found higher rates for the ICD-10 criteria of Postconcussion Syndrome in the mild TBI group (64%) compared to the extracranial control group (40%). McCauley and colleagues (2013) also found that a diagnosis of mild TBI compared to an orthopedic injury was associated with PCS at one week and one month, over and above demographic characteristics and preinjury depression and resilience. Participants with a mild TBI had greater levels of PCS, as well as acute anxiety and PTSD symptoms, than did the orthopedic control group.

Although some individuals with mild TBI report symptoms months and even years following a concussion, the available longitudinal literature indicates that these symptoms are less likely to be related to the mild TBI as time goes by (Losoi et al., 2015; Meares et al., 2008; Meares et al., 2011; Ponsford et al., 2012) and that the natural course of mild TBI is recovery (Meares et al., 2011). As might be expected with nonspecific symptoms (e.g., headaches, fatigue, insomnia, concentration problems, irritability) in the general population postconcussion-like symptoms following mild TBI wax and wane over time (Meares et al., 2011). Further, these studies

show that these symptoms are generally not related to mild TBI, particularly as time goes by, but instead are associated with accompanying acute posttraumatic stress, and depression or anxiety disorders (Boake et al., 2005; Meares et al., 2008; Meares et al., 2011; Ponsford et al., 2012). As such, the prevailing viewpoint appears to be that while neurological factors contribute to acute symptoms, psychological factors likely account for ongoing symptoms. Longitudinal studies with appropriate injured controls are critical in understanding etiology and time course of symptom complaints.

Regardless of etiology, a minority of individuals complain of cognitive difficulty and other distressing symptoms months (Alves, Macciocchi, & Barth, 1993; Dikmen, Machamer, Fann, & Temkin, 2010; Dikmen, McLean, & Temkin, 1986; McCrea et al., 2013; Powell, Collin, & Sutton, 1996) or years postinjury (Alexander, 1992; Boake et al., 2005; Deb, Lyons, & Koutzoukis, 1999; Dikmen et al., 2010; Hartlage, Durant-Wilson, & Patch, 2001) after having a concussion. Some have suggested that these symptoms are due to subtle neurological dysfunction allegedly beneath the detection threshold of routine diagnostic procedures such as CT, MRI, and EEG (see Hayes & Dixon, 1994). However, as discussed on pp. 417–419, as well as in a review of the neuroimaging literature (Belanger, Vanderploeg, Curtiss, & Warden, 2007), even more sensitive imaging modalities (such as functional MRI) have yet to explain chronic symptom complaints in a convincing way.

At the present time, most research suggests that postconcussion-like symptoms are indistinguishable from the diffuse, nonspecific symptoms experienced by many normal healthy individuals and symptoms that are at increased rates following physical injury or periods of stress, or associated with a variety of mental health conditions (Gunstad & Suhr, 2004; Smith-Seemiller, Fow, Kant, & Franzen, 2003). In fact, a recent study demonstrates that the frequency of this cluster of symptoms is higher in a variety of psychiatric disorders than it is in the chronic phase of mild TBI (Donnell, Kim, Silva, & Vanderploeg, 2012).

Therefore, it is safe to conclude, as suggested by Silver and Kay (2013), that if symptoms persist for more than a few months, increase over time, spread into multiple domains, and become associated with global functional impairment, it is no longer reasonable to speak of a Postconcussion Syndrome or PCS. Instead it is more accurate to say that there is a problem of persistent symptoms that occurred surrounding a concussion but in which multiple factors play a role. The original concussion is no longer the force driving the symptoms and resulting dysfunction.

### ***Dementia***

The association between mild TBI and the development of Alzheimer's disease has been thoroughly reviewed, with mixed findings (Bazarian, Cernak, Noble-Haeusslein, Potalicchio, & Temkin, 2009; Jellinger, 2004; Plassman et al.,

2000). One such review (Bazarian et al., 2009) concluded that dementia of the Alzheimer's type was associated with moderate and severe TBI, but not with mild TBI unless there was loss of consciousness, though the evidence for the latter was limited. Most epidemiological studies suggest an increased risk of dementia/Alzheimer's disease following severe TBI, relative to the general population, though again the evidence regarding mild TBI is limited and inconclusive. A recent, retrospective analysis of a national insurance administrative database in Taiwan (Lee et al., 2013) found a relationship between a mild TBI diagnosis (gleaned from ICD-9 codes) and a dementia diagnosis (with an odds ratio of 3.26) after controlling for age, gender, and various other demographic and health status variables. However, the average duration between mild TBI diagnosis and the dementia diagnosis was only one year, calling into question how generalizable these findings might be.

### **Selected Factors Affecting Outcomes**

There are a myriad of factors that can affect outcomes following concussion. Variability on these factors likely account for individual differences in outcome. A model is proposed to depict the various factors that have been associated with outcomes across time (see Figure 18.2). This model is an amalgamation of previously proposed models (Silverberg & Iverson, 2011; Vanderploeg, Belanger, & Curtiss, 2006) and is based on existing literature, which will be briefly summarized in this section. As can be seen in Figure 18.2, it is hypothesized that predisposing factors and causal factors, as well as perpetuating and mitigating factors, have both direct and indirect effects on one another and on outcome. In addition, factors may interact in complex ways to adversely affect outcome. So, for example, the presence of pain may adversely affect sleep which in turn might adversely affect cognition or may exacerbate other symptoms (e.g., Gosselin et al., 2012; Khoury et al., 2013). Despite the complexities in any one person, however, the general rule is one of recovery over time following a single concussion, regardless of the outcome of interest.

### ***Injury Severity***

It would seem intuitive that greater injury severity might be associated with worse outcome. In a prospective study of emergency department patients, those with recent mild TBI and PTA or LOC were more likely to have neurocranial traumatic findings on CT but were not any more likely to require neurosurgical intervention than those without PTA/LOC (Smits et al., 2007). In this study, those with GCS of 15 and certain symptoms (such as vomiting, headache, seizure, etc.) constituted the "without PTA/LOC" group.

Generally speaking, the strongest predictors of outcome in moderate to severe TBI are injury severity variables (i.e., GCS, PTA, LOC). However, within an exclusively mild TBI

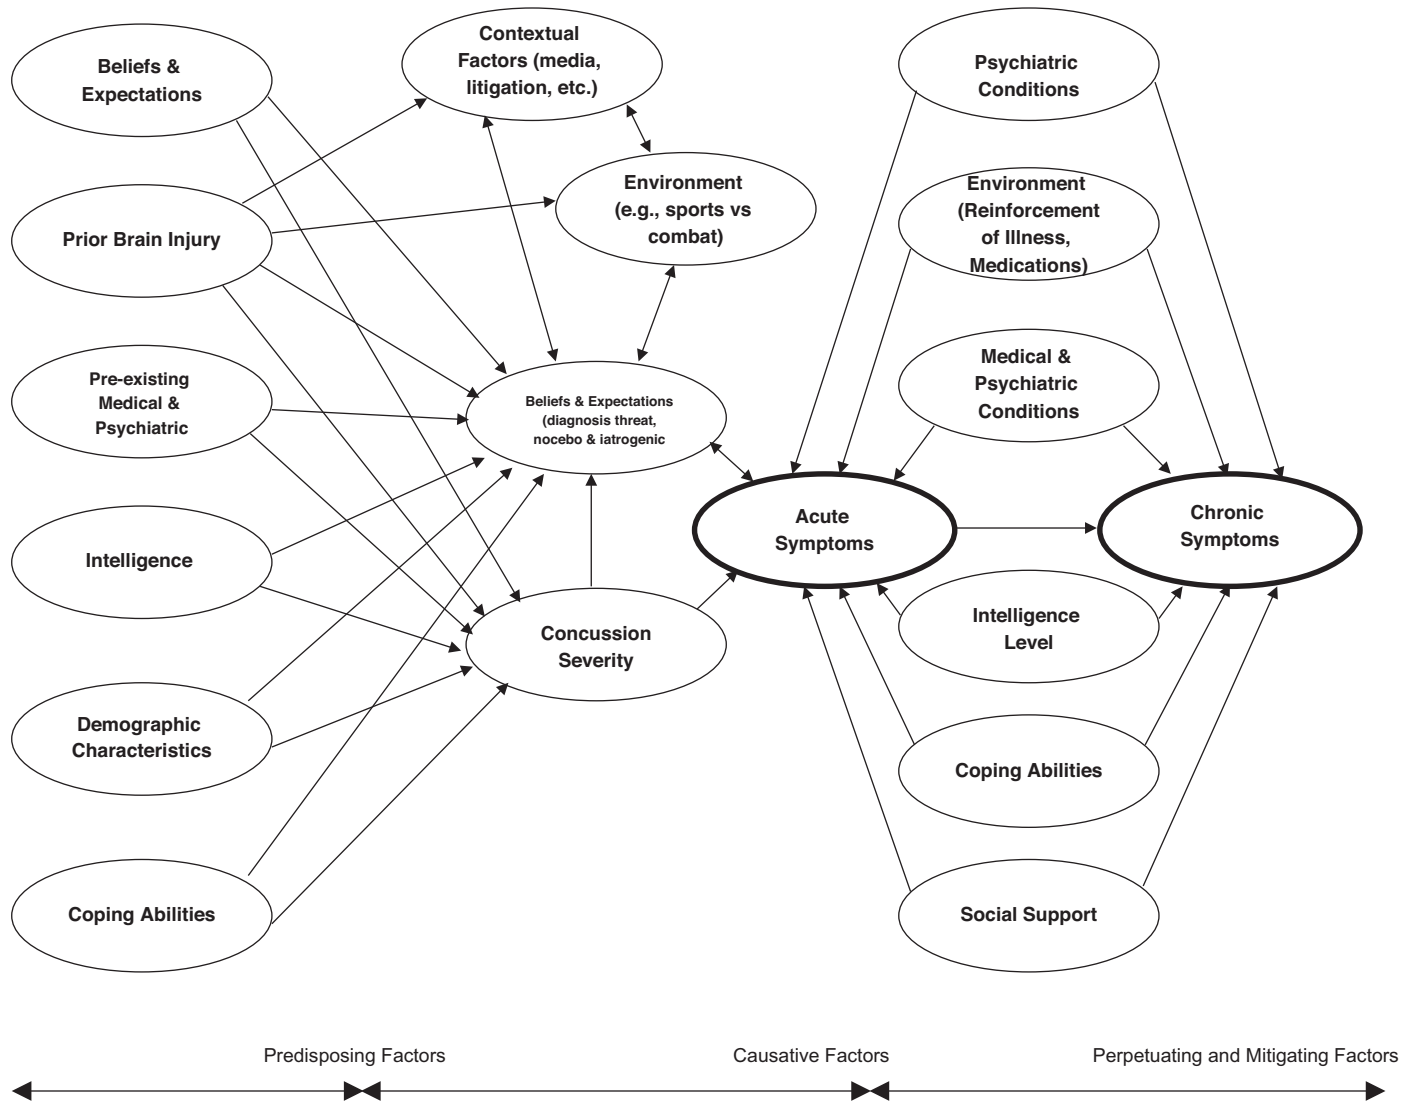

Figure 18.2 A proposed model of factors related to concussion outcome

population, the data are mixed. This may be because we often do not have medical records that give us good estimates of these injury severity indices following a mild TBI, or it may be because injury severity is predictive acutely but that psychological factors play a more prominent role in the long run. So, for example, prospective study in children postconcussion has shown that while injury characteristics like LOC predict symptoms in the first months following mild TBI, there is decreasing contribution over time (McNally et al., 2013).

One way to examine the contribution of TBI severity to the presence and duration of PCS is to compare mild TBI with moderate to severe TBI. In a mixed sample of patients admitted to the hospital for acute TBI, Sigurdardottir et al. (2009) found that those with mild TBI were more likely to meet ICD-10 symptom criteria for Postconcussion Syndrome at three months. However, this difference disappeared

by one year, when mild, moderate, and severe TBI patients all had similar rates of Postconcussion Syndrome and similar symptom severity level (Sigurdardottir, et al., 2009). These findings are consistent with cross-sectional data in a chronic sample of veterans showing no differences in PCS severity reporting across TBI severity levels, once PTSD symptom severity is controlled for in analyses (Belanger, Kretzmer, Vanderploeg, & French, 2010). Dikmen et al. (Dikmen et al., 2010) found differences by TBI severity only on memory complaints one year following injury, with a greater percentage of severely injured TBI patients reporting memory problems. However, there were no differences with other symptoms.

Another way to examine the contribution of TBI severity to the presence and duration of PCS within mild TBI is to examine the presence or absence of LOC. On one hand, some investigators have found no relationship between LOC and outcomes in adults with a history of mild TBI. Chrisman et

al. (2013) found no difference between those with LOC and no LOC in terms of symptoms lasting more than a week in athletes. Kennedy (Kennedy et al., 2012) similarly found that LOC was not a predictor of return-to-duty amongst a sample of 337 service members seen for acute concussion evaluation following medical evacuation from the battlefield. Whittaker, Kemp, and House (2007) found that measures of severity (GCS, PTA, and LOC) were not associated with Postconcussion Syndrome three months postinjury, nor were they associated with functional outcome. On the other hand, McCrea (McCrea et al., 2013) found that LOC was a predictor of prolonged recovery (defined as a lack of relative improvement on symptom reporting compared to controls within seven days) in a small sample of athletes, as was duration of PTA and greater symptom severity acutely. Finally, in a sample of 47 athletes who sustained concussion and were followed by Erlanger et al. (2003) with Internet-based symptom assessments until resolution of symptoms, the presence of LOC, dizziness, nausea, or headache at the first assessment was predictive of the total number of symptoms reported. However, LOC was not associated with the number of symptoms reported at the first follow-up an average of two days later, nor was it associated with the overall duration of symptoms.

In terms of cognitive performance measures, studies have consistently found no association with LOC or PTA duration. Lovell et al. (Lovell, Iverson, Collins, McKeag, & Maroon, 1999) found no differences on neuropsychological measures between those with and without LOC in a large sample of patients seen in an emergency department and assessed within seven days postinjury. Similarly, Hanlon et al. (Hanlon et al. 1999) found no differences on comprehensive neuropsychological measures or on vocational outcome between those with LOC and without LOC in 100 consecutive referrals to a concussion care clinic in patients who were three to 40 months postinjury. Drag et al. (2012) found no relationship between self-reported injury characteristics and cognitive functioning in their chronic sample of veterans. This is similar to findings from Ruff et al. (1999) in a sample of civilian, mixed medical/legal cases an average of 14 months postinjury. There was no relationship between groups based on LOC/PTA duration and performance on neuropsychological measures.

Beyond LOC, another way to examine the contribution of TBI severity to the presence and duration of PCS within mild TBI is to examine the duration of PTA as well as the presence of retrograde amnesia. Prospective study of 71 patients with mild TBI and 60 orthopedic controls followed longitudinally after being seen in the Emergency Department with mild TBI revealed that presence of retrograde and anterograde amnesia was predictive of DSM-defined PCS at three months, but not six months (Bazarian et al., 1999). Meares et al. (Meares et al., 2008) found no relationship between duration of PTA and ICD-10 diagnosis of Postconcussion Syndrome in those who were admitted to a hospital for mild TBI and assessed

an average of 4.9 days later. Ponsford et al. (Ponsford et al., 2000) likewise found no relationship between PTA duration and symptom reporting at three months postinjury in their prospective study of consecutive mild TBI patients presenting to emergency departments. Overall, there does not seem to be a reliable association between PTA duration and PCS. Presence of retrograde amnesia may be predictive in the postacute stage but not longer-term.

Studies conducted with veterans and military samples have examined the relationship between injury severity variables and outcomes within mild TBI samples that were examined a year or more postinjury. In these chronic samples, LOC has been found to be related to greater symptom reporting in some studies (Drag et al., 2012; Walker, McDonald, Ketchum, Nichols, & Cifu, 2013). In such studies, however, it is important to note that the presence or absence of LOC is typically determined through self-report and the patient's retrospective recall. This is obviously problematic, as symptomatic patients are likely in distress and may be more apt to have a negative recall bias about their injury. It's unclear that people can accurately report LOC, or any other presumed injury severity indicator. Furthermore, these studies are typically conducted in clinical samples (i.e., those having difficulties) and therefore are not representative of mild TBI in general. VA samples in particular typically rely on the VA's TBI screening and evaluation process to recruit patients and as such exclude nonsymptomatic patients with history of mild TBI. Hoge et al. (2008) reported an association between LOC and PCS, but controlling for PTSD symptoms nullified the relationship except for headaches. Psychiatric distress also mediated the relationship between injury severity variables (PTA and/or LOC) and PCS in the Drag et al. sample (2012) as well.

One study of civilians presenting to an emergency department followed them into the postacute and chronic stages (Bazarian et al., 1999). This was a prospective, observational, case-control study of 71 patients who met very conservative criteria for mild TBI (i.e., LOC < 10 minutes or the presence of amnesia, GCS of 15, not admitted to the hospital, clean neuroimaging, etc.). In this study, LOC, when entered collectively into a model with other clinical variables, was not predictive of DSM-defined PCS at any time point. Retrograde and anterograde amnesia were predictive at one and three months (though the effects were very small), but not at six months.

In summary, it appears as though injury severity variables are not associated with cognitive performance or other performance-based variables like return-to-duty or vocational status in mild TBI patients. There is greater inconsistency of findings related to symptom reporting, particularly whether or not there is increased symptom reporting associated with the presence of LOC. There does not seem to be a reliable association between PTA duration and PCS. Presence of retrograde amnesia may be predictive in the postacute stage but not in more chronic stages.

### Comorbidities

The presence of a mood disorder and/or mood symptoms following mild TBI may adversely impact outcome. Vasterling et al. (2012) found, for example, that while history of mild TBI was not predictive of cognitive decline postdeployment, current depressive and PTSD symptoms were predictive of cognitive decline. Specifically, greater severity of PTSD and depression symptom reporting was associated with pre- to postdeployment decrements in reaction time, learning efficiency, and recall. In addition, PTSD and depression symptoms were associated with self-reported decrements in health and cognitive functioning. So, both performance-based and subjective outcomes were associated with psychiatric variables, but not mild TBI. These findings are similar to other prospective studies, underscoring the importance of psychiatric status on outcomes (Meares et al., 2008; Ponsford et al., 2012) and with other studies that were not longitudinal but similarly found psychiatric variables to be more predictive of symptom reporting than mild TBI in military and veteran samples (Donnell et al., 2012; Fear et al., 2009; Hoge et al., 2008; Schneiderman, Braver, & Kang, 2008; Vanderploeg et al., 2012). It is important to note that the presence of *premorbid* mood disorder/symptoms are also predictive of outcome (Dikmen et al., 2010; Luis, Vanderploeg, & Curtiss, 2003; Meares et al., 2011; Ponsford et al., 2012; Ponsford et al., 2000). In the Vasterling et al. study (2012), premorbid psychiatric symptom severity was controlled for in the analyses, suggesting that the relationship between cognitive performance and current mood symptoms was not due to premorbid mood factors.

In summary, the presence of anxiety and depressive symptomatology can adversely affect outcomes, both cognitive and subjective, following a mild TBI. Iverson (2005) compared meta-analytic studies of the neuropsychological impact of mild TBI vis-à-vis various disorders. By putting different disorders on the same neuropsychologic metric, he demonstrated that mild TBI, particularly in the chronic phase, has virtually no effect on cognitive outcomes, whereas moderate to severe TBI, depression, malingering, and chronic benzodiazepine use have much greater effects.

Pain and sleep problems are also common comorbidities that can affect outcome in those with mild TBI. In samples recruited from emergency departments, estimates of opioid administration acutely to mild TBI patients are 61%–63% (Meares et al., 2008; Ponsford et al., 2012), and 34% within 14 days postinjury (Meares et al., 2011), with minimal use at longer term follow-up (Ponsford et al., 2012). In their prospective study, Ponsford et al. (2012) found that pain severity at one week postinjury was a significant predictor of ongoing PCS three months postinjury, as was concurrent pain severity at three months. Similarly, Meares et al. (2008) found that while mild TBI was not predictive of ICD-10-defined Postconcussion Syndrome acutely (i.e., within five days postinjury), the presence of an anxiety or affective disorder

and pain severity were predictive. In prospective studies, Sheedy and colleagues (Sheedy, Geffen, Donnelly, & Faux, 2006; Sheedy, Harvey, Faux, Geffen, & Shores, 2009) have found that although there were no differences in levels of reported pain in the emergency department between those with mild TBI versus those with orthopedic injury, acute pain at the time of injury was significantly associated with PCS severity at one and three months postinjury. These findings are similar to cross-sectional studies with more chronic patients, in which PCS severity is associated with pain, even when controlling for depression (Gasquoine, 2000; Mooney et al., 2005; Smith-Seemiller et al., 2003). Opioid analgesia administered on the day of assessment is not related to performance on cognitive tasks or psychological distress (Meares et al., 2008). Opioid use in the more chronic phase is associated with slowed reaction time (Meares et al., 2011). Interestingly, each unit increase in pain for mild TBI patients is associated with increased odds of acute PCS, whereas for trauma controls, each unit increase in pain actually *reduces* the likelihood of acute PCS (Meares et al., 2008). Studies investigating the role of pain on cognitive performance have found no effect within 4.5 days of injury (Landre et al., 2006) though the general consensus is that chronic pain can adversely impact neurocognitive performance independently of TBI (Block & Cianfrini, 2013; Hart, Martelli, & Zasler, 2000).

Sleep is obviously another variable to consider when thinking about outcome following mild TBI, given its known impact on cognitive performance (Fortier-Brochu, Beaulieu-Bonneau, Ivers, & Morin, 2012). Most studies have found that mild TBI patients report significantly more sleep problems than patients with moderate to severe TBI (Beetar, Guilmette, & Sparadeo, 1996; Clinchot, Bogner, Mysiw, Fugate, & Corrigan, 1998; Fichtenberg, Millis, Mann, Zafonte, & Millard, 2000; Mahmood, Rapport, Hanks, & Fichtenberg, 2004; Ouellet, Beaulieu-Bonneau, & Morin, 2006; Parcell, Ponsford, Rajaratnam, & Redman, 2006) though other studies have found no differences in sleep complaints by TBI severity (Hou et al., 2013; Ponsford, Parcell, Sinclair, Roper, & Rajaratnam, 2013). These different findings are likely due to sample differences such as the presence of mood symptoms, pain, and other factors that have a demonstrated relationship with sleep. Fichtenberg et al. (2000) did a logistic regression on their postacute outpatient rehabilitation TBI sample and found that only depression and GCS scores made unique contributions to insomnia (and not pain or litigation status).

Unfortunately, the prevalence of objective sleep difficulties following mild TBI has not been well studied. In a pediatric sample, 18% complained of at least one sleep symptom an average of three years postinjury (Kaufman et al., 2001). Further, sleep difficulties were objectively found using polysomnography and actigraphy at a rate that exceeded age and gender-matched controls. Unfortunately, there are currently no prospective studies with concomitant objective assessment

of sleep in mild TBI. Self-reported sleep disturbance in individuals with a history of mild TBI is estimated to be between 32% and 38% (Ouellet et al., 2006; Segalowitz & Lawson, 1995). After controlling for gender, age, and depression, having a self-reported history of mild TBI is associated with self-reported sleep disturbance (Segalowitz & Lawson, 1995). When sleep complaints differentiate mild TBI groups from controls initially, this difference disappears at long-term follow-up (Dikmen et al., 1986). Using polysomnography, Schreiber et al. (2008) found abnormal sleep architecture and excessive daytime episodes of sleep in clinical samples of mild TBI. Due to sample bias and lack of a control group, the specific role of mild TBI cannot be determined.

Finally, alcohol and substance abuse represent comorbidities that may be problematic. Estimates suggest that between 36% and 51% of individuals who present with TBI are intoxicated at the time of injury (Corrigan, 1995; Parry-Jones, Vaughan, & Miles Cox, 2006). While it makes intuitive sense that substance abuse might adversely affect outcomes, the data suggest otherwise. Specifically, Sigurdardottir et al. (2009) found no effect of current alcohol/drug consumption on functional outcome (as measured by the GOSE) one year postinjury. Similarly, Meares et al. (2008) found that preinjury substance abuse was not predictive of ICD-10-defined Postconcussion Syndrome in the first five days postinjury. Studies conducted with all TBI severity levels have also produced mixed results, with some studies suggesting that alcohol may be neuroprotective, while others suggest increased morbidity. More research is needed.

### ***Premorbid Factors: Demographics and Mental/Physical Health***

Demographic variables such as age, education, and gender are known to be associated with outcomes, both in terms of cognitive performance and symptom reporting. In general, for adults, female gender, older age, and less education are associated with worse outcomes following a mild TBI (Alves, Macciocchi, & Barth, 1993; Bazarian et al., 1999; Covassin, Elbin, Harris, Parker, & Kontos, 2012; Dougan, Horswill, & Geffen, 2013; Jacobs et al., 2010; Lannsjö, Backheden, Johansson, Af Geijerstam, & Borg, 2013; Meares et al., 2008; Ponsford et al., 2012; Ponsford et al., 2000). Bazarian et al. (1999) observe that different mechanisms of injury may underlie some of the gender differences, as females are more likely to be injured in car accidents and males in sports, at least in their sample, the latter of which is associated with fewer symptoms and better outcomes more generally. Gender differences in neuropsychological functioning may not be apparent at longer-term follow-up (Tsushima, Lum, & Geling, 2009).

Some investigators have found an interaction between gender and age such that women who sustain TBI at age 30 or older have poorer outcomes than men and women younger than 30 (Kirkness, Burr, Mitchell, & Newell, 2004;

Tsushima et al., 2009). However, sampling and methodological issues such as participant involvement in litigation, lack of control group, etc., make these studies somewhat difficult to interpret.

Preexisting physical injuries/disease and psychiatric disorders tend to have an adverse impact on outcome following concussion. So, for example, Ponsford et al. (2012) found that pre-injury physical and psychiatric problems were predictive of PCS at both one week and three months postconcussion. Similarly, those with premorbid alcohol abuse and psychiatric histories tended to report more symptoms at one year postinjury (Dikmen et al., 2010). Luis et al. (2003) found that early life psychiatric difficulties, limited social support, lower intelligence, and the interactions among these variables predicted ICD-10 and DSM-IV diagnosis of Postconcussion Syndrome in a large sample of Vietnam veterans. These findings are similar to a prospective study (Meares et al., 2008) that found female gender, preinjury psychiatric diagnosis, estimated IQ, performance on the Symbol Digits Modalities Test, and acute stress to be predictive of Postconcussion Syndrome within two weeks of injury. Being diagnosed with concussion versus some other trauma was not predictive of Postconcussion Syndrome. Finally, recent work suggests that constructs such as “anxiety sensitivity,” defined as sensitivity to one’s own bodily sensations with a tendency to misinterpret autonomic arousal, may have utility in predicting PCS severity (Wood, O’Hagan, Williams, McCabe, & Chadwick, 2014).

Luis et al. (2003) examined the association between a remote history of mild TBI and current Postconcussion Syndrome in a large epidemiological sample of veterans who, following their military service, suffered a civilian mild TBI an average of six years prior to assessment. Demographic factors accounted for 9.2% unique variance in predicting current Postconcussion Syndrome, and preexisting psychiatric conditions accounted for 6.3% unique variance, but history of concussion still accounted for 1.3% unique variance in current postconcussion symptom complex. Similarly, in a university sample, concussion was associated with modestly elevated mean level of PCS reporting for somatic and cognitive symptoms, relative to orthopedic controls (Ettenhofer & Barry, 2012), but not affective symptoms. In a follow-up study (Ettenhofer, Reinhardt, & Barry, 2013) examining factors associated with postconcussion-like symptoms, female gender, and a history of depression and anxiety were the most potent predictors, followed by other mental health issues and learning problems. A lifetime history of mild TBI was also a significant predictor, but accounted for far less variance.

### ***Beliefs/Expectations***

It is important to realize that beliefs, expectations, and attributions have an impact on recovery from mild TBI. Calling attention to a person’s history of mild TBI can adversely

affect both cognitive performance (Ozen & Fernandes, 2011; Pavawalla, Salazar, Cimino, Belanger, & Vanderploeg, 2013; Suhr & Gunstad, 2002) and symptom reporting (Ozen & Fernandes, 2011). This is presumably because people associate a mild TBI with negative outcomes and experience a type of “diagnosis threat.” As Sullivan and Edmed (2012b) demonstrated, even a very mild TBI vignette among nonconcussed undergraduates can elicit expectations of significant PCS. Hou and colleagues (2012) found that negative perceptions of mild TBI were the best predictor of PCS at six months postinjury.

People may also underestimate the extent to which they experienced “postconcussion symptoms” prior to their TBI (Gunstad & Suhr, 2001; Mittenberg, DiGiulio, Perrin, & Bass, 1992). This finding is called the “expectation as etiology” principle (Mittenberg et al., 1992). In other words, some percentage of PCS reporting is likely due to (potentially false) attributions to mild TBI. Snell, Hay-Smith, Surgenor, and Siegert (2013) found that those individuals endorsing (a) stronger injury identity beliefs (i.e., the extent to which symptoms are attributed to mild TBI), (b) expectations of lasting severe consequences following injury, and (c) greater distress at three months post-mild TBI had greater odds of poor outcome at six months postinjury.

“Postconcussion” symptoms, particularly in the chronic phase, are not specific to TBI. However, people may nonetheless attribute their current symptoms and difficulties to having sustained a brain injury. Indeed, Larson and colleagues (2012) reported that attribution to concussion was associated with more severe PCS reporting in their sample of veterans. Similarly, Belanger, Barwick, Kip, Kretzmer, and Vanderploeg (2013) found that the most potent predictor of PCS severity was attribution—that is, the extent to which one attributed symptoms to mild TBI versus other potential causes. Importantly, work in other specialties suggests that attributional styles are mutable and can be modified (Peters, Constans, & Mathews, 2011).

It’s important to note that method of assessment has an impact on symptom reporting as well, most likely because method of assessment has an impact on perception of the construct. So, for example, asking about symptoms in an open-ended manner tends to elicit fewer symptoms than using checklists or structured interviews (Sullivan & Edmed, 2012a). Suggesting symptoms to an examinee may make the examinee more likely to endorse them. Iverson, Brooks, Ashton, and Lange (2010) found, for example, that participants endorsed an average of 3.3 symptoms when queried in an open-ended manner versus 9.1 symptoms when queried via standardized questionnaire.

In an interesting longitudinal study, Whittaker et al. (2007) found that PCS at three months postinjury was not related to injury severity or psychological distress but rather was related to what they termed “consequences” and “timeline.” “Consequences” was the extent to which people believed that a mild TBI would have a negative impact on their lives, while “timeline” was the extent to which people believed

concussion-related symptoms would last. In a regression analysis, only “consequences” was a significant predictor of outcome. Patients who believed that the symptoms they experienced following a mild TBI have serious negative consequences on their lives, and likely will continue to do so, were at heightened risk of experiencing enduring symptoms. Interpreting symptoms as serious and enduring puts patients at risk of chronic PCS. However, initial severity of PCS was not an independent predictor of persisting symptoms. Furthermore, anxiety, depression, and PTSD symptom severity did not significantly improve the predictive model of chronic PCS. In summary, what people believe about mild TBI plays an important role in outcome, suggesting the need to assess and manage patient perceptions and beliefs.

### *Number of Injuries*

While the long-term effect of a single concussion on cognitive measures has been relatively well studied and with consistent findings, much less is known about the long-term impact of multiple concussions, and there has been more inconsistency in findings. For instance, while some studies have found adverse long-term effects on cognitive performance (Collins, Lovell, & McKeag, 1999; Moser & Schatz, 2002; Moser, Schatz, & Jordan, 2005; Wall et al., 2006), others have not (Gaetz, Goodman, & Weinberg, 2000; Iverson, Brooks, Collins, & Lovell, 2006; Iverson, Brooks, Lovell, & Collins, 2006; Macciocchi, Barth, Littlefield, & Cantu, 2001). Furthermore, some studies have found that athletes with two prior concussions recover more slowly (Guskiewicz et al., 2003; Wrightson & Gronwall, 1981) from a concussion, while other studies find no such relationship between recovery time and prior concussion history (Iverson, 2007). We (Belanger, Spiegel, & Vanderploeg, 2010) conducted a meta-analysis that found that the overall effect of multiple mild TBIs on neuropsychological functioning was minimal and not significant ( $d = 0.06$ ). However, follow-up analyses in each cognitive domain revealed that multiple concussions (vs. a single concussion) were associated with poorer performance on measures of delayed memory and executive functioning.

The extent to which there may be a “threshold effect” has yet to be determined. (A threshold effect would be the minimum number of concussions or amount of accumulated brain damage that is sufficient to produce long-term cognitive deficit or to start some type of neurodegenerative cascade.) In sports, age may be associated with worse outcomes to the extent that it serves as a proxy for exposure. That is, older participants in a risky sport are likely to have participated in it longer and therefore will have had more opportunity for TBI. So, for example, in boxing, one of the risk factors for dementia pugilistica is boxing for longer than ten years (Rabadi & Jordan, 2001).

In a meta-analysis of the effect of mild TBI on cognition in athletes, Belanger and Vanderploeg (2005) found that athletes involved in risky sports (i.e., soccer and boxing), as

compared to control participants in less risky sports (e.g., track and field), had significantly worse performance on cognitive measures ( $d = 0.31$ ). The overall effect ( $d$ ) of “exposure” as measured by examining the correlation between length of participation and neuropsychological functioning was .71 ( $p < .05$ ) based on four effect-size estimates. In these studies, exposure was determined by number of boxing bouts and/or length of career, or frequency of heading in soccer. The largest effects were noted in the domains of delayed memory, executive functions, and language. Finally, there is evidence from retrospective research that late adult, former athletes with a history of concussion do more poorly on neuropsychological assessment than age-similar former athletes with no concussion history (De Beaumont et al., 2009; Tremblay et al., 2012). In addition, they exhibit abnormal enlargement of the ventricles, cortical thinning, and various neurometabolic and neuroelectrical abnormalities.

As with cognitive performance outcomes, findings related to the presence and severity of PCS and number of concussions is mixed. Among rugby players, concussion exposure is associated with an increase in symptom severity, but not diminished neurocognitive functioning (Hollis et al., 2009). More specifically, extent of concussion exposure (i.e., greater number of concussions) is associated with increased memory complaints and overall PCS endorsements in a dose-dependent manner for retired and older recreational players, but not for those who are younger (Thornton, Cox, Whitfield, & Fouladi, 2008).

In general samples seen in concussion clinics, the data are mixed with regard to PCS. Silverberg et al., in a cross-sectional retrospective study (2013), found no relationship between number of concussions and PCS reporting. However, a longitudinal study found that those who had not recovered by three months postinjury in terms of PCS were more likely to have a history of prior TBI (Ponsford, et al., 2000). Other cross-sectional studies also suggest greater PCS severity with multiple concussions (Iverson, Gaetz, Lovell, & Collins, 2004; Schatz, Moser, Covassin, & Karpf, 2011).

Limited neuroimaging data suggest that a history of two or more concussions is not associated with changes in brain activation (via Blood-Oxygen-Level Dependent fMRI) during working memory tasks, relative to those with no concussion histories (Elbin et al., 2012; Terry et al., 2012). However, Tremblay et al. (2012) found that relative to athlete controls with no concussion history, those with a history of concussion(s) decades earlier (average of two concussions) had abnormal ventricular enlargement, greater cortical thinning, various neurometabolic anomalies, and episodic memory and verbal fluency decline. There remains much to be understood about how multiple concussive events might affect the evolution and progression of any medical imaging brain abnormalities observed in this population.

Finally, the association between repeated mild TBIs and the development of dementia has been investigated with mostly mixed findings. Guskiewicz et al. (2005) found an association between a history of repeat concussion and

clinically diagnosed mild cognitive impairment (MCI) in a large sample of retired National Football League (NFL) football players. Retired players with three or more reported concussions had a fivefold prevalence of MCI diagnosis and a threefold prevalence of reported significant memory problems compared with retirees without a history of concussion. There was a trend of earlier onset of Alzheimer’s disease in the retirees as compared to the general U.S. male population, though there was no overall association between a history of repetitive concussion and Alzheimer’s disease. This study was retrospective and therefore susceptible to recall bias of participants. A recent mortality study of retired NFL players (Lehman, Hein, Baron, & Gersic, 2012) found a significantly increased risk of death from Alzheimer’s disease and amyotrophic lateral sclerosis (ALS). Further analysis found that non-line players were at higher risk than line players, possibly because of an increased risk of concussion. As has been pointed out by Karantzoulis and Randolph (2013), however, the overall rate of death is significantly lower among retired NFL players, as compared to the general male population, and so the conclusions that can be rendered are limited (there were only six deaths due to ALS and two deaths due to Alzheimer’s disease out of 334 deaths). Finally, a retrospective analysis of high school football players between 1946 to 1956 (when headgear was less protective than current headgear) revealed no increased risk of dementia, Parkinson’s disease, or ALS among the 438 football players compared with the 140 non-football-playing male classmate controls (Savica, Parisi, Wold, Josephs, & Ahlskog, 2012).

Rather than simple “black and white” answers regarding multiple injuries, it is likely that there is some threshold after which adverse outcomes may occur. This threshold may vary by an individual’s genetic make-up, demographics, premorbid intelligence, general health, and other factors, as well as injury-related factors, such as the number of concussions, severity of concussions, time interval between concussions, etc. Recent animal work suggests, for example, that increasing the time interval between concussions to one month versus one day or one week attenuates adverse cognitive outcomes following multiple injuries (Meehan, Zhang, Mannix, & Whalen, 2012). Similar findings have been reported in humans such that the impact of multiple concussions on PCS lessens as time between concussions increases (Silverberg et al., 2013).

## Context

### Sports

The CDC estimates that 173,285 sports-related concussion among children and adolescents present to U.S. emergency departments each year (Centers for Disease Control, 2011). Many probably do not receive medical attention, so this number is likely an underestimate. In fact, it has been estimated that there are 1.6 million to 3.8 million sports-related concussions a year in the United States (Langlois, Rutland-Brown, & Wald,

2006). Football and ice hockey are associated with the highest percentage of concussions each year (Giza et al., 2013; Lincoln et al., 2011). For females, the greatest concussion risk is associated with soccer (Giza et al., 2013; Lincoln et al., 2011).

The majority of athletes recover from a mild TBI within seven days (Belanger & Vanderploeg, 2005), with parallel recovery of initial symptoms, cognitive impairment, and postural instability (McCrea et al., 2003). Importantly, non-concussive bodily injuries can cause acute cognitive impairment (Hutchison, Comper, Mainwaring, & Richards, 2011) emphasizing the importance of using injured controls in prospective studies of concussion. In general, those who sustain mild TBI from sports report fewer symptoms than those injured via other mechanisms (Bazarian et al., 1999). More prolonged recovery in terms of PCS (i.e., greater than seven days of symptoms) occurs in about 10% of concussed athletes and is predicted by LOC, PTA, more severe acute symptoms (McCrea et al., 2013), and the presence of dizziness (Lau, Kontos, Collins, Mucha, & Lovell, 2011). Neuropsychological assessment, as well as symptom scales, and balance testing are recommended for repeated assessment following concussion in athletes and are included in well-established guidelines for evaluation and clinical management following a sports-related concussion (Giza et al., 2013). However, there is some controversy surrounding the utility of baseline and follow-up neuropsychological testing in particular, given the lack of sensitivity to change and lack of incremental utility beyond symptom resolution (Randolph, 2011; Randolph, McCrea, & Barr, 2005). Please see Chapter 27 for more details about mild TBI sustained in sports.

### Forensic

Research has shown that compensation and litigation factors are the single most stable predictor of prolonged PCS in mild TBI samples (Carroll et al., 2004). This is based in part on a meta-analysis by Binder and Rohling (1996) that found financial compensation was a strong risk factor for long-term disability, symptoms, and poorer cognitive performance after mild TBI. Importantly, financial incentives appeared to play a more powerful role in patients with mild versus moderate/severe head injuries. Subsequent to that meta-analysis, Paniak and colleagues (Paniak et al., 2002; Paniak, Toller-Lobe, Reynolds, Melnyk, & Nagy, 2000) found that compensation-seeking strongly predicted delayed return to work, more long-term symptoms and greater symptom severity, independent of mild TBI injury severity. Similarly, Cassidy and colleagues (2004) found that making tort claims following motor vehicle accidents was one of the strongest factors associated with slower recovery. In another meta-analysis, Belanger et al. (2005) also found greater neuropsychological impairment in the late stage of recovery among concussion samples who were involved in litigation compared to prospectively followed samples. Secondary gain factors clearly negatively affect both subjective PCS reporting and objective neuropsychological performance.

Although important in all evaluation settings, validity assessment is crucial in forensic settings. Larrabee (2012) has suggested the use of the terms “performance validity testing” (PVT) and “symptom validity testing” (SVT) to be more accurate and descriptive than terms such as *tests of effort* or *response bias*. Performance validity refers to the extent to which a person’s cognitive or neuropsychological test performance reflects their actual level of ability. In contrast, symptom validity refers to the accuracy of symptom reporting on self-report symptom measures. Tests such as the MMPI-2 and Personality Assessment Inventory have scales of symptom exaggeration and these can be considered symptom validity indices. Both performance validity and symptom validity are significant issues of concern in the evaluation of mild TBI, particularly in forensic settings where secondary gain issues can be prominent (e.g., personal injury legal suits, disability determination evaluations, workers’ compensation evaluations, and veterans’ compensation and pension examinations).

It should not be surprising that base rates of performance validity test failure are increased among compensation-seeking individuals (Heilbronner, Sweet, Morgan, Larrabee, & Millis, 2009). Larrabee (2003) reviewed the literature up to 2003 and found 11 studies yielding 548/1363 subjects (40%) that were identified with motivated performance deficits suggestive of malingering. The frequency of invalid performance ranged from 15% (Trueblood & Schmidt, 1993) to 64% (Heaton, Smith, Lehman, & Vogt, 1978). These base rates are similar to those found by Mooney and colleagues (2005) in a sample of mild TBI patients with poor recovery from PCS (i.e., base rates ranging from 28% to 59% across performance validity indices). Similarly, evidence of noncredible somatic disability presentation (i.e., exaggeration of somatic symptoms) shows base rates of 30%–40% in secondary gain contexts (Greve, Ord, Bianchini, & Curtis, 2009; Meyers, Millis, & Volkert, 2002; Mittenberg, Patton, Canyock, & Condit, 2002).

Importantly, however, failure on performance validity measures also occurs in nonforensic settings. For example, in one longitudinal study that followed people with mild TBI after attending an emergency department in the Netherlands, 110 people were asked to participate in neuropsychological evaluations an average of six months postinjury. In that nonreferred sample, 27% failed performance validity measures. Failure was associated with lower education, changes in work status, psychological distress, fatigue, and negative affect, but not with litigation (Stulemeijer, Andriessen, Brauer, Vos, & Van Der Werf, 2007).

### Military

Mild TBI may occur in as many as 20% of combatants (Hoge et al., 2008; Tanielian & Jaycox, 2008; Terrio et al., 2009) and has been called the “signature injury” of recent wars. Identifying and treating mild TBI has been a high priority within both the U.S. Department of Defense (DoD) and the VA since the onset of operations Enduring Freedom (OEF), Iraqi Freedom (OIF), and more recently New Dawn (OND). Being injured via an explosion or other event in a

combat zone, often in the midst of a firefight, is an emotionally charged event. Given such circumstances, it is difficult to know whether any reported “alteration” in consciousness is due to a brain concussion, emotional trauma, adrenaline rush, pain related to other bodily injuries, or some other cause. A TBI-induced alteration of consciousness (i.e., confusion, disorientation, incoherency at the scene of the event) is different from a psychologically induced alteration of consciousness, although they may be difficult to distinguish, particularly if information is being obtained months later.

However, the role of expectation must be considered in the military context. The media attention of concussion as a “signature injury” of deployment, and the discussion of PTSD, depression, suicidality, and cognitive impairment in the same context, brings to the fore the adverse effects of beliefs, expectations and attributions on outcomes. Secondary gain is also relevant, both in the potential avoidance of further deployments and in possible disability or compensation benefits. However, these factors may be partially offset by the warrior mentality and sense of duty and unit cohesion similar to the sports concussion context. Please see the “Political/Media” section to follow, as well as Chapter 33, for more details about mild TBI sustained in combat.

#### *Political/Media*

It is important to realize and appreciate the power of expectation and the role that media coverage plays in this regard. To experimentally investigate the effects of media messages on health outcomes, Witthoft and Rubin (2013) randomly assigned healthy university research volunteers (i.e., students and staff) to watch a real television report that promoted a link between exposure to Wi-Fi and symptoms ( $n = 76$ ) or a control film about the security of mobile phone data transmission ( $n = 71$ ). After watching their respective films, participants received a 15-minute sham exposure to a Wi-Fi signal. More than half of the television Wi-Fi report participants (54%) reported symptoms that they attributed to the sham exposure. These included: tingling in fingers, hands, and feet; pressure and tingling in the head; stomachaches; and trouble concentrating. Two of the participants found the experience so unpleasant that they had to stop the sham Wi-Fi exposure before their time was up. Simply watching the television report about potential effects of Wi-Fi exposure increased health worries. Sham Wi-Fi exposure subsequently increased symptom levels, more so in those with higher pre-exposure anxiety who were also more likely to attribute their symptoms to the sham Wi-Fi exposure.

Sensational media attention in recent years regarding the adverse effects of sports-concussions (and resulting chronic traumatic encephalopathy, or CTE) and concussions in military personnel exposed to blasts is the same scenario as the media Wi-Fi study described. These repeated media messages likely create a heightened and biased perception about adverse health outcomes following mild TBI. DoD and VA post-deployment screening for concussion within this context sets the

stage for negative expectancies to exert an adverse influence on the patient’s belief system and to attribute many or all difficulties to TBI (Mittenberg et al., 1992). The work of Suhr and Gunstad (Suhr & Gunstad, 2002, 2005) has been particularly illustrative of the effects of the context of the evaluation on cognitive performance outcomes, a situation they refer to as “diagnosis threat.” They have demonstrated that calling attention to one’s brain injury diagnosis tends to increase symptom reporting and decrease cognitive performance.

Given the disparagement experienced by many returning Vietnam Era veterans, there currently is a very strong desire to “do the right thing” for OEF/OIF/OND war-injured veterans. If there is any indication of exposure to or injury from blasts, or having sustained a mild TBI, there may be unwitting pressure to assume that current symptoms and complaints are valid and related to deployment-related events like TBI and further to favor physical diagnoses over psychological diagnoses.

Furthermore, with the advent of population-based screening and evaluation for concussion in the military and VA, as well as increased media attention on concussion, there is likely much more evaluation and treatment following concussion than ever before. In such a context, there is greater potential for diagnosis threat (discussed on p., 426), nocebo effects, iatrogenic effects, and “good old day” bias (Gunstad & Suhr, 2001; Vanderploeg & Belanger, 2013).

Not only are individuals with a history of mild TBI affected by expectations, but clinicians can be as well. The explosion of media attention surrounding mild TBI, both in the sports and postcombat arenas, can create a biased perception (perhaps even subconsciously) of poor recovery rates following a mild TBI, even in the most astute clinician. Additionally, with the increased presence of clinical neuropsychology in the forensic arena over the past decade (Sweet, Meyer, Nelson, & Moberg, 2011), there may be financial incentives (again, possibly subconscious) to overestimate the likelihood of chronic disability in any given case of mild TBI. In contrast, group studies suggesting recovery may obscure a clinician’s ability to appreciate the possibility of continued difficulties in individual patients.

#### **Treatment**

For individuals who have sustained a mild TBI and experience PCS, research has shown the benefit of acute, brief psychological treatment for significantly reducing the severity and duration of symptoms. Several standardized, empirically supported treatment manuals are available (Mittenberg, Tremont, Zielinski, Fichera, & Rayls, 1996; Mittenberg, Zielinski, & Fichera, 1993). Mittenberg et al. (1996) demonstrated that a psychoeducational intervention, which included giving the patient a printed manual and having them meet with a therapist for one hour prior to hospital discharge, resulted in significantly shorter symptom duration and significantly fewer symptoms at six month follow-up compared to a matched control group who received routine hospital care. This one hour meeting included reviewing the

nature and incidence of expected symptoms, providing a cognitive-behavioral model of symptom maintenance and treatment, providing symptom-specific strategies, and providing instructions for gradual resumption of activities.

Table 18.5 summarizes the studies published to date with regard to nonmedication interventions following mild TBI. The right-most column details whether or not there was a positive outcome with regard to symptom reduction. First, it is important to realize that not all these studies were designed with the goal of symptom reduction. For example, Hinkle et al. (1986) conducted a trial with the goal of “restoring

social competence.” Nonetheless, as can be seen from the table, in the acute phase (studies in bold), brief treatment has demonstrated efficacy in reducing symptoms at follow-up in patients following mild TBI in most but not all studies (78% of studies conducted within the first seven to ten days show positive impact). Closer examination of those studies conducted within this time frame is illustrative. The three studies with prospective recruitment within one week of injury (i.e., Mittenberg et al., 1996; Ponsford et al., 2002; Wade, King, Wenden, Crawford, & Caldwell, 1998) all demonstrated significantly reduced symptoms at follow-up secondary to

Table 18.5 Nonmedication intervention studies with mild TBI patients

<i>First Author</i>	<i>Year Published</i>	<i>Design</i>	<i>Intervention(s) Tested</i>	<i>Study Sample</i>	<i>Tx and Control Groups</i>	<i>Follow-Up</i>	<i>Tx Effect?</i>
<b>Alves</b>	<b>1993</b>	<b>RCT</b>	<b>1. Information + reassurance of recovery 2. Information only 3. Control</b>	<b>Hospitalized after mild TBI</b>	<b>N = 201 N = 176 N = 210</b>	<b>3, 6, 12 months</b>	<b>Yes*</b>

Notes: Studies in **bold** font are studies with participants in the acute phase postinjury.

\*For reassurance treatment group only, assuming that patients not seen at follow-up are asymptomatic.

\*\* Outcome measures were depression, PTSD, and impact of event.

\*\*\*Exercise group improved cognitive performance but not mood or sleep.

\*\*\*\*No difference in symptom reporting but treatment groups returned to work sooner. RCT = randomized controlled trial; CBT = cognitive behavioral therapy; Tx = Treatment; LOC = loss of consciousness; CBT = cognitive behavioral therapy.

educational interventions. These studies all involved interventions that were psychoeducational in nature (e.g., providing an informational booklet that outlined common symptoms, as well as their likely time course and suggested coping strategies) with a varying degree of additional support.

One study conducted in the acute phase that did not find a positive impact of intervention was the Relander et al. (1972) study. However, they did not use a standardized measure of PCS and did report improvements in return to work in their

intervention group. This study was conducted in the 1970s with hospitalized patients and did not provide much detail about the intervention other than participants were seen daily, were encouraged to get out of bed, and participated in physical therapy. Additionally, one study (Ghaffar, McCullagh, Ouchterlony, & Feinstein, 2006) found that multidisciplinary treatment in the acute phase was not useful in reducing PCS.

Taken together, these studies suggest that providing education in the acute phase is useful in reducing PCS. Examination

of findings related to interventions administered during the postacute to chronic stages does not provide as much clarity. Differences between interventions, samples studied, and methodologies make comparisons difficult. For example, one study by Hanna-Pladdy et al. 2001, was a test of relaxation training, rather than an educational/supportive intervention. It is also notable that most of the studies with null findings used frequency counts of symptoms as the dependent measure, rather than symptom severity. It may be that the effect of these interventions in the postacute to chronic phases is small and that nonparametric statistics are less likely to reveal treatment effects.

It is also notable that Paniak and colleagues (Paniak, Toller-Lobe, Durand, and Nagy, 1998; Paniak et al., 2000), in their randomized controlled trial in the postacute phase, found that there was no added benefit in providing more extensive treatment (as is typically provided following more severe TBI) as compared to a single informational meeting during which patients' post-TBI experiences were legitimized, education was provided about common symptoms and coping strategies, and reassurance of positive outcomes was provided. Given the present literature, it is unknown if patients seen more chronically (i.e., months or more postinjury) can benefit from brief psychoeducational interventions. Positive results (Huckans et al., 2010; Tiersky et al., 2005) observed during the time frame included much more involved interventions than the studies conducted on patients evaluated soon after injury.

In summary, careful review of the extant literature suggests a positive impact of psychoeducational interventions provided in the acute care setting (i.e., in the emergency room or within one week of injury). Beyond that, results are less clear. Indeed, providing education about mild TBI in the chronic phase may actually "neurologize" (Paniak et al., 1998) difficulties that are due to psychological issues such as posttraumatic stress, chronic pain, or other factors. Furthermore, it is notable that the presence of financial compensation significantly inflates symptom reporting regardless of time since injury (Paniak et al., 2002). It is worth noting that there is evidence that treating comorbid psychological conditions in those with a history of mild TBI is effective; in other words, there is no evidence that psychological interventions should be withheld in those with a history of mild TBI. Bryant, Moulds, Guthrie, and Nixon (2003), for example, found that PTSD was much more likely to be prevented in those individuals with acute stress disorder following mild TBI who were treated with five sessions of cognitive behavioral therapy.

## Controversies and Future Directions

### Biomarkers

In recent years, owing to the frustration surrounding the lack of objective markers of the milder forms of brain injury, interest in biomarkers of TBI has increased. A biomarker is a physiological indicator of disease or injury and may include neuroimaging or blood-based markers. As reviewed on

pp. 418–419, newer neuroimaging techniques, such as DTI, have demonstrated sensitivity to mild TBI in tissue that appears normal on standard clinical scans. The question of longer-term utility remains, however, as there has yet to be any demonstration that subtle injury found in the acute or postacute stages has any long-term prognostic utility.

In terms of blood-borne biomarkers, investigators have examined various proteins in the hopes that a low-cost blood test might prove useful in deciding which patients might need neuroimaging in the emergency room. The most widely studied biomarker is S100B, which is a protein predominantly expressed by astrocytes; levels of S100B increase during the acute phase of brain damage and decrease later on. It has excellent sensitivity to injury but poor specificity. Indeed, the utility of S100B lies in its negative predictive value, meaning its ability to confirm the absence of injury that might require neurosurgical intervention. As such, the American College of Emergency Physicians issued a "Level C" guideline stating that a CT scan is optional in patients without significant extracranial injury if serum S100B is less than 0.1 ng/mL within the first four hours of injury (Jagoda et al., 2008). It is thought that the negative predictive value of S100B is due to the fact that serum S100B levels reflect blood-brain barrier permeability changes (Jeter et al., 2013). In other words, because S100B does not cross the blood-brain barrier, there is poor correlation between its values in the CSF versus the blood.

Many other biomarkers have been explored, including other proteins, microRNAs, and metabolites. None have sufficient sensitivity and specificity to serve as stand-alone diagnostic tests for mild TBI (see Jeter et al., 2013, for review), nor have any been able to provide a means of early identification of those cases that will have long-term functional difficulties. However, a recent study by Siman et al. (2011) suggests that a neurodegeneration biomarker called *calpain-cleaved all-spectrin N-terminal fragment* (SNTF) may hold promise. SNTF is released from neurons upon plasma membrane disruption. The researchers assessed three groups of participants within 24 hours of injury: 17 with CT-negative mild TBI, 13 with orthopedic injury, and 8 normal, uninjured controls. Elevated SNTF in a subset of 7 mild TBI cases and 3 orthopedic injury cases was related to DTI-assessed abnormalities in the corpus callosum and uncinate fasciculus and with cognitive impairment that persisted for three months. The elevation of SNTF in the three orthopedic injury cases, coupled with neurocognitive dysfunction and microstructural abnormalities, raises the possibility that SNTF on the day of injury may be helpful in diagnosing heretofore "unknown" cases of mild TBI. Additional, larger studies are needed to validate these findings.

### Genetics

Interest in the relationship between genetics and mild TBI stems largely from a desire to explain the heterogeneity and individual differences apparent in outcome. Genetic make-up may influence not only response and recovery from injury,

but also proclivity to injury, extent of injury, and extent of cognitive reserve, among other factors (McAllister, 2010). Though there is very little study of genetic influence specific to mild TBI, this is likely to change with the recent mapping of the human genome and trends in personalized medicine.

The most commonly studied genetic influence to TBI outcome is that of the apolipoprotein E (APOE) gene, located on chromosome 19, which is responsible for lipid transport in the brain and may have a role in recovery after neurological injury. Of the three alleles ( $\epsilon 2$ ,  $\epsilon 3$ , and  $\epsilon 4$ ), APOE- $\epsilon 4$  is implicated in A $\beta$  pathology in Alzheimer's disease. There has been general acceptance that carriers of the  $\epsilon 4$  allele have increased risk of Alzheimer's disease compared to those without this allele (Bookheimer et al., 2000). In those with a history of TBI, the  $\epsilon 4$  allele is associated with unfavorable cognitive and functional recovery (Crawford et al., 2002; Friedman et al., 1999) in samples of primarily moderate to severe TBI. Nonetheless, the extent to which the  $\epsilon 4$  allele may moderate increased risk for Alzheimer's disease following TBI is controversial, with conflicting findings (Lye & Shores, 2000). Few studies have specifically examined this question in mild TBI alone. In a study that specifically examined mild TBI, Sundstrom et al. (2007) found that among 543 community-dwelling participants, those with prior mild TBI without APOE  $\epsilon 4$  status had no increased risk of dementia at five years after baseline whereas those with the  $\epsilon 4$  allele had a significantly increased risk of dementia.

In a prospective study of mild to moderate TBI, Chameilian, Reis, and Feinstein (2004) found no association between the presence of APOE- $\epsilon 4$  and neurocognitive performance, emotional distress, global functioning (as measured by the Glasgow Outcome Scale), psychosocial outcome, or post-concussion symptom severity six months postinjury. These findings were consistent with an earlier study (Lieberman, Stewart, Wesnes, & Troncoso, 2002) of 87 patients also with mild to moderate TBI, which failed to find a relationship between APOE- $\epsilon 4$  status and neuropsychological recovery at six weeks postinjury. Likewise, Terrell et al. (2008) failed to find a relationship between APOE- $\epsilon 4$  status and risk for concussion in their exclusively mild TBI sample. However, they did find a nearly threefold increase in risk of self-reported concussion for those with the APOE promoter G-219T TT genotype compared to those with the GG genotype. They did not find any association between concussion risk and tau protein genotypes. A large, prospective study will be needed to confirm these findings, as well as to determine whether there is any association between APOE promoter G-219T TT genotype and clinical outcome following mild TBI.

In sum, the relationship between mild TBI, APOE status, and dementia requires further study. There is evidence that APOE allele status does affect clinical outcome following TBI broadly, although this does not appear to be the case in those studies that look solely at mild TBI. Specifically, APOE- $\epsilon 4$  status does not seem to be related to cognitive or functional recovery in those with mild TBI. Research in

genetic influence on TBI outcome is in its infancy and has yet to examine many of the potential candidates, let alone their interactions with each other and with environmental factors. Given the small effect sizes and frequency of different alleles in the population, very large prospective studies are likely needed (McAllister, 2010).

### *Chronic Traumatic Encephalopathy (CTE)*

There is growing concern that repetitive head trauma can lead to the pathologic findings associated with CTE, a histopathologically defined condition that is hypothesized to be secondary to repetitive head trauma and to represent a degenerative condition that leads to pronounced behavior and cognitive dysfunction (McKee et al., 2009). Historically, the term "dementia pugilistica" or "punch drunk syndrome" was used to denote a similar entity, described in boxers with repetitive head trauma (Bazarian et al., 2009). Pathologically, CTE is most commonly described to include: presence of perivascular foci of p-tau immunoreactive astrocytic tangles and neurofibrillary tangles, irregular cortical distribution of p-tau immunoreactive neurofibrillary tangles and astrocytic tangles with a predilection for the depth of cerebral sulci, clusters of subpial and periventricular astrocytic tangles in the cerebral cortex, diencephalon, basal ganglia and brain stem, and neurofibrillary tangles in the cerebral cortex located preferentially in the superficial layers (McKee et al., 2013). The hallmark of CTE is the neurofibrillary tangles. Unlike in Alzheimer's disease, the neurofibrillary tangles are unevenly distributed with a predilection for the depths of the sulci and around blood vessels (Mez, Stern, & McKee, 2013), particularly early in the disease. Deposition of beta-amyloid (A $\beta$ ) plaques, a hallmark of Alzheimer's disease along with tangles, occurs in fewer than half the cases of traumatic encephalopathy (McKee et al., 2009).

There are no consensus criteria for the neuropathology of CTE. The two prominent labs in this line of research have promulgated different criteria. Omalu et al. (2011a) propose four distinct phenotypes based on the varying histopathological features and distribution of neurofibrillary tangles and neuritic threads, while McKee et al. (2013) describe four pathological criteria they deem necessary to CTE. One key difference is that Omalu et al. have not described marked accumulation and/or prominent perivascular distribution of tau immunoreactive astrocytes. The discrepancies between these labs illustrate the central conundrum of CTE. The broad and heterogeneous pathological criteria become rather nonspecific. Indeed, neurofibrillary tangles, the hallmark of CTE, are present in some elderly people with no cognitive impairment (Bennett et al., 2006), and they are present in 11 of the 18 control brains (or 61%) described in McKee et al. (2013) and absent in 17 of the 85 (or 20%) individuals with repetitive head trauma. Additionally, Hazrati et al. (2013) reported a case series in which the *absence* of CTE was notable in several retired Canadian football players who

had sustained multiple mild TBIs and significant cognitive decline. As Wortzel, Brenner, and Arciniegas (2013) argue, establishment of the sensitivity and specificity of the core histopathological features is critical.

Further complicating the picture are the broad clinical phenotypes described to date. Clinical features described have included depression, anxiety, PTSD, alcohol/substance abuse/dependence, dysarthria, dysphagia, gaze disturbance, chronic pain, anabolic steroid use, coronary artery disease, headaches, suicide, aggression, dementia, poor impulse control, gait instability/parkinsonism, ocular deficits, cognitive difficulties, paranoid ideations, poor insight, disinhibition, inappropriate sexual behavior, apathy, and risk taking. Furthermore, the clinical symptoms begin an average of eight to ten years after the proposed causal traumatic injury(ies) (McKee et al., 2013). As with fronto-temporal dementia, CTE reportedly begins most typically in midlife with behavior and personality changes (McKee et al., 2013), though Stern et al. (2013) suggest different clinical subtypes based on symptom presentation and onset, with a “behavioral/mood” group having earlier onset (mean age of onset of 35) than a “cognitive” group (mean age of onset of 59). Nonetheless, the time lag makes tying the repetitive (often temporally spaced out) trauma to the behavior and ultimately the neuropathology difficult. Though a recent report detailing CTE in a “blast-exposed” veteran with PTSD who committed suicide has received attention (Omalu et al., 2011b) as suggesting the possibility that CTE might be caused by mere blast exposure or possibly PTSD, review of the case description details a complex history that includes premilitary substance abuse, acting-out behaviors prior to reported concussive events, and possibly several concussions.

Importantly, it is impossible to estimate the incidence and prevalence of CTE due to the ascertainment bias inherent in autopsy studies. That is, families of individuals with significant cognitive and/or behavioral difficulties are more likely to initiate and participate in brain donation. Prospective studies are needed to determine what causes CTE. Post hoc associations between behavioral disturbances and histopathology are an important first step in advancing science. However, they are inherently biased and self-selecting. Additionally, while retrospective case studies from autopsy cases have revealed some commonalities (such as irritability, impulsivity, aggression, depression, suicidality, memory impairment), there are presently no clinical criteria for CTE.

The highly publicized accounts of these high-profile cases can give the public a biased perception of recovery rates expected following a concussion, even a single concussion. Sensational media attention in recent years on individual cases who have exhibited drastic behavior (e.g., suicide) in association with pathological findings consistent with CTE at autopsy also tends to create a biased perception among the public. However, as Iverson notes (Iverson, 2014), there are no published cross-sectional, epidemiological or prospective studies showing a relation between contact sports and risk of

suicide. One published epidemiological study (Baron, Hein, Lehman, & Gersic, 2012) suggests that retired NFL players have decreased mortality compared to the general population and are actually less likely to die by suicide. In a case series reported by McKee et al. (2013), six out of the ten former athletes who committed suicide were in the control (i.e., non-CTE pathology) group. Clearly, as Iverson cogently observes, “there is a mature body of evidence suggesting that the causes of suicide are complex, multifactorial and difficult to predict in individual cases” (Iverson, 2014: 163).

In sum, the broad and nonspecific clinical and histopathological phenomenology of CTE, as currently conceptualized, is problematic and is currently based on samples of convenience. The described pathology could be secondary to a host of factors, repetitive brain trauma being one of them. The described clinical presentation likewise is probably broadly determined. Even a behavioral correlate like “cognitive impairment,” seemingly both objectively determined and somewhat clear-cut, is determined by a complex set of factors. In two large epidemiological clinical-pathologic studies, brain pathology accounted for only 40% of the variance in cognitive decline (Boyle et al., 2013). Prospective epidemiological study is needed to clarify the incidence of prevalence of CTE and its associated risk factors. Additionally, controlled prospective study of the clinical features with blinded neuropathological study will be needed.

### *Subconcussions*

Animal models suggest that repetitive, subthreshold force, which typically does not cause cellular death, can nonetheless cause damage when repeated several times within short periods (Slemmer & Weber, 2005). As such, it is possible that this happens in human beings. The questions then become: how frequent, what is the minimal force required, how close in time must they occur, and how many are needed to sustain this damage? Additionally, what might the long-term consequences be?

A “subconcussive” blow is one that does not meet the clinical diagnosis of concussion, yet may have an adverse long-term effect, particularly via repetitive occurrences. A recent review of the subconcussion literature (Bailes, Petraglia, Omalu, Nauman, & Talavage, 2013) concludes that subconcussive blows may have a deleterious neurological effect over time. Not surprisingly, human data comes primarily from football players, who endure an average of 652 impacts to the helmet per season at the high school level (Broglia et al., 2010). Pellman, Viano, Tucker, Casson (2003) found that a force in excess of 98gs is 75% specific to concussion in the NFL while Schnebel, Gwin, Anderson, and Gatlin (2007) reported a range of 90–120gs in collegiate players. Perhaps surprisingly, the magnitude of impacts to the helmet does not necessarily correlate with the probability of sustaining a concussion (Guskiewicz & Mihalik, 2011) suggesting that there may not be a “threshold effect”

for concussion with respect to force. Clinical studies of the neurological/neuropsychological impact of subconcussive blows have been mixed.

Gysland et al. (2012) studied 46 collegiate football players by assessing them with neuropsychological, sensory, balance, and symptom-based measures both before and after a single season during which a head impact telemetry system recorded head impacts. Changes in performance were mostly independent of prior concussion history, and the total number, magnitude, and location of sustained impacts over one season. Specifically, head impact variables (including the total number of impacts, the total number of impacts greater than 90gs, the total cumulative magnitude of impacts, and the total number of impacts to the top of the head) did not predict neurocognitive performance over time, nor did they predict changes in balance on the Sensory Organization Test or total symptom severity. On another measure of balance (the Balance Error Scoring System), they found somewhat contradictory findings. That is, a higher number of impacts and higher number of prior concussions was predictive of improved balance over the course of the season, while a higher cumulative magnitude of head impacts predicted declining balance. Finally, while total symptom severity was not related to head impact variables, an increase in the total number of symptoms reported was related to having a higher number of severe head impacts (over 90gs) and a higher number of impacts to the top of the head. This study of course does not address the potential effects of lifetime dose, though it did find that the amount of college football exposure (based on number of years played) was associated with poorer balance and increased symptom reporting. Miller, Adamson, Pink, and Sweetet al. (2007) similarly assessed 76 collegiate football players at preseason, midseason, and post-season on neuropsychological measures and found no significant declines throughout the season despite likely repeated subconcussive impacts. Of note, these researchers did not measure head impacts, so the relationship between magnitude and number of blows was not directly assessed. Finally, McAllister et al. (2012) followed 214 collegiate football and hockey players from pre- to postseason and compared them to 45 noncontact-sport athletes assessed at the same intervals. They found no significant between-athlete group differences by time on a variety of neuropsychological measures, despite the contact athletes sustaining an average of 469 head impacts over the season with an average acceleration of 132 gs. They concluded that the number of head impacts does not have a widespread short-term detrimental effect. These authors did additional analyses to examine if there were a subset of individuals who did worse than expected at postseason, based on the noncontact athletes' preseason performance and test-retest interval. After conducting multiple comparisons, they found that a statistically significantly higher percentage (24% vs. 3.6%) of athletes in the contact sport group performed below predicted performance on the California Verbal Learning Test (CVLT), a verbal memory

measure. However, performance on the CVLT was not significantly correlated with head impact exposure, though Trails B and reaction time were.

Overall, studies employing neuropsychological assessment within a single season have failed to demonstrate any consistent relationship between number and severity of subconcussive blows and cognitive change. Further prospective study is needed to determine if there is a lifetime dose effect. However, recent studies that have included a neuroimaging component have demonstrated a potential cumulative effect of subconcussive blows, at least in a subset of individuals. Specifically, in a prospective study of 21 high school football players during the 2009 season who were assessed pre- and postseason (with some assessed in-season as well), it was found that four of the eight non-concussed players who were reassessed in-season had significant reductions on verbal and/or visual memory scores and significantly decreased fMRI activation levels in the dorsolateral prefrontal cortex and cerebellum (Talavage et al., 2013) during working memory tasks. Furthermore, these players' cognitive and fMRI data were similar to those three players who sustained a concussion during the season. This group also had a greater total number of collision events throughout the season. The number of impacts experienced in the week immediately preceding in-season assessment was significantly correlated with changes in fMRI activation. It was further demonstrated that while the total number of blows differentiated the groups, the median peak linear acceleration did not (Breedlove et al., 2012). Oddly, these authors did not report pre-post season comparisons, nor did they report whether total season impact variables correlated with functional variables. Thus, while there may be a subset of individuals who show acute clinical changes related to recent subconcussive impacts, the longer-term (or even season-specific) implications are unclear.

Recent work has also employed DTI to investigate subconcussive blows. In a prospective cohort of nine football/ice hockey high school athletes and six controls (some injured, some not), changes in white matter, as detected using DTI, were most apparent in the one concussed athlete, followed by the nonconcussed athletes (with subconcussive blows), followed by the controls (Bazarian, Zhu, Blyth, Borrino, & Zhong, 2012). However, the changes in fractional anisotropy and mean diffusivity were in both directions (both increased and decreased), making interpretation difficult. Additionally, the "subconcussive group" did not report more symptoms than the control group and did not perform any differently than the control group on cognitive measures (and in fact outperformed them on visual motor speed and reaction time). So the subconcussive-relevant findings seem restricted to white matter changes of unclear meaning. Unfortunately, this study relied on retrospective self-reported diaries for its assessment of subconcussive blows, further limiting its interpretability. Again, given that this study followed the

athletes for only one season, the longer-term implications are unclear.

In summary, while it seems as though the magnitude of impacts does not correlate with the probability of sustaining a concussion, there is recent interest in the potential cumulative impact of repeated subconcussive blows. Clinical studies of the neurological/neuropsychological impact of subconcussive blows have been mixed, however. Studies relying on cognitive measures have failed to demonstrate a relationship with head impact variables. Though some findings related to balance and symptoms have been reported, they are inconsistent and the sheer number of comparisons made in these studies suggests the need for replication in other samples. Studies conducted with neuroimaging modalities hold promise, but the long-term implications are unclear at present.

### Summary and Conclusions

Despite decades of research suggesting minimal long-term sequelae associated with a single mild TBI (and to a much lesser extent, even two mild TBIs), there continues to be intense controversy about long-term sequelae of concussion. We now have multiple, independent meta-analyses, as well as seminal, prospective studies (e.g., Dikmen, Machamer, Winn, & Temkin, 1995; Levin et al., 1987; Meares et al., 2011) that suggest significant impairment due to mild TBI is unlikely to persist more than a month. This ongoing controversy is probably due to several factors, including increased forensic work in this area as well as increased media attention.

The etiology of PCS has been hypothesized to be due to neural damage, pre- and postinjury psychological factors, somatization, malingering, etc. Nonetheless, trying to determine the extent to which any given patient's difficulties are "biologically based" may be misguided. Overly focusing on biological or physiological etiology leads to "black and white" thinking, when most clinical phenomena are determined by multiple factors that may have independent and interactive effects. Given emerging, highly sensitive neuroimaging techniques and the existence of some patients who have chronic symptoms, it may be more productive to try to tease apart the many possible factors that may be related to ongoing difficulties: e.g., (a) genetic predisposition; (b) subtle brain changes; (c) psychological factors such as beliefs, expectations, and premorbid and comorbid conditions; and (d) media, medical, and legal messages conveyed either overtly or covertly. This would lay the foundation for developing algorithms for use in identifying who is at risk (Stulemeijer et al., 2008), and then test targeted intervention strategies.

The long-term impact of repeated mild TBI is less clear. The importance of large, prospective studies with appropriate, orthopedically injured controls, as well as well-defined and characterized injuries, cannot be overstated as science moves forward in this arena.

# 19 Neurocognitive Assessment in Epilepsy

## Advances and Challenges

*Joseph I. Tracy and Jennifer R. Tinker*

The pathophysiology of seizures is closely linked to the formation of networks subserving cognition. Epilepsy research has provided us with landmark insights into amnesia and set the foundation for our understanding of episodic memory. H.M., who suffered severe anterograde amnesia as a result of bilateral medial temporal lobe resection to control seizures, is likely the best known, and most studied, patient in the history of neuroscience (Squire, 2009). Many of the fundamental principles of episodic memory owe a great debt to lesional epilepsy, particularly early models focused on the temporal stages of processing. Seizure activity, however, induces neuroplasticity, and our conceptualization of the cognitive effects of epilepsy is expanding beyond the focal/modular approach common to early lesional models towards more dynamic network models of dysfunction.

In this chapter, we will present evidence for cognitive network dysfunction in epilepsy, emphasizing seizure-induced neuroplasticity, and its broad effects on cognition and brain network organization. We will present data from functional imaging and other sources, demonstrating that even focal epilepsies can induce more widespread neuropsychological changes than originally thought. We will briefly discuss models of network organization in the setting of seizures, noting how these help explain the complex nonfocal deficit patterns that are often observed. In line with the notion that ongoing seizures create a dynamic, not static, cognitive profile, we review the evidence for cognitive reorganization, and describe the impact of variables with cognitive impacts that vary with age or development (e.g., age of onset, chronicity, hemispheric dominance, and medication). We will also examine the changing algorithm for presurgical assessments in epilepsy, and the impact these changes have on our methods for predicting neuropsychological and emotional/behavioral status postsurgery. The advent of technologies that can more directly link cognition to underlying neurobiologic mechanisms (e.g., structural and functional neuroimaging, electrocorticography) will both challenge and enhance the role of neuropsychologists who work in surgical epilepsy centers. Our use of these technologies to refine and improve our understanding of brain-behavior relationships will make neuropsychologists particularly well-suited to contribute to surgical decision-making, and greatly advance our understanding of epilepsy's cognitive effects. Throughout this

chapter, we emphasize that only by understanding the neuroplasticity initiated by seizures will we be able to effectively identify cognitive status and predict cognitive outcomes in epilepsy, as it is these neuroplastic responses that govern the status of both neurocognitive and epileptogenic networks.

### **Seizures, Neuroplasticity, and Cognition**

The key to grasping the paradigm shift from a focal, modular approach to that of a network approach is to understand that the neural mechanisms underlying network development (i.e., neuroplasticity) and the neuropathology of seizures are similar. Indeed, little separates the neurobiology of learning and of seizures. Many of the neural mechanisms of learning are key factors in the regulation of seizures, and the highly plastic brain regions specialized for learning and memory are particularly susceptible to seizures. More than characterizing the effects of seizures or predicting outcomes after surgery, there are fundamental cognitive neuroscience reasons for neuropsychologists to study epilepsy.

Epilepsy is an electrical disorder characterized by neural cell hypersynchrony. The origin of this hypersynchrony can vary as epilepsy is the end state of a wide range of pathologic mechanisms (e.g., trauma, stroke, genetic, tumor, atrophy, dysplasia, infection). Epileptogenesis can begin with a single neuron. A seizing neuron recruits adjacent neurons into a hypersynchronous process until a critical mass of tissue transforms into a single active unit whose components no longer respond to existing functional network connections. Therefore, the process of epileptogenesis provides us with an avenue for studying the development of favored neural pathways that are distinct from developmentally and adaptively formed neural networks. The degree to which these maladaptive seizure networks overlap and interact with either established or developing cognitive networks is what neuropsychologists must determine when conducting their evaluations.

Broadly speaking, the ramifications of epileptic activity in the brain include: (a) intracellular changes (i.e., expression of cellular proteins or alterations in calcium channels, signaling molecules, or neurotransmitters such as GABA), (b) injury to cortical pyramidal neurons that make membrane ion channels more amenable to excitatory input, (c)

mossy fiber and axonal sprouting within pyramidal cells that enhance excitatory connections, (d) hyperinnervation, (e) failure to prune immature connections when occurring early in life, and (f) changes in glial cells and in the organization of axons and dendrites to favor hypersynchrony (Ben-Ari, Crepel, & Represa, 2008; Jacobs, Graber, Kharazia, Parada, & Prince, 2000; Somera-Molina et al., 2007; Sutula & Dudek, 2007). These neuroplastic changes are most evident within the hippocampus, but have been observed in the neocortex as well (Schwartzkroin, 2001). All constitute mechanisms of neuroplasticity at different levels of organization, working in a single or combined way to restructure surviving synapses, leading to reorganization of surviving neuronal networks.

Both seizures and plasticity are controlled and regulated by complex molecular mechanisms and recent research has focused largely on inhibitory processes (Brooks-Kayal, 2011; Kullmann, Moreau, Bakiri, & Nicholson, 2012). GABA<sub>A</sub> receptors mediate most fast synaptic inhibition and are crucial in regulating both neuronal excitability and the impact of excitatory synapses. There is increasing evidence that GABAergic synapses are plastic and demonstrate long-term, bidirectional changes in connectivity strength throughout the brain (Castillo, Chiu, & Carroll, 2011). Studies examining GABA<sub>A</sub> subunit alterations have uncovered seizure-induced pathways that contribute to epileptogenesis, with several transcription factors regulating GABA<sub>A</sub> in a way that leads to chronic epilepsy (Grabenstatter, Russek, & Brooks-Kayal, 2012). These transcription factors and cell modulators (e.g., brain-derived neurotrophic factor, cAMP response element binding protein, inducible cAMP early repressor, and early growth response factors) are the focus of intense investigation in epilepsy as potential targets for antiepileptic drugs.

Mesial temporal lobe epilepsy (MTL) is the best-characterized type of epilepsy, due to its high relative incidence and relatively homogenous etiology (e.g., hippocampal sclerosis). The temporal lobe is particularly vulnerable to epileptogenesis due to the neuroanatomic and neurochemical properties that support learning and memory. Regions specialized for learning and memory in the brain, such as the hippocampus, appear most prone to seizures. The main neurotransmitters associated with seizures are GABA and NMDA. NMDA receptor density is high in the CA1 and CA3 regions of the hippocampus (Coultrap, Nixon, Alvestad, Valenzuela, & Browning, 2005). In fact, NMDA receptor density predicts both the probability of Hebbian learning and epileptogenicity (McClelland, 2001; Nicoll & Malenka, 1999). Hebbian learning mechanisms of long-term potentiation (LTP) and long-term depression (LTD) are the primary mechanisms of neural network development and underlie the processes of learning and remembering. The immature brain exhibits greater plasticity potential than the adult brain. Ironically, the plasticity that makes the immature brain quite responsive to environmental stimulation and facile at learning also means that the environment, stress, injury, and illness (i.e., seizures) can have a more profound and devastating effect.

Some have argued that epilepsy, along with other conditions (e.g., intellectual disabilities, autism spectrum disorders), may be best understood as disorders of synaptic plasticity that result in a developmental imbalance of excitation and inhibition (Brooks-Kayal, 2011).<sup>1</sup>

Given the cellular and synaptic transmission modifications at work, one can see that there are ample opportunities for cognitive deficits to emerge in regions outside the primary epileptogenic focus. When cells in these remote sites seize (i.e., display abnormal spiking patterns) following initial activity in the original epileptic focus, these intense epileptic dynamics can force the abnormal integration of these remote cells into the epileptogenic network (Schneider-Mizell et al., 2010). After joining the hypersynchronous activity of the ictal focus, these remote cells may eventually come to initiate seizures independently (Morrell & deTolledo-Morrell, 1999), potentially forcing both functional and structural connectivity changes. Thus, the ictal focus of a seizure can be seen as initiating a neural circuit, a circuit that if instantiated repeatedly by ongoing seizures leads to frequent aberrant neural “communication” with other regions of the brain. Cells downstream from the seizure generator will respond to the excitation of seizures as if learning has occurred. From this perspective, epileptogenesis appears to be a process similar to LTP (Shimizu et al., 2000; Tracy et al., 2009), with these aberrant networks active not just during ictal stimulation but also during cognitive stimulation of one or more seizure network nodes, ultimately disrupting the underlying cognition. Eventually, through a process that reduces action potential thresholds similar to neural kindling (Goddard, 1967; Wada & Mizoguchi, 1984), these epileptogenic pathways create a biased, favored network that is both maladaptive to cognition and pathologic to otherwise healthy neural tissue, as it now has to bear the burden of periodic epileptiform activity. In this way, seizures produce a dysfunctional, maladaptive cognitive network by linking brain areas randomly through seizure propagations and secondary epileptogenesis, rather than through normal adaptive learning and experience driven plasticity and connectivity. Accordingly, the development of normal neural networks, through the LTP or LTD associated with normal learning, appears to bear a striking resemblance to epileptogenesis. More specifically, injury, pathology, or genetically driven abnormal excitability (and inhibition) induces neuronal neuroplastic responses, causing cognitive network dysfunction both directly and indirectly through the formation of seizure/epileptiform networks. Interventions such as resective surgery, ablation, or medication can also trigger cognitive reorganization adaptively through seizure control, or maladaptively by allowing seizure recurrence. Figure 19.1 illustrates a pathway depicting the development of seizure networks, maladaptive to cognition triggering reorganization, carried through to additional potential cognitive reorganization related to intervention such as temporal lobe surgery.

### Seizure Recurrence

*Continue maladaptive neuronal network formation and reinforcement*

**Figure 19.1** Pathway depicting the development of seizure networks, maladaptive to cognition but triggering reorganization, carried through to intervention by anterior temporal lobectomy (ATL). More specifically, pathology or genetically driven abnormal excitability induces neuronal neuroplastic responses contributing both directly and indirectly (through seizure/epileptiform networks) to cognitive network dysfunction. Interventions such as ATL can also trigger cognitive reorganization adaptively through seizure control, or maladaptively through seizure recurrence.

### Seizure-Induced Reorganization of Cognitive Networks

The central nervous system in adults continues to adjust and adapt over the course of the lifetime. These adaptations generally occur in two contexts: neuroplastic processes operating in a normal brain as part of development or in response to experience, and those that operate in the abnormal or pathologic brain creating an atypical historical environment for the organism (injury-induced plasticity). Brain plasticity is evident in the normal brain and occurs with normal learning (May, 2011; Tracy et al., 2003). Injury-induced plasticity has been demonstrated in acute brain injury (Demirtas-Tatlidede, Vahabzadeh-Hagh, Bernabeu, Tormos, & Pascual-Leone, 2012; Xiong, Mahmood, & Chopp, 2010), stroke (Meinzer, Harnish, Conway, & Crosson, 2011), and resective surgery (McCormick, Quraan, Cohn, Valiante, & McAndrews, 2013). In this section, we discuss the evidence for cognitive reorganization in epilepsy.<sup>2</sup>

Neuropsychological, intracarotid amobarbital (popularly known as the *Wada test*), functional magnetic resonance imaging (fMRI), and functional connectivity (FC) studies have all provided evidence that the brain representation of cognitive functions in patients with temporal lobe epilepsy (TLE), for a variety of tasks, can reorganize to regions not seen in matched control samples. Neuropsychological and intracarotid amobarbital studies, particularly in early onset left TLE, provided the initial evidence for reorganization of verbal memory and expressive language skills, with indications of either a left-to-right interhemispheric or anterior-to-posterior intrahemispheric reorganization pattern (Jokeit, Ebner, Holthausen, Markowitsch, & Tuxhorn, 1996; Seidenberg et al., 1997).

Task-driven fMRI studies have demonstrated that TLE patients show altered organization of major cognitive

networks such as those involved in expressive language. An fMRI study by Wilke et al. (2011), using narrative and letter sound processing tasks in epileptic children and matched controls, found a high rate of atypical language organization, with the homotopic contralateral region the most common site of reorganization, though the distribution of left hemisphere representations (frontal and temporal regions) also showed alterations from normative locations (e.g., classical Broca's and Wernicke's areas). Cousin, Baciú, Pichat, Kahane, and Le Bas (2008) found that the asymmetry of typical language lateralization was significantly lower in left TLE patients than controls, with early onset patients showing stronger signs of right temporal and parietal reorganization than late-onset patients, in addition to a tendency toward intrahemispheric reorganization involving the frontal lobe. They also found that hippocampal sclerosis increased the probability of interhemispheric shift of the temporal lobe activation. Rosenberger and colleagues (2009) looked at fMRI language activation patterns in left TLE patients during a lexical decision task (e.g., correct/incorrect definitions provided auditorily) and found an increased frequency of atypical language representations involving right hemisphere language areas, homologs of left hemisphere Broca and Wernicke's areas. Interestingly, they found little evidence for intrahemispheric reorganization in patients with left hemisphere epilepsy who remained left language dominant by fMRI, and these effects did not vary by age at epilepsy onset, duration of epilepsy, or pathology. Hamberger and Cole (2011) reviewed the area of language reorganization and found that preserved naming ability in the setting of hippocampal sclerosis was associated with intrahemispheric (i.e., more posterior temporal) reorganization in response to early disease in the mesial temporal region. They noted that this pattern makes sense given the known bias of TLE seizure

discharges to proceed anteriorly. It remains unclear how large the epileptogenic region (or lesion) has to be to force contralateral language reorganization. Also unclear is the degree to which interhemispheric reorganization is dependent on the particular brain region housing the pathology. There is, however, some evidence that damage to the hippocampus may be the crucial structure compelling contralateral, as opposed to ipsilateral, language reorganization (for review see Tracy & Boswell, 2008).

Memory also appears to reorganize in the face of intractable seizures. Figueiredo et al. (2008) utilized a visual episodic memory fMRI task, and found that, relative to controls, right TLE patients with hippocampal sclerosis demonstrated functional reorganization through the transfer of function from the right to the left hemisphere, with preserved visual memory performance. Richardson, Strange, Duncan, and Dolan (2003) utilized a verbal encoding fMRI task and found that successful encoding was associated with activation of the left hippocampus in nonpatients, but the right hippocampus and parahippocampal gyrus in left TLE patients. A study of verbal semantic memory by Koyle et al. (2006) showed that, compared to controls, left TLE patients showed a shift in activation from the typical left frontal and medial temporal areas to homologs in the right hemisphere. The left TLE patients also recruited subcortical structures such as the thalamus and putamen to accomplish the task. In contrast, the right TLE patients more closely resembled healthy controls, though they did exhibit bilateral frontal hypoactivation. Alessio et al. (2013) studied verbal and visual memory in patients with hippocampal sclerosis, and found that left hippocampal sclerosis (HS) patients produced more bilateral or right-lateralized verbal encoding-related activations, suggesting reorganization in reaction to a dysfunctional mesial temporal lobe. For the visual memory encoding task in this study, the left and right HS groups, in addition to the controls, recruited widespread cortex bilaterally. The right HS group was the only group recruiting the left inferior temporal cortex, interpreted by the authors to reflect material-specific memory compensation of right mesial temporal dysfunction. Finally, in a FC study from our lab, examining memory, we found significant FC reductions in both left and right TLE localized in angular gyri, thalami, posterior cingulum, and medial frontal cortex. We found that the FC between the left non-pathologic MTL and the medial frontal cortex was positively correlated with the delayed recall score of a nonverbal memory test in right MTLE patients, suggesting potential adaptive changes to preserve this memory function (see Figure 19.2). In contrast, we observed a negative correlation between a verbal memory test and the FC between the left pathologic MTL and posterior cingulum in left MTLE patients, suggesting potential functional maladaptive changes in the pathologic hemisphere. Overall, this study provided some indication that left MTLE may be more impairing than right MTLE patients to normative functional connectivity. The data also indicated that the pattern

of extratemporal FC might vary as a function of episodic memory material and each hemisphere's capacity for cognitive reorganization.

Interestingly, there is evidence from task-based fMRI studies of memory that reorganization may not always be adaptive. For instance, a study by Vannest, Szaflarski, Privitera, Schefft, and Holland (2008) demonstrated that intractable epilepsy (mixed pathology, some mesial temporal sclerosis, or MTS) influenced the functional neuroanatomy of a scene-encoding task, with both left and right epilepsy patients showing a pattern of increased contralateral medial temporal activation, within the setting of broader bilateral activation compared to healthy controls. This contralateral activation was associated with decreased memory performance, potentially providing evidence that not all reorganization is necessarily adaptive. It is important to note, however, that when unique (nonnormative) fMRI activation patterns are associated with lower cognitive performance, this could still represent adaptive compensation, emerging from incomplete or flawed compensation efforts.

Whole-brain network alterations have been observed in TLE relative to healthy controls in several specific functional networks including the well-known default mode network (DMN), in addition to attention, perceptual, and language networks (Liao et al., 2010; Waites, Briellmann, Saling, Abbott, & Jackson, 2006; Zhang, Lu, Zhong, Tan, Liao et al., 2009; Zhang et al., 2010; Zhang, Lu, Zhong, Tan, Yang, et al., 2009). These studies provide strong evidence that epileptic activity causes functional changes in complex and widespread resting-state networks (RSNs), putting at risk a wide range of neurocognitive and affective functions.

Most studies of resting-state FC in mesial TLE have focused on FC emerging from the ictal hippocampus (Doucet, Osipowicz, Sharan, Sperling, & Tracy, 2013; Morgan, Rogers, Sonmezturk, Gore, & Abou-Khalil, 2011; Pereira et al., 2010; Z. Zhang et al., 2010). The findings suggest that, compared to controls, there is increased connectivity with the contralateral hippocampus, as well as other contralateral limbic structures, with this interpreted as a form of compensatory connectivity (Bettus et al., 2010; Bettus et al., 2009; Doucet, Osipowicz, et al., 2013; Pittau, Grova, Moeller, Dubeau, & Gotman, 2012). Finally, resting-state FC work from our lab (Tracy et al., 2014) has shown that highly focal, unilateral TLE, with no evidence of interictal activity outside the ictal temporal lobe, is associated with a strong inhibitory surround (i.e., anticorrelated activity) in the contralateral hemisphere (see Figure 19.3). In contrast, TLE patients who display extratemporal interictal activity lack this surrounding anti-correlated activity. Thus, large regions of healthy cortex seem to respond, through contralateral anticorrelated activity, even to focal seizures, representing a form of protective and adaptive inhibition, helping to constrain epileptiform activity to the pathologic temporal lobe. The cognitive cost of maintaining such an inhibitory surround is unknown, but clearly this could put a variety of functions

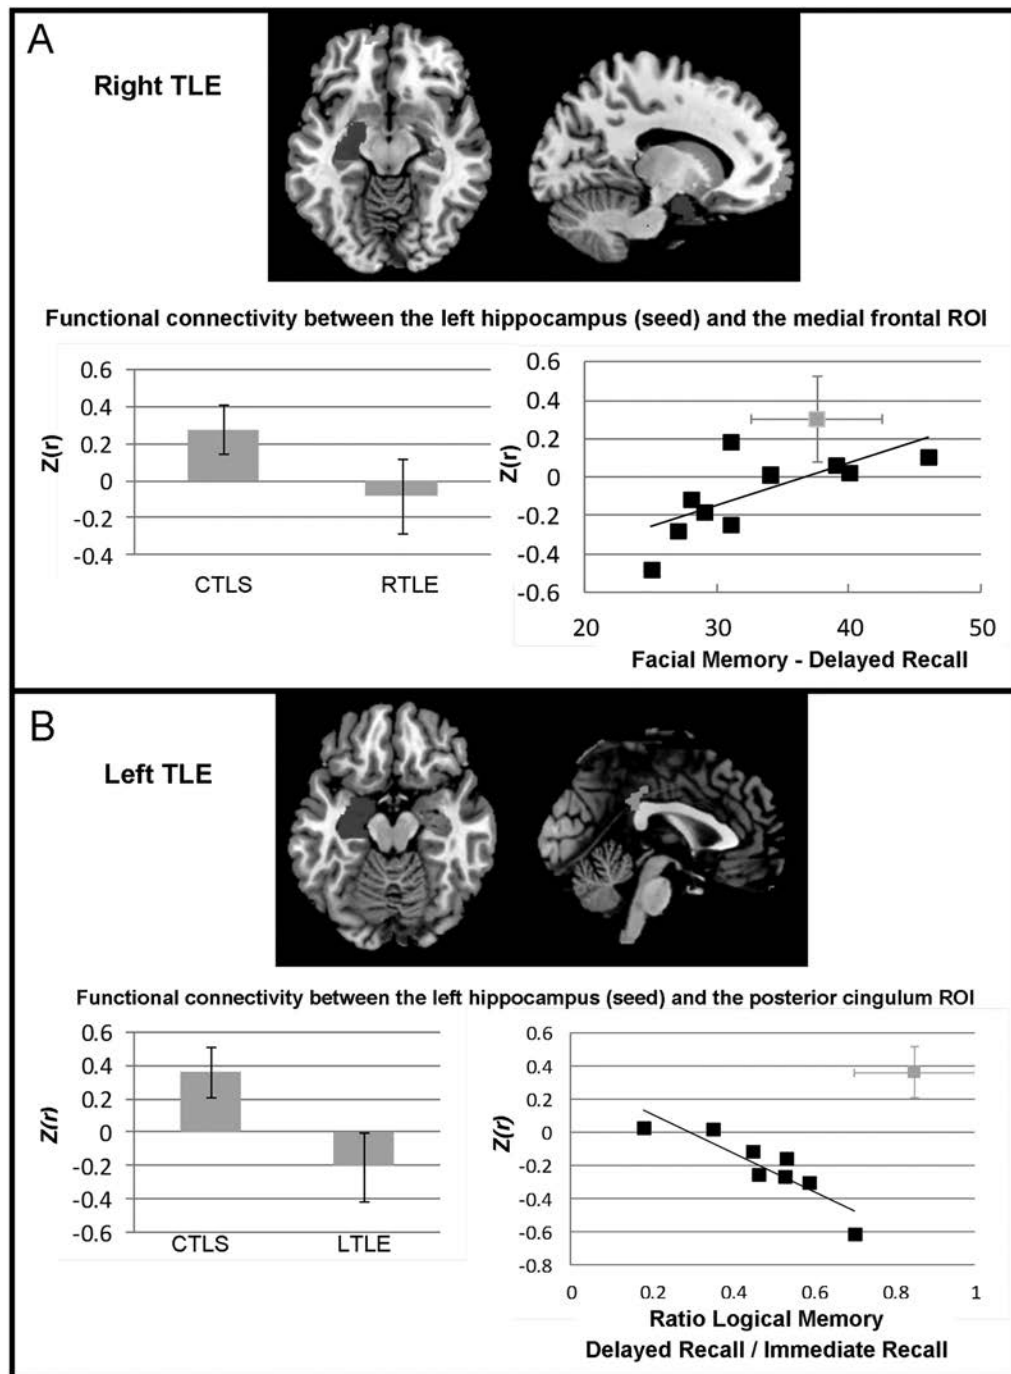

Figure 19.2 Correlation between FC values with the left hippocampal seed in right mesial TLE (RTLE), Panel A, and in left mesial TLE (LTLE), Panel B, with episodic memory scores. A color version of this figure can be found in Plate section 2

Modified and reprinted with permission from Human Brain Mapping, Doucet et al., (2013a), John Wiley and Sons.

Panel A: reduced FC between the left hippocampal seed (blue) and medial frontal cortex (green,  $x = -14$ ,  $y = 56$ ,  $z = -10$ ; also see Table 3) in right mesial TLE patients compared with controls (left bottom plot); positive correlation between FC values between these two regions and the Facial Memory II Delayed Recall scores (right bottom plot, Spearman correlation,  $r = 0.78$ ;  $p = 0.0045$ ). The normative values of the controls on the right bottom plot are shown by the green data point where the  $y$ -axis indicates the average FC value of the controls' data and the  $x$ -axis is the normative value of age-matched healthy controls of the Facial Memory II Delayed Recall scores II score. Bars indicate standard deviation.

Panel B: reduced FC between the left seed (blue) and posterior cingulate cortex (green,  $x = 2$ ,  $y = -36$ ,  $z = 32$ ; also see Table 3) in left mesial TLE patients compared with controls (left bottom plot); negative correlation between the FC values between these two regions and the ratio Logical Memory II Delayed Recall scores/ Logical memory I Immediate Recall scores (right bottom plot, Spearman correlation,  $r = -0.93$ ;  $p = 0.001$ ). The normative values of the controls are shown through the green data point where the  $y$ -axis indicates the average FC value of the controls' data and the  $x$ -axis is the normative value of age-matched healthy controls of the Logical Memory ration (II/I) score. Bars indicate standard deviation.

**Figure 19.3** Positive (+) and negative (–) functional connectivity with the right temporal lobe ROI (\*) in right unilateral TLE patients. DFG = medial part of superior frontal gyrus; MFG = middle frontal gyrus; IFG = inferior frontal gyrus; SPL = superior parietal lobule. *A color version of this figure can be found in Plate section 2*

at risk. Even lesional epilepsy with focal seizures appears to cause reactions throughout large regions of the brain, potentially impacting multiple cognitive functions and networks.

Importantly, these changes in network organization and FC appear related to actual cognitive performance, raising the possibility that episodic memory deficits in TLE are associated with changes in neocortical-hippocampal communication or interactions (i.e., changes in the excitatory/inhibitory balance) (Bartolomei et al., 2004; Liao et al., 2010; Tracy et al., 2014; Waites et al., 2006). For instance, Wagner and colleagues (2007) showed that stronger FC between the hippocampus and neocortical regions (e.g., inferior frontal and superior temporal cortices) was associated with better performance in right and left TLE patients during a verbal encoding and recognition memory task composed of concrete and highly imaginable word-pairs. Work from our lab (Doucet, Osipowicz, et al., 2013) has found the FC between the left non-pathologic mesial TL and the medial frontal cortex was positively correlated with delayed recall scores on a nonverbal memory task in right TLE patients, suggesting adaptive connectivity changes took place to preserve this memory function. In contrast, we observed a negative correlation between verbal memory performance and the level of FC between the left pathologic mesial TL and posterior cingulate cortex in left TLE patients, suggesting potential maladaptive changes in the pathologic hemisphere.

White matter (WM) connectivity can also be used to address issues of network reorganization. Fractional anisotropy (FA), which reflects microstructural integrity of WM, has shown that tracts proximal to the ictal focus have reduced FA in chronic TLE patients, i.e., the uncinate, the parahippocampal fasciculus, and the inferior longitudinal fasciculus (Ahmadi et al., 2009; Concha, Beaulieu, Collins, & Gross, 2009; Liacu, Idy-Peretti, Ducreux, Bouilleret, & de Marco, 2012). In addition, there is evidence that WM tracts in areas remote from the pathology have reduced FA as well, i.e., the

corpus callosum, the internal/external capsules, and the arcuate fasciculus (Arfanakis et al., 2002; Otte et al., 2012). FA reductions, at least in part, appear to depend on the side of epilepsy, with left TLE associated with more extensive FA reductions bilaterally, whereas those with right TLE have more limited reductions often restricted to ipsilateral tracts (Kemmtsu et al., 2011; Pustina, Doucet, Skidmore, Sperling, & Tracy, 2014; Voets et al., 2009). These FA reductions in some instances correlate with diminished memory performance (Diehl et al., 2008; Yogarajah et al., 2008). Recent pilot data from our lab, however, suggest that the relationship between FA and seizures is mediated by other factors. We compared healthy controls with unilateral (ictal) TLE patients who had either bilateral or unilateral interictal spikes on EEG. Unexpectedly, patients with bilateral interictal spikes had more normative FA values in tracts connecting the two hemispheres, suggesting that the spread of epileptic pathology occurs in the context of better WM structural connectivity (Osipowicz et al., under review). Thus, impaired WM connectivity indexed by an FA decrease may have the benefit of isolating the ictal focus from the rest of the brain, mitigating or delaying the effect of epileptic activity on remote healthy areas. In other work from our lab we examined several WM tracts to determine which, in the setting of TLE, might be most associated with seizure spread. Our results indicated that the tapetum was associated with contralateral epileptiform activity, implicating this structure in seizures and possible secondary epileptogenesis. We describe two mechanisms that might explain this association (the interruption of inhibitory signals or the toxic effect of carrying epileptiform signals toward the healthy hemisphere), but also acknowledge other rival factors that may be at work. In this study, we also report that TLE patients with bilateral spikes had increased lateral bitemporal lobe functional connectivity. This study brought together important functional and structural data to elucidate the basis of contralateral interictal activity in focal, unilateral epilepsy. Finally, in our lab (Pustina et al., 2014a) we examined right and left anterior temporal lobectomy (ATL) patients, and found that in left ATL patients, preexisting low FA values in right superior longitudinal and uncinate fasciculi normalized after surgery. Preoperative verbal fluency correlated with FA values in all areas that later increased FA in left TLE patients, but postoperative verbal fluency correlated only with FA of the right superior longitudinal fasciculus. The results demonstrated that genuine reorganization occurs in nondominant language tracts after dominant hemisphere resection, a process that may help implement the interhemispheric shift of language activation found in fMRI studies. Moreover, the results indicate that left TLE patients, despite showing more initial WM damage, have the potential for greater adaptive changes postoperatively than right TLE patients.

Based on all the previously discussed work on cognitive network reorganization in TLE, it is tempting to conclude that recruiting regions of the healthy hemisphere into the

network is an adaptive response to seizures, perhaps following the logic of material specificity (e.g., verbal memory shows a left-to-right hemisphere shift and recruitment in the setting of left temporal pathology and left language dominance). The evidence, however, is still too mixed, and other influential factors in terms of seizure type, strength of hemispheric dominance, education, chronological age, and variations in brain reserve have yet to be adequately explored. Indeed, when altered networks in TLE are discovered it is very difficult to know whether the pattern is innate and pre-morbid, or one that was initially organized normally and then reorganized in response to emergent and ongoing seizures, with the latter being the working assumption of most studies.

### Multifocal Deficits in Focal Epilepsies

Given the clear evidence for pathological mechanisms and reorganization effects operating outside the epileptogenic zone, it is no surprise that patients with intractable, long-standing focal epilepsy exhibit greater cognitive dysfunction than would be expected solely on the basis of their focal epileptogenic pathology (Hermann, Seidenberg, Schoenfeld, & Davies, 1997). While it is readily known that generalized tonic-clonic (Wang et al., 2011) and absence seizures (Luo et al., 2011) can cause widespread disruptions of neural connectivity patterns and lead to diffuse cognitive dysfunction, well beyond the regions considered most likely to be the ictal generator (i.e., the thalamus), there is also evidence that such remote effects emerge from focal epilepsies such as TLE (Liao et al., 2010; Waites et al., 2006), with both ictal and interictal activity playing a role (Fahoum, Lopes, Pittau, Dubeau, & Gotman, 2012). For instance, Oyegbile and colleagues (2004) demonstrated that, in comparison to a group of healthy controls, patients with TLE exhibited not only worse memory performance, but also inferior performance on measures of intelligence, language, executive function, and motor speed, highlighting the extratemporal and sometimes widespread neurocognitive deficits associated with a focal epilepsy syndrome. One of the most difficult challenges for neuropsychologists is the variability in cognitive outcome in individual epilepsy patients. While relatively robust effects of memory impairment have been demonstrated, there is also a persistent finding of interindividual variability among epilepsy patients, both among those who demonstrate a good response to medication and those who remain refractory to medical or surgical treatment. Hermann, Seidenberg, Lee, Chan, and Rutecki (2007) utilized a taxonomic approach to predict cognitive and behavioral outcome by identifying distinct cognitive phenotypes based solely on classification by cognitive profile. By utilizing cluster analysis techniques to identify demographic, seizure, and neurobiological features associated with different cognitive phenotypes, the authors highlighted the multifocal nature of cognitive deficits in TLE patients (see Figure 19.4). In an examination of 96 patients

Figure 19.4 Mean cluster performance across cognitive domains. Cluster 1 = minimally impaired group; Cluster 2 = memory impaired group; Cluster 3 = memory, executive, and speed impaired group.

Modified and reprinted with permission from *Journal of the International Neuropsychological Society*, Hermann et al. (2006), Cambridge University Press.

with TLE and 82 healthy controls, three distinct cognitive profile types emerged: minimally impaired (47%); memory impaired (24%); and memory, executive, and speed impaired (29%). The more globally impaired group was older, had a longer duration of epilepsy, was prescribed more medications, and demonstrated abnormal WM and CSF volume. The authors concluded that this group was most likely to have incurred an early neurodevelopmental insult, and a more protracted and severe course of epilepsy that led to greater overall neurocognitive dysfunction. The search for cognitive phenotypes may yield greater understanding of the variability within epilepsy groups. Before turning to summarize some of the major neuropsychological findings within the most commonly encountered examples of focal epilepsy, it important to consider the factors that cause multifocal deficit patterns.

Several mechanisms appear to offer a more specific explanation for deficits in cognitive functions not typically associated with region of ictal focus. These include: undiagnosed seizure activity elsewhere in the brain, diaschisis (downstream impact on functioning), seizure propagation (spread, secondary generalization, interictal activity), secondary epileptogenesis (new neural connections built up by seizures), or the neuronal burden of maintaining an inhibitory surround to control seizures (see Tracy, Osipowicz, Stamos, and Berman, 2010 for further exploration of these processes). While areas proximal to the epileptogenic zone may be most strongly affected, more remote regions relying on either long or indirect pathway connections could be susceptible to these processes (Eliashiv, Dewar, Wainwright, Engel, & Fried, 1997; Weiser, 2004). These extratemporal effects are not considered truly random, as they likely take advantage of relative differences in the breakdown of protective/inhibitory neuronal processes in other brain areas. For instance, ipsilateral frontal cortex seems to be a common dispersion

pathway for temporal lobe seizures, spreading through the uncinate fasciculus, with the contralateral temporal lobe (Morrell & deToledo-Morrell, 1999) being another common spread path. Neuropsychological testing can be sensitive to these extratemporal effects, but no current method exists to distinguish between deficits caused by the ictal focus versus those emerging from these other mechanisms. The hope is that by better integration of the neuropsychological data with techniques that can distinguish between these mechanisms (electrocorticography, functional connectivity analyses) finer-grained linkages between the neuropsychological data to specific epileptogenic processes can be made.

### *Temporal Lobe Epilepsy*

Neuropsychological deficits within the episodic memory domain are well established in patients with MTLE (Bonilha, Alessio, et al., 2007; Helmstaedter & Kockelmann, 2006; Marques et al., 2007). Such impairments can be logically correlated with underlying medial temporal lobe pathology. However, patients with focal, lesional TLE have consistently demonstrated neurocognitive impairments in intelligence, language, visuospatial, executive, or motor function—impairments that cannot be solely explained by the underlying focal mesial neuropathology (Hermann, Seidenberg, & Jones, 2008). Several studies have documented that cognitive dysfunction in mesial TLE can, in particular, extend to domains such as language (e.g., naming and fluency) and executive functioning (Bartha et al., 2004; Corcoran & Thompson, 1993; Grant, Henry, Fernandez, Hill, & Sathian, 2005; Hermann, Wyler, & Richey, 1988; Howell, Saling, Bradley, & Berkovic, 1994; Martin et al., 2000; Schefft, Marc Testa, Dulay, Privitera, & Yeh, 2003; Shulman, 2000; Strauss, Hunter, & Wada, 1993; Tracy & Boswell, 2008; Trenerry, Jack, & Ivnik, 1993). For instance, Rzezak and colleagues (2007) identified significant executive dysfunction in 84% of a cohort of children and adolescents with TLE.

With regard to these deficits, it is likely extensive anatomic and functional connectivity between the frontal and temporal lobes that allows the temporal epileptogenic focus to impact frontal and prefrontal regions (Braakman et al., 2011). Evidence of the extratemporal seizure impact can be found in remote nonictal gray matter. For instance, structural neuroimaging studies have consistently shown atrophy in an extensive bilateral extratemporal network in unilateral TLE patients, most reliably in thalami, parietal, cerebellar, and contralateral temporal cortex including the contralateral hippocampus and parahippocampal gyrus (Bonilha, Rorden, et al., 2007; see review of Keller & Roberts, 2008; Riederer et al., 2008; Staba et al., 2012). Also, patients with a mesial temporal epileptogenic focus demonstrate ipsilateral reductions in extratemporal regions, including the thalamus, posterior cingulate cortex, cerebellum, and frontal and parietal opercular cortex (Cormack et al., 2005). Research with magnetic resonance imaging (MRI) using voxel-based

morphometry (VBM) found hippocampal atrophy correlated with a reduction of gray matter concentrations in extra-hippocampal limbic regions, lateral temporal lobe, and orbito-frontal cortex (Bonilha et al., 2006; Duzel et al., 2006; Guerreiro et al., 1999).

This extratemporal seizure burden also appears in WM, with diffusivity abnormalities in TLE patients not restricted to the known epileptogenic temporal lobe (Gross, 2011), but extending to regions such as the posterior corpus callosum (Arfanakis et al., 2002), cerebellum, and the contralateral WM near the healthy (i.e., nonsclerotic) hippocampus, amygdala, and temporal pole (Thivard et al., 2005). Yu et al. (2008) found WM reductions in both temporal lobes, bilateral frontal lobes, and the corpus callosum. Even more distant from the epileptogenic region, cerebellar atrophy in the cerebellum has also been noted (Sandok, O'Brien, Jack, & So, 2000). In our lab (Pustina et al., 2014b), we examined right and left ATL lobectomy patients, and found that left ATL patients had lower FA values in tracts outside the pathologic temporal lobe (e.g., right superior longitudinal and uncinate fasciculi). In terms of still other measures, metabolic compromise appears to emerge both in the ipsilateral (ictal) and contralateral hemisphere in TLE patients, consisting of abnormal N-acetyl aspartate/choline ratios as derived from magnetic resonance spectroscopy. Blumenfeld and colleagues (2004) found increased cerebral blood flow (CBF) in the ipsilateral temporal lobe associated with seizure activity and simultaneously diminished CBF in frontal and parietal cortical regions. Arnold et al. (1996) reported suppressed regional cerebral glucose metabolism in the hippocampus, parahippocampal gyrus, and middle temporal gyrus, all ipsilateral to the epileptogenic focus. Blumenfeld et al. (2004) reported prominent slow-wave EEG activity in extratemporal areas during temporal lobe seizures, most notably the bilateral frontal and ipsilateral parietal association regions. Clearly, distinguishing the cognitive effects of these different seizure-related impacts and the time frame of their effects would be ideal, but is currently beyond reach by standard neuropsychological testing.

### *Frontal Lobe Epilepsy*

Frontal lobe epilepsy (FLE) is the second most common localization-related or focal epilepsy. However, there are relatively few systematic studies examining the effect of FLE on cognition, and there are no known group studies examining neuropsychological functioning in nonlesional FLE cases. It has been more difficult to establish a “cognitive profile” of FLE due to the functional heterogeneity of the frontal lobes, the strong interconnections between prefrontal regions and associated brain regions, and the rapid propagation of frontal lobe seizures both bilaterally and to other cortical regions (Elger, Helmstaedter, & Kurthen, 2004; Lee, 2010; Yu et al., 2008). That said, there is good evidence suggesting the cognitive dysfunction in FLE is characterized by impairments

similar to those seen in other frontal lobe diseases, with prominent behavioral changes and deficits in motor skills, attention, working memory, psychomotor speed, response inhibition, concept formation, and fluency (Exner et al., 2002; Helmstaedter, Kemper, & Elger, 1996). In a review of childhood FLE, attention, visuospatial organization, verbal search, mental flexibility, impulse control, working memory, complex motor sequences and coordination, and executive function (planning ability, response inhibition) deficits were the primary deficits, but there was significant interindividual variability. General reductions in IQ, language impairment, and memory deficits have also been reported (Braakman et al., 2011).

Emerging evidence from resting-state fMRI of altered network organization and connectivity patterns supports the network model of cognitive dysfunction in FLE. Vaessen and colleagues (2014) revealed whole-brain resting-state network abnormalities in children with FLE. In their cohort, children with more isolated functional brain subnetworks demonstrated greater cognitive impairment, suggesting less efficient interregional transfer. The authors concluded that decreased coupling between large-scale functional network modules is a hallmark for impaired cognition in childhood FLE. This line of research is in its infancy, with other data suggesting both high local and remote connectivity abnormalities compared to healthy controls (Luo, An, Yao, & Gotman, 2014). Centeno and colleagues (2014) reported evidence from structural MRI of increased gray matter volume in the piriform cortex, amygdala, and parahippocampal gyrus bilaterally, as well as the left mid-temporal gyrus of patients relative to controls, suggesting involvement of these areas in the epileptogenic network of FLE. Braakman et al. (2014) conducted diffusion tensor imaging (DTI) examining cerebral WM properties in children with FLE and healthy controls and revealed WM abnormalities predominantly in posterior brain regions beyond the epileptogenic focus. Importantly, the extent of WM abnormalities correlated with the severity of cognitive impairment. Abnormal structural network connectivity is increasingly being associated with impaired neurocognitive function (Widjaja, Zamyadi, Raybaud, Snead, & Smith, 2013).

### ***Parietal and Occipital Lobe Epilepsy***

Parietal lobe epilepsy (PLE) is rare even in large specialty centers, and few investigational series of PLE patients have been reported. The parietal lobe is comprised of large areas of association cortex and an extensive synaptic network that lends itself towards multiple seizure spread patterns, particularly to the frontal and temporal lobes (Foldvary et al., 2001; Williamson et al., 1992). Electrophysiological studies suggest that the interictal epileptiform discharges in PLE are widespread and multifocal, and often bilateral, suggesting an irritative zone that extends well beyond the epileptogenic focus (Binder et al., 2009). In addressing the

frequent mislocalization of parietal lobe seizures on EEG, Ristic, Alexopoulos, So, Wong, and Najm (2012) refer to PLE as the “great imitator” among focal epilepsies due to greater variability in interictal and ictal EEG findings compared to FLE or TLE. Aura and ictal phenomena associated with PLE are often somatosensory in nature, and include paresthesias and dysesthesias, but ictal spread to the frontal lobe often transmutes ictal and postictal symptoms (Jokeit & Schacher, 2004). There have been very few studies exclusively examining cognition in PLE, likely due to the low frequency of such cases. Lesions in the parietal lobe have been associated with visual associative agnosia; attentional dysfunction, including hemineglect; visuospatial deficits; apraxia; and linguistic deficits. There is some evidence suggesting cognitive impairment extending beyond the epileptogenic zone, as children with PLE demonstrate diminished IQ, poor memory, inattention, and executive dysfunction (Gleissner, Kuczaty, Clusmann, Elger, & Helmstaedter, 2008).

Regarding occipital lobe epilepsy (OLE), ictal spread into frontal and temporal regions is quite frequent. Knopman and colleagues (2014) examined the cognitive profile of pre-surgical OLE patients with functional neuroimaging and neuropsychological assessment. Mild impairments in IQ, speed attention, and executive functioning were identified. In this sample, OLE was associated with widespread cognitive comorbidity, suggesting cortical dysfunction beyond the occipital lobe, another example of remote cortical dysfunction in focal epilepsy. Further, the investigators found that verbal memory impairment was associated with left temporal lobe hypometabolism, supporting the relationship between neuropsychological dysfunction and remote hypometabolism in focal epilepsy. Bilo et al. (2013) identified impairments in complex visuospatial and executive skills in a group of normal IQ patients with cryptogenic and idiopathic OLE, again suggesting that frontal and visuospatial cognitive deficits may reflect epileptic activity spreading within a neural network that extends beyond the occipital lobe.

### **Factors Mediating Cognitive Network Reorganization in Epilepsy**

#### ***Age of Onset and Chronological Age***

The best substantiated cases of cognitive reorganization involve individuals with early onset epilepsy (Springer et al., 1999). While seizures at an early age put individuals at risk for the effects of chronicity, the young brain exhibits greater plasticity, making it both more hyperexcitable and prone to seizures (Raol, Budreck, & Brooks-Kayal, 2003), but also better suited for cognitive reorganization. Left-sided hemispherectomy patients can display reorganization of language to the right side, though these children still have significant language deficits. This is particularly evident when removal of the dominant hemisphere occurs after age 6, a critical period for language acquisition (Hertz-Pannier et al., 2002;

Vargha-Khadem et al., 1997). Approximately 30% of children with epilepsy have intellectual and developmental disabilities (Tuchman, Moshe, & Rapin, 2009).

Atypical language networks in pediatric populations have been established through both intracarotid amobarbital studies (Rasmussen & Milner, 1977) and an abundant fMRI literature (Anderson et al., 2006; Yuan et al., 2006), with good evidence that patients with symptomatic and cryptogenic left TLE demonstrate varying evidence of language reorganization. In nonpatients, the natural developmental course of language shows a trend of increasingly left hemispheric lateralization from childhood to adulthood, with language lateralization in the dominant hemisphere increasing between the ages of 5–20, plateauing between ages 20–25, and slowly decreasing between ages 25–70 (Szaflarski, Holland, Schmithorst, & Byars, 2006). In order to disentangle the effect of pure epilepsy from lesional epilepsy in the pediatric population, Datta and colleagues (2013) examined the rates of atypical language dominance in children with benign epilepsy with centrotemporal spikes (BECTS), a common idiopathic pediatric epilepsy variant. While BECTS patients did not differ neurocognitively (perhaps due to the relatively mild nature of cognitive deficits associated with BECTS), patients demonstrated significantly lower language laterality indices than controls, with greater bilateral or right hemispheric activations during a sentence generation task. Notably, this finding persisted when controlled for duration of epilepsy and medication side effects.

At both a neuronal and cognitive level, neurocognitive reorganization can come at a cost. Animal studies have suggested a concomitant depletion in neural progenitor cells associated with neural repair. For instance, Dallison and Kolb (2003) found that when rats suffered early brain damage, hippocampal neurogenesis in adulthood was far below that of controls. The concept of “crowding effects” also demonstrates this phenomenon. The reduction of typically right hemisphere functions in favor of dominant hemisphere verbal memory processing implies that language can reorganize to the right hemisphere in left hemisphere epilepsy; however, there is often a cost in terms of material-specific memory loss or conflicts in information processing—disabling, for instance, simultaneous verbal and visual-spatial processing (Elger et al., 2004).

### ***Impact of Chronicity***

Factors such as the temporal pattern of the brain insult (i.e., slow vs. rapid) change the likelihood of both reorganization and the restoration of function. “Slow growing” pathologies (e.g., intractable seizures) increase the probability and efficiency of reorganization processes (Braun et al., 2008), particularly in regions more remote from the “at risk” skill or function. Interestingly, the initial brain insult that might produce a seizure is often followed by a latency period of epileptogenesis, which can take up to years before a clinically

observable seizure occurs. Likewise, cognitive problems are often not demonstrated until after this latency period. Yet, once seizures begin, the disease and cognitive problems can progress even during the nonsymptomatic interictal state, although very little is known about the potentially unique cognitive impact of this interictal period.

Cognitive network reorganization is dynamic and there is an inherent constant evolution of these networks in response to chronic, intractable seizures. Consequently, the cognitive impact of seizures must be conceptualized with this underlying framework in mind, as well as interplay between cognitive network reorganization and the effects of advancing age. Resting-state FC research has begun to disambiguate these complex interactions. For instance, a resting-state study by Morgan et al. (2011) showed that cross-hippocampal connectivity varied with TLE duration. In the first ten years of seizures, connectivity was variable and often diminished, but beyond that point interhemispheric connectivity appeared to increase. Wang et al. (2011) investigated generalized tonic-clonic seizure (GTCS) patients at rest, and found that the degree of FC within key regions of either the DMN (the right medial prefrontal cortex), or the dorsal attention network (e.g., left intraparietal sulcus) were negatively correlated with epilepsy duration, suggesting damage accrues to these networks in association with more chronic GTCS. FC data from our lab (Doucet, Osipowicz, et al., 2013; Doucet et al., 2014) suggest that the characteristics of whole-brain organization (e.g., measures of segregation such as clustering coefficient, or CC) vary as an interaction between age of seizure onset and lesional status in TLE. For instance, when TLE onset comes early in life, the impact of MTS, the most common etiology for TLE, on whole-brain organization may be mitigated. In our data the late-onset MTS group, who had more perturbed whole-brain organization relative to matched controls, had an illness duration three times shorter than the early onset group, suggesting that the adult injured brain may need more time to develop compensatory responses to adult MTS pathology. Interestingly, we found very few differences between the late- and early onset groups in non-lesional TLE (i.e., no evidence of a structural lesion), suggesting that age of onset has little progressive impact on FC when no focal lesion is detectable.

Little is known about the effect of chronic seizures on the temporal stability of large-scale brain networks, such as those known to be involved in key cognitive function such as memory (i.e., the ventral default mode network, or vDMN). In our lab, we devised a measure of temporal stability of functional resting-state connectivity, capturing temporal variations of BOLD correlations between brain regions. In a comparison of TLE patients and matched, healthy controls, we found that temporal stability in the vDMN involving the temporal lobe does characterize the healthy brain, but that such functional connectivity in TLE patients shows instability (Robinson et al., 2014). It was unclear whether such instability arose as a pathologic mechanism from the

impact of seizures or as a protective mechanism to ensure functional integrity and prevent seizure spread (Tracy et al., 2014). Given the link of the vDMN network with episodic memory, the findings raise the possibility that the episodic memory disorder observed in TLE may be related to instability of the vDMN network. Electrophysiology research is beginning to address the dynamic changes that occur in networks over various time scales (Honey, Kotter, Breakspear, & Sporns, 2007). As this knowledge increases, we will be able to distinguish the more transient acute effects (i.e., ictal or temporary interictal effects) from the initial and more drawn-out effects of chronic seizures.

**Impact of Cerebral Dominance**

There is strong evidence that early onset epilepsy is associated with higher rates of atypical language representation involving either bilateral or more complete language representation in the right hemisphere. In an intracarotid amobarbital study of TLE from our lab (Tracy et al., 2009), we found that 40.3% of left TLE patients ( $n = 124$ ) displayed atypical language organization (i.e., stronger right hemisphere representation) on at least one language skill (e.g., repetition, naming, comprehension, reading, and speech quality/dysarthria; see Figure 19.5). While the majority (60%) of patients showing atypical language representation do so on more than one language skill, the proportion showing atypicality on all five skills was low, only 5.6% of the left TLE sample. These data clearly show atypical hemispheric dominance is not an “all-or-nothing” phenomenon, with

all aspects of language reorganizing together in a monolithic fashion. Thus, hemispheric language dominance and its reorganization is a heterogeneous, complex process, with distinct language systems showing independence, making clear that the pressures compelling atypical reorganization in TLE do not work with equal force on all language functions.

Finally, it is worth noting that there is some evidence that gray matter extra-temporal damage is more widespread in left compared to right-sided TLE (Riederer et al., 2008), raising the possibility that regional seizure network growth may be influenced by brain function properties such as the presence of language dominance.

**Cognitive and Behavioral Impact of Medications**

Antiepileptic drugs (AEDs) are frequently associated with cognitive side effects. While the newer AEDs typically exhibit less-adverse neurocognitive profiles, medication must be considered when distinguishing the multiple forces influencing a patient’s cognition. Medication side effects can negatively affect medication compliance, everyday functioning, and quality of life (Witt & Helmstaedter, 2013). Side effects are generally based on four factors: dose concentration, inherent side effects, idiosyncratic effects, and drug load (i.e., additive or interactive effects of multiple medications). While a comprehensive review is beyond the scope of this chapter, a basic knowledge of AED side effect profiles is necessary for neuropsychological evaluation of patients with seizure disorders.

Figure 19.5 Significant effect of four level variable reflecting age of onset and seizure focus groups for Reading (Chi Square [3] = 11.95,  $p < 0.01$ ), and the Grand Mean (Chi Square [3] = 9.7,  $p < 0.05$ ).

Panel A, left chart. Percent of total sample ( $N = 124$ ) showing atypical dominance for one, two, three, four, or all five language skills.

Panel B, right chart. Mean Laterality Index of five language skills for left and early, left and late, right and early, right and late, and all four groups.

Table 19.1 Overview of affected domains by different antiepileptic medications

Antiepileptic agent	Affected Domains		
Carbamazepine	↓	↓	
Clobazam	↓	0	↓
Felbamate	(↓)		
Gabapentin	↓	0	0
Lamotrigine	0	0	0
Oxcarbazepine	0	0	
Phenobarbital	↓/↑	0	
Phenytoin	↓	↓	↓
Tiagabine	↓	↓	
Topiramate	0	0	0
Valproic Acid	↓	↓	↓
Vigabatrin	↓	↓	0
Zonisamide	0	0	0

↓, negative effect; ↑, positive effect; (↓): possible effect; 0: no deficits. Modified and reprinted with permission from *Epilepsy & Behavior*, Witt & Helmstaedter (2013).

Table 19.1 depicts in general terms the cognitive profile associated with the major current antiepileptic medications.

Importantly, while much of the literature compares and contrasts the relative cognitive impact of AEDs, the majority of medications have some, albeit sometimes subtle, impact on cognitive functioning, particularly attention and memory (Witt & Helmstaedter, 2013). Of the traditional AEDs, benzodiazepines and phenobarbital are more commonly associated with negative cognitive side effects in comparison to phenytoin, valproic acid, or carbamazepine. Phenobarbital has been linked to lower IQ (Farwell et al., 1990), slowed psychomotor speed, impaired attention, and reduced processing speed (Manni, Ratti, Perucca, Galimberti, & Tartara, 1993). While relatively less impactful, phenytoin has been associated with declines in visuomotor function (Pulliainen & Jokelainen, 1995) and carbamazepine has been associated with reductions in information processing speed, attention, memory, and verbal fluency (Wesnes, Edgar, Dean, & Wroe, 2009). Valproic acid has consistently demonstrated minimal cognitive interference (Eddy, Rickards, & Cavanna, 2011), but has been associated with Parkinsonism in a very small subset of patients (Ristic, Vojvodic, Jankovic, Sindelic, & Sokic, 2006).

In large part, second-generation AEDs have a superior cognitive profile, with the exceptions of topiramate and, potentially, zonisamide. Topiramate is notorious among AEDs for cognitive side effects, and while attention and a specific verbal fluency deficit are most common, impaired concentration, cognitive slowing, psychomotor slowing, short-term memory, and working memory have all been reported (Coppola et al., 2002; Fritz et al., 2005; Froscher et al., 2005; Gomer et al., 2007). There is evidence of improvement in cognitive functions following topiramate withdrawal (Kockelmann, Elger, & Helmstaedter, 2003). There is also emerging evidence of

cognitive dysfunction associated with zonisamide. A prospective, randomized trial of the long-term effects of zonisamide monotherapy demonstrated good seizure control and minimal increase in psychiatric symptomatology but significant reductions in aspects of memory, verbal fluency, and information processing speed (Park et al., 2008).

Amongst the second-generation AEDs, levetiracetam and lamotrigine demonstrate the most appealing neurocognitive profiles. Studies have consistently shown no cognitive impact for these AEDs (Bootsma et al., 2008; Huang, Pai, & Tsai, 2008; Levisohn et al., 2009; Pressler, Binnie, Coleshill, Chorley, & Robinson, 2006). In fact, both have been shown to have positive effects on cognition. For instance, a randomized, double-blind, placebo-controlled examination of levetiracetam reported improvements in cognitive set-shifting, attention, and verbal memory in patients with complex partial seizures in comparison to healthy controls (Zhou et al., 2008). As a result of such work, levetiracetam is being evaluated for broader use as a cognitive enhancer. Similarly, few adverse cognitive effects have been associated with tiagabine (Aikia, Jutila, Salmenpera, Mervaala, & Kalviainen, 2006) and there is some evidence of improvement in motor speed, concentration, and verbal fluency with tiagabine therapy (Dodrill et al., 1998). Unstudied aspects of antiepileptic medications remain the effects of shorter versus longer term use, and the way particular medications may interact with aging.

### Are Cognitive Deficits Progressive?

There are somewhat mixed results in the literature when trying to determine if cognitive deficits in epilepsy worsen with continued seizures. Some studies suggest a relative stability in cognitive status over time (Dodrill & Wilensky, 1992), whereas most others suggest that when seizures remain intractable there is steady damage to hippocampal circuitry, with progressive and cumulative adverse cognitive effects (Bernhardt, Chen, He, Evans, & Bernasconi, 2011; Sutula, 2004). Several studies of TLE have suggested that neuropsychological deficits increase with epilepsy duration (Helmstaedter, 2002; B. Hermann, Seidenberg, & Bell, 2002; Jokeit & Ebner, 2002). A longitudinal study of ATL patients post-surgery revealed progressive cognitive decline with ongoing intractable seizures (Helmstaedter, Kurthen, Lux, Reuber, & Elger, 2003). There does appear to be a mild accumulating and deteriorative effect on IQ in TLE (Dodrill, 2004), with some cross-sectional studies suggesting IQ declines after about three decades (Jokeit & Ebner, 2002). Other longitudinal studies make clear that TLE causes a slow and steady decline in episodic memory that cannot strictly be accounted for by age (Hamberger & Cole, 2011; Jokeit & Ebner, 1999; Rausch et al., 2003). It may be that duration of active epilepsy is a better predictor of the severity of cognitive deficits than type or even location of the seizures (Farwell, Dodrill, & Batzel, 1985). Fortunately, there is some data that suggests

memory decline in epilepsy can be stopped, if not reversed, if seizures are fully controlled (C. Helmstaedter et al., 2003).

There are clear neuroanatomical differences in chronic TLE patients in comparison to healthy controls. Dabbs and colleagues (2012) reported extensive anatomic abnormalities in a group of adults ( $N = 55$ ) with childhood/adolescent onset epilepsy. The authors identified significant abnormalities in subcortical structures, cerebral gray matter, and WM, in terms of both total volume and thickness in temporal and extratemporal lobes (frontal and parietal). In comparison to healthy controls, however, age-accelerated changes were identified in the third and lateral ventricles only, suggesting that brain changes occurring in epilepsy progressed in a largely age-appropriate manner, with the exception of age-accelerated ventricular expansion.

Helmstaedter et al. (2014) suggest a developmental hindrance effect, such that the majority of cognitive deficits evolve at the onset of, if not before, the first seizure, and interfere with normal cognitive development. Critical phases for episodic memory are at work throughout childhood and young adulthood; when these critical periods are interfered upon, the risk for premature cognitive decline increases. This notion is supported by a Helmstaedter and Elger (2009) study examining cross-sectional comparisons of age-related regressions on verbal learning and memory in a large TLE sample ( $n = 1,156$ ) compared to healthy controls ( $n = 1,000$ ). The authors identified critical phases during which epilepsy interfered with normal cognitive development during childhood and in adolescence. The learning/memory curve for TLE patients peaked earlier (ages 16–17 vs. 23–24 in healthy controls), but was then comparable to the normal group. However, due to the initial discrepancy between groups, TLE patients reached levels of impairment significantly earlier. The implications of this model highlight the importance of early control of epilepsy, and the value of examining the interaction between the life course of epilepsy and aging/developmental effects.

### **Interaction Between Cognitive and Emotional/Behavioral Disruptions**

The comorbidity of epilepsy and depression is well established (Fuller-Thomson & Brennenstuhl, 2009; Tellez-Zenteno, Patten, Jette, Williams, & Wiebe, 2007). Depression and anxiety represent the most commonly reported comorbid symptoms by TLE patients (Tracy, Dechant, Sperling, Cho, & Glosser, 2007; Tracy, Lippincott, et al., 2007). Lifetime prevalence estimates of depression in epilepsy range from 13% to 35%, with much of the variability accounted for by the heterogeneity in depression ascertainment methods (Fiest et al., 2013). Depression is the strongest predictor of diminished quality of life in epilepsy, not seizure frequency, nor age of epilepsy onset (Boylan et al., 2004; Tracy, Dechant, et al., 2007).

Historically, patients with TLE were thought to experience more depressive symptoms than patients with generalized

epilepsy or extra-temporal foci (Harden, 2002), although this finding has not been consistently replicated. There are multiple cumulative factors that contribute to depression in epilepsy, including seizure frequency, age of onset, laterality of temporal lobe focus, and concomitant frontal lobe dysfunction (Garcia, 2012).

More recently, we have begun to understand the neurobiology behind the comorbidity of psychiatric symptoms and TLE, with some arguing that depression emerges from epileptic activity (Reuber, Andersen, Elger, & Helmstaedter, 2004). Given the major role of the amygdala in the processing of fear and related emotions (LeDoux, 2000; Phelps & LeDoux, 2005), several studies have suggested this structure plays a role in the expression of comorbid emotional conditions (see review of Kondziella, Alvestad, Vaaler, & Sonnewald, 2007). A positive correlation has been described between the left amygdala volume and depression severity in left TLE patients (Tebartz van Elst, Woermann, Lemieux, & Trimble, 2000, 1999), with the authors suggesting the amygdala is hyperactive in anxiety and mood disorders (Tebartz van Elst et al., 1999). Physiologic studies have demonstrated a positive correlation between the density of neuropeptide Y-positive neurons in the amygdala and depression scores in MTLE patients (Frisch et al., 2009). Also, studies in psychiatric samples have revealed a direct relation between atypical amygdala responsiveness and either anxiety (Killgore & Yurgelun-Todd, 2005; Thomas et al., 2001) or depression levels (Abercrombie et al., 1998; Roberson-Nay et al., 2006). The amygdala, and more generally the limbic system, of the right hemisphere is more highly involved in emotional processing (see reviews of Davidson, 2003; Gainotti, 2012), and is associated with higher levels of panic and other emotional disorders than the left hemisphere (Sazgar, Carlen, & Wenberg, 2003).

As was the case with cognition, neuroimaging techniques are providing a growing body of evidence that the functional abnormalities in MTLE associated with their psychiatric status are not limited to the epileptogenic region. For instance, task (i.e., emotion-driven) fMRI imaging has provided evidence of amygdala abnormalities in MTLE. Bonelli et al. (2009) showed that left MTLE patients had significantly reduced activation in left and right amygdala compared to controls and right MTLE patients during the viewing of fearful and neutral faces. In addition, these authors demonstrated that in right but not left MTLE patients, bilateral amygdala activation was significantly related to the level of anxiety and depression reported. Data from our lab showed that FC emerging from subdivisions of the amygdala are distinct and vary with the side of the epileptic pathology. Right MTLE patients show more functional network impairments involving the amygdala compared to controls than left MTLE patients, with these impairments associated with increased psychiatric symptomatology (see Figure 19.6; see also Doucet, Skidmore et al., 2013).

As these findings vary by amygdala subregions, they suggest that lateralized epileptic pathology may disturb specific emotional processes and psychiatric symptoms, with indications that different symptoms are subserved by different functional connectivity networks. Thus, epileptic pathology in the emotion-dominant right hemisphere appears to negatively impact the expression of emotion-related networks. Our data highlight opposite functional connectivity relations between anxiety, depression, and brain functioning in right and left MTLE, arguing against a simple or highly general conceptualization of reorganization in unilateral TLE. There may be several types of reorganization, with right hemisphere pathology playing a crucial role in the reorganization of emotion functions. Thus, hemispheric function and dominance may have a large impact on the nature of seizure-related reorganization, with left MTLE patients showing more hippocampal-based disruptions in association with verbal memory (Doucet, Osipowicz, Sharan, Sperling, & Tracy, 2012), and right MTLE patients showing more amygdala-based disruptions in association with emotional states and emotion processing.

Another recent pilot study from our lab identified psychiatric changes postsurgically in both left (LTLE) and right TLE (RTLE). However, the direction of the effects differed in the groups such that the LTLE group consistently demonstrated a worsening of symptoms postsurgery, whereas the RTLE group had lower levels of anxiety/stress in association with the decreases in right amygdala volume that came with the right temporal lobe resection (see Figure 19.7). In combination, these data may suggest the catalyst of postsurgical psychiatric symptom change differs in the two ATL groups, with the left group more susceptible to causes less related to brain structure and more related to diminished dominant hemisphere functions (e.g., language/memory), and the impact of these deficits on communication or vocational

skills. In contrast, psychiatric symptom change in right ATL appeared more closely aligned with structural change (i.e., loss) in the ipsilateral amygdala, reducing pathologic emotion processing (Moadel et al., 2014).

The functional consequences of these potential amygdala effects most clearly manifest in emotion processing and psychiatric symptoms, but limbic system effects involving depression and emotional status may also have a deleterious impact on cognitive performance in TLE (Tracy, Lippincott, et al., 2007).

### Predicting Neuropsychological Status After Resective or Ablative Surgery

Improved seizure control is the driving factor in epilepsy surgical decision making, but preservation of cognitive function is also important. The potential for cognitive decline following surgery is balanced by the competing need to remove all of the potential epileptogenic tissue; however, exact identification is uncertain, as even the best imaging and electrocorticography techniques leave uncertain the epileptogenicity of areas surrounding the epileptic focus. The role of functional neuroimaging (both task driven and resting-state BOLD) has expanded to help inform surgical planning and strategy, while neuropsychology has also improved its ability to identify cognitive functions at risk and is beginning to contribute more strongly to predictive algorithms. The gold standard for good outcome remains strong seizure control, and this is the case for both clinicians and patients. For example, an examination of health-related quality of life (HRQOL) in patients undergoing epilepsy surgery found an improvement in HRQOL in those patients who were seizure-free postsurgically, despite memory declines (Langfitt et al., 2007). HRQOL among the patients who were not in seizure remission at two and five year intervals remained stable when there

Comparison of Pre- and Post-Surgery PAI Subscale Scores in LTLE and RTLE Patients

Figure 19.7 Average pre- and post-surgical PAIANX, PAIDEP, and PAIARD scores plotted pre- and postsurgery. Psychiatric scores tend to decrease in RTLE patients postsurgery, whereas scores tend to increase postsurgery in LTLE patients.

was no change in memory, but HRQOL was significantly lower at these intervals when memory declined. Thus, while seizure freedom is often paramount, in the face of continued seizures, cognitive changes are particularly distressing and debilitating.

Most of the data predicting cognitive outcome postsurgically comes from ATL patients. In this group, up to 80% of patients experience significant seizure reduction postsurgery (Engel, 1993; McLachlan et al., 1997; Sperling, O'Connor, Saykin, & Plummer, 1996). While it is intuitive to suggest that reduced seizure freedom will lead to improved cognitive functioning, there is evidence that what accounts for this effect is the improved status of nonresected regions related to the release from seizure burden (Rausch, 1987; Rausch & Crandall, 1982).

The abundant postsurgical literature has identified clear risk factors for significant cognitive decline postsurgically. Factors associated with worse cognitive outcomes are, most notably: good structural and functional integrity of the to-be-resected tissue, bilateral or multifocal epileptogenic focus, dominant hemisphere resection, cerebral volume loss, and earlier age of onset. Each factor tends to emphasize either the role played by the functional adequacy of the to be resected tissue, or the functional reserve of nonresected tissue, to generate potential cognitive reorganization and the underlying neuroplastic processes associated with the maintenance and/or recovery of function. It is interesting to note that the predictors of good surgical outcome are similar (though not identical) to those that predict a good cognitive outcome: namely, a lesional MRI (e.g., MTS), unilateral temporal lobe spikes, concordant EEG, and a history of febrile seizures (Spencer, 2005). Approximately 30%–60% of dominant ATL patients experience substantive decline in verbal memory (Hamberger & Drake, 2006; McCormick et al., 2013). While identifying a discrete pattern of visual memory decline in nondominant ATL patients has been more elusive, there is some evidence that spatial memory and learning are affected more by right than left hemisphere surgery (Dulay et al., 2009). Faced with such group data, the challenge and question for neuropsychologists becomes how to predict decline in the individual case.

Memory declines are more likely if there is evidence that the to-be-resected temporal lobe is structurally and functionally intact and contributes to normal memory function (Bell, Lin, Seidenberg, & Hermann, 2011; Chelune, Naugle, & Luders, 1991; Harvey et al., 2008). High preoperative verbal memory scores results in greater cognitive risk. For instance, Chelune et al. (1991) found that 67% of MTL patients with average memory scores presurgery had a decline of at least 10% six months after surgery, whereas only 12% of those with borderline or poor preoperative memory showed a 10% decline postsurgery. This risk has been replicated in visual memory in RATL patients. Dulay and colleagues (2009) demonstrated declines in spatial location memory in RATL patients, with a particular vulnerability evident in patients

with stronger presurgical spatial memory. Studies examining hippocampal pyramidal cell density (Sass et al., 1990), hippocampal neuron loss (Rausch & Babb, 1993), and the pathological status of the mesial temporal lobe (Hermann, Wyler, Somes, Berry, & Dohan, 1992) have consistently demonstrated that the risk of postoperative memory change is greatest in those with less hippocampal cell volume loss and presumably a more functionally intact hippocampus. Conversely, a lack of hippocampal integrity, as seen in unilateral, circumscribed lesions (e.g., MTS) have better postsurgical cognitive outcomes (Clusmann et al., 2002). Severe hippocampal sclerosis (HS), as determined in the preoperative MRI, is thought to indicate a low risk for memory decline following ATL as compared to mild HS (Martin et al., 2002). Figure 19.8 illustrates the difference in verbal memory changes in relation to hippocampal pathology.

Neurocognitive risk following nondominant hemisphere surgery is lower than surgery to the language dominant hemisphere (Chelune et al., 1991; Ivnik, Sharvrough, & Laws, 1988; Lee, Loring, & Thompson, 1989; Milner, 1975; Morris, Mueller, Swanson, & Inglese, 2005; Ojemann & Dodrill, 1985; Saykin, Gur, Sussman, O'Connor, & Gur, 1989; Seidenberg et al., 1998) (Bell, Davies, Haltiner, & Walter, 2000; Meador, 2002; Sabsevitz et al., 2003). In contrast, studies have found that removal of the language-dominant

**Figure 19.8** Verbal memory change following left ATL in relation to hippocampal pathology. Resection of left hippocampus with no or minimal sclerosis results in significant preoperative to postoperative decline in trial-to-trial learning. Long-delay recall is  $\approx$  35% lower compared with preoperative performance. Resection of left hippocampus with significant hippocampal sclerosis has a minimal effect on postoperative trial-to-trial learning compared to preoperative performance. All patients were confirmed to be left-hemisphere-speech dominant by the Wada test. Abbreviation: CVLT, California Verbal Learning Test.

temporal lobe, high preoperative verbal memory scores, and intact memory with contralateral injection on the IAP, all present with high risk for cognitive deficit. These predictors of outcome appear to hold regardless of whether the patient remains seizure-free following surgery. Chelune et al. (1991) found in a multivariate regression model predicting cognitive (memory) outcome that side of surgery was the best single predictor, with the nondominant hemisphere associated with a better outcome.

As might be expected, bilateral temporal lobe damage (e.g., MTS contralateral to the side of surgery) presents greater risk than unilateral, focal damage for postoperative memory impairment, if memory still appears functional. Other identified cognitive risk factors include age of onset and cerebral volume loss. Earlier age of onset is associated with poorer presurgical memory but less decline after ATL (Saykin et al., 1989), likely secondary to the increased probability of focal hippocampal pathology in early onset forms of temporal lobe disease (Bell et al., 2011; Davies et al., 1996). MR volume loss is related to hippocampal loss (Casino, Jack, & Parisi, 1991; Cendes, Leproux, & Melanson, 1993; Kuzniecky, de la Sayette, & Ethier, 1987; Lencz, McCarthy, & Bronen, 1992) and individuals with more extensive pathology show worse memory preoperatively and more declines postoperatively (Trenerry et al., 1993; Trenerry, Jack, & Ivnik, 1991), although several studies have not observed a reliable relationship between those variables (Hermann, Wyler, & Somes, 1993; Leonard, 1991; Loring, Lee, & Meador, 1991). Studies examining long-term outcome following ATL have revealed hemisphere-specific patterns of cognitive change over time. Alpherts and colleagues (2006) demonstrated a dynamic decline in verbal memory in LTLE patients for the first two years following surgery, followed by a stabilization of verbal memory. LTLE patients showed an ongoing memory decline for acquisition and consolidation of verbal material at six-month and two-year time points, with this remaining stable six years postsurgery. Interestingly, RTLE patients demonstrated initial improvement in learning and memory that did not persist long-term. Notably, as demonstrated elsewhere, mesial temporal sclerosis was predictive of poorer verbal memory performance, but the degree of decline was greater for the LTLE patients with MTS in comparison to those without MTS. Arguing against the notion that temporal lobe resection can exert delayed effects, Andersson-Roswall, Engman, Samuelsson, and Malmgren (2010) demonstrated cognitive stability in memory functions from two to ten years after temporal lobe resection. Dominant hemisphere resection patients exhibited expected declines in postsurgical verbal memory that was present two years postoperatively, but remained stable at a ten-year interval.

While much has been learned from studies identifying individual predictors of cognitive and behavioral outcome postsurgically, the most promising research focuses on multivariate prediction that can utilize multiple information sources (Bell et al., 2011). Stroup et al. (2003) developed a

multivariate risk factor model to predict postoperative verbal memory decline utilizing routine pre-surgical data, including side of resection, preoperative memory testing, IAP performance, and extent of hippocampal sclerosis, each of which provided independent outcome information. Binder and colleagues (2008) examined a group of 60 LATL patients in order to determine whether preoperative language mapping using fMRI could contribute to the prediction of verbal memory decline following LATL. In the 30% of the cohort that experienced verbal memory decline, good preoperative memory performance, late age of epilepsy onset, left hemisphere language dominance on fMRI, and left hemisphere dominance on preoperative intracarotid amobarbital testing were each predictive of postsurgical memory decline. Presurgical memory performance and age of onset collectively accounted for 50% of the variance, with an additional 10% of the variance explained by the fMRI language index.

### **The Changing Surgical Algorithm and Neuroimaging**

At most centers the procedure followed for selecting patients for temporal lobe surgery involves an algorithm that includes scalp/sphenoidal ictal EEG (rhythmic 3–8Hz over the temporal lobe within the first seconds of seizure onset), scalp interictal EEG (state dependent localized spikes or focal slow wave activity), and MRI with evidence of mesial temporal sclerosis or gliosis (hippocampal atrophy and increased T2 signal). Additional criteria include FDG positron emission tomography (PET) interictal hypometabolism in the temporal lobe, asymmetric language and memory findings from both neuropsychological testing and the IAP implicating deficits on the surgery target side along with integrity in the contralateral side, semiology and EEG findings consistent with temporal lobe seizures, ictal single photon emission computed tomography (SPECT) hypoperfusion in the temporal lobe, and localized background EEG abnormalities in the temporal lobe. If the localization of seizures is equivocal, then cortical surface and possibly depth electrodes and electrocorticography procedures are used to better localize the epileptogenic zone. With implants in place—often as part of the same surgical procedure—electrocortical stimulation (ECS) is undertaken through a “knock out” test paradigm to determine the cognitive functionality of the neural tissue adjacent to the implanted electrode (Zangaladze et al., 2008).

fMRI and other functional imaging modalities are becoming an essential part of the surgical algorithm. In fact, at our center, we have all but replaced the IAP with fMRI, with only a handful of exceptional cases each year warranting Wada testing. The literature supports this transition, given the strong concordance rates between fMRI and the IAP for both language (Woermann et al., 2003) and memory (Jokeit, Okujava, & Woermann, 2001), and the safer and less invasive nature of fMRI. Emerging technologies, including functional connectivity MRI (fcMRI) and DTI (or more

advanced diffusion techniques such as Neurite Orientation Dispersion and Density Imaging; see Zhang, Schneider, Wheeler-Kingshott, & Alexander, 2012), are now being utilized to enhance the visual rendering of the underlying neuroanatomy. Diffusion imaging can be seen as a means of verifying the anatomical connection between the gray matter regions. fcMRI can be viewed as a means of verifying that the relevant gray matter regions are indeed communicating and signaling each other. In this context, fMRI can then be viewed as a means of determining the content or nature of the signal (i.e., what the regions are communicating about).

### *fMRI*

fMRI is a safer and cheaper alternative to the IAP, and is capable of providing a depiction of the full circuit of regions involved in a task. This technique measures changes in cerebral blood flow, specifically changes in the concentration of deoxyhemoglobin in local vasculature following regional brain activation, to map neural activity. Functional MRI has the advantage of giving a picture of the full neural circuit that is actually used, but it does not test the necessity of any one particular region for carrying out the relevant cognitive activity. This broad sensitivity to brain functional status shares similarity with neuropsychological testing, and for both procedures it is a quality that lessens their ability to conclusively point to specific areas of the brain that are impaired. The BOLD signal is best associated with local field potentials, not multiunit potentials, and thus it reflects local synaptic and not spiking neurons (Logothetis & Pfeuffer, 2004). Nevertheless, fMRI can show neocortical regional involvement in a task with millimeter resolution. Particularly advantageous for clinical populations, fMRI does not require the use of endogenous contrast and repeated scanning sessions in the same individual and can be conducted even over a short time interval. fMRI in epilepsy has been used to determine hemispheric representation of language and memory, to predict outcomes after temporal lobectomy, to predict the side of seizure focus and seizure outcome, and to verify the functional reorganization of skills such as language.

### *Diffusion Imaging*

DTI takes advantage of the directionality created by structural constraints on the diffusion of water in the brain (i.e., anisotropic diffusion), allowing it to measure the structural orientation and density of WM tracts. In the context of epilepsy, it has been shown previously that hippocampal sclerosis confirmed on MRI is often associated with creation of a seizure focus (Brooks et al., 1990). Using DTI, the WM regions neighboring these epileptogenic zones have demonstrated reduced anisotropy. Further, these abnormal areas appear to extend into regions of the brain that appear normal on MRI. Hence, DTI may serve to enhance presurgical evaluation by providing corroborating evidence of the

epileptogenic region, and its impact on connected afferent and efferent WM structural networks.

The most important current use of DTI in presurgical mapping involves delineation of important sensory and motor tracts that need to be avoided during surgery. Damage to Meyers loop, the most anterior part of the optic radiation, results in a visual field deficit (VFD) in 50%–100% of patients (Barton, Hefter, Chang, Schomer, & Drislane, 2005; Nilsson, Malmgren, Rydenhag, & Frisen, 2004). Given that a primary motivation for surgery is the ability to drive, limiting VFD is fundamental in improving quality of life outcomes. In a cohort of 21 patients who underwent anterior temporal lobe resection, Winston and colleagues (2014) demonstrated that the use of preoperative optic radiation tractography and intraoperative MRI (iMRI) improved outcome. The severity of VFD in the contralateral superior quadrant was significantly reduced with tractography and iMRI guidance. Supporting the importance of integrating such techniques into neuronavigation technologies, none of the patients in the iMRI cohort developed a VFD that precluded driving, whereas 13% of the non-iMRI cohort failed to meet driving criteria. Tracts that connect gray matter regions would, of course, form important neurocognitive circuits for memory and language, which could potentially become reliably depicted by DTI, but this research is in its infancy (Zhang et al., 2012).

### *Functional Connectivity MRI*

fcMRI utilizes the temporal correlation of neurophysiological activity in different brain regions to assess functional connections between brain areas (i.e., neural communication and potential information sharing), and characterizes their organization in terms of participation in integrated or segregated neural network. Functional connectivity has been previously defined as the temporal correlation of a neurophysiological index measured in different brain areas (Friston, Frith, Liddle, & Frackowiak, 1993). Low-frequency hemodynamic fluctuations constitute such a neurophysiological index, and functional connectivity maps can be created based on these fluctuations. In healthy persons, there is a high degree of co-occurrence between the functional connectivity maps (using resting-state image time series) and functional activation maps obtained in cognitive task studies. This suggests that generating functional connectivity maps using correlated low frequency oscillation of cerebral hemodynamic parameters (i.e., perfusion, oxygenation) represent a robust approach for brain functional imaging. Functional synchrony in particular brain areas can be quantified by means of cross-correlation coefficients of low-frequency spontaneous oscillation of the BOLD signal in different areas. Great advances have also been made in utilizing resting-state fMRI data for development of a whole-brain connectome and using graph theory statistics of connectivity to understand the organization and function of brain networks instantiated during both rest and

a variety of cognitive activities. Resting state functional connectivity has distinct advantages over task-driven fMRI and Wada. Such data can be collected with only a five-minute scanning period. Resting-state FC methods have an advantage over task-based fMRI methods as they allow for more careful individual analysis of the role played by the strength of particular regional connections in the determination of language dominance. Resting state FC also offers advantages in terms of testing impaired patient populations who cannot otherwise cooperate or respond effectively to the demands of either fMRI or IAP.

### ***Electrocorticography***

When the localization of the epileptogenic focus remains equivocal after all noninvasive measures have been exhausted, extraoperative and/or intraoperative subdural electrocorticography is often used to identify the epileptogenic zone and to guide surgical resection, with a focus on sparing eloquent cortex. The patient undergoes a craniotomy, followed by surgical implantation of strip and grid electrodes on the surface of the cortex based on the information collected during the preoperative evaluation. With implants in place, often as part of the same surgical procedure, electro-cortical stimulation mapping (ESM) is undertaken to map out functions associated with the neural tissue adjacent to the implanted electrode, with the goal of preserving function postoperatively. When current is applied to a functional cortical area, a positive response may be elicited or a specific function may be disabled. Depth electrode placements in areas such as the hippocampus are done routinely to locate seizure foci through passive EEG recordings. Depth electrodes are typically used when patients have a suspected focal seizure onset but surface EEG is not definitive.

Electrical stimulation of these electrodes provides the means to demonstrate the necessity of a particular pool of neurons for carrying a specific cognitive task. In contrast, fMRI has the ability to provide a complete map of the brain regions implementing a given task. In this sense, ESM and fMRI are complementary. ESM can indicate the structures necessary for a task, while fMRI can depict the full neural circuit that is sufficient for its successful completion.

### **Summary**

In terms of functional assessments, fMRI and fcMRI as brain-mapping techniques will likely become as common an early step as neuropsychological testing, reducing the need for the IAP, which, due to its inherent risks, would be the last to use of the functional techniques. The hope is that techniques such as diffusion imaging and fcMRI will yield important information about structural and functional connectivity of networks that implement cognitive functions, and give better functional and anatomical grounding to the network of activation implied by fMRI.

To render all these sources of information (functional neurocognitive maps, WM tracts, vascular structures, implanted electrodes stimulated during ESM) into a single multimodal

image that can be imported into a probe-based neuronavigation system is the goal. However, numerous registration problems exist as each imaging modality and its related information brings with it its own set of distortions. For instance, at our center we currently utilize the functional data from neuropsychological testing, IAP, fMRI, rsfMRI, and ECS with structural information from MRI, diffusion, and CT (which contains the exact location of the electrodes used during ECS), but improvement is needed to integrate these into a seamless multimodal rendering that captures all structural and functional components together in one image that can be used during surgery for neuronavigation.

It is likely these emergent technologies will transform the daily activities of the neuropsychologist. As the ultimate goal is to obtain an integrated model of brain structure and function, the field of neuropsychology will be forced to adapt in order to make continued contributions to the presurgical assessment algorithms. Just as the relative contributions of the neuropsychologist to make localization and lateralization decisions have improved with the advent of functional neuroimaging, neuropsychology will need to shift again as the integration of technologies advances. Future neuropsychologists will need to accommodate and integrate cognitive tests with techniques that have better temporal (e.g., surface and depth electrocorticography; brain electrical stimulation) or spatial resolutions (fMRI, fcMRI, diffusion) in order to provide a more robust method for capturing the strength, location, and organization of specific cognitive functions and network connectivity. This integrative shift has the goal of improving neuronavigation during the resective, stimulation, or ablative techniques aimed at stopping seizures. It is likely that future neuropsychological assessments in the setting of epilepsy will require the development of new assessment procedures and protocols that are uniquely suited to easy integration with these other functional and structural technologies.

### **Notes**

- 1 That said, it is not clear that the neural mechanisms involved in epileptogenesis, particularly in the hippocampus, can fully account for the cognitive and behavioral deficits associated with temporal lobe epilepsy. Early life seizures are not generally associated with cell loss or mossy fiber sprouting, despite the presence of cognitive deficits (Toth, Yan, Haftoglou, Ribak, & Baram, 1998). Also, experimental rats that kindle rapidly do not necessarily learn rapidly (Leech & McIntyre, 1976). More generally, cell death, synaptic reorganization, and altered neurogenesis do not appear the most likely explanation of cognitive deficits in epilepsy. Mechanisms related to increased inhibitory neurotransmission (e.g., increased postsynaptic inhibition of GABA<sub>A</sub> receptor changes, increased presynaptic inhibition involving HCN changes), decreased excitatory neurotransmission (decreased dendritic spine density, reduced NMDA receptor expression), and altered regulatory and neuromodulatory pathways (CREB, CHN) appear to be much more likely causes of cognitive dysfunction (Brooks-Kayal, 2005).
- 2 In Tracy and Osipowicz (2011) we defined several mechanisms of cognitive reorganization. These included functional redundancy,

functional substitution, cognitive control, cognitive reserve, and normalization. We view these types of reorganization as occurring in the setting of a complex network, with the particular task function or cognitive component that is redundant, substituted, etc., varying not just with the nature of task, but in accord with the clinical pathology, disease duration, chronological age, and a host of other factors. We define functional redundancy as the presence of duplicate representation of a function, which gets unmasked and recruited into a network, and is then used to successfully implement the task following acquired injury (i.e., resective surgery). Functional substitution utilizes a new, previously unincorporated neural region to substitute for the function of a lost node, a node that lacked redundant representation in the brain. Cognitive control utilizes supervisory systems to alter the affected or impaired network by increasing attentional resources, facilitating information exchange, improving sensory filtering/suppression, or increasing executive monitoring. Cognitive reserve is a general mechanism of resiliency, utilizing the remaining healthy brain to withstand injury and protect against a loss of function. Finally, the normalization mechanism is defined, based on evidence that patients with surgically relieved seizure burden can undergo cognitive reorganization of language function or other cognitive functions that returns functional neuroanatomical representations to their more normative locations (Lutz, Clusmann, Elger, Schramm, & Helms-taedter, 2004; Martin et al., 2000; Takaya et al., 2009). Importantly, normalization, which takes into account the potential abnormal functional organization presurgery, highlights the fact that the new area(s) recruited may be normative for the task. In the context of neuroimaging, normalization involves the reorganization of cognitive networks not through the formation of atypical, compensatory networks, as is the case with the other mechanisms noted earlier, but by the emergence of a network that better resembles the normative, age appropriate network implementing a task. In this sense, the first four cognitive mechanisms appear more suited to explaining neuroplastic compensation following acute injury, such as traumatic brain injury or stroke. One must be careful in applying them to chronic disorders, such as epilepsy, which may have the propensity to disrupt functional neuroanatomy early on, altering or perhaps never even allowing for normative patterns to develop (for a review see Cadotte et al., 2009; Elger et al., 2004).

## 20 Neurotropic Infections

### Herpes Simplex Virus, Human Immunodeficiency Virus, and Lyme Disease

*Richard F. Kaplan and Ronald A. Cohen*

#### Introduction

The brain, spinal cord and adjacent structures can become infected by many kinds of microorganisms. The four main categories include bacteria, viruses, fungi, and protozoa. These microorganisms can have acute and chronic effects on brain function and consequently cognitive functioning. Depending on the location of the invading microorganism, different names are given to the diseases. Meningitis is an infection of the meninges, the tough layer of tissue that surrounds the brain and the spinal cord. Meningitis can be caused by bacterial infection, viruses, and fungi. If not treated, meningitis can lead to brain swelling, which could result in coma, permanent disability, and death. Encephalitis is an inflammation of the brain itself. It is usually caused by a viral infection. Viral infections of the brain are typically referred to as aseptic, although this is a misnomer because aseptic literally means an absence of infection. Nevertheless this terminology persists and an aseptic meningitis or encephalitis has come to mean that the inflammation is not caused by a pyogenic bacteria. As it is beyond the scope of this chapter to cover every microorganism capable of invading the nervous system, we will focus on those bacterial and viral infections most common in neuropsychology practice. These will include herpes simplex virus (HSV), human immunodeficiency virus (HIV), and the most common tick-borne bacterial infection, *Borrelia burgdorferi*, the agent responsible for Lyme disease.

#### Herpes Simplex Encephalitis

A 22-year-old woman was hospitalized after she presented in the emergency room with a high fever (over 104°), nausea, severe headache, and confusion. Herpes simplex encephalitis (HSE) was suspected by history, and viral DNA identification was confirmed by polymerase chain reaction (PCR). She was started on antiviral therapy and was hospitalized for three weeks. Prior to her hospitalization she had been working as a waitress and living independently. After discharge she moved in with her mother and sister, as she was no longer able to care for herself. The mother and sister reported aphasia, memory loss, confusion, and personality change. The relationship with her mother became strained as

she became increasingly irritable, paranoid, and aggressive. Her mother noted that she could be “out of control.” For example, in one instance, the patient took off in the car and the police were called. She was able to care for her dressing and hygiene but she was unable to cook. She also began “binge eating” and started smoking cigarettes. An EEG was reported to show left hemisphere spike/sharp wave pattern—which had not been seen during her initial hospitalization—and she was started on an anticonvulsant. A second EEG one month later showed left temporo-parieto-occipital delta slowing, but no epileptiform discharges, with normal alpha rhythm in the right hemisphere. Magnetic resonance imaging (MRI) showed abnormalities consistent with HSE such as left temporal encephalomalacia including the hippocampus (Figure 20.1). Neuropsychological testing revealed impaired performances in virtually every cognitive domain, with only

**Figure 20.1** Coronal MRI T2-weighted image showing increased signal enhancement in the left temporal lobe including hippocampus and amygdala of a 22-year-old woman with confirmed HSE. The remaining brain parenchyma is unremarkable.

nonverbal skills, nonverbal problem solving, block design, judgment of line orientation, and copying relatively intact. Language testing showed expressive and receptive language deficits indicative of a global aphasia, although she was able to communicate through gesturing.

### **Neuropathology**

HSV Type 1 (HSV1) and Type 2 (HSV2), and varicella-zoster virus, are human neurotropic viruses and members of the herpesviridae family of DNA viruses (Steiner, Kennedy, & Pachner, 2007). HSV must contact mucosal surfaces or abraded skin to initiate infection and the type of herpes virus that develops is a function of the host's immune system (Whitley & Roizman, 2001). Infection with HSV1 is thought to occur in childhood with detectable antibodies found in 60%–90% of the adult population. However, recent research shows seroprevalence to be declining among younger people (Bradley, Markowitz, Gibson, & McQuillan, 2014). HSE is primarily caused by HSV1 in adults and HSV2 in neonates via transmission from infected mothers (Whitley & Roizman, 2001). HSV1 is acquired and spread by saliva, and once infected persists for life, albeit in a latent form (Fatahzadeh & Schwartz, 2007). In contrast, HSV2 is typically sexually transmitted. Given the prevalence of HSV in the general population, HSE is a relatively rare disease and occurs in approximately one in 150,000 individuals. A Swedish study showed the incidence of confirmed cases to be 2.2 per million per year (Hjalmarsson, Blomqvist, & Skoldenberg, 2007). Primary infection occurs in the mucosal membranes and is spread by the trigeminal or olfactory tract to the central nervous system (CNS). In patients with recurrent infection leading to HSE, reactivation of the virus peripherally has been suggested as the initial event. After initial infection the virus can remain latent indefinitely (Steiner et al., 2007) and in situ reactivation of a latent infection in the dorsal root ganglion appears to be more likely than retrograde spread along a cranial nerve in at least a third of all patients (Levitz, 1998). What causes the latent virus to become active is not completely clear, but a wide variety of internal and external triggers may lead to reactivation. These include psychological stress, fatigue, fever, immunosuppression, and corticosteroid administration (Fatahzadeh & Schwartz, 2007; Sarrazin, Bonneville, & Martin-Blondel, 2012). Although it is relatively rare, HSE is the most common nonepidemic encephalitis and the most common cause of sporadic lethal encephalitis. Untreated HSE is progressive, with a 70% mortality rate in 7–14 days. Even with antiviral treatment, HSE has a significant rate of mortality, 15%–20%, and morbidity (Karanjia, 1996).

In the brain, HSE has an affinity for the frontal and temporal lobes, which is likely due to the anatomical proximity of these structures to the olfactory nerve. The damage usually begins in the anterior part of the temporal lobe and can include parahippocampal gyrus, amygdala, and head

of the hippocampus. It can also extend back and reach the inferior orbital cortex, the cingulate gyrus, and insula. Acute focal, necrotizing encephalitis with inflammation and swelling of the brain is a characteristic feature (Skoldenberg et al., 2006). Disease begins unilaterally, and then spreads to the contralateral temporal lobe. The lesion is clearly hyperintense in the T1 MRI sequence and hypointense in the T2 and fluid attenuated inversion recovery (FLAIR) sequence (Sarrazin et al., 2012) as described earlier and shown in Figure 20.1. The EEG is abnormal in about 85% of all cases, with lateralized epileptiform discharges superimposed on a disorganized background over one or both temporal areas (Karanjia, 1996). Although the pathogenesis of HSE-related brain damage is not completely understood, current thinking is that direct virus mechanisms and indirect immune-mediated factors both play a role (Aurelius, Andersson, Forsgren, Skoldenberg, & Strannegard, 1994). In a recent study, researchers found N-Methyl-D-Aspartate (NMDA) receptor antibodies in 30% of patients with PCR-confirmed HSE cases (Pruss et al., 2012). The NMDA receptors in the hippocampus have been directly linked to synaptic plasticity and memory (Liu et al., 2004), which may explain a potential mechanism causing amnesia in some HSE patients.

### **Clinical Considerations**

The clinical presentation of HSE includes malaise, fever, headache, and nausea, followed by or in combination with acute or subacute onset of an encephalopathy with symptoms that typically include lethargy, confusion, and delirium. There can be seizures and coma during the course of the disease (Sarrazin et al., 2012). The cerebrospinal fluid in HSE is variable, but usually consists of a pleocytosis with both polymorphonuclear leukocytes and monocytes. The protein concentration is characteristically elevated, glucose is usually normal, and red blood cells are frequently present (Karanjia, 1996). The clinical presentation does not reliably distinguish HSE from other types of viral and bacterial encephalitis. In the past a brain biopsy provided the most definitive diagnosis, but this has largely been replaced by MRI and PCR of cerebral spinal fluid (CSF).

### **Neuropsychology**

In his now-classic paper, Cermak (Cermak, 1976) described the profound amnesia that can result from HSE. Patient S.S. was a 44-year-old male physicist when he contracted the disorder that permanently changed his life. A pneumoencephalogram revealed dilated lateral and third ventricles, marked atrophy of the left temporal lobe, some atrophy of the right temporal lobe, and possible atrophy of the thalamus. When evaluated two years later, he had a Wechsler Adult Intelligence Scale (WAIS) IQ score of 133, and Wechsler Memory Scale (WMS) score of 83. Although there was improvement in his performance several years

later, and S.S. was able to use his analytical abilities, he could not retain previously learned information in memory (Cermak & O'Connor, 1983). In one of the first studies to utilize magnetic resonance imaging (MRI) Kapur and colleagues (Kapur et al., 1994) reported on a series of ten recovered HSE cases. The extent of pathology and degree of cognitive impairment varied between individuals. Damage to the hippocampus, either unilaterally or bilaterally, was always accompanied by damage to adjacent structures such as the parahippocampal gyrus, anterior and inferior temporal lobe gyri, insula, mammillary bodies, fornix, and the amygdala. As with patient S.S., WAIS subtest scores were mostly normal, with the greatest impairment on Information, which mainly measures general knowledge. Sixty percent of the patients showed a dense amnesia (WMS-R Quotient < 50), 40% showed impairment on picture naming, and 40% were impaired on a modified card-sorting test. Patients with naming deficits were otherwise fluent in conversational language. With the small number of subjects the authors were unable to correlate cognitive deficits with individual brain regions, but did report that the extent of medial temporal involvement was correlated with the severity of memory impairment. A more recent case study (Pimental & Gregor, 2012), did show the pattern of neuropsychological deficits to correspond with MRI and EEG findings. A 66-year-old man was hospitalized after an apparent seizure. PCR analysis of CSF was positive for HSE. An EEG showed abnormal slowing consistent with a generalized cerebral process, while the MRI revealed abnormal signal from the left temporal lobe extending into the left hippocampus and insular cortex. The neuropsychological test results were significant for deficits in memory and language indicative of greater left hemisphere dysfunction.

In addition to amnesia, dysphasia, and other related cognitive disorders, HSE is a known etiology for the human Kluver-Bucy syndrome. The human Kluver-Bucy syndrome is similar to that described in Rhesus monkeys after anterior bilateral temporal lobectomy. The syndrome, first described by Heinrich Kluver and Paul Bucy in 1937 in monkeys included loss of fear, indiscriminate dietary behavior, changes in diet, hypermetamorphosis (a tendency to react to every visual stimulus), hypersexuality, hyperorality (a tendency to examine all objects by mouth), and visual agnosia. The human syndrome was first reported by Terzian and Ore (1955) in a patient with temporal lobectomy, and other cases have since been reported involving damage to deep temporal lobe structure including HSE. Rarely is the full syndrome present in humans and most studies report on a limited number of cases. Moreover, unlike animal studies that are based on circumscribed surgical lesions, the extent and pattern of mesial temporal brain damage in humans afflicted with HSE varies and is related to residual cognitive and psychiatric outcomes (Caparros-Lefebvre et al., 1996). In a report describing the natural history of three HSE cases treated with antiviral

agents, all initially showed hypersexuality, increased appetite, and varying degrees of visual agnosia in addition to memory, language, and other cognitive impairments. All three patients showed substantial functional recovery in the weeks to months after treatment (Hart, Kwentus, Frazier, & Hormel, 1986).

Although amnesia can occur with herpetic and nonherpetic encephalitis (Hokkanen, Salonen, & Launes, 1996), the long-term prognosis of patients with HSE appears worse than for patients with acute encephalitis from other etiologies (Hokkanen, Poutiainen, et al., 1996; Pewter, Williams, Haslam, & Kay, 2007).

If HSE is left untreated, only 2%–5% of surviving patients regain normal neurological function (Whitley & Roizman, 2001). Treatment with antivirals clearly reduces morbidity in HSE (Hokkanen & Launes, 1997; Hokkanen, Poutiainen, et al., 1996). Antiviral therapy does not cure the infection, but modifies the clinical course through inhibition of viral replication and prevention of subsequent tissue damage. Diagnosing HSE quickly is critical because the virus multiplies rapidly and the prognosis of the patient is highly dependent on when treatment begins. The use of idoxuridine in the 1960s and 1970s showed some promise in comparison to nontreatment (Nolan, Carruthers, & Lerner, 1970), however, neuropsychological follow-up studies of treated patients showed residual cognitive deficits—particularly memory loss—in most patients (Rennick, Nolan, Bauer, & Lerner, 1973). Currently, acyclovir, a synthetic acyclic purine-nucleoside analogue, is the standard therapy for HSV infections (Whitley & Roizman, 2001). In a retrospective study of the long-term outcome of 42 patients with confirmed HSE who were treated with acyclovir, 70% of the patients survived. Of the survivors, the most frequent residual cognitive deficits were memory impairment, 69%; personality and behavioral abnormalities, 45%; and language deficits, 41% (McGrath, Anderson, Croxson, & Powell, 1997). Of the 45% reported to have personality and behavioral abnormalities, symptoms included depression, anxiety, insomnia, irritability, poor motivation, and emotional lability. It has been suggested that psychiatric symptoms such as depression may be more prevalent in patients who are less aware of their cognitive impairment, although this finding was based on a relatively small sample (Pewter et al., 2007). Although there is a clear relationship between HSE lesions and the frontal and temporal brain regions, case studies suggest considerable anatomic variability with shorter times between first symptom and the initiation of treatment predicting better outcomes (Kaplan & Bain, 1999).

### Acquired Immunodeficiency Syndrome

During a routine visit to the infectious medicine clinic, a 52-year old man with a 25-year history of HIV infection reported that he was experiencing memory problems, episodes of confusion, and difficulty managing his finances. He

indicated that he had become cognizant of these difficulties when his partner began complaining about a year ago that he was not remembering their conversations and recent events. His activities of daily living were largely intact. He continued to work in managerial position in a large corporation, but was experiencing some difficulty with multitasking and some of his coworkers were concerned that he was taking longer to complete tasks than in the past. He had experienced some depressive symptoms after his initial diagnosis and following the death of his partner at the time from acquired immunodeficiency syndrome (AIDS), but indicated that he was no longer. He reported some concern about the possibility that his memory was failing.

The patient was first diagnosed with HIV in the late 1980s when a blood test was conducted after his homosexual partner was diagnosed with AIDS. An enzyme-linked immunosorbent assay (ELISA) revealed that he was HIV-seropositive, though was asymptomatic, never having experienced any medical problems associated with AIDS. Subsequent blood tests of immune function indicated a CD4 cell count of 350, which indicated T-cell levels that were below normal. He remained asymptomatic as an adult, though four years after his initial diagnosis his immunological status had worsened (CD4 = 150), and a viral load assay indicated moderately elevated HIV-RNA (24,000 copies/ml). He was started on antiretroviral therapy, which has continued until the present time. After six months his immune function had reconstituted (CD4 = 520) and his viral load was no longer detectable. Combined antiretroviral therapy (CART) was initiated a decade ago after he experienced a sustained drop in his CD4 cell count. His HIV status has been stable since. Five years ago he was diagnosed as having a metabolic syndrome, with prediabetic insulin resistance, moderate obesity, hypertension, and elevated total cholesterol and triglyceride levels. He has no family history of Alzheimer's disease or other neurodegenerative disease.

The patient was referred for a neuropsychological assessment by his physician. He did not exhibit global cognitive dysfunction indicative of dementia, nor was there aphasia, apraxia, agnosia, or other neuropsychological syndrome indicative of a focal lesion. However, he had mild to moderate impairments in processing speed, attention, executive function, working memory, new learning and delayed recall. Delayed recall was impaired on both the Hopkins Verbal Learning Test and Brief Visual Memory Test, with recognition memory intact. Neuroimaging was obtained within two weeks of the neuropsychological evaluation to assess structural brain integrity. Consistent with the neuropsychological findings, there were no focal cortical or subcortical lesions on the T1 images and no signs of opportunistic brain infection. However, there was greater than expected cortical atrophy for his age. Furthermore, FLAIR imaging revealed the presence of white matter hyperintensities (WMH) not normally found in middle-aged adults.

### Clinical Considerations

Despite major advances in the treatment and clinical management of HIV, it continues to be very prevalent in this country and to an even greater extent worldwide. The advent of CART led to dramatic reductions in HIV-associated mortality and morbidity. Yet, HIV resides in the body tissues of even effectively treated people once they are infected, as efforts to fully eradicate the virus have not yet been successful. Accordingly, HIV-infected people live with a chronic illness that has the potential to cause severe medical problems, with clinical efforts largely directed at managing the infection by (a) suppressing viral replication, (b) enhancing immune functions, reducing various secondary factors and comorbid conditions that contribute to poor health outcome, and (c) treating opportunistic infections when they occur.

HIV status is determined by laboratory and clinical findings. For most patients, this first involves discovery that their blood contains antibodies to HIV on ELISA. The health of the immune system is then determined by assessing the cluster of differentiation-4 of a specific glycoprotein found on the surface of immune system cells, such as T-cells, macrophages, and monocytes found in blood samples. Healthy people usually have CD4 cell counts in the range of 500–1,000 cells/ml. When otherwise healthy people are actively fighting an infection (e.g., influenza), it is common for white blood cells (T-cells) to increase. However, in people with compromised immune function, CD4 cell count decreases to the point that they are no longer able to effectively combat infections. HIV infection impairs the immune system, resulting in reduced CD4 cell count. Clinical outcome in HIV is associated with immune function integrity as reflected by CD4 cell count (Dragic et al., 1996; Flanigan et al., 1992; Janssen, Nwanyanwu, Selik, & Stehr-Green, 1992; Lillo et al., 1999; Mayer et al., 1992; Nockher, Bergmann, & Scherberich, 1994; Palella et al., 1998; Thiebmont, Weiss, Sadeghi, Estcourt, & Haefner-Cavaillon, 1995; Veugelers et al., 1997).

A diagnosis of AIDS is made if CD4 levels fall below 200 cells/ml. This cut point is somewhat arbitrary, though there is strong evidence that below this level, people are more likely to experience opportunistic diseases, with risk increasing the closer CD4 is to zero. The lowest CD4 count that a particular patient ever experienced is referred to as the *nadir CD4* and has been shown to be predictive of brain disturbances in a number of studies. Past studies showed a relationship between CD4 and neurocognitive functioning, dementia risk, and EEG and MRI abnormalities (Becker et al., 1997; Bowman et al., 1998; Brew, Dunbar, Pemberton, & Kaldor, 1996; De Ronchi et al., 2002; Egan, Chiswick, Brettle, & Goodwin, 1993; Ellis, Deutsch, et al., 1997; Gruzelier et al., 1996; Harrison et al., 1998; Heaton et al., 1995; Heaton et al., 2004; S. Letendre, Ances, Gibson, & Ellis, 2007; Marcotte et al., 2003; Wallace et al., 1997; Wallace et al., 1996; Wilkie et al., 2003). This relationship was most obvious prior to CART. The risk of cognitive impairment associated with HIV is clearly

greatest among symptomatic patients with AIDS who have very low CD4 cell counts (Clark & Bessinger, 1997; Cohen et al., 2001; Odiase, Ogunrin, & Ogunniyi, 2006) with a three-fold increase in risk among patients with CD4 counts below 200 mm<sup>3</sup>, and sevenfold among patients with CD4 counts below 100 cells/ml (Mellors et al., 1997). We previously found strongest associations with neurocognitive performance when CD4 levels fall below 100, with dramatic increases in impairment at this level CD4 (Bornstein et al., 1991). In the early years of the HIV epidemic, AIDS was primarily diagnosed on the basis of the occurrence of opportunistic infection, AIDS-associated disease, or other symptoms. Symptomatic HIV is no longer required for a diagnosis of AIDS, though whether or not a person has experienced AIDS symptoms remains an important clinical consideration. This is particularly true for opportunistic brain infections, which include toxoplasmosis, cytomegalovirus, and JC virus, which cause progressive multifocal leukoencephalopathy.

Today a much more complex relationship exists between CD4 and neurocognitive functioning. Some studies continue to find reduced CD4 levels to be associated with cognitive dysfunction, but others do not (Marcotte et al., 2003; McArthur et al., 1997; Miller et al., 1990; Tozzi et al., 2005; Villa et al., 1996). There are several reasons for differences across studies: (a) The range of CD4 among patients in particular cohorts varies quite dramatically; (b) the CD4 levels used to group patients is often quite different; (c) CD4 nadir (i.e., lowest level of immune function during disease course), duration of CD4 suppression, and duration of infection vary across studies; (d) whether or not symptomatic patients are considered in a study; and (e) what treatments were available at the time a particular study was conducted. In the post-highly active antiretroviral therapy era, the relationship between CD4 cell count and cognitive impairment has become less clear cut. It is possible that plasma levels of HIV RNA and CD4 cell count may or may not fully reflect the degree of viral suppression in the CSF, because of differential penetration of drugs across the blood-brain barrier. While neurocognitive studies of impaired immune function have primarily focused on CD4, other lymphocytes have also been implicated in HIV infection (e.g., CD8, CD16, CD57) (Aronsson, Troye-Blomberg, & Smedman, 2004).

While various issues remain unresolved regarding neurocognitive dysfunction in the context of immune system suppression, several conclusions can be reached:

- 1 Asymptomatic patients with CD4 levels greater than 400 or 500 cells/ml typically have little cognitive impairment that can be attributed to HIV after other factors are accounted for.
- 2 Patients with CD4 levels below 100 are much more likely to have impairments.
- 3 When CD4 drops below 200 cell/ml, a curvilinear relationship seems to exist with the greatest impairments when CD4 levels have fallen below 50.

While CD4 reflects immune system impairment, the burden of HIV is ultimately a function of viral load: i.e., the number of copies of HIV-RNA detected in the blood plasma or CSF (Geskus et al., 2003). Historically, plasma viral load was shown to be associated with the development of symptoms and HIV prognosis. Patients with plasma HIV RNA > 50,000 copies/μl have 12–18 times the risk for developing AIDS and dying. Risk dramatically increases between 500 and 50,000 copies/mL, doubling between 500 and 3,000, with six- to tenfold increases at viral load of 50,000 (Mellors et al., 1997; Mellors, 1997). Both plasma and CSF viral load are associated with neurocognitive dysfunction and HIV-associated dementia (Gonzalez et al., 2003; Vitiello et al., 2007). Plasma viral loads of greater than 50,000 copies/mL were predictive of subsequent dementia, with a relative hazard of 9.1 compared to those patients with viral loads < 500 (Childs et al., 1999). Patients with lower CD4 cell counts at baseline also had increased risk for developing dementia (Childs et al., 1999). Similar findings have been reported by other groups (DalPan et al., 1998). HIV infection of the brain is characterized by replication of viral RNA in the CSF, as well as rapid turnover, suggesting that the CNS effects are caused by rapidly proliferating cells (Eggers, van Lunzen, Buhk, & Stellbrink, 1999). As one might expect, CSF viral load has tended to relate more strongly than plasma viral load with neurocognitive performance and the occurrence of HIV-associated dementia (HAD; Bandaru et al., 2007; Chang, Ernst, Leonido-Yee, Walot, & Singer, 1999; Chang et al., 2003; Christo, Greco, Aleixo, & Livramento, 2005; Cysique et al., 2005; Ellis, Hsia, et al., 1997; Heaton et al., 1995; Krivine et al., 1999; Letendre et al., 2004; Marcotte et al., 1999; Robertson et al., 1998; Vitiello et al., 2007; Wiley et al., 1998).

Following several months of antiretroviral therapy, the majority of patients exhibit undetectable viral loads (e.g., HIV-RNA < 50 copies (Gulick et al., 1997). Yet, HIV continues to replicate despite suppression of free virus, which may create a substantial burden on the system over time (Chun et al., 2005). This is important given the continued prevalence of HIV-associated neurocognitive disorder (HAND) among people with reconstituted immune function and suppressed HIV-RNA secondary to CART, despite a reduced incidence of dementia (Gartner, 2000). Quantitative methods were developed for measuring cell-associated “proviral” HIV-DNA (Coombs, 1998; Panther et al., 1999). A significant relationship has been shown between levels of circulating provirus and HAD (Shiramizu et al., 2005; Shiramizu et al., 2007) and milder cognitive dysfunction as well (Shiramizu et al., 2007).

Complicating the clinical presentation is that HIV typically occurs against the backdrop of other medical and psychiatric comorbidities, as well as various psychosocial factors, all of which contribute to poorer functional outcome. For example, previous exposure to measles seems to have a synergistic effect on HIV (Aronsson et al., 2004). Of particular

concern is coinfection with hepatitis C virus (HCV), which is particularly common among people with history of intravenous drug use or sexual contact with infected people. While HCV infection is characterized by chronic inflammation of the liver and development of hepatic cancer in many cases (Moriishi & Matsuura, 2003), it also contributes to cognitive impairments and decline in its own right that cannot be explained by psychiatric symptoms, drug abuse status, or hepatic failure (Hilsabeck, Hassanein, Carlson, Ziegler, & Perry, 2003; Hilsabeck, Perry, & Hassanein, 2002). In fact, we have found that HCV is currently a major contributor to HAND as well as associated brain abnormalities. Cortical electrophysiological changes occur with HCV, including delayed P300 latencies. These correlate with cognitive impairment (Kramer et al., 2002), apart from interferon treatment, which is also known to cause fatigue and affect cognition (Dieperink, Willenbring, & Ho, 2000; Kamei et al., 2002).

### **Neuropathology**

HIV infection affects the brain both directly and indirectly (Clifford, 1997; Price et al., 1988). Damage to axons, myelin, and large astrocytes may occur as either a direct effect of HIV and also may be due to encephalitis or other secondary infections. Vasculitis may develop in patients, and this is associated with increased risk of infarctions secondary to hemorrhage in subcortical regions of the brain. Brain abnormalities are considered to be directly caused by HIV if they can be attributed to neuropathological factors attributable directly to the effects of virus in the brain. Alternatively, secondary brain abnormalities occur due to opportunistic infections and other diseases that develop as HIV infection progresses to AIDS. Evidence of direct CNS effects comes from cases in which there has been no opportunistic infection of the brain, yet there is significant neurocognitive impairment that is not attributable to other neurological brain diseases. Human studies and animal studies have both demonstrated that the virus can be detected in the brain within two weeks of initial infection, where it presumably remains until death (Davis et al., 1992; Goulsmith, DeWolf, & Paul, 1986; Palmer, Hjeelle, & Wiley, 1994). While the mechanisms underlying direct effects of HIV on the brain are still not fully understood, elevated free calcium is thought to occur directly from HIV effects, such as the enveloping of proteins (e.g., gpl20), with calcium influx via ionic channels causing neuronal damage (Price et al., 1988). Excitatory amino acids and receptor antagonists, such as quinolinic acid, also seem to play a direct role or as a secondary response to the presence of the virus or its "immunological footprint" in the brain.

HIV has a predilection for the basal ganglia and white matter pathways (Aylward, Henderer, & McCarthur, 1993; Budka, 1991; Budka et al., 1991; I. Everall, P. Luthert, & P. Lantos, 1993; Everall, P. J. Luthert, & P. L. Lantos, 1993; Navia, Cho, & Petito, 1986; Wiley et al., 1999; Wiley et al.,

1991). The reason for this is not fully understood, though it may relate to blood-brain barrier dysfunction of the parenchyma surrounding the basal ganglia facilitating CNS penetration, perhaps secondary to particular glycoproteins (Toneatto, Finco, van der Putten, Abrignani, & Annunziata, 1999). Analysis of autopsies of people with HIV between 1988 and 1996 revealed brain lesions in 79% of patients (Lanjewar, Jain, & Shetty, 1998). Both focal and diffuse brain lesions were evident, with various types of pathology present including multifocal myelin loss (21%), microglial nodules (18%), infarcts-hemorrhage (15%), angiocentric pallor (6%), and calcification (5%). At a cellular level, multinucleated giant cells, macrophagic subcortical infiltration, myelin pallor, and gliosis may occur. Leukoencephalopathy (myelin loss, nucleated macrophages/microglia, reactive astrogliosis) is very common. Vacuolar leukoencephalopathy is associated with deep white matter swelling.

Opportunistic viral and nonviral infections, tumors, and cerebrovascular disturbances can produce severe brain dysfunction among people with HIV (Bernick & Gregorios, 1984; Clifford, 1997; Cysique et al., 2005; Eberwein, Hansen, & Agostini, 2005; Gonzales & Davis, 1988; Korálnik et al., 2005; Lanjewar, Surve, Maheshwari, Shenoy, & Hira, 1998; Lee, Chen, Wang, Yen, & Hsu, 2007; Lepout et al., 1988; McMurtry, Nakamoto, Shikuma, & Valcour, 2007; Mobley, Rotterdam, Lerner, & Tapper, 1985; Paul et al., 2007; Post et al., 1983; Price et al., 1988; Ramsey & Geremia, 1988; Schmidbauer et al., 1990; Vago et al., 1996). Opportunistic brain infections (e.g., progressive multifocal leukoencephalopathy) still occur, causing severe cognitive disturbances with very poor prognosis (Lanjewar, Surve, et al., 1998; Reuter, 2005). Fortunately such cases have become relatively uncommon in recent years, and only a small percentage of HIV-infected individuals have secondary brain infections. Moreover, most of these infections are treatable and a majority of patients recover (Lepout et al., 1988).

HIV causes structural and functional brain abnormalities on neuroimaging. The most dramatic structural abnormalities occur in patients with opportunistic brain infections, tumors, or cerebrovascular disturbances who are experiencing immunosuppression (Guiloff & Tan, 1992; Mundinger et al., 1992; Steinmetz et al., 1995). For example, toxoplasmosis (a parasitic infection) often produces large brain lesions apparent on CT or MRI. Progressive multifocal leukoencephalopathy produces multifocal white matter lesions that become more extensive over time and are easily seen on FLAIR MRI. However, in the absence of opportunistic infections or symptomatic AIDS, in the current post-CART era, people with chronic HIV tend to exhibit more subtle structural brain abnormalities (Heindel et al., 1994; Jernigan et al., 1993; Stout et al., 1998). While changes in brain structure may be evident through visual analysis of MRI scans over time, more often than not determination of such changes requires quantitative analysis of WMH, and cortical subcortical volume or other indices. Furthermore, these

structural abnormalities correspond with clinical factors tied to HIV status, including immunologic and proinflammatory pathophysiology, chronic viral exposure, disease and treatment history, and comorbid medical conditions (Jellinger et al., 2000; Mahadevan et al., 2007; Masliah, DeTeresa, Mallory, & Hansen, 2000; Morgello, Mahboob, Yakoushina, Khan, & Hague, 2002; Neuenburg et al., 2002; Silva et al., 2012; Xing et al., 2009).

Though functional neuroimaging is less commonly conducted as part of routine neurodiagnostic evaluations, when it is done, it reveals abnormalities that are quite robust among HIV-infected people. Disturbances of both resting-state and task-associated functional MRI (fMRI) are relatively easily demonstrated when people with HIV are compared to seronegative controls. Alterations in activation of brain regions known to be involved in working memory, attention, and executive control occur, along with abnormal deactivation of brain regions comprising the default network. HIV causes a reduction in the dynamic range of functional brain response that seems to be associated with cognitive frailty in people with chronic infection.

Cerebral metabolite abnormalities are also well documented among HIV-infected people, using magnetic resonance spectroscopy (MRS). Depletion of certain metabolites that reflect neuronal loss (e.g., N-Acetyl Aspartate, Glutamate) occurs in cortical and subcortical gray and white matter, along with increased concentrations of other metabolites (e.g., choline, myo-inositol) associated with pro-inflammatory processes and cell membrane disturbances. The basal ganglia have been shown to be particularly vulnerable to these metabolite disturbances. MRS abnormalities have been shown to correspond with structural and functional brain abnormalities (via fMRI), and also with HIV clinical factors and cognitive performance.

### **Neuropsychology**

When AIDS was first discovered in the early 1980s, severe cognitive and functional disturbances were very common. Many infected patients experienced dementia (Navia et al., 1986), though most subsequently died given the lack of therapy to combat the virus. The neurocognitive performance of patients with AIDS dementia was similar to that described at the time as a “frontal-subcortical” dementia, which reinforced the idea that HIV had a predilection for the basal ganglia, frontal-striatal systems, and white matter pathways. Of course, not all patients developed dementia, and a milder form of cognitive-motor disturbance was also observed in many infected people. The cognitive problems that occurred in these individuals were similar to that of AIDS dementia, though less severe. The fact that both cognitive and motor disturbance were observed is important as it reflects the dominant finding of cognitive and motor slowing that tended to occur among most patients with neurological symptoms.

Soon after antiretroviral therapy was first introduced, there was a reduction in the incidence of dementia. However, cognitive-motor disturbances continued to be common, although their occurrence tended to be greatest in patients with symptomatic AIDS, and to correspond with severe immune system impairment and elevated viral loads. Between the mid-1980s and late 1990s, people without compromised immune functions, elevated viral load, or AIDS symptomatology tended not to experience significant cognitive dysfunction. Yet, neurocognitive impairments continued to also be observed among people whose HIV infection was not well controlled. Studies during this period reported impairments on tests of working memory, processing speed, focused attention, and certain aspects of executive control. Impairments were commonly found on the Trail Making, Stroop, and Verbal Fluency tests, as well as motor tasks such as Grooved Pegboard. Deficits on symbol coding, sequencing, and other tests with attention-executive and working memory demands also tended to be affected. Learning inefficiencies were also described, though impairments of learning and memory were less consistently reported. Language (e.g., naming), semantics, visual perception, and other core cognitive functions tended to be largely spared. While learning inefficiency and memory recall problems occurred in some patients, severe impairments were uncommon, and primary amnesic disturbances as seen in Alzheimer’s and other neurodegenerative diseases were very rare.

The situation continued to improve with the advent of CART, as treated patients exhibited improved cognitive functioning, whereas untreated patients worsened. CART was widely adopted and the incidence of HAD decreased dramatically. This led many in the field to conclude that the neurological manifestations of HIV would cease to be a major problem in the future. Unfortunately, this initial optimism was dashed when studies conducted over the past decade continued to report HAND in as many as 50% of infected people. These impairments were occurring among people whose immune functions were no longer suppressed and without elevated viral load, suggesting that prior HIV history may continue to impact the brain even after the infection is controlled. Of particular concern is the fact that many recent studies still have found problems with learning and memory recall among people with chronic HIV.

There is also growing evidence that HIV is contributing to premature cognitive aging in many people. Whereas healthy adults often exhibit generalized slowing and problems with tasks requiring working memory, focused attention, and executive control as they advance in age into their 70s or 80s, HIV-infected people are exhibiting these changes much earlier in life. A number of studies have reported an increase in age-associated cognitive deficits among people with HIV who are in their 50s, suggesting that HIV and aging may interact to adversely affect the brain and cognition.

Even though mortality and morbidity have been greatly reduced in this country, HIV continues to be rampant around

the world, and is particularly prevalent in underdeveloped countries without modern or accessible health care systems. In sum, many challenges remain. It seems likely that HIV will continue to be a significant clinical and public health problem in the foreseeable future and the source of brain dysfunction and concern about impending cognitive and functional decline as people age with this chronic infection.

### Lyme Disease and Related Disorders

A 30-year-old man was referred for neuropsychological testing by his internist who reported joint pain, a peripheral neuropathy, arms and legs, and decreased cognitive functioning as symptoms. The patient stated that he had been diagnosed with Lyme disease three years earlier, and was treated with three weeks of oral doxycycline, the current standard antibiotic treatment for Lyme. He initially got better, but six months prior to this referral he described recurring symptoms. These included joint pain, a peripheral neuropathy and decreased cognitive functioning as symptoms. He also described problems with concentration, word finding, memory, fatigue and depression. These symptoms have affected his work. A Western Blot Test for Lyme disease was serum-positive for Lyme, but his CSF tests were negative. He was treated as an outpatient with IV antibiotics, but the treatment was discontinued after a month due to a blood clot at the infusion site. After treatment the patient continued to report problems with concentration, word finding, and memory; however, his neuropsychological profile was mostly normal, with above-average memory performances.

### Clinical Considerations

Lyme disease is a tick-borne infection caused by the spirochete *Borrelia burgdorferi* (Steere et al., 1983). It is a multi-system disorder that may affect the skin, joints, heart, eyes, and nervous system. The classic neurological symptoms of early stage Lyme disease include meningitis, cranial neuritis, and radiculoneuritis. These may occur alone or in combination in 15% of untreated patients (Pachner & Steere, 1985). Diagnosis is made by pleocytosis, the synthesis of intrathecal antibodies to *Borrelia burgdorferi*, detection by culture, or PCR in CSF (Stanek, Lusa, Ogrinc, Markowicz, & Strle, 2013). For most patients ten days of oral doxycycline, a tetracycline antibiotic, provide an optimal recovery rate at 30 months posttreatment, and additional antibiotics do not improve outcome (Wormser et al., 2003). A small percentage of patients develop a mild to moderate encephalopathy, often following long periods of latent infection. The encephalitic symptoms tend to be diffuse and nonspecific, and typically include memory loss, naming problems, difficulty concentrating, reduced efficiency, somnolence, and fatigue. For patients with these symptoms, it has been proposed (Finkel, Halperin, & Finkel, 1992; Garcia-Monco & Benach, 1995) that those with abnormal CSF, characterized by intrathecal production

of antibody to *Borrelia burgdorferi*, increased CSF protein, or both, have a neurological basis to their illness, although the mechanism is not fully understood. There have been case reports of more serious neurological involvement related to Lyme disease (Reik, Smith, Khan, & Nelson, 1985), although documented cases are rare.

Traditional brain neurophysiological and neuroimaging techniques have not been shown to be highly sensitive to the pathophysiology of CNS Lyme disease. The routine EEG is typically normal and although MRI abnormalities have been described in Lyme patients, these are nonspecific and relatively infrequent (Finkel et al., 1992). MRI abnormalities described in patients with Lyme disease suggest an inflammatory process and usually involve the subcortical white matter (Krupp et al., 1991). Even in patients with confirmed CNS involvement, MRI evidence of tissue damage is rare (Agosta et al., 2006). Single photon emission computed tomography (SPECT), a functional imaging technique that measures regional cerebral blood flow to provide information about metabolic activity in specific brain regions, has shown some promise in localizing the neuroanatomic basis for cognitive symptoms in Lyme disease. Logigian et al. (1997) studied a series of 13 patients with objective evidence of Lyme encephalopathy using a quantitative SPECT technique. The Lyme patients showed patterns of multifocal hypoperfusion, most notably in frontal subcortical areas including the basal ganglia and white matter of the cerebral hemispheres, which was not apparent in normal controls. Six months posttreatment with IV ceftriaxone, cerebral perfusion improved in all 13 cases, suggesting that the reduced cerebral perfusion in frontal and temporal lobe structures may be the neuroanatomical basis of Lyme encephalopathy (see Figure 20.2). Moreover, these same white matter regions form the large-scale neurocognitive networks involved in mediating memory and attention (Mesulam, 1990), consistent with the nature of cognitive symptoms. Other studies have similarly reported decreased regional blood flow in white matter in Lyme encephalopathy. Reductions have been linked to deficits in memory (Fallon, Keilp, Prohovnik, Heertum, & Mann, 2003) and some clinicians advocate using this in making a definitive diagnosis. However, while sensitive to brain abnormalities, SPECT hypoperfusion in these brain regions is not specific to Lyme disease and can be found in other conditions such as depression (Ito et al., 1996) and chronic fatigue syndrome (Schwartz et al., 1994), which have overlapping symptoms. Therefore although quantitative SPECT provides an objective and useful measure of cerebral hypoperfusion in Lyme encephalopathy, it cannot be used alone in diagnosing the condition.

### Neuropsychology

Neuropsychological studies of individuals with Lyme disease have almost exclusively been comprised treated patients with persistent symptoms. An exception was a

*Figure 20.2* Representative MRI (left column) and SPECT images (middle column), and superimposed MRISPECT (right column) in a normal subject (top row) and a patient with objective evidence of Lyme encephalopathy prior to treatment (middle row) and six months after treatment (bottom row). A brain surface rendering demonstrating the slice plane is shown in the lower left. Although the MR images in the patient were normal, there was reduced tracer activity in a multifocal pattern in cortical and subcortical structures in the pretreatment SPECT and a moderately elevated perfusion defect index. In the posttreatment SPECT, the uptake improved, and the defect index declined. Color scale: blue corresponds to lower and orange to higher perfusion. *A color version of this figure can be found in Plate section 2*

group studied by Halperin and colleagues (Halperin, Pass, Anand, Luft, Volkman, & Dattwyler 1988) before and after antibiotic treatment. Although Halperin et al. reported pretreatment cognitive deficits in almost every area examined, the data are difficult to interpret because they did not include a normative comparison group, and because there was no indication of the number of patients whose performance was outside of the normative range. Nevertheless, there were statistically significant improvements following treatment on standardized measures of visuospatial skills, speed of processing, executive functioning, and verbal recall with short-term attention span, verbal fluency, and recognition memory unchanged. Patients also completed the self-administered depression inventory, and while there was no evidence of significant depression before treatment, the average depression score was almost halved following treatment. In a study of treated Lyme patients who still reported memory deficits, Krupp et al. (1991) reported relatively lower scores on several memory tests, and a word fluency test compared to normal controls, but no differences in Wechsler IQ subtest scores or executive functioning tests. List-learning verbal memory tests, such as the California Verbal Learning (CVLT) (Delis, Kramer, Kaplan, & Ober, 1987) and Selective Reminding Test (SRT) (Buschke & Fuld, 1974) have been shown to be the most reliable indicators of neuropsychological impairment in treated Lyme patients (Halperin et al., 1988; Kaplan, Meadows, Vincent, Logigian, & Steere, 1992; Krupp et al., 1991; Ravdin, Hilton, Primeau, Clements, & Barr, 1996; Shadick et al., 1994; Westervelt & McCaffrey, 2002). Because neuropsychological impairment was not correlated with either serum or CSF antibody titers to *Borrelia burgdorferi* in these patients, the Krupp group proposed that cognitive deficits could occur in patients who no longer have evidence of active disease. However, this remains controversial. In a study comparing Lyme patients with evidence of infection in their CSF with Lyme patients without CSF abnormalities and normal controls, Kaplan and colleagues (Kaplan, Jones-Woodward, Workman, Steere, Logigian, & Meadows, 1999) showed that the Lyme disease group with abnormal CSF had significantly lower memory scores than the Lyme patients with normal CSF and normal controls. Memory test performances were not correlated with either greater depression or increased anxiety scores in any of the groups. The nature and magnitude of cognitive problems in the Lyme encephalopathy group were similar to those reported previously (Krupp et al., 1991); namely, lower memory scores on the retrieval measures of the SRT, a word-learning measure. Although the test battery sampled a wide range of cognitive abilities—including measures of attention, executive functioning and language—neither patient group had other deficits in comparison to the controls. However, both Lyme disease groups had higher depression scores than the control subjects, and the Lyme group with normal CSF also showed greater anxiety scores than controls. Objective memory

test performances were not correlated with either greater depression or increased anxiety scores in any of the groups.

Some patients report persistent symptoms after the recommended antibiotic treatment (Bujak, Weinstein, & Dornbush, 1996), which has been termed *post-Lyme disease syndrome* or *chronic Lyme disease*. Although the majority of these patients present with cognitive complaints, attempts to provide objective evidence of cognitive impairment, using neuropsychological tests, have been variable and inconclusive. In a study of previously treated patients with Lyme disease who continued to report memory problems three to 12 months following standard antibiotic therapy, the patients performed significantly worse on measures of verbal fluency and memory than healthy controls, but did not differ on tests of attention, psychomotor skills, and executive functioning (Krupp et al., 1991). However, other investigators found virtually no objective evidence of neuropsychological dysfunction in 125 chronic Lyme patients, although 70% reported memory decline as a primary symptom (Kaplan et al., 2003). Self-reported cognitive dysfunction was related to greater self-reported pain, limits in role functioning, and symptoms of depression, and was only weakly related to objective measures of cognitive dysfunction. Although there was a slight improvement in scores on a number of attention and memory tests in follow-up, there was no benefit of antimicrobials over placebo for patients with self-reported neurocognitive symptoms that do not show clear evidence of persisting *Borrelia burgdorferi* infection or evidence of cognitive impairment.

Lyme encephalopathy with the characteristic clinical picture of a positive serology to *Borrelia burgdorferi* and abnormal CSF, is likely due to active infection (Wormser et al., 2006). Neuropsychological testing in these patients typically shows mild, but significant, deficits on memory testing (Kaplan et al., 1992) and reduced cerebral perfusion on SPECT images (Logigian et al., 1997). In addition to demonstrated neuropsychological deficits, Lyme patients have also often shown affective symptoms and fatigue. Although there appears to be little relationship between objective neuropsychological functioning and affective symptoms such as depression, these may be related to the perception of cognitive loss (Kaplan et al., 2003; Westervelt & McCaffrey, 2002). After standard antibiotic therapy, most patients show significant improvements in their cognitive functioning (Halperin et al., 1988; Logigian, Kaplan, & Steere, 1990, 1999) and better cerebral perfusion (Logigian et al., 1997). However, a small minority of Lyme patients without evidence of memory loss on objective testing continues to have memory complaints. This is not unique to Lyme disease. The perception of memory loss has been shown to be weakly related to memory test performance and strongly associated with psychiatric symptoms in a number of disorders (Bolla, Lindgren, Bonaccorsy, & Bleecker, 1991; Broadbent, Cooper, FitzGerald, & Parkes, 1982). Moreover, there is little scientific evidence that chronic Lyme disease without evidence of

an active *Borrelia burgdorferi* infection in CSF is the cause of Lyme-related neurological disease (Feder et al., 2007). Unfortunately, some advocates for chronic Lyme continue to argue for an occult latent infection that can respond only to long-term antibiotics, such that the argument has become political rather than scientific (Auwaerter et al., 2011). That patients with previously treated Lyme disease have persistent symptoms is not the issue. The issue is whether these symptoms are caused by a *Borrelia burgdorferi* infection, and the available science does not support that. An autoimmune response (Steere, 2001) or coinfections with other tick-borne infections like human granulocytic anaplasmosis (also known as *ehrlichiosis*) and babesiosis remain potential candidates.

Steere, Gross, Meyer, and Huber (2001) proposed a model to explain treatment-resistant Lyme arthritis via an autoimmune response resulting from the initial *Borrelia burgdorferi* infection. Patients with Lyme arthritis who carry the HLA-DR4 or DR2 allele are more vulnerable to developing a chronic antibiotic-resistant arthritis. Chronic Lyme patients also have higher amounts of *Borrelia burgdorferi*-specific foxhead box P3 (FoxP3) than healthy controls, indicating that regulatory T-cells might also play a role, by immunosuppression, in the development of chronic Lyme disease. FoxP3 is a specific marker of regulatory T cells. The signaling pathway p38 mitogen activated protein kinase (p38 MAP kinase) has also been identified as promoting expression of proinflammatory cytokines from *Borrelia burgdorferi* (Jarefors, Janefjord, Forsberg, Jenmalm, & Ekerfelt, 2007). In addition to *Borrelia burgdorferi*, the Ixodes tick can be coinfecting with and transmit other pathogens such as *Anaplasma phagocytophilum* and *Babesia microti*. Human granulocytic anaplasmosis (HGA) is a rickettsial infection caused by *Anaplasma phagocytophilum*, a gram-negative bacterium that is unusual in its tropism to neutrophils (Wormser et al., 2006). Clinical manifestations are nonspecific and may include fever, chills, headache, and myalgia. Serologic testing using an indirect fluorescent antibody assay provides the most reliable diagnosis, and doxycycline is the recommended treatment. Chronic HGA infections have not been described in humans, and to our knowledge there have been no neuropsychological sequelae reported in affected patients. However, even without evidence of neurological involvement, encephalitic symptoms probably have been often associated with many types of systemic infections (Halperin, 2008). *Babesia microti*, the primary cause of babesiosis, seems a more likely candidate. It is also tick-borne infection that exists in the same endemic areas as Lyme disease (Wormser et al., 2006). This parasite attacks red blood cells in much the same way as the parasite that causes malaria, and the clinical presentation can be similar (Boustani & Gelfand, 1996). Approximately 10% of patients with Lyme disease in southern New England are coinfecting with babesiosis (Mylonakis, 2001). Symptoms develop one to six weeks after tick feeding and often include fever, fatigue, chills, sweats, and headache. Less common are

myalgia, anorexia, cough, nausea, vomiting, arthralgia, emotional lability, and depression (Krause, 2002). A combination of atovaquone and azithromycin is currently the treatment of choice for mild to moderate babesiosis (Vannier & Krause, 2012). If left untreated, symptoms may continue for months or even years. Unlike HGA, babesiosis is known to have encephalic symptoms and may be a more likely culprit in some cases of the treatment-resistant “Lyme” encephalopathy since there is known coinfection and babesiosis does not respond to the standard treatments for Lyme.

## Conclusion

Neurotropic infectious diseases have long been within the purview of neuropsychology practice. As with other neurobehavioral syndromes, neuropsychological assessment has been an integral part of diagnosis, rehabilitation, and research. With improved diagnostic methods and more effective treatments, neuropsychological methods become even more important in defining the phenotype and natural history of encephalitic disorders, particularly those with previously unknown etiologies. This chapter provided a glimpse into just three neurotropic infections—herpes simplex encephalitis, HIV and Lyme disease—but as noted earlier, there are many other brain infections, each with its own neuropsychological profile, response to treatment, and long-term outcome. While it was beyond the scope of this chapter to review the many infections capable of producing brain disease, it is important for neuropsychologists to stay abreast of the advances in brain infection research and remain relevant by designing assessments to best delineate the cognitive and emotional aspects of these disorders.

# 21 Hypoxia of the Central Nervous System

Ramona O. Hopkins

## Introduction

More than 424,000 deaths due to cardiac and respiratory arrest occur each year in the United States (Kudenchuk et al., 2015). Improvements in emergency and critical care medicine have resulted in an increase in successful cardiopulmonary resuscitation, which has led to a fairly stable mortality rate over the last 20 years (Sandroni, Nolan, Cavallaro, & Antonelli, 2007). However, more than half of all survivors experience significant morbidities such as long-term cognitive impairments that include impairments in memory and executive function and they experience depression, anxiety and reduced quality of life (Moulaert, Verbunt, van Heugten, & Wade, 2009). A significant percent of patients with anoxia (up to 90%) are unable to return to their premorbid level of function (Kaplan, 1999). Patient outcomes vary based on the location (in hospital vs. out of hospital) and the cause of cardiac arrest (Kudenchuk et al., 2015). In addition to cardiac or respiratory arrest, a number of other disorders cause a lack of oxygen to the brain. Anoxia, hypoxia, or ischemia occur in a variety of disorders including asthma, cardiac or respiratory arrest, cardiac disease or surgery, carbon monoxide poisoning, attempted hanging, complications of anesthesia, near drowning, obstructive sleep apnea (OSA), chronic obstructive pulmonary disease (COPD), and acute respiratory distress syndrome. Given that a number of disorders result in an anoxic/ischemic event, a substantial number of individuals will subsequently develop hypoxic brain injury along with its associated morbidities.

## Hypoxic Brain Injury

The human brain constitutes approximately 2% of the total body mass but utilizes up to 25% of the body's total oxygen consumption (Haddad & Jiang, 1993). Due to a high metabolic demand, the brain requires a constant supply of oxygen and glucose to produce energy and uses aerobic glucose oxidation to produce 95% of the brain's adenosine triphosphate (ATP) (Hicks, 1968). It is essential that the neocortical and subcortical areas receive a continuous supply of oxygen, as neurons are not able to store oxygen and glucose for later use (Hicks, 1968). Slight decreases in oxygen delivery to the brain may lead to permanent biochemical and morphological

changes. Both hypoxia and ischemia result in decreased oxygen delivery to the tissues. *Ischemia* is defined as insufficient blood supply to the brain or other organs (i.e. cardiac arrest) due to interruption or reduction of blood delivery, *anoxia* is the absence or near complete absence of oxygen in the arterial blood supply to an organ or tissue, *hypoxia* is diminished availability of oxygen to the tissues, and *hypoxemia* is a condition in which there is reduced oxygenation of the blood (Biagas, 1999; Kuroiwa & Okeda, 1994).

Effects of oxygen deprivation on cognitive function are well known. Early studies found that a decrease in the partial pressure of arterial oxygen (PaO<sub>2</sub>) in humans such that PaO<sub>2</sub> is 75% of normal impairs complex task performance; at 65%, memory impairments are manifest; at 50%, judgment is impaired and unconscious may occur; and very low levels (30%–40%) death will occur (Blass & Gibson, 1979). Regional brain oxygen utilization is not homogeneous, as some brain regions are more vulnerable to the effects of hypoxia than are others. Neural structures in the marginal zones of the vascular supply (end arteries), structures with high metabolic rates, or proximity to structures with high levels of excitatory amino acids such as glutamate or aspartate are affected differentially by hypoxia (Miyamoto & Auer, 2000). Vulnerable brain regions include the neocortex, hippocampus, basal ganglia, cerebellar Purkinje cells, primary visual cortex, frontal regions, and the thalamus (Chalela, Wolf, Maldjian, & Kasner, 2001; Oechmichen & Meissner, 2006). The time course of hypoxic-induced neuronal injury varies over time in different brain regions, with lesions of the basal ganglia and cortex occurring in the first few hours following hypoxia, whereas damage to the hippocampus may not occur for days to weeks (Kuroiwa & Okeda, 1994). In rodents who undergo anoxia, cell death in the globus pallidus, thalamus, and dentate gyrus occurred in the first 24 to 48 hours and the rate of neuronal cell death declined rapidly, or alternatively cell death in the cortex, striatum and CA1 subregion of the hippocampus worsen over the first week (Nakajima et al., 2000). Early neuronal injury occurs from acute mechanisms of injury including oxygen deprivation and reduction, ATP, and brain edema, leading to a decline in cerebral perfusion and disruption of the blood-brain barrier (Oechmichen & Meissner, 2006). Delayed neuronal damage is due to mechanisms of secondary neuronal injury, including antiapoptotic

growth factor, vulnerability of microtubule-associated protein and tubulin, and disrupted protein synthesis (Bodsch, Barbier, Oehmichen, Grosse Ophoff, & Hossmann, 1986; Miyamoto & Auer, 2000).

### **Mechanisms of Brain Injury**

The mechanisms of hypoxic brain injury have been elucidated over the last several decades, in both in vivo and in vitro models. For detailed reviews of mechanisms of hypoxic brain injury, see Busl and Greer (2010), Guo, Yu, and Ma (2011), and Oehmichen and Meissner (2006). Mechanisms of hypoxic brain injury are divided into several categories: (a) biochemical effects, (b) functional neuronal changes, (c) reperfusion or reoxygenation injury, and (d) neuronal cell death from necrosis and apoptosis (Busl & Greer, 2010).

#### **Biochemical Changes**

A brief description of the biochemical changes that occur in hypoxic brain injury follows. Early injury is mediated by prolonged axonal depolarization and subsequent increased calcium influx (approximately a 25% increase via the NMDA receptors), and concomitant intracellular accumulation of calcium due to ionic pump failure (Kass & Lipton, 1986; Schurr, Lipton, West, & Rigor, 1990). Increased intracellular calcium activates calpain, which leads to cell death via apoptosis Busl and Greer (2010). Decreasing ATP production without decreasing ATP utilization results in energy depletion leading to cell death (Lutz & Nilsson, 1994). Energy failure results in ionic pump failure, outflow of  $K^+$ , and inflow of  $Ca^{2+}$  (Lutz & Nilsson, 1994). Lactic acidosis due to anaerobic metabolism also results in neural injury (Michenfelder & Sundt, 1971). High blood glucose levels and concomitant hypoxia result in elevated brain lactate levels posthypoxia (Siemkiewicz & Hansen, 1978; Welsh, Ginsberg, Rieder, & Budd, 1980). The energy failure opens postsynaptic excitatory receptors, especially voltage-gated NMDA glutamate receptors (Gilland, Puka-Sundvall, Hillered, & Hagberg, 1998) and destructive enzymes such as lipases, proteases, and nucleases. Neuronal cell death due to neurotoxicity of excitatory amino acid (EAA) neurotransmitters such as glutamate and aspartate, which are released in relatively large quantities following hypoxia and cause increased neuronal firing, calcium influx, and subsequent neuronal death (Olney, 1969). Excitotoxic-induced neuronal damage occurs in the hippocampus (Kuroiwa & Okeda, 1994), cerebellum (Inage, Itoh, Wada, & Takashima, 1998), cerebral cortex, and basal ganglia (Johnston, Nakajima, & Hagberg, 2002), as well as multiple brain regions depending on the duration of anoxia/hypoxia. Hypoxia also decreases expression of the glutamate transporter EAAT4 expression (i.e., removes glutamate from the synapse) in Purkinje cells and is linked to glutamate toxicity (Inage et al., 1998).

### **Functional Neuronal Changes**

Functional cellular changes include mitochondrial damage, disaggregation of polyribosomes and abnormal Golgi complexes, resulting in a loss of cell structure due to cytoskeletal damage via intracellular calcium accumulation (Busl & Greer, 2010; Petito, Feldmann, Pulsinelli, & Plum, 1987). In hypoxia, depressed protein synthesis is increased by elevated levels of intracellular calcium, aggravating cytoskeletal damage (Raley-Susman & Lipton, 1990). Finally, activation of glutamate receptors activates early gene upregulation (Busl & Greer, 2010).

### **Reperfusion or Reoxygenation Injury**

With the return of oxygenation to the brain, the risk to the brain is not over—reoxygenation and reperfusion injury occurs. The formation of oxygen radicals during reperfusion or reoxygenation can lead to cell death. During hypoxia ATP levels fall and xanthine accumulates and glutamate release can occur along the neural shifts in calcium (Bottiger, Schmitz, Wiessner, Vogel, & Hossmann, 1998). Upon reperfusion and reoxygenation xanthine oxidase catalyzes the conversion of xanthine to uric acid resulting in superoxide, which impairs cell proliferation, gene expression, and disrupts membrane function (Biagas, 1999; Floyd, 1990; Granger, McCord, Parks, & Hollwarth, 1986). Nitric oxide synthase (NOS) is expressed in inflammatory cells (i.e., macrophages) and can be induced by hypoxia. It contributes to brain injury via impaired neurotransmission, impaired protein synthesis, and membrane peroxidation (Biagas, 1999). Thus, hypoxic brain injury results in a cascade of pathophysiological processes that result in cell damage and subsequent neuronal cell death (see Table 21.1).

### **Apoptosis and Necrosis**

Hypoxia and associated biochemical cascades can initiate necrosis and/or apoptosis. Necrosis occurs due to edema and rupture of the cell sending the intracellular contents into the extra cellular space, resulting influx of inflammatory cells and vascular disruption (Biagas, 1999). Cell damage often culminates in necrotic cell death (Hossmann, Oschlies, Schwindt, & Krep, 2001). Apoptosis is programmed cell death with associated cell shrinkage, DNA fragmentation, and cellular changes, and appearance of apoptotic bodies, secondary inflammation, and fibrosis (Steller, 1995). Apoptosis is triggered by hypoxia-induced free radicals, nitric oxide, and reduced mitochondrial function (Busl & Greer, 2010). Neurons in the anoxic-ischemic region die from necrosis, neurons in the penumbra (bordering areas) die due to necrosis and apoptosis, and distant neurons like those in the hippocampus initially survive and then undergo delayed apoptotic cell death (Beilharz, Williams, Dragunow, Sirimanne, & Gluckman, 1995; Li, Powers, Jiang, & Chopp, 1998).

Table 21.1 Mechanisms of neuronal damage and death following hypoxic brain injury

<i>Mechanisms</i>	<i>Etiology of Cellular Death</i>
<b>Biochemical Changes</b>	
Decreased ATP production	• Energy failure and ionic outflow
Calcium Induced Neuronal Death	• Calcium influx and release from intracellular stores
Excitotoxicity	• Ionic pump failure @ cell death
	• Release catabolic enzymes @ cellular proteolysis
	• Excessive release of excitatory amino acid neurotransmitters (EAAs) (e.g., glutamate)
	• Calcium influx @ cell death
	• Decreased expression of excitatory amino acid transporter-4 (EAAT4) (glutamate transporter)
<b>Functional Neuronal Changes</b>	
	• Mitochondrial damage
	• Disaggregation of polyribosomes
	• Loss of cell structures @ cytoskeletal damage via calcium
	• Depressed protein synthesis
	• Activation of glutamate receptors via early gene upregulation
<b>Reperfusion or Reoxygenation Injury</b>	
Reperfusion	• Secondary disruption of energy metabolism
Oxidative Injury	• Xanthine catalyzed to uric acid @ reactive oxygen species such as the hydrogen peroxide, superoxide anion and the hydroxyl radical (OH)
	• Reactive oxygen radicals attack cell membranes.
	• Lipid peroxidation impairs cell proliferation and gene expression
	• Inflammatory mediators (lipid-derived factors, cytokines, neutrophils, platelet adhesion, etc.)
	• Formation of nitric oxide
	• Alters neuronal transmission
	• Disrupts proteins
	• Cause membrane peroxidation
<b>Necrosis and Apoptosis</b>	
Necrosis	• Edema
Apoptosis	• Rupture of cell membrane
	• Influx of inflammatory cells
	• Vascular Disruption
	• Programmed cell death triggered by
	• free radicals
	• nitric oxide
	• reduced mitochondrial function

## Neuroimaging Findings

Hypoxic brain injury can result in both focal and diffuse neuropathologic lesions and atrophy. Brain regions are affected differentially based on their selective vulnerability to hypoxia due to their arterial supply and location in the brain, such as in watershed areas (White, Zhang, Helvey, & Omojola, 2013). For example, hypoxia may result profound damage such as in diffuse damage to the cerebral cortex (Bachevalier & Meunier, 1996; Caine & Watson, 2000; Hopkins, Kesner, & Goldstein, 1995a); also see Figure 21.1). Cortical injury can be easily identified on diffusion-weighted imaging and is manifest as hypointense areas in the gray matter (White et al., 2013). Cortical regions that are vulnerable include occipital and perirondalic cortices (Rademakers, van der Knaap, Verbeeten, Barth, & Valk, 1995); primary sensory motor region (Macey et al., 2002); and insula, cingulate, and ventromedial prefrontal cortex (Harper, Kumar, Ogren, & Macey, 2013).

Focal damage occurs in a variety of neural structures, including the basal ganglia and hippocampi, which are more vulnerable to hypoxia compared to adjacent cortical regions such as the parahippocampal gyrus or other temporal lobe

gyri (Hopkins et al., 1995; Kesner & Hopkins, 2001; Press, Amaral, & Squire, 1989). Significant hippocampal atrophy occurs following hypoxic brain injury (Hopkins et al., 1995; Kesner & Hopkins, 2001; Manns, Hopkins, Reed, Kitchener, & Squire, 2003; Press et al., 1989), and lesions in the hippocampus (Bayley, Gold, Hopkins, & Squire, 2005; Bayley, Hopkins, & Squire, 2003; Manns et al., 2003) (see Figure 21.2), basal ganglia (see Figure 21.3), and cerebellum are common (Armengol, 2000; Speach, Wong, Cattarin, & Livecchi, 1998). Hypoxic brain injury results in white matter changes including lesions in the cerebellar white matter (Mascalchi, Petrucci, & Zampa, 1996), subcortical and periventricular white matter lesions (Davies et al., 2001; Parkinson et al., 2002), and corpus callosum atrophy (Porter, Hopkins, Weaver, Bigler, & Blatter, 2002). A study using diffusion tensor imaging found reduced white matter integrity in the cerebellum, basal ganglia, limbic regions, corpus callosum, and within the corona radiata; the changes in white matter integrity were associated with hypoxia (Kumar et al., 2014). In a review of the literature of anoxia, Caine and Watson (2000) reviewed a number of studies in 90 patients with

*Figure 21.1* This figure shows magnetic resonance imaging of the brain in a normal individual (panels A thru D) and a participant who has had an anoxic brain injury (panels 1 thru 4). For the normal participant, Panel A shows a three-dimensional reconstruction of the brain, Panel B an axial view of the brain thru the body of the lateral ventricles, Panel C the midsagittal slice through the corpus callosum, and Panel D a coronal view through the hippocampus. For the anoxic brain-injured participant; Panel 1 shows a three-dimensional reconstruction with significant gyral atrophy and sulcal widening. Panel 2 shows an axial view thru the body of the lateral ventricles with significant ventricular enlargement and sulcal widening. Panel 3 show the midsagittal view thru the corpus callosum showing significant colossal atrophy. Finally, Panel 4 shows a coronal view thru the hippocampus-showing enlargement of the lateral ventricles, third ventricle, and temporal horns of the lateral ventricles, and bilateral hippocampal atrophy.

*Figure 21.2* This figure shows brain magnetic resonance images in the coronal plane through the hippocampus at the level of the fourth ventricle. Panel A shows a brain MRI in a normal individual, Panel B shows a participant with anoxic brain injury who has bilateral hippocampal atrophy, and Panel C shows a second participant with an anoxic brain injury who has bilateral hippocampal lesions.

hypoxia who underwent brain imaging. Of the 90 patients, 44% had cortical edema or atrophy, 33% had cerebellar lesions, 22% had basal ganglia lesions, 21% had hippocampal atrophy, and 3% had thalamic lesions (Caine & Watson, 2000). In a systematic review of near drowning, in 46 cases, 36% had diffuse cerebral atrophy, 15% had infarcts, and 75% had basal ganglia lesions (Nucci-da-Silva & Amaro, 2009). The high prevalence of basal ganglia lesions in near drowning is similar to that found after carbon monoxide

poisoning, which occurs in 32% to 86% of individuals (Hopkins, Fearing, Weaver, & Foley, 2006).

During the acute period following hypoxic brain injury, conventional magnetic resonance imaging (MRI) and computed tomography (CT) findings may be normal or exhibit only subtle changes. Imaging techniques such as diffusion-weighted MRI (which measures cytotoxic edema) found more extensive neuropathologic changes in the early acute phase than previously reported. For example, individuals

**Figure 21.3** This figure shows brain MRI in the axial plane thru the basal ganglia in anoxic participants. The panel in the top left shows an anoxic participant on the day of injury (carbon monoxide poisoning) and the top panel on the right shows the same participant two weeks postinjury with bilateral lesions in the globus pallidus (arrows). The lower left panel shows an anoxic participant (carbon monoxide poisoning) 4.5 weeks post injury and the lower right panel shows the same participant 8 months postinjury with numerous foci of abnormal signal intensity in the deep cerebral white matter and basal ganglia bilaterally and symmetrically.

with hypoxia had early and extensive abnormalities in the basal ganglia, cerebellum and cortex in the acute period and gray and white matter abnormalities in the subacute period on diffusion-weighted MRI (Arbelaez, Castillo, & Mukherji, 1999). Chalela, Wolf, Maldjian, and Kasner (2001) found white matter abnormalities within seven days of hypoxic brain injury on diffusion-weighted MRI. The pattern and extent of brain abnormalities identified on diffusion-weighted MRI may be markers for prognosis following hypoxic brain injury (Singhal, Topcuoglu, & Koroshetz, 2002).

### **Limbic System**

As discussed previously the mesial temporal lobes, in particular the hippocampus, are selectively vulnerable to hypoxic brain injury, which manifests as lesions and atrophy that

are associated with memory impairments (Bayley et al., 2005; Bayley et al., 2003; Manns et al., 2003). Because of the hippocampus's distinct anatomy and location in the brain, hippocampal volumes can be readily quantified (Bigler et al., 1997; Bigler & Clement, 1997; White et al., 2013). Hippocampal atrophy is a common finding in OSA (Gale & Hopkins, 2004; Macey et al., 2002; Morrell et al., 2003). The temporal horns of the lateral ventricles are sensitive to temporal lobe damage and neuronal loss, and may indicate temporal lobe and/or hippocampal atrophy (Bigler, 2001). Lesions are also found in the fornix and cingulum (White et al., 2013). Kesler, Hopkins, Blatter, Edge-Booth, and Bigler, (2001) measured cross-sectional surface areas of the fornix in a group of hypoxic brain injury subjects following carbon monoxide poisoning and found mild atrophy of the fornix. Since the fornix is the major output pathway from the hippocampus to the mammillary bodies, it follows that fornix would atrophy due to anterograde degeneration of the hippocampal axons following hippocampal neuronal loss.

### **Cerebellum**

The cerebellum is vulnerable to hypoxic brain injury (lesions can be diffuse or focal in nature) and Purkinje cell death due to excitotoxicity results in diffuse and focal injury (Welsh et al., 1980). Both necrotic processes and demyelination occur in the cerebellum (Chang, Han, Kim, Wie, & Han, 1992; Mascacchi et al., 1996). Cerebellar atrophy correlates with low Glasgow coma scores, profound acidosis, and electrocardiograph abnormalities (O'Donnell, Buxton, Pitkin, & Jarvis, 2000). Cerebellar damage occurs in the cerebellar cortex and deep nuclei (Harper et al., 2013), and it results in ataxia or motor incoordination, problems initiating or ending purposeful movements, impaired balance, difficulty maintaining posture, problems with gait, wide-based stance, and a positive Romberg sign (Heimer, 1995). Cognitive deficits secondary to cerebellar pathology include impaired executive function, visuospatial processing, and language, as well as impaired memory and affective changes (Schmahmann & Pandya, 1997).

### **Brain Stem**

While the effects of hypoxic brain injury on the cerebral cortex, cerebellum, hippocampus, and thalamus are well described, less is known about the effects on the brain stem. Lesions in brain stem nuclei following hypoxia (Gilles, 1969; Lindenberg, 1963) occur in widely distributed regions including the midbrain, pons, locus coeruleus, superior olive, inferior colliculi, reticular formation, and cranial nerve nuclei (Revesz & Geddes, 1988). Lesions have been reported in the dorsal, ventral, and ventrolateral medulla in individuals with OSA (Kumar, Macey, Woo, Alger, & Harper, 2008). Functional markers of brain stem integrity include evoked potentials. Abnormal

somatosensory evoked potentials (Chen, Bolton, & Young, 1996), and brain stem auditory evoked potentials (Goldberg & Karazim, 1998), are indicators of poor survival following hypoxic brain injury. Alternatively, normal brain stem auditory evoked potentials have been reported in individuals with anoxic coma, indicating sparing of rostral brain stem function.

### Neuropsychological Effects

Regardless of the etiology, neuropsychological deficits are a common morbidity following hypoxic brain injury. Neuropsychological impairments include impaired memory (Bigler & Alfano, 1988; Hopkins et al., 1995b; Hopkins, Weaver, et al., 2005; Hopkins & Woon, 2006; Zola-Morgan & Squire, 1990), dysexecutive function (Hopkins et al., 1995; Lezak, Howieson, Bigler, & Tranel, 2012), agnosia (Farah, 1990), visual-spatial deficits (Barat, Blanchard, & Carriet, 1989), and generalized decline in intellectual function (Bigler & Alfano, 1988; Parkin, Miller, & Vincent, 1987; Wilson, 1996). A review of neuropsychological outcomes following hypoxia identified 67 cases of which 54% had amnesia, 46.2% impaired executive function or personality change, 31.3% visuospatial deficits, and 9% language impairments (Caine & Watson, 2000). Motor disturbances are also common following hypoxic brain injury and include difficulties with posture, gait, involuntary movements, Parkinsonian symptoms, and apraxia (Lishman, 1998). Although hypoxic brain injury may result in diffuse neuroanatomical damage (Bachevalier & Meunier, 1996; Hopkins et al., 1995a), in select cases cell death appears limited to (or particularly severe in) the hippocampus (Zola-Morgan, Squire, & Amaral, 1986). A number of studies show that memory impairments are associated with hippocampal atrophy (Hopkins et al., 1995; Manns et al., 2003). The degree of neuropsychological impairment appears to parallel the degree of morphologic abnormalities (Hopkins et al., 1995; Hopkins, Tate, & Bigler, 2005).

Controversy exists in the literature regarding whether hypoxia in the absence of ischemia can result in brain injury (Miyamoto & Auer, 2000). Neurologic sequelae following hypoxia without ischemia in a study of 22 patients with hypoxia without hypotension found that while all patients experienced coma, recovery to their premorbid level of function occurred in only 50% of the patients (Gray & Horner, 1970). In a case study of three patients with hypoxia ( $PO_2$  less than 45 mm Hg) without ischemia, all patients died of cardiac failure due to hypoxia even though they did not have hypotension (Rie & Bernad, 1980). Alternatively, evidence in a variety of pulmonary disorders provide evidence that hypoxia can cause cognitive impairments.

Patients with pulmonary disorders including COPD and OSA with concomitant hypoxia have similar neuropsychological deficits to patients with anoxia. Prigatano Wright, and Levin (1984) found mild impairments in problem solving in patients with COPD who experienced mild hypoxemia.

Other COPD studies find impaired memory, impaired executive function including inability to form new concepts, inability to think flexibly (Grant, Heaton, McSweeney, Adams, & Timms, 1982), impaired attention, and slow processing speed (Fix, Golden, Daughton, Kass, & Bell, 1982) that correlated with the severity of the hypoxemia (Hopkins et al., 1995; Hopkins, Weaver, et al., 2005). Studies in patients with OSA find these individuals have impaired memory, executive function, perception, spatial abilities (Kales et al., 1985), attention, memory, and problem solving abilities (Findley et al., 1986). A meta-review of cognitive impairments in OSA found mild to severe cognitive deficits were associated with severity of hypoxemia; specifically, severe groups could be identified based on a higher apnea-hypopnea index score (Bucks, Olaithe, & Eastwood, 2013). The neuropsychological deficits in the OSA patients correlate with the severity of the nocturnal hypoxemia (Bedard, Montplaisir, Richer, Rouleau, & Malo, 1991) and with sleep fragmentation (Naismith, Winter, Gotsopoulos, Hickie, & Cistulli, 2004). It is unclear whether sleep fragmentation or hypoxia is the best predictor of cognitive function in OSA (Naismith et al., 2004; Tsai, 2010); however, the majority of studies in OSA find deficits in attention, memory, visuospatial abilities, and executive function, with sparing of language and psychomotor abilities (Bucks et al., 2013).

Studies in critically ill patients with acute respiratory distress syndrome (ARDS) have demonstrated the relationship between hypoxia and cognitive impairments. A study by Hopkins and colleagues found ARDS survivors had impairments in memory, attention, concentration, and mental processing speed, as well as global cognitive decline (Hopkins, Weaver, Pope, Orme, Bigler, & Larson-Lohr, 1999). At one-year follow-up, 30% of the patients had lower intellectual function and 78% had impaired memory, attention, concentration and/or mental processing speed. The ARDS survivors' average duration of hypoxemia was measured using continuous pulse oximetry during their intensive care treatment. The mean duration of hypoxemia was  $< 90\% = 122 \pm 144$  hours,  $< 85\% = 13 \pm 18$  hours, and  $< 80\% = 1 \pm 3$  hours, and the hypoxemia significantly correlated with neuropsychological impairments (Hopkins et al., 1999). In addition, a subset of ARDS survivors exhibited brain atrophy, significantly enlarged ventricles, and an increased Ventricle-to-Brain Ratio (a measure of generalized atrophy) compared to the matched controls, suggesting that hypoxia results in global brain injury and cognitive impairments (Hopkins, Gale, Pope, Weaver, & Bigler, 2000). The association between lower oxygenation values and cognitive impairment was confirmed in a second study of ARDS survivors with moderate to severe hypoxia (Mikkelsen et al., 2012). Of these patients, 55% had cognitive impairments at 12 months, and patients with cognitive impairments had significantly lower  $PaO_2$  values compared to the ARDS patients who did not develop cognitive impairments. The severity of hypoxemia may serve as a marker

of illness severity and risk for developing cognitive impairments (Mikkelsen et al., 2012).

This research suggests that hypoxia and not the etiology of the hypoxic brain injury may be the critical factor in determining the effects on neurocognitive function. There are only a few studies that compare neuropsychological outcome in hypoxic patients with different etiologies. For example, neuropsychological impairments observed with OSA were similar to COPD patients for complex reasoning and memory (Roehrs et al., 1995). Alternatively, Gale and Hopkins (2004) found neuropathologic abnormalities and impaired cognitive impairments in patients with carbon monoxide poisoning and OSA, however the carbon monoxide group consistently performed worse on most cognitive measures while the OSA group had more selective impairments. The variability of these results mirrors the heterogeneity reported neuropsychological outcome following hypoxic brain injury.

Weaver and colleagues (2002) studied individuals with hypoxic brain injury due to acute carbon monoxide poisoning who were compared for cognitive outcome following either hyperbaric oxygen or normobaric oxygen treatment in a randomized double-blind clinical trial. The cognitive impairments were significantly more frequent in the normobaric oxygen group (14.5%) as compared with (3.9%;  $P=0.03$ ) in the hyperbaric oxygen group (Weaver et al., 2002). Hyperbaric oxygen therapy reduced cognitive impairments by 46% at six-week outcome. Both groups improved with time, but the difference in cognitive impairments between the groups was maintained at 12 months (Weaver et al., 2002). These results suggest that treatments such as hyperbaric oxygen may potentially ameliorate hypoxia-associated cognitive impairments.

### *Psychiatric and Affective Changes*

Psychiatric and behavioral changes following hypoxic brain injury include euphoria, irritability, hostility, depression, and anxiety (Bahrke & Schukitt-Hale, 1993; Li et al., 2000). Studies have shown that exposure to acute hypobaric hypoxia is associated with development of negative moods which progressively worsen with longer duration of exposure and increased severity of the hypoxia (Bahrke & Schukitt-Hale, 1993; Li et al., 2000). Psychiatric disorders are not only common but also vary in type and severity following hypoxic brain injury (Gale et al., 1999; Hopkins, Tate, et al., 2005; Hopkins, Weaver, et al., 2005; Wilson, 1996). The psychiatric disorders include depression (Bruno, Wagner, & Orrison, 1993; Gale et al., 1999; Hopkins, Key, Suchyta, Weaver, & Orme, 2010), anxiety (Bruno et al., 1993), personality changes (Chapel & Husain, 1978), and emotional lability (Chapel & Husain, 1978). Some individuals may show lack of concern for or awareness of their deficits, show little emotional response to their cognitive impairments, or exhibit emotional lability including anger, agitation, and depression on one extreme and laughter or mania on the other (Armengol, 2000). Secondary mania posthypoxic brain injury has been reported; symptoms include irritable mood, hyperactivity, push of speech, flight of ideas, grandiosity, decreased sleep, distractibility, and lack of judgment (Krauthammer & Klerman, 1978; Sullivan & Jenkins, 1995). Finally, patients with basal ganglia lesions may develop obsessive-compulsive disorder with stereotyped behaviors, loss of drive, and flattened affect (Laplaine et al., 1989). (Laplaine et al., 1989).

#### *Case Study*

##### **Adult: Focal Anoxic Brain Injury**

Case A1 is a 26-year-old Caucasian male who sustained a full cardiopulmonary arrest and underwent cardiopulmonary resuscitation following a motor-vehicle accident in January 1990. Additionally, he received resuscitation (45 minutes of open cardiac resuscitation) intraoperatively while undergoing exploratory laparotomy and left anterior thoracotomy. The brain CT scan on the same date was incomplete, but read as normal. He was treated in the intensive care unit and was placed on mechanical ventilation after he developed acute respiratory distress syndrome. His blood alcohol on admission was 0.23 mg%. An electroencephalogram (EEG) during his hospital stay was "borderline normal." He was confused and agitated but had no complications or seizures while hospitalized.

Social History: A1 completed high school and one year of college with grades of Bs and Cs. Prior to his injury, he was employed as a carpenter. He had no history of prior learning disabilities, traumatic brain injury, or psychiatric problems. He occasionally drank alcohol (one to two beers per day) with occasional marijuana and cocaine use. He has been drug free since in the years since his injury.

A1's ICU length of stay was 12 days and he was then transferred to an inpatient rehabilitation unit where he remained for 60 days. On admission to the rehabilitation unit he exhibited moderate to severe cognitive and language deficits and lacked insight into his deficits, however he was able to follow simple two-step commands. He exhibited inappropriate and impulsive behavior that improved with administration of carbamazepine. Following his discharge from the rehabilitation unit, he continued to have significant impairments in memory, attention, and judgment. He returned to Utah to live with his parents and receive outpatient rehabilitation services.

Brain MRI showed significant hippocampal atrophy (see Figure 21.2, Panel B). Table 21.2 shows his neuropsychological scores. He continued to have persistent and severe verbal and visual memory impairments. In order to remember things, he writes everything down in a planner or notebook, including what he had for breakfast and any appointments. He has been unemployed for the majority of the time since his injury due to his memory impairments and received disability payments.

The above case illustrates the variable outcome that can occur following anoxic brain injury, with some individuals having diffuse neuropathological abnormalities with diffuse cognitive impairments and other having more focal brain abnormalities and more select cognitive impairments.

### Characterization and Treatment of Cognitive Impairment

Outcome following hypoxic brain injury is variable; however, the majority of patients have poor outcome (Bachman & Katz, 1997). Information regarding the effects of

rehabilitation on neurocognitive outcome following hypoxic brain injury is limited. For patients with severe anoxia coma (> 24 hours), both survival, if they do survive, and recovery of function is poor (Groswasser, Cohen, & Costeff, 1989). Survival rates following postanoxic coma range from 9% to 40% (Bedell, Delbanco, Cook, & Epstein, 1983; Levy et al., 1985; Snyder et al., 1980). Patients who survived anoxic coma may regain mobility and ability to perform activities of daily living, but they do not return to their preinjury level of cognitive function (Groswasser et al., 1989). Outcome following anoxic coma is not predicted by age, sex, site of resuscitation, cause of anoxia, nor presence of postanoxic seizures (Levy et al., 1985). A single case study suggested that “relatively”

good cognitive function in the first month postanoxic coma may indicate improved recovery and benefit from rehabilitation (Kaplan, 1999); however, this is not generally reported.

Groswasser et al. (1989) followed a group of 31 patients following cardiopulmonary arrest with coma. On long-term follow-up, 13 were independent in activities of daily living, two had regained premorbid cognitive function, and four had returned to work, but only one to the same job. Patients who were younger with shorter duration of coma had had somewhat better outcomes but often they did not return to their pre-injury level of functioning. In addition, cognitive and functional recovery was significantly worse in patients with hypoxic brain injury compared to patients with traumatic brain injury with prolonged coma. The differences in recovery may be due to the interaction between diffuse damage and delayed cell death, but was not related to the etiology of the hypoxic brain injury (Groswasser et al., 1989).

Armengol (2000) reported eight individuals with severe anoxia who underwent treatment in a neurobehavioral rehabilitation program. Six of the eight individuals had poor outcome, with significant cognitive impairments including deficits in attention, executive function, memory, reasoning, language, visuospatial, and motor skills. The two remaining patients had mild cognitive impairments. Similar findings of significant cognitive impairments and affective dysregulation that significantly complicated rehabilitation were reported in a single case (Parkin et al., 1987). A study following hypoxic brain injury found that in-patient rehabilitation improved functional status (measured by the Functional Independence Measure, with individuals who had higher scores on admission having the best outcome), however, few of the patients were able to resume their previous jobs and level of function (Schmidt, Drew-Cates, & Dombrov, 1997).

## Conclusions

Patients with hypoxic brain injury have both diffuse and focal brain injury, and concomitant neuropsychological impairments. The etiology of hypoxic brain injury is variable, but includes asthma, cardiac or respiratory arrest, cardiac disease or surgery, carbon monoxide poisoning, attempted hanging, complications of anesthesia, near drowning, OSA, COPD, and acute respiratory distress syndrome that result in anoxia, hypoxia, or ischemia. Hypoxic brain injury results in focal and diffuse neuropathological lesions and atrophy including hippocampal, basal ganglia, cerebellar, and white matter abnormalities. Cognitive impairments include intellectual decline, memory deficits, decreased attention, visuoperceptual, problem solving, executive dysfunction, and decreased mental processing speed and location of the damage are associated with the cognitive impairments. Hypoxic brain injury results in a high prevalence of psychiatric disorders including new euphoria, irritability, hostility, depression, and anxiety and personality changes. The rate of psychiatric disorders is variable and may depend on the etiology of the hypoxia (e.g.,

COPD 37%–42%, asthma 24%–42%, OSA 40%, and carbon monoxide poisoning 39%–60%), and the prevalence rate is significantly higher than that observed in the general population (2%–9% major depression and 3% generalized anxiety) and the rate observed in medical populations (12%). Hypoxic brain injury results in significant neurological structural and functional abnormalities, as well as neuropsychological impairments—and recovery of function appears limited.

## 22 Parkinson's Disease and Other Movement Disorders

*Alexander I. Tröster and Robin Garrett*

### Introduction

This chapter focuses on Parkinson's disease (PD), an  $\alpha$ -synucleinopathy associated primarily with dysfunction of the basal ganglia and fronto-striatal circuits and manifesting as a hypokinetic movement disorder with a constellation of nonmotor symptoms. It describes the epidemiology, genetics, pathology, pathophysiology, and neurobehavioral features of the disease, including the recent concept of mild cognitive impairment (MCI) in PD (PD-MCI). Medical and surgical treatments of PD and their impact on cognition and behavior are also reviewed. Although it remains controversial whether PD with dementia (PDD) and dementia with Lewy bodies (DLB) are distinct entities or two sides of the same coin, similarities and differences between the two conditions are briefly summarized. The chapter then briefly describes neuropsychological aspects of atypical parkinsonian conditions, including one synucleinopathy (multiple system atrophy, or MSA) and two tauopathies (progressive supranuclear palsy, or PSP, and corticobasal syndrome, or CBS). After summarizing neuropsychological aspects of a hyperkinetic movement disorder (Huntington's disease, or HD), the key neuropsychological features of essential tremor and dystonia are briefly described. Brief mention is also made of psychogenic movement disorders (PMDs) to alert the neuropsychologist to possible somatoform disorders among persons with movement disorders. Tourette syndrome, given its vast range of neuropsychological features, is beyond the scope of this chapter and the interested reader is referred to a recent review (Murphy & Eddy, 2013). The chapter also includes a general strategy for the neuropsychological evaluation of persons with movement disorders and some case presentations that highlight some of the information described. While citing recent empirical research, the chapter seeks to provide references especially to recent reviews that permit readers to delve in greater depth into those topics of particular interest to them.

### Parkinson's Disease, Parkinson's Disease With Dementia, and Dementia With Lewy Bodies

At the outset it is important to note that PD is not the same as parkinsonism. Whereas the former is a distinct disease,

parkinsonism refers to a constellation of four signs (gait instability, rigidity, tremor, and bradykinesia) that are observable in a host of conditions, both neurological and psychogenic. Commonly used to diagnose PD, the UK Brain Bank criteria are listed in **Table 22.1**.

*Table 22.1* UK Parkinson's Disease Society Brain Bank (Queen Square) criteria for diagnosis of PD

- 
- 1 Presence of parkinsonian syndrome evidenced by
    - bradykinesia
    - at least one of:
      - muscular rigidity,
      - 4–6 Hz resting tremor, or
      - postural instability not related to proprioceptive, vestibular, visual, or cerebellar dysfunction.
  - 2 Exclusion, by history, of:
    - repeated strokes,
    - repeated head injury,
    - use of antipsychotic or dopamine-depleting drugs,
    - encephalitis,
    - multiple affected relatives,
    - no response to levodopa,
    - sustained remission of symptoms,
    - continued unilateral symptoms after three years,
    - gaze palsy,
    - early dementia,
    - exposure to known neurotoxin,
    - evidence on neuroimaging of tumor or communicating hydrocephalus,
    - cerebellar signs,
    - early dysautonomia, or
    - Babinski sign.
  - 3 Definite PD defined by at least three of the following supportive features:
    - unilateral onset,
    - persistence of symptom asymmetry,
    - progression of symptoms,
    - excellent response to levodopa,
    - levodopa response sustained for five years,
    - resting tremor,
    - levodopa-induced dyskinesias, or
    - clinical course over ten years.
-

### Historical Perspectives

The illness bearing his name was first described by James Parkinson in 1817. In that description of six patients (of whom Parkinson had personally examined three), it was categorically asserted that intellect and senses were preserved, but the author's recognition of depression in these patients is suggested by his use of terms such as *melancholia* (see also Darvesh & Freedman, 1996; Parkinson, 1817). Though the assertion that PD leaves cognition unscathed was challenged by Charcot and Vulpian (1861, 1862), and by isolated reports in the late 19th and early 20th centuries, many outside France remained unconvinced of cognitive compromise in PD probably until the middle of the 20th century (see Goetz, 1992). Naville (1922) introduced the term "bradyphrenia" to capture the phenomena of slowed information processing and diminished attention in postencephalitic parkinsonians without dementia. Dementia was rarely a topic of early medical manuscripts concerned with *paralysis agitans*. Interestingly, Fritz Lewy—whose name the eosinophilic, neuronal inclusion bodies bear since 1918 (see Schiller, 2000)—did not distinguish between depression and dementia when he described the neuropathology and mental alterations of PD (Lewy, 1912, 1923). Furthermore, Lewy apparently did not appreciate the significance of the inclusion bodies he had identified, and the entity of DLB was not recognized until the last 30 years of the 20th century (Holdorff, 2002).

Neuropsychological investigations using standardized, psychometric tests were rarely carried out in early studies of PD, but the likely first published use of such tests can be traced to Shaskin, Yarnell, and Alper (1942) administration of the Wechsler Bellevue Scale, an intelligence scale, to postencephalitic parkinsonians. A further catalyst for neuropsychological evaluation (using projective tests and tests of cognition and intelligence) in PD was the advent in the 1950s of the neurosurgical treatment of parkinsonism (idiopathic, postencephalitic, and vascular; see, for example, Diller, Riklan, & Cooper, 1956). Though the number of surgical interventions for PD declined dramatically after the introduction of levodopa in the late 1960s (Siegfried & Blond, 1997), numerous psychometric studies of the neuropsychological effects of thalamotomy and pallidotomy were carried out both in North America (e.g., Jurko & Andy, 1964; Riklan & Levita, 1969; Shapiro, Sadowsky, Henderson, & Van Buren, 1973) and on the other side of the Atlantic (e.g., Almgren, Andersson, & Kullberg, 1969; Asso, Crown, Russell, & Logue, 1969; Christensen, Juul-Jensen, Malmros, & Harmsen, 1970; Fünfgeld, 1967; McFie, 1960; Vilkki & Laitinen, 1974; Welman, 1971). The clinical focus of early neuropsychological studies of PD was maintained by investigators examining the cognitive effects of levodopa in the 1960s and 1970s (e.g., Beardsley & Puletti, 1971). By the 1980s, clinically oriented studies concerned themselves with the neuropsychological characterization of dementia in PD and its discriminability from other dementias (e.g., Huber,

Shuttleworth, Paulson, Bellchambers, & Clapp, 1986; Pilon, Dubois, Lhermitte, & Agid, 1986; Pirozzolo, Hansch, Mortimer, Webster, & Kuskowski, 1982). In parallel, studies increasingly informed by cognitive psychological theory began to provide more detailed and sophisticated descriptions of neuropsychological deficits in PD (e.g., Boller, Mizutani, Roessmann, & Gambetti, 1980; Brown & Marsden, 1988; Cooper, Sagar, Jordan, Harvey, & Sullivan, 1991; Lees & Smith, 1983; Levin, Llabre, & Weiner, 1989; Taylor, Saint-Cyr, & Lang, 1986). Advances in understanding the neural substrates and cognitive mechanisms underlying neuropsychological deficits in PD continued as functional neuroimaging technology matured and became more readily available (e.g., Cools, Stefanova, Barker, Robbins, & Owen, 2002; Dagher, Owen, Boecker, & Brooks, 1999; Feigin et al., 2003; Owen, Doyon, Dagher, Sadikot, & Evans, 1998) and as radioactive tracers became available for specific neurotransmitter systems (Bohnen et al., 2007; Klein et al., 2010; Pfeiffer, Lokkegaard, Zoetmulder, Friberg, & Werdelin, 2014). The 1990s saw a renaissance of neurobehavioral studies of surgical treatments of PD, including deep brain stimulation (DBS), that continues today. Studies in the late 20th and early 21st century examining differences between PDD and DLB, are yet to resolve controversy about whether the conditions are distinct or two sides of one coin (Goldman, Williams-Gray, Barker, Duda, & Galvin, 2014). The difficulty distinguishing these conditions may in part have been an impetus to better understand predementia cognitive impairment in PD and the formulation of MCI criteria (Litvan et al., 2012; Tröster, 2011). Indeed, there is now interest in the possibility that subtle cognitive changes may be present in the premotor phase of the disease, i.e., persons deemed at risk for PD (Hawkins et al., 2010; Thaler et al., 2012).

### Epidemiology

The number of new cases per year (incidence) and the total number of cases at a given time (prevalence) vary as a function of case ascertainment, meaning the methods and criteria by which cases of PD are searched, for, screened, and diagnosed. Generally, reported disease rates are higher when broad rather than when strict diagnostic criteria are applied. Population-based door-to-door survey followed by clinical examination is the most complete case-finding strategy. Because prevalence is impacted by survival, incidence might be a more precise estimate of PD occurrence.

PD rarely occurs before age 50 years, and age-specific prevalence increases until the ninth decade. Reported overall prevalence rates of PD range from 167 to 5,703 per 100,000 persons per year (Wirdefeldt, Adami, Cole, Trichopoulos, & Mandel, 2011). Worldwide, the prevalence of PD in individuals above 50 was between 4.1 and 4.6 million in 2005, with that number projected to rise to between 8.7 and 9.3 million by 2030 (Dorsey et al., 2007). Among studies that report gender differences, a higher prevalence is consistently

found among males than females, specifically, twofold in a recent study (Baldereschi et al., 2000). Lower PD prevalence among Blacks than Whites and Hispanics may be an artifact of apparently diminished survival.

Overall, incidence rates for PD among all age groups ranged between 1.5 and 22 per 100,000 person-years (Wirdfeldt et al., 2011). Based on the eight studies deemed to be of the best quality, the median standardized incidence rate in developed countries was estimated to be 14 per 100,000 person-years. This number increases to about 160 per 100,000 person-years among those 65 years and older (Hirtz et al., 2007). Incidence of parkinsonism is obviously higher than that of PD by virtue of including a larger number of conditions: One North American study reported an annual incidence of 26 per 100,000 of *parkinsonism*, and a PD incidence of 11 per 100,000 (Bower, Maraganore, McDonnell, & Rocca, 1999).

Dementia prevalence estimates vary from 8% to 93%, depending upon diagnostic criteria, sampling, and case ascertainment methods used, but the most accepted prevalence rates are 20% to 40% (Mohr, Mendis, & Grimes, 1995) with the highest-quality studies yielding a prevalence of 31% (Aarsland, Zaccai, & Brayne, 2005). Dementia incidence is about 3% for persons with PD younger than 60 years and 15% for persons with PD older than 80 years (Biggins et al., 1992; Marder, Tang, Cote, Stern, & Mayeux, 1995; Mayeux et al., 1990). MCI is thought to occur in about a third of patients, though recent criteria have yielded some higher estimates (Goldman et al., 2013).

### Genetics

Genetic factors do not play a major role in sporadic PD. Were genetic factors to play a major role in the etiology of PD, then concordance rates for PD ought to be much higher among monozygotic than dizygotic twins, which is not the case. Nonetheless, 10%–15% of patients have a family history of the disease, suggesting a genetic contribution in those patients, particularly in early onset disease. A number of genetic mutations and loci (PARK 1–20, at the time of writing) linked to parkinsonism have been identified (Clarimon & Kulisevsky, 2013). These genetic findings may help identify molecular pathways of therapeutic relevance. The monogenic (or Mendelian) transmission of PD is not entirely straightforward because often there is incomplete penetrance, meaning that a carrier of the mutation may not develop the disease (perhaps because the gene interacts with other genes or the environment). Furthermore, several of the genes identified each may have various alterations (e.g., mutations or variations in copy number) with different clinical expressions or phenotypes (Halliday, Leverenz, Schneider, & Adler, 2014). In addition to monogenic transmission, various genetic polymorphisms (variations common in the population) may increase disease risk, although disease will be expressed only in the presence of other factors. More

recently, studies have begun to examine potential genetic contributions to cognitive dysfunction in PD, including genes implicated in other cognition-compromising diseases (e.g., APOE) and in PD per se (e.g., SNCA, LRRK2) (Sharp & Alcalay, 2015). Frequent issues that have plagued these studies are a lack of statistical power and the use of relatively insensitive cognitive screening measures or patient report. Nonetheless, the research with positive findings allows one to raise hypotheses regarding potential genetic contributions to cognitive decline in PD.

Among genes implicated in PD, PARKIN (PARK2), which is linked to autosomal recessive inheritance of PD and early disease onset, seems not to associate with cognitive impairment. Indeed, gene carriers may perform similarly (Caccapolo et al., 2011) or better than early onset PD noncarriers or healthy controls on neuropsychological tests tapping perception, attention, and memory (Alcalay et al., 2014). SNCA, the gene encoding for  $\alpha$ -synuclein that is the building block of Lewy bodies, causes autosomal dominant PD by virtue of mutations (PARK1) or copy-number variations (PARK4). However, the expressed phenotype is variable. This gene is of particular neuropsychological interest as the Iowa kindred (PARK4) tends to develop early dementia (Farrer et al., 1999), and the Contursi kindred (PARK1) may show atypical clinical features including fluent aphasia and palilalia (Golbe et al., 1996). Unfortunately, due to rarity (the gene accounts for only 2% of autosomal dominant PD cases) and the lack of sophisticated neuropsychological study, precise cognitive characterizations are lacking. One study did report early perceptual deficit followed by executive and memory dysfunction in one family (Muentzer et al., 1998), but another failed to find an association between SNCA and a broad range of neuropsychological tests (Mata et al., 2014).

Studies of potential cognitive differences between carriers of LRRK2 mutations (PARK8), the most frequently mutated gene in PD and inherited in autosomal dominant fashion, have yielded contradictory findings. Whereas some studies report similar performance on cognitive screening measures (Aasly et al., 2005; Alcalay et al., 2010), others have observed poorer performance among LRRK2 carriers than noncarriers (Healy et al., 2008; Lesage et al., 2006). The number of studies addressing cognition and psychiatric features in person with PINK1 (PARK6) are few and generally lack lengthy follow-up, but it is possible that dementia is relatively rare among carriers (Ephraty et al., 2007; Healy et al., 2004). One study found no association between LRRK2, MCI, dementia, and anxiety (Estanga et al., 2014). Similarly, cognitive characteristics of carriers of DJ-1 mutations are rarely described, but one study suggests that the phenotype resembles PD-Dementia-ALS complex and involves dementia within ten years of symptom onset (Annesi et al., 2005).

Cognitive correlates have also been studied for genes related to other neurodegenerative disease (e.g., APOE, MAPT) and dopaminergic function (e.g., COMT and BDNF). The APOE  $\epsilon$ 4 allele increases risk for Alzheimer's disease (AD) and two

meta-analyses have reported this allele to be either associated with greater risk of PDD (Huang, Chen, Kaufer, Troster, & Poole, 2006) or to be overrepresented among those with PDD relative to those without dementia (Williams-Gray, Goris, et al., 2009). Prospective studies have been less apt to find such an association, with two finding no association between the allele and dementia (Kurz et al., 2009) or Mini Mental State Exam (MMSE) score change (Williams-Gray, Goris, et al., 2009), whilst another study reported the allele to be associated with greater change on the Dementia Rating Scale (DRS) (Morley et al., 2012). Among PD patients without dementia, the  $\epsilon 4$  allele is associated with poorer memory and semantic fluency (Mata et al., 2014). A combination of polymorphisms referred to as the H1/H1 haplotype of the microtubule-associated protein tau (MAPT) gene are linked to tau formation and have been implicated in AD and progressive supranuclear palsy. The predominance of evidence implicates the haplotype in cognitive decline and dementia risk in PD (Goris et al., 2007; Williams-Gray, Evans, et al., 2009), although this finding may obtain only in those persons developing dementia fairly early in the disease course. In patients with longer disease duration, the haplotype may be associated with impaired memory (Morley et al., 2012), but another study failed to find an association between MAPT and neuropsychological test performance (Mata et al., 2014).

Dopamine is degraded by enzymes including catechol-O-methyl-transferase (COMT). The COMT met/met polymorphism leads to lower enzyme activity (and thus presumably higher synaptic dopamine levels) than the val/val variant and is associated with better performance on the Wisconsin Card Sorting Test (WCST) in healthy persons. Counterintuitively, one study found that an increasing number of met alleles was associated with *poorer* planning performance on the Tower of London (Foltynie, Goldberg, et al., 2004). Although two other studies associated the COMT polymorphism with attention impairment (Morley et al., 2012; Williams-Gray, Hampshire, Barker, & Owen, 2008), a large study using an extensive neuropsychological test battery failed to find any effect (Hoogland et al., 2010). It is possible that the conflicting findings may relate to patients' severity of dopamine depletion and medication. The role of the brain-derived neurotrophic factor (BDNF) gene polymorphisms remains unclear. Dopamine release and dopaminergic cell survival are shown to be activated and enhanced by BDNF. The finding that the low secretion (met) allele of BDNF was associated with better planning on the Tower of London task than the high secretion val allele, like the COMT finding, again seems counterintuitive. Indeed, the finding linking cognition and BDNF in PD has not been replicated (Gao et al., 2010).

### Neuropathology and Pathophysiology

PD involves the loss of pigmented cells from the substantia nigra and it is estimated that 70%–80% of this system's neurons have been lost when PD symptoms emerge (Bernheimer,

Birkmayer, Hornykiewicz, Jellinger, & Seitelberger, 1973). Dopamine depletion in the striatum is more profound in the putamen than the caudate, and eventual abnormalities in the dopaminergic mesolimbic and mesocortical projection systems contribute to neurobehavioral changes. Dysfunction and pathology in other neurotransmitter systems also contribute to the neurobehavioral features of PD (Halliday et al., 2014). Cell loss in PD is also evident in the locus coeruleus (noradrenergic), the dorsal raphe nuclei (serotonergic), the nucleus basalis of Meynert (cholinergic), and the dorsal vagal nucleus. Dysfunction of these neurotransmitter systems has also been linked especially to executive and affective changes in PD, and imaging studies of dopaminergic (Ito et al., 2002; O'Brien et al., 2009), cholinergic (Bohnen et al., 2007; Bohnen et al., 2006; Hilker et al., 2005; Klein et al., 2010), and noradrenergic systems (Remy, Doder, Lees, Turjanski, & Brooks, 2005) have yielded complementary findings regarding these systems' neuropsychological impact in PD.

An important feature of the neuropathology of PD is the presence of Lewy bodies in the brain stem and/or amygdala and, later in the disease, in neocortex. These Lewy bodies contain the protein  $\alpha$ -synuclein. The stages of the evolution of the neuroanatomical pathology of PD was described by Braak and colleagues (2003) (see Table 22.2 and Figure 22.1). Although this description has been challenged because the evolution of clinical features of PD is heterogeneous and sometimes inconsistent with such a systematic evolution of pathology, the model has heuristic value. From a neuropsychological standpoint it is useful to note that by the time a diagnosis of PD is made (Stage 3 or 4), even a relatively

Table 22.2 Braak staging of neuropathology in Parkinson's Disease (after Braak et al., 2003)

Stage	Primary Brain Region Affected	Loci of Pathology
1	medulla	Dorsal IX/X motor nucleus and/or immediate reticular zone
2	medulla and	Stage 1 + caudal raphe nuclei, gigantocellular reticular pontine tegmentum nucleus and caeruleus-subcaeruleus complex
3	midbrain	Stage 2 + midbrain (esp. pars compacta of substantia nigra)
4	basal prosencephalon	Stage 3 + prosencephalon (confined to transentorhinal and mesocortex region and CA2-plexus)
5	neocortex	Stage 4 + high order sensory association areas of the neocortex and prefrontal cortex
6	neocortex	Stage 5 + first order sensory association neocortical areas and premotor areas; may be some mild changes in primary sensory areas and primary motor field

Figure 22.1 Progression of pathology in PD according to the Braak staging system (from allocortex through mesocortex to neocortex)

Figure courtesy of Prof. Dr. Heiko Braak.

insensitive measure such as the MMSE may disclose cognitive impairment in some patients (Braak, Rub, & Del Tredici, 2006; Braak, Rub, Jansen Steur, Del Tredici, & de Vos, 2005), a finding consistent with the observation that as many as one-fifth to one-third of patients may show at least subtle

impairments on neuropsychological tests at or near the time of PD diagnosis (Aarsland, Bronnick, Larsen, Tysnes, & Alves, 2009; Elgh et al., 2009; Foltynie, Brayne, Robbins, & Barker, 2004; Muslimovic, Post, Speelman, & Schmand, 2005). Severity of dementia has been associated with cortical Lewy body burden (Hurtig et al., 2000), but there are cases of PDD that lack cortical pathology (Perry et al., 1985; Xuereb et al., 1990) and cases of PD that meet neuropathological criteria for DLB at autopsy but do not have a history of dementia (Colosimo, Hughes, Kilford, & Lees, 2003). Cognitive changes are not simply a manifestation of synuclein pathology, however. Coexisting pathologic AD may be evident in 10%–40% of persons with PDD (Irwin et al., 2012), and AD-like pathology, particularly  $\beta$ -amyloid containing plaques in an even higher proportion, though tau-related tangles are seen less frequently (Apaydin, Ahlskog, Parisi, Boeve, & Dickson, 2002). These pathologic findings are consonant with the association between cerebrospinal fluid (CSF) reductions in  $\beta$ -amyloid and cognition (Leverenz et al., 2011; Montine et al., 2010) and the absence of the elevated tau levels seen in AD CSF. Nonetheless, an association between CSF tau levels and memory and executive decline in PD may be found once dopaminergic therapy is initiated (Liu et al., 2015). Given the consistency of findings implicating  $\beta$ -amyloid in the cognitive decline of PD/PDD, the apparent lack of association between cognitive impairment and imaged brain  $\beta$ -amyloid burden in PD is puzzling (Gomperts et al., 2012). PDD may also be related to vascular pathology (Jellinger & Attems, 2008), as may some cases of PD-MCI (Adler et al., 2010).

The pathology underlying different phenotypes of Lewy body disease may also differ. The prospective Sydney Multicenter Study of PD (Halliday & McCann, 2010), showed three phenotypes of patients: one group with early, prominent dementia and akinetic-rigid PD (clinically resembling DLB); another group of older (> 70 years) patients with widespread alpha-synuclein pathology who develop dementia in three to ten years (clinically resembling PDD); and a final, slightly younger group (disease onset before 70 years) who develop dementia after ten to 15 years and who have brain atrophy with lesser alpha-synuclein deposition. Consistent with the Sydney study, another study reported that PD patients developing dementia late in the disease (after about ten years) have less cortical alpha-synuclein pathology and fewer plaques but greater cholinergic abnormalities than those developing dementia early on, whose pathology resembled more strongly that of DLB (Ballard et al., 2006).

Neurobehavioral changes in PD (and its motor signs) can also be understood by considering the pathophysiology of fronto-striatal circuits (Zgaljardic, Borod, Foldi, & Mattis, 2003). The original model of frontal-basal ganglionic-thalamic-frontal circuits (Alexander, DeLong, & Strick, 1986) has undergone refinement (Wichmann & De Long, 2015). Recent research has shown that the information from limbic circuits may be shared with the associative and motor

circuits, that the basal ganglia interact with the cerebellar-cortical circuits, and that several of the subcortical structures may have direct links with cortex, including nonfrontal cortex, and among each other (Middleton & Strick, 2000). For example, animal work has identified a hyperdirect pathway between frontal cortex and subthalamic nucleus (STN; see Haynes & Haber, 2013) that may explain some of the behavioral effects of subthalamic stimulation. According to the simplified model, the frontal cortex, basal ganglia and thalamus are linked by five anatomically and functionally segregated circuits that retain their relative position to each other and share the same neurotransmitters at each point. The circuits, named for their origin (dorsolateral, orbitofrontal, anterior cingulate, motor, and oculomotor), are closed but have open elements to permit communication with cortical regions implicated in functions similar to those of a circuit. The dorsolateral, orbitofrontal, and cingulate circuits are particularly important in the regulation of cognition, affect, and motivation, respectively. The circuits have both direct and indirect pathways linking the striatum with the substantia nigra and internal globus pallidus (GPi), with the indirect pathway involving the external globus pallidus (GPe) and STN (Figure 22.2). In PD, the STN is overactive and excessively activates the GPi. This effect is amplified

by the direct pathway's diminished inhibition of the GPi. A result of the of the GPi's overactivity is an excessive braking of the thalamus, and the subsequent dampening of the thalamus' excitatory influence on cortical regions. The pathophysiologic changes in these and other neural circuits probably interact to produce the complex behavioral syndromes observed in PD. Specific cognitive deficits can also be understood in terms of specific neural network dysfunctions and the neurotransmitter abnormalities affecting these networks in different stages of PD (Gratwicke, Jahanshahi, & Foltynie, 2015).

### Neurobehavioral Features of Parkinson's Disease

Subtle cognitive alterations may precede PD diagnosis and be evident already at time of diagnosis. As PD progresses, the disease can compromise a variety of cognitive domains along a continuum of severity ranging from subclinical changes to MCI and eventually dementia. Deficits in early PD are most apparent on those tasks demanding of self-initiated information processing strategies (Taylor & Saint-Cyr, 1995), but executive impairments cannot account for the full range of cognitive deficits in PD (Tröster & Fields, 1995). If signs of cortical dysfunction (apraxia, amnesia, aphasia,

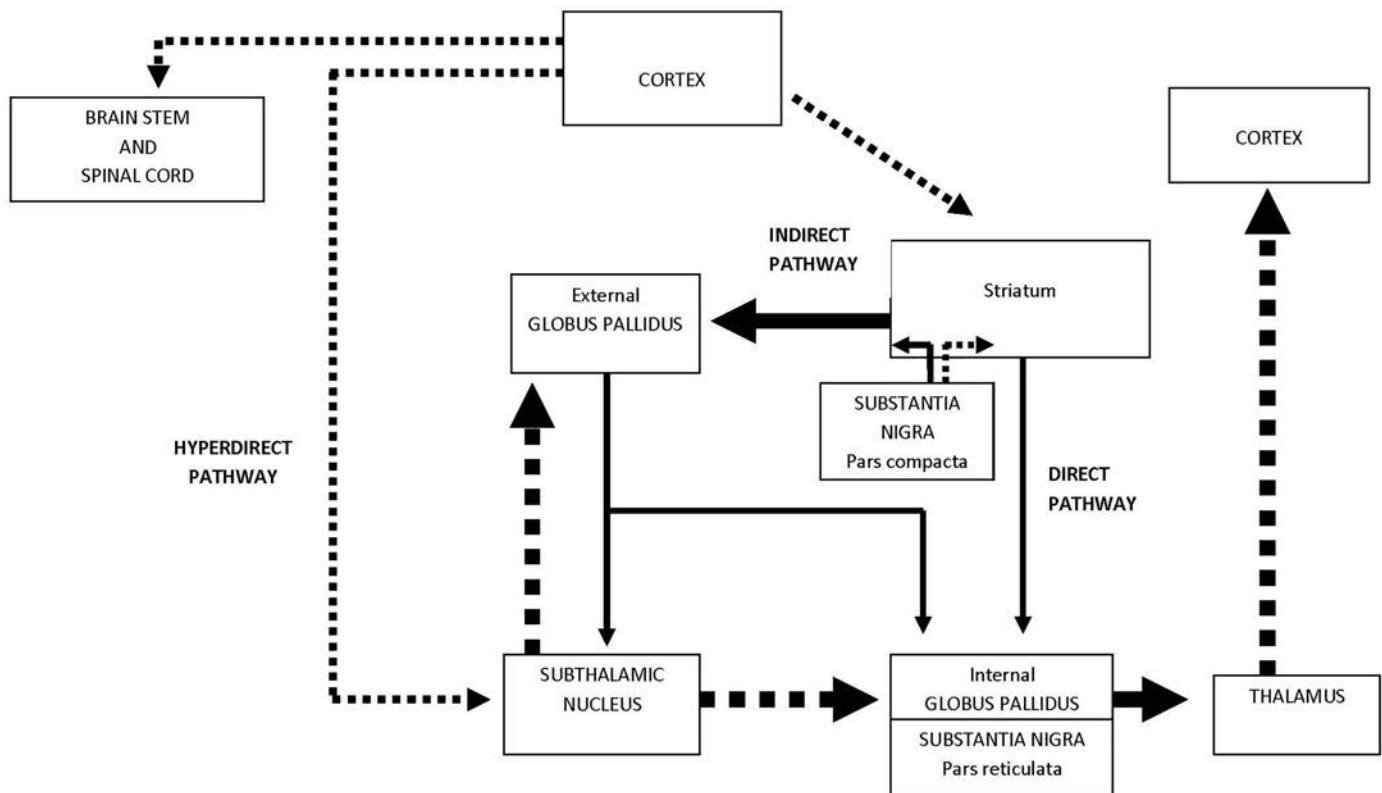

Figure 22.2 Fronto-striatal circuit dysfunction in PD

Key: solid arrows, inhibitory influence; dotted arrows, excitatory influence; narrow arrows, underactive relative to normal; broad arrows, overactive relative to normal

and agnosia) are evident within the first year of motor signs, these deficits suggest the presence of another condition, such as AD, DLB, atypical parkinsonism, or vascular dementia. The vast majority of findings relating to cognitive deficits in PD have led to the postulated existence of two distinct cognitive syndromes: at first, a predominantly dopamine-mediated frontal-subcortical executive syndrome compromising, for example, working memory, planning, and set shifting; and later, another syndrome characterized by compromise of cognitive functions (e.g., memory, visuospatial perception) mediated primarily by posterior cortical regions and related to dysfunction in cholinergic, serotonergic, and noradrenergic systems (Kehagia, Barker, & Robbins, 2010).

### *Specific Cognitive (Dys)Functions in Parkinson's Disease*

The following discussion examines how various cognitive functions are impacted or spared by PD and its treatment, the performance by parkinsonians on clinical neuropsychological tests evaluating these functions, and some of the putative mechanisms underlying deficient task performance.

#### INTELLIGENCE

Intelligence is preserved in PD until dementia evolves, though even patients without dementia may perform more poorly than expected on Performance Scale subtests of the Wechsler Adult Intelligence Scales (WAIS; Ross et al., 1996). To our knowledge WAIS-IV performance has not been examined in PD, but studies using earlier versions of the Wechsler scales found impoverished performance especially on Digit Symbol, Picture Arrangement, and Object Assembly.

#### ATTENTION AND WORKING MEMORY

Working memory is a limited-capacity, multicomponent system allowing temporary, online manipulation and storage of information to guide and control action. Consequently, working memory deficits can impact performance on other cognitive tasks. The role of dopaminergic system dysfunction in the PD working memory impairment is well established (Cools, 2006) and dopaminergic medications may transiently improve working memory in early stages of the disease (Kehagia et al., 2010), especially on tasks involving longer delays between presentation and recall (Moustafa, Bell, Eissa, & Hewedi, 2013).

Performance on simple attention tasks, such as digit span and spatial span, is often intact or only very mildly impaired in early PD. Performance, however, becomes increasingly impaired as tasks make greater demands on the manipulation of information within working memory. A meta-analysis of 56 studies reported deficits in PD in tasks tapping verbal simple attention (digit span forward), visual simple attention (Corsi blocks), verbal complex attention (digit

span backward), and visual complex attention (CANTAB spatial working memory test) (Siegert, Weatherall, Taylor, & Abernethy, 2008). The impairment was mild for verbal span but moderate for complex verbal as well as simple and complex visual spans. The authors provided several explanations for the more pronounced visual attention impairment: (a) visuospatial impairment is primary in PD; (b) visuospatial span tasks may be more difficult and demanding of central executive resources; (c) more patients in the analysis had left-sided onset and thus, presumably, greater right hemisphere dysfunction; and (e) the role of the right hemisphere in the maintenance and control of attention and working memory storage/recall. Working memory deficits in PD have variously been attributed to reduced capacity of the system (Gabrieli, Singh, Stebbins, & Goetz, 1996), difficulty manipulating information within working memory (Lewis et al., 2003), and difficulty inhibiting responses (Kensinger, Shearer, Locascio, & Growdon, 2003; Rieger, Gauggel, & Burmeister, 2003). Whether deficits updating working memory might be due to increased susceptibility to the entry of irrelevant information or resistance of existing information to deletion has not been resolved.

As regards performance on other working memory and attention tasks, even newly diagnosed patients with PD are impaired on the Digit Ordering Task, during which they are read a randomly ordered string of digits they are then asked to repeat in ascending order (Stebbins, Gabrieli, Masciari, Monti, & Goetz, 1999). Similarly, patients with PD are likely to demonstrate difficulty on tasks requiring divided or selective attention, though impairments may be task dependent (Lee, Wild, Hollnagel, & Grafman, 1999). Both limited attentional resources and attentional set shifting may contribute to patients' poor performance on Stroop-like tasks (Woodward, Bub, & Hunter, 2002). Patients typically show impairments on visual search and cancellation tasks presumably due to impaired selective attention and vigilance rather than motor slowing (Filoteo, Williams, Rilling, & Roberts, 1997).

#### EXECUTIVE FUNCTIONS

Executive functions—including planning, conceptualization, flexibility of thought, insight, judgment, self-monitoring, and self-regulation—are important to evaluate given that PD affects several of these functions. Consistent with the hypothesis that early executive deficits are linked to dopaminergic dysfunction, a study of more than 300 drug-naïve patients revealed that executive function (but not memory or visuospatial) differences between patients and controls were related to nigrostriatal dysfunction as indexed by diminished striatal dopamine transporter binding on DAT-SPECT scan (Siepel et al., 2014). Executive functions are important to assess from a pragmatic standpoint because these functions are linked to the realization of goals, to the capacity to consent to medical treatment (Dymek, Atchison, Harrell, &

Marson, 2001), and to the ability to engage in instrumental activities of daily living (IADLs) (Cahn et al., 1998). Executive dysfunction may also be an early indicator of incipient dementia in PD (Mahieux et al., 1998; Woods & Tröster, 2003), although some find that tests mediated predominantly by posterior brain regions provide a more imminent signal of dementia (Williams-Gray, Evans, et al., 2009; Williams-Gray et al., 2013). In addition, although the driving accident rate in PD as a whole is comparable to that of the rest of the population (Homann et al., 2003), patients with cognitive flexibility and working memory compromise might be at greater risk for accidents (Ranchet et al., 2013).

An important issue in neuropsychological evaluation is whether diminished awareness of deficits (anosognosia) is likely to compromise the validity of information obtained on interview and self-report measures. Advancing PD might involve metacognitive compromise (Seltzer, Vasterling, Mathias, & Brennan, 2001), but PD patients as a group do not have significantly diminished awareness (Seltzer et al., 2001). Brown, MacCarthy, Jahanshahi, and Marsden (1989) found that persons with PD-MCI, even when depressed, validly completed self-report measures. Another study found that patient and caregiver report was related to performance on cognitive tests (Naismith, Pereira, Shine, & Lewis, 2011). However, accuracy of self-report, and presumably awareness, may decline as cognitive impairment advances (Sitek, Soltan, Wiczorek, Robowski, & Slawek, 2011) and patients may demonstrate lack of awareness of motor versus cognitive deficits (Amanzio et al., 2010; Maier et al., 2012), including dyskinesias (Pietracupa et al., 2013). This lack of motor deficit awareness might be related to right hemisphere dysfunction, motor phenotype, and proprioceptive deficits.

Several clinical neuropsychological tests are routinely used to assess executive functions in PD, the most common among them Tower of London, card sorting, verbal fluency, Trail Making and interference tasks. A meta-analysis showed that all five of these tasks reveal differences of medium to large effect size between patients and healthy individuals, but the clinical significance of such findings remains elusive (Kudlicka, Clare, & Hindle, 2011). Numerous studies have evaluated planning in PD using the Tower of Hanoi or variants thereof (e.g., Tower of Toronto, Tower of London). While some studies found PD patients to show normal accuracy (number of moves) but a slowness in problem solving (e.g., Morris et al., 1988), others also observed diminished planning accuracy (Owen et al., 1995; Saint-Cyr, Taylor, & Lang, 1988) and planning deficits associated with decreased motivation (Weintraub et al., 2005). One study reported deficits with problem solving only on tasks with a high visuospatial content (McKinlay et al., 2010). Card-sorting tests evaluate, among other functions, the ability to conceptualize and form, maintain and switch set. Studies using tasks such as the WCST (Heaton, Chelune, Talley, Kay, & Curtiss, 1993) have, with only rare exception, found patients with PD to have difficulty with one or more of set formation, set

maintenance, and set shifting. The number of sorts completed on the WCST, indicating indexing concept formation, is often reduced already in early PD (Pillon, Dubois, Ploska, & Agid, 1991). Patients with PD may also be slow to conceptualize, as inferred from an increased number of trials needed to complete the first series of consecutive correct sorts (Taylor et al., 1986); have set-shifting difficulty as revealed by perseverative errors (Cooper et al., 1991); and lose set, especially later in PD, as evident from nonperseverative errors and failures to maintain set (Taylor et al., 1986). The impairment in set shifting may be a critical determinant of whether patients with PD demonstrate difficulty on various executive function tasks (Cronin-Golomb, Corkin, & Growdon, 1994), but is not ubiquitous. Thus, research suggests that patients with PD have difficulty with extradimensional set shifting (i.e., responding to a new stimulus dimension, as when one has to respond to the color of a stimulus instead of its shape), but not intradimensional set shifting (responding to one characteristic of a stimulus dimension instead of another characteristic, as one might when required to respond to yellow rather than blue stimuli); for a very lucid review of this topic, see Robbins, Owen, and Sahakian (1998).

A test evaluating decision making, judgment and impulsivity is the Iowa Gambling Task (IGT; see Bechara, 2007). Examinees are instructed to maximize their gambling winnings by choosing cards from different decks that yield either a high payoff coupled with high risk, or a low payoff at low risk. Over the long run, the low payoff, low-risk decks are advantageous, resulting in net winnings, while the high payoff, high-risk decks are designed to yield net losses. A review of 13 studies did not find a clear relationship between executive functioning or other cognitive functions and performance on the IGT, and concluded that PD patients treated with dopaminergic medications demonstrated preserved IGT performance (Poletti, Cavedini, & Bonuccelli, 2011). Nonetheless, Czernecki et al. (2002) found that patients' performance on the gambling task did not improve across assessments, suggesting a failure to benefit from experience. Deficits on gambling tasks may be observable only when patients are on dopaminergic medications (Cools, Barker, Sahakian, & Robbins, 2003), a finding consistent with the reported association of pathological gambling with dopaminergic therapy in PD (Gschwandtner, Aston, Renaud, & Fuhr, 2001).

#### LANGUAGE

Motor speech abnormalities (dysarthria, hypophonia) are often evident in advanced PD and may impact performance on some language tasks such as sentence repetition (Matison, Mayeux, Rosen, & Fahn, 1982). Certain aspects of language are compromised in PD patients with dementia, but these patients rarely have a frank aphasia (Levin & Katzen, 1995). Subtle alterations in performance on language tasks are also observed in patients without dementia, but these changes are often attributed to diminished attention, working memory,

or inefficient information processing strategy development and deployment.

Visual confrontation naming task performance, requiring naming of pictured or actual objects, is preserved in PD (Levin et al., 1989; Lewis, Lapointe, & Murdoch, 1998), though rare studies report subtle naming impairments in early PD (Globus, Mildworf, & Melamed, 1985). Patients with obvious cognitive impairment, in contrast, do show naming impairments (Beatty & Monson, 1989; Lewis et al., 1998), which are less severe and emerge later than in AD (Stern et al., 1998).

Verbal fluency tasks require patients to orally generate as many words as possible within a time limit that either begin with a given letter of the alphabet, or belong to a category. Patients with dementia perform more poorly on these tasks than those without dementia (Azuma et al., 1997; Cummings, Darkins, Mendez, Hill, & Benson, 1988; Tröster et al., 1998; Troyer, Moscovitch, Winocur, Leach, & Freedman, 1998), and indeed, patients without dementia may demonstrate intact performance (Cohen, Bouchard, Scherzer, & Whitaker, 1994; Lewis et al., 1998). Two verbal fluency tasks especially sensitive to PD are alternating word fluency, requiring retrieval of consecutive words from alternate semantic or letter categories (Kudlicka et al., 2011; Zec et al., 1999); and verb fluency tasks, requiring naming of actions (Piatt, Fields, Paolo, Koller, & Tröster, 1999). Indeed, when asked to generate verbs (action fluency), patients with PD may be even more impaired than those with AD (McDowd et al., 2011). The impairment in action fluency is more pronounced when patients are off than on medication, and when off medication they tend to generate mainly higher-frequency verbs (Herrera, Cuetos, & Ribacoba, 2012).

Research suggests that diminished phonemic and semantic verbal fluency may be related to diminished processing speed (McDowd et al., 2011), semantic memory alterations (Henry & Crawford, 2004), retrieval deficits, or to a deficit in an underlying process such as switching but not clustering (which respectively refer to the processes of disengaging from one category of words to produce those from another category, and the production of consecutive words from the same semantic or phonemic category). Thus, switching impairments are more readily observed among patients with PDD than in AD, while deficits in clustering are more pronounced in AD than PDD (Tröster et al., 1998; Troyer et al., 1998). Even when verbal fluency output is diminished in PD patients without dementia, clustering appears to be preserved (Heiss, Kalbe, & Kessler, 2001).

Other subtle linguistic impairments observed in PD include those in syntactic comprehension and production (Murray, 2000). The mechanisms underlying the subtle sentence comprehension deficits in PD remain controversial, but proposed ones include grammatical processing deficits (Cohen et al., 1994; Ullman et al., 1997), slowed information processing (Grossman et al., 2002), and diminished attention (Lee, Grossman, Morris, Stern, & Hurtig, 2003) or

working memory. There may also be mild phonetic and pragmatics impairments in early PD. Grossman, Carvell, Stern, Gollomp, and Hurtig (1992) and Lee et al. (2003) found that patients had difficulty detecting phonetic errors in words. Patients with PD have been reported to have problems in conversational appropriateness, turn taking, prosody, and proxemics (McNamara & Durso, 2003).

#### VISUOPERCEPTUAL AND SPATIAL FUNCTIONS

Visuospatial deficits may be among the earliest and most readily observable neurobehavioral deficits in PD (Passafiume, Boller, & Keefe, 1986), though the nature of impairments may be a function of disease duration, disease severity, and presence of dementia (Alegret, Pere, Junqué, Valldeoriola, & Tolosa, 2001; Levin et al., 1991). It has also been reported that visuospatial impairments might be more evident in patients with left motor symptom onset (right hemisphere dysfunction), but that such a difference may be evident only in samples with longer disease duration (Karadi et al., 2015) or only in persons in whom symptoms other than tremor are prominent (Seichepine, Nearing, Davidsdottir, Reynolds, & Cronin-Golomb, 2015). Furthermore, the ability to elicit impairments on drawing tasks (e.g., complex figure, clock) may depend on the scoring method used (Karadi et al., 2015; Seichepine et al., 2015).

Tasks that patients with PD might perform poorly include following a route; assembling blocks to match a pattern; drawing, tracing, or copying complex figures; matching pictures of faces; matching lines of similar spatial orientation; identifying objects from fragmented pictures; and identifying drawings embedded among lines (embedded figures) (Bowen, Hoehn, & Yahr, 1972; Pirozzolo et al., 1982; Stern, Mayeux, & Rosen, 1984). It has been suggested that visuospatial task deficits may be secondary to motor impairments or limitations in information processing resources and executive strategies (Brown & Marsden, 1986; Higginson, Wheelock, Levine, Pappas, & Sigvardt, 2011). However, it is unlikely that motor or executive impairments can fully account for visuooperceptual and spatial deficits in PD, because impairments on visuooperceptual and spatial tasks are also observed when tasks' motor demands are minimized (Lee, Harris, & Calvert, 1998; Levin et al., 1991). Similarly, although impaired saccadic eye movements may contribute to visuooperceptual impairments, they cannot fully account for them (Bodis-Wollner, 2003).

One motor-demand-free visuooperceptual task on which patients with PD may demonstrate difficulty is a facial matching task (Levin et al., 1989). Facial identification relies on perceptual processing of both individual features or components and feature configurations. Cousins, Hanley, Davies, Turnbull, and Playfer (2000) found that the facial recognition impairment in PD was associated with configural (but not componential) visuooperceptual processing difficulties, even after controlling for intelligence, age, and

depressive symptoms. Because the two forms of processing are unlikely to differentially tax information processing resources, it appears that PD-associated facial matching difficulties are unlikely to be just a manifestation of limitations in information processing resources and their allocation. Another visuospatial task free of motor demands is one requiring patients to match lines of similar spatial orientation. Alegret et al. (2001) and Finton, Lucas, Graff-Radford, and Uitti (1998) found that PD patients made more serious errors on the Judgment of Line Orientation (JLO) test than control groups. Patients with PD committed more errors that involved confusing an oblique line with one from the same quadrant that was displaced by two or three 18° segments from the target line, and in Alegret et al.'s (2001) study the patients also made more errors than controls involving mismatching of horizontal lines.

Though motor deficits can certainly contribute to PD patient's difficulty with visuo-constructional tasks, an error analysis of drawings of patients with PDD makes it clear that cognitive and visuo-perceptual problems also underlie these patients' drawing difficulties. Specifically, Freeman et al. (2000) compared errors made by patients with PDD on the Rey-Osterrieth Complex Figure test to those made by healthy controls and patients with AD. Compared to these two groups, the PD patients made more placement errors, configural errors, errors of omission, and perseverations, and produced more fragmented drawings that lacked more of the clusters of elements within the figure. In contrast, recognition of the figure after a delay was much better in PD than AD.

#### MEMORY AND LEARNING

The classic notion holds that the impairment in new learning and memory in PD is due to a retrieval deficit, and the primary evidence for this is the finding of poor immediate recall accompanied by intact (Beatty, Staton, Weir, Monson, & Whitaker, 1989), or at least better (if not completely intact) recognition of memoranda (Whittington, Podd, & Kan, 2000). An issue with this interpretation is that early studies may have assumed rather than demonstrated intact encoding. The preponderance of evidence now suggests that PD anterograde (declarative) memory deficits may be due to either or both of deficient encoding and retrieval. Indeed, shallow encoding may be sufficient to support adequate recognition but not recall. The mild recall impairment in PD without dementia is evident on many tasks: word lists (Buytenhuijs et al., 1994), paired associate learning (Huber, Shuttleworth, & Paulson, 1986), recall of prose passages (Tröster, Stalp, Paolo, Fields, & Koller, 1995), complex figure reproduction (Stefanova, Kostic, Ziropadja, Ocic, & Markovic, 2001), memory for spatial locations on maps (Beatty et al., 1989), and abstract designs (Sullivan & Sagar, 1989). As patients develop more global cognitive impairments both recall and recognition are affected, though in comparison to AD, recognition may still be disproportionately better than

recall (Tierney et al., 1994). Memory impairment in PD can also be exacerbated by depression (Tröster et al., 1995).

The learning of new information may be slowed in PD (Faglioni, Saetti, & Botti, 2000). The rate with which a semantic encoding strategy evolves across word list learning trials is slow and diminished in comparison to healthy elderly persons (Berger et al., 1999; Bronnick, Alves, Aarsland, Tysnes, & Larsen, 2011; Buytenhuijs et al., 1994), and if learning of persons with PD and controls is equated on a semantically related word list, recall and recognition are comparable between the groups (Chiaravalloti et al., 2014). In contrast to semantic encoding, serial encoding appears to be preserved (Berger et al., 1999; Buytenhuijs et al., 1994), as are serial position effects (Stefanova et al., 2001). One explanation for these findings is that serial encoding reflects the use of an externally imposed strategy, whereas semantic encoding relies more on self-initiated learning strategies that are diminished in PD (Taylor & Saint-Cyr, 1995). Given this difficulty in spontaneously developing effective encoding strategies, it is not surprising then that patients benefit from externally supported retrieval as provided by cuing (Knoke, Taylor, & Saint-Cyr, 1998) and recognition formats (van Oostrom et al., 2003). However, the finding of similar performance under incidental and intentional recall conditions (Ellfolk, Huurainen, Joutsa, & Karrasch, 2012) would not be predicted by such an explanation. Some have found that encoding is impaired while the patient is on dopaminergic medication, whilst retrieval is impaired off medication, suggesting encoding to be mediated by ventral striatum but retrieval by dorsal striatum (MacDonald et al., 2013). However, the finding of encoding deficits in never-medicated patients (Bronnick et al., 2011) challenges this hypothesis. Retention of word lists over time is usually normal (Massman, Delis, Butters, Levin, & Salmon, 1990), and intrusion errors (production of nonlist words during recall) are typically semantically related to the words on the list and qualitatively similar to those of normal elderly (Massman et al., 1990).

As more severe cognitive impairment develops in PD, a multiplicity of memory mechanisms become affected, including storage, as suggested by rapid rates of forgetting, though these are not observed in all patients. Given that there are probably multiple neuropathological bases for the cognitive impairment in PD it is not surprising that the memory profiles of patients with PD can be quite heterogeneous, with some patients displaying normal learning and memory, others showing deficits that are reminiscent of those in subcortical dementias such as HD, and yet others showing impairments characteristic of AD (Filoteo, Rilling, et al., 1997).

Recollection of information from the past is typically preserved. Fama et al. (2000) found that patients with PD were as accurate as a normal control group in recalling and recognizing past presidents' and presidential candidates' names, and in identifying them from photographs. Similar findings have been reported by others: Unless demented, patients with PD

were as able as healthy elderly people to identify once-famous individuals from photographs and to answer questions about famous persons and well-known public and historical events (Freedman, Rivoira, Butters, Sax, & Feldman, 1984; Huber et al., 1986; Leplow et al., 1997), although one study reported impairments in recalling and dating public events (Venneri et al., 1997). Retrieval of autobiographical memories may be impaired in PD without dementia (Souchay & Smith, 2013). Unlike their nondemented counterparts, patients with PDD do develop impairments in remote memory (Freedman et al., 1984; Huber et al., 1986; Leplow et al., 1997). However, unlike in AD, the impairment in PD is equally severe for information across past decades.

Prospective memory, or memory and execution of intended future actions tends to be impaired in PD, although this impairment may be contingent upon the presence of MCI (Costa et al., 2015). Prospective memory tasks differ in the cues utilized and the nature of the cues may be critical in determining whether or not impairments in PD are evidenced. Specifically, the cues to which memory retrieval and action execution is linked may be time- or event-based, and embedded within the ongoing task (focal) or not (nonfocal). Katai, Maruyama, Hashimoto, and Ikeda (2003) found an impairment on an event-based prospective memory task in PD relative to controls, but others have reported impairments in time-based tasks only, which may relate to the greater executive function demands that these time-based tasks place on the person (Costa, Peppe, Caltagirone, & Carlesimo, 2008; Raskin et al., 2010). Although it has been suggested that prospective memory impairment in PD tends to emerge when strategic monitoring demands of the tasks are high (Kliegel, Altgassen, Hering, & Rose, 2011), impairments can be observed on both focal (low demand) and nonfocal cue (high demand) tasks (Costa et al., 2015). Assessment of prospective memory in clinical settings will likely assume greater importance given the important role of this type of memory in the execution of activities of daily living (Costa et al., 2015).

Findings with respect to nondeclarative memory in PD are inconsistent and this form of memory is rarely assessed in clinical contexts. In general, studies have reported preserved priming in PD without dementia (Filoteo et al., 2003) and even in PDD (Kuzis et al., 1999). Impairments on procedural memory tasks (which require the acquisition of perceptual, motor, or cognitive skills through exposure to an activity that is constrained by certain rules) may be found only in a subset of patients or be task specific, although impairments tend to be found on tasks that require learning from feedback and especially positive feedback or reward (Foerde & Shohamy, 2011).

### ***Mild Cognitive Impairment in Parkinson's Disease***

MCI is conceptualized in the traditional sense as a transition state between normal cognition and dementia, but it is

important to recall that some patients with MCI never progress to dementia. With the evolution of the concept of MCI from a mild memory impairment to impairment in single or multiple cognitive domains (which may or may not include memory; see Petersen, 2011), the relevance of MCI to PD increased. The notion of a cognitive syndrome such as MCI is of particular relevance when evaluating the presence or absence of cognitive impairments in the individual, rather than differences between various patient or control groups, and in determining risk factors for decline, protective factors against decline, and the efficacy of treatment (Schmand & Tröster, 2015). Early studies of MCI frequently used *mild* as an adjective rather than referring to a specific syndrome, and when referring to a syndrome used inconsistent definitions and ascertainment methods. Consequently, preliminary research criteria (Tröster, 2011) and formal clinical criteria for PD-MCI (see Table 22.3) were proposed. Whereas the research criteria involve two sets of criteria differing on the basis of the probability that the MCI is attributable to PD versus a comorbid condition, the clinical criteria require a judgment that the impairment is due to PD. However, the clinical criteria involve two levels of ascertainment (varying in extent of neuropsychological assessment), with the more extensive Level II assessment allowing subtyping of MCI and greater confidence of MCI presence/absence. It is emphasized that the criteria were intended to lead to research that would address their utility and potential revision. Furthermore, rather than specifying a specific test cutoff score or test for identification of MCI, latitude was incorporated into the criteria as regards extent of deficit (test scores of one to two standard deviations below the mean) and the standard against which the deficit was defined (e.g., normative vs. relative to estimated premorbid functioning) specifically to facilitate clinical use and judgment.

Research evaluating the new criteria has just begun to be published, and findings are exclusively based on retrospective analyses. This initial research suggests that the criteria have good interrater reliability ( $\kappa = 0.91$ ) (Broeders et al., 2013), but often identify a higher rate of MCI (33%–62% using Level II criteria; see Goldman et al., 2013; Marras et al., 2013) and especially multidomain MCI (65%–97% of those with MCI) than might be anticipated on the basis of studies completed prior to publication of the criteria (Broeders et al., 2013; Marras et al., 2013). Concern has been expressed that persons diagnosed with PD-MCI might show a high reversion rate to normal over two years (25% among multidomain PD-MCI) (Loftus et al., 2015) and three years (22%) (Pedersen, Larsen, Tysnes, & Alves, 2013). However, a study carefully applying level II criteria found reversion rates of only 8.5% between baseline and Year 3 and 6% between Year 3 and Year 5 follow-up (Broeders et al., 2013). Furthermore, even in one of the studies reporting high reversion rates, the rate was only 9% if MCI had been consistently diagnosed in consecutive years (Pedersen et al., 2013). Although the criteria will require further study,

Table 22.3 PD-MCI criteria and assessment strategies based on Movement Disorder Society Task Force Guidelines (Litvan et al., 2012)

<i>Inclusion Criteria</i>	<i>Exclusion Criteria</i>
<ul style="list-style-type: none"> <li>• Diagnosis of PD per UK PD Brain Bank Criteria</li> <li>• Gradual cognitive decline reported by patient, informant, or observed by clinician</li> <li>• Cognitive decline evident on neuropsychological testing and/or PD-appropriate cognitive screening instrument or global cognitive measure</li> <li>• Cognitive decline may make activities of daily living more effortful or challenging but does not compromise functional independence</li> </ul> <p><i>Level I-Abbreviated assessment</i></p> <ul style="list-style-type: none"> <li>• Impairment on PD-appropriate global cognitive ability scale (e.g., DRS)</li> <li>• Impairment on at least two neuropsychological tests when a limited set of tests is used (fewer than two tests per domain or fewer than five cognitive domains assessed)</li> </ul> <p><i>PD-MCI Subtype classification (comprehensive, Level II assessment required)</i></p> <ul style="list-style-type: none"> <li>• Single domain: impairment on two tests in one domain</li> <li>• Multiple domain: impairment on at least one test in each of two or more domains</li> </ul>	<ul style="list-style-type: none"> <li>• Diagnosis of dementia</li> <li>• Other potential explanation for impairment (e.g., medication, medical condition)</li> <li>• Conditions comorbid with PD that impact neuropsychological test performance (e.g., motor impairment, fatigue, psychosis)</li> </ul> <p><i>Level II-Comprehensive assessment</i></p> <ul style="list-style-type: none"> <li>• Neuropsychological testing includes two tests per domain (attention and working memory, executive functions, language, memory, and visuospatial skills)</li> <li>• Impairment on two tests in one domain or impairment on one test in two different domains</li> <li>• Impairment shown by score 1–2 SD below norms, or significant decline on serial testing, or significant decline from estimated premorbid functioning</li> </ul>

and the diagnosis of multidomain MCI may benefit from stricter or more conservative criteria (e.g., impairments on two tests in each of two or more domains rather than on only one test in each domain), they do seem to have utility in identifying heightened risk for dementia. Among newly diagnosed patients, 14%–17% of those with MCI developed dementia within two-year epochs across the five-year follow-up (Broeders et al., 2013) and in another study of newly diagnosed, initially drug-naive patients, 27% of MCI developed dementia within three years versus 1% of those without MCI (Pedersen et al., 2013).

### ***Mood, Affect, and Psychiatric Disturbances in Parkinson's Disease***

The most recent version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013) contains within the categories of depressive, anxiety, and schizophrenia spectrum and other psychotic disorders those caused by another medical condition (such as PD). Adjustment reactions (such as those that might be precipitated by diagnosis of a chronic illness or discrete, related stressors) are classified under trauma and stressor-related disorders. Impulse control disorders, receiving increasing attention in PD, are not formally classified except for gambling. Within the disorders caused by another medical condition, there is within DSM-5 less specification than for the same disorders not attributable to a medical

condition. For example, although the DSM-IV criteria for major depression, minor depression, and dysthymia were deemed to be applicable to PD (Starkstein et al., 2008), within DSM-5 depressive disorders due to a medical condition only allow specification of either the presence of depressive features, major depressive-like episode, or mixed features (of mania or hypomania). Similarly, anxiety disorders due to a general medical condition are not subtyped as corresponding to generalized anxiety or one of the phobias, although there is a separate category due to a medical condition within the obsessive-compulsive and related disorders. The impact of these classifications on the accuracy of prevalence and incidence estimates, as well as treatment implications remain to be empirically evaluated. Pre-DSM-5 studies observed that despite a depression prevalence of up to 50% among persons with PD (McDonald, Richard, & DeLong, 2003; Reijnders, Ehrt, Weber, Aarsland, & Leentjens, 2008; Slaughter, Slaughter, Nichols, Holmes, & Martens, 2001) and anxiety in almost 50% (Pontone et al., 2009), these conditions may go underrecognized (Shulman, Taback, Rabinstein, & Weiner, 2002) and undertreated (Weintraub, Moberg, Duda, Katz, & Stern, 2003).

### ***Depression***

Incidence and prevalence rates of depression in PD are considerably higher in research centers than in community samples (about 50% vs. 10%). Among patients with

depression, about half have a minor mood disturbance while the other half meet diagnostic criteria for major depression. Even among early, still untreated PD patients, significant depressive symptoms may be evident in almost 15% (Weintraub, Simuni, et al., 2015). Nonetheless, suicide is uncommon (below 0.1%), and is tenfold lower in PD than among the elderly in general (Myslobodsky, Lalonde, & Hicks, 2001) per National Center for Health Statistics data, although higher rates have been reported in small cohort studies.

Assessment and diagnosis of depression in PD is complicated by symptom overlap in depression and PD (Marsh & Dobkin, 2015). For example, sleep disturbance, psychomotor retardation, lack of energy, stooped posture, masked facial expression, dry mouth, and sexual dysfunction can be observed in both conditions. Whilst some have suggested

that early morning awakening, anergia, and psychomotor slowing not be considered when diagnosing depression in PD (Starkstein, Bolduc, Mayberg, Preziosi, & Robinson, 1990), a National Institutes of Health (NIH) workgroup recommended attribution of overlapping somatic and neurovegetative symptoms to depression rather than PD (Marsh, McDonald, Cummings, & Ravina, 2006). Because depression and PD symptoms overlap, self-report and rating instruments probably overestimate depression in PD. Attempts to address this issue include the evaluation of various depression scales in PD and the development of cutoff scores to screen for and diagnose depression specifically in PD (Table 22.4). A comparison of nine scales using modified cutoffs found that all of the scales using modified cutoffs provided adequate sensitivity and specificity in screening for depression but that the 30-item Geriatric Depression

Table 22.4 Self-report and rating scales with empirically modified cutoff scores to detect depression in PD (Tröster et al., 2013)

<i>Scale (Reference)</i>	<i>Number of Items; Maximum Score; Traditional Cutoff (*)</i>	<i>PD Cutoffs Recommended By:</i>	<i>Recommended Cutoff to Distinguish Depressed vs. Nondepressed PD (Sensitivity/ Specificity)</i>	<i>Recommended Screening Cutoff for PD (Sensitivity/ Specificity)</i>	<i>Recommended Diagnostic Cutoff for PD (Sensitivity/ Specificity)</i>
Beck Depression Inventory (Beck, Ward, Mendelson, Mock, & Erbaugh, 1961)	21 items; maximum = 63 10 = mild 12 = moderate 30 = severe	Leentjens, Verhey, Luijckx, and Troost (2000)	13/14 (0.67/0.88)	8/9 (0.92/0.59)	16/17 (0.42/0.98)

Montgomery-Åsberg Depression Rating Scale (Montgomery & Åsberg, 1979)	10 items; maximum = 60 15 = mild 25 = moderate 31 = severe 44 = very severe	Leentjens, Verhey, Lousberg, et al. (2000)	14/15 (0.88/0.89)	14/15 (0.88/0.89)	17/18 (0.63/0.94)
Hospital Anxiety and Depression Scale (Zigmond & Snaith, 1983)	Depression subscale; 7 items; maximum = 21 8 = mild 11 = severe	Mondolo et al. (2006)	10/11 (1.00/0.95)	10/11 (1.00/0.95)	11/12 (0.80/0.98)

Scale (GDS) may be favored given its brevity, psychometric properties, and availability in the public domain (Williams et al., 2012).

The treatment of depression is of great importance in PD given its considerable impact on quality of life of the patient (Hinnell et al., 2012) and caregiver (Aarsland, Larsen, Karlsen, Lim, & Tandberg, 1999), and because depression exacerbates cognitive impairment (Fernandez et al., 2009; Troster et al., 1995; Tröster, Prizer, & Baxley, 2013). Furthermore, depression hastens progression to disability (Cole et al., 1996) and increases health care utilization (Chen et al., 2007). Despite widespread use of selective serotonin reuptake inhibitors in PD, it is only relatively recently that adequately sized, randomized clinical trials have supported the use in PD depression of agents targeting serotonin and/or norepinephrine, such as desipramine (Devos et al., 2008), nortriptyline (Menza et al., 2009), citalopram (Devos et al., 2008), venlafaxine (Richard et al., 2012), and paroxetine (Menza et al., 2009; Richard et al., 2012). Nonetheless, long-term treatment effects remain unknown. Literature concerning the benefit of depression treatment on cognition remains inconclusive per a meta-analysis (Price et al., 2011). However, preliminary evidence suggests that executive dysfunction predicts response to antidepressant treatment (Dobkin et al., 2010). Psychological interventions for depression in PD remain understudied, but preliminary evidence affords support for the effectiveness of cognitive behavioral therapy (Dobkin et al., 2011; Veazey, Cook, Stanley, Lai, & Kunik, 2009), which may also afford modest improvements in verbal memory and executive function (Dobkin et al., 2014). In the case of cognitive behavioral therapy too, baseline executive function may be predictive of treatment response.

### *Anxiety*

Probably about 50% of patients with PD have significant symptoms of anxiety, and as many as 75% of those patients with PD *and* depression may have a comorbid anxiety disorder (Schiffer, Kurlan, Rubin, & Boer, 1988). Among early, untreated patients, questionnaire assessment indicates clinically remarkable anxiety symptoms in about 20% of persons (Weintraub, Simuni, et al., 2015). However, the reported prevalence of actual anxiety disorders (vs. symptoms) in PD ranges from 5% to 40% (Walsh & Bennett, 2001). Stein, Heuser, Juncos, and Uhde (1990) found that almost 20% of PD patients had generalized anxiety and 20% had a social phobia, while 16% to 20% experience significant social anxiety (Bolluk, Ozel-Kizil, Akbostanci, & Atbasoglu, 2010), and recurrent panic attacks may occur in up to 24% of patients treated with levodopa (Vazquez, Jimenez-Jimenez, Garcia-Ruiz, & Garcia-Urra, 1993). Although patients with PD rarely meet the full DSM criteria for obsessive-compulsive disorder (OCD) (about 3%; see Nuti et al., 2004), a considerable number have

symptoms of OCD. The severity of OCD symptoms may be greater later in the disease (Alegret, Junqué, et al., 2001) and associated with severity of left-sided motor symptoms (Tomer & Levin, 1993). Such symptoms may be more common in familial parkinsonism (Lauterbach & Duvoisin, 1991).

As was true for depression, diagnosis of an anxiety disorder in PD is hindered by symptom overlap between PD and anxiety disorders. Unfortunately, the validity and reliability of anxiety rating instruments have not been widely studied. In evaluating the Beck Anxiety Inventory (BAI) and Profile of Mood States (POMS), Higginson, Fields, Koller, and Tröster. (2001) found that, among 59 patients, the two instruments yielded scores associated with clinical anxiety in 54% and 63% of patients, respectively. Although these rates are higher than that of the clinical diagnosis of anxiety (38%) based on interview (Stein et al., 1990), elimination of symptom inventory items reflecting manifestations of autonomic and neurophysiologic function was not advised as it was felt that this would lead to underestimation of anxiety in PD. Other symptom inventories that have been used to assess various aspects of anxiety in PD include the State-Trait Anxiety Inventory, Profile of Mood States, Hospital Anxiety and Depression Scale, Maudsley Obsessional-Compulsive Inventory, and the Yale-Brown Obsessive Compulsive Scale. Scales recommended for use in PD by the International Parkinson and Movement Disorders Society are listed in Table 22.5. In addition, a scale for specific use in PD, the Parkinson Anxiety Scale (PAS; see Leentjens et al., 2014) has undergone initial validation (Forjaz et al., 2015).

### *Apathy*

*Apathy* refers to a diminution of motivation and a reduction in interest, emotion, and goal-directed behavior. Unlike persons with depression, those with apathy typically are not distressed by this condition. Apathy can occur together with depression or cognitive impairment (most often executive deficits), or as an independent phenomenon. A meta-analysis of 23 studies estimated that about 40% of individuals with PD have apathy, but that almost half of those have no associated depression or cognitive compromise (den Brok et al., 2015). The study identified increasing age, disability, depression, more severe motor symptoms, and cognitive impairment to be associated with apathy. One recent model conceives of apathy as involving four domains that in isolation and overlap produce the clinical behavioral syndrome: a reward deficiency component (best treated with dopamine agonists, bupropion, methylphenidate), emotional distress/negative affect (best treated with antidepressants), executive dysfunction (best treated with cholinesterase inhibitors), and an autoactivation deficit or psychic akinesia (responsive to dopamine agonists) (Pagonabarraga, Kulisevsky, Strafella, & Krack, 2015).

Table 22.5 Movement Disorder Society (MDS) recommended and suggested rating scales for the assessment of neuropsychological and psychiatric features of PD

	<i>Recommended Scales (Stronger Evidence)</i>	<i>Suggested Scales (Weaker Evidence)</i>
Depression (Schrag et al., 2007)	Screening (and recommended cutoff in PD): Hamilton Depression Rating Scale (HAM-D, 9/10); Beck Depression Inventory (BDI, 13/14); Hospital Anxiety and Depression Scale (HADS, 10/11); Montgomery-Asberg Depression Rating Scale (MADRS; 14/15); Geriatric Depression Scale (GDS-30: 9/10; GDS-15: 4/5)	For patients with dementia (though insufficient evidence): MADRS; GDS; Cornell Scale for Depression in Dementia (CSDD, 5/6)
Anxiety (Leentjens et al., 2008a)	None	Beck Anxiety Inventory (BAI), HADS, Zung Self-Rated Anxiety Scale (Zung SAS), Zung Anxiety Status Inventory (Zung ASI), State-Trait Anxiety Inventory (STAI), Hamilton Anxiety Rating Scale (HARS), Neuropsychiatric Inventory (NPI) anxiety section
Apathy and anhedonia (Leentjens et al., 2008b)	Apathy Scale (Starkstein et al., 1992) (screening cutoff 13/14); Unified Parkinson's Disease Rating Scale (UPDRS) Item 4 (motivation/initiative) (screening cutoff 2/3)	Apathy Evaluation Scale (AES) (Marin, Biedrzycki, & Firinciogullari, 1991) (screening cutoff 38/39); Lille Apathy Rating Scale (LARS) (screening cutoff 16/17); Neuropsychiatric Inventory (NPI) Item 7; Snaith-Hamilton Pleasure Scale (SHAPS) (screening cutoff 2/3)
Psychosis (Fernandez et al., 2008)	Neuropsychiatric Inventory (NPI); Brief Psychiatric Rating Scale (BPRS); Positive and Negative Syndrome Scale (PANNS); Schedule for Assessment of Positive Symptoms (SAPS)	Parkinson Psychosis Rating Scale (PPRS); Parkinson Psychosis Questionnaire (PPQ); Behavioral Pathology in Alzheimer's Disease Rating Scale (Behave-AD); Clinical Global Impression Scale (CGIS)
Sleep disturbances (Hogel et al., 2010)	<i>Daytime sleepiness:</i> Epworth Sleepiness Scale (ESS) <i>Overall sleep impairment:</i> Parkinson's Disease Sleep Scale (PDSS); Pittsburgh Sleep Quality Index (PSQI); Scales for Outcomes in Parkinson's Disease (SCOPA-Sleep)	<i>Daytime sleepiness:</i> Inappropriate Sleep Composite Score (ISCS); Stanford Sleepiness Scale (SSS)
Fatigue (Friedman et al., 2010)	Fatigue Severity Scale (for severity and screening); Multidimensional Fatigue Inventory (for severity); Parkinson's Fatigue Scale (for screening); Functional Assessment of Chronic Illness Therapy—Fatigue Scale (for screening)	Multidimensional Fatigue Inventory (for screening); Fatigue Assessment Inventory (for severity and screening); Functional Assessment of Chronic Illness Therapy—Fatigue Scale (for severity); Parkinson's Fatigue Scale (for severity); Fatigue Impact Scale for Daily Use (for severity)

### *Impulsive and Related Behaviors*

In the DOMINION study, involving more than 3,000 individuals with PD, impulse control disorders (ICDs) were estimated to occur in about 14% (Weintraub et al., 2010). These disorders include excessive gambling, eating, shopping, dopaminergic medication use, and hypersexuality (Voon, 2015; Weintraub, David, Evans, Grant, & Stacy, 2015; Weintraub & Goldman, 2015). Some also include under this rubric compulsive behaviors such as punding (simple prolonged, purposeless, and stereotyped behaviors such as sorting buttons), hobbyism (excessive time spent on complex, goal-directed behaviors such as assembling model airplanes), and walkabout (aimless wandering). The overuse of dopaminergic medications in PD was initially referred to as *hedonistic homeostatic dysregulation syndrome* (Giovannoni, O'Sullivan, Turner, Manson, & Lees, 2000a) but the term *dopaminergic dysregulation syndrome* has also been used (Evans & Lees, 2004). Risk factors for ICDs include use of dopamine agonists (almost threefold risk) or levodopa use (1.5-fold risk) (Weintraub et al., 2010).

Other risk factors have been more extensively studied for gambling than other ICDs, but they include being younger, single, male, having a family history of pathological gambling, and having a personal or family history of alcohol use (Voon, 2015). Females seem more likely than males to engage in impulsive eating and buying (Weintraub, David, et al., 2015). A scale has been developed for assessment of ICDs and related behaviors in PD, namely the Questionnaire for Impulsive-Compulsive Disorders in Parkinson's disease (QUIP) (Weintraub et al., 2009) and its derivative, the briefer QUIP-RS (Weintraub et al., 2012). Treatment usually involves withdrawal or reduction of the offending medication, although cognitive behavioral therapy may also be beneficial (Okai et al., 2013).

Several studies have explored neuropsychological functions in patients with PD and impulsive behaviors, and a review indicates that these studies have revealed deficits in executive functions, increased risk taking, novelty seeking, enhanced learning based on gain versus loss, and altered reward–punishment learning (Aarsland, Taylor, & Weintraub, 2014).

*Psychosis*

Typically, psychosis presents as delusions and hallucinations and occurs in about one-third of persons with PD (although hallucinations are far more common than delusions, the latter affecting only about 5%–10% of treated patients; see Fenelon & Alves, 2010). Most often hallucinations are visual, well-formed, and nonthreatening to the patient, but hallucinations can occur in all sensory modalities, particularly later in the disease course (Goetz, Stebbins, & Ouyang, 2011). Later in the disease course, patients may lose insight that hallucinations are not real. Psychosis impacts patient quality of life, hastens institutionalization, increases risk of mortality, and increases care-partner stress (Weintraub & Goldman, 2015). Furthermore, hallucinators tend to have poorer attention and executive and visuospatial functioning than patients without hallucinations (Tröster et al., 2013; Weintraub & Goldman, 2015).

The proposed criteria for PD-associated psychosis (Ravina et al., 2007) extend the definition of psychosis to include more minor phenomena such as illusions (misperceptions such as perceiving a fire hydrant as a dog) and a sense of presence (someone being close by when there is no one). In addition, passage phenomena (i.e., peripheral visual phenomena of moving persons and animals) are considered minor visual hallucinations. Treatment with dopaminergic medications is neither a necessary nor sufficient condition for psychosis in PD, but in treatment, the most likely offending agent may be tapered. Preferred for treatment of psychosis in PD are atypical antipsychotics (e.g., quetiapine) that act predominantly by serotonergic antagonism rather than dopamine receptor blockade that aggravates the movement disorder. Nonpharmacologic treatment strategies for hallucinations (nightlights, reassurance, coping techniques) have also been suggested (Diederich, Pieri, & Goetz, 2003). Several scales have been recommended by MDS for the assessment of psychosis in PD (see Table 22.5) (Fernandez et al., 2008) although none specifically is designed for use in PD.

***Case Examples: Parkinson's Disease and Parkinson's Disease With Dementia***

Neuropsychological test results for a PD patient without dementia are presented in Table 22.6. This 74-year-old, White male with 12 years of education had worked full-time as a motorcycle mechanic until he retired at age 65 years, 3 years after being diagnosed with PD. He had continued to work part-time until a year before the evaluation. Medications included levodopa, entacapone, and pramipexole. He acknowledged disability due to physical limitations, but he and his family denied changes in activities of daily living related to cognitive decline. Psychiatric illness was denied.

His neuropsychological test results are chosen for presentation because they are atypical of the traditional “subcortical” profile expected in PD, yet reflect a cognitive profile that

is not uncommon (see earlier discussion of heterogeneity of memory profiles in PD). His executive function is intact: indeed, the patient performed very well on the Wisconsin Card Sorting task, and in the average range on the DRS

**Figure 22.3** Drawing-to-command of a clock by a patient with PD. When asked to draw a clock, to include all the numbers, and set the hands at 10 minutes after 11, the patient initially drew a small circle. The small circle drawn initially may reflect poor foresight and planning. When asked to draw a big clock face, the patient had little difficulty. Although tremor is evident, the numbers are correct, well spaced, and the hands correctly placed allowing for tremor.

Conceptualization scale. Letter fluency is low average and weaker than category fluency (well above average), which is seen in PD. Visual confrontation naming is well preserved, as is praxis (see Figure 22.3). Striking is the patient's poor performance on learning and memory tests. On the list learning task his immediate recall across learning trials is average, but delayed recall is impaired. Though recognition is better than recall it is not intact. In contrast, on a visual learning task, his immediate recall of the figures across trials is poor, yet delayed recall and recognition are intact. Given the intact praxis, category fluency, and visual confrontation naming, coupled with no decline in activities of daily living, the possibility of AD is remote. DLB is unlikely given a lack of fluctuation in cognition, absence of hallucinations, a long course of PD with minimal cognitive impairment and extended employment, and the relative preservation of visuospatial and attentional functions.

<b>Beck Depression Inventory</b>	17	

The neuropsychological test results of a patient with PD (early onset) and dementia are presented in Table 22.7. This 55-year-old White male with two years of college education had had symptoms of PD for 11 years and complained of increasing concentration problems and forgetfulness

for the two years before evaluation. He acknowledged occasionally failing to pay bills, but denied other distressing memory changes. His wife, in contrast, considered his cognitive deficits as interfering significantly with ability to carry out instrumental ADLs. Though his current mood was described as good, the patient acknowledged past depression with suicidal ideation but without plan or intent. He described improved mood since treated with sertraline. He had a history of treatment for posttraumatic stress disorder in the remote past. Hallucinations, delusions, and fluctuating levels of cognition were denied. Anti-Parkinsonian medications included levodopa and pramipexole. He demonstrated difficulty on tasks demanding of working memory, divided and selective attention, and information processing speed (WAIS-III: Arithmetic, Digit Symbol, Symbol Search, Trail Making Part B, and all parts of the Stroop, though susceptibility to interference was normal). While he demonstrated executive dysfunction (DRS and WCST), more pronounced was his difficulty learning and retaining new information. Visual confrontation naming and verbal fluency were preserved. He also has dramatic difficulty with clock drawing (see Figures 22.4, 22.5, and 22.6). His apparently rapid decline in cognition over two years, coupled with

Figure 22.4 Drawing-to-command of a clock by a patient with PD and dementia. When asked to draw a clock, to include all the numbers, and set the hands at 10 minutes after 11, the patient drew a circular clock face and correctly placed the number 3, 6, 9, and 12. Despite guiding his attempt to place other numbers by drawing additional diameter lines, he misplaced the 4, then realized this error and made a new attempt at drawing the clock (see Figure 22.4)

Figure 22.5 The PD with dementia patient's second attempt at drawing a clock to command. After placing the 12 inside the clock face, the patient places the 3, 6, and 9 outside the clock face. Without the guidance of the diameter lines he drew previously (see Figure 22.3), he simply places the remaining numbers incorrectly within the right half of the clock face. This reveals stimulus-bound behavior and loss of a detailed concept of how a clock face looks.

Figure 22.6 Clock drawing of the patient with PDD. Even after the examiner draws the clock face and places the numbers on the clock face, the patient has difficulty setting the hands to show "10 after 11." The hands do not originate in the center of the clock face and the size discrepancy between the big and small hands is excessive. Again, a conceptual loss is evident—the patient no longer "knows," or no longer has a representation of the gestalt, that the big hand at the "2" reflects the passage of 10 minutes past the hour. He compensates for this loss by inserting two five-minute depictions between the numbers 12 and 2 (revealing that he still knows that five minutes elapse when the big hand moves from one number to the next).

pronounced learning and recall, attention, and visuoconstructional deficits superimposed on milder executive dysfunction and bradyphrenia, suggests a possible AD-related dementia superimposed upon the cognitive deficits observed in PD.

### ***Neuropsychological Evaluation in the Differential Diagnosis of Parkinson's Disease With Dementia and Dementia With Lewy Bodies***

While group comparisons of cognitive profiles associated with various dementias and movement disorders (e.g., AD, DLB, PDD, and progressive supranuclear palsy) are helpful in highlighting the similarities and differences among these profiles, and thus in suggesting etiologies and neural bases of cognitive disturbances, the diagnostic sensitivity and specificity of cognitive profiles remains largely unknown. Group comparisons of AD and DLB have yielded rather consistent findings, although it should be borne in mind that probably more studies have compared AD and DLB with coexisting AD pathology rather than pure cases of DLB. Generally, these comparisons reveal that AD is characterized by more prominent memory impairment, especially rapid forgetting and poor recognition (Hamilton et al., 2004) whereas DLB is associated with more pronounced visuo-perceptual, attentional, and verbal fluency impairments (Aarsland, Litvan, et al., 2003; Connor et al., 1998; Galasko, Katzman, Salmon, & Hansen, 1996; Gnanalingham, Byrne, Thornton, Sambrook, & Bannister, 1997; Sahgal et al., 1992; Salmon & Galasko, 1996; Salmon et al., 1996; Shimomura et al., 1998; Walker, Allen, Shergill, & Katona, 1997). Although sensitivity and specificity of neuropsychological tests in differential diagnosis of AD and DLB has rarely been addressed, one study reported that poor naming (Boston Naming Test) and rapid forgetting (on the Auditory Verbal Learning Test) pointed toward an AD diagnosis, whereas poor Rey-Osterrieth figure copy and poor Trail Making Part A performance (processing speed) pointed to a diagnosis of DLB. These tests in tandem differentiated AD and DLB with 83% sensitivity and 91% specificity (Ferman et al., 2006).

Comparisons between DLB and PDD using neuropsychological rather than cognitive screening measures are rarer. Interpretation of Gnanalingham et al.'s (1997) finding of more pronounced attentional and frontal function impairments in DLB than PD is difficult because the DLB group demonstrated greater overall cognitive impairment than the PD group. However, similar findings were reported by Downes et al. (1998), who matched DLB and PDD groups for age, education, estimated premorbid IQ, and overall severity of cognitive impairment (MMSE score). DLB demonstrated more severe impairments than PDD on tasks involving attention and working memory (WAIS-R Arithmetic, Stroop), and verbal fluency (letter, category, and alternating fluency). Although the greater attention impairment in DLB than PDD may be associated with the fluctuating level

of cognition observed in DLB (Walker et al., 2000), not all studies find this attentional impairment. Employing computerized simple and choice reaction time and vigilance tasks, Ballard et al. (2002) failed to demonstrate differences in attention between DLB and PDD. Noe et al. (2004) also failed to observe any neuropsychological differences between PDD and DLB groups equated for overall severity of dementia, though they did replicate others' findings of greater memory impairment in AD than DLB and PDD, and greater attention, visuo-perceptual, and constructional deficits in DLB than AD. The similarities between PDD and DLB cognitive and behavioral profiles may be even more accentuated when PDD patients develop cognitive fluctuations (Varanese et al., 2010). Although specific aspects of test performance may differ between DLB and PDD—such as increased perseverations in PDD but more severe overall memory impairment and faster forgetting in DLB on list learning tests (Filoteo et al., 2009)—such findings remain to be replicated, especially in longitudinal studies because the test-retest reliability of more fine grained learning and memory parameters may be less than optimal. Before neuropsychological findings can be used with confidence in differential diagnosis, large prospective studies will need to evaluate their predictive power, sensitivity, and specificity. Although other differences in the clinical phenotypes of PDD and DLB exist to support the separation of these disorders (Goldman et al., 2014), it appears that neuropsychological features are less helpful in supporting the distinction between DLB and PDD, except perhaps for showing differences in the time course when cognitive and motor features occur in the two conditions.

### ***Neurobehavioral Impact of Pharmacological Treatments***

Table 22.8 lists the medications most often used to treat PD and their possible adverse and beneficial neurobehavioral effects. Agents that augment dopamine (levodopa) or act as dopamine agonists all have the potential to cause psychotic symptoms such as hallucinations and delusions as well as sleep disturbance. The non-ergot-- dopamine agonists in particular may be associated with somnolence. While levodopa does not have a convincing or clinically significant antidepressant effect in PD, it can impact mood, either through its administration or withdrawal. For example, acute infusions of levodopa reduce anxiety and dysphoria in patients with motor fluctuations when they are in the "off" state. In addition, some dopamine agonists have been noted to elevate mood. Hedonistic homeostatic dysregulation syndrome (Giovannoni, O'Sullivan, Turner, Manson, & Lees, 2000b) or dopamine dysregulation syndrome (Lawrence, Evans, & Lees, 2003), is associated with dopamine replacement therapy.

Findings concerning the impact of levodopa on cognition are inconsistent and reveal both positive and negative effects (Cools, 2006). Levodopa probably has at least short-term

Table 22.8 Possible neurobehavioral effects of medications commonly used in the treatment of PD

<i>Drug Category</i>	<i>Generic Name(s)</i>	<i>Trade Name(s)</i>	<i>Possible Neurobehavioral Adverse Effects in PD</i>	<i>Possible Neurobehavioral Therapeutic Effects in PD</i>
<b><i>Dopamine Replacement</i></b>	Levodopa + carbidopa	Sinemet Atamet	Hallucinations, delusions, euphoria, confusion, depression, anxiety, agitation, nightmares; hedonistic homeostatic dysregulation syndrome (Giovannoni et al., 2000b); hypomania/mania (Maier et al., 2014); cognitive (“frontal”) effects vary by disease stage	May improve working memory early in disease (Costa et al., 2003); may improve dysphoria; may improve creativity (Faust-Socher, Kenett, Cohen, Hassin-Baer, & Inzelberg, 2014)
		Rytary (combination immediate and delayed release carbidopa + levodopa in 1:4 ratio) Duodopa (enteral suspension)	Anxiety, insomnia, depression, anxiety, confusion	
<b><i>Combined Dopamine Replacement and Catechol-O-methyltransferase (COMT) Inhibitor</i></b>	levodopa + carbidopa + entacapone	Stalevo	Depression, psychosis, but generally unstudied due to novelty of drug	
<b><i>Dopamine Agonists</i></b>	ergot alkaloids	bromocriptine	Parlodel	As for levodopa, possibly more severe; minimal effect on cognition (Cooper et al., 1993; Piccirilli et al., 1986; Weddell & Weiser, 1995)
		pergolide	Permax	As for levodopa, possibly more severe somnolence; minimal cognitive effect (Brusa et al., 2005; Stern, Mayeux, Ilson, et al., 1984)
	non-ergot alkaloids	pramipexole	Mirapex	Similar to levodopa; fatigue, somnolence, impulse control disorder; may impair cognition (Brusa et al., 2003)
		ropinirole rotigotine	Requip Neupro	Similar to levodopa; fatigue, somnolence, impulse control disorder; as for other agonists
<b><i>COMT-Inhibitors</i></b>	entacapone tolcapone (rarely used due to liver toxicity)	Comtan Tasmar	Hallucinations	Possible attention and memory improvement when used as adjunct to levodopa (Gasparini, Fabrizio, Bonifati, & Meco, 1997)
<b><i>MAO-Inhibitors</i></b>	selegiline rasagiline	Eldepryl Deprenyl Azilect	Rare confusion or hallucinations; sleepiness, depressed mood	Small, uncontrolled studies suggest possible cognitive benefits (Finali, Piccirilli, & Piccinin, 1994; Hietanen, 1991) but not confirmed in large prospective study (Kieburtz et al., 1994)
<b><i>Anticholinergics</i></b>	trihexyphenidyl biperiden benztropine	Artane Akineton Cogentin	Sedation, delirium, memory impairment, executive dysfunction (Bedard et al., 1999; Koller, 1984; Meco et al., 1984; Reid et al., 1992)	
<b><i>Antiglutamatergics</i></b>	amantadine	Symmetrel	Cognitive deficits	

effects on selected aspects of memory (specifically working memory) and executive functions in the early disease stages, and it may differentially impair functions (e.g., stimulus–stimulus associations) mediated by ventral striatum, but facilitate functions (e.g., decision making in ambiguous contexts) mediated by dorsal striatum (MacDonald et al., 2011). Kulisevsky and colleagues (2000) reported short-term improvements in learning and memory, visual perception, and select executive functions with dopamine replacement in drug-naive patients, but these improvements were not maintained. Owen et al. (1995) reported that planning accuracy was improved by levodopa therapy early in the disease, while response latency on planning tasks were unaffected. Studies of the effects of levodopa withdrawal also show only very selective and limited cognitive alterations, for example, declines in working memory (Fournet, Moreaud, Roulin, Naegele, & Pellat, 2000; Lange et al., 1992). These selective cognitive effects of levodopa may be related to its alteration of dorsolateral frontal cortical blood flow during executive task performance (Cools et al., 2002). Dopamine agonists such as pergolide (Stern, Mayeux, Ilson, et al., 1984) and bromocriptine (Cooper, Sagar, & Sullivan, 1993; Piccirilli et al., 1986; Weddell & Weiser, 1995) have limited if any cognitive effects at therapeutic doses, acutely or after chronic administration.

Catechol-O-methyl-transferase (COMT) inhibitors are used to reduce peripheral breakdown of levodopa and thereby increase the amount of levodopa reaching the brain. COMT in the brain is principally found in nonneuronal cells such as glia and is thought to be especially important in intrasynaptic dopamine regulation in the prefrontal cortex (Winterer & Goldman, 2003). One study has found that after six months of treatment with the COMT-inhibitor tolcapone (and gradually decreasing doses of levodopa) patients demonstrated better attention, memory, and constructional skills (Gasparini et al., 1997). It remains to be determined whether these cognitive improvements relate to COMT therapy directly, increased brain availability of levodopa, or a reduction in possible adverse effects of levodopa therapy.

Anticholinergic medications used to treat motor symptoms (e.g., bentsropine and trihexyphenidyl) can adversely affect executive functions (Bedard et al., 1999) and memory (Koller, 1984; Meco et al., 1984; Reid et al., 1992). Anticholinergic-induced memory impairments are most likely to occur in patients with preexisting cognitive impairment (Saint-Cyr et al., 1993), and anticholinergics are to be avoided in elderly patients susceptible to confusion (Pondal, Del Ser, & Bermejo, 1996). The profound impact that anticholinergics can have on memory in PD is illustrated by the memory test results shown in Table 22.9. This patient had notable memory deficits but atypical in quality for PD (impaired delayed recall and recognition of a word list). He was tapered off anticholinergic medication (trihexyphenidyl, 2 mg, four times daily) prescribed to control tremor and reevaluated six

Table 22.9 Cognitive screening, language, and memory test results in a patient with PD before and one month after discontinuation of anticholinergic medication

weeks later. Memory scores improved well beyond the extent expected by practice effects alone.

While cholinesterase inhibitors are widely used in the treatment of AD, they were initially used cautiously in PDD and DLB because they might exacerbate motor symptoms (Richard, Justus, Greig, Marshall, & Kurlan, 2002). Subsequent studies, however, suggest that cholinesterase inhibitors such as donepezil, rivastigmine, and galantamine can be safely used to ameliorate the neuropsychiatric, and to lesser extent, the cognitive symptoms in PDD and DLB (Bullock & Cameron, 2002; Kaufer, 2002; McKeith et al., 2000; Reading, Luce, & McKeith, 2001). A recent meta-analysis of the efficacy and safety of cholinesterase inhibitors and memantine in PD, PDD, and DLB concluded that memantine and

cholinesterase inhibitors improve Clinician Global Impression of Change ratings, but only cholinesterase inhibitors produce positive results on the MMSE (Wang et al., 2015). Unfortunately, the analysis was based on only ten trials (four of them with 28 or fewer subjects) using different agents, outcome measures, and patient populations that limit the conclusions that can be drawn. Only one small trial included PD patients with MCI, and indeed, a Cochrane review indicated inadequate support for the use of these agents in PD without dementia, although it too supported use of cholinesterase inhibitors in PDD based on positive effects on cognition, behavior, and activities of daily living (Rolinski, Fox, Maidment, & McShane, 2012). At this time, in the United States, the only FDA-approved medication for PDD is rivastigmine.

### **Neurobehavioral Impact of Neurosurgical Treatments**

Surgical treatments of PD, like drug treatments, are symptomatic rather than curative and fall into four broad categories: ablation, DBS, tissue transplantation, and gene therapy. Though ablative operations such as pallidotomy, thalamotomy, and subthalamotomies were carried out for PD in the 1940s and 1950s, the use of these treatments declined dramatically after the introduction of levodopa in the 1960s (Siegfried & Blond, 1997). Realization of the limitations of drug treatments, accompanied by advances in neurosurgery,

radiology, and knowledge about basal ganglia physiology, prompted a renaissance of surgical treatments in the 1990s. Possible neurobehavioral consequences of various surgical procedures are summarized in Table 22.10.

Ablative procedures are far less frequently done in the United States or Europe since the advent of DBS, but retain a place in the surgical armamentarium. Early ablative interventions were associated with considerable cognitive morbidity (for review, see Tröster & Woods, 2003). Although modern unilateral ablative interventions targeting the thalamus (Hugdahl & Wester, 2000), STN (Alvarez et al., 2001; Patel et al., 2003), or GPi appear relatively safe from a cognitive perspective they are not without occasional complications affecting verbal fluency, attention, memory, and executive functions. Putative risk factors for cognitive decline after unilateral pallidotomy include cognitive impairment, age, and side of surgery (dominant hemisphere). Bilateral pallidotomy has been variously associated with minimal cognitive change, purported gains in memory, and marked cognitive deterioration. Given the perceived risk of cognitive dysfunction, bilateral pallidotomy is typically not advocated by experts, particularly since the advent of DBS.

DBS involves unilateral or bilateral implantation of electrodes and the application of high frequency electrical stimulation from an implanted pulse generator to the thalamus, GPi, or STN. Unilateral thalamic DBS appears to be well tolerated (Woods et al., 2001), but it is rarely done for PD

Table 22.10 Possible neurobehavioral effects of modern surgical interventions for PD

<i>Procedure Type</i>	<i>Target</i>	<i>Possible Adverse Effects in PD</i>	<i>Possible Beneficial Effects in PD</i>
<b>Ablation</b>	GPi	Confusion, depression, dypomania, cognitive impairment (esp. after bilateral procedure)	Reduction in obsessive-compulsive symptoms
	Ventralintermediate nucleus of Thalamus (Vim)	Confusion, rare cognitive impairment	Reduction in depressive and obsessive symptoms
	STN (modern target)	Mild cognitive deficits	Not reported
<b>DBS</b>	GPi	Rare cognitive dysfunction, hypomania, depression	Mildly improved performance on some memory tests (probably not a true memory improvement), reduced anxiety and depressive symptoms
	Vim		Reduction in depressive symptoms, mild naming improvement
	STN	Apathy, depression (incl. suicidality), (hyppo)mania, psychosis, euphoria/mirth, impulse control disorders, cognitive impairment	Improved psychomotor speed, reduced depressive and anxiety symptoms
<b>Transplantation</b>	Putamen and/or caudate	Psychosis, depression, cognitive dysfunction	Transient memory improvement

given that its principal effect is on tremor and other targets provide relief of a wider range of symptoms. Unilateral GPi and STN DBS are relatively safe from a neurobehavioral standpoint, although postoperative declines in verbal fluency are possible. Debate persists regarding the comparative safety of bilateral GPi and STN DBS. Although studies using small samples and a limited range of tests have suggested that GPi DBS may be cognitively safer (Williams, Foote, & Okun, 2014) and result in greater reduction in Beck Depression Inventory scores (Liu et al., 2014), two large, randomized trials have failed to establish any large or clinically meaningful differences in the cognitive or behavioral outcomes of the two procedures (Odekerken et al., 2015; Odekerken et al., 2013; Rothlind et al., 2015). Although the trials yield somewhat different estimates of cognitive and behavioral risk, it seems reasonable to conclude that declines on multiple cognitive tests, sufficient to be associated with quality of life change, are evident in 11% or more of patients 6–12 months after DBS. Older patients with cognitive deficits may be at higher risk of adverse outcomes after DBS (Fields, 2015). Dementia is a contraindication for DBS, but the role of MCI in surgical outcome remains unclear. Two retrospective analyses (one using Level I criteria, the other Level II criteria) reported no difference in outcome after STN DBS between those with and without MCI (Abboud et al., 2014; Merola et al., 2014), but the exact nature of cognitive impairment may have important consequences. For example, attentional impairment has been shown to increase risk of postoperative confusion and length of hospitalization (Abboud et al., 2014), and together with preoperative levodopa response and age might predict cognitive outcome after STN DBS (Smeding, Speelman, Huizenga, Schuurman, & Schmand, 2011).

Despite the relative cognitive safety of STN DBS, numerous psychiatric issues have been identified as associated with STN DBS (although disease progression, medication changes, and psychosocial factors may also play a role). Such psychiatric issues include suicidality; apathy; hypomania, hypersexuality, and other impulse control phenomena; depression; anxiety; disinhibition; and psychosis (Mosley & Marsh, 2015; Volkmann, Daniels, & Witt, 2010).

Fetal mesencephalic cell transplantation is not currently being pursued given disappointing outcomes in initial trials, but the use of induced pluripotent and embryonic stem cells may be brought from bench to clinic in the not-too-distant future (Buttery & Barker, 2014). In addition, clinical trials are under way evaluating gene therapies that seek to replace dopamine, although a trial seeking to inhibit the STN via glutamic acid decarboxylase yielded disappointing results (LeWitt et al., 2011).

### **Cognitive Rehabilitation**

Very little data are available regarding nonpharmacologic treatment of cognition in PD, and particularly about cognitive rehabilitation (Hindle, Petrelli, Clare, & Kalbe, 2013).

Two reviews concluded that there was insufficient empirical evidence to recommend the use of such interventions in PD (Calleo et al., 2012; Langenbahn, Ashman, Cantor, & Trott, 2013). Nonetheless, several studies, many with only small samples, at least hint at patient acceptability of attention training in PD (Mohlman, Chazin, & Georgescu, 2011) and the feasibility of improving attention, memory, and executive functions by using cognitive rehabilitation. One study described gains on a Stroop-like task after approximately six months of training with Sudoku-like puzzles (Nombela et al., 2011). Another study, albeit with inadequately described cognitive and motor interventions, reported that a six-week training program lead to improvements in verbal fluency, executive functions, and memory (Sinforiani, Banchieri, Zucchella, Pacchetti, & Sandrini, 2004), whilst another reported gains in executive functions after as little as ten 30-minute sessions of cognitive training compared to standard physical and occupational therapy (Sammer, Reuter, Hullmann, Kaps, & Vaitl, 2006). A recent randomized trial of integrated cognitive training versus occupational activities for three weekly sessions for three months showed that cognitive training produced significantly greater gains in visual memory, theory of mind task performance, processing speed, and functional disability (Pena et al., 2014). Another study using a wait-list control group showed that a program encompassing psychoeducation and cognitive training, and also targeting mood and health behaviors, delivered for two hours, twice weekly, for seven weeks, yielded gains on the Logical Memory paragraphs in the treatment group (Naismith, Mowszowski, Diamond, & Lewis, 2013). Finally, one study showed gains in a wide range of cognitive functions, including visuospatial, executive, verbal fluency, attention, and processing speed after four weeks of three weekly 45-minute sessions of computerized and pencil-and-paper tasks training versus speech therapy. However, these gains did not translate into patient perceptions of improvements in quality of life or day-to-day cognition (Paris et al., 2011). In addition to raising the issue of whether gains on tests translate into better functioning, another study questioned the specificity of the effect of cognitive training, noting that nonspecific computerized sports games produced as much gain as cognition-specific computerized training (Zimmermann et al., 2014).

### **Atypical Parkinsonian Disorders**

#### ***Progressive Supranuclear Palsy (Steele-Richardson-Olszewski Syndrome)***

##### *Epidemiology and Genetics*

The prevalence and incidence of progressive supranuclear palsy (PSP) is understudied. While a survey in New Jersey reported an age-adjusted prevalence of PSP of about 1.4 per 100,000 (Golbe, Davis, Schoenberg, & Duvoisin, 1988), epidemiologic studies using strict diagnostic criteria reveal

an age-adjusted prevalence of about five per 100,000 (Nath et al., 2001; Schrag, Ben-Shlomo, & Quinn, 1999). Average annual incidence across ages 50–99 years has also been estimated at per 100,000 (Bower, Maraganore, McDonnell, & Rocca, 1997), with a marked increase in incidence with age (from 1.7 per 100,000 at ages 50–59 years to 14.7 per 100,000 at ages 80–99 years).

Most cases of PSP are sporadic. Some forms of familial PSP (usually atypical in presentation) may relate to tau gene mutations though some refer to such cases as familial tauopathies rather than PSP (Wszolek et al., 2001). Nonetheless, polymorphisms in the tau gene may be associated with PSP (Conrad et al., 1997).

### Neuropathology

Unlike in PD, the pathology of PSP includes the entire substantia nigra, and dopaminergic depletion is comparable in caudate and putamen. There is neuronal loss and gliosis in the whole globus pallidus, subthalamic nuclei, red nuclei, dentate, superior colliculi, and periaqueductal gray matter. Neurofibrillary tangles different from those seen in AD, and they, along with neuropil threads, are readily observed in the basal ganglia, brain stem, dentate, and nucleus basalis of Meynert, the latter of which is associated with cholinergic depletion. Figures 22.7a, b and 22.8a, b show the brain changes visible in magnetic resonance imaging (MRI) in a patient with PSP over a two year span.

### Neurobehavioral Features of Progressive Supranuclear Palsy

When first described in eight cases by Richardson, Steele, and Olszewski in the early 1960s, PSP was said to involve dementia (Colosimo, Bak, Bologna, & Berardelli, 2014). Almost ten years later Albert, Feldman, and Willis (1974) more precisely characterized the PSP neurobehavioral syndrome as a *subcortical dementia* (a term originated by von Stockert in 1932 but described by Naville in 1922). Dementia, estimated to occur in 50%–80% of persons with PSP, is argued by some to reflect an overestimate given the severe bradyphrenia (as well as emotional and visual dysfunction) often seen in PSP. The presence of neurobehavioral dysfunction varies by PSP phenotype. Whereas the traditional Richardson syndrome<sup>1</sup> frequently involves early cognitive and psychiatric alterations (frontal dysfunction in more than 50% of cases within two years), the parkinsonian variant does not (Williams et al., 2005). Parkinsonian signs predominate in this variant and it may at least transiently respond to dopaminergic therapy. Recent analysis of 100 pathologically verified cases suggests even greater phenotypic heterogeneity of PSP: possibly seven phenotypes with many cases showing overlapping features (Respondek et al., 2014). Nonetheless, it is generally accepted that PSP often involves a pattern of neurobehavioral deficits reminiscent of the prototypical subcortical dementia, involving bradyphrenia and executive dysfunction (Dubois, Deweer, & Pillon, 1996; Grafman, Litvan, & Stark, 1995;

Figures 22.7 Baseline sagittal and axial MRI scans of a patient with presumed PSP. The 67-year-old patient, a right-handed, White female, noticed insidious onset of an upgoing right toe and gait difficulty. She was diagnosed as having right-sided dystonia and brain MRI was read as revealing mild cortical atrophy.

(Images courtesy of Xuemei Huang, MD, PhD).

**Figures 22.8** Repeat sagittal and axial MRIs of the patient with PSP (about three years after baseline MRI). The patient's gait and cognitive status continued to deteriorate and she became wheelchair bound about two years after initial evaluation. After three years she was not orientated to year, and date, could not spell "WORLD" backwards, had pseudobulbar affect, supranuclear gaze palsy, and severe axial (greater than distal) rigidity and bradykinesia. The repeat brain MRI reveals thinning of the anterior-posterior diameter of the midbrain tectum and tegmentum with atrophy of the colliculi and disproportionate enlargement of the Sylvian fissures and posterior third ventricle.

(Images courtesy of Xuemei Huang, MD, PhD)

Maher, Smith, & Lees, 1985). This executive dysfunction was long thought to reflect a frontal deafferentation or the downstream frontal cortical effects of basal ganglia pathology. One study (Cordato et al., 2002), however, found that MRI-measured frontal gray matter volume was strongly related to the "frontal" behavioral symptoms of PSP, suggesting that frontal lobe pathology contributes directly to neurobehavioral deficits.

Patients with PSP frequently have early and prominent executive dysfunction (Gerstenecker, Mast, et al., 2013). Patients perform more poorly than patients with PD on tests sensitive to frontal lobe dysfunction, such as card sorting, verbal fluency, and execution of graphic sequences (Dubois, Pillon, Legault, Agid, & Lhermitte, 1988; Pillon, Gouider-Khouja, et al., 1995). In addition, visual search and card-sorting task performance may decline more rapidly in PSP than PD (Soliveri et al., 2000). Episodic memory impairments (e.g., in prose recall, list learning, and paired-associate learning) are observed in PSP (Litvan, Grafman, Gomez, & Chase, 1989; Pillon et al., 1986; Pillon, Gouider-Khouja, et al., 1995). The severity of the episodic memory impairment may be comparable to that in PD, and less severe than that in AD (Aarsland, Hutchinson, & Larsen, 2003; Pillon et al., 1986; Pillon et al., 1991), but more severe than that in striatonigral degeneration (SND)

corresponding to the parkinsonian form of multiple system atrophy (MSA-P) (Pillon, Gouider-Khouja, et al., 1995). Nondeclarative memory performance is task-dependent—generally, patients with PSP do poorly on procedural learning tasks, but show intact priming (Grafman et al., 1995). Though language and semantic memory have been held to be intact in PSP, van der Hurk and Hodges (1995) found PSP patients to show similar impairments to AD on a visual confrontation naming test (Boston Naming Test), with 44% of the PSP patients scoring in the impaired range, and more profound impairment in determining whether members of word pairs have similar or different meanings. In addition, on rare occasion, PSP can present resembling primary progressive aphasia (PPA) (Boeve et al., 2003; Mochizuki et al., 2003).

From a psychiatric standpoint, patients with PSP frequently report apathy and to lesser extent (but in a third or more of cases) depression and disinhibition (Aarsland, Litvan, & Larsen, 2001; Gerstenecker, Duff, Mast, Litvan, & Group, 2013; Litvan, Mega, Cummings, & Fairbanks, 1996).

#### Case Example

The patient, a 78-year-old male with a doctorate in engineering, with history of lower extremity radiculopathy, over the

course of almost a year became slower in mobility and developed severe hoarseness, dysarthria, cognitive decline, and gait problems. The disorder responded minimally to levodopa. Blood tests were unremarkable and brain MRI, aside from revealing mild volume loss and presumed small vessel disease, was also unremarkable. Neurological exam revealed difficulty executing a two-step command and word-finding difficulty for more complex words. Extraocular movements were markedly abnormal: Smooth pursuit had broken down and saccadic eye movements were slow. Up- and downgaze were limited. Facial animation was reduced, but sensation was not. Speech was severely dysarthric and hypophonic and tongue movements were slowed. Neck muscle tone was increased. Rigidity was mild and symmetrical in the upper extremities, somewhat greater in the lower extremities. There was no tremor. Bradykinesia was moderate to severe and symmetrical. Sensory exam was abnormal in the distal lower extremities, with vibratory sense absent in the toes bilaterally. Tendon reflexes were normal in the upper extremities, brisk in the knees, and absent at the ankles.

Neuropsychological evaluation (see Table 22.11) revealed diminished intelligence from estimated premorbid levels, impaired visual confrontation naming, lower than expected (but not impaired) written word and design fluency (both average), borderline information processing speed, poor visuomotor speed and dexterity (greater impairment on the right than left), executive dysfunction, and generally below-average memory. Attention and praxis were intact (see Figures 22.9 and 22.10).

### Multiple System Atrophy

MSA is a sporadic, progressive neurodegenerative condition with a clinical picture that involves a variable combination of cerebellar ataxia, autonomic dysfunction, and both pyramidal and extrapyramidal (parkinsonian) motor signs. The combination of three conditions previously thought to be distinct—SND, Shy-Drager syndrome (SDS), and olivopontocerebellar atrophy (OPCA)—into the single MSA category was largely a result of the recognition that all three conditions are multisystem degenerations with unique oligodendroglial cytoplasmic inclusions (Wenning, Colosimo, Geser, & Poewe, 2004). These inclusions were later shown reactive to alpha-synuclein immunostaining, and thus MSA, like PD and DLB, is considered an alpha-synucleinopathy. Recently, it has been suggested that neuron-to-oligodendrocyte transfer of alpha-synuclein by a prion-like spread may induce myelin and oligodendritic dysfunction and system neurodegeneration in MSA (Jellinger, 2014). There are two predominant motor presentations of MSA: the parkinsonian subtype (MSA-P) in about 80% of cases, and the cerebellar ataxia subtype (MSA-C) in approximately 20% of cases. These subtypes closely correspond to SND and OPCA both clinically and neuropathologically.

Unfortunately, given the changes in terminology over time, it is difficult to compare previous epidemiological and

neurobehavioral studies' results, because it is often unclear to what extent OPCA, SND, and SDS were represented within MSA samples. Although consensual probabilistic criteria for MSA have been revised (Gilman et al., 2008), the utility of these diagnostic criteria remains to be evaluated in prospective studies. Given poor diagnostic accuracy in the past (25%–50%, depending on disease stage) (Wenning, Seppi, Scherfler, Stefanova, & Puschban, 2001), it is unclear how

Figure 22.9 Drawing-to-command of a cube by a patient with PSP. When asked to draw a cube so that the top and two sides are visible, the patient has no difficulty, indicating an absence of constructional apraxia.

Figure 22.10 Drawing-to-Command of a Clock by the Patient with Presumed Progressive Supranuclear Palsy (PSP). Though the patient clearly retains the general concept of a clock and knows how to set the hands to show a time of “10 after 11,” stimulus-bound behavior is evident. He draws the clock face and sets the hands at positions he indicates by the numbers “11” and “10” (after correctly starting with a “2” and then overwriting the incorrect “10” with the “2”). Subtle errors are evident from his drawing the numbers outside the clock face and from big and small hands that are indistinguishable in size.

accurate the neurobehavioral characterizations of clinically diagnosed (rather than pathologically confirmed) MSA are.

*Epidemiology and Genetics*

Bower et al. (1997), examining MSA incidence in Olmsted County, Minnesota, found an annual incidence of three per 100,000 among persons aged 50–99 years. Prevalence estimates range from about two to five per 100,000 (see Wenning et al. 2004). Although there are familial cases of OPCA, MSA is considered a sporadic disorder.

*Neuropathology*

Cell loss and gliosis are seen in the striatum (especially the caudal and dorsolateral aspects of the putamen), substantia nigra pars compacta, and the basis pontis. There is a loss of pontocerebellar transverse fibers and the middle cerebellar peduncle appears shrunken. The relative brunt of the pathology is nigrostriatal in MSA-P, and olivopontocerebellar in MSA-C. Figure 22.11 shows an MRI revealing the marked pontine and cerebellar atrophy in a case of MSA-C. As noted, glial cytoplasmic inclusions are a hallmark of MSA, and these inclusions, as well as neuronal inclusions are a result of alpha-synuclein aggregation.

Figure 22.11 Sagittal MRI of a patient with presumed MSA-C (olivopontocerebellar atrophy) showing severe pontine and cerebellar atrophy. The 63-year-old, right-handed, White male noticed insidious onset of shuffling gait, slurred speech, and falls. Neurological examination revealed greater axial than distal rigidity, bradykinesia, left Babinski sign, left greater than right dysmetria, and gait ataxia. Movement disorder was unresponsive to medications.

### *Neurobehavioral Features of Multiple System Atrophy*

Consensus diagnostic criteria considered severe cognitive disorder as not supporting an MSA diagnosis (Gilman et al., 2008). In 2014, the Neuropsychology Task Force of the MDS Multiple System Atrophy (MODIMSA) Study Group, based on an extensive literature review, concluded that MSA-P and MSA-C often impair executive functions (including verbal fluency) and sometimes impair attention, visuospatial functions, and aspects of memory (recall and/or recognition) (Stankovic et al., 2014). Furthermore, it was recognized that cognitive impairment can span a full spectrum of severity, and that depression and anxiety are common.

In MSA-P impairments have been noted relative to healthy persons in verbal fluency, visual search and attention, executive functions, and verbal memory (Dujardin, Defebvre, Krystkowiak, Degreef, & Destee, 2003; Monza et al., 1998). Though there may be some subtle differences in the cognitive profiles of PD and MSA, there are many similarities (Pillon, Gouider-Khouja, et al., 1995; Robbins et al., 1992; Robbins et al., 1994), and commonalities appear to exceed differences. Verbal fluency may be more impaired in MSA than PD (even when the groups are equated for overall level of cognitive impairment and disease severity indexed) (Dujardin et al., 2003; Monza et al., 1998; Soliveri et al., 2000), though this is not a uniform finding (Lange et al., 2003; Testa et al., 1993). Similarly, attention may be more impaired in MSA than PD (Meco, Gasparini, & Doricchi, 1996; Pirtosek, Jahanshahi, Barrett, & Lees, 2001).

Impairment on detailed cognitive screening measures is more common in PSP than MSA (57% vs. 20%) (Brown et al., 2010). Cognitive impairments are probably also less severe in MSA than PSP. Lange et al. (2003) and Monza et al. (1998) found that verbal fluency deficits are less pronounced in MSA than PSP. In addition, using a broader test battery than Lange et al. (2003) and Monza et al. (1998) also found executive, visuospatial and attention impairments to be less severe in MSA than PSP, findings consistent with those of Pillon, Gouider-Khouja et al. (1995) and Soliveri et al. (2000). In comparison to persons with MSA-C, those with MSA-P may have more severe recognition memory and verbal fluency deficits (Berent et al., 2002). However, dementia may be more prevalent in familial than sporadic MSA-C (Berciano, 1982). With regard to affective disturbance, PD patients may be more anxious and depressed than those with MSA, but emotional blunting (unresponsive to levodopa therapy) may be more evident in MSA than PD (Fetoni, Soliveri, Monza, Testa, & Girotti, 1999). However, psychiatric complaints are common in MSA, perhaps reported by 50%–80% of patients (Colosimo et al., 2010).

### ***Corticobasal Ganglionic Degeneration: Distinction Between Corticobasal Syndrome and Corticobasal Degeneration***

First described as corticodentatonigral degeneration with neuronal achromasia (Rebeiz, Kolodny, & Richardson, 1968), corticobasal ganglionic degeneration (CBGD) was long thought to be predominantly a motor disorder. The motor presentation most often involves a progressive, asymmetric, akinetic-rigid parkinsonism of insidious onset that is poorly responsive to levodopa and is sometimes accompanied by dystonia or myoclonus. Cortical signs that are common in CBGD include apraxia and alien hand sign. This mixture of motor and cortical and subcortical signs are hallmarks of CBGD. However, the recognition of CBGD as a tauopathy that has heterogeneous presentations, including PSP, progressive aphasia, and fronto-temporal dementia (Kertesz, Martinez-Lage, Davidson, & Munoz, 2000), has led some to argue that CBD is a member of the “Pick complex” of disorders, including primary progressive aphasia, progressive supranuclear palsy, and fronto-temporal dementia (Kertesz, 2003). Given the clinically heterogeneous presentation of CBGD, and the fact that the core features of CBGD can be produced by other conditions, it was recommended that the term *corticobasal syndrome* (CBS) be applied to the core clinical features of CBD regardless of etiology. In contrast, the term *corticobasal degeneration* (CBD) should be reserved for the distinctive neuropathological condition of corticobasal ganglionic degeneration, regardless of its clinical presentation (Lang, 2003).

Initial findings were inconsistent about whether neurobehavioral abnormalities are presenting features of CBD and how frequently they occur in the later disease stages (Grimes, Lang, & Bergeron, 1999; Rinne, Lee, Thompson, & Marsden, 1994). It is now widely accepted that neurobehavioral abnormalities occur in most if not all patients already early in the disease course (Burrell, Hodges, & Rowe, 2014). Indeed, new diagnostic criteria based on clinical material, and case and literature review, recognize not only that cognitive compromise is evident in more than 50% of cases at presentation, but also that it characterizes two of four CBD phenotypes on the basis of neurobehavioral disturbances (i.e., the frontal behavioral-spatial syndrome and the nonfluent/agrammatic variant of primary progressive aphasia) (Armstrong et al., 2013).

### *Epidemiology and Genetics*

Prevalence and incidence of CBD are unknown; poor diagnostic accuracy (Litvan et al., 1997), even of the new diagnostic criteria (Alexander et al., 2014), no doubt contributes to this. Although the H1/H1 tau haplotype has been identified as heightening susceptibility to both CBD and PSP, no clear genetic etiology has been identified. Disease onset is

usually in the sixth decade of life, and mean time to death from diagnosis is about seven years.

### *Neuropathology*

Among cortical regions, the frontal and fronto-parietal cortices show asymmetric atrophy. The pons, medulla, and dentate are also atrophied, and the caudate may appear flattened. The substantia nigra shows decreased pigmentation and cell loss. Neuronal loss and gliosis, in addition to being evident in fronto-parietal cortex, is seen in basal ganglia, thalamus, STN, dentate, and red nucleus. Ballooned and achromatic neurons, hallmark of CBD, are most numerous usually in fronto-parietal cortex, but are also seen in the anterior cingulate, amygdala, and insular cortex. Neuronal and glial inclusions are immunoreactive for tau but not alpha synuclein. Imaging of CBS reveals especially primary motor cortex atrophy. Imaging also shows more variable involvement of supplementary motor, inferior parietal, and posterior temporal regions, perhaps related to heterogeneity of underlying pathology (Burrell et al., 2014).

### *Neurobehavioral Features of Corticobasal Degeneration*

CBD involves an asymmetric apraxia, typically of the ideomotor variety, with ideational and limb kinetic apraxias occurring more rarely (Leiguarda, Lees, Merello, Starkstein, & Marsden, 1994; Pharr et al., 2001; Pillon, Blin, et al., 1995; Soliveri et al., 1999). Thus, patients most often have difficulty demonstrating the use of tools. Poor drawing (constructional apraxia) is also commonly seen. CBD can present as a primary progressive aphasia. Graham, Bak, and Hodges (2003) noted in their review of published cases mentioning aphasia in CBD, that the aphasia is most often nonfluent (about 56% of cases), followed in frequency by anomic aphasia (30%). Fluent and mixed cases were quite rare: each about 5%–7% of cases. The pattern of performance on language tests in patients with the traditional CBD presentation is somewhat inconsistent across studies, but it has been suggested that phonological impairments may be a key feature of the language problems in CBD (Graham, Bak, Patterson, & Hodges, 2003). In general, performance on verbal fluency tasks is impaired (Graham, Bak, Patterson, et al., 2003; Pillon, Blin, et al., 1995) probably in large part due to the executive demands of those tasks rather than aphasia (Hohler, Ransom, Chun, Tröster, & Samii, 2003). Performance on semantic memory tasks such as conceptual matching and visual confrontation naming (Graham, Bak, Patterson, et al., 2003), and on expressive vocabulary (Massman, Kreiter, Jankovic, & Doody, 1996; Mimura, White, & Albert, 1997), is relatively preserved and impaired in a minority of patients. When naming is impaired, disproportionate

benefit is derived from cuing suggesting a retrieval rather than semantic memory deficit (Beatty, Scott, Wilson, Prince, & Williamson, 1995; Massman et al., 1996). Patients also may have agraphia with both central and peripheral components (Riley & Lang, 1996).

Executive dysfunction, as indicated by poor performance on tasks such as the WCST (Pillon, Blin, et al., 1995; Soliveri et al., 1999) and Trail Making test (Beatty et al., 1995; Mimura et al., 1997), is common. The episodic memory impairments in CBD are more pronounced than in AD, and appear to involve both encoding and retrieval deficits (Massman et al., 1996; Pillon, Blin, et al., 1995). Remote memory impairment may be attributable to retrieval deficits given poor recall but intact recognition on remote memory tasks (Beatty et al., 1995). Visuospatial impairments have been observed (Graham, Bak, & Hodges, 2003; Soliveri et al., 1999).

With respect to emotional and neuropsychiatric issues, Litvan et al. (1998), using the Neuropsychiatric Inventory (NPI) found depression in 73% of CBD patients, with apathy (40%), irritability (20%), and agitation (20%) also occurring at notable rates. In comparison to PSP patients, CBD patients have less apathy, but more depression and irritability. Changes in personality and social cognition may resemble those seen in fronto-temporal dementia (Burrell, Hornberger, Villemagne, Rowe, & Hodges, 2013). We have previously described in detail the neurologic and neuropsychological features of a case of CBS (Tröster & Browner, 2013).

### *The Use of Neuropsychological Tests in Differentiating Among Atypical Parkinsonisms*

Although many tests are useful in detecting cognitive impairments in PD and atypical parkinsonisms relative to normal, there is overlap in the test performances of these groups. Thus, although group comparison studies among PD and atypical parkinsonism sometimes reveal statistically significant differences in mean scores, their utility in differential diagnosis in the individual case is unknown. A meta-analysis (Lee, Williams, & Storey, 2012) identified 19 of 1,038 articles meeting inclusion criteria. Test utility was then defined on the basis of effect size of the difference between group means (Cohen's *d*) or positive likelihood ratio (ratio of posttest to pretest probability of the condition of interest given a positive test result). The larger the effect size, the less the overlap in test score distributions, and the higher the diagnostic utility. For discussion here, only tests deemed moderately (20%–29% overlap) to very useful (less than 20% overlap) in differentiating between two or more groups are presented in Table 22.12. In brief, neuropsychological tests appear more helpful in differentiating PD from atypical parkinsonisms than in differentiating among atypical parkinsonisms. Tests of praxis seem especially useful in identifying CBD, whereas

Table 22.12 Neuropsychological tests deemed moderately to very useful (Lee et al., 2012) in distinguishing between PD and atypical Parkinsonian disorders

Conditions Differentiated	PD	PSP	MSA	CBS
PD	–	Semantic fluency, phonemic fluency, alternating semantic fluency, Wisconsin Card Sorting (categories, errors, perseverative errors), trail Making A, frontal assessment battery, Digit Span, JOL, orientation choice reaction time, (all worse in PSP)	Trail Making B, Stroop (both worse in MSA)	Orofacial and ideomotor apraxia (both worse in CBS)
PSP	–	–	Semantic fluency, phonemic Fluency, alternating phonemic fluency, semantic fluency, alternating semantic fluency, Wisconsin Card Sorting (categories and errors), addenbrooke's cognitive examination (ACE), JOL (all worse in PSP)	None
MSA	–	–	–	Orofacial apraxia (worse in CBS)

Abbreviations: PD: PD, PSP: Progressive Supranuclear Palsy, MSA: Multiple System Atrophy, CBS: Corticobasal Syndrome

verbal fluency tests are useful in identifying PSP, a conclusion confirmed by the findings that this task had sensitivity and specificity of 0.90 or higher in differentiating PSP from PD (Rittman et al., 2013) and of a recent meta-analysis (Lee, Williams, & Anderson, 2016).

### Huntington's Disease

Unlike the other neurodegenerative conditions discussed in this chapter, the cause of HD (Huntington, 1872) is well established: It is an autosomal dominantly inherited condition. HD is a hyperkinetic movement disorder characterized by choreiform movements and dystonias early on, but bradykinesia and incoordination also occur later on. Cognitive and psychiatric disturbance is almost invariable and may predate motor symptom onset. It is likely that the triad of cognitive, emotional, and motor symptoms contributes to functional disability, but it has been difficult to disentangle the impact of motor and cognitive dysfunction (Fink et al., 2014). Diagnosis remains clinical and is based on the finding of an extrapyramidal movement disorder in the context of a positive genetic test for the HD CAG expansion or a positive family history of HD. Despite evidence that cognitive changes such as psychomotor speed and executive functions can progress prior to motor symptom onset (Paulsen & Long, 2014), cognitive variables are not considered among biomarkers of premanifest HD (Ross & Tabrizi, 2011). Cognitive variables are, however, considered to be relevant clinical trial outcomes (Papoutsis, Labuschagne, Tabrizi, & Stout, 2014; Tabrizi et al., 2012; Tabrizi et al., 2013).

### Epidemiology and Genetics

Prevalence of HD ranges from 4–10 per 100,000 in the Western world. The most common age at onset is in the 40s, though juvenile and senescent onset occurs, and disease duration is about 15–20 years (Ross & Tabrizi, 2011). One estimate indicates that 38% of prodromal HD individuals have deficits on neuropsychological testing (Repeatable Battery for the Assessment of Neuropsychological Status, or RBANS; see Duff, Beglinger, Theriault, Allison, & Paulsen, 2010).

An expansion of the CAG triplet in the Huntington gene on chromosome 4 results in the misfolding of the protein coded in this sequence, and its accumulation in the cell body leads to cell death. HD is inherited in an autosomal dominant manner, meaning if one parent carries the gene, the offspring has a 50% chance of inheriting it. Usually the number of CAG repeats is reported for each of the two alleles. The normal number of CAG repeats ranges from 10 to 35: Those with an allele with 36–39 repeats may or may not develop symptoms, whereas those with 40 or more repeats almost always do. Penetrance is age dependent and is almost 100% by age 65. Although the relationship between CAG repeat length and age at disease onset is not linear, a greater number of repeats are generally associated with earlier onset but not rate of progression. The phenomenon of anticipation refers to the observation that as the altered HTT gene is passed from generation to generation, the number of CAG trinucleotide repeats increases and symptom onset is earlier (esp. when transmission is paternal).

### Neuropathology

Although the cellular functions of the HTT protein are not yet known, it is likely that HD arises largely from a gain of toxic function from an abnormal conformation of mutant HTT. Even though HTT is expressed in the body and throughout the brain, it relatively selectively affects the striatum early on, perhaps due to an interaction of HTT with the Rhes protein in the striatum, glutamate excitotoxicity, or loss of BDNF. Specifically, there is an early decline in the GABAergic medium spiny neurons of the striatum, especially in the caudate, and on imaging there is evidence of striatal atrophy and abnormality in the white matter tracts connecting striatum and cortex (Tabrizi et al., 2012; Tabrizi et al., 2013). Eventually more widespread atrophy occurs, which manifests in a wide range of neurocognitive deficits (Papoutsis et al., 2014).

From a pathophysiologic standpoint, HD can be understood from the model of cortico-striatal-thalamic dysfunction used to explain PD. However, unlike in PD, in which the thalamus is underactive, HD involves hyperactivity of the thalamus related to a decrease in the GABAergic inhibitory control exerted over it by the GPi and substantia nigra pars reticulata. The underactivity of GPi is attributable to its excessive inhibition via the direct pathway and the insufficient excitatory influence of the STN via the indirect pathway.

### Neurobehavioral Features of Huntington's Disease

Studies in the 1980s and 1990s often compared neuropsychological features of HD and either AD or PD to highlight differences among prototypical cortical and subcortical dementias and to infer cognitive functions of the striatum. More recent studies have focused on which cognitive changes emerge before disease diagnosis and whether these have clear neuroimaging correlates. In manifest HD, the neuropsychological changes have been well described (Brandt, 2009), and an increasing number of studies have documented the tests on which persons estimated to be within ten years of manifest disease have deficits (Paulsen, 2011). In the prodrome, many tests tapping processing speed, motor speed, attention, and executive functions are sensitive to deficits. One study outlined the effect sizes associated with differences in test performance in persons within 9 years, 9–15 years, and more than 15 years of HD diagnosis relative to controls (Stout et al., 2011). Although tests of emotional recognition revealed deficits in those 15 or more years from diagnosis, it is generally acknowledged that there is little evidence for measurable or meaningful cognitive deficits ten years or more before diagnosis (Papoutsis et al., 2014). Test revealing medium to large effect sizes in the 9–15 and less than 9 years prediagnosis groups included motor tasks (e.g., finger tapping), Symbol Digit Modalities, smell test, Hopkins Verbal Learning Test total

learning, Trail Making Part B, Stroop, and phonemic verbal fluency among others.

Patients with manifest HD are impaired on attention tasks demanding of vigilance and response flexibility and executive tasks such as Trail Making, Wisconsin Card Sorting, Stroop, and verbal fluency (Brandt, 2009). Visuospatial perception and visuomotor integration may also be compromised, and this likely reflects posterior cortical dysfunction (Wolf et al., 2014). Memory impairments are characterized by impoverished encoding and retrieval deficits (Montoya et al., 2006). If remote memory is affected, it is less so than in AD and characterized by lack of temporal gradient likely due to general retrieval difficulties (Beatty, Salmon, Butters, Heindel, & Granholm, 1988). Language is relatively intact, although as the disease progresses speech problems and processing speed/multitasking deficits can compromise communication (Paulsen, 2011). At this time, the limited studies of treatment of cognitive dysfunction in HD have yielded disappointing findings regarding the use of antidepressants, atypical stimulants (e.g., modafinil), and cholinesterase inhibitors (Killoran & Biglan, 2014).

In addition to cognitive changes, psychiatric conditions are common in HD, and it has been estimated that psychiatric symptoms occur in 30%–70% of those with HD (van Duijn, Kingma, & van der Mast, 2007). Unlike the time course shown in HD for motor and cognitive symptoms, there is no predictable time course for psychiatric features. The most common behavioral symptom in HD is irritability (40%–80%) (van Duijn et al., 2007) which is often accompanied by aggression. One study reported that at first HD clinic visit, 60% of caregivers reported aggression by the patient (Marder et al., 2000). Also, apathy occurs in about 50% of patients. Suicide risk is fourfold that of the general population: Whilst completed suicide rates are 3%–7%, attempts have been reported among as many as 25% of patients during the course of illness (Weintraub, Siderowf, Troster, & Anderson, 2011). Psychosis is rarer, most often involving delusions and occurring most often among those with early disease onset.

### Case Example of Huntington's Disease

Neuropsychological test results for a patient with HD are presented in Table 22.13. The 58-year-old man with 18 years of education was diagnosed with HD three years prior to the neuropsychological evaluation (roughly one year after his wife had noticed his mild abnormal facial and shoulder movements) on the basis of clinical examination, genetic testing (42 CAG repeats), and family history. Cognitively, the patient reported problems with speech (slow and slurred at times), occasional word-finding difficulty, short-term memory problems, attentional problems, decreased problem-solving ability (difficulty multitasking and requiring checklists to complete complex tasks), and visuo-perceptual changes (requiring more room to

park a car and causing several minor car accidents). The patient's wife noted that his information processing and verbal response speed had slowed, and that he was less able to complete small home repairs. Cognitive changes had caused difficulty in his work as a corporation's chief financial officer, including several costly financial errors. Psychiatric history was notable for depression without suicidality, the onset of which coincided with his HD diagnosis and initially involved low mood, anergia, and sleep disturbance. Although mood improved with the use of citalopram, he attributed mild, recent dysphoria and worry to difficulty performing his job.

He ambulated independently and without unsteadiness or imbalance, but had mild truncal and limb choreiform movements. Neuropsychological tests disclosed impairments in the areas of processing speed, visual-spatial perception and judgment, and learning and memory. Learning and memory impairment was characterized by slow learning and retrieval deficits on recall, but relatively adequate recognition. Memory was better for externally structured material (e.g., prose). Some of his executive function test scores fell into the low average to mildly impaired range, possibly also related to slow processing speed. Finger tapping speed was impaired bilaterally. Self-report scales relating to mood and personality were valid for interpretation and did not disclose clinical psychopathology. Overall, findings of multiple cognitive impairments impacting occupational functioning were deemed consistent with mild dementia secondary to HD.

## A Bird's-Eye View of Some Other Movement Disorders: Essential Tremor, Dystonia, and Psychogenic Movement Disorders

### *Essential Tremor*

Essential tremor (ET) is one of the most common movement disorders, with prevalence estimates averaging 4.6% among those 65 years and older (Louis & Ferreira, 2010). The condition is characterized by postural tremor when the limb is held against gravity, or kinetic tremor during actions which can affect a range of ADLs including writing, eating, grooming, and dressing. Despite its moniker of “benign” tremor, ET can significantly disrupt social and occupational functioning and quality of life (Troster, Pahwa, Fields, Tanner, & Lyons, 2005). In about half of cases the tremor is hereditary, although mutations identified in two genes impact only a small minority of patients (Zeuner & Deuschl, 2012).

Given the role of the cerebellum in cognition (Schmahmann, 2001; Schmahmann & Sherman, 1998), and the putative cerebello-thalamo-cortical basis of ET (Deuschl & Bergman, 2002), it is not surprising that ET, once thought exclusively a motor disorder, might have neurobehavioral manifestations. Visuospatial and executive dysfunction have also been linked to fronto-parietal white matter abnormalities by mean, radial, and axial diffusivity on diffusion tensor imaging (Bhalsing et al., 2015). The cognitive characteristics of ET were first studied among patients with family histories of ET versus PD (Gasparini et al., 2001) and candidates for thalamic DBS (Lacritz, Dewey, Giller, & Cullum, 2002; Lombardi, Woolston, Roberts, & Gross, 2001; Tröster et al., 2002). These studies most frequently identify problems with executive functions, complex attention, verbal fluency, and to lesser extent memory (Janicki, Cosentino, & Louis, 2013; Lyons & Tröster, 2015). ET may involve increased risk for MCI (Benito-Leon, Louis, Mitchell, & Bermejo-Pareja, 2011) and dementia (Benito-Leon, Louis, & Bermejo-Pareja, 2006) but the concept of neurodegeneration in ET remains controversial (Rajput, Adler, Shill, & Rajput, 2012). When MCI is identified, it is most often nonamnestic in nature (Park et al., 2015). Executive problems impact quality of life and functioning in ET (Woods, Scott, Fields, Poquette, & Troster, 2008), and the cognitive problems are independent of psychiatric comorbidity (Janicki et al., 2013). Patients with ET have increased rates of anxiety and social phobia, and often feel embarrassed and stigmatized (Tröster & Tucker, 2005). Because tremor may be alcohol-responsive, neuropsychological interview should routinely cover possible alcohol abuse. Treatments for ET most often employ beta-blockers or antiepileptic drugs. Some of these drugs (e.g., gabapentin, topiramate) may affect cognition (e.g., attention or word finding). Thalamic DBS is relatively safe, and the most common cognitive risk involves declines in verbal fluency (Fields, 2015; Fields et al., 2003).

### *Dystonia*

Dystonia, with a prevalence of about 15 per 100,000 is the third most common movement disorder (after essential tremor and PD) and involves sustained or intermittent muscle contractions causing abnormal movements (twisting, tremor) or postures. A proposed dystonia classification system uses two axes: clinical characteristics (age at onset, body distribution, temporal pattern) and associated features (additional movement disorders or neurological features) along one axis, and etiology (nervous system pathology and inheritance) on the other (Albanese et al., 2013). The exact pathophysiology of dystonia has not been specified, but the basal ganglia and cerebellum have been clearly implicated (Torkamani & Jahanshahi, 2015).

Whereas primary dystonias (i.e., idiopathic or genetic) are less often associated with cognitive deficits, dystonia plus syndromes (myoclonus dystonia, dopa-responsive dystonia, and X-linked parkinsonism dystonia), though rarely studied, are more often associated with cognitive changes (executive function and memory). When cognitive changes are identified in primary dystonia, they most often involve attention (shifting, sustained, divided), working memory, or executive functions (e.g., verbal fluency, perseverations on the WCST) (Jahanshahi, Rowe, & Fuller, 2003; Scott et al., 2003; Torkamani & Jahanshahi, 2015). DBS treatment appears relatively safe from a cognitive standpoint. Changes observed in individual patients are difficult to interpret given possible practice effects and confounds of motor improvement and anticholinergic medicine reduction (Jahanshahi, Czernecki, & Zurowski, 2011).

### *Psychogenic Movement Disorders*

Psychogenic counterparts may be seen for almost all movement disorders, though psychogenic tremor and dystonia are estimated to account for almost three quarters of all PMDs (Lang, 2011). One classification of PMD (Gupta & Lang, 2009) is based on diagnostic certainty. A *documented* PMD is a condition that remits with suggestion, placebo, physiotherapy, psychotherapy, or when the person is “unobserved.” A *clinically established* diagnosis is based on observation that the movement disorder is inconsistent over time, incongruent with a clinical condition, and has other features such as false neurological signs and multiple somatizations with or without obvious psychiatric disturbance. A *clinically definite* diagnosis requires both the documented and clinically established criteria to be met, whilst a *laboratory-supported definite* diagnosis require electrophysiologic confirmation of psychogenicity.

Neuropsychological studies of cognition in PMD are virtually nonexistent. A preliminary study found that two of eight patients with PMD who had low scores on a test of effort (the Test of Memory Malingering, or TOMM), also

had variable performance across neuropsychological tests. However, it was concluded that tests probably lack adequate sensitivity and specificity to characterize volition in individual cases (Nahan & Levin, 2011). Even psychological assessment has been rarely reported and studies have more often used psychiatric interviews (Anderson, 2011), or documented outcomes of psychotherapy or antidepressant treatment with anxiety and depression scales (Hinson, Weinstein, Bernard, Leurgans, & Goetz, 2006; Voon & Lang, 2005). Depression and anxiety are common in psychogenic tremor, dystonia, and myoclonus, occurring in about half or more of cases in small sample studies (Koller, Marjama, & Tröster, 2002). One report based on DSM diagnoses via interview (Feinstein, Stergiopoulos, Fine, & Lang, 2001), but was likely marred by a strong self-selection bias (42 of 88 PMD patients agreed to be interviewed), found point prevalence being 38% for anxiety disorders, 19% for major depression, and 12% for comorbid anxiety and depression. 45% of patients were deemed to have a personality disorder. In another study (Kranick et al., 2011), patients with PMD relative to age- and sex-matched controls and hand dystonia patients had higher rates of childhood trauma (emotional abuse and physical neglect, but not physical or sexual abuse). However, unlike the former study this study did not find PMD patients to have higher rates of psychiatric diagnoses. In addition, the groups did not differ in personality traits or dissociative experiences. Although direct empirical evidence appears lacking, the PAI, by virtue of the structure of the Somatic Complaints subscale and provision of clinical correlates for conversion and somatization, has been recommended in the assessment of PMD and suspected malingering (Rogers & Wooley, 2011). Psychotherapy (Morgante, Edwards, & Espay, 2013) and physical therapy/rehabilitation (Jordbru, Smedstad, Klungsoy, & Martinsen, 2014) may both be beneficial in treating PMD, although outcome studies are limited. Clearly, given the prevalence of PMD, further neuropsychological research is much needed.

### **Practical Clinical Issues in the Neuropsychological Evaluation of Patients With Movement Disorders**

#### *Utility of Clinical Neuropsychological Evaluation in Persons With Movement Disorders*

Tröster and Woods (2003) outlined several ways in which neuropsychological evaluation informs and potentially enriches the management of the patient with PD, and these utilities of neuropsychological evaluation apply to the other movement disorders and associated dementias as well. Specifically, neuropsychological evaluation can:

- provide information about the likely etiology of recent cognitive deterioration;
- yield objective data in the assessment of competence to consent to medical treatment;

- facilitate financial, legal, and living situation decision making by patient and family;
- provide a profile of cognitive and behavioral strengths and weaknesses, thereby
  - informing adaptive changes in the home or work environment to minimize handicap,
  - guiding development of strategies that minimize the impact of cognitive changes on day-to-day functioning, and
  - suggesting rehabilitation services such as speech therapy and psychotherapy;
- serve as an aid in adjudicating the appropriateness of certain medical and surgical interventions for a given patient with a movement disorder such as PD (e.g., Saint-Cyr & Trépanier, 2000; Tröster & Fields, 2003) and to document neurobehavioral and quality of life outcomes of such treatments; and
- help identify persons with PMDs (see Koller et al., 2002).

#### *Selecting Neuropsychological Test Batteries for Movement Disorders and Possible Test Modifications*

Specific test batteries have been proposed for evaluating patients with PD and other movement disorders. While these efforts are well-intentioned, there is probably greater agreement about the domains one should assess than about the specific tests best used. Test selection should rest on the referral question(s), patient and caregiver questions, the clinician's competence in using specific tests, the normative and psychometric properties of the tests (e.g., availability of alternate forms, test-retest reliability, validity for use in movement disorders), the patient's ability to tolerate and cooperate with the tests, and a thorough awareness of how manifestations of PD and other movement disorders can impact evaluation (e.g., motor "on-off" fluctuations, wearing off and freezing, sleep disturbance and fatigability, choreiform and dystonic dyskinesias, gaze palsy, apraxia, dysarthria, and hypersalivation). Thus, neuropsychologists should conduct a careful interview with the patient that asks about his or her symptoms, their time course, and his or her medication schedule. This allows planning of a successful evaluation. Examples of tests often used in the evaluation of PD and other movement disorders are presented in Table 22.14.

Standard administration methods may sometimes have to be modified for test use with patients with movement disorders. Patients with PSP, for example, often have downward gaze palsy, making it difficult for them to voluntarily look down at test forms. In such cases, stimuli may be held up for the patient to see. When impediments such as slurred speech are evident, patients may be asked to repeat responses if they are unclear, although it need be borne in mind that this is often frustrating and tiring to the patient, perhaps necessitating testing over multiple brief sessions. Patients with

Table 22.14 Commonly used neuropsychological tests by cognitive domain assessed

Cognitive Domain	Test
Premorbid Estimates	North American Adult Reading Test (NAART); Wechsler Test of Adult Reading (WTAR); Wide Range Achievement Test (WRAT); Advanced Clinical Solutions Test of Premorbid Functioning (TOPF)
Neuropsychological Screening	Mattis DRS; MMSE; Repeatable Battery for the Assessment of Neuropsychological Status (RBANS); Montreal Cognitive Assessment; Parkinson's Disease–Cognitive Rating Scale; Frontal Assessment Battery
Intelligence	Raven's Progressive Matrices; Wechsler Abbreviated Scale of Intelligence (WASI); Wechsler Adult Intelligence Scale (WAIS) (recent editions)
Attention and Working Memory	Auditory Consonant Trigrams (ACT); Brief Test of Attention (BTA); Continuous Performance Tests (CPT); Digit and Visual Spans; Paced Auditory Serial Addition Test (PASAT); Stroop Test *
Executive Function	Cognitive Estimation Test (CET); Delis-Kaplan Executive Function Scale (DKEFS); Halstead Category Test; Trailmaking Test (TMT)*; WCST; Tower of Toronto; Tower of London
Memory	Benton Visual Retention Test (BVRT-R); California Verbal Learning Test (CVLT-II); Rey Auditory Verbal Learning Test (RAVLT); Selective Reminding Test; Rey Complex Figure Test (RCFT) *; Wechsler Memory Scale (WMS) (recent editions) *
Language	Boston Naming Test (BNT); Controlled Oral Word Association Test (COWAT); Sentence Repetition; Token Test; Complex Ideational Material
Visuoperception	Benton Facial Recognition Test; Benton Judgment of Line Orientation (JLO); Hooper Visual Organization Test (VOT); Visual Object and Space Perception Battery
Motor and Sensory-Perception	Finger Tapping*; Grooved Pegboard*; Hand Dynamometer*; Sensory-Perceptual Examination
Mood State and Personality	Beck Anxiety Inventory (BAI); Beck Depression Inventory (BDI); Hamilton Depression Scale (HDS) or Inventory (HDI); The Neuropsychiatric Inventory (NPI); Minnesota Multiphasic Personality Inventory (MMPI) (recent editions); Profile of Mood States (POMS); State-Trait Anxiety Inventory (STAI); Maudsley Obsessional-Compulsive Inventory; Yale-Brown Obsessive Compulsive Scale; Hospital Anxiety and Depression Scale (HADS); Montgomery–Åsberg Depression Rating Scale
Quality of Life, Coping, and Stressors	Parkinson's Disease Questionnaire (PDQ); Medical Outcomes Study 36-item short form (SF-36); Sickness Impact Profile (SIP); Coping Responses Inventory (CRI); Ways of Coping Questionnaire; Life Stressors and Social Resources Inventory (LISRES)

(\*Test may not be appropriate for patients with marked motor impairment)

hypophonia may be provided an amplification device to minimize the number of times they are asked to repeat answers. A patient with tremor, choreiform dyskinesias or dystonia who is to be administered tests or questionnaires requiring writing, circling of alternatives, or filling in of “multiple choice “bubbles” will probably require the examiner to make the motor responses corresponding to the patient's oral verbal response. Similarly, on some tasks, such as card sorting or tower tests, it may behoove the examiner to hold and move the cards or blocks/beads as instructed by the patient. In contrast, tests requiring pointing rather than oral responses may be more appropriate for patients with speech impairment. In general, tests with significant motor demands are better avoided with patients who have movement disorders. In parkinsonians with fatigability, severe motor “off” periods, or frequent fluctuations, breaks will need to be taken. Though nonmotor tasks might be administered when patients have dyskinesias, the patient may still be distracted by these movements and this needs to be considered in interpreting the test results. Although there may occasionally be a need to compare performances in the “on” and “off” medications, it is recommended that patients be tested while on their medications. Some have found that similarities outweigh differences when test performances are compared in motor “on” and “off” states (Delis & Massman, 1992), but this may only be

true earlier in the disease when the difference between motor “on” and “off” is much smaller than later in the disease, when this difference is pronounced. In more advanced PD, testing during the “off” state can be unnecessarily challenging for patient and test administrator, and the patient may also experience increased dysphoria and anxiety, further complicating test interpretation.

### Note

- 1 The traditional Richardson syndrome is equivalent to what is commonly understood to be PSP.

## 23 Cognitive Functions in Adults With Central Nervous System and Non-Central Nervous System Cancers

*Denise D. Correa and James C. Root*

### Introduction

Cognitive dysfunction is common in many cancer patients and can be related to the disease and to treatment with chemotherapy and/or radiotherapy (RT). The neuropsychological domains affected and the severity of the deficits may vary as a result of disease and treatment type, but difficulties in executive functions, motor speed, and learning, and retrieval of information are the most prevalent. In a significant number of cancer patients, changes in cognitive functions interfere with their ability to resume work and social activities at prediagnosis levels.

There has been an increase in the number of studies and clinical trials that incorporate standardized cognitive outcome measures for the assessment of patients with cancer of the central nervous system (CNS; see Correa, 2006; Taphoorn & Klein, 2004). New developments have been described in the study of the cognitive side effects of chemotherapy for non-CNS cancers (Correa & Ahles, 2008). These lines of research have provided valuable information about the incidence of cognitive dysfunction in patients with various cancers, and the contribution of treatments involving different regimens and modalities. Studies have also begun to investigate the underlying mechanisms that may contribute to the neurotoxicity of RT and chemotherapy (Dietrich, Han, Yang, Mayer-Proschel, & Noble, 2006; Nordal & Wong, 2005) and interventions to minimize or prevent both structural and functional damage associated with these regimens have been proposed (Gehring, Sitskoorn, Aaronson, & Taphoorn, 2008).

The current chapter reviews studies involving patients with brain tumors and breast cancer, considering that most of the research has been conducted in these patient groups. Of note, other emerging areas of study include cognitive dysfunction associated with androgen ablation for prostate cancer (Jamadar, Winters, & Maki, 2012; Nelson, Lee, Gamboa, & Roth, 2008), chemotherapy for ovarian cancer (Correa & Hess, 2012; Correa et al., 2012; Correa, Zhou, Thaler, Maziarz, Hurley, & Hensley, 2010), and high-dose chemotherapy and stem cell transplantation for hematological cancers (Correa et al., 2013; Syrjala et al., 2011; Syrjala, Dikmen, Langer, Roth-Roemer, & Abrams, 2004).

### Brain Tumors

Primary brain tumors are classified by their predominant histologic appearance and location; they account for less than 2% of all cancers. Gliomas are the most common primary tumors accounting for approximately 40% of all CNS neoplasms (Greenberg, Chandler, & Sandler, 1999). High-grade gliomas (WHO Grade III-IV) include glioblastoma multiforme, anaplastic astrocytomas, anaplastic oligodendrogliomas, and anaplastic mixed gliomas. Low-grade gliomas (WHO Grade I-II) include astrocytomas, oligodendrogliomas, and mixed gliomas. Other less frequent brain tumors are primary CNS lymphoma (PCNSL), ependymomas, meningiomas, and medulloblastomas (Bondy, El-Zein, Wrench, 2005). Brain metastases are also common intracranial tumors in adults (Mehta & Tremont-Lukas, 2004)

*Figure 23.1* Coronal and axial MRIs showing a brain tumor involving cortical and subcortical regions

As effective treatment interventions have increased survival, there has been greater awareness that many brain tumor patients experience cognitive dysfunction, despite adequate disease control (Poortmans et al., 2003). This dysfunction can be related to both the disease and its treatment including surgery, RT, and chemotherapy. The side effects of medications such as corticosteroids and antiepileptics often contribute to or exacerbate these cognitive difficulties. The relevance of including cognitive and quality of life (QoL) evaluations as outcome variables in neuro-oncology research has been increasingly recognized (Johnson & Wefel, 2013; Meyers & Brown, 2006) and the National Cancer Institute (NCI) Brain Tumor Progress Review Group report has recommended that routine cognitive and QoL assessment become the standard care for patients with brain tumors (BTPRG, 2000). Meyers and Brown (2006) published guidelines for the neuropsychological assessment of patients with brain tumors within the context of clinical trials. The suggested core neuropsychological test batteries include standardized instruments with demonstrated sensitivity to the neurotoxic effects of cancer treatment and include tests of attention, executive functions, learning, and retrieval of new information, and graphomotor speed (Correa et al., 2004; Wefel, Kayl, & Meyers, 2004). The feasibility of incorporating a relatively brief cognitive test battery in multi-institutional clinical trials within the context of the Radiation Therapy Oncology Group (RTOG) has also been demonstrated (Meyers et al., 2004; Regine et al., 2004).

Recent longitudinal studies documented that along with age, histology, and performance status, cognitive functioning is a sensitive and important factor in clinical trials involving patients with high-grade tumors (Reardon et al., 2011; Wefel et al., 2011). Performance on a test of verbal memory was independently and strongly related to survival after accounting for age, performance status, histology, extent of resection, number of recurrences, and time since diagnosis in patients with glioblastoma or anaplastic astrocytoma (Meyers, Hess, Yung, & Levin, 2000). Neuropsychological test performance predicted survival in patients with metastases and leptomeningeal disease (Meyers et al., 2004), and glioblastomas (Johnson, Sawyer, Meyers, O'Neill, & Wefel, 2012; Klein et al., 2003). Cognitive decline preceded radiographic evidence of tumor progression by several weeks in glioma patients (Armstrong, Goldstein, SHERA, Ledakis, & Tallent, 2003; Brown et al., 2006; Meyers & Hess, 2003). However, these results are interpreted with caution considering that some studies had missing data, lacked a control group, and did not account for the possible effects of medications (Mauer et al., 2007).

### ***Disease and Treatment Effects***

Seizures, headaches, increased intracranial pressure, focal neurological signs, and cognitive impairment are common presenting symptoms in patients with brain tumors. Several studies documented cognitive impairment at diagnosis and prior to RT or chemotherapy in patients with high-grade

gliomas (Klein et al., 2001), low-grade gliomas (Klein et al., 2002), and PCNSLs (Correa, DeAngelis, & Shi, 2007). Cognitive difficulties present at the time of diagnosis are often related to the location of the tumor (Klein et al., 2001), but a diffuse pattern of deficits has also been reported (Crossen, Goldman, Dahlborg, & Neuwelt, 1992). Rate of tumor growth is a predictor of cognitive impairment, as slow-growing tumors (e.g., low-grade gliomas) are often associated with less severe cognitive dysfunction than rapidly growing tumors (e.g., high-grade gliomas) (Anderson, Damasio, & Tranel, 1990; Hom & Reitan, 1984). Tumor type or volume has not been found to predict cognitive performance (Kayl & Meyers, 2003).

Surgical resection can be associated with transient neurological and cognitive deficits due to damage to tumor-surrounding tissue and edema (Bosma et al., 2007; Duffau, 2005), with impairments often consistent with tumor location (Klein, 2012). Intraoperative stimulation mapping has been used in patients undergoing surgical resection for gliomas, and a recent meta-analysis (De Witt Hamer, Robles, Zwiderman, Duffau, & Berger, 2012) showed that the procedure was associated with fewer neurological deficits and allowed for more extensive resections. However, the incidence and extent of cognitive dysfunction related to tumor surgical resection is unknown, given the relatively limited number of studies including pre- and postsurgical neuropsychological evaluations. In addition, the specific contribution of the tumor to cognitive performance is difficult to ascertain considering that the majority of patients receive corticosteroids and antiepileptic medications following diagnosis and perioperatively. Steroids may improve cognitive deficits due to resolution of edema (Klein et al., 2001), but can also be associated with transient mood disturbance and working memory difficulties (Bosma et al., 2007; Lupien, Gillin, & Hauger, 1999). Antiepileptics can disrupt some aspects of cognitive functions in brain tumor patients, particularly graphomotor speed and executive abilities (van Breemen, Wilms, & Vecht, 2007).

### ***Whole-Brain and Conformal Radiotherapy***

#### MECHANISMS OF CNS INJURY

The pathophysiological mechanisms of radiation injury involve interactions between multiple cell types within the brain including astrocytes, endothelial cells, microglia, neurons, and oligodendrocytes (Greene-Schloesser, Moore, & Robbins, 2013; Greene-Schloesser et al., 2012). Suggested mechanisms include depletion of glial progenitor cells and perpetuation of oxidative stress (Tofilon & Fike, 2000). Radiation may diminish the reproductive capacity of the O-2A progenitors of oligodendrocytes, disrupting the normal turnover of myelin. Blood-vessel dilatation and wall thickening with hyalinization, increased blood-brain barrier

(BBB) permeability due to endothelial cell loss and apoptosis, and a decrease in vessel density have also been hypothesized to lead to white matter necrosis (Nordal & Wong, 2005; Warrington et al., 2013). The extent to which radiation damage is due to direct toxicity on cells or secondary to deleterious effects on the vasculature remains to be elucidated (Noble & Dietrich, 2002). Progressive demyelination may take months to cause symptoms because of the slow turnover of oligodendrocytes, contributing to the latency in onset of neurotoxicity and its progressive nature. In addition, RT achieves therapeutic effects in part through DNA damage by introducing interstrand DNA and DNA-protein crosslinks, single- and double-stranded DNA breaks, methylation, oxidation, and by increasing formation of reactive oxygen species (ROS). Increased numbers of reactive astrocytes and microglia have been shown to produce ROS, proinflammatory cytokines, and growth factors that may cause progressive inflammatory injury (Kim, Brown, Jenrow, & Ryu, 2008). The accumulation of DNA damage in neuronal cells, when unrepaired, can lead to the transcription of defective proteins, apoptosis, and neurodegeneration (Fishel, Vasko, & Kelley, 2007). Recent animal and human studies have documented that RT, chemotherapy, and corticosteroids can disrupt hippocampal neurogenesis (Dietrich et al., 2006; Fike, Rosi, & Limoli, 2009; Monje & Dietrich, 2012; Monje et al., 2007). RT produces elevation of inflammatory cytokines in the brain (Lee, Sonntag, Mitschelen, Yan, & Lee, 2010), and inflammation surrounding neural stem cells may contribute to neurogenesis inhibition (Monje, Toda, & Palmer, 2003). RT-induced apoptosis and a decline in neurogenesis in the subgranular zone of the dentate gyrus were associated with deficits in hippocampal-dependent tasks in some studies (Madsen, Kristjansen, Bolwig, & Wortwein, 2003; Raber et al., 2004).

#### CLINICAL FINDINGS

Radiation encephalopathy has been classified into three phases according to the time between the administration of RT and the development of symptoms (DeAngelis & Posner, 2009). These are described as acute, early delayed, and late delayed. Acute encephalopathy develops within days of RT and the most common symptoms are nausea, headache, and worsening of neurological signs. Disruption of the BBB by endothelial apoptosis, increased cerebral edema, and intracranial pressure have been suggested as underlying mechanisms. Early delayed effects occur within a few weeks to six months following RT and are reversible in most cases. Lethargy, somnolence, and resurgence of neurological signs, and a transient decline in cognitive functioning may occur, but these factors are not predictive of delayed cognitive deficits. Transient white matter hyperintensities suggesting demyelination may be seen on magnetic resonance imaging (MRI), and are thought to be related to BBB disruption or injury to oligodendrocytes.

The late-delayed effects of RT become apparent a few months to many years after treatment, and often produce irreversible and progressive damage to the CNS (Sheline, Wara, & Smith, 1980). Risk factors for developing delayed RT-induced brain injury include greater volume of irradiated tissue, higher total dose of RT (> 2 Gy dose per fraction), concomitant administration of chemotherapy, age greater than 60 years, and presence of comorbid vascular risk factors (Behin, 2003; Constine, Konski, Ekholm, McDonald, & Rubin, 1988; DeAngelis & Posner, 2009). MRI typically shows hyperintensities in periventricular and subcortical white matter, and these changes are often more pronounced in older patients (see Figure 23.2). Radiation-induced microbleeds were recently described in patients with gliomas treated with external-beam RT (Bian, Hess, Chang, Nelson, & Lupo, 2013). In a diffusion tensor imaging (DTI) study, there was evidence of early dose-dependent progressive demyelination and axonal degeneration after RT, and subsequent diffuse dose-independent demyelination (Chapman et al., 2013; Nagesh et al., 2008). Chapman et al. (2013) used DTI to study 14 patients with brain metastases before and after whole-brain RT  $\pm$  chemotherapy. The results showed regional variation in white matter changes post-RT, with a significant decrease in fractional anisotropy in the cingulate and fornix. A study using positron emission tomography (PET) in a small cohort of brain tumor patients reported dose-dependent reduction in glucose metabolism in brain regions that received greater than 40 Gy at three- and six-month follow-ups; these changes correlated with decreased performance on tests of problem solving and cognitive flexibility (Hahn et al., 2009).

A substantial number of brain tumor patients treated with RT experience cognitive dysfunction that varies from mild to severe, and it is currently considered the most frequent complication among long-term survivors (Behin, 2003). The peak of neurocognitive difficulties resulting from RT occurs

Figure 23.2 T1-weighted axial MRIs showing periventricular white matter abnormalities in a 50-year-old man six years post treatment with high-dose chemotherapy and whole-brain radiotherapy

approximately six months to two years after treatment completion, and its incidence is proportional to the percentage of patients with disease-free survival (DeAngelis, Yahalom, Thaler, & Kher, 1992). The variability in the documented frequency of RT-induced cognitive deficits may be partially associated with the insensitivity of the methods of assessment used, duration of follow-up, retrospective nature of many studies, inclusion of patients treated with different regimens, and population discrepancies. In addition, the high incidence of tumor recurrence and short-term survival in patients with high-grade malignancies have often been considered confounding variables that hampered the ability to quantify the frequency, onset, and course of the delayed cognitive effects of RT (Crossen, Garwood, Glatstein, & Neuwelt, 1994). A review of the literature suggests that the pattern of neuropsychological impairments associated with the delayed effects of whole-brain RT is diffuse (Duffey, Chari, Cartlidge, & Shaw, 1996), and most consistent with frontal-subcortical dysfunction with deficits in attention, executive functions, learning and retrieval of new information, and graphomotor speed (Archibald et al., 1994; Crossen et al., 1994; Salander, Karlsson, Bergenheim, & Henriksson, 1995; Scheibel, Meyers, & Levin, 1996; Taphoorn & Klein, 2004; Wefel, Kayl, et al., 2004; Weitzner & Meyers, 1997).

In recent years, conformal RT that includes the area of the tumor and surrounding margin has supplanted whole-brain RT in the treatment of gliomas due to equivalent efficacy and reduced neurotoxicity (DeGroot, Aldape, & Colman, 2005). Some studies suggest that conformal RT is associated with less severe cognitive dysfunction than whole-brain RT (Torres et al., 2003), but most studies were retrospective and revealed variable outcomes ranging from no morbidity to marked cognitive deficits (Armstrong et al., 2000; Armstrong et al., 2002; Postma et al., 2002; Surma-aho et al., 2001; Taphoorn et al., 1994). Recent research reported that radiation dose to specific regions, such as the right temporal lobes and the hippocampi, may be more predictive of cognitive impairment than total RT dose (Peiffer et al., 2013). Similarly, a prospective study of patients with low-grade or benign tumors treated with fractionated stereotactic RT reported a dose-response relationship, with higher RT doses to the hippocampi showing an association with impairment in word-list delayed recall (Gondi, Hermann, Mehta, & Tome, 2013).

#### *Chemotherapy Alone or Combined With Radiotherapy*

The pathophysiological mechanisms of chemotherapy-induced CNS damage are not well understood. Candidate mechanisms include demyelination, secondary inflammatory response, oxidative stress, and DNA damage; immune dysregulation; and microvascular injury (Ahles & Saykin, 2007). There is increasing evidence that chemotherapy has direct toxic effects on progenitor cells, oligodendrocytes, white matter, gliogenesis, and neurogenesis (Dietrich, 2010). Increased cell death and decreased cell division in the subventricular

zone and in the dentate gyrus of the hippocampus have been reported in mice (Dietrich et al., 2006; Dietrich, Monje, Wefel, & Meyers, 2008); neural progenitor cells and oligodendrocytes are particularly vulnerable.

Neurotoxicity has been reported after high-dose regimens with procarbazine, lomustine, and vincristine (PCV) chemotherapy (Postma et al., 1998), and after high-dose methotrexate (HD-MTX) and high-dose cytarabine, particularly if RT is administered before or during chemotherapy (DeAngelis & Shapiro, 1991; see Figure 23.2). Chemotherapy administered intrathecally is more likely to cause CNS toxicity than when it is applied systemically. Combined treatment with RT and chemotherapy may have a synergistic effect (Keime-Guibert, Napolitano, & Delattre, 1998), as chemotherapy agents may interfere with the same cellular structures as radiation and may act as a radiosensitizer. Radiation may alter the distribution kinetics of chemotherapeutic agents in the CNS by increasing the permeability of the BBB, affecting the ability of arachnoid granulations or choroid plexus to clear the drug, or interrupting the ependymal barrier to allow drugs in the cerebrospinal fluid to enter the white matter. Finally, RT-induced cellular changes may allow greater amounts of the drug to enter nontumor cells or less of it to exit. The interactions between RT and HD-MTX are the most clearly demonstrated (Keime-Guibert et al., 1998), and nonenhancing, confluent lesions in the periventricular and subcortical white matter have been documented on MRI studies (Correa et al., 2004; Keime-Guibert et al., 1998). Decrease in white matter density in the corpus callosum, hippocampal cell death, and memory impairments were reported in rats treated with HD-MTX (Seigers et al., 2009). Carmustine, cyclophosphamide, cisplatin, cytarabine, thiotepa, and methotrexate were found to be associated with neurotoxicity, with changes in cortical and subcortical brain regions (Rzeski et al., 2004). Deficits in spatial and nonspatial memory have been described after administration of methotrexate and 5-fluorouracil in mice (Winocur, Vardy, Binns, Kerr, & Tannock, 2006). However, the cognitive side-effects of chemotherapy are often difficult to determine in brain tumor patients as most also receive RT in the course of their treatment.

Variation in genetic polymorphisms may increase the susceptibility to cognitive dysfunction following RT  $\pm$  chemotherapy. In a recent cross-sectional study (Correa, et al., 2013), brain tumor patients with at least one Apolipoprotein E (APOE)  $\epsilon$ -4 allele had significantly lower scores in verbal learning and delayed recall, and marginally significant lower scores in executive function, in comparison to non-carriers of a  $\epsilon$ -4 allele.

#### *Neuropsychological Studies*

##### *High-Grade Tumors*

Patients with high-grade gliomas often present with symptoms of increased intracranial pressure, seizures or focal

neurological signs (Greenberg et al., 1999). The majority of patients undergo surgical tumor resection and receive a combined modality regimen of RT and chemotherapy; recent trials involving glioblastoma patients have also included anti-angiogenic therapy with bevacizumab (Gilbert et al., 2014). The median survival time is less than two years for patients with glioblastomas, and two to three years for anaplastic astrocytomas (Carson, Grossman, Fisher, & Shaw, 2007; Stupp et al., 2005). Cognitive impairment in patients with high-grade gliomas is multifactorial and includes the tumor and the adverse effects of treatment. Disease recurrence and short-term survival have been considered confounding variables that limit the ability to quantify the frequency, onset, and course of the delayed cognitive effects of RT and chemotherapy. Several studies have suggested that tumor progression contributes significantly to cognitive decline, and that relatively stable performance is seen in patients without recurrent disease (Brown et al., 2006).

Klein et al. (2001) studied cognitive functioning in 61 patients with high-grade gliomas following surgery or biopsy, and included comparison groups of 50 patients with lung cancer and age-matched healthy controls. As compared to healthy controls, cognitive impairment (i.e., attention and executive functions) was evident in all glioma patients and 52% of lung cancer patients. The use of antiepileptic medication was associated with working memory deficits. Patients with tumors in the right hemisphere had greater difficulties in visuospatial tests, and patients with left hemisphere tumors showed greater susceptibility to interference and slower visual scanning. Bosma et al. (2007) assessed cognitive functions at eight- and 16-month intervals after RT in 32 and 18 high-grade glioma patients, respectively. Patients with tumor progression had a more pronounced cognitive decline (i.e., psychomotor speed, executive functions) than patients who remained stable; however, the decline was also considered to be in part related to the side effects of antiepileptics and corticosteroids. However, in a recent study of patients with high-grade tumors (de Groot et al., 2013) treated with levetiracetam ( $n = 35$ ), valproic acid or phenytoin ( $n = 38$ ), or no antiepileptics ( $n = 44$ ), there were no significant differences on cognitive test performance between patients on newer compared to older antiepileptics and patients receiving no medication six weeks postsurgery; there was a beneficial effect of both antiepileptics on verbal memory.

Hilverda et al. (2010) studied 13 patients with glioblastoma multiforme treated with RT and temozolomide with no evidence of disease progression. Neurocognitive evaluations were performed after surgery, six weeks post-RT and concomitant temozolomide, and after three cycles of adjuvant temozolomide in progression-free patients. The results showed that at baseline, 11 patients had impaired attention, information processing speed, and executive functions in comparison to healthy controls. At the first follow-up, four patients improved, four deteriorated, and the others were relatively stable. At the last follow-up, cognitive

performance remained stable in all domains for 11 patients, with one patient improving and one patient declining in the interim. The authors concluded that cognitive functions are likely to be relatively stable in the absence of disease progression. Froklage and colleagues (2013) assessed cognitive functions and radiological abnormalities in patients with newly diagnosed high-grade gliomas treated with chemoradiation followed by adjuvant temozolomide. Neuropsychological assessments were conducted before treatment and prior to adjuvant temozolomide ( $n = 33$ ), during and after temozolomide ( $n = 25$  and  $17$ , respectively), and three and seven months post treatment completion ( $n = 9$  and  $5$ , respectively); patient dropout was primarily due to disease progression. In comparison to matched healthy controls, 63% of patients had deficits in executive functions, processing speed, and working memory at baseline. Approximately 70% of the patients remained stable during the follow-up period, and most of the patients who declined had tumor progression. Cerebral atrophy and white matter hyperintensities developed or worsened in approximately 45% of patients during follow-up.

Brown et al. (2006) reported the results of prospective Mini-Mental Status Examinations (MMSE) in 1,244 high-grade tumor patients who participated in the North Central Cancer Treatment Group treatment trials, which used radiation and nitrosurea-based chemotherapy. The proportion of patients without tumor progression who had significant cognitive deterioration ranged from 13% to 18%, and remained stable over the 24-month follow-up period; a decline in MMSE scores was a predictor of more rapid time to tumor progression and preceded radiographic changes. Corn et al. (2009) examined QoL and mental status in 203 patients with glioblastoma multiforme within the context of a Phase I/II study of the RTOG to assess the impact of dose escalation conformal RT. Patients were administered the MMSE at the start and at the end of radiation, and at four-month intervals subsequently. The results showed a decline in the MMSE over the follow-up period, and this was considered to be at least in part related to RT. However, considering the demonstrated low sensitivity of cognitive screening measures (e.g., MMSE) to detect cognitive dysfunction in brain tumor patients (Meyers & Wefel, 2003), the findings of these two large studies may represent an underestimation.

A Phase II trial evaluated cognitive functioning in 167 patients with recurrent glioblastoma treated with bevacizumab-based therapy (Wefel et al., 2011). Patients with objective response to treatment or progression free survival greater than six months had stable median cognitive test scores across the 24-month follow-up, but patients with evidence of progressive disease exhibited cognitive decline. In a prospective study of newly diagnosed glioblastoma patients treated with temozolomide, hypofractionated stereotactic RT and bevacizumab, 37 patients underwent longitudinal neuropsychological evaluations (Correa et al., 2011). Linear mixed model analyses showed a significant decline in

set-shifting and verbal learning ( $p < 0.05$ ) from baseline to the four-month follow-up, and performance remained stable or improved slightly at subsequent intervals. Visuospatial memory was stable at four months, but showed a trend toward a decline at subsequent follow-ups. The decline in executive functions and memory in the early phase of treatment was thought to be related to the acute effects of RT. In a recent, large clinical trial for patients with newly diagnosed glioblastoma comparing the efficacy of standard chemo-radiation, maintenance temozolomide, and placebo or bevacizumab, cognitive evaluations were performed longitudinally in patients without disease progression (Gilbert et al., 2014). The initial results suggested that patients randomized to bevacizumab, compared to placebo, experienced greater decline over time in executive functions and information processing speed, suggesting either bevacizumab-related neurotoxicity or unrecognized tumor progression. In a recent study of long-term survivors of anaplastic oligodendrogliomas treated with RT versus RT and procarbazine, lomustine and vincristine (Habets et al., 2014), a variable pattern of cognitive impairment was seen in 75% of patients who were progression free, regardless of initial treatment type.

#### *Low-Grade Tumors*

Low-grade gliomas are slow-growing infiltrative tumors most common in young and middle-aged adults, and the majority of patients present with seizures and headaches (Greenberg et al., 1999). The median survival ranges from five to ten years, and these tumors invariably progress to more aggressive high-grade gliomas (Shaw et al., 2002). Treatment interventions remain controversial regarding the optimal timing of surgical intervention, RT, and chemotherapy (Cairncross, 2000; Kiebert et al., 1998; Shaw et al., 2002; Soffietti et al., 2010). Several studies that documented cognitive dysfunction in low-grade glioma patients found that the tumor itself, rather than RT, was the primary contributing factor (Laack et al., 2003; Taphoorn et al., 1994; Torres et al., 2003). However, studies including long-term survivors reported that both partial and whole-brain RT was associated with cognitive dysfunction several years after treatment completion (Douw et al., 2009), and a decline in nonverbal memory was evident in some studies. Tumor-related epilepsy and the side effects of antiepileptic medications also contribute to cognitive dysfunction in these patients (Klein, 2012). Methodological problems including differences in the sensitivity of the neuropsychological measures administered, retrospective designs, and the inclusion of patients with high- and low-grade tumors, and patients treated with partial and whole-brain RT (Imperato, Paleologos, & Vick, 1990; Kleinberg, Wallner, & Malkin, 1993; Torres et al., 2003) may account for some of the variability of the findings in the literature. A recent report by the Response Assessment in Neuro-Oncology group (RANO), recommended that standardized assessments of cognitive functions and QoL be incorporated

in clinical trials involving low-grade glioma patients (van den Bent et al., 2011). The characterization of tumor- and treatment-related cognitive dysfunction in patients with low-grade tumors is particularly relevant given the relatively prolonged survival and the controversy in the effectiveness of early treatment.

A cross-sectional study assessed cognitive outcome in 195 low-grade glioma patients (104 treated with RT 1–22 years prior to enrollment) compared to 100 low-grade hematological cancer patients, and 194 healthy controls (Taphoorn et al., 1994). Glioma patients completed the cognitive evaluation at a mean of six years after diagnosis, and obtained lower test scores than the cancer control group on psychomotor speed, visual memory, and executive functions. Although the authors concluded that the tumor had the most detrimental effects on cognition, decreased verbal and visual memory was evident in patients who received RT in daily fractions exceeding 2 Gy, and some of the cognitive test scores declined over time only among those treated with RT. Antiepileptic treatment was associated with more pronounced cognitive dysfunction. A follow-up study (Douw et al., 2009) included 65 of these patients who underwent a neuropsychological re-evaluation at a mean of 12 years (range 6–28 years) after the initial assessment. Patients who received RT showed a decline in attention, executive function, and information processing speed, regardless of fraction dose. White matter hyperintensities and cortical atrophy correlated with worse cognitive test performance. Surma-aho et al. (2001) assessed cognitive functioning in low-grade glioma patients approximately seven years post-RT  $\pm$  chemotherapy ( $n = 28$ ) or surgical resection alone ( $n = 23$ ); 19 patients had whole-brain RT and nine had focal RT. The results showed that patients treated with RT had significantly lower scores in percent retention of visual materials and estimated Performance IQ, and more extensive periventricular white matter abnormalities on MRI, in comparison to patients who did not receive RT. The authors concluded that RT increased the risk for cognitive impairment and leukoencephalopathy in patients with low-grade tumors.

Correa et al. (2007) studied cognitive functions in 40 patients with low-grade gliomas: 24 patients had surgery only, and 16 had conformal RT  $\pm$  chemotherapy. Patients treated with RT  $\pm$  chemotherapy had lower scores in attention and executive functions, psychomotor speed, verbal and nonverbal memory, and naming than untreated patients. In addition, patients who completed treatment at intervals greater than three years had significantly lower scores in nonverbal memory. Antiepileptic polytherapy, treatment history, and disease duration contributed to reduced psychomotor speed; 62% of treated patients had white matter disease on MRI, whereas only 10% of the untreated patients had such changes. In a subsequent study (Correa et al., 2008), 25 of these patients completed additional cognitive follow-ups. The results showed a mild decline in nonverbal memory 12 months after the initial evaluation regardless of treatment

status; scores remained one standard deviation below normative values in other cognitive domains. Among the 16 patients who completed a subsequent evaluation (12–27 months later), there was improvement in untreated patients, but a decline in some aspects of executive function in patients treated with RT  $\pm$  chemotherapy. Disease duration and treatment history were thought to contribute to the pattern of findings.

Armstrong et al. (2000) assessed cognitive functions prospectively in 20 patients with low-grade tumors treated with conformal RT. A decrement in verbal memory retrieval was evident during the early delayed period following RT with improvement at longer intervals. The long-term effects of RT on cognition were examined in a subsequent study involving 26 patients with low-grade tumors (Armstrong, Stern, & Corn, 2001). A selective decline in learning and recall of visual information five years post-RT was detected despite continued improvement up to that point. Long-term improvements were noted on tests of attention, executive functions, and verbal recall. The authors concluded that partial RT was not associated with significant delayed cognitive impairments in this population. In a recent study (Gondi et al., 2013), 18 patients with low-grade or benign tumors treated with fractionated stereotactic RT completed a neuropsychological evaluation at baseline and 18 months following treatment. The results suggested that RT dose greater than 7.3 Gy to 40% of the bilateral hippocampi was associated with impairment on a list-learning delayed recall test. Alterations in functional connectivity using magnetoencephalography have also been described recently in patients with low-grade gliomas (Bosma et al., 2008).

#### *Primary Central Nervous System Lymphoma (PCNSL)*

PCNSL is a rare infiltrative tumor that develops most frequently in the subcortical periventricular white matter, with single lesions occurring in 60%–70% of patients and multifocal lesions in 30%–40%. It is a disease of middle and late adult life with a mean age at diagnosis of 60 years, and it is slightly more common in men. Focal neurological signs are the most common presentation followed by psychiatric symptoms, headaches, and seizures (Batchelor et al., 2012; Rubenstein, Ferreri, & Pittaluga, 2008). The standard treatment for PCNSL often includes HD-MTX regimens and whole-brain RT. Although this treatment approach is effective, with a median survival of 30 to 60 months (DeAngelis et al., 2002), it is associated with delayed neurotoxicity in most patients (Correa et al., 2012; Poortmans et al., 2003; Thiel et al., 2010). Delayed treatment-related cognitive dysfunction has been recognized as a frequent complication among long-term survivors, and may interfere with QoL (Correa et al., 2007). Recent studies suggest that HD-MTX without RT can be efficacious in the treatment of PCNSL and diminish the risk for delayed neurotoxicity (Juergens et al., 2010; Rubenstein et al., 2013; Thiel et al., 2010). However, since disease relapse

is relatively common and some patients require salvage therapy, the optimal induction and consolidative therapy for PCNSL remains controversial. The importance of assessing the incidence and extent of cognitive dysfunction associated with HD-MTX regimens with and without WBRT has been recognized by the International Primary CNS Lymphoma Collaborative Group (IPCG; (Abrey et al., 2005; Ferreri, Zucca, Armitage, Cavalli, & Batchelor, 2013) and guidelines for standardized cognitive assessments to be incorporated in clinical trials have been developed (Correa et al., 2007). A literature review indicated that cognitive function was evaluated systematically in a relatively limited number of studies, and methodological problems limited the understanding of the contribution of disease and treatments (Correa et al., 2007).

#### RT AND CHEMOTHERAPY REGIMENS

Studies involving patients treated with whole-brain RT and HD-MTX, or with whole-brain RT and chemotherapy with BBB disruption reported significant cognitive impairment. The pattern of cognitive deficits was diffuse and the domains disrupted included attention and executive functions, psychomotor speed, and learning and retrieval of new information. Harder et al. (2004) studied cognitive functions in 19 PCNSL patients at a mean of 23 months after treatment with HD-MTX followed by whole-brain RT. In comparison to a non-CNS-cancer control group, PCNSL patients had lower scores on verbal and nonverbal memory, attention, executive function, and motor speed. Correa et al. (2012) studied 50 PCNSL treated with whole-brain RT and HD-MTX ( $n = 24$ ), or HD-MTX alone ( $n = 26$ ) between three and 54 months posttreatment. Patients treated with whole-brain RT and HD-MTX had impairments in selective attention and executive functions, verbal memory, and psychomotor speed across most cognitive domains; these were of sufficient severity to interfere with QoL as more than 50% were not working due to their illness. Patients treated with HD-MTX alone had significantly higher scores on tests of selective attention and memory than patients treated with the combined modality regimen. Patients with more extensive white matter disease on MRIs had lower scores on tests of set-shifting and memory. Thirty-three patients completed an additional follow-up cognitive evaluation at a mean of 14–16 months after the initial visit. The results suggested no significant changes on any of the cognitive tests among patients treated with whole-brain RT and HD-MTX, but patients who received HD-MTX alone obtained a significantly higher score on auditory attention. Doolittle, Korfel, et al. (2013) studied neuropsychological functions and neuroimaging outcomes in 80 patients with PCNSL evaluated at a median of 5.5 years (range: 2 to 26 years) after diagnosis. Treatment modalities included: HD-MTX ( $n = 32$ ), HD-MTX (intra-arterial) in conjunction with BBB disruption ( $n = 25$ ), HD-MTX followed by high-dose chemotherapy and

autologous stem cell transplant (ASCT) ( $n = 8$ ), and HD-MTX followed by whole-brain RT ( $n = 15$ ); five of these patients also received high-dose chemotherapy and ASCT prior to whole-brain RT. Patients treated with HD-MTX and whole-brain RT had significantly lower mean scores in attention, executive function, and motor speed than patients treated with HD-MTX in conjunction with BBB disruption, and all patients treated without WBRT combined. Among patients treated with BBB disruption chemotherapy, there was a significant improvement in executive functions and no evidence of decline in other domains (Doolittle, Dosa, et al., 2013). White matter abnormalities were more extensive in the patients treated with RT. The findings were consistent with other studies, suggesting increased risk for delayed neurotoxicity following combined modality regimens. However, the retrospective nature of these studies limited the ability to examine the specific contributions of the tumor and the delayed effects of treatment.

In a recent prospective study (Correa et al., 2009; Morris et al., 2013), PCNSL patients treated with induction rituximab, methotrexate, procarbazine, and vincristine (R-MPV) followed by consolidation reduced-dose whole-brain RT (23.4 Gy) and cytarabine underwent cognitive evaluations prior to treatment and up to four years after treatment completion. At baseline, impairments in selective attention, memory, and motor speed were evident. After induction chemotherapy, there was a significant improvement in executive function and memory. There was no evidence of significant cognitive decline during the follow-up period, except for motor speed. The preliminary findings were interpreted as evidence that cognitive dysfunction was primarily related to the disease, and that the new treatment approach with low-dose RT may not be associated with progressive cognitive decline.

#### CHEMOTHERAPY REGIMENS

The studies that reported cognitive outcome in PCNSL patients treated with HD-MTX alone or with BBB disruption chemotherapy without RT were mostly prospective (Correa et al., 2007). Several studies documented cognitive impairment prior to therapy in attention, executive functions, memory, graphomotor speed, and language. Posttreatment follow-up intervals were variable across studies, but several reported either stable or improved cognitive performance. Methodological problems in several of these studies, however, limited the ability to discern the specific contributions of the disease and chemotherapy alone regimens to cognitive dysfunction.

Pels et al. (2003) performed cognitive evaluations in 22 patients between four and 82 months after completion of treatment with HD-MTX. There was no evidence of decline in attention, verbal memory, visual memory, word fluency, or visual-construction abilities in patients who had either a partial or a complete response to treatment. Fliessbach et al. (2005) assessed cognitive functions in 23 patients prior

to and up to a median of 44 months after treatment with HD-MTX (all patients were in disease remission). At the pretreatment baseline, impairments were evident in attention and executive functions, verbal and nonverbal memory, and word fluency; these were classified as mild ( $z \leq -1.5$ ) in three patients, moderate ( $z \leq -2$  and  $> -3$ ) in ten, and severe ( $z \leq -3$ ) in six patients. At the last follow-up, impairment (in at least one domain) was mild in five patients, moderate in five, and severe in one; 12 patients had no deficits. Twenty-one patients improved, but scores remained in the low average range on tests of attention, non-verbal memory, and word fluency. The authors concluded that the cognitive deficits were associated primarily with tumor and there was no treatment-related cognitive decline. The most sensitive domains were attention, executive functions, and memory.

McAllister et al. (2000) studied a cohort of 23 prior to and post BBB disruption chemotherapy (mean = 16.5 months, SD = 10.9). The results showed significantly improved cognitive functioning posttreatment (summary  $z$ -score). When examining individual tests, there was evidence of improvement in intellectual functioning, learning, memory, attention, and visuospatial skills, with a nonsignificant trend demonstrated for executive functioning; seven patients had cognitive decline, mostly in motor speed. Neuwelt et al. (1991) studied 15 patients before and one year after BBB disruption chemotherapy; nine patients were also seen for long-term follow-up (mean of 3.5 years after diagnosis). Focus of data analysis was on the summary  $z$ -score, which ranged at baseline from  $-2.59$  to  $0.46$  with a mean of  $-1.1$  (SD = 1.1). At the end of treatment, the summary score ranged from  $-1.45$  to  $0.26$  with a mean of  $0.35$  (SD = 0.52), suggesting a significant improvement in cognitive functioning from baseline. As reported recently by Doolittle, Dosa, et al. (2013), long-term follow-up of PCNSL patients at a median of 12 years after BBB disruption chemotherapy indicated either stable or improved cognitive functions.

#### Metastatic Brain Tumors

Brain metastases are common and develop most often in patients with lung cancer (50%), followed by breast cancer (15%–20%) and melanoma (10%), and less frequently in other cancers (e.g., colorectal, kidney) (Lassman & DeAngelis, 2003). Patients may present with headaches, focal weakness, altered mental status, and seizures. Standard treatment has involved surgical resection and external beam whole-brain RT; the median survival is four to six months (Lassman & DeAngelis, 2003). Recent randomized trials comparing stereotactic radiosurgery plus whole-brain RT versus whole-brain RT alone reported improvement in survival with the addition of radiosurgery in patients with solitary metastases (Andrews et al., 2004; Ayoma et al., 2006). Temozolomide and radiosensitizers have also been added to the regimen recently (Abrey et al., 2001). Although whole-brain RT has been shown to improve tumor control across

several studies (Brown, Asher, & Farace, 2008) and to reduce the development of subsequent metastases (Kocher et al., 2011), the neurotoxicity of whole-brain RT, including cognitive dysfunction, has been a concern. A recent report by RANO supports the inclusion of standardized assessments of cognitive functions and QoL in clinical trials involving patients with brain metastases (Lin et al., 2013).

Deficits in memory and motor speed have been documented in patients with newly diagnosed or recurrent metastases evaluated either during or after whole-brain RT (Herman et al., 2003; Platta, Khuntia, Mehta, & Suh, 2010). Several studies also documented cognitive dysfunction prior to therapy, and Meyers et al. (2004) reported that baseline cognitive performance predicted survival in patients with brain metastases. A pilot study including 15 patients treated with stereotactic radiosurgery alone (Chang et al., 2007) documented impaired executive function, manual dexterity, and memory at baseline; 13 patients declined on one or more tests at the one-month follow-up, and the five long-term survivors had stable or improved cognitive performance. Welzel et al. (2008) studied memory functions prospectively in 44 patients treated with prophylactic RT for small-cell lung cancer and in patients with brain metastases treated with whole-brain RT. At baseline, lung cancer patients had lower memory scores than patients with brain metastasis. Verbal memory decline was evident during RT in patients with metastases only, but at the eight-week post-RT follow-up both groups had memory impairment.

Meyers et al. (2004) studied cognitive outcome in the context of a Phase II randomized trial involving 400 patients with brain metastases treated with whole-brain RT alone or in combination with motexafin gadolinium. At baseline, 91% of patients had impairment in one or more cognitive domains, and 42% had impairment in four of eight tests. Optimal tumor control following treatment correlated with preservation of cognitive function, and in a small group of long-term survivors there was stable or improved performance. In a Phase III trial involving 554 patients with brain metastasis (Mehta et al., 2009), the interval to neurocognitive decline was prolonged in the group treated with whole-brain RT and motexafin gadolinium. Serial neurocognitive assessments were performed in the context of a randomized trial involving patients with one to three brain metastases treated with radiosurgery ( $n = 30$ ) versus radiosurgery plus whole-brain-RT ( $n = 28$ ) (Chang et al., 2009). Patients treated with radiosurgery plus whole-brain RT were significantly more likely to show a decline in verbal learning at four months posttreatment than patients treated with radiosurgery alone. In a study of 208 brain metastases patients treated with whole-brain RT (30 Gy) (Li, Bentzen, Renschler, & Mehta, 2007), the median time to decline in executive and motor functions was longer in patients with a poor response to treatment (i.e., less tumor shrinkage). In patients surviving more than 15 months, reduced tumor size was correlated with preserved executive and motor functions, but not with memory

performance; a significant decline in memory at four months posttreatment was noted. In addition, the risk of delayed leukoencephalopathy was found to be significantly higher for patients with brain metastases treated with radiosurgery and whole-brain RT relative to patients who had radiosurgery alone (Monaco et al., 2013). A recent review of randomized controlled studies involving patients treated with prophylactic RT, radiosurgery, and radiosurgery and whole-brain RT suggested that whole-brain RT, particularly high-dose regimens (36 vs. 25 Gy), was associated with a deleterious effect in memory, executive functions, and processing speed (McDuff et al., 2013).

#### *Preventive or Treatment Interventions*

There are no established preventive or therapeutic interventions for cancer-treatment-related cognitive dysfunction. Ghia et al. (2007) developed a hippocampal-sparing intensity-modulated approach to whole-brain RT that limits the radiation dose to the hippocampus with the intent of reducing the neurocognitive sequelae of RT. Preliminary results from a clinical trial involving 113 patients with brain metastases (Gondi et al., 2013) showed that sparing the subgranular zone of the hippocampus during whole-brain RT was associated with more preserved memory function at the four- and six-month posttreatment follow-ups, in comparison to historical controls treated with standard whole-brain RT; however, only 28 patients were available for the six-month assessment (Brown et al., 2013). In a randomized study, the potential protective effects of memantine versus placebo on cognitive function were evaluated in 508 patients with brain metastases receiving whole-brain RT (Brown et al., 2013). The results showed that patients treated with memantine had significantly longer time to cognitive decline, and a reduced rate of decline in memory, executive function, and processing speed compared to placebo; however, attrition may have limited statistical power as only 29% of patients completed the 24-week assessment.

Treatments that target the vascular mechanism of RT damage including hyperbaric oxygenation, anticoagulation, and aspirin have been attempted, but without clear benefits (DeAngelis & Posner, 2009). There is preliminary evidence suggesting that bevacizumab may reduce abnormal enhancement associated with necrosis, possibly through the removal of VEGF-induced reactive vascularization (Torcuator et al., 2009). In a placebo-controlled, randomized study of bevacizumab for the treatment of RT necrosis in 14 brain tumor patients (Levin et al., 2011), there was a decrease in MRI enhancement and improvement in neurological symptoms in all patients treated with bevacizumab. A decrease in radiation necrosis on MRI following bevacizumab was also reported in 11 patients with brain metastases treated with stereotactic radiosurgery (Boothe et al., 2013). However, a recent review of the use of bevacizumab for the treatment of RT necrosis suggested that although most studies reported

a reduction in radiographic volume of necrosis-associated edema, a high rate of serious complications raised concerns about this treatment approach (Lubelski, Abdullah, Weil, & Marko, 2013).

Pharmacological treatments for RT-induced cognitive dysfunction have been based primarily on therapies used for other neurological disorders that cause similar symptoms (Kim et al., 2008). Agents such as psychostimulants and acetylcholinesterase inhibitors have been used to treat cognitive dysfunction in patients with brain tumors. Comprehensive reviews of studies on interventions for this clinical population indicated that there are several completed and ongoing trials using these and other medications, as well as cognitive rehabilitation and behavioral interventions (Gehring, Aaronson, Taphoorn, & Sitskoorn, 2010; Wefel, Kayl, et al., 2004). A prospective open-label Phase II study was conducted to assess the efficacy of donepezil in the treatment of cognitive dysfunction in 24 patients with primary brain tumors (Shaw et al., 2006). After 24 weeks of treatment there was evidence of improvement in attention, verbal and visual memory, in mood, and QoL. A recent open-label randomized pilot study examined the efficacy of four weeks of methylphenidate and modafinil in 24 brain tumor patients either during or following treatment with RT or chemotherapy (Gehring et al., 2012). The results showed a beneficial effect of stimulant treatment in speed of processing and executive functions requiring divided attention, and on patient-reported fatigue and QoL, regardless of the medication used. However, the results were interpreted with caution give the small sample size and large proportion of dropouts. A recent multicenter double-blind placebo-controlled study including 37 patients with primary brain tumors treated with modafinil for six weeks showed no beneficial effects on cognitive function, fatigue, or mood in comparison to placebo (Boele et al., 2013).

The small number of studies using cognitive rehabilitation in brain tumor patients suggests some beneficial effects, but problems with accrual and attrition and methodological problems limit the evaluation of its efficacy (Gehring et al., 2010). In a study involving 13 brain tumor patients (Sherer, Meyers, & Bergloff, 1997), there was a significant increase in functional independence in approximately half of the patients following three to 12 weeks of training in the use of compensatory strategies. Locke et al. (2008) compared the feasibility of memory and problem solving training in dyads of primary brain tumor patients and caregivers versus a no-intervention control group. At the three-month follow-up 50% of patients reported using the strategies, but there was no significant intervention effect on QoL and functional capacity and not enough patients completed the neuropsychological assessment. Gehring et al. (2008) conducted a randomized controlled trial to assess the efficacy of computer-based attention training and compensatory skills training in 140 patients with gliomas; patients were randomly assigned to the intervention group or to a wait list control

group. There was a significant improvement in self-reported cognitive function but not on neuropsychological test performance immediately after completion of the seven-week program. Conversely, at the six-month follow-up patients showed an improvement in attention and verbal memory, but not on self-reported cognitive function. The prevention of cognitive deficits with agents that may protect neurons from treatment-induced damage is an area of growing interest (Kim et al., 2008), and the potential neuroprotective effects of lithium and other agents are under investigation (Gehring et al., 2010; Khasraw, Ashley, Wheeler, & Berk, 2012; Wefel, Kayl, et al., 2004).

### Non-CNS Cancers

Beyond the effects of primary CNS cancers on cognition, non-CNS cancer diagnosis and treatment has also been found to be associated with cognitive dysfunction. Among primary cancers, breast cancer is relatively common, with approximately 124 per 100,000 new cases diagnosed each year, and a prevalence of approximately 2.8 million women currently diagnosed in the United States alone (<http://seer.cancer.gov/statfacts/html/breast.html>), with 89% survival rates of five years or more. Given its prevalence and survival rates, cognitive changes associated with breast cancer diagnosis and treatment have been most widely studied. In this section we review cross-sectional and longitudinal studies assessing neuropsychological outcome and self-reported cognitive dysfunction in individuals diagnosed with breast cancer. Contributions of structural and functional imaging that may help to clarify the underlying changes in brain structure and function following treatment are then discussed, followed by potential mechanisms by which treatments may exert an effect on the brain and cognition.

While terms such as *chemo-brain* and *chemo-fog* would indicate a primary role for chemotherapy, recent research has questioned whether chemotherapy exposure alone is either necessary or sufficient for cognitive decline following treatment (Hurria, Somlo, & Ahles, 2007). Treatment varies with stage of disease but includes surgical resection potentially in combination with radiation treatment to the breast, adjuvant chemotherapy in later stages, and endocrine therapies depending on receptor characteristics of tumor cells. Surgical resection alone (lumpectomy or mastectomy) may be performed in early stage disease in cases in which the tumor is relatively small and there is no evidence of extended disease either to the lymph nodes or other anatomical sites. Adjuvant chemotherapy treatment, in which chemotherapy drugs are delivered following surgical resection, may be used to prevent recurrence or in cases in which the disease is found to extend, i.e., to have metastasized, beyond the primary site. Radiation may be used to reduce the size of a tumor prior to resection, and to prevent recurrence following resection, as well as in later stages of the disease. Hormonal therapies may be used following primary treatment on an extended basis

in cases in which tumor cells are found to have a high receptor count for either progesterone or estrogen; these therapies work by reducing availability of estrogen and so lower the promotion of tumor cells.

### ***Self-Reported Cognitive Changes Following Treatment***

Changes in cognitive function following treatment, including slowing, inattention, distraction, forgetfulness, difficulties in multitasking, and language function, are commonly reported by cancer survivors. Early research found that approximately half of cancer patients reported some change in cognition at one point in their treatment (Cull, Stewart, & Altman, 1995). Six or more months following treatment, 30% of lymphoma patients reported concentration difficulties and 52% reported forgetfulness (Cull et al., 1996). Schagen et al. (1999) described persistent self-reported difficulties in concentration (31%) and memory (21%) in breast cancer survivors at longer intervals. Ahles et al. (2002) described self-reported difficulties in concentration and complex attention in survivors of breast cancer and lymphoma up to ten years after chemotherapy. Incidence of self-reported cognitive dysfunction at similar intervals was found in other studies surveying the effects of treatment of diverse cancers on cognition (Castellon et al., 2004; Downie, Mar Fan, Houede-Tchen, Yi, & Tannock, 2006; Hermelink et al., 2007; Jansen, Dodd, Miaskowski, Dowling, & Kramer, 2008; Mehnert et al., 2007; Poppelreuter et al., 2004; Schagen et al., 2008; Shilling & Jenkins, 2007; van Dam et al., 1998).

### ***Cross-Sectional Neuropsychological Studies—Posttreatment***

The first studies to examine cognitive effects of treatment were generally cross-sectional, comparing cancer patients and healthy control groups, or comparing cancer patients stratified by treatment regimen. In an early study comparing high-dose chemotherapy, low-dose chemotherapy, and healthy control groups two years after completion of treatment, individuals treated with high-dose chemotherapy performed significantly worse in measures of attention, psychomotor speed, visual memory, and motor function than healthy controls, while the high-dose group performed significantly worse than the low-dose group only on a measure of reaction time (van Dam et al., 1998). In a study examining breast cancer survivors approximately two years following completion of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) chemotherapy treatment compared with survivors treated with surgery and radiation only, significantly greater impairment was found in the chemotherapy group in domains of psychomotor speed, motor function, attention, mental flexibility, and visual memory (Schagen et al., 1999). Evidence for cognitive

effects at longer intervals was found by Ahles et al. (2002) at approximately five years postdiagnosis, between chemotherapy and no-chemotherapy groups in the domains of verbal memory and psychomotor speed. While other studies found similar differences between treatment groups and healthy controls (Yamada, Denburg, Beglinger, & Schultz, 2010), a subset found significant differences only between cancer-diagnosed (regardless of treatment) and healthy control groups or normative data (Jim et al., 2009; Scherwath et al., 2006), while a minority failed to find any difference between treatments or health status (Donovan et al., 2005; Inagaki et al., 2007; Yoshikawa et al., 2005). The most recent and largest study ( $N = 196$ ) of long-term effects of chemotherapy exposure (mean = 20 years) found significantly lower performance on measures of immediate and delayed verbal memory, psychomotor speed, and executive functioning in chemotherapy-treated subjects compared to healthy controls (Koppelmans et al., 2012).

The interpretation of these cross-sectional studies and later ones is limited due to the absence of a pretreatment, baseline time point. This is a significant limitation since work following initial cross-sectional studies suggests that significant cognitive differences exist prior to treatment. Wefel et al. (2004) found that 35% of women exhibited cognitive impairment prior to cancer treatment, specifically in verbal learning (18%) and memory function (25%). Ahles et al. (2008) investigated pretreatment cognitive ability in healthy controls, and patients diagnosed with invasive (Stages 1–3) and noninvasive (Stage 0) breast cancer, and found significantly slowed reaction time in the invasive group compared to healthy controls, and lower overall performance in the invasive group compared to the healthy and noninvasive patient groups. While pretreatment, baseline differences remain poorly understood in regard to mechanism or etiology, that differences are present prior to treatment between groups requires that longitudinal assessments be conducted to delineate specific treatment-related contributions to cognitive dysfunction.

### ***Longitudinal Neuropsychological Studies: Pre- and Posttreatment***

Given the potential for pretreatment cognitive dysfunction, longitudinal studies generally find more modest declines in cognitive dysfunction than cross-sectional, posttreatment studies have reported. These studies have generally found that a subset of patients are affected following treatment within a larger cohort of unaffected individuals; as a result, rates of impairment or decline are more useful in assessing putative effects of treatment than reliance on group mean differences, since group means will tend to obscure subgroup differences. Also problematic are widely varying assessment batteries and screening instruments, making aggregation of numerous studies in systematic reviews or meta-analyses difficult. Despite these issues, available data do suggest

significant treatment related effects found in longitudinal studies, although a subset of studies have reported null results.

In an early longitudinal study using published normative data for comparison, Wefel et al. (2004) found that 61% of chemotherapy treated patients exhibited a decline in one or more cognitive domains, mainly consisting of psychomotor speed, attention, and learning three weeks following completion of treatment. Shilling, Jenkins, Morris, Deutsch, and Bloomfield (2005) found significant reliable change (declines on at least two or more measures) from pretreatment baseline to six months posttreatment compared to healthy controls in 34% of patients (18.6% in healthy controls); they also found significant declines (time X group interactions) in the patient group as compared to controls were found in selective attention, working memory, and delayed verbal memory measures. Schagen et al. (2006) found a greater proportion of high-dose chemotherapy patients declined from baseline to six-months posttreatment time points (25%) compared with healthy control subjects (6.7%), while standard-dose and cancer-diagnosed subjects not treated with chemotherapy did not exhibit any significant difference. Stewart et al. (2008) found a greater proportion of chemotherapy-treated patients exhibited a reliable decline (31%) than patients not treated with chemotherapy (12%) with working memory the most affected. Collins et al. (2009) found significant declines in working memory and visual memory for chemotherapy treated patients from baseline to six months posttreatment compared to patients treated with hormonal therapies. Quesnel, Savard, and Ivers (2009) compared groups treated with combination chemotherapy/RT to RT alone and to healthy controls before and after treatment, and three months posttreatment; significant pretreatment attentional differences were noted in the patient group compared to healthy controls, with significant posttreatment verbal memory declines in both patient groups and significantly greater verbal fluency decline in the chemotherapy treated group. Vearncombe et al. (2009) compared groups treated with chemotherapy with or without hormonal and RT to a group not treated with adjuvant therapies at baseline and four weeks following completion of treatment: 16.9% of the chemotherapy group exhibited decline in verbal learning and memory, abstract reasoning, and motor function following treatment, with an association of decreased hemoglobin and increased anxiety to impairment.

Ahles et al. (2010) compared performance of patients treated with chemotherapy, patients not treated with chemotherapy, and healthy controls at baseline, one month, and six months following treatment. The chemotherapy group failed to improve in verbal ability at the one-month time point compared to the other groups, and a significant contribution of age and baseline cognitive reserve to chemotherapy-related cognitive decline in processing speed was found; performance in the chemotherapy group was

similar to no-chemotherapy and healthy controls at the six-month time point. Wefel et al. (2010) examined performance in a single group of chemotherapy-treated patients at pretreatment, during treatment, and approximately one month following completion of treatment: 21% exhibited dysfunction predominantly in learning and memory, executive function, and psychomotor speed at the pretreatment time point; 65% of patients exhibited significant decline in the same domains during or shortly after treatment compared to baseline. Hedayati, Alinaghizadeh, Schedin, Nyman, and Albertsson (2012) compared chemotherapy, hormone therapy, no therapy, and healthy controls prior to surgery, prior to adjuvant treatment, six months after start of adjuvant treatment, and three months after completion of treatment; results indicated significantly worse memory performance for breast cancer diagnosed subjects regardless of treatment, and lower memory and processing speed performance following chemotherapy treatment compared with the pretreatment time point. Jansen, Cooper, Dodd, and Miaskowski (2011) examined cognitive changes in patients treated with doxorubicin and cyclophosphamide combination (referred to as AC) therapy alone and AC therapy followed by taxane before treatment, one week and six months following completion of treatment. Prior to therapy, 23% of patients exhibited cognitive impairment with significant declines in visuospatial ability, attention, and delayed memory immediately following treatment, and general improvement after six months. Biglia et al. (2012) examined cognitive functioning in a single group of women diagnosed with breast cancer before and immediately after completion of chemotherapy treatment, and reported a significant decline in attention. Collins, Mackenzie, Tasca, Scherling, and Smith (2013b) compared chemotherapy and healthy control groups shortly after completion of treatment and one year following completion of treatment: Results suggested significantly improved global cognition performance at one year with a specific improvement in working memory; however, approximately one-third of patients exhibited persistent cognitive dysfunction at the one-year time point. In a novel study examining dose-response in chemotherapy treatment, Collins, MacKenzie, Tasca, Scherling, and Smith (2013a) conducted serial assessments in women undergoing active treatment with chemotherapy and compared these to seven yoked time points in a healthy control group; declines in global cognitive performance as well as specific declines in working memory, psychomotor speed, verbal and visual memory performance were exhibited with increasing frequency over the seven assessment points (chemotherapy group impairment time 1 = 11.7% and at time 7 = 37%; control group impairment time 1 = 10% and at time 7 = 15.2%).

Other studies examining cognitive abilities at short intervals following treatment have failed to find significant effects. Jenkins et al. (2006) found no significant differences between groups treated with chemotherapy, endocrine/RT, and

healthy controls from pretreatment baseline to six months posttreatment, but did find a potential effect of treatment-related menopause initiation on attention and memory measures. Hermelink et al. (2007) assessed a single group of patients before and toward the end of active treatment and found mean performance before treatment to be significantly below normative values in five out of 12 neuropsychological measures. At the second time point, approximately equal proportions of patients exhibited reliable improvement (28%) or decline (27%) from pretreatment performance, although interpretation is limited given that no control group was available for comparison. Mehlsen, Pedersen, Jensen, and Zachariae (2009) compared patients treated with chemotherapy, cardiac patients, and healthy controls, but failed to find any increased rate of impairment or decline in the chemotherapy group. Debess, Riis, Pedersen, and Ewertz (2009) compared chemotherapy, chemotherapy and hormonal therapy, no-chemotherapy, and healthy control groups and found no significant differences six months following completion of treatment in any cognitive domain. Tager et al. (2010) compared chemotherapy and no-chemotherapy groups at baseline and at six months and one year following treatment; while no significant cognitive effect was exhibited, women not treated with chemotherapy improved in motor functioning compared to those treated with chemotherapy, which was interpreted as being potentially related to improvement in treatment-related peripheral neuropathy.

Several studies have examined longer-term cognitive effects of treatment at one-year time points and beyond. At one year posttreatment, Wefel et al. (2004) found improvement in approximately 50% of affected patients, and persistent dysfunction was evident in the remaining half of the sample. In a study with baseline assessment during active treatment, one-year, and two-year time points, Mar Fan et al. (2008) found 16% of patients on active treatment exhibited moderate to severe impairment on the High Sensitivity Cognitive Screen (compared with 5% in the healthy control group). These effects appeared to decline in severity at one- and two-year time points, with 4.4% exhibiting moderate to severe dysfunction in the chemotherapy group at one year (3.6% in healthy controls), and 3.8% at two years (0% in healthy controls), although significant practice effects for this screening measure are implicated. In a single group of chemotherapy-treated patients using normative data as comparison, Wefel et al. (2010) found that 61% of patients exhibited either new or persistent decline at one year posttreatment with most frequent decline in learning and memory. In contrast, in a study with pretreatment, six-month, and one-year time points, Collins et al. (2009) found no difference in impairment in chemotherapy-treated and hormone-treated patients (11% and 10% respectively) at one year, although, significantly, those patients treated with chemotherapy and on active hormonal treatments at one year exhibited decreased psychomotor speed and verbal memory. Similarly, Ahles et al. (2010) found no significant difference in performance for chemotherapy,

no-chemotherapy, and healthy control groups at one year following treatment.

### *Summary of Neuropsychological Findings*

Based on the literature reviewed, cognitive dysfunction following diagnosis and treatment of breast cancer is a significant concern in the immediate to intermediate periods following active treatment, with a subset of studies finding persistent cognitive dysfunction at one year and greater time points, and even at 20 years posttreatment. Contextualization of these findings is important as several factors influence interpretation of these results. First, estimates of self-reported dysfunction would suggest much higher rates of cognitive difficulties (up to 50%) than are found in either cross-sectional or longitudinal studies employing objective measures. Disagreement between self-report and objective assessment is a well-known and typical finding in several other neurocognitive syndromes (Reid & MacLulich, 2006). Sources of disagreement that lead to overestimates of cognitive dysfunction include emotional factors that lead to negative perceptions of functioning, and priming as a result of knowledge of potential effects of treatment (Schagen, Das, & van Dam, 2009). Factors that potentially lead to underestimates of cognitive dysfunction following treatment include insensitivity of objective measures to subtle cognitive dysfunction, assessment of performance in the rarefied environment of the consulting office that limits distraction and competing demands, and potentially poor ecological validity of objective measures resulting in poor approximation of real-world cognitive demands.

Second, cross-sectional objective studies would also suggest higher rates of cognitive dysfunction than similar longitudinal studies. As discussed in the previous section, this may be due to preexisting cognitive dysfunction in patients prior to treatment as has been found in a subset of studies. It is important to note that "pretreatment" in this case is before adjuvant chemotherapy treatment but not necessarily before surgical resection. In the study by Ahles et al. (2008), all patients were postsurgery at baseline, and in Wefel et al. (2004) 50% of patients had already undergone either lumpectomy or mastectomy at baseline. Underscoring the importance of this observation, Wefel et al. reported that patients who underwent surgical resection were approximately twice as likely to have cognitive impairment compared to biopsy alone ( $p = 0.03$ ), although this did not meet the a priori significance level specified by the authors ( $p = 0.01$ ). Another potential influence on cognitive function prior to chemotherapy treatment is the stress related to cancer diagnosis and treatment. In general, in those studies that formally assessed mood symptoms, cognitive performance was not associated with self-reported anxiety, although direct effects of chronic stress and hypothalamic-pituitary-adrenal axis (HPA) dysregulation may be one promising future research direction that so far had been only minimally studied. Regardless of

etiology, effects of other variables—e.g., stress of diagnosis and treatment, surgical stress and potential inflammatory dysregulation, and anesthetic exposure, all of which precede chemotherapy treatment—may play a role in addition to specific effects of adjuvant therapies that follow.

Finally, longitudinal studies suggest that cognitive dysfunction following treatment may be subtle and exhibited in only a subset of patients. Several potential mechanisms and risk factors for posttreatment cognitive dysfunction have been proposed (Ahles, Root, & Ryan, 2012; Ahles & Saykin, 2007) that may predispose individuals to decline. Age and cognitive reserve have been found to be associated with significantly greater declines in processing speed from pre- to posttreatment in older individuals with lower cognitive reserve (Ahles et al., 2010). Genetic contributions have also been identified, including interaction of the COMT-Val (Val+; Val/Val; Val/Met) genotype with treatment regimen on cognition (Small et al., 2011), as well as the APOE-e4 genotype (Ahles et al., 2003). To the extent that diagnosis and treatment may interact with specific risk factors prior to treatment, averaging cognitive test performance within a given treatment group may obscure significant patient subgroups in whom risk for cognitive dysfunction may be heightened. In addition to clarifying the longitudinal course of cognitive dysfunction in survivors following treatment, potential mechanisms of cognitive dysfunction have received increasing attention. Principal among these has been research investigating underlying brain structure and function and potential changes due to cancer diagnosis and treatment.

### ***Structural and Functional Imaging Studies***

Imaging studies investigating potential effects of cancer and treatment on brain structure and function have accumulated in recent years, and multiple reviews are available summarizing these findings (Ahles et al., 2012; de Ruiter & Schagen, 2013; Deprez, Billiet, Sunaert, & Leemans, 2013; McDonald & Saykin, 2013; Reuter-Lorenz & Cimprich, 2013; see also Tables 23.1 and 23.2). Following a similar trajectory as in neuropsychological studies, early structural and functional research focused on cross-sectional designs posttreatment, limiting the interpretability of results given no pretreatment baseline comparisons. Cross-sectional, posttreatment studies using MRI (Abraham et al., 2008; Dale, Fischl, & Sereno, 1999; de Ruiter, Reneman, Boogerd, Veltman, Caan, et al., 2011; Deprez et al., 2011; Inagaki et al., 2007) have documented reductions in gray matter, primarily in frontal cortex and the hippocampus, and white matter integrity in cancer survivors treated with chemotherapy, although negative results have also been reported. In the most recent study utilizing DTI methods, while no group difference was reported, significant associations of white matter integrity with time since treatment were found within a breast cancer cohort at mean interval of 20 years since treatment (Koppelmans et al., 2014).

Longitudinal studies have reported similar results: First, decreased gray matter density in bilateral frontal, temporal (including hippocampus), and cerebellar regions and right thalamus at one month postchemotherapy, with only partial recovery at one year postchemotherapy in several structures, compared with no significant changes in gray matter over time in the no-chemotherapy cancer group or the healthy controls (McDonald et al., 2010); and second, decreased frontal, parietal, and occipital white matter integrity in chemotherapy-exposed patients, with no changes in the no-chemotherapy group or healthy controls posttreatment (Deprez et al., 2012). Gray matter density alterations were replicated by McDonald, Conroy, Smith, West, and Saykin (2013), who found reduced gray matter density one month after completion of treatment, which was associated with greater self-reported executive dysfunction.

Cross-sectional studies of cancer survivors using functional imaging techniques, including functional MRI (fMRI) (de Ruiter, Reneman, Boogerd, Veltman, van Dam, et al., 2011; Ferguson, McDonald, Saykin, & Ahles, 2007; Kesler et al., 2009; Kesler et al., 2011) and functional positron emission tomography (fPET) (Silverman et al., 2007), have demonstrated areas of increased and decreased activation during performance, primarily in working memory and executive functioning tasks, in survivors exposed to chemotherapy, as compared with controls, in areas similar to the structural differences described. McDonald et al. (2012) conducted a longitudinal study using fMRI and found frontal lobe hyperactivation to support a working memory task before treatment, decreased activation one month postchemotherapy, and a return to pretreatment hyperactivation at one year posttreatment. Interestingly, two other studies reported hyperactivation during a memory task before treatment in patients with cancer compared with healthy controls, consistent with the reports of neuropsychological deficits at pretreatment (Cimprich et al., 2010; Scherling et al., 2011). One interpretation is that pretreatment hyperactivation represents an attempt to compensate for preexisting deficits; however, over years, patients lose the ability for compensatory activation as a result of exposure to cancer treatments and/or age-associated changes in the brain. More recent work has found associations of functional recruitment with verbal working memory (Lopez Zunini et al., 2013). In a novel pilot-study, reductions in functional connectivity shortly after treatment were found in the dorsal attention network and default mode network, with partial resolution in the dorsal attention network at one year but persistent reduced connectivity in the default mode network (Dumas et al., 2013).

The most recent imaging work has investigated putative mechanisms of structural and functional alterations following treatment. A potential role of proinflammatory cytokines is suggested by recent work finding an association of inflammatory biomarkers (IL-1ra; sTNF-RI) with regional brain metabolism (Pomykala et al., 2013) utilizing fPET. Similarly, hippocampal volumes and verbal memory performance have

Table 23.1 Structural imaging studies

<i>Authors</i>	<i>Design/ Modality</i>	<i>Assessment schedule</i>	<i>Participants</i>	<i>Outcomes</i>
Yoshikawa et al. (2005)	Cross-sectional MRI	t1: 12 months post-tx	CTX+: <i>n</i> = 44 CTX-: <i>n</i> = 31	No difference in hippocampal volume or memory performance between CTX+ and CTX- at 12 months posttreatment.
Inagaki et al. (2007)	Cross-sectional MRI	t1: > 12 months post-tx	CTX+: <i>n</i> = 51 CTX-: <i>n</i> = 54 HC: <i>n</i> = 55	Smaller gray and white matter in prefrontal, parahippocampal, cingulate, and precuneus in CTX+ compared to CTX- at 12 months posttreatment.
Inagaki et al. (2007)	Cross-sectional MRI	t1: > 36 months post-tx	CTX+: <i>n</i> = 73 CTX-: <i>n</i> = 59 HC: <i>n</i> = 37	No difference between CTX+ and CTX- at 36 months posttreatment.
Abraham et al. (2008)	Cross-sectional DTI	t1: 22 months post-tx	CTX+: <i>n</i> = 10 HC: <i>n</i> = 9	Lower FA in genu and slower processing speed in CTX+ compared with healthy controls at 22 months posttreatment.
McDonald, Conroy, Ahles, West, and Saykin (2010)	Longitudinal MRI	t1: pre-tx t2: one month post-tx t3: 12 months post-tx	CTX+: <i>n</i> = 17 CTX-: <i>n</i> = 12 HC: <i>n</i> = 18	Decreased gray matter density in both CTX+ and CTX- compared with healthy controls at one month posttreatment. Decreased frontal, temporal, thalamic, and cerebellar gray matter density in CTX+ at one month posttreatment compared with pretreatment. Gray matter density recovered in the CTX+ group with areas of reduced density remaining at one year posttreatment.
Koppelmans et al. (2011)	Cross-sectional MRI	t1: 21 years post-tx	CTX+: <i>n</i> = 184 HC: <i>n</i> = 368	Smaller total brain volume and gray matter volume in CTX+ compared with health controls at 21 years posttreatment.
Deprez et al. (2011)	Cross-sectional MRI DTI	t1: 80–160 days post-tx	CTX+ <i>n</i> = 18 CTX- <i>n</i> = 10 HC <i>n</i> = 18	Decreased frontal and temporal FA and increased frontal MD in CTX+ compared to CTX- and healthy controls 80–160 days posttreatment.
Deprez et al. (2012)	Longitudinal MRI, DTI	t1: pre-tx t2: 3–4 months post-tx	CTX+ <i>n</i> = 34 CTX- <i>n</i> = 16 HC <i>n</i> = 19	Decreased frontal, parietal, and occipital FA in CTX+ with no changes in either CTX- or healthy controls at three to four months —posttreatment.
de Ruiter and Schagen (2013)	Cross-sectional MRI, DTI, MRS	t1: > 9 years post-tx	CTX+: <i>n</i> = 17 CTX-: <i>n</i> = 15	Reduced white matter integrity in CTX+ compared with CTX- > 9 years —posttreatment. Reduced N-acetylaspartate/creatine in left centrum semiovale in CTX+ compared with CTX- > 9 years —posttreatment. Smaller posterior parietal volume in CTX+ compared with CTX- > 9 years —posttreatment
McDonald et al. (2013)	Longitudinal MRI	t1: pre-tx t2: 1 month post-tx	CTX+ <i>n</i> = 27 CTX- <i>n</i> = 28 HC <i>n</i> = 24	Reduced gray matter density in the chemotherapy treated group at one month post-completion of treatment.
Kesler et al. (2013)	Cross-sectional MRI	t1: average 5 years post-tx	CTX+ <i>n</i> = 42 HC <i>n</i> = 35	Left hippocampal volume reduced in chemotherapy treated group. IL-6 and TNFa increased in chemotherapy group. Hippocampal volume positively correlated with TNFa and negatively correlated with IL-6.
Conroy et al. (2013)	Cross-sectional MRI	t1: average 6 years post-tx	CTX+ <i>n</i> = 24 HC <i>n</i> = 23	CTX+ group exhibited regional reductions in gray matter density compared to HC. Time since treatment was associated with greater gray matter density in CTX+ group. Oxidative DNA damage was negatively correlated with gray matter density.
Koppelmans et al. (2014)	Cross sectional DTI	t1: average 20 years post-tx	CTX+ <i>n</i> = 187 HC <i>n</i> = 374	No significant difference in global or regional white matter integrity. Time since treatment was associated with declining white matter integrity.

*Notes:* CTX+ = chemotherapy; CTX- = no chemotherapy; MRS = magnetic resonance spectroscopy; HC = healthy controls; FA = fractional anisotropy; MD = mean diffusivity

Table 23.2 Functional imaging studies

<i>Authors</i>	<i>Design/Modality</i>	<i>Assessment Schedule</i>	<i>Participants</i>	<i>In-Scanner Task</i>	<i>Outcomes</i>
<i>Pretreatment</i>					
Cimprich et al. (2010)	Cross-sectional fMRI	t1: pre-tx only	BC: <i>n</i> = 10 HC: <i>n</i> = 9	Verbal working memory	Greater bilateral activation during verbal working memory task in breast cancer diagnosed subjects compared to healthy controls pretreatment.
Scherling, Collins, Mackenzie, Bielajew, and Smith (2011)	Cross-sectional fMRI	t1: pre-tx only	BC: <i>n</i> = 23 HC: <i>n</i> = 23	Visual N-back	Greater inferior frontal gyrus, insula, thalamus and midbrain activations during working memory task in breast cancer diagnosed subjects compared with healthy controls pretreatment.
<i>Posttreatment</i>					
Ferguson et al. (2007)	Cross-sectional MRI; fMRI	t1: 22 months post-tx	CTX+: <i>n</i> = 1 HC: <i>n</i> = 1	Auditory N-back	Greater WM hyperintensities and greater spatial extent of frontal activation during working memory in the CTX+ case compared with twin healthy control case.
Silverman et al. (2007)	Cross-sectional PET	t1: 5–10 years post-tx	CTX+: <i>n</i> = 5 CTX+Tam: <i>n</i> = 7 CTX-: <i>n</i> = 5 HC: <i>n</i> = 3	Paired word memory task 10-minute delay, 1-day delay	Lower inferior frontal gyrus metabolism in CTX+ compared to CTX- and healthy controls 5 to 10 years posttreatment. Lower basal ganglia metabolism in CTX+Tam treated subjects compared to CTX+, CTX-, and healthy controls 5 to 10 years posttreatment.
Kesler, Bennett, Mahaffey, and Spiegel (2009)	Cross-sectional fMRI	t1: 3 years post-tx	CTX+: <i>n</i> = 14 HC: <i>n</i> = 14	Verbal declarative encoding Verbal declarative recognition	Lower prefrontal cortex activation during encoding in CTX+ compared to healthy controls 3 years posttreatment. Greater regional activations during recall in CTX+ compared to healthy controls 3 years posttreatment.
Kesler, Kent, and O'Hara (2011)	Cross-sectional fMRI	t1: 5 years post-tx	CTX+: <i>n</i> = 25 CTX-: <i>n</i> = 19	Card sorting task	Lower left middle dorsolateral prefrontal cortex activation and premotor cortex activation in breast cancer diagnosed subjects compared to healthy controls. Lower left caudal lateral prefrontal cortex activation in CTX+ compared with CTX- and healthy controls 5 years posttreatment.
de Ruiter et al. (2011)	Cross-sectional fMRI	t1: 10 years post-tx	CTX+: <i>n</i> = 19 CTX-: <i>n</i> = 15	Tower of London, Paired Associates	Lower dorsolateral prefrontal cortex activity during Tower of London task, lower parahippocampal gyrus activity during paired associates task in CTX+ compared to CTX- 10 years posttreatment.
McDonald et al. (2012)	Longitudinal fMRI	t1: pre-tx t2: 1 month post-tx t3: 1 year post-tx	CTX+: <i>n</i> = 16 CTX-: <i>n</i> = 12 HC: <i>n</i> = 15	N-Back Task	Greater frontal activation and lower parietal activation at baseline in BC diagnosed patients relative to controls. Lower frontal activation in BC-diagnosed patients relative to healthy controls immediately following treatment. Greater frontal activation in BC diagnosed patients relative to healthy controls one year following treatment.
Lopez Zunini et al. (2013)	Longitudinal fMRI	t1: pre-tx t2: 1 month post-tx	CTX+: <i>n</i> = 21 HC: <i>n</i> = 21	Verbal recall task	At pre-tx, CTX+ exhibited reduced recruitment in anterior cingulate compared to controls. At one month post-tx, CTX+ exhibited reduced recruitment in bilateral insula, left inferior orbitofrontal cortex and left middle temporal gyrus compared to controls. Fatigue, depression, and anxiety were associated with a subset of difference in recruitment.
Dumas et al. (2013)	Longitudinal fMRI	T1: pre-tx T2: 1 month post-tx T3: 1 year post-tx	CTX+ <i>n</i> = 9	Resting state functional connectivity	Reductions in functional connectivity shortly after treatment were found in the dorsal attention network and default mode network, with partial resolution in the dorsal attention network at one year but persistent reduced connectivity in the default mode network.
Pomykala et al. (2013)	Longitudinal PET	T1: post-tx T2: 1 year post-tx	CTX+ <i>n</i> = 23 CTX- <i>n</i> = 10	Resting FDG PET	Association of inflammatory biomarkers (IL-1ra; sTNF-RI) with regional brain metabolism utilizing PET.

Key: Ctx+ = chemotherapy; Ctx- = no chemotherapy; fMRI = functional magnetic resonance imaging

been found to be associated with serum inflammatory cytokines (TNF $\alpha$ ; IL6) following treatment (Kesler, Janelsins, et al., 2013). A potential role of DNA damage and its association with cortical gray matter was recently suggested in a study by Conroy et al. (2013) that found higher oxidative DNA damage in a sample of breast cancer survivors than in healthy controls and associations of oxidative DNA damage with gray matter density.

### **Treatment Interventions**

Treatment of cognitive dysfunction in breast cancer patients is a challenging clinical need and newly expanding area of research. One particularly challenging aspect with regard to rehabilitation in this cohort is the often significant but subtle cognitive dysfunction exhibited in these patients. In contrast to rehabilitation programs in traumatic brain injury or primary CNS tumors, the target of cognitive rehabilitation in non-CNS cancers may be difficult to discern, and multiple diffuse processes may be affected. Treatment has generally taken the form of both compensatory and direct (restitutive) rehabilitation, as well as cognitive behavioral therapy, and pharmacologic treatment. Although it is not the focus of this brief review, mindfulness-based programs and exercise regimens have also been considered either as alternatives to cognitive rehabilitation programs or as parts of a multitreatment strategy. Generally, outcomes of treatment are promising but the research on which they are based is still in the early stage of development and no definitive conclusions can be drawn from the handful of studies that have been conducted.

In an early, single-arm study to address treatment strategies for cognitive dysfunction following treatment (Ferguson, Ahles, et al., 2007), a program of Memory and Attention Adaptation Training (MAAT) was tested that included (a) education on memory and attention; (b) self-awareness training; (c) self-regulation via relaxation training; and (d) compensatory strategy training. Improved self-reported and objective cognitive function was found, along with adequate feasibility and patient satisfaction, although no comparison arm is available for assessing placebo and practice effects. In a later, two-arm trial (Ferguson et al., 2012), patients were randomized to receive either MAAT or assigned to a wait-list control group. Patients treated with MAAT exhibited significantly improved verbal memory as compared to the wait list control group, as well as significantly improved self-reported "spiritual well-being," although no significant effect was found for other cognitive domains or for other self-reported cognitive outcomes. Poppelreuter, Weis, and Bartsch (2009) compared the effectiveness of computer-based training, and a rehabilitation program to a control group at baseline, at end of rehabilitation, and at six months, although no specific effect of intervention was found, with all groups improving over time on measures of cognitive function. Von Ah et al. (2012) studied effects of memory or processing speed training versus a wait list control group at baseline, shortly

following training, and two months after completion of the intervention, with significant effects for processing speed at both the immediate and two month follow-up evaluation, and significant memory effects at the two month follow-up evaluation; interpretation of delayed effects are complicated by no significant effect immediately following training. Cherrier et al. (2013) examined the effectiveness of a compensatory and mindfulness rehabilitation program versus control at baseline and following training and found improvement on self-reported cognitive function as well as in objective attention functioning. In a cognitive-training rehabilitation study, Kesler et al. (2013) utilized online training software to examine remediation of executive functioning skills and found significant improvements on the Wisconsin Card Sorting Test, Symbol Search, and letter fluency in the active treatment group versus controls, together with improved self-reported cognitive functioning in the active treatment group.

In addition to direct and compensatory rehabilitation programs, pharmacologic treatments have also been investigated including modafinil and dexamethylphenidate. Results are mixed regarding efficacy of dexamethylphenidate, with a subset of studies finding significant improvement in fatigue and cognition (Lower et al., 2009) while others find no beneficial effect (Mar Fan et al., 2008). Modafinil has received increasing attention for its efficacy in treating cognitive dysfunction following treatment, again specifically with regard to treatment of attentional dysfunction and fatigue, with promising results (Kohli et al., 2009; Lundorff, Jonsson, & Sjogren, 2009).

### **Conclusion**

The recent literature suggests that both brain tumor and the adverse effects of treatment contribute to cognitive dysfunction in a significant number of brain tumor patients. The studies reviewed indicated that whole-brain RT alone or in combination with chemotherapy result in more pronounced cognitive dysfunction than either partial RT or chemotherapy alone. Antiepileptics and corticosteroids, often used in the treatment of these patients, may also further disrupt cognitive functioning. The cognitive domains suggested to be particularly sensitive to treatment-induced cognitive dysfunction include several aspects of attention and executive functions, learning and retrieval of new information, and graphomotor speed.

Advancements in the field include the development of guidelines for the use of standardized neuropsychological tests in the context of clinical trials, and the inclusion of cognitive outcome measures in several recent and ongoing multi-center studies and clinical trials in neuro-oncology. The findings from such studies would improve our understanding of the toxicity of various treatment modalities, and enable both physicians and patients to make decisions regarding treatment based not only on survival rates and time to disease progression, but also on QoL.

In non-CNS cancers, the body of literature on self-reported cognitive dysfunction, cross-sectional and longitudinal objective cognitive assessments before and after treatment, and structural and functional imaging findings strongly support the occurrence of neuropsychological dysfunction associated with diagnosis and treatment for breast cancer. Cognitive changes may appear early in the posttreatment course but may become more apparent after physical/medical factors and concerns have resolved or when patients attempt to return to prediagnosis responsibilities (school, work, household demands). Currently, long-term effects are poorly understood, with the majority of studies suggesting persistent cognitive problems and another subset suggesting relative resolution of difficulties over time.

Recent studies have begun to describe the pathophysiological mechanisms that may underline the adverse effects of RT and chemotherapy, and additional research is necessary to identify contributing factors for the development of treatment-related cognitive dysfunction (e.g., genetic susceptibility). The efficacy of pharmacological and behavioral interventions to improve cognitive function is increasingly being investigated in studies involving patients with brain tumors and non-CNS cancers.

## 24 Toxins in the Central Nervous System

*Marc W. Haut, Jennifer Wiener Hartzell, and Maria T. Moran*

### Introduction

In this chapter, we review a variety of substances that are toxic to the brain. It is beyond the scope of this chapter to cover all toxins; thus, we focus on the most common, most well-studied, and those which we believe are the most interesting. We refer readers to more comprehensive reviews when greater depth is warranted. We begin with toxins occurring most commonly in the workplace, including heavy metals and solvents, and then discuss carbon monoxide poisoning, which may occur at work or at home. We then discuss substances of abuse and complete our review with a description of the neurotoxic effects of chemotherapy for non-central nervous system (CNS) cancers. Although chemotherapy is not typically discussed in chapters related to toxic exposure, it is a toxin to both cancerous and healthy cells, and there is a growing body of literature highlighting the cognitive, neuroanatomical, and functional changes that substantiate the phenomenon of “chemo-brain.” For each toxin, we address common neuropsychological deficits, relevant emotional and behavioral changes, and structural magnetic resonance imaging (MRI) findings. Less frequently, we incorporate functional imaging findings to illustrate particular points related to toxic exposure.

There are a few themes to keep in mind while reading. The vast majority of studies in this area are cross-sectional. When longitudinal data are available, they are generally collected after the onset of abuse or exposure and then during the course of continued abuse, exposure, abstinence, or cessation. Cross-sectional data create quite a “chicken or the egg” problem: Are cognitive and structural brain differences in exposed individuals the direct consequence of abuse or exposure or, instead, do they represent preexisting differences that render individuals vulnerable to the effects of toxic exposure or substance abuse? For example, in one study comparing stimulant-dependent subjects to their stimulant-naïve siblings and normal controls, the sibling pairs demonstrated the same abnormalities in fronto-striatal brain systems relative to controls (Ersche et al., 2012). Of course, cognitive and structural deficits observed with toxic exposure may represent a combination of preexisting and predisposing deficits, as well as the direct consequences of exposure or abuse.

There are some exceptions in studies that are prospective in nature that we will highlight.

There are two other common limitations inherent to the majority of studies on toxic exposure. First, data regarding exposure or abuse are frequently based on self-report. Thus, there are limitations in establishing a dose-response effect. Second, many individuals are poly-substance abusers or exposed to multiple toxins, which makes it challenging to obtain a clean or homogenous sample to investigate the specific effects of neurotoxins. These issues impact the *quality* of the data at hand.

With specific regard to substance abuse, there are occasions when the available data do not fully support a long-term toxic effect of certain substances; however, we believe it is reasonable to assume that there are consequences of chronic substance abuse on brain structure and function. Substances are abused to begin with because they alter how individuals feel or experience the world, which occurs through neural processes. While it is reasonable to assume that, at a certain level of exposure, toxins will produce permanent changes to the CNS, the science must catch up to prove this assumption true. Regardless of whether the deficits associated with toxic exposure are a cause or effect of the exposure, such deficits impact one’s ability to participate in and benefit from available treatment options. This concept, in particular, is of great importance when considering the societal effects.

### Heavy Metals

The impact of heavy metals on the human brain has been recognized and studied for centuries, dating as far back as the second century B.C. (Needleman, 2004). Loosely, the term *heavy metals* refers to a subset of naturally occurring elements with metallic properties that exert a toxic effect on the environment and living organisms (Duruibe, Ogwuegbu, & Egwurugwu, 2007). Industry and the environment constitute the primary mechanisms of neurotoxic exposure.

### Lead

The neurotoxic effects of lead were recognized as far back as antiquity among metal workers and wine drinkers. Centuries ago, the use of lead in wine making was banned, but

industry remained a viable source of toxicity (Needleman, 2004; Sandstead, 1986). By the early 1900s, leaded paints and gasoline became major sources of environmental pollution. In 1970s, the U.S. government banned residential and public use of lead-based paints and began phasing out leaded gasoline because of scientific studies demonstrating neurotoxic effects on children (Ibrahim, Froberg, Wolf, & Rusyniak, 2006; Needleman, 1975).

Lead permeates the blood-brain barrier and alters neural activity (Khalil et al., 2009). Children are especially susceptible to lead toxicity during fetal and early development as lead is more easily absorbed by the developing CNS. Lead may be transmitted from mother to child through the umbilical cord and breast milk (Needleman, 2004; Sanders, Liu, Buchner, & Tchounwou, 2009). Prenatal lead exposure has been linked with developmental, cognitive, and neurobehavioral effects. Elevated lead levels were found in children with encephalopathy, mental retardation, learning disabilities, and hyperactivity (Moore, Meredith, & Goldberg, 1977; Marlowe et al., 1982; Needleman, 2004). Relative to children with low lead concentrations, children with high levels of lead were found to have lower intelligence (Landrigan et al., 1975; Needleman, Gunnoe, Leviton, & Peresie, 1978; Needleman, Geiger, & Frank, 1985).

There is a clear dose-response effect, but adverse effects are observed in children with low levels of lead exposure (Needleman, 2009; Needleman et al., 1979). Studies conducted by Herbert Needleman in the late 1970s and 1980s demonstrated intellectual and cognitive deficits in children who did not show overt clinical signs of lead intoxication (Ibrahim et al., 2006; Needleman, 2004; Needleman et al., 1978; Needleman et al., 1979). Specific deficits in overall intelligence, verbal abilities, attention, reaction time, and behavior were identified (Needleman et al., 1979). In a follow-up 11 years later, the same cognitive deficits persisted and higher childhood lead levels were associated with worse academic performance and increased absenteeism in high school (Needleman, Schell, Bellinger, Leviton, & Allred, 1990). This significant and persistent inverse relationship between childhood lead exposure and intellectual functioning has been well-replicated (Bellinger, Stiles, & Needleman, 1992; Lanphear et al., 2005; Mazumdar et al., 2011; Needleman et al., 1985; Needleman & Landrigan, 1981; Tong, Baghurst, McMichael, Sawyer, & Mudge, 1996).

Childhood lead exposure has also been linked with significant social and behavioral problems, including aggression, hyperactivity, impulsivity, delinquency, conduct problems, and antisocial behavior (Dietrich, Ris, Succop, Berger, & Bornsheim, 2001; Carpenter, 2001; Marcus, Fulton, & Clarke, 2010; Needleman et al., 1996). A meta-analysis found that lead burden was associated with attention deficit/hyperactivity disorder (ADHD) symptoms; the effect size was similar to the effect sizes between lead and intelligence, as well as lead and conduct problems (Goodlad, Marcus, & Fulton, 2013).

Occupational lead exposure represents the most common route of lead poisoning in adults. There is a high risk

of occupational toxicity among miners, welders, smelters, battery plant workers, painters, and construction workers (Ibrahim et al., 2006). Neurologic symptoms of acute lead toxicity include headache, fatigue, emotional lability, tremor, neuropathy, ataxia, and, rarely, encephalopathy (Ibrahim et al., 2006; Järup, 2003; Kim & Kim, 2012). The bilateral wrist drop is a pathognomonic sign (Ibrahim et al., 2006). Behaviorally, lead-exposed workers display increased rates of depression, anxiety, irritability, anger, and hallucinations (Baker, Feldman, White, & Harley, 1983; Flora, Gupta, & Tiwari, 2012; Jeyaratnam, Boey, Ong, Chia, & Phoon, 1986). Workers exposed to lead demonstrate significant and long-term deficits in general intellect, spatial ability, memory, motor speed, and reaction time relative to controls (Baker et al., 1983; Hogstedt, Hane, Agrell, & Bodin, 1983; Jeyaratnam et al., 1986; Khalil et al., 2009).

There is mounting evidence that cognitive deficits associated with lead toxicity progress over time. In old age, former lead-exposed workers demonstrate poorer performance on measures of visuospatial ability, learning and memory, executive functions, and manual dexterity (Needleman, 2004; Schwartz et al., 2000; Shih et al., 2006). Some researchers assert that lead plays a role in the development of neurodegenerative disorders, such as Alzheimer's disease and amyotrophic lateral sclerosis (ALS), although a direct causal link has not been identified (Johnson & Atchison, 2009; Liu, Hao, Zeng, Dai, & Gu, 2013; Vinceti, Bottecchi, Fan, Finkelshtein, & Mandrioll, 2012; Weiss, 2011).

On structural neuroimaging, adults exposed to lead during childhood or early adulthood demonstrate white matter lesions, total brain atrophy, and region-specific declines in gray matter volume, particularly in the frontal lobes (Brubaker, Dietrich, Lanphear, & Cecil, 2010; Cecil et al., 2008; Schwartz et al., 2010; Stewart et al., 2006). There is evidence of a longitudinal association between cumulative lead dose and cognitive dysfunction, white matter lesions, and brain volume loss (Schwartz et al., 2010). Similarly, diffusion tensor imaging (DTI) studies illustrate that childhood lead exposure alters early brain myelination and produces long-term, persistent deficits in axonal integrity (Brubaker et al., 2009).

Unfortunately, the toxic effects of lead are nearly impossible to treat or reverse. Although chelation therapy successfully lowers blood lead levels through accelerating the excretion of heavy metals, it does not reduce lead-related morbidity and mortality in children or adults (Dietrich et al., 2004; Kosnett, 2010; Rogan et al., 2001). Other than simply terminating the exposure, efforts are geared toward primary prevention (Flora & Pachauri, 2010; Needleman, 2004).

### *Mercury*

Mercury has been used in industry and medicine for centuries. The toxic properties of mercury were initially recognized in the 1800s, during which time hat makers used mercury to

treat animal skins and produce felt for hats. The saying “mad as a hatter” comes from the observed toxic effects among hat makers. The main feature of Mad Hatter’s disease, as the condition was labeled, was *erethism*: a behavioral presentation characterized by shyness, social anxiety, paranoia, irritability, and mood lability. Accompanying fatigue, tremor, ataxia, and cognitive changes were also reported (Haut et al., 1999; O’Carroll, Masterton, Dougall, Ebmeier, & Goodwing, 1995).

In the 1950s, the neurotoxic effects of mercury gained more serious global attention. A Japanese chemical plant discharged methyl mercury and contaminated the water and aquatic life of Minamata Bay. The first outbreak of Minamata disease, as mercury poisoning came to be called, occurred in 1953 and has affected thousands since then, primarily through consumption of contaminated fish (Ekino, Susa, Ninomiya, Imamura, & Kitamura, 2007; O’Carroll et al., 1995).

Accidental and occupational mercury exposure still occurs today by way of inhalation of mercury vapor, oral ingestion of liquid mercury (e.g., quicksilver), or cutaneous exposure (Haut et al., 1999; Ibrahim et al., 2006). The most common routes of modern exposure include fish consumption, dental amalgams, and vaccines (Clarkson, Magos, & Myers, 2003; Risher, Murray, & Prince, 2002). Mercury crosses the blood-brain barrier and concentrates within neurons, thus interfering with normal cell function (Ibrahim et al., 2006). Neuropathological studies indicate that occipital and cerebellar neurons are prime targets of mercury-related degeneration (Clarkson et al., 2003; Davidson, Myers, & Weiss, 2004; Ekino et al., 2007).

Prenatal mercury exposure has been correlated with developmental delays and widespread cognitive deficits (Davidson et al., 2004; Grandjean et al., 1997). Beginning in the 1990s, the U.S. Food and Drug Administration (FDA) began issuing advisories on limiting fish consumption during pregnancy (Counter & Buchanan, 2004). Studies conducted in the Faroe Islands, where whale meat was heavily consumed, found long-term deficits affecting motor functions, attention, visuospatial skills, language, and memory among prenatally exposed children (Counter & Buchanan, 2004; Davidson et al., 2004; Grandjean et al., 1997). The Seychelles Child Development Study investigated the effects of lower levels of prenatal mercury exposure from consuming fish and did not find cognitive deficits (Davidson et al., 2004; Davidson et al., 2010; Davidson, Myers, Weiss, Shamlaye, & Cox, 2006).

Among adults, acute mercury poisoning is associated with an array of clinical symptoms. Cerebellar dysfunction is common with gait ataxia, tremor, dysmetria, dysarthria, or gaze nystagmus. Primary visual disturbance is reflected through constriction of the visual fields. Hearing impairment, olfactory and gustatory disturbances, and somatosensory dysfunction are also observed. Behaviorally, erethism remains characteristic of mercury intoxication. Personality change may manifest as disinhibition, emotional lability, emotional

hypersensitivity, paranoia, or social anxiety (Ekino et al., 2007; Haut et al., 1999; Kim & Kim, 2012). Clinical symptoms of acute toxicity may present within hours of exposure. Although symptoms of chronic, lower-level mercury poisoning develop more gradually, the same domains are affected (Haut et al., 1999; Ibrahim et al., 2006; Järup, 2003; Risher et al., 2002). The timing of onset, rate of progression, and overall severity of symptoms are contingent upon the level of exposure (Ibrahim et al., 2006).

Neuropsychological deficits associated with mercury toxicity are widespread and nonspecific, but executive dysfunction is a strong theme. Cognitive deficits affecting motor functions, attention and concentration, processing speed, verbal memory, cognitive flexibility, and abstraction have been documented in cases of acute and chronic mercury exposure (Haut et al., 1999; Neghab, Norouzi, Choobineh, Kardaniyan, & Zadeh, 2012; O’Carroll et al., 1995). The severity of cognitive deficits, however, is relatively mild. In a meta-analysis examining the effects of occupational mercury exposure on neuropsychological function, a mild effect size was found, there was no dose-response relationship, and cessation of exposure led to cognitive recovery (Rohling & Demakis, 2006).

Mercury intoxication causes changes to the cerebrum and cerebellum. At autopsy, atrophy of the cerebellar vermis and hemispheres, calcarine cortex, precentral gyrus, postcentral gyrus, and transverse temporal gyri are noted (Eto, 1997). These structural findings correlate with the cerebellar, visual, motor, and various sensory changes observed clinically. In patients with known mercury poisoning, atrophy of the calcarine and cerebellar cortices are most striking on computed tomography (CT) and MRI, and decreased cerebellar blood flow has been demonstrated with single photon emission computed tomography (SPECT) (Eto, 1997; Eto, 2000; Eto, Marumoto, & Takeya, 2010; Farina, Avila, da Rocha, & Aschner, 2012; Itoh et al., 2001; Kim & Kim, 2012; Korogi, Takahashi, Okajima & Eto, 1998). Functional imaging studies suggest a dose-response effect. In one study conducted with the prenatally exposed Faroe Islanders, higher mercury exposure correlated with more widespread brain activation on visual and motor tasks (White et al., 2011).

Theories about the pathogenic role of mercury in neurodegenerative diseases, such as Alzheimer’s disease, have also been put forth. Although mercury and other heavy metals may contribute to the onset or progression of neurodegenerative conditions, we emphasize that no causal link has been identified (Carpenter, 2001; Johnson & Atchison, 2009; Mutter, Naumann, Sadaghiani, Schneider, & Walach, 2004; Weiss, 2011).

As with lead toxicity, prevention of mercury intoxication is superior to treatment. Modern preventative efforts include removing amalgam fillings and avoiding high intake of certain fish, such as shark, tuna, and swordfish (Järup, 2003). Antioxidants show promise as potential therapeutic agents, but their efficacy remains unclear. Chelating therapies may

partially remove mercury from the body, but cannot reverse CNS damage (Clarkson et al., 2003; Farina et al., 2012). Ultimately, mercury exerts an enduring toxic effect upon living organisms.

### **Organic Solvents**

Organic solvents are used in a wide range of industries in manufacturing and cleaning processes. Exposure may occur through inhalation, dermal absorption, oral routes, or through a combination of these. Acute effects of solvent exposure are similar to the acute effects of alcohol (which is also a solvent), such as feelings of intoxication, dizziness, discoordination, and headache. There is an ever-growing body of research on the effects of chronic exposure to solvents. The reader is referred to prior reviews for details, but the cognitive deficits typically observed after solvent exposure affect attention, memory, motor skills, and visual perception. Processing speed, working memory, and other executive functions may also be impaired (Baker, 1994; Jin et al., 2004; Morrow, Muldoon, & Sandstrom, 2001; van Valen et al., 2012; White & Proctor, 1993). Some studies do not report cognitive deficits following exposure and there has been speculation that chronic low-level exposure does not result in permanent deficits (Dick et al., 2010); however, several well-controlled studies, including a twin study and prospective studies, have documented deficits (Hanninen, Antti-Poika, Juntunen, Koskenvuo, 1991; Morrow, Steinhauer, Condray, & Hodgson, 1997). A meta-analysis of solvent-exposed individuals compared to nonexposed controls reported significant effect sizes. Measures of attention, processing speed, and response inhibition showed particularly strong effects. It should be noted that the meta-analysis failed to document a dose-response relationship, which the authors attributed to the incomplete descriptions of exposure in the studies examined. Individual studies, however, have reported dose-response relationships, such that a greater severity and longer duration of exposure is associated with a greater degree of cognitive deficit (Morrow et al., 2001; Nilson, Bäckman, Sällsten, Hagberg, Barregård, 2003). Indeed, despite the well-demonstrated cognitive effects of solvent exposure, variability in study methodology and individual exposure factors do exist and result in inconsistent findings. In addition, the precise amount and duration of exposure necessary to produce symptoms has not been determined and there is no specific biologic marker that is critical to document exposure. Individuals are also frequently exposed to more than one substance.

The long-term outcome of cognitive deficits following solvent exposure is also debated. Deficits are reversible in some individuals (Morrow et al., 1997), while other studies suggest that aging may exacerbate cognitive deficits (Nilson et al., 2003). It has been hypothesized that solvent-exposed individuals are at increased risk of dementia, but this is not consistently supported in the literature (Berr et al., 2010;

Dick et al., 2010). Cognitive reserve may also play a role in the expression of cognitive deficits following solvent exposure, as lower educational attainment was associated with greater cognitive dysfunction in solvent-exposed workers (Sabbath et al., 2012).

Emotional changes are also common, with high rates of depression, anxiety, and personality disturbance in those exposed to solvents (Condray, Morrow, Steinhauer, Hodgson, & Kelley, 2000; Morrow et al., 2000; Visser et al., 2011). Up to 71% of a solvent-exposed sample may meet criteria for an active Axis I condition (Morrow et al., 2000). A positive association has been demonstrated between psychiatric symptoms and the severity and duration of exposure (Condray et al., 2000; Morrow et al., 2000); however, emotional symptoms do not fully account for resultant cognitive deficits (Perrson, Osterberg, Karlson, & Orbaek, 2000; Morrow et al., 2001).

Neuroimaging studies have provided some elucidation of the underlying structural effects of solvent-related cognitive deficits but there are few studies, thus limiting conclusions. There is evidence of white matter change based on proton magnetic resonance spectroscopy (MRS), DTI, and volumetric measurement of the corpus callosum, with an association between degree of white matter change and severity of exposure (Alkan et al., 2004; Haut et al., 2006; Visser et al., 2008). The lipophilic properties of organic solvents are thought to account for their affinity for white matter, as myelin has a high fat content. Changes to gray matter may be expected as well, but have been less thoroughly examined. There is evidence of brain atrophy based on readings of individual clinical scans (Keski-Santti, Mantyla, Lamminen, Hyvarinen, & Sainio, 2009). Functional imaging studies using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have documented alterations in frontal lobe activation during working memory tasks (Haut et al., 2000; Tang et al., 2011).

### **Carbon Monoxide**

Carbon monoxide (CO) is a colorless, odorless gas, produced by incomplete combustion of carbons. The affinity of CO for hemoglobin is more than 200 times that of oxygen, displacing oxygen from hemoglobin. Carboxyhemoglobin is formed and interferes with the transport of oxygen to tissue, leading to hypoxia. Common mechanisms of exposure include motor vehicle exhaust, heating units, and generators. Poisoning may be intentional (suicide attempt) or unintentional (fire or faulty heating). There are increases in unintentional exposures with cold temperatures in the winter months and with incorrect use of generators during power outages from natural disasters (CDC, 2009; Iqbal et al., 2012). CO is the most common cause of death by poisoning in the United States (Prockop & Chichkova, 2007). In 2007 alone, there were more than 21,000 visits to emergency departments and 2,300 hospitalizations from confirmed cases of CO

poisoning (Iqbal et al., 2012). Because of the nonspecific nature of symptoms, exposures may go unnoticed and, therefore, rates may be underestimated. The literature regarding CO exposure focuses primarily on acute CO poisoning, as it is more readily identified and more frequently comes to clinical attention. The rate of chronic, long-term CO exposure is unknown and its effects are poorly understood. Unless otherwise stated, the findings discussed in this section refer to acute CO poisoning.

The symptoms of exposure range from flu-like symptoms of headache, dizziness, weakness, and nausea to more severe symptoms of syncope, coma, and death. Cardiac symptoms, such as angina and arrhythmias, may occur. Individuals in the same CO exposure event may display different clinical presentations, and the severity of exposure can differ between individuals in the same location (Prockop, 2005). There may be complicating factors of substance intoxication with both accidental exposure and suicide attempts.

CO poisoning is associated with impairments in memory, attention, processing speed, visual-spatial skills, executive functions, and intellect (Chambers, Hopkins, Weaver, & Key, 2008; Gale et al., 1999; Kesler et al., 2001; Parkinson et al., 2002; Porter, Hopkins, Weaver, Bigler, & Blatter, 2002; Prockop, 2005). There is wide individual variability in cognitive deficits and long-term outcome following acute CO exposure (Hopkins & Woon, 2006). This variability may be explained by severity of exposure, but not consistently so. For example, Chambers and colleagues (2008) prospectively examined the neuropsychological performance of 256 individuals with CO poisoning, stratified by severity of exposure (55 less severe, 201 more severe), at serial intervals following the initial exposure. The two groups did not differ in prevalence of cognitive deficits at six weeks, six months, or 12 months postexposure. At six weeks, rates of exposure were 39% and 35% for the less and more severe groups respectively.

Behavioral and emotional symptoms following CO poisoning include depression, anxiety, and mood lability (Chambers et al., 2008; Gale et al., 1999; Jasper, Hopkins, Duker, Waver, 2005). Psychiatric disturbance may predate CO exposure (i.e., depression in individuals with CO poisoning from suicide attempts) and may persist. In general, individuals with CO poisoning due to suicide attempts show higher rates of depression and anxiety relative to individuals who were accidentally exposed (Jasper et al., 2005). Interestingly, depression and anxiety may actually be more common in less-severely poisoned patients early in the course of recovery (Chambers et al., 2008). There are also rare case reports of new-onset obsessive-compulsive disorder (OCD) and symptoms associated with Kluver-Bucy syndrome (Hopkins & Woon, 2006). While behavioral and emotional symptoms may influence cognitive deficits, they do not fully account for cognitive dysfunction in individuals exposed to CO (Porter et al., 2002).

Some individuals experience a delayed-onset neuropsychiatric syndrome with symptoms emerging 7–14 days after

exposure, and after an apparent recovery from acute symptoms. The syndrome is typically characterized by parkinsonian symptoms including bradykinesia, masked facies, and gait disturbance. Prevalence estimates range from 0.06% to 40% of CO-exposed individuals (Hopkins & Woon, 2006), and there may be increased risk of the delayed syndrome with increasing age, longer duration of coma, and prolonged anoxia (Min, 1986). The structural neuroimaging findings and clinical symptoms associated with the delayed syndrome may or may not resolve (Choi, 2002; Cocito et al., 2005; Min, 1986; Sohn, Jeong, Kim, Im, & Kim, 2000).

Neuroimaging findings have revealed atrophy in the brains of individuals who have been exposed to CO. In addition to whole-brain atrophy, regional atrophic changes may affect the fornix, hippocampus, corpus callosum, and basal ganglia (Gale et al., 1999; Kesler et al., 2001; Porter et al., 2002; Pulsipher, Hopkins, & Weaver, 2006). Atrophy of the corpus callosum was identified in 80% of patients within six months of exposure (Porter et al., 2002), but there was no correlation with cognitive performance. Infarcts in the bilateral hippocampi have been reported and associated with amnesia (Bourgeois, 2000; Gottfried & Chatterjee, 2001). Voxel-based morphometry reveals lower gray matter volumes in the basal ganglia, claustrum, amygdala, hippocampus, and frontal and parietal regions, as well as a correlation between lower gray matter volume and slower psychomotor speed (Chen, Chen et al., 2013).

Basal ganglia structures, particularly the globus pallidus, have known susceptibility to CO exposure; however, basal ganglia lesions are not universally identified and may even be absent in the presence of parkinsonian symptoms (Cocito et al., 2005; O'Donnell, Buxton, Pitkin, & Jarvis, 2000; Prockop, 2005). For example, following the same exposure event, one individual experienced parkinsonian symptoms without a lesion in the globus pallidus, while another individual had pallidal lesions without parkinsonian symptoms (Sohn et al., 2000). Reliance on individual case reports of observable lesions may be misleading, as other neuroimaging methods have revealed structural compromise in the absence of observable lesions. Pulsipher and colleagues (2006) found decreased basal ganglia volume in 28% of a prospective sample of patients with CO at six months postexposure, with an observable lesion in only one individual.

Damage to white matter, particularly in periventricular regions, is commonly reported following CO exposure and white matter may be more sensitive than gray matter in the acute phases of exposure (Prockop & Chichkova, 2007; Sener, 2003). White matter hyperintensities on MRI have remained stable at six-month follow-up (Parkinson et al., 2002). Using diffusion-weighted imaging, Chen, Huang and colleagues (2013) documented elevations in apparent diffusion coefficient (ADC, a marker of tissue injury) in the globus pallidus and corpus callosum acutely (< two weeks), subacutely (two weeks to six months), and chronically (> one year) following CO exposure. ADC values correlated

with cognitive performance. The delayed neuropsychiatric syndrome that may follow CO exposure has also been associated with changes in gray and white matter (Chu et al., 2004; Cocito et al., 2005; Lo et al., 2007). DTI studies have revealed white matter disruption in normal appearing white matter that correlates with cognitive performance and persists after hyperbaric oxygen treatment (Lin et al., 2009; Lo et al., 2007).

Treatment of CO poisoning involves administration of oxygen. Guidelines typically suggest normobaric treatment for lower levels of exposure and less severe symptoms, while hyperbaric treatment is generally utilized in more severe exposures; however, it can be difficult to initially determine the exposure severity (Prockop & Chichkova, 2007). There is also some debate about whether hyperbaric treatment yields a better outcome than normobaric treatment (Stoller, 2007; Weaver et al., 2002; Wolf, Levonas, Sloan, & Jagoda, 2008).

## Substances of Abuse

### *Cannabis*

Cannabis use has increased in recent years across the United States. This trend may be, in part, due to the legalization of marijuana's medicinal use in 20 states and recreational use in two states. While there are clear, acute effects of cannabis use on cognition, hence its propensity for use, there are very few prospective studies examining the long-term cognitive effects of cannabis use. One study conducted through the Dunedin Multidisciplinary Health and Development Study seems to provide strong evidence for long-term effects of cannabis on intellect and cognition, at least at first glance (Meier et al., 2012). In this study, a cohort of 1037 individuals was followed from birth to age 38, with cannabis use documented at ages 18, 21, 26, 32, and 38 years. Participants were evaluated at age 13, before cannabis use began, and then again at age 38. Intelligence was reassessed at multiple time points, but more comprehensive neuropsychological evaluations occurred at age 38 only; therefore, true prospective longitudinal data are available only for intelligence. Results illustrated a decline in intelligence in cannabis users, as well as a pattern of increasing intellectual decline with increasing use. The effect was general and impacted all aspects of intelligence, including all four Wechsler Adult Intelligence Scale-IV (WAIS-IV) indices (Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed). Cognitive deficits were associated with adolescent-onset use, but less so with adult-onset use, and cessation of cannabis use did not fully reverse the cognitive effects. Despite the strengths of this study, including the prospective design and large sample size, there are several potential confounds, such as personality and socioeconomic status, that may account for intellectual changes independent of cannabis use (Daly, 2013; Rogeberg, 2013).

If one carefully examines the Meier study (Meier et al., 2012) and other studies, there are indications that cannabis

exerts a long-term impact on variety of neuropsychological functions. The most common deficits observed affect learning and memory and secondary deficits involve working memory, reasoning/judgment, and inhibitory control (Crane et al., 2013; Gonzalez, 2007). Neurodevelopment factors and sex differences are also important variables to consider. Adolescent-onset cannabis use appears to have a more detrimental impact on cognition relative to adult-onset use. Additionally, males appear to have more problems with reasoning/judgment, whereas females have more problems with memory (Crane et al., 2013).

In terms of the structural underpinnings of cannabis-related cognitive deficits, the evidence points to changes in the prefrontal cortex, subcortical striatal structures, and the limbic system (Mata et al., 2010; Smith et al., 2013; Yucel et al., 2008). There is some evidence that heavy use is not associated with differences in brain volume between users and controls although, within users, the volumes of the amygdala and hippocampus varied negatively with use (Cousijn et al., 2012). One particular study of interest examined memory performance using the California Verbal Learning Test-II (CVLT-II) in adolescents who were abstinent for at least six months and correlated their performance with hippocampal volume (Ashtari et al., 2011). Performance was lower in users relative to controls, and correlated with smaller right hippocampal volumes. This structure-function correlation is important, but does not provide definitive evidence linking cannabis use to impaired learning and memory as a result of changes in the hippocampus.

Along the same lines, there is evidence of an association between cannabis use and reduced medial orbital frontal volume, as well as correlation between volume reductions and decision-making deficits (Churchwell, Lopez-Larson, & Yurgelun-Todd, 2010). These findings were accompanied by a dose-response effect. Smith and colleagues (2013) found differences in striatal and thalamic shape among cannabis users, and these differences in brain structure shape correlated with working memory deficits.

### *Amphetamines and MDMA*

Both amphetamines and MDMA (3,4-Methylenedioxymethamphetamine) have high rates of abuse and, in particular, heavy use on college campuses. This brief review will focus most on MDMA. Other amphetamines (speed and methamphetamine) are associated with cognitive deficits affecting attention, inhibition, executive functions, visual spatial skills, and learning and memory (Ersche & Sahakian, 2007; Scott et al., 2007). Methamphetamine abuse is hypothesized to impact fronto-striatal systems, in particular (Scott et al., 2007). Changes are noted in the frontal gray and white matter (Daumann et al., 2011; Koester et al., 2012; Nakam et al., 2011; Tobia et al., 2010), and there is some suggestion that frontal lobe deficits may predate abuse and then worsen secondary to abuse (Winhusen et al., 2013). Questions also

remain about the permanency of the deficits, thus it is important to consider moderator variables with individual cases (Dean, Groman, Morales, & London, 2013). Additionally, there are some data to support a causal link between abstinence and improved cognition (Iudicello et al., 2010). It has also been shown that abstinent users are dopamine-deficient and experience memory deficits that are associated with striatal dopamine reductions (McCann et al., 2008).

We chose to focus on MDMA in this review because of its cultural popularity among young adults and the availability of prospective data. In one prospective study of 188 MDMA-naive users who had a high likelihood of use, de Win and colleagues (2008) employed a variety of structural (MRS, DTI) and functional imaging techniques (SPECT to study serotonin transporters and perfusion-weighted imaging to study blood volume). Changes were observed in blood flow in the putamen and globus pallidus and fractional anisotropy in the fronto-parietal white matter and thalamus, with no changes observed in the serotonin system or brain metabolites measured by MRS. These changes occurred after an average use of six tablets. Unfortunately, cognitive data were not provided. A recent review suggests that, while not all aspects of cognition are affected by MDMA abuse, memory and executive functions are most commonly affected (Parrot, 2013). Indeed, some studies report minimal differences between users and controls (Halpern et al., 2010), but there are prospective cognitive data to support memory impairment in MDMA users (Wagner, Becker, Koester, Gouzoulis-Mayfrank, & Daumann, 2012).

### Opiates

Opiate use has resurged in recent years with abuse of prescription-based opiate pain medications, which is a particular problem here in Appalachia, and with heroin use and celebrity overdoses making national news. Neuropsychological deficits in long-term opiate users include visual spatial deficits, impaired attention and memory, and more prominent frontal lobe dysfunction (Gruber, Silveri, & Yurgelun-Todd, 2007). Some of these deficits may be related to personality characteristics that actually lead individuals to become users in the first place (Prosser et al., 2008). It is of particular interest that the treatments used for opiate addiction, namely methadone and buprenorphine, are opiates themselves and thus may also have a negative impact on cognition (Prosser et al., 2006; Rapeli, Fabritius, Kalska, & Alho, 2009, 2011). Some data suggest that the effect of methadone is greater (van Holst & Schilt, 2011), but such findings are tentative due to methodological limitations.

Neuroimaging studies suggest that changes in gray matter volume are present immediately after abstinence and that, while some areas may improve over time (i.e., superior frontal gyrus), differences between users and controls remain in the middle frontal gyrus and cingulate (Wang et al., 2012). White matter changes are also present using DTI, with

fractional anisotropy (FA) reductions observed in the parahippocampus correlating with memory performance and FA reductions in the orbital frontal white matter correlating with performance on the Iowa Gambling Task (Lin et al., 2012; Qiu et al., 2013).

### Alcohol

From a neuropsychological perspective, alcohol is the most widely and thoroughly studied substance of abuse. There are many excellent reviews (e.g., Parsons, 1994; Parsons, 1998; Parsons & Nixon, 1998; Rourke and Loberg, 1993), so we will just briefly summarize the knowledge as we understand it. Cognitive deficits occur in a wide range of areas, including memory, attention, processing, visual spatial skills and frontal lobe/executive functions. Some deficits may improve with abstinence, but some individuals with a sufficiently long duration and intensity of abuse experience persistent deficits. Cognitive deficits can be mild, and in some cases reversible, but may also rise to the level of a dementia syndrome. In those cases, some level of residual cognitive impairment is likely even with prolonged abstinence. Mild cognitive deficits can be detected in social drinkers or those with alcohol dependence (Parsons, 1998). Of course, Korsakoff's amnesia may also present in individuals who abuse alcohol and have concurrent nutritional deficits. We refer readers to a recent series of review articles on this subject published in *Neuropsychology Review* (2012, Volume 22).

Neuroimaging deficits associated with alcohol abuse and dependence affect a wide range of brain structures, including both gray and white matter. MRI demonstrates reduction in the volume of frontal gray and white matter, as well as the cerebellum (Rosenbloom & Pfefferbaum, 2008). As with cognitive deficits, structural brain changes may at least partially reverse with abstinence, and improvements in brain structure are related to improvements in brain function (Sullivan, Harris, & Pfefferbaum, 2010). Consistent with other substances of abuse, there is evidence of preexisting, genetically linked structural deficits that may predispose certain individuals to alcohol abuse (Gierski et al., 2013). In addition, use and abuse during adolescence, when the brain is exceedingly vulnerable to insult, may have particularly negative effects on brain structure (Lisdahl, Gilbert, Wright, Shollenbarger, 2013). There are also some prospective data noting declines in white matter integrity in adolescents who use both alcohol and cannabis, but not in those who use alcohol alone (Jacobus, Squeglia, Bava, & Taper, 2013).

### Chemotherapy

Alkylating agents were first introduced as anticancer therapies following World War II. The cytotoxic effects of nitrogen mustards became evident secondary to chemical warfare and, thereafter, mustine or "HN2" became the first chemotherapy drug. Although toxic effects to human tissue were recognized

early in the introduction of nitrogen mustard therapy, it was presumed that anticancer agents did not cross the blood-brain barrier and that any cognitive changes occurring in the context of non-CNS tumors were secondary to other factors (Ahles & Saykin, 2007a; Goodman et al., 1946; Karnofsky, 1958; Rhoads, 1946; Silberfarb, Philibert, & Levine, 1980). The neurotoxic effects of chemotherapy were not discussed until the 1980s, when researchers at Dartmouth put forth that cognitive impairment in chemotherapy-treated cancer patients was independent of affective disturbance (Nelson & Suls, 2013; Oxman & Silberfarb, 1980; Silberfarb, 1983; Silberfarb et al., 1980). In the late 1990s, chemotherapy-related cognitive impairment gained more substantial scientific attention and the phenomenon of “chemo-brain” was born (Ahles, 2012; Ahles & Whedon, 1999; van Dam et al., 1998).

Chemo-brain, alternatively known as “chemo-fog” and “chemotherapy-related cognitive impairment,” refers to cognitive changes caused by chemotherapy itself (Raffa et al., 2006; Hodgson, Hutchinson, Wilson, & Nettelbeck, 2013). Although high-dose chemotherapy exerts a more potent effect on cognition than standard-dose chemotherapy, both are sufficient to produce cognitive deficits (van Dam et al., 1998). The bulk of research on chemo-brain has been derived from studies of patients having undergone standard-dose chemotherapy for breast cancer, lymphoma, and other non-CNS cancers (Abrey, 2012; Saykin, Ahles, & McDonald, 2003). The precise mechanisms underlying chemotherapy-induced neurotoxicity are not well understood, although the integrity of the blood-brain barrier and oxidative stress are believed to play a role (Saykin et al., 2003; Seigers, Schagen, Tellingen, & Dietrich, 2013).

Between 15% and 75% of cancer patients report at least mild cognitive impairment at some point during or after treatment, while up to 61% may experience persistent post-treatment cognitive deficits (Ahles, 2012; Ahles & Saykin, 2007b; Janelins et al., 2011; Wefel, Lenzi, Theriault, Davis, & Meyers, 2004). Cognitive deficits in attention, concentration, processing speed, verbal and visual memory, and multitasking are commonly reported following treatment (Ahles & Saykin, 2002; Wefel et al., 2004). A recent meta-analysis of chemotherapy-related cognitive impairment found that the domains of memory and executive function are most consistently affected on neuropsychological testing (Hodgson et al., 2013). Although some cancer patients experience resolution of cognitive symptoms following treatment, others face more persistent cognitive difficulties for up to 20 years following treatment (de Ruiter et al., 2011; Koppelmans et al., 2012).

Mood disturbance is common among cancer patients and may at least partially fuel subjective cognitive complaints (Koppelmans et al., 2012). The prevalence of major depression in cancer survivors has been estimated at between 10% and 25% (Fann et al., 2008), which is fairly consistent with recent estimates from the U.S. adult population (9% as reported by CDC, 2010). Most cancer survivors do not meet clinical criteria for major depression and actually experience

fewer depression symptoms relative to normal controls (Koppelmans et al., 2012). There is also evidence that cancer patients experience clinical depression and anxiety prior to cancer treatment (Linden, Vodermaier, MacKenzie, & Greig, 2012). Thus, it does not appear that chemotherapy triggers mood disturbance in the same way that it leads to cognitive deficits, but rather that preexisting depression and anxiety and treatment effects, such as fatigue, contribute to the cognitive sequelae known as chemo-brain.

Some propose that the effects of chemo-brain cannot be fully captured through neuropsychological measures (Reuter-Lorenz & Cimprich, 2013). When cognitive complaints exceed objective deficits, clinicians frequently write the discrepancy off to stress, fatigue, or mood disturbance (Scherling & Smith, 2013). Neuroimaging offers an alternative mechanism to explore the effect of chemotherapy on cognition and the brain.

Structural imaging studies applying tensor-based and voxel-based morphometry demonstrate reductions in total brain volume and gray matter volume in chemotherapy-exposed patients relative to healthy controls (Conroy et al., 2013; Inagaki et al., 2007; Koppelmans et al., 2012; McDonald, Conroy, Ahles, West, & Saykin, 2010). These changes have been documented shortly after treatment and at long-term follow-up, mainly in cross-sectional designs and at least one prospective study (McDonald et al., 2010).

Significant reductions in white matter integrity are consistently reported in DTI studies of patients receiving chemotherapy (Abraham et al., 2008; Deprez, Billiet, Sunaert, & Leemans, 2013; Deprez et al., 2011; Deprez et al., 2012). Decreased FA in various white matter tracts has been found to correlate with neuropsychological performance on measures of processing speed, attention and short-term memory (Abraham et al., 2008; Deprez et al., 2011; Deprez et al., 2012).

Functional imaging studies suggest that chemotherapy influences the way cancer patients use their brains during cognitive tasks (Haut, Wiener, Marano, & Abraham, 2013). As early as one month after chemotherapy, patients demonstrate decreased frontal activation on working memory tasks relative to healthy controls (de Ruiter & Schagen, 2013; McDonald et al., 2012). Some report a return to neurofunctional baseline at one year after treatment, while others report persistent changes in brain activation. In an fMRI study conducted ten years after chemotherapy, breast cancer survivors showed task-specific hyporesponsiveness of the dorsolateral prefrontal cortex and parahippocampal gyrus, in addition to generalized hyporesponsiveness of the bilateral posterior parietal cortex (de Ruiter et al., 2011). Other follow-up studies suggest similar activation patterns and a correlation between frontal activation and cognitive performance (Conroy et al., 2013; Kesler, Kent, & O'Hara, 2011; Simó, Rifa-Ros, Rodriguez-Fornells, & Bruna, 2013).

Functional imaging studies have also documented significantly increased cortical activation in chemotherapy-treated

cancer patients relative to healthy controls (Kesler, Bennett, Mahaffey, & Spiegel, 2009). In one study comparing two monozygotic twins, only one of whom received chemotherapy for breast cancer, the chemotherapy-treated twin demonstrated a wider extent of spatial activation during an *n-back* working memory task, but no difference in performance (Ferguson, McDonald, Saykin, & Ahles, 2007). Similarly, one study using <sup>18</sup>fluorodeoxyglucose-PET found lower resting metabolism in the inferior frontal cortex of patients treated with chemotherapy 5–10 years earlier relative to controls, but then increased frontal activation during a memory task (Silverman et al., 2007). These findings may stem from decreased cognitive efficiency or some sort of compensatory mechanism.

Although cognitive deficits resulting from standard-dose systemic chemotherapy are usually mild, the effect on quality of life may be more substantial (Saykin et al., 2003). Cognitive complaints have been associated with poorer functional outcome (Reid-Arndt et al., 2010). Chemo-brain can influence basic functioning, self-esteem, social relationships, educational goals, and career decisions (Ahles & Saykin, 2001; Ahles & Whedon, 1999; Voh Ah et al., 2013). Social support and fatigue are also important predictors of quality of life (Reid-Arndt, Hsieh, & Perry, 2010). Thus, preventative efforts or treatment are important.

In the last few years, cognitive-behavioral interventions targeting chemo-brain have been developed and researched. Preliminary findings from two recent randomized controlled trials suggest that brief cognitive behavioral therapy (CBT) or cognitive rehabilitation improves cognitive performance and overall life satisfaction in chemotherapy-treated cancer patients relative to no-treatment controls (Cherrier et al., 2013; Ferguson et al., 2012). These results are very promising. Other treatment options include pharmacological interventions targeting attention/alertness, sleep, mood, diet, and physical activity, which mitigate chemotherapy-induced cognitive deficits. The utility of cholinesterase inhibitors and herbal supplements, such as Ginkgo biloba, is unknown (Fardell, Vardy, Johnston, & Winocur, 2011).

### Assessment and Other Issues

Although cognitive symptoms vary depending upon the toxin, attention and executive functions are almost universally affected and should be assessed thoroughly as part of a neuropsychological examination. In cases of occupational toxic exposure, issues of secondary gain and malingering must be considered. A substantial portion of patients with suspected chronic toxic encephalopathy demonstrates suboptimal effort on cognitive tests (Greve et al., 2006; van Hout, Schmand, Wekking, & Deelman, 2006; van Hout, Schmand, Wekking, Hageman, & Deelman, 2003) and, therefore, inclusion of performance/symptom validity measures is recommended.

### Conclusions

There is clearly individual variability in the effects and sequelae associated with exposure to CNS toxins. From a cognitive perspective, executive dysfunction is a common theme across the toxins discussed in this chapter. Hand-in-hand with this, emotional lability is a frequent behavioral consequence. Apart from alcohol, the threshold for neurotoxicity is poorly understood across toxins. Additionally, because longitudinal data are lacking, the persistence of resultant symptoms is unclear and it is challenging to determine if the deficits observed are, in fact, a consequence of toxic exposure, or a predisposition. There is increasing evidence of structural brain predispositions to substance abuse, in particular. Further research that takes into account genetic and structural vulnerabilities to the effects of toxins is necessary to elucidate threshold and permanency issues.

# 25 Multiple Sclerosis and Related Disorders

*Peter A. Arnett, Jessica E. Meyer, Victoria C. Merritt, and Lauren B. Strober*

## Introduction

Multiple sclerosis (MS) is the most common nontraumatic neurological condition of early to middle adulthood, and the most common demyelinating condition. Other demyelinating conditions include concentric sclerosis (also known as *Balo's disease*), Schilder's disease, Devic's disease, central pontine myelinolysis, and Marchiafava-Bignami disease. Rarer still are acute disseminated encephalomyelitis and acute hemorrhagic leukoencephalitis. Because MS is the only one of these conditions that has been adequately examined neuropsychologically, the focus of this chapter will be on MS.

## Neuropathology

A central feature of MS is demyelination that is presumed to be caused by an autoimmune process, a slow-acting virus, or a delayed reaction to a common virus (Brassington & Marsh, 1998). Multiple discrete plaques at demyelinated sites are formed, in part, by proliferating astrocytes. The plaques are comprised of demyelination, inflammation, gliosis and axonal injury, and myelin sheaths within plaques are swollen and fragmented, or destroyed entirely. When intact, nerves of the central nervous system (CNS) are enclosed in myelin sheaths, which are separated by synaptic gaps from which the nerve impulse fires, facilitating neural conduction. Plaques associated with MS thus interfere with or block neural transmission by limiting this saltatory conduction process. Axons and cell bodies of neurons often remain intact. Lesions are typically found in a random or asymmetrical pattern in the periventricular, juxtacortical, and infratentorial regions.

Plaques occur in both the brain and spinal cord, and the location of plaques is highly heterogeneous among patients. Plaques in the cerebrum are most commonly located near the lateral and third ventricles and the periventricular region. The frontal lobes are next most commonly affected, but plaques in other major lobes of the brain are also frequently seen. Additionally, plaques are commonly seen in the optic nerves, chiasm, or tracts, as well as the corpus callosum, brain stem, and cerebellum. Furthermore, plaques can be found in white matter regions of the thalamus, hypothalamus, and basal ganglia.

Despite long-standing classification as a white matter disease, recent research has suggested significant involvement of gray matter, even early on in the disease (Zivadinov & Pirko, 2012). The most affected gray matter regions include the cingulate, thalamus, basal ganglia, hypothalamus, cerebellum, hippocampus, and frontal and temporal lobes (Horakova, Kalincik, Dusankova, & Dolezal, 2012). This type of cortical demyelination occurs most frequently in Progressive forms of MS and may be indicative of disease progression and potential irreversible disability (Popescu & Lucchinetti, 2012).

## Epidemiology

The incidence of MS is lowest in regions close to the equator, with larger numbers of cases in northern and southern latitudes (from about 60 to 300 per 100,000, respectively). There are about 400,000 people with MS in the United States, and 2.5 million people worldwide (National MS Society, 2009). Females are approximately 2.5 times more likely than males to get MS, with some recent work suggesting this disparity is increasing (Koch-Henriksen & Sørensen, 2010), and peak onset for the disease is around age 30 (Chitnis et al., 2011). Those living north of latitude 40 degrees North are about three times as likely to have MS as are those living in the southern United States, a geographic pattern suggesting an environmental contribution to the disease. Still, the 30%–40% concordance rate in identical twins versus only 1%–13% in fraternal twins implicates a substantial genetic contribution, as well. Onset of the disease occurs between age 20 and 40 in 70% of patients (Compston et al., 2005); onset after age 40 is often characterized by quicker progression and greater morbidity. Life expectancy beyond disease onset is approximately 30 years, but there is significant variability around this mean.

## Symptom Onset and Diagnosis

Early MS symptoms are variable, but the most common initial symptoms include muscle weakness, paresthesias (i.e., numbness and tingling in the limbs, trunk, or face), gait/balance problems, and visual disturbances. The latter usually involve decreased visual acuity, blurry vision, or diplopia. Urinary disturbance is also common, as are

balance difficulties. Cognitive dysfunction, fatigue, and depression are frequently observed, as well. MS symptoms are often transient and unpredictable. For example, visual disturbances and paresthesias may last for seconds or hours. Because of the short-lived and sometimes bizarre nature of the symptoms, it is not uncommon for patients to be diagnosed with hysteric/somatization disorders prior to a formal diagnosis of MS.

The diagnosis of MS is based on guidelines developed by McDonald and colleagues (2001), and these were subsequently revised in 2005 (Polman et al., 2005), and 2010 (Polman et al., 2010). The revision by Polman and colleagues in 2010 was the result of a consensus panel designed to simplify the criteria. Classifications in this new diagnostic system include “MS,” “not MS,” and “possible MS.” Central factors for an MS diagnosis in this new system involve both clinical and paraclinical (e.g., the presence of oligoclonal bands in the cerebral spinal fluid, or CSF) assessments, lesions that are disseminated in space (DIS) and time (DIT), and disease attacks that last at least 24 hours. DIS occurs with the presence of at least one T2 lesion in at least two of four MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord), or by a clinical attack that implicates a different CNS site. DIT occurs when a new T2 and/or gadolinium-enhancing lesion(s) appears on follow-up MRI after a baseline scan has been conducted; DIT can also be demonstrated by the simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions.

Per the McDonald et al. (2001) system, MS sometimes presents with an insidious progression rather than via discrete attacks, and is known as Primary Progressive MS. For this to be demonstrated there must be evidence of at least one year of disease progression, as well as at least two of the following: (a) evidence for DIS in the brain, (b) evidence for DIS in the spinal cord based on the presence of at least two T2 spinal cord lesions, or (c) positive CSF findings (isoelectric evidence of oligoclonal bands and/or elevated IgG index).

Prior to the mid-1990s, MS was classified into two major disease course types: Relapsing-Remitting and Chronic Progressive. An updated system was then developed and is now more commonly used (Lublin & Reingold, 1996). Presently, there are four course types in this new system: Relapsing-Remitting, Secondary Progressive, Primary Progressive, and Progressive Relapsing. Relapsing-Remitting is the most common type and affects more than half of all patients. Relapsing-Remitting MS is characterized by clearly defined disease relapses where recovery can be complete or with sequelae and residual deficit; however, there is no progression of disease between relapses. Relapses typically last days to weeks, with a duration of hours or months being less common. The frequency of relapses is highly variable, and can occur weeks or even years apart.

The remaining course types are all progressive in nature and were formerly encompassed by the Chronic Progressive term. The Secondary Progressive course is next most common and

always begins as a Relapsing-Remitting course, but is defined by progression occurring even between relapses, and relapses and remissions with this course may or may not occur. The median time to conversion from Relapsing-Remitting to Secondary Progressive course is 15–20 years (Loitfelder et al., 2011). The Primary Progressive type is next most common, and involves an unremitting disease progression from disease onset for most patients with no clear relapses. The least common MS course type is Progressive Relapsing, and this involves disease progression from onset that is punctuated by acute relapses from which patients may or may not fully recover.

## **Cognitive Functioning**

### *Patterns and Prevalence*

Rao, Leo, Bernadin, and Unverzagt's (1991) seminal study remains the definitive examination of prevalence of cognitive dysfunction in MS in a community-based sample, as it compared 100 community-based MS patients with 100 matched healthy controls on an extensive neuropsychological battery. This study showed that individuals with MS demonstrated the greatest impairment on measures of recent memory, sustained attention, verbal fluency, and conceptual reasoning, and were less frequently impaired on measures of language, visuospatial perception, and immediate and remote memory. From this, Rao and colleagues proposed a brief battery—subsequently named the *Brief Repeatable Battery* (BRB) of neuropsychological tests likely to be most sensitive to cognitive impairment in MS, based on the tests that most differentiated MS and normal controls in their study. This initial battery included the Paced Auditory Serial Addition Test (PASAT), Controlled Oral Word Association Test (COWAT), 7/24 Spatial Recall, and the Verbal Selective Reminding Test (SRT). The Symbol Digit Modalities Test (SDMT) was subsequently added for a five-test battery that took about 30 minutes to administer, and included multiple alternate forms for each test (Rao and the Cognitive Function Study Group of the National Multiple Sclerosis Society, 1990). Additionally, the 7/24 Spatial Recall was expanded into a 10/36 Spatial Recall test that required more items to recall to enhance sensitivity. Subsequent studies have generally supported Rao and colleagues' findings about cognitive domains most affected in MS (Benedict et al., 2006; Bobholz & Rao, 2003; Chiaravalloti & DeLuca, 2010). Benedict and colleagues conducted their study on a clinic-based MS sample consisting of 291 MS patients and 56 healthy matched controls. The prevalence rates for cognitive impairment in their MS sample were often higher than Rao et al., though the same general pattern of domains typically affected was found. When discussing the different cognitive domains below, we will primarily reference Rao et al. and Benedict et al.'s studies, with prevalence rates of impairment typical of community-based samples based on the former and rates

typical of clinic-based samples based on the latter study. The two studies used similar cutoffs for impairment, with Rao and colleagues defining impairment at the fifth percentile (relative to controls) and Benedict et al. using 1.5 standard deviations below the mean of controls.

#### SIMPLE AND COMPLEX ATTENTION, INFORMATION PROCESSING SPEED

Simple attention span (as measured by tests such as Digit Span) is usually intact in MS patients, but mild impairments are sometimes found. However, MS patients typically show their greatest difficulty on tasks requiring rapid and complex information processing, including those requiring swift application of working memory operations, attentional switching, or rapid visual scanning. About 25%–30% of community-based MS patients and 25–50% of clinic-based patients show impairments on such tasks of complex attention and processing speed. Some investigators have asserted that slowed information processing is the most fundamental cognitive deficit in MS, noting that such difficulties impact new learning and the ability to perform higher-order cognitive functions (Chiaravalloti & DeLuca, 2010). Working memory and processing speed are typically measured by tasks such as the PASAT and SDMT. The SDMT appears to be more sensitive than the PASAT, perhaps due to its visual nature given that many MS patients have visual problems. Supporting this hypothesis, at least one study (Bruce, Bruce, & Arnett, 2007) has shown that primary visual acuity problems contribute significantly to performance on the SDMT in MS patients, even in patient groups who have been prescreened for significant visual problems. Thus, it appears that even subtle visual anomalies can impact performance on the SDMT, and perhaps inflate sensitivity measures in MS patients. Furthermore, rudimentary oralmotor deficits contribute to group differences on tasks such as the SDMT in MS (Arnett, Smith, Barwick, Benedict, & Ahlstrom, 2008), suggesting that both primary visual and primary oral motor factors may inflate sensitivity measures of the SDMT in MS. In terms of the practical impact of these types of deficits, patients with MS often complain of problems tracking things in conversation, following details of movies or television programs, and quickly and efficiently performing work tasks. Such everyday difficulties may stem from problems with complex attention and speeded information processing.

#### MEMORY

Memory difficulties in MS are usually manifested as deficits with immediate recall on neuropsychological testing. Although delayed recall is also commonly impaired, this appears to be mostly a function of limited immediate recall, as opposed to actual forgetting. Tests that are most commonly used to measure memory functioning in MS include the California Verbal Learning Test, second edition (CVLT-II),

Brief Visuospatial Memory Test–Revised (BVM-T-R), 10/36 Spatial Recall, and story memory tests such as Logical Memory from the Wechsler Memory Scale, or the Story Recall test. In community-based MS groups, about 25%–30% of patients have impaired recall, compared with 25% to more than 50% of clinic-based patients. Regarding the upper value for clinic-based patients, this is solely due to MS patients' impairment on the BVM-T-R, so this latter test appears to be unusually sensitive to cognitive impairment in clinic-based MS samples. With that said, given the visual-motor problems that are common to MS, it may be that such a test has an inflated sensitivity because it may be affected by noncognitive (i.e., motor, visual) factors in addition to cognitive factors. Consistent with such a hypothesis, Benedict and colleagues (2011) found a high inverse correlation ( $r = -0.45$ ) between BVM-T-R performance and upper extremity function (as measured by the 9-Hole Peg Test, or 9-HPT). Their interpretation of such data was different, however, as they suggested that the causal relationship may run in the other direction, with higher-order cognitive functions impacting motor performance and thus accounting for the relationship. Such an interpretation was based, in part, by the fact that the 9-HPT was inversely correlated with performance on a number of other cognitively demanding tests with significant executive components (e.g., Delis-Kaplan Executive Function System [D-KEFS] Sorting Test, PASAT, and SDMT).

The learning curve across repeated trials of memory tests (e.g., CVLT-II, BVM-T-R) is typically similar in slope in MS compared with controls, but is lower in magnitude. Working memory, or the ability to maintain and manipulate information “online,” is also commonly impaired in MS. However, percent retention, recognition, incidental memory following a delay, remote memory, and semantic memory are usually intact.

Because memory-impaired patients usually display intact recognition memory, MS patients' memory recall problems were initially thought to be due to problems with retrieval (Rao et al., 1991). However, based on additional work finding that patients could recall a normative amount of information if given enough initial learning trials, some investigators asserted that these memory recall problems were primarily due to initial acquisition difficulties (DeLuca, Barbieri-Berger, & Johnson, 1994; Lafosse, Mitchell, Corboy, & Filley, 2013). More recent work has suggested that information processing speed deficits are much more predictive of memory recall problems than working memory deficits, suggesting the primacy of processing speed problems in memory recall tasks (Chiaravalloti, Stojanovic-Radic, & DeLuca, 2014).

In addition to being among the most common cognitive deficits found in MS using objective tests, patients with MS often come to the clinic complaining of memory problems. In practical terms, these get manifested as complaints of difficulty remembering conversations, appointments, and work tasks that are sometimes so debilitating that patients can no longer work at cognitively demanding jobs.

## EXECUTIVE FUNCTIONING

The next most common cognitive domain typically affected in MS is executive functioning. Deficits in cognitive flexibility, concept formation, verbal abstraction, problem solving, and planning are very common. Tests most commonly used to measure these cognitive skills include the Wisconsin Card Sorting Test, D-KEFS Sorting Test, Stroop Color-Word Test, Booklet Category Test, and verbal fluency tests, among others. In community-based samples, 15%–20% of individuals with MS show impairments in this domain, whereas the range is between 10% and 25% in clinic-based samples. The range of variability is higher for clinic-based samples because in Benedict and colleagues' (2006) study, they found that very few patients displayed verbal fluency deficits on the COWAT, with more showing impairments on the D-KEFS Sorting Test. In everyday terms, problems in this very broadly defined executive functioning domain can manifest themselves in patients reporting problems planning their day-to-day activities (e.g., job tasks, meals, grocery shopping), organizational difficulties, and problems collecting their thoughts and maintaining the flow of conversation.

## VERBAL-LINGUISTIC FUNCTIONING

Depending on the complexity of the task, verbal and linguistic skill deficits can be seen in MS. It is rare (though not unheard of) for patients to have aphasic disorders (Arnett, Hussain, Rao, Swanson, & Hammeke, 1996); mild confrontation naming difficulties are relatively more common, though still usually occur in less than 10% of community-based samples of MS patients. Similarly, alexia, agraphia, and apraxia are very rare. In contrast, speech abnormalities such as dysarthria and hypophonia are common in MS (Arnett, Vargas, Ukueberuwa, & Rabinowitz, 2013). As referred to earlier in the discussion of executive tasks, deficits in verbal fluency are found in 20%–25% of community-based patients, with a surprisingly lower number of clinic-based patients (less than 15% from Benedict et al.'s 2006 study) showing deficits. Still, the latter finding appears somewhat anomalous, as a meta-analysis in more severely affected (Chronic Progressive) patients (who would presumably most closely mirror Benedict and colleagues' clinic-based patients) showed a medium effect size across many studies for verbal fluency tasks in MS relative to healthy controls (Henry & Beatty, 2006). Evidence suggests that impairments in verbal fluency may be as great as impairments in speeded information processing (Henry & Beatty, 2006). This may be due to the fact that performance on verbal fluency tasks requires rapid information processing, so patients' poor performance on such measures may also be reflective of their speeded information processing deficits. It is also important to keep in mind that slowed speech in MS can contribute to patients' verbal fluency deficits (Arnett et al., 2013). In practical terms, patients who have verbal fluency deficits may complain of

frequent word-finding problems in conversation, and generally feel as though their ability to readily communicate with others is impacted.

## VISUOSPATIAL FUNCTIONING

Visuospatial functioning in neuropsychological terms involves perceiving relationships in space. In MS, visuospatial functioning is commonly screened using tasks such as Judgment of Line Orientation (JLO), with more complex tasks such as the Facial Recognition Test sometimes used. Deficits in this domain are relatively common in MS; in both community- and clinic-based samples, 15%–20% of patients show impairments. It is unclear whether higher order visual deficits are a function of primary visual disturbances involving blurred vision and diplopia (Rao et al., 1991). Patients who report problems in their daily lives with regard to visuospatial functioning may complain of problems running into things frequently while walking (e.g., doorways) or driving (e.g., hitting curbs) because of visual miscalculations.

## INTELLECTUAL FUNCTIONING AND ACHIEVEMENT

Intellectual functioning is usually considered to be well-preserved in MS, and is in many patients. Still, in Rao and colleagues' (1991) seminal study, slightly over 20% of patients had deficits in verbal intelligence. Of note, however, few patients (less than 10%) displayed impairments in their fund of knowledge (Information subtest from the Wechsler Adult Intelligence Scale—WAIS), so the Information test may represent a reasonably good index of premorbid cognitive functioning in MS. Finally, there has been little systematic research in how achievement-related skills (e.g., reading, writing, and math) may change with MS progression, but they are generally assumed to be significantly affected in few patients.

*Longitudinal Course*

Cognitive impairment can occur at any stage of MS and across all disease courses. Even patients with recently diagnosed MS or clinically isolated syndrome (CIS) commonly show deficits, with 45%–49% of individuals with early MS or CIS patients in one study demonstrating impairment on at least one measure (Glanz et al., 2012). Cognitive deficits in and of themselves appear to confer risk for further cognitive decline, even over a two-to-three-year period (Kujala, Portin, & Ruutiainen, 1997). When examined longitudinally, declines in information processing speed, verbal learning and memory, visual memory, and attention/working memory are usually seen in MS, at least over relatively shorter time periods of three to five years (Glanz et al., 2012; Kujala et al., 1997; Nordin & Rorsman, 2012). Verbal fluency and executive function skills also decline during these shorter periods, but this is less common (Glanz et al., 2012; Till et al., 2012).

Longer-term longitudinal investigations (e.g., seven to ten years) reveal declines in long-term verbal memory (Feinstein, 2011), information processing speed, motor speed, reaction time, visuospatial ability, and visual short-term memory (Vattakatchery, Rickards, & Cavanna, 2011). Amato, Ponziani, Siracusa, and Sorbi (2001) have conducted one of the most comprehensive longitudinal studies to date (spanning ten years). They reported that when individuals with MS are followed from shortly after diagnosis, they show initial deficits on indices of concentration, verbal memory, and abstract reasoning, with the development of later impairments in verbal fluency, verbal comprehension, and short-term verbal and spatial memory/attention. Most strikingly, 26% of patients displayed cognitive impairment at the time of study entry, but this increased to 56% at the ten-year follow-up point.

#### *Relationship to Disease Variables*

Studies have consistently shown that patients with a Relapsing-Remitting course type exhibit less severe cognitive impairment than those with Progressive courses. One large meta-analytic study revealed that those patients with a Chronic Progressive course (encompassing all progressive types of MS) were more likely to have frontal-executive impairments, and those with Relapsing-Remitting courses more commonly showed memory-related impairments (Zakzanis, 2000).

#### *Measurement*

For cognitive difficulties to be detected in MS, it is important to employ test batteries that assess key areas of cognitive functioning, as the precise pattern of cognitive impairment often varies significantly among individuals. MS patients who show impairment in one domain of cognitive functioning are not necessarily impaired in others (Rao et al., 1991). Optimally, test batteries should be limited to about two to three hours, or less, to circumvent secondary problems (e.g., fatigue) that may compromise performance over a long period of time. There is evidence that MS patients' performance declines more than controls over the course of a long battery (Krupp & Elkins, 2000), and even within the context of a single task, such as the PASAT (Walker, Berard, Berigan, Rees, & Freedman, 2012). There are at least two well-validated batteries for assessing cognitive impairment in MS, and both will be discussed in the following sections. Additional approaches and considerations will also be discussed.

THE BRIEF REPEATABLE BATTERY (RAO AND THE COGNITIVE FUNCTION STUDY GROUP OF THE NATIONAL MULTIPLE SCLEROSIS SOCIETY, 1990)

This battery consists of five tests that were shown to be most sensitive to cognitive impairments typically seen in MS from

Rao's seminal MS study (Rao et al., 1991). As noted earlier, the BRB includes the SDMT, 10/36 Spatial Recall, Six-Trial version of the SRT, PASAT (2s & 3s version), and Word List Generation (WLG). Most of these tests also include 15 alternate forms (in English) to facilitate serial testing. Additionally, a two-form (A and B) version of the BRB has been developed by the European Study Group on Interferon beta-1b in Secondary Progressive MS (Boringa et al., 2001), but with some limitations noted in the comparability of the forms. The BRB has also been shown to have excellent specificity (94%) and adequate sensitivity (71%; see Rao et al., 1991). It has advantages over other batteries in that it has been translated into several languages other than English. The battery, or parts of the battery, have also been explored in Dutch (Boringa et al., 2001), Brazilian (Brooks, 2011), Serbian (Obradovic, Petrovic, Antanasijevic, Marinkovic, & Stojanovic, 2012), Greek (Potagas, Giogkaraki, Koutsis, Mandellos, & Tsirempolou, 2008), and Italian (Goretti et al., 2014) samples, among others. Even an abbreviated version administered in an Italian sample (Portaccio, Goretti, Zipoli, Siracusa, & Sorbi, 2009) showed excellent sensitivity (94%) and specificity (84%) in a group of Relapsing-Remitting patients. Regarding the latter study, the investigators included only the Selective Reminding Test, PASAT (3s version), and SDMT. The BRB takes about 20–30 minutes to administer.

One continuing limitation of the BRB is that adequate norms across the alternate forms of the tests comprising it are generally not available. Boringa and colleagues' study (2001) was a Dutch sample and included only the A and B forms developed by the European Study Group. Even examining only these two forms, the investigators found that scores were higher on the B form for three of the tests (SDMT, WLG, and 10/36 Spatial Recall), so great caution is warranted when using these two forms in repeat testing. Benedict and colleagues (Benedict et al., 2012) developed two alternate forms for the SDMT that were comparable to the original oral form of the SDMT; however, this study was based on a very small sample (25 healthy controls, including six men), so a replication of their findings is warranted before broad clinical application of these new forms takes place. In the absence of good normative data and clear-cut form equivalence for the BRB, one possible solution is to create standardized scores from these authors' control data for each form that could then be compared across different testings.

MINIMAL ASSESSMENT OF COGNITIVE FUNCTION IN MS (MACFIMS; BENEDICT ET AL., 2002)

The MACFIMS was developed as a result of a consensus conference and designed to provide a somewhat more extensive battery than the BRB. The MACFIMS takes about 90 minutes to administer and includes measures of memory (CVLT-II and BVMT-R), Attention and Concentration/Processing Speed (SDMT [Oral Version]), PASAT [2s &

3s]), Verbal-Linguistic Functioning (COWAT), Executive Functioning (D-KEFS Sorting Test), and Visuospatial Skill (JLO). Optional measures were suggested for this battery to measure Premorbid Intellectual Functioning (North American Adult Reading Test, or NAART), Emotional Functioning (BDI–Fast Screen, or BDI-FS), Fatigue (Fatigue Impact Scale, or FIS), Sensorimotor Functioning (9-HPT, Maximum Repetition Rate of Syllables and Multisyllabic Combinations (MRRSMC), and the Rosenbaum Pocket Vision Screener. Depression should be routinely screened in MS because it is so common, and because some research has shown an association between depression and cognitive dysfunction in MS (Arnett, Barwick, & Beeney, 2008).

Besides English (Benedict et al., 2006), the MACFIMS has been validated in Czech (Dusankova, Kalincik, Havrdova, & Benedict, 2012) and Persian (Eshaghi, Riyahi-Alam, Roostaei, Haeri, & Aghsaei, 2012), with reasonably good validity data being reported in these latter languages.

At least two studies recently compared the BRB and the MACFIMS (Goksel Karatepe et al., 2011; Strober et al., 2009), and suggested that these batteries have comparable sensitivity. The SDMT was shown to be the best predictor of MS status in both studies, but with verbal fluency and verbal memory also contributing independently. Although the SDMT has much appeal, given its high level of sensitivity and ease of administration, performance on it can be compromised by the slowed speech that is common in MS (Arnett et al., 2013), as well as relatively minor rudimentary visual problems (Bruce et al., 2007). In terms of comparing the different verbal and visual learning and memory tasks in these batteries, the SRT and CVLT-II appear to be comparable, but the BVMT-R appears superior to the 10/36 Spatial Recall.

#### BRIEF INTERNATIONAL COGNITIVE ASSESSMENT FOR MS (BICAMS) (BENEDICT, AMATO, ET AL., 2012)

The BICAMS has yet to be validated, but has been suggested by an international consensus panel of expert neuropsychologists and neurologists in MS. It was developed in recognition of the fact that many centers where patients with MS are tested have limited resources, and may not have the time or expertise to administer and interpret extensive neuropsychological batteries. With this in mind, this group has recommended the adoption of the following tests as targets for validation across a number of cultures and languages: SDMT, BVMT-R, and CVLT-II. Such a battery would be easier to administer than the BRB and takes only about 15 minutes. However, the validation of this protocol across cultures and languages is still in process.

These approaches to neuropsychological assessment in MS attempt to survey the core cognitive domains typically affected in the disease and differ primarily in their comprehensiveness. Selection of one battery versus another depends upon the goals for the evaluation, in addition to the setting in which the evaluation takes place.

### *Ecological Validity of Neuropsychological Tests in MS*

An important aspect of the validity of any neuropsychological test, especially regarding its clinical applicability, is whether it relates to everyday functioning. There is an emerging literature on the ecological validity of these tests in MS that suggests they are associated with important real-world tasks. We now turn to a brief review of the literature on the association of neuropsychological tests to driving and employment.

#### *Driving*

The motor, visual, and cognitive symptoms of MS can all contribute to difficulties with driving. Akinwuntan and colleagues (2013) aimed to determine what tests would best predict driving ability as measured by performance on a road test. Forty-four mostly female, middle-aged individuals with Relapsing-Remitting MS completed a comprehensive battery of cognitive, physical, and visual tests. Although 12 cognitive and 3 visual tests were moderately correlated ( $r = 0.31$ – $0.63$ ) with performance on the road test, multiple regression revealed that a model containing the following five tests accounted for the most variance ( $R^2 = 0.59$ ) of performance on the road driving test: time to complete the Stroop Color-Word test; the Stroke Driver Screening Assessment (SDSA) directions, compass, and road sign recognition subtests; and the Useful Field of View speed of processing test.

Schultheis et al. (2010) focused on the cognitive contributors to difficulties with driving by measuring cognitive functioning and driving abilities in community-dwelling participants with MS who had no reported visual impairments. Sixty-six middle-aged, mostly female, and Relapsing-Remitting participants with clinically definite MS were included. Participants underwent comprehensive neuropsychological evaluations and behind-the-wheel driving evaluations, and their state-issued driver history abstracts were obtained from the Department of Motor Vehicles to evaluate recent collision and violation involvement. Logistic regression revealed that information processing speed, as measured by the SDMT, was the strongest predictor of behind-the-wheel driving performance (marginally significant at  $p = .07$ ) while visuospatial learning and recall, as measured by the 7/24 spatial recall test, was the strongest predictor of collision and violation frequency (marginally significant at  $p = .06$ ).

#### *Employment*

Employment status is a critical aspect of daily functioning and an important area of MS research, as most people with MS are diagnosed well before typical retirement age. Demographic, cognitive, physical, and emotional factors of MS have been evaluated as potential predictors of employment status. Honarmand and colleagues (2011) examined 106

participants with confirmed MS or CIS who completed a battery of neurological, cognitive, and psychological assessments. The sample was comprised of mostly middle-aged female patients who had Relapsing-Remitting or Secondary Progressive course types. A binary logistic regression, with employment status as the dependent variable, revealed that the Multiple Sclerosis Functional Composite (MSFC; 9-HPT, 25-foot Timed Walk Test, and the PASAT) was the most robust predictor of employment status ( $R^2 = 0.31$ , 68% correctly classified). Although the addition of the Expanded Disability Status Scale (EDSS) to the model did not increase its predictive value, the addition of both the NEO Five Factor Inventory (NEO-FFI) Agreeableness scale and the Hospital Anxiety and Depression Scale Depression (HADS) subscale did; the addition of these variables substantially increased the predictive value of the model to 50% of the variance in employment status accounted for ( $R^2 = 0.50$ , 83% correctly classified). The robust predictive value of the MSFC may be related to its assessment of both cognitive and motor symptoms of MS.

The utility of the PASAT in the MSFC has been questioned, as its predictive value, independent of the motor tasks in the MSFC, has been inconsistent across studies. Strober and colleagues (2014) examined a sample of 77 mostly female and Relapsing-Remitting or Secondary Progressive MS patients. These investigators administered a comprehensive neuropsychological battery, but only the SDMT emerged as a significant predictor of employment status in a stepwise logistic regression analysis, accounting for 15%–20% of the variance with 67% overall classification accuracy. These researchers asserted that their findings provided support for the addition of the SDMT to the MSFC and the potential replacement of the PASAT with the SDMT, given the high association of SDMT performance and employment status.

For both driving and employment, then, the SDMT appears to provide excellent predictive validity, underscoring its usefulness as a core neuropsychological screening measure.

### ***Remediating Cognitive Impairment in MS***

#### *Prospective Memory and Emotional Valence*

Deficits in prospective memory (PM), or the memory for future intentions, are often seen in MS. PM is essential for the successful completion of many everyday tasks necessary for independent living and improving PM is therefore a valuable target for intervention in MS. Rendell et al. (2012) investigated the efficacy of the use of emotionally valenced information to improve PM in participants with MS. A group of 30 MS participants with confirmed MS diagnoses and 30 age, sex, and education-matched controls took part in this study. A laboratory measure of PM, Virtual Week (which is designed like a computerized board game), was used to assess PM. The MS group performed significantly worse

than controls on both the event-based and time-based emotionally valenced Virtual Week tasks. Positivity and negativity enhancement/impairment indices were calculated and it was found that the MS group's performance on event-based tasks was significantly improved by the use of emotionally positive material in the tasks. These results suggest that the use of positive emotional associations and cuing might help to improve PM performance in individuals with MS.

#### *Self-Generated Learning*

O'Brien Chiaravalloti, Arango-Lasprilla, Lengenfelder, and DeLuca (2007) examined the generation effect in MS to assess whether it would improve memory functioning. With the generation effect, material that is produced by an individual is learned and remembered better than information that is provided to that individual. These investigators explored whether even cognitively impaired individuals with MS would benefit from using the generation effect. MS participants were compared with healthy controls and TBI patients. In addition to administering a few standard neuropsychological tests, these authors included a generation effect protocol. This involved 32 sentences presented individually on separate pages. In the Generated Condition, 16 sentences were presented with the last word missing. In the Provided Condition, 16 complete sentences were provided with the last word underlined. The task required participants to read the 32 (alternating) sentences presented individually on separate pages. In the Generated Condition, they had to fill in the blank at the end of the sentence with an appropriate word, and in the Provided Condition, they simply had to read the sentence, including the underlined word. Participants then performed a distractor task, and then were asked to recall the words immediately following this, at a 30-minute delay, and after one week. At both the immediate recall and 30-minute delay, MS participants displayed significantly better recall in the Generated versus Provided condition. These data suggested that MS patients may remember information better when they generate it themselves.

#### *The Testing Effect*

Sumowski and colleagues (2010) examined the testing effect in a group of MS patients that included a subgroup with significant memory deficits. The testing effect has been shown to be a robust cognitive phenomenon. It involves practicing recall rather than simply restudying something to be learned. These investigators examined this effect in an MS patient group matched to a healthy control group on a verbal paired associates (VPA) task that included three conditions: massed restudy (MR), spaced restudy (SR), and spaced testing (ST). Recall on the VPA test using cued recall was measured after a 45-minute delay. These investigators found that both MS and controls had better recall on the VPA list after they did spaced testing compared with the MR and SR conditions.

The effect held even for a subgroup of 16 MS patients who had objective memory impairment. These findings were extremely promising, and suggest the possibility that applying such a spaced testing method to rehabilitation of memory problems in MS could be effective.

### *Cognitive Rehabilitation Interventions*

Parisi et al. (2014) sought to examine the effectiveness of a cognitive rehabilitation program in a group of MS patients, and to determine the relationship between functional neuroimaging (functional magnetic resonance imaging, or fMRI) and performance on neuropsychological measures. Their sample was small, consisting of 18 female Relapsing-Remitting MS patients; half of the patients were assigned to the treatment condition and the other half served as controls. Participants were administered a battery of neuropsychological tests at baseline, after completion of the 12-week cognitive rehabilitation program, and then again at six months, and resting state fMRI was acquired at baseline and at 12 weeks. These investigators found that participants who received the treatment displayed significantly better performance on measures of attention and executive function. Furthermore, the treatment group demonstrated significantly lower levels of depression and improved quality of life. With respect to the neuroimaging findings, the authors reported that better test performance was associated with greater resting state functional connectivity within default mode network regions.

### *Neuroimaging Studies on Cognitive Function in MS*

#### *Structural Neuroimaging*

Generally, cognitive deficits are proportional to MRI-visualized total lesion load on T2 sequences (Bagert, Campbell, & Bourdette, 2002), and regional associations have been reported as well. Sperling and colleagues (2001) found that frontal and parietal region lesion load were correlated with deficits in processing speed and memory. Some studies have also reported an association between MRI lesion location and particular patterns of dysfunction, with primarily frontal lesion patterns associated with executive task dysfunction (Arnett et al., 1994).

Atrophy measures have proven to be as or more associated with patterns of cognitive impairment in MS than lesion burden. Atrophy measures such as bi-caudate ratio, third ventricular width, and brain parenchymal fraction have all been shown to be significantly associated with cognitive impairment in MS (Tekok-Kilic, Benedict, & Zivadinov, 2006; Zivadinov et al., 2001), with some specificity in terms of brain region affected and the types of cognitive impairments observed. Regional frontal volume has been shown to be correlated with performance on measures assessing executive function, attention, and processing speed, while left

temporal atrophy has been shown to be predictive of poor verbal memory and both left and right temporal atrophy associated with visual memory performance (Tekok-Kilic et al., 2006).

Several recent studies have also shown that fiber tract integrity in the brain, as measured by diffusion tensor imaging (DTI), is associated with cognitive impairment in MS. Hulst et al. (2013) compared “Cognitively Impaired” and “Cognitively Preserved” MS patients on common DTI measures. They found that, compared with the Cognitively Preserved patients, the Cognitively Impaired patients demonstrated significantly greater white matter integrity changes in a number of brain regions. Koenig et al. (2013) sought to investigate the relationship between common DTI measures (specifically in the fornix) and cognitive performance in mostly Relapsing-Remitting MS patients and healthy controls. Compared with healthy controls, the MS group showed significantly greater mean diffusivity and longitudinal diffusivity, as well as lower fractional anisotropy, suggesting compromised fiber tract integrity in the MS group. Additionally, the MS group demonstrated significantly worse performance than the healthy controls on a neuropsychological test battery consisting of measures of episodic memory, working memory, and attention. Llufrui et al. (2014) examined the relationship between cognitive performance and structural brain damage using DTI in a sample of Relapsing-Remitting MS patients and healthy controls. They found that MS patients demonstrated widespread abnormalities on DTI indices in both gray matter regions and white matter tracts as compared to control participants. Interestingly, the abnormalities observed within the white matter tracts accounted for more of the variance in cognitive dysfunction.

#### *Functional Neuroimaging*

Initial studies using functional neuroimaging measures showed that MS patients displayed *greater* increases in brain activation relative to non-MS controls when performing complex cognitive tasks (Forn et al., 2006; Hillary et al., 2003). More recently, Loitfelder and colleagues (2011) reported similar findings. They examined fMRI activation patterns during a Go/No Go Discrimination Task and found that Relapsing-Remitting and Secondary Progressive patients displayed greater activation increases during task performance compared with controls. Interestingly, the patterns of increased activation were more pronounced in the Secondary Progressive patients who showed more widespread activation, and also less deactivation.

Findings from other studies have supported a general increase in brain activation in MS patients; however, this pattern has not been consistently observed across all brain areas. On the Computerized Test of Information Processing, Smith and colleagues (2012) found that, compared with controls, MS patients displayed a significant increase in activation in the prefrontal cortex (PFC) and right temporal gyrus;

however, the MS patients displayed *decreased* activation in areas of the left temporal gyrus. This study suggested that the broadly greater task activation in MS patients versus controls may not always hold true across brain areas. Additional research is needed to clarify the conditions under which increased versus decreased activation occur in MS during task performance.

Wojtowicz, Mazerolle, Bhan, and Fisk (2014) sought to explore the relationship between performance variability (on measures of processing speed) and resting-state functional connectivity in a sample of age-matched Relapsing-Remitting MS participants and healthy controls. The authors reported that performance variability was greater in MS patients as compared to healthy controls. Furthermore, MS patients were found to have decreased functional connectivity between regions associated with the default mode network. Finally, with respect to MS patients, those exhibiting less performance variability (better performance) showed increased connectivity between the ventral medial prefrontal cortex (PFC) and the frontal pole.

## Psychiatric Issues

### Depression

The risk for lifetime major depression in MS is approximately 50% (Arnett, Barwick, et al., 2008; Chwastiak et al., 2002; Sadvnick et al., 1996), a figure much higher than the 8% lifetime risk in the general population, but also greater than many other neurological disorders and chronic illnesses.

#### SCREENING FOR DEPRESSION

A common problem associated with the assessment of depression in MS pertains to the overlap between neurovegetative symptoms of depression and MS disease symptoms. Symptoms such as fatigue, sleep disturbance, sexual dysfunction, and concentration difficulties are all neurovegetative symptoms of depression, but they are also symptoms of MS itself. This makes the assessment of depression in MS complicated, because the meaning of such symptoms in MS is unclear. One solution that has been suggested in the literature is to simply discard such symptoms, focusing instead on mood and negative evaluative depression symptoms. Nyenhuis et al. (1995) developed the Chicago Multiscale Depression Inventory (CMDI) for this purpose. The test consists of three 14-item scales, each measuring a different domain of depression. These investigators suggested using only the Mood subscale of the CMDI, as it was least potentially overlapping with MS disease symptoms.

An alternative to the CMDI is the BDI-FS (Beck, Steer, & Brown, 2000). This measure was explicitly developed with medical patients in mind, and includes only mood and negative evaluative symptoms in its seven-item format. There is much to be said for the BDI-FS as a screening measure for

depression in MS. It takes only a few minutes to administer, and has been shown to be valid for detecting depression in MS by Benedict and colleagues (2003). They found that it was highly correlated with other self-report measures of depression, other-report measures of depression, and also distinguished between depressed MS patients in treatment and those not being treated.

Another approach to addressing the neurovegetative depression symptom/MS symptom overlap has been suggested by Strober and Arnett (2010). These investigators proposed a “trunk and branch” model of depression in MS. Rather than disregard neurovegetative symptoms entirely, this model distinguishes between symptoms common to the medical condition (“trunk” symptoms), and those independent of the medical condition that are likely to reflect depression (“branch” symptoms). To test this model, a criterion group of likely depressed MS patients was identified. They were compared to a nondepressed MS group and a group of healthy controls on the BDI (Beck & Steer, 1987). Trunk symptoms were those on which the MS group (depressed and nondepressed combined) endorsed significantly more often than the healthy controls (see Figure 25.1). Branch symptoms were those that were endorsed significantly more often by depressed compared with MS compared with nondepressed MS. The researchers also found that there were some trunk symptoms that were more severe in the depressed compared with nondepressed MS group, so these were also considered core MS depression symptoms. As shown in Figure 25.1, the initial branch symptoms and these latter additional symptoms comprised 12 items from the original BDI.

Strober and Arnett (2015) followed up this study and examined the new 12-item “MS-BDI” relative to existing depression measures commonly used in MS, including the BDI-FS, the CMDI, and the BDI-II. The BDI-FS and the CMDI-Mood subscale had the best sensitivity at 94%. The MS-BDI, however, had the highest specificity and corresponding Positive Likelihood Ratio (PLR) of 12.81. PLR is a measure of the increase in the likelihood an individual has a condition (i.e., depression in this case) if he or she scores above a cutoff. A PLR greater than 10 is almost conclusive for the condition, so the MS-BDI fared extremely well when a cutoff of 7 was used.

Strober and Arnett (2015) examined the validity of the depression measures in another way, by comparing the point prevalence rates they produced with that of the criterion group. When selecting the criterion depressed group from the larger sample of 84 individuals with MS, the point prevalence rate for depression was 20%. Importantly, the MS-BDI also produced a point prevalence rate of 20% when the cutoff of 7 was again used, suggesting that scores on it are tightly linked to more rigorous approaches to diagnosing depression that include clinical interviews. An important caveat to this consideration of the MS-BDI is that the data are based on one study only. With that said, the MS-BDI is appealing because it has the highest PLR of any of the

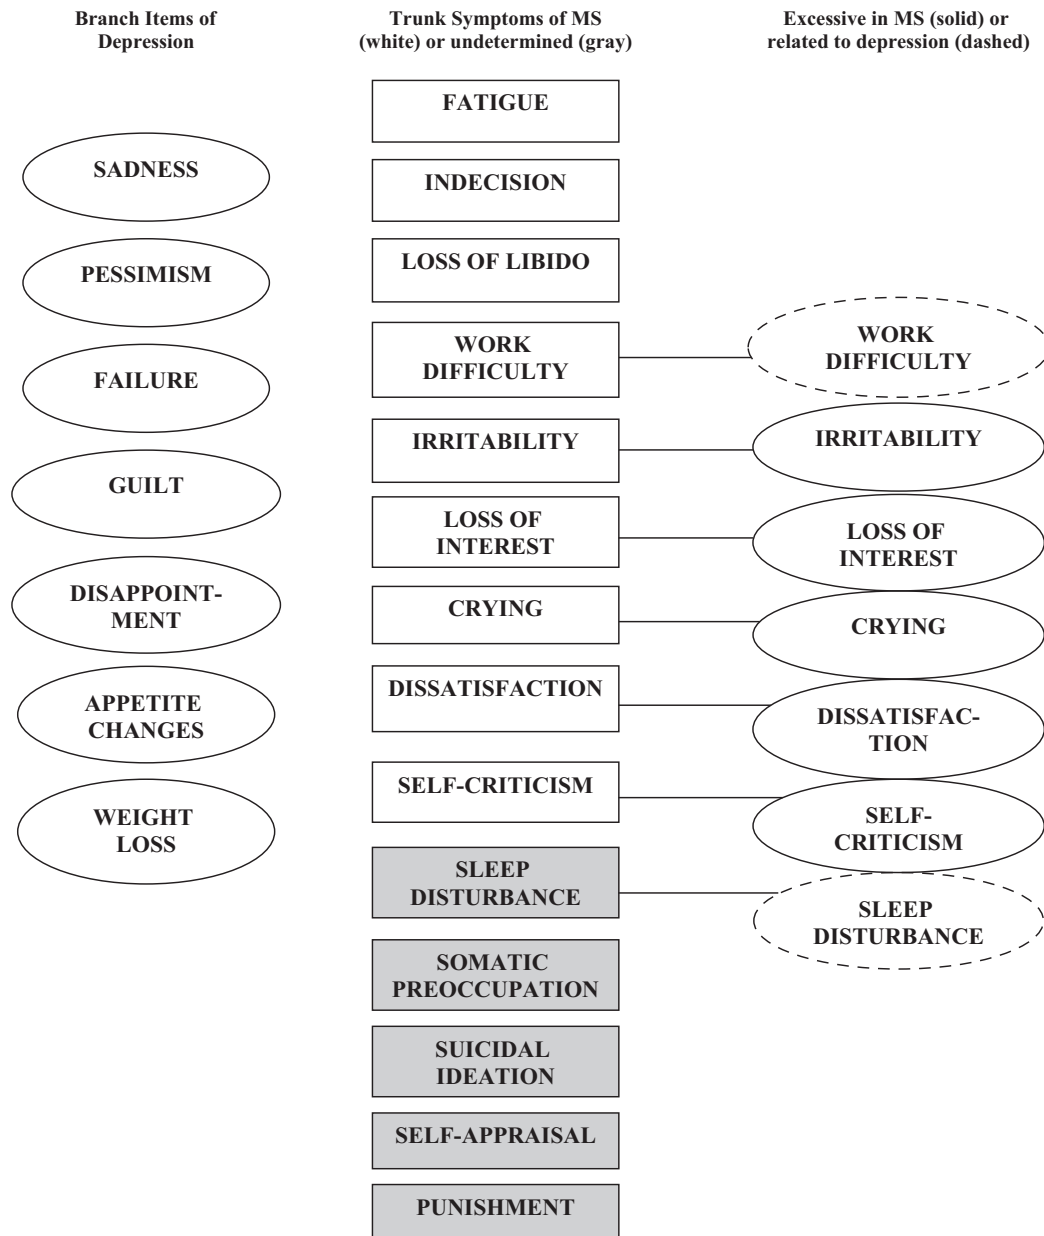

Figure 25.1 Trunk and branch model of depression in MS

Used with permission (Strober & Arnett, 2010)

depression measures assessed, is theoretically driven in relation to MS, incorporates some neurovegetative symptoms, and has prevalence rates comparable to those derived from using a rigorously identified criterion group of depressed MS patients. Still, a cross-validation study on a larger sample will be necessary before clinical application of the MS-BDI would be appropriate.

Another depression measure that has been frequently used in MS is the HADS. This 14-item measure has advantages over the other depression scales already discussed in that it also measures anxiety, which, as will be discussed, is very common in MS. Honarmand and Feinstein (2009) examined

the Depression scale of the HADS in an MS sample and found excellent sensitivity (.90) and specificity (.87). Using a cutoff of 8, it also resulted in a point prevalence rate of depression in their sample of 16%, a value close to the 20% for the MS-BDI and the criterion group from Strober and Arnett's (2015) study.

As far as clinical recommendations, at this stage of our knowledge, the BDI-FS clearly appears to be the best screening measure for depression in MS. Its sensitivity is very high, and a cutoff of 4 or above has been demonstrated to be best in at least two studies, a cutoff that is also consistent with what is recommended in the BDI-FS manual for medical

patients in general. The sensitivity and specificity of the HADS Depression scale are also excellent; the one caveat is that it has been validated in one MS study only, so greater caution in its use is recommended.

Because of the high prevalence of depression in MS, patients should be routinely screened, with particular optimal approaches for this outlined earlier. Also, it is very treatable through brief and even telephone-based cognitive behavioral therapy (Hind et al., 2014; Mohr et al., 2005; Mohr et al., 2000), as well as group therapy. Still, depression has historically been undertreated in MS, despite the fact that it is unlikely to remit spontaneously.

#### COPING AND DEPRESSION

Depression in MS has also been consistently found to be associated with the increased use of generally less effective emotion-focused or avoidant-focused coping strategies, and the decreased use of more adaptive active or problem-focused strategies (Arnett, Higginson, Voss, & Randolph, 2002; McCabe, McKern, & McDonald, 2004; Mohr, Goodkin, Gatto, & Van Der Wende, 1997; Pakenham, 1999; Rabinowitz & Arnett, 2009). Despite this, coping strategies are not routinely screened for in clinical evaluations. There is a need for reliable and well-validated coping measures for clinical use, but to our knowledge, none have been fully validated in MS patients. This is unfortunate, because knowledge of coping strategies, especially in psychotherapy contexts, would be useful in guiding therapy. In addition to providing a potential treatment target, and improving quality of life and well-being, altering maladaptive coping strategies in MS patients might also mitigate the impact of cognitive dysfunction on mood (Arnett et al., 2002; Rabinowitz & Arnett, 2009), and fatigue (Ukueberuwa & Arnett, 2014).

#### OTHER FACTORS ASSOCIATED WITH DEPRESSION

Even though depression is treatable in many MS patients, treatments are effective in reducing depression to remission only about 50% of the time (Ehde et al., 2008; Mohr, Boudewyn, Goodkin, Bostrom, & Epstein, 2001). Depression in MS negatively affects quality of life, adaptive functioning, and well-being (Vargas & Arnett, 2010); interferes with medication adherence (Bruce, Hancock, Arnett, & Lynch, 2010); and may increase mortality (Feinstein, O'Conner, & Feinstein, 2002). There is a need for developing models with greater explanatory power that could result in the development of better treatments to reduce depression in MS.

A history of depression appears to increase risk for future depressive or manic states in MS. Some studies show that depression is associated with cognitive dysfunction, with impairments in complex attention and information processing speed, as well as executive deficits, showing the greatest associations (Arnett, Barwick, et al., 2008; Sundgren,

Maurex, Wahlin, Piehl, & Brismar, 2013). These associations are most likely to be seen when depression symptoms contaminated by MS symptomatology (e.g., neurovegetative symptoms) are excluded from the measurement of depression and the focus is on mood and negative evaluative depression symptoms (Arnett, Higginson, & Randolph, 2001; Sundgren et al., 2013). Coping may also be an important moderator between cognitive dysfunction and depression in MS, with cognitive deficits most likely to predict depression if patients rely on avoidant coping or minimally use active coping (Arnett et al., 2002; Rabinowitz & Arnett, 2009). The severity of neurologic disability is inconsistently related to depression in MS (Arnett, Barwick, et al., 2008).

Numerous factors appear to be associated with depression in MS, including high levels of perceived stress, low levels of perceived social support, and disease exacerbation/pharmacological treatment (Arnett, Barwick, et al., 2008). Depression in MS is unlikely to be governed by genetic factors, because studies show that unipolar major depression is not more common in first-degree relatives of depressed MS patients compared with first-degree relatives of non-depressed MS patients. Still, biological factors are clearly associated with depression in MS, as indicated by research showing that depression is predicted by both neuroanatomical and functional neuroimaging parameters.

#### PHYSICAL ACTIVITY AND DEPRESSION

The mood-boosting effects of physical activity have been observed in healthy controls as well as psychiatric populations, leading it to be studied as a potential cost-effective treatment for depression. Physical activity may be an optimal intervention for those with MS, as this disease is often characterized by high rates of depression and low levels of physical activity. Kratz and colleagues (2014) established physical activity as a successful intervention for depression in MS and additionally evaluated positive and negative affect as mediators for the effects of physical activity counseling on depressive symptoms. Ninety-two individuals with clinically definite MS were randomized into a treatment condition ( $n = 44$ ) and a waitlist control condition ( $n = 48$ ). The groups were well-matched in terms of sex and course type. Depressive symptoms and positive and negative affect were evaluated before and after a 12-week motivational interviewing intervention focused on increasing physical activity. Mediation analyses showed that motivational interviewing had significant effects on both positive and negative affect, and these in turn both significantly influenced depressive symptoms. When physical activity, as measured by the 7-day Physical Activity Recall Interview, was included in the model, however, only positive affect mediated the relationship between changes in physical activity and depressive symptoms. These results suggest that physical activity may improve depressive symptoms through an increase in positive affect, and supplementary treatment should be pursued to decrease negative affect and further reduce depressive symptoms.

Neuropathology has generally been shown to be associated with depression in MS (Feinstein, 2004). Together, lesion load, brain atrophy, and white matter fiber tract integrity account for up to 43% of depression variance in MS (Bakshi et al., 2000; Feinstein et al., 2010), with temporal and frontal brain regions most often implicated (Arnett, Barwick, et al., 2008; Feinstein et al., 2010). However, a study by Gobbi et al. (2013) was not as conclusive. These investigators examined structural neuroanatomical correlates of both depression and fatigue in MS and failed to find any significant relationships between lesion distribution and depression or fatigue. Similarly, there were no significant relationships between white matter atrophy and depression or fatigue. However, gray matter atrophy in several brain regions (including frontal, parietal, and occipital lobes) was significantly related to both depression and fatigue, and the left middle frontal gyrus and right inferior frontal gyrus were associated with depression but not fatigue. With these studies in mind, the mechanisms by which this type of structural brain damage leads to depression in MS are unclear. It may be that such structural changes lead to characteristic functional brain changes that in turn predict depression in MS.

Functional brain variables in relation to emotional functioning in MS have been examined in only a limited way in one study. Passamonti and colleagues (2009) explored emotional processing in a small group ( $N = 12$ ) of Relapsing-Remitting MS participants. They found that, compared with controls, MS participants showed a lack of functional connectivity between the amygdala and the PFC during an emotional processing task involving the matching of affective faces. Although the MS participants in the study were not clinically depressed, they reported significantly higher scores on depression measures than controls. These authors hypothesized that reduced functional connectivity could reflect a disruption in an important affective processing system in the brain of MS patients early in the disease process that might ultimately put them at risk for emotional difficulties such as depression. Clearly, further work examining functional neuroimaging and depression in MS is warranted.

### Anxiety

Anxiety has sometimes been shown to be more common than depression in MS, but has been studied far less extensively. The point prevalence of clinically significant anxiety is thought to be about 25%, but lifetime prevalence is unknown. The cause of anxiety in MS is unknown, but it tends to be prominent in the early stages of the disease when the diagnosis and prognosis are most uncertain. Decline in distress is associated with more definitive diagnostic statements by treatment professionals. There are no published studies treating specific anxiety disorders in MS. At least one study has shown that comorbidity of anxiety and depression in MS is more associated with thoughts of self-harm, social

dysfunction, and somatic complaints than either alone (Feinstein, O'Connor, Gray, & Feinstein, 1999). The only other emotional disorder occurring with any significant frequency in MS is bipolar disorder, with point prevalence estimated at 0%–2% and lifetime prevalence at 13%–16%. There are no published treatment studies of bipolar disorder in MS.

### Conclusion

MS is the most common nontraumatic neurological condition of early to middle adulthood, and the most common demyelinating condition. In this chapter, we have reviewed common sequelae associated with MS, especially focusing on neurocognitive impairments and emotional difficulties including depression and anxiety. We have also included practical suggestions for neuropsychological assessment and for the assessment of depression. Neuropsychologists can play a critical role in the assessment and treatment of cognitive and emotional difficulties in MS. This chapter provides some evidence-based suggestions that can optimize patient care.

# 26 Neuropsychological Functioning in Autoimmune Disorders

*Elizabeth Kozora, Andrew Burlison, and Christopher M. Filley*

## Introduction

Autoimmune disorders represent a spectrum of conditions in which the immune system mistakenly attacks and destroys healthy body tissue. There are more than 80 autoimmune disorders, and the prevalence of autoimmune disease in the United States is about 8%, or approximately 23.5 million people. Women make up an estimated 75% of autoimmune patients, and according to the 2004 U.S. National Women's Health Center, these diseases constitute the fourth largest cause of disability among women. Many autoimmune diseases are characterized by circulating autoantibodies that target healthy tissue, and the brain may be prominently affected. Cognitive dysfunction is one of many manifestations of autoimmune central nervous system (CNS) involvement. Despite an exponential increase in studies over the past ten years, the course, prognosis, neurobiological mechanisms, and optimal treatment of cognitive dysfunction in autoimmune diseases have remained largely elusive.

The most extensive investigation regarding the prevalence and biobehavioral correlates of cognitive dysfunction in disorders of autoimmunity has centered on systemic lupus erythematosus (SLE). However, there is accumulating evidence that other autoimmune disorders such as antiphospholipid syndrome (APS), rheumatoid arthritis (RA), and primary Sjögren's syndrome (PSS) commonly feature cognitive dysfunction that may be directly associated with the autoimmune pathologic process. This chapter will present the basic epidemiology and review the neuropsychological literature in SLE, APS, RA and PSS, four autoimmune disorders that have been the focus of many recent neurobehavioral studies. In addition, the biobehavioral mechanisms and neuroimaging correlates of cognitive dysfunction for these disorders will be discussed.

## Systemic Lupus Erythematosus

### *Definition and Epidemiology*

SLE is typified by the production of autoantibodies, and a hallmark of the disease is the presence of serum antibodies directed to nuclear constituents of the cell body. The prevalence of SLE worldwide is approximately 20–150 cases per 100,000, and in women rates vary from 164 (in Caucasians)

to 406 (in African Americans) per 100,000 (Chakravarty, Bush, Manzi, Clarke, & Ward, 2007; Lawrence et al., 1998; Pons-Estel, Alarcon, Scofield, Reinlib, & Cooper, 2010). SLE can damage almost any organ of the body, including the brain. Other organ systems prominently affected are the skin, joints, heart, lungs, and kidneys. Epidemiological research estimates that 0.51% of the U.S. population has SLE, or approximately 1.4–1.5 million people. Approximately 90% of SLE patients are women. Patients are most frequently diagnosed with SLE in their 20s and 30s. In the United States, most studies suggest that SLE is more common in African Americans, African Caribbeans, and those with Asian backgrounds in comparison to Caucasians. The diagnosis of SLE is currently based on the presence of at least four out of 11 manifestations (Hochberg, 1997) including malar (butterfly) rash, discoid rash, photosensitivity, oral ulcers, arthritis, serositis (pericarditis or pleuritis), renal dysfunction, neurologic syndromes, hematologic disorder, immunologic disorder, and the presence of an abnormally high titer of antinuclear antibody.

### *Neuropsychiatric Systemic Lupus Erythematosus*

Over 50% of patients with SLE demonstrate psychiatric or neurologic disorders indicating CNS involvement (Bluestein, 1992; West, 2007). Neuropsychiatric (NP) manifestations in SLE are diverse, and may include clinically major overt disorders such as stroke, seizures, and psychotic events, or less dramatic but still significant syndromes such as depression, anxiety, headache, and mild cognitive dysfunction (MCD; see Kozora & Filley, 2011). Estimates of the prevalence of NP manifestations in SLE range from 14% to 75%, a variability that largely reflects differences in classification, assessment tools, subject selection, and attribution of cause (Hanly, 2007).

In SLE patients with NP involvement, pathogenic mechanisms have been distinguished on the basis of NP presentation (West, 1994; West, Emlen, Wener, & Kotzin, 1995). In those with diffuse manifestations (e.g., psychosis and depression), autoantibodies directed to CNS antigens have been proposed as important pathogenic factors. In these cases, immunologically mediated neuronal injury is hypothesized to be caused by a variety of antineuronal autoantibodies

(Bluestein & Woods, 1982; Kelly & Denburg, 1987; Robbins et al., 1988; Temesvari et al., 1983; Wekking, Nossent, van Dam, & Swaak, 1991; Zvaifler & Bluestein, 1982). Anti-ribosomal P antibodies, anti-neuronal antibodies, and, in the cerebrospinal fluid (CSF), elevated IgG index (a major class of immunoglobulins) and oligoclonal bands, have all been regarded as biological markers of diffuse CNS pathology in SLE (West, 1994; West et al., 1995). In contrast to diffuse disease, focal CNS presentations in SLE such as stroke syndromes, seizures (often of focal onset), movement disorders, and myelopathy have been postulated to be due to ischemia (West, 1994; West et al., 1995). These cases appear to be secondary to CNS hypercoagulability (e.g., related to antiphospholipid antibodies) and thrombosis, and less commonly to vasculitis. Focal stroke presentations are typically due to vascular occlusion, and these patients usually have evidence of antiphospholipid antibodies and abnormal brain magnetic resonance imaging (MRI) scans (West et al., 1995). A bland, diffuse, noninflammatory microvasculopathy, sometimes in association with leukocyte plugging, and mediated by complement and endothelial cell activation, is the predominant vascular abnormality in autopsy studies of SLE patients (Belmont, Abramson, & Lie, 1996; Belmont et al., 1986; Ellis & Verity, 1979; Hanly et al., 1992; Johnson & Richardson, 1968). These changes, which appear to be independent of antiphospholipid antibodies, are found in anatomical proximity to cerebral microinfarction, indicating a causative association.

As described in the past (West, 1994; West et al., 1995), altered transport properties of the choroid plexus due to deposition of complement (serum proteins involved in immunoreactivity) in NPSLE are thought to interfere with CNS activity. Inflammatory processes as well as the effects of cytokines (interleukin-1, interleukin-6, and tumor necrosis factor) have also been recognized as potential mediators of CNS alterations. Neuroendocrine and immune system interactions resulting from chronic stress, antioxidative mechanisms, and neuropeptides and endocrine factors also appear to be related to NPSLE. The neuropeptides vasopressin, neuropeptide, and substance P also appear related to NP activity in SLE in animal models (Bracci-Laudiero, Aloe, Lundeberg, Theodorsson, & Stenfors, 1999; Sakic et al., 1999) and human studies (Harle et al., 2006; Lapteva, Yarboro, & Roebuck-Spencer, 2006). Additional mechanisms causing or related to NP symptoms in SLE are diverse and may include infections, medications, hypertension, uremia, electrolyte imbalances, fever, thyroid disease, atherosclerosis, fibromyalgia, and sleep apnea.

In 1999, definitions for 19 NP syndromes were developed, and diagnostic agreement was empirically evaluated by a multidisciplinary committee convened by the American College of Rheumatology (ACR) (1999). Definitions of NPSLE syndromes were developed for CNS and peripheral nervous system (PNS) NP manifestations (Table 26.2), and recommendations for diagnostic testing were produced with input

from several disciplines, including neuropsychology. Since none of the syndromes are specific to SLE, relevant factors were listed as “exclusions” if they caused identical symptoms and could be separated from the SLE process (i.e., history of diabetes), and “associations” if the symptoms could be caused by SLE or by another nonmodifiable factor (i.e., drug effects). In a recent review of studies between April 1999 and May of 2008 evaluating classification of the 19 NP syndromes proposed by the ACR, the prevalence of NP syndromes in 2049 SLE patients was estimated to be 56.3%, and the most frequent NP syndromes were headache (28.3%), mood disorders (20.7%), cognitive dysfunction (19.7%), seizures (9.9%), and cerebrovascular disease (8.0%) (Unterman et al., 2011). In another study of 1047 SLE patients between 1999 to 2010, 47.2% of the patients had one or more NP events, and the most frequent NP syndromes were headache (52%), mood disorders (14.4%), seizure disorder (5.8%), anxiety (5.7%), and cerebrovascular disease (5.1%) (Hanly et al., 2011).

### *Cognitive Dysfunction*

The ACR defined the NPSLE syndrome of “cognitive dysfunction” as the presence of “significant deficits in any or all of the following cognitive functions: complex attention, executive skills (e.g., planning, organizing, and sequencing), memory (e.g., learning and recall), visual-spatial processing, language (e.g., verbal fluency) and psychomotor speed.” The committee reviewed a number of brief mental status examinations, but because of high false negative rates of these tests, and their failure to detect mild cognitive deficits in many cases (Karzmark, 1997; Nelson, Fogel, & Faust, 1986), the committee concluded that there was no substitute for detailed neuropsychological assessment. Due to the limitations imposed by longer and comprehensive batteries (i.e., time requirements and financial burden), the committee recommended a short one-hour battery. The tests selected for this battery had demonstrated decline in SLE patients in prior studies, and include measures of estimated IQ; complex attention verbal and visual learning and memory; verbal fluency; and complex visuomotor tasks (1999). Cognitive studies subsequent to these recommendations commonly (but not always) included these domains as the minimum to be surveyed. Notably, in the review of studies by Unterman et al. (2011), there was a wide range of cognitive dysfunction prevalence (0%–80%), mostly due to the use of different methods of neuropsychological testing, and in some cases the use of chart-driven self-report methods.

Cognitive deficits using standard neuropsychological tests are well documented in patients with SLE. Deficits in attention, learning and recall, fluency, complex psychomotor functions, visuospatial skills, and motor dexterity have been most commonly identified (Brey et al., 2002; Carbotte, Denburg, & Denburg, 1986; Conti et al., 2012; Denburg, Carbotte, & Denburg, 1997; Ferstl, Niemann, Biehl, Hinrichsen, & Kirch, 1992; Ginsburg et al., 1992; Glanz et al.,

1997; Hanly et al., 1993; Koffler, 1987; Kozora et al., 2008; Kozora et al., 2011; Kozora, Ellison, & West, 2004; Kozora, Filley, et al., 2012; Kozora, Thompson, West, & Kotzin, 1996; Maneeton, Maneeton, & Louthrenoo, 2010; Peretti et al., 2012; Sonies, Klippel, Gerber, & Gerber, 1982; Wekking, Nossent, et al., 1991). Across studies, the incidence of cognitive impairment in SLE patients with overt NP activity such as seizures, stroke, and major depression has ranged from 20% to 87%, with earlier studies demonstrating a higher incidence (Abda et al., 2013; Carbotte et al., 1986; Conti et al., 2012; Denburg et al., 1987a; Glanz, Schur, Lew, & Khoshbin, 2005; Hanly et al., 1992; Hay, Black, Huddy, Creed, Tomenson, Bernstein, & Holt., 1992; Koffler, 1987; Kutner, Busch, Mahmood, Racis, & Krey, 1988; Sonies et al., 1982; Stein, Walters, Dillon, & Schulzer, 1986; Vogel, Bhattacharya, Larsen, & Jacobsen, 2011; Wekking, Nossent, et al., 1991). In the absence of other NP disorders such as seizures and stroke (i.e., non-NPSLE), cognitive dysfunction has been reported in some 20%–60% of SLE patients (Brey et al., 2002; Carbotte et al., 1986; Denburg et al., 1987a; Hanly et al., 1992; Hay et al., 1992; Koffler, 1987; Kozora, Arciniegas, Duggan, West, & Filley, 2013; Kozora & Filley, 2011; Kozora et al., 1996; Kutner et al., 1988; Maneeton et al., 2010; Norwicka-Sauer, Czuszyńska, Smolenskda, & Siebert, 2011; Peretti, Peretti, Kozora, Papathanassiou, Chouinard, & Chouinard, 2012; Wekking, Nossent, et al., 1991; Wekking, Vingerhoets, van Dam, Nossent, & Swaak, 1991). For the purposes of this chapter, we continue to use the terms *NPSLE* and *non-NPSLE*; however, we acknowledge the confusion that may be associated with this terminology. As noted earlier, there are 19 NP syndromes in SLE, one of which is cognitive dysfunction. Many SLE investigators, intending to focus on mechanisms and neuroimaging analysis of cognitive dysfunction, exclude patients with any other overt CNS activity such as stroke, seizures, etc. (non-NPSLE) to exclude confounding influence on cognition.

In Figure 26.1 we illustrate the range of cognitive impairment found in studies of NPSLE, non-NPSLE, and (where available) controls. Differences between studies are largely methodological, related to differing characteristics of the SLE sample, selection of tests, and classification of impairment. The classification of impairment is also problematic, as it has been based on several approaches (as outlined at the bottom of Figure 26.1). Some studies compare patient and control groups on tests to assess statistical decline. Other studies utilize norm-referenced criteria and “domain” groups to determine if SLE patients are performing in the “impaired” range. Definitions of impairment frequently refer to one or two standard deviations below the norm on individual tests or domains. Estimated premorbid intellectual levels have also been used to estimate decline in performance across specific cognitive areas.

Despite the recommendations of the ACR to standardize assessment and classification schemes, diversity across study

design is prevalent (see Tables 26.1 and 26.2). The ACR proposed a battery of tests, and our group established the reliability and validity of this cognitive battery in relation to a larger SLE battery (Kozora et al., 2004). The inclusion of specific “tests” proposed by the ACR has more consistently emerged across study sites of cognition in SLE (Doninger, Fink, & Utset, 2005; Emori et al., 2005; Julian et al., 2012), but there is still variation in the definition of “cognitive impairment” and no published studies have attempted to compare classification schemes or establish the sensitivity and specificity of the neuropsychological batteries in SLE. In 2007, an Ad Hoc Cognition Sub-committee for the Committee on Lupus Response Criteria further expanded the definition of cognitive dysfunction to include definitions of focal decline (impairment in one or more measures within one domain) and multifocal impairment (decline if impairment exists on measures spanning two or more domains) (Sub-committee, 2007). These definitions, if widely used, may help to standardize cognitive changes over time in SLE patients.

### *Evidence of Mild Cognitive Dysfunction*

Studies over several decades have supported the existence of MCD in SLE (MCD-SLE), although this descriptor was not formally introduced until 2011 (Kozora & Filley, 2011).

Physical Inactivity

Carbotte et al. (1986) reported that 42% of the SLE subjects with no known additional NP activity were cognitively impaired in a wide variety of areas. Kutner et al. (1988) found that 50% of the SLE patients with no known additional NP activity were impaired on their battery. Denburg et al. (1987a) reported that 42% of the SLE patients without any additional NP diagnoses were globally impaired. Wekking,

Nossent, et al. (1991) observed that 40% of their SLE patients with no additional NP activity had deficits on three or more cognitive tests. In similar SLE cohorts, cognitive impairment was found in 17% (Hay et al., 1992), 20% (Carlomagno et al., 2000; Hanly et al., 1992), and 27%. (Monastero et al., 2001) of subjects. Finally, Norwicka-Sauer et al., (2011) reported that 47.2% of the non-NPSLE had one to three tests in the impaired range, with none severely impaired.

In our original study (Kozora et al., 1996), 29% of non-NPSLE patients had deficits consistent MCD-SLE (based on two out of eight domain scores considered impaired). Compared to controls, the non-NPSLE patients were impaired on composite domain scores of attention and fluency, which included both verbal and nonverbal modalities. In our 2004 study (with a new cohort of 22 non-NPSLE patients), we reported that 23% of the subjects had deficits consistent with MCD-SLE, including significantly lowered scores in visuo-motor speed, attention, and motor functioning in comparison to controls (Kozora et al., 2004). In a third cohort of 84 non-NPSLE patients, 23.8% had MCD-SLE, with lower cognitive performance on measures of visuo-motor speed, working memory, verbal learning, and sustained visual attention when compared to controls (Kozora et al., 2012). In a smaller group ( $n = 20$ ) of non-NPSLE patients in a new geographic site (screened and tested in New York with identical methods and test battery as in our original Denver studies) we found a prevalence of MCD-SLE of 60% (Kozora, Erkan, et al., 2013). Compared to the 84 SLE patients in Denver, these patients had greater deficits in areas of verbal fluency, visuo-motor speed, and sequencing skills. To adjust for differences in sample size, we selected 20 SLE patients from the Denver group to match to the New York group. Reanalysis continued to disclose large differences in the frequency of MCD-SLE (60% in New York compared to 25% in Denver). The greater duration of disease and higher prevalence of medical complications in the New York group might have contributed to this difference. Future studies that better evaluate site or selection bias are warranted.

### *Domains of Cognitive Impairment*

A summary of 20 studies that included at least four or more domains of cognitive testing using standardized neuropsychological tests in SLE patients from 1987 through 2014 can be found in Table 26.3. We have reorganized our domain categories from a prior version (Kozora, 2008) and acknowledge that this approach provides only a broad "estimate" of impaired cognitive domains within SLE. Not all the studies investigating a particular domain appear in Table 26.3; sample sizes across studies range from 20 to 93. The columns in the table are ordered based on the number of studies that included tests within a domain. For example, learning and memory was the most commonly studied domain and appears first in the table. Adjusting for the studies that included this domain, 79% of the studies report impairment

Table 26.3 Neuropsychological impairment by domain in SLE: summary of battery-approach Studies

<b>Total Impairment</b>	<b>1,023</b>	<b>14/20 (70%)</b>	<b>15/19 (79%)</b>	<b>13 / 18 (72%)</b>	<b>12/16 (75%)</b>	<b>12/14(86%)</b>	<b>8/15 (53%)</b>	<b>2/9 (22%)</b>	<b>5/9 (56%)</b>	<b>3/6 (50%)</b>

Note: Due to differences in each author's methodology and information available, this table is intended as our interpretation of the literature and should only be considered an overall estimate of cognitive impairment in SLE.

in verbal learning and memory, and 70% in visual learning and memory. Attention (which includes auditory and visual tasks, sustained visual attention, selective attention, and rapid auditory information processing) was impaired in 72% of the studies. Executive functions (measuring problem solving, hypothesis testing, fluency, and sequential visuomotor abilities such as Trail Making Test B) were impaired in 75% of the studies. Motor functions (including motor coordination, speed, and reaction time) were impaired in 56% of the studies. Visuospatial measures (i.e., visuoperceptual and visuoconstructional tasks) were impaired in 53% of the studies. Additional studies not included in the table (because of a focus on one domain or test) clearly suggest that attention and information processing, learning and memory, visuomotor speed, and various measures of executive functions continue to be found impaired in studies from 2005 to 2014 (Conti et al., 2012; Emori et al., 2005; Glanz et al., 2005; Julian et al., 2012; Kozora et al., 2012; Norwicka-Sauer et al., 2011; Paran et al., 2009). Language skills (including auditory and reading comprehension and naming) have been rarely studied in SLE, and, when included, have been found to be impaired in less than 22% of the SLE subjects. Some studies do report deficits in aspects of verbal skills and auditory comprehension (Brey et al., 2002; Maneeton et al.,

2010). Although half of the studies suggest lowered overall intelligence (Denburg et al., 1987a; Koffler, 1987; Kozora et al., 1996; Loukkola et al., 2003; Papero, Bluestein, White, & Lipnick, 1990), few studies included this domain (see Table 26.2).

#### LEARNING AND MEMORY

As illustrated in Table 26.3, a majority of the cognitive studies in SLE have included measures of verbal and non-verbal learning and memory, and deficits using normative data, comparison with control groups, or decline from premorbid levels have been identified (Brey et al., 2002; Carbotte et al., 1986; Denburg et al., 1987a; Emori et al., 2005; Ferstl et al., 1992; Glanz et al., 2005; Glanz et al., 1997; Hanly et al., 1992; Kozora et al., 2004; Kozora et al., 1996; Kutner et al., 1988; Loukkola et al., 2003; Menon et al., 1999; Monastero et al., 2001; Paran et al., 2009; Rummelt et al., 1991; Sailer et al., 1997). In our original study, non-NPSLE patients demonstrated a greater frequency of impairment in a learning domain (combined verbal and visual tasks) compared to controls (Kozora et al., 1996). In a later study, a combined NPSLE and non-NPSLE group showed a greater frequency of impairment in visual

memory tasks compared to verbal tasks (Kozora et al., 2004). In our recent study of 64 non-NPSLE patients, we found that more than 20% were impaired in verbal memory, and more than 40% were impaired in visual memory (Kozora et al., 2008). Although some authors studying SLE have suggested that visual memory may be more impaired in SLE compared to verbal memory (Coin-Mejias et al., 2008; Ferstl et al., 1992), a review of studies comparing SLE patients to healthy controls on verbal and nonverbal domains would suggest that most are impaired on both these aspects of memory.

#### ATTENTION AND INFORMATION PROCESSING

Impairment in sustained attention, complex attention, and information processing are also commonly measured and impaired in SLE (Brey et al., 2002; Ginsburg et al., 1992; Glanz et al., 2005; Hanly et al., 1992; Holliday, Navarete, Escalante, Saklad, & Brey, 2000; Kozora et al., 2004; Loukkola et al., 2003; Maneeton et al., 2010; Norwicka-Sauer et al., 2011; Peretti et al., 2012; Petri, Naqibuddin, Carson, Wallace, et al., 2008; Sailer et al., 1997; Vogel et al., 2011; Wekking, Nossent, et al., 1991). When accounting for all the studies in this area (many not represented in Table 26.2), this may be the most impaired cognitive domain in SLE. A variety of auditory and visual tasks of sustained attention, selective attention, and working memory have been studied in SLE. Several studies have explored more demanding attentional tasks in SLE, including the Paced Auditory Serial Addition Test (PASAT) (Gronwall, 1977), a task that assesses these cognitive processes by requiring attention to auditory input and inhibition of response encoding while attending to the next presented number, and performing at an externally determined pace (Spree & Strauss, 1991). In 2004, we reported that global PASAT performance was significantly lower in SLE patients with and without NP manifestations compared to controls. SLE patients with NP symptoms performed in the mildly to moderately impaired range while SLE patients without NP activity performed in the mildly impaired range (Kozora et al., 2004). In a study including SLE patients and controls, Shucard, Parrish, Shucard, McCabe, Benedict, and Ambrus (2004) reported higher rates of impaired PASAT performance in relation to the pace of the task: 11.1% of SLE and 7.4% of controls were impaired on the 2.4-second rate, and 17.8% of SLE and 3.7% of controls on the 2.0-second rate. Covey, Shucard, Shucard, Stegen, and Benedict (2012) found that SLE patients performed more poorly than controls on the PASAT total score, and identified the PASAT as the most sensitive measure of SLE-induced cognitive impairment from a larger battery of cognitive tests. In a study with non-NPSLE, 29% of the subjects were impaired on the PASAT (Kozora, Arciniegas, et al., 2013). Several studies have further analyzed the pattern of responses on the PASAT in SLE and show that SLE patients used strategies such as “chunking,” suggesting a

tendency to use less-demanding working memory strategies to complete the task (Kozora, Arciniegas, et al., 2013; Shucard et al., 2004)

#### PROBLEM SOLVING AND EXECUTIVE FUNCTIONING

Problem-solving deficits and poor executive function have been identified in many SLE patients. However, classification of tests as specifically assessing executive function, problem solving, and/or attention has varied across studies, an issue that makes generalizations about this domain difficult. Using problem-solving tasks that focus on higher level verbal and nonverbal reasoning as well as hypothesis testing and decision making, deficits were noted in approximately 60% of the studies reviewed (Brey et al., 2002; Conti et al., 2012; Denburg et al., 1987a; Kutner et al., 1988; Papero et al., 1990; Peretti et al., 2012; Sailer et al., 1997; Vogel et al., 2011). Expanding the category to include fluency and visuomotor sequencing tasks increases the number of studies that report impairment in this area (Denburg et al., 1987a; Emori et al., 2005; Glanz et al., 2005; Kozora et al., 1996; Menon et al., 1999; Norwicka-Sauer et al., 2011).

#### VISUOSPATIAL/VISUOCONSTRUCTION

Fewer than half of the studies in Table 26.3 include this domain, and the findings are somewhat mixed. These differences may be related to the variety of assessment techniques ranging from graphomotor drawings to copy-and-command as well as visuoconstruction with blocks or visuoperception with puzzles (Conti et al., 2012; Ginsburg et al., 1992; Hanly et al., 1992; Koffler, 1987; Kutner et al., 1988; Monastero et al., 2001; Vogel et al., 2011). In several studies, visuoconstruction using blocks was impaired compared to controls (Denburg, Carbotte, Ginsberg, & Denburg, 1997; Kozora et al., 2004) but not in others (Emori et al., 2005; Glanz et al., 2005; Glanz et al., 1997; Kozora & Filley, 2011; Loukkola et al., 2003). Drawings from copy are not commonly impaired compared to controls (Denburg et al., 1987a), although in one study NPSLE and non-NPSLE were more impaired (Monastero et al., 2001). In a recent study of 58 consecutive SLE patients, the visuospatial domain was the most impaired (Conti et al., 2012). Visuomotor functions, including basic psychomotor tasks, are commonly impaired in SLE, as shown in Table 26.3 and as reviewed in the computerized screening section.

#### LANGUAGE

Disturbances in language are rarely observed in SLE, although it is apparent that they are rarely sought (Table 26.3). The commonplace clinical impression of preserved language in most cases of SLE therefore has some limited support, but more study of this question is needed.

## MOTOR FUNCTION AND REACTION TIME

Reaction time (Ferstl et al., 1992; Menon et al., 1999; Sailer et al., 1997) as well as tests measuring psychomotor speed (i.e., motor coordination and motor speed) are also commonly impaired in SLE patients (Brey et al., 2002; Denburg et al., 1987a; Emori et al., 2005; Glanz et al., 2005; Glanz et al., 1997; Hanly et al., 1992; Kozora et al., 2004; Kutner et al., 1988; Loukkola et al., 2003; Rummelt et al., 1991). Many studies using computerized testing further support a decline in reaction time in SLE compared to controls, as reviewed in the next section.

*Neuropsychological Screening*

The use of brief neuropsychological screening batteries and computer-assisted cognitive testing is increasingly common for generating outcome measures in clinical trials across a range of neurobehavioral disorders. To date, a number of “computerized” assessments have been proposed and used in SLE research, and have the advantages of minimizing patient time and expense. Future studies relevant to scientific advancement in our understanding MCD in SLE may require highly specialized testing, but the increasing need to improve access, reduce financial burden, and provide more immediate and useful information for clinical care in SLE suggest that continued study of brief screening and computerized measures is warranted. The most commonly used computerized assessment in SLE and other autoimmune diseases has been the Automated Neuropsychological Assessment Metrics (ANAM) (Reeves, Kane, & Winter, 1996), a self-administered computerized battery of tests that requires approximately 30–45 minutes to complete. Several studies have found that the ANAM identifies cognitive dysfunction in SLE compared to controls (Holliday et al., 2003; McLaurin, Holliday, Williams, & Brey, 2005; Petri, Naqibuddin, Carson, Sampedro, et al., 2008; Roebuck-Spencer et al., 2006), suggesting that this battery is sufficient for screening cognitive dysfunction in SLE. Roebuck-Spencer et al. (2006) found that in 60 SLE subjects, the ANAM subtests were largely associated with standardized tests requiring psychomotor speed and complex attention. Petri, Naqibuddin, Carson, Wallace, et al. (2008) reported that four of nine subtests measuring sustained attention, working memory, and simple reaction time were impaired in 111 recently diagnosed SLE patients compared to 79 normal controls. Hanly, Omisade, Su, Farewell, and Fisk (2010) clarified the limitations of this tool, and in one study comparing SLE, RA, and multiple sclerosis (MS), they concluded that although the ANAM is sensitive to cognitive impairment as a screening tool it is “lacking specificity as a reliable indicator of impairment of higher cognitive function in SLE patients.”

Additional screening measures have been used in SLE studies. As noted earlier, brief mental status examinations appear to be relatively insensitive to cognitive problems in

SLE. The popular Mini-mental State Examination (Folstein, Folstein, & McHugh, 1975), for example, did not show good discrimination between SLE and controls (Karzmark, 1997; Nelson et al., 1986) although it did in one later study (Maneeton et al., 2010). The Montreal Cognitive Assessment Scale (MoCA; see Nasreddine et al., 2005), however, may be more useful. Results of MoCA testing have been published in two SLE cohorts. In one study (Adhikari, 2011), the MoCA was administered to 44 SLE patients, and 29.5% were identified as impaired (compared to 25% impaired on the ANAM). In another study, 30 SLE patients scored significantly lower on the MoCA (mean score 14.7) compared to controls (mean score 27.9) (El-Shafey, Abd-El-Geleel, & Soliman, 2012). Self-report measures of cognitive dysfunction are another commonly used screening method to describe SLE patient’s perceived cognitive impairments. Our prior study indicated that self-report of cognitive difficulties, measured via lengthy previously established measures, was not related to more objective methods of cognitive assessment in SLE patients (Kozora, Ellison, & West, 2006). Hanly, Su, Omisade, Farewell, and Fisk (2012) reported that a self-reported questionnaire of cognitive symptoms was not associated with an objective measure of cognitive processing in 68 SLE patients; however, self-report complaints were higher in the presence of anxiety and depression. A recent study (Julian et al., 2012) reported that perceived cognitive deficits using a self-report questionnaire yielded lower sensitivity compared to standardized cognitive measures.

*Longitudinal Studies of Cognition*

Prospective studies of cognition in SLE are limited, and longitudinal evaluation remains understudied. Persistent, emergent, and improved cognition were noted in studies of 28%–59% of SLE patients at one- to five-year intervals, but many methodological issues limit the utility of these findings (Carlomagno et al., 2000; Hanly, Fisk, Sherwood, & Eastwood, 1994; Hay et al., 1994; Holliday, Naqibuddin, Brey, & Petri, 2005; Naqibuddin et al., 2005; Waterloo et al., 2001). Differences in overall findings may relate to subject selection (the presence or absence of NP involvement, varying levels of disease activity, and the presence or absence of control subjects), intervals of retesting (three months to five years), selection of the test battery (comprehensive, brief, or computerized testing) and statistical analyses. In one long-term study (Mikdashi & Handwerker, 2004), 130 unselected SLE patients were followed over seven years, finding that early MRI abnormalities, Caucasian ethnicity, and aPL elevations influenced the emergence of NP disease. Seven years later, half of the 130 patients had not acquired major NP dysfunction; however, cognitive impairment as measured by standardized testing had emerged as the most common NP syndrome (27.3%). Additional studies suggest fluctuating cognitive functioning in SLE patients over time. Hay et al. (1994) reported that the prevalence of cognitive impairment

and psychiatric disorder was similar at two time points for 49 SLE patients; however, only one of the nine patients with cognitive impairment at the first interview remained impaired two years later. Additionally, the change in cognitive impairment was associated with improvement in psychiatric status. Hay and colleagues concluded that impaired performance on cognitive testing at one time point does not predict future NP events but the study may have been influenced by the high prevalence of psychiatric SLE events at the start, a high drop-out rate, missing data, and limited test battery. Hanly et al. (1994) followed an SLE cohort and found that significant fluctuations in cognitive function occurred, with 21% of patients impaired at baseline and 12% impaired after one year. Throughout the study period, three patients had persistent impairment, 12 showed resolved impairment, and four others showed emergent dysfunction. In a later study, Hanly, Cassell, and Fisk (1997) reported that among 47 SLE patients examined at three time points over five years, 64% were never impaired, 19% with cognitive impairment at baseline resolved over time, 9% showed emergent cognitive dysfunction, 4% fluctuated, and 4% stayed cognitively impaired. These results suggest that cognitive deficits in SLE may not be “cumulative.” The conclusions of this study are similar to those of Hay et al. (1994) in suggesting that the presence of cognitive deficits does not predict later overt NP symptoms or death.

In contrast, other studies have not reported decline, and have even reported improvement in neuropsychological functioning over time in SLE patients. Carlomagno et al. (2000) reported stable cognitive function in 51 SLE patients over one to three year intervals. These findings may be confounded by time points being specifically selected during times of stable neurological functioning; i.e., 27 of the 51 patients had NP symptoms at the first assessment, and these patients were assessed at least four weeks after resolution. Waterloo et al. (2001) examined 28 SLE patients with mild disease at baseline and then five years later. Their results indicated that neuropsychological functions remained unchanged in 78% of the patients and improved in 22%. They reported that a majority of the patients had MCD and remained at this level through follow-up. These findings, however, may be limited by the small sample size, lack of control subjects with whom to compare change over time, and limited level of cognitive testing (eight tests that did not include major areas such as learning and memory). Several recent studies demonstrate cognitive improvement over time in SLE, although practice effects interfere with interpretation. Holliday et al. (2005) reported that of 21 SLE patients tested at baseline and three months later, more than half demonstrated significant improvement in one of the nine subtests. Control subjects who were examined twice in one day also showed significant practice effects on all tests. Holliday et al. (2003) concluded that both SLE and controls had significant practice effects on the computerized battery. In a larger cohort of the same study, Naqibuddin et al.

(2005) evaluated cognition using the identical computerized battery in 106 SLE patients and 79 controls at baseline and at three-month intervals for several years. Significant improvement occurred across a majority of subtests at most time sequences, especially during the first three and six months, suggestive of practice effects rather than true clinical change. Overall, the paucity of longitudinal studies in this area exposes the lack of outcome data and highlights an obstacle in our understanding and informed treatment recommendations of cognitive dysfunction in SLE.

### ***Biobehavioral Mechanisms of Cognitive Dysfunction***

The mechanisms underlying cognitive abnormalities in SLE remain relatively obscure, and findings across studies remain inconsistent despite improving methodologies. As indicated in Table 26.1, cognitive impairment is now classified as one of 19 NP manifestations of SLE. The mechanisms underlying these cognitive deficits are likely multifactorial, and, as noted in Table 26.2, a variety of disease characteristics, biological abnormalities, and behavioral factors have been studied as potential contributors.

### ***Disease Characteristics***

No consistent relationships between duration of disease, disease severity, medication use, and neuropsychological dysfunction have been documented in SLE patients with or without NP activity. Some aspects of SLE disease were related to cognition in some studies of NPSLE patients (Conti et al., 2012; Ferstl et al., 1992; Fisk, Eastwood, Sherwood, & Hanly, 1993; Hanly et al., 1993; Papero et al., 1990; Sailer et al., 1997; Tomietto et al., 2007) but not in a majority of studies (Carbotte et al., 1986; Carbotte, Denburg, & Denburg, 1995; Carlomagno et al., 2000; Ferstl et al., 1992; Ginsburg et al., 1992; Glanz et al., 1997; Hanly et al., 1997; Hanly et al., 1994; Hay et al., 1992; Leritz, Brandt, Minor, Reis-Jensen, & Petri, 2000; Maneeton et al., 2010; Monastero et al., 2001; Norwicka-Sauer et al., 2011; Paran et al., 2009; Sailer et al., 1997; Vogel et al., 2011; Waterloo, Omdal, Husby, & Mellgren, 2002; Waterloo et al., 2001).

### **DURATION OF DISEASE**

Papero et al. (1990) reported that a longer duration of SLE was related to lower cognitive status in adolescents, a finding that could suggest that early onset SLE patients have a higher risk of CNS involvement. A majority of studies of adult onset SLE have not found a strong relationship between duration of disease and cognitive dysfunction (Kozora et al., 1996; Monastero et al., 2001; Maneeton et al., 2010; Vogel et al., 2011; Norwicka-Sauer et al., 2011). A majority of our studies with separate cohorts of non-NPSLE patients found no associations between cognitive dysfunction and duration

of disease (Kozora et al., 2008; Kozora, Ellison, et al., 2006; Kozora et al., 1996); however, we recently found a higher duration of disease in 20 non-NPSLE patients in New York compared to 20 non-NPSLE patients (matched demographically and screened in a similar fashion) in Denver (both groups screened with similar procedures), and that higher duration of disease was associated with increased cognitive impairment (Kozora, Erkan, et al., 2013). The New York subjects also had higher levels of serositis and renal failure. Disease duration, especially in relationship to specific SLE symptoms, may continue to play a role in cognitive dysfunction in SLE.

#### DISEASE ACTIVITY

Aspects of disease activity have been associated with cognitive deficits in SLE, but consistent findings are difficult to identify, likely due to methodological issues (i.e., data not acquired, not analyzed, or not similar across studies). Hanly et al. (1992) reported that a history of serositis was more common in cognitively impaired non-NPSLE patients. Using the same group of SLE patients, Denburg, Denburg, Carbotte, Fisk, and Hanly (1993) further examined the effect of disease activity on cognition by controlling for corticosteroid use and NP status. Results indicated that greater SLE disease activity was associated with impaired immediate memory and attention, suggesting some impact of generalized disease on CNS functioning. Ferstl et al. (1992) also reported a correlation with disease activity and cognition in a group of patients on corticosteroid therapy. Tomietto et al. (2007) found an association between chronic SLE damage and severity of cognitive impairment, and further identified that the presence of hypertension was related to cognitive dysfunction in 52 SLE patients. In addition, the presence of Raynaud's phenomenon and obesity were correlated with the number of cognitive functions impaired. One study found that cognitive dysfunction was correlated with disease activity in 62 SLE patients at time of diagnosis but not at the time of testing (Maneeton et al., 2010) and more recent study reported that cognitive dysfunction was related both to disease severity and cumulative chronic damage in 58 SLE patients (Conti et al., 2012). Recent studies are also suggesting that cardiopulmonary and cardiovascular dysfunction negatively impact cognition in SLE patients (Katz et al., 2012; Kozora, Swigris, et al., 2013). In a pilot study, we reported that SLE patients had worse lung function compared to controls, and that measures of lung function are associated with poor cognition (Kozora, Swigris, et al., 2013).

Some studies have also compared cognition in active and inactive SLE disease states. All of the studies to date indicate a relatively high prevalence of cognitive impairment even in the absence of active disease. Cognitive impairment was noted in 53% of SLE patients without active disease in one study (Carbotte et al., 1995), and measures of global cognitive impairment were not associated with measures of SLE

disease activity. Glanz et al. (1997) studied 58 inactive SLE patients, classifying 43% as cognitively impaired. Gladman et al. (2000) reported that 43% of their inactive SLE patients had cognitive impairment; however, based on history, those patients with previously high disease activity or with vasculitis tended to have greater cognitive impairment. There was no relationship between specific organ involvement and cognitive status. Although the majority of studies reporting on disease severity and cognition are negative (Kozora, 2008; Kozora et al., 1996), there is some evidence that aspects of SLE disease activity, organ damage, and related physical impairments may mediate cognitive dysfunction.

#### MEDICATION USE

The use of prednisone, a mainstay of SLE treatment, has not consistently emerged as an independent factor impacting cognition in SLE (Carbotte et al., 1986; Carlomagno et al., 2000; Denburg et al., 1987; Denburg, Carbotte, & Denburg, 1994; Emori et al., 2005; Fisk et al., 1993; Ginsburg et al., 1992; Gladman et al., 2000; Glanz et al., 1997; Hay et al., 1992; Holliday et al., 2000; Koffler, 1987; Kozora et al., 2008; Kozora, Ellison, et al., 2006; Kozora, Erkan, et al., 2013; Kozora et al., 1996; Maneeton et al., 2010; Monastero et al., 2001; Norwicka-Sauer et al., 2011; Peretti et al., 2012; Waterloo et al., 2001). Few studies have included analyses regarding other medications. Carlomagno et al. (2000) found no relationship between nonsteroidal anti-inflammatory therapy and cognitive impairment, and Waterloo et al. (2001) found no difference in cognitively impaired and nonimpaired SLE patients in terms of the type, presence, or duration of medications. Studies documenting a relationship between cognitive dysfunction and prednisone use in SLE are rare. Ferstl et al. (1992) investigated a small sample of SLE patients, corticosteroid-only patients, and controls. Results in this study suggested that nonverbal memory in SLE may be related to both SLE disease activity and corticosteroid use. Hanly et al. (1992) reported that a higher proportion of SLE patients with cognitive impairment were on prednisone, but did not find a difference in the mean dosage of prednisone between these two groups. Another study reported a relationship between prednisone use and decline in immediate memory and reaction time (Brey et al., 2002). No relationship between cognition and medication has been found longitudinally (Carlomagno et al., 2000; Hanly et al., 1997; Hay et al., 1994; Waterloo et al., 2002). Although group studies do not suggest strong associations between treatment medications in SLE and cognitive impairment, individual SLE patients may often have unique factors impacting cognition that should be considered in a clinical setting.

#### *Autoantibodies*

Autoantibody-mediated neuronal injury is thought to be the primary mechanism for some NP syndromes in SLE,

including cognitive dysfunction. Autoantibodies are found in serum, CSF (Bluestein, Williams, & Steinberg, 1981), and neural tissue from patients who have died from the disease (Zvaifler & Bluestein, 1982). Autoantibodies associated with general NP activity in SLE to date include antineuronal antibodies, brain cross-reactive lymphocytotoxic antibodies, antibodies to N-methyl-D-aspartate (anti-NMDA) receptors, aPL including lupus anticoagulant (LAC) and anticardiolipin (aCL), antibodies to Anti- $\beta$ 2-glycoprotein-I antibody (a $\beta$ 2GPI), and antibodies to anti-ribosomal P. Some studies have investigated the relationship between these particular autoantibodies and cognitive functioning.

#### ANTINEURONAL ANTIBODIES

The relationship between antineuronal antibodies and cognitive dysfunction in SLE has not been strong. Initially, Denburg et al. (1987) reported a relationship between cognition and IgG antineuronal antibody in 97 SLE patients. They found that 84% of the antibody-positive SLE patients were cognitively impaired. Despite the higher incidence of antineuronal antibody in cognitively impaired patients, the finding was not very specific given the high level of impairment (67%) in the antibody negative group. No other studies have reported such an association. Hanly et al. (1993) found that in 70 unselected SLE patients, 34% had elevated antineuronal antibodies; however, there was no difference between the cognitively impaired or unimpaired patients. In another study, antineuronal antibodies were not different between cognitively impaired and unimpaired SLE patients (Sailer et al., 1997). Studies have also examined lymphocytotoxic antibody activity in SLE. Denburg, Carbotte, Long, and Denburg (1988) and Long, Denburg, Carbotte, Singal, and Denburg (1990) studied 98 unselected SLE patients, and reported that 74% of the lymphocytotoxic positive patients and only 48% of the lymphocytotoxic negative SLE patients were cognitively impaired. They further suggested that patterns of visuospatial and cognitive flexibility deficits are associated with elevations of this autoantibody. Interestingly, the SLE patients with a history or presence of NPSLE were not different than the non-NPSLE patients with regard to lymphocytotoxic activity. Hanly et al. (1993) reported elevated lymphocytotoxic antibodies in 47% of their entire SLE group, but found no antibody differences between the cognitively impaired and unimpaired SLE patients.

#### N-METHYL-D-ASPARTATE (NMDA) RECEPTOR ANTIBODIES

The NMDA receptor is a subtype of glutamate receptor. Antibodies against the NMDA receptor are a subset of pathogenic anti-double stranded DNA (anti-dsDNA) antibodies that cross-react with a consensus peptide sequence of the extracellular, ligand-binding domain of the NMDA receptors NR2a and NR2b (anti-NR2) (DeGiorgio et al., 2001). The NR2 receptors are expressed on neurons in the

hippocampus and neocortex, and they bind the neurotransmitter glutamate. These receptors have been postulated to be important in mechanisms underlying learning and memory (Lipton & Rosenberg, 1994). Anti-NR2 antibodies have been demonstrated in the serum and CSF of SLE patients (Rhianon, 2008). In mouse models, these antibodies can gain access to the CSF through a compromised blood-brain barrier (BBB), after which they can bind to hippocampal neurons, alter hippocampal metabolism, or cause excitotoxic neuronal death by excessive calcium entry into cells, and impair memory and learning (Kowal, DeGiorgio, Nakaoka, Diamond, & Volpe, 2004). Studies to date have not consistently reported a relationship between cognitive functions and the presence of serum markers of anti-NR2 in SLE (Hanly, Robichaud, & Fisk, 2006; Harrison, Ravdin, Volpe, Diamond, & Lockshin, 2004; Kozora et al., 2010; Lapteva, 2004). In one study, poor performance on measures of immediate visual memory, fine motor function, and psychological functioning was associated with elevated levels of anti-NR2 in 57 SLE patients (Omdal et al., 2005), but only two of the 20 cognitive tests showed an association, and all of the tests were within normal limits. Harrison et al. (2004) reported that 25.8% of 93 SLE patients had positive anti-NR2 antibodies; however, no relationship between antibody positivity and cognitive dysfunction, depression, or anxiety was found. Lapteva, Nowak, et al. (2006) reported that 26.6% of 60 SLE patients demonstrated the presence of anti-NR2; no relationship with global or individual cognitive test performance was reported, but a relationship with increased depression levels was found. Hanly et al. (2006) reported that 35% of 65 women with SLE had anti-NR2 antibodies, but they were not associated with cognitive performance at baseline or approximately five years later. These authors also showed that persistence of anti-NR2 antibodies was not related to the development of NP events. Steup-Beekman, Steens, van Buchem, and Huizinga (2007) found no relationship between cognition and NMDA metabolism in SLE. Our group found that the frequency of elevated anti-NR2 was low in 43 non-NPSLE patients (14%), and not significantly different from controls (Kozora et al., 2010). In addition, there was no relationship between the presence of anti-NR2 in serum and global cognitive or memory indices or with level of depression. Taken together, these studies indicate that serum anti-NR2 is not likely related to cognition in non-NPSLE patients. The absence of a relationship between anti-NR2 and cognitive dysfunction suggests that NMDA antibody activity measured in serum is not a fruitful approach to understanding mechanisms of cognitive dysfunction in SLE. Antibody measurement in the CSF, however, may be more productive. A recent study suggested that elevated CSF anti-NR2 was associated with diffuse NP activity in SLE (Arinuma, Yanagida, & Hirohata, 2008); 12.5 % of these patients had cognitive dysfunction. Another study reported a stronger association between NP events and CSF autoantibodies than circulating anti-NR2 (Yoshio, Onda, Nara, & Minota, 2006). In earlier animal

models, breakdown of the BBB was necessary for antibodies against the NMDA receptor to alter hippocampal metabolism, cause neuronal death, and produce cognitive dysfunction (Kowal et al., 2004). Continued studies of anti-NR2 and cognitive dysfunction in SLE are warranted using CSF samples to explore compromise of the BBB in more detail.

#### ANTIPHOSPHOLIPID ANTIBODIES (APL)

Antiphospholipid antibodies including LAC, aCL, and  $\beta$ 2GPI are common in patients with SLE, and appear to correlate with microvascular thrombosis and other neurologic events (Asherson et al., 1989; Leaven & Welch, 1987). Antiphospholipid antibodies including LAC and aCL are frequently identified as the cause of neurological syndromes such as stroke, seizures, confusional states, and migraine (Gorman & Cummings, 1993). Initial estimates suggested that 30%–40% of SLE patients had positive aPL (Love & Santoro, 1990a), but in a recent multisite study, percentages of aPL were lower with 13.4% for aCL, 15.2%  $\beta$ 2GPI, and 21.9% LAC (Hanly et al., 2011). In a study of 323 consecutive SLE patients, 39.3% were classified as having aPL, and aPL was significantly higher in SLE patients with overt NP activity (Sanna et al., 2003). Multiple studies have found an association between aPL and cognition in SLE patients, both with and without NP activity (Denburg, Carbotte, Ginsberg, et al., 1997; Hanly, Hong, Smith, & Fisk, 1999; Leritz, Brandt, Minor, Reis-Jensen, & Petri, 2002; Menon et al., 1999; Tomietto et al., 2007). The presence of aPL (via LAC, aCL and  $\beta$ 2GPI) has been associated with greater impairment in memory, visuomotor speed, and visuoconstruction/visuospatial functions in SLE patients.

A majority of the SLE studies have used LAC and aCL, or both, as markers of aPL. Denburg, Carbotte, Ginsberg, et al. (1997) reported that the 39 LAC-positive SLE patients were two to three times more likely than the 79 LAC-negative group to be defined as cognitively impaired. Further analysis indicated significant differences between these two groups on measures of verbal learning and psychomotor speed. These investigators (Denburg, Carbotte, & Denburg, 1993) also investigated SLE patients who were consistently positive for LAC (over three time periods) and reported that these patients had greater cognitive dysfunction than the patients who were persistently negative, a finding likely related to microvascular thrombosis in the LAC positive group. Sanna et al. (2003) more recently reported that aPL, particularly LAC, was statistically more frequent (15.7%) in SLE patients classified as having a cognitive disorder compared to those who were not (7.6%). Some studies of antiphospholipid activity using the aCL marker have not found a relationship with cognitive dysfunction in SLE (Hanly et al., 2011; Sailer et al., 1997; Waterloo et al., 1999; Waterloo et al., 2001; Sanna et al., 2003). Hanly et al. (1993) reported decreased recognition performance on a verbal memory task in patients with positive aCL, and also reported that

patients with persistently elevated IgG aCL had a significant decline in psychomotor speed, and persistently elevated IgA aCL was related to decline in conceptual reasoning and executive ability (Hanly et al., 1999). Menon et al. (1999) studied 45 unselected SLE patients at baseline and at 12–18 month follow-up. The patients who had consistently elevated IgG aCLs over time performed worse on neuropsychological testing. Tomietto et al. (2007), identified a relationship between aPL positivity and impairment in complex attention and executive function over a three-month period. The longitudinal relationship between persistently elevated aCL antibodies and cognitive dysfunction in SLE (Hanly et al., 1999; Menon et al., 1999) indicates the importance of longitudinal designs in exploring the role of aPLs in cognitive dysfunction. More recently, McLaurin et al. (2005) indicated that in 123 patients studied every four months for three years, declining cognitive function was related to the presence of consistently positive aPL. Some studies have not found associations between aPL and cognition in SLE. In our study of 64 non-NPSLE, we reported higher LAC, aCL, and  $\beta$ 2GPI, but compared to controls these were not significantly different (Kozora et al., 2012). We did not find significant correlations between the aPL measures and a global cognitive score, nor were there differences between cognitively impaired and unimpaired SLE on levels of aPL. This finding is consistent with some prior studies (Carlomagno et al., 2000; Emori et al., 2005; Hanly et al., 1993; Sailer et al., 1997; Waterloo et al., 2001). A minority of SLE patients demonstrated elevated aCL-IgM (5.56%), elevated activated partial thromboplastin time (APTT; 6.56%). These frequencies were relatively low compared to other SLE studies, and may be explained by subject selection (i.e., patients without overt NP activity).

#### ANTI-RIBOSOMAL P

Several studies have shown that SLE patients with major NP syndromes (i.e., major depression and psychosis) have had elevated serum levels of autoantibodies to ribosomal P proteins (Bonfa et al., 1987; Schneebaum et al., 1991). In a study of 1,047 SLE patients, 9.2% had anti-ribosomal P antibodies, and their presence at baseline was associated with subsequent psychosis (Hanly et al., 2011). Although the question has not extensively investigated, antiribosomal P does not appear to be strongly associated with cognitive impairment in SLE. Hanly et al. (1993) reported the presence of antiribosomal P antibodies in only 17% of SLE patients, and found no difference in the presence of antiribosomal P in cognitively impaired and unimpaired groups. In our prior study, 28% of the SLE patients had elevated antiribosomal P (Kozora et al., 1996), but there were no associations with cognitive dysfunction, or other measures such as psychological functioning and disease activity. Finally, antiribosomal P was not found to be a significant predictor variable along with other demographic and health factors in a model attempting to predict cognitive speed and efficiency in SLE (Holliday et al., 2000).

### Mediators of Inflammation

There has been growing evidence that neural, endocrine, and immune cells share common communication molecules and receptors, and are functionally linked to form a brain–endocrine immune axis that integrates physiological responses (DeSouza, 1993; Maier & Watkins, 1998). Studies evaluating inflammation via cytokine activity and other inflammatory measures in SLE suggest they are likely mediators of cognitive dysfunction.

#### CYTOKINES

Proinflammatory cytokines are elevated in acute anti-inflammatory responses in both animal models and in studies of SLE and RA (al-Janadi, al-Balla, al-Dalaan, & Raziuddin, 1993; Elliott & Maini, 1995; Linker-Israeli et al., 1991; Singh, 1992). Patients with active NPSLE have demonstrated elevations of IL-1, IL-6, IFN- $\alpha$ , and tumor necrosis factor (TNF) in the CSF (Alcocer-Varela, Aleman-Hoey, & Alarcon-Segovia, 1992; Benveniste, 1992; Dellalibera-Joviliano, Dos Reis, Cunha Fde, & Donadi, 2003; Hirohata & Miyamoto, 1990; Shiozawa, Kuroki, Kim, Hirohata, & Ogino, 1992; Tsai et al., 1994; Yeh et al., 1994). Few studies have explored cytokine activity (serum or CSF) in relation to neuropsychological functioning in SLE. Our group did not find that serum IL-6 differed in an early study of 15 non-NPSLE, 15 RA, and 15 healthy control subjects (Kozora, Laudenslager, Lemieux, & West, 2001); however, we did report that IL-6 contributed uniquely to measures of learning beyond the effects of depression, prednisone therapy, and hormonal measures. These findings also suggested that the relationship between IL-6 production and cognitive functioning might be quadratic (as an inverted U-shaped function) whereby moderate levels facilitate, but very low and very high levels disrupt learning capacity. Inflammation measured with c-reactive protein (CRP) was associated with deficits in information processing in SLE patients (Shucard, Gaines, Ambrus, & Shucard, 2007). In a more recent study, IFN-alpha and IL-6 were elevated in 64 non-NPSLE patients compared to controls and lower IFN-alpha was related to a variety of global cognitive scores, memory scores, and individual tests of visuomotor speed and attention (Kozora et al., 2012). These findings were unexpected, as higher IFN-alpha has been associated with NPSLE activity in CSF (Okamoto, Kobayashi, & Yamanaka, 2010), and with other medical disorders such as hepatitis C. IFN-alpha treatment has resulted in cognitive decline (Perry, Hilsabeck, & Hassanein, 2008). Given the relatively weak correlations, our findings remain unremarkable, although they might suggest that peripheral IFN-alpha may act to suppress disease activity in the SLE brain. In contrast to our expectation, elevated IL-6 was not related to a majority of the cognitive summary scores or individual tests in this study. This finding differs from our initial study (Kozora et al., 1998), yet there were no apparent

differences in demographics or health characteristics between the subjects included in our current and prior SLE cohorts.

#### MATRIX METALLOPROTEINASES

Other potentially important inflammatory mediators are matrix metalloproteinases (MMPs), a family of endoperoxidases that degrade extracellular matrix components (Lijnen, 2001). MMP-9 plays a key role in the disruption of the BBB, while its natural inhibitor—tissue inhibitor matrix metalloproteinase-1 (TIMP-1)—is important for stabilizing the BBB. Patients with NPSLE, especially those with cognitive impairment, have elevated levels of MMP-9 in serum (Ainiala et al., 2004), and CSF (Trysberg, Blennow, Zachrisson, & Tarkowski, 2004). The correlation between CSF MMP-9 levels, proinflammatory cytokines, and biomarkers of neuronal and glial degradation in SLE patients (Trysberg et al., 2004) suggests that enhanced production of MMP-9 is linked to CNS damage in SLE and is a likely mediator of cognitive dysfunction in this population.

#### SERUM VERSUS CSF STUDIES

Some controversy exists regarding the analysis of serum versus CSF cytokines, and it is possible that reliance on serum cytokine levels explains, at least in part, the relatively limited findings of inflammation related to cognition in SLE studies to date. Trysberg, Carlsten, and Tarkowski (2000) reported that serum IL-6 did not differ between SLE patients with and without NP syndromes, but observed that 86% of the SLE patients with NPSLE demonstrated intrathecal elevations of IL-6. Based on this observation, they suggested that primary systemic production of cytokines with subsequent passage to CSF is not the most likely mechanism by which these cytokines exert their adverse effects on the CNS. As discussed earlier if serum analysis is not useful for understanding the immunopathogenesis of cognitive dysfunction in SLE, it may be more useful to examine the CSF, which will enable assessment of BBB integrity as well as the measurement of intrathecal immune activity including autoantibodies and a variety of soluble cytokines, chemokines, and MMPs. Direct CSF examination may enable more focused investigation or the cascade of molecular changes in the brain that influence cognitive dysfunction in SLE. Several proinflammatory cytokines and chemokines have been detected in the CSF of patients with active NPSLE (Lu et al., 2010; Okamoto et al., 2010), and it is possible that autoantibodies cross a dysfunctional BBB, or are produced intrathecally, to interact with their cognate neuronal antigen and form immune complexes in the CSF. Recent studies have shown that CSF immune complexes can induce CNS microglial cells to produce IFN- $\alpha$ , IL-6, IL-8, and MCP-1 (Santer, Yoshio, Minota, Moller, & Elkon, 2009). IFN- $\alpha$  can cause cognitive difficulties, and can also feed back to further facilitate production of many cytokines and chemokines. IL-8 and MCP-1 can chemoattract

immune cells into the CNS that may contribute to intrathecal autoantibody production. There is evidence that IL-6 and IL-8 can upregulate MMP-9 production by resident cells within the CNS. MMP-9 can then contribute to further disruption of the BBB, allowing more influx of autoantibodies into the CSF as well as causing myelin destruction (Trysberg et al., 2004).

### *Neuropeptide and Hormonal Factors*

Dehydroepiandrosterone (DHEA) is the most abundant adrenal steroid hormone in humans, and may relate to cognitive dysfunction in SLE. Interactions of DHEA with the nervous system have been associated with cognitive functions in both animals and human studies (Flood, Morley, & Roberts, 1992; Flood & Roberts, 1988; Melchior & Ritzmann, 1996). Lower DHEA levels have been reported in humans with memory problems (Leblhuber et al., 1993; Nasman et al., 1991) and SLE patients have been found to have lower levels of DHEA (Suzuki, Suzuki, Engleman, Mizushima, & Sakane, 1995). DHEA and DHEA-sulfate were found to be significantly lower in non-NPSLE and RA patients compared to control subjects and lower DHEA-S was related to lowered attention and concentration (Kozora, West, Forrest, & Young, 2001). As noted earlier, several neuropeptides have been linked to behavioral and cognitive changes in animal and human studies, and the role of vasopressin in cognition has been studied extensively (Bennett, Ballard, Watson, & Fone, 1997; Frank & Landgraf, 2008; Ring, 2005). Lapteva, Yarboro, et al. (2006) reported higher serum concentrations of calcitonin gene-related peptide and a trend toward higher concentrations of serum vasopressin in 27 cognitively impaired SLE patients (based on standardized neuropsychological testing) compared to 19 nonimpaired SLE patients. In contrast, oxytocin, vasoactive intestinal peptide, and neuropeptide Y did not differ across their groups. No additional studies have confirmed or disputed the role of hormonal changes or neuropeptides in cognitive dysfunction in SLE, but future studies would be useful in expanding a list of potential mechanistic features of MCD-SLE.

### *Behavioral Mechanisms*

#### PSYCHOLOGICAL FACTORS

Overall, psychological distress has been found to be elevated in patients with SLE compared to other autoimmune patients and healthy controls (Bluestein, 1992; Carbotte et al., 1986; Denburg et al., 1987a; Giang, 1991; Gladman et al., 2000; Koffler, 1987; Kozora, Ellison, et al., 2006; Kozora et al., 1996; Liang et al., 1984; Liang, Socher, Larson, & Schur, 1989; Monastero et al., 2001; Rummelt et al., 1991; Sabbadini et al., 1999; Sonies et al., 1982; Wekking, Nossent, et al., 1991; West, 1994; West et al., 1995). Several studies further demonstrated that SLE patients with overt NP disorders

have stronger associations between psychological distress and cognitive functions (Denburg et al., 1987; Hay et al., 1992; Hay et al., 1994; Kozora, Ellison, et al., 2006; Monastero et al., 2001; Wekking, Nossent, et al., 1991). NPSLE patients with psychiatric histories have been found impaired on motor speed and attention and verbal learning (Sonies et al., 1982), and cognitively impaired SLE patients with psychiatric distress showed greater impairment in short-term retention and verbal fluency when compared to cognitively impaired SLE patients without psychiatric distress (Denburg et al., 1987). In a prospective study, improvement in cognitive abilities paralleled improvement in psychological status, Hay et al. (1994) reported that, at baseline, 26% of their SLE patients had cognitive impairment, whereas two years later, impairment was present in only 17%. Eight-ninths of the non-NPSLE were not impaired at follow-up, a change that mirrored their improvement in psychological status (Glanz et al., 1997).

In contrast, several studies of SLE patients with NPSLE have found no relationship between psychiatric histories, overall psychological function, and cognitive status (Carbotte et al., 1986; Carlomagno et al., 2000; Maneeton et al., 2010; Sailer et al., 1997). Furthermore, SLE patients with inactive disease show little relationship between cognitive and psychological status (Gladman et al., 2000). In most studies with non-NPSLE patients, cognitive deficits have not been related to psychological distress (Carbotte et al., 1986; Denburg et al., 1987; Kozora et al., 2008; Kozora, Ellison, et al., 2006; Rummelt et al., 1991). In a prior study, we did not find our cognitively impaired non-NPSLE patients to have greater psychological distress on any of the six selected scales of the MMPI. However, we found a moderate correlation between a summary cognitive t-score (mean t-score for all eight domains) and the summary psychological t-score (mean of six MMPI-T scores). These correlational findings suggest that a relationship between psychological distress and global cognitive functions might exist even in non-NPSLE patients who have been screened for major psychiatric disorders.

Depression and anxiety as measured by standardized questionnaires of mood and personality are frequently found to be elevated in SLE patients. For example, in our first study, 42% of the non-NPSLE group had psychological distress when six select MMPI-2 scales were analyzed (Kozora et al., 1996), with specific scales indicating higher depression, anxiety, and confused thinking. Depression has been the most frequently documented psychiatric problem in patients with SLE (Giang, 1991; Iverson, 1995, 2002; Iverson & Anderson, 1994; Kozora et al., 1996; Wekking, 1993). Standard questionnaire measures of depression have been related to cognitive dysfunction in SLE (Brey et al., 2002; Holliday et al., 2000; Monastero et al., 2001; Rummelt et al., 1991) but not in others (Denburg et al., 1987; Glanz et al., 2005; Glanz et al., 1997; Kozora, Arciniegas, et al., 2006; Loukkola et al., 2003; Sailer et al., 1997; Vogel et al., 2011). As there is evidence that “depressive” symptoms likely impact cognitive

abilities in psychiatric populations (King & Caine, 1996), studies that examine the similarities and differences in cognitive deficits between depressed outpatients and depressed SLE patients may yield important information. Denburg and Denburg (1999) reported that eight depressed SLE patients were more impaired than eight depressed outpatients in tests of verbal fluency, sustained mental effort, verbal and nonverbal fluency, and visuospatial planning. In a larger study on depression in SLE, significant differences between patient self-report using standardized questionnaires, physician ratings, of depression and results of structured psychiatric interviews were noted, suggesting methods may impact findings (Kozora, Arciniegas, et al., 2006; Kozora et al., 2001). Continued studies in this area are necessary to better understand the underlying processes of depression and its relationship to NP and cognitive changes.

#### FATIGUE AND PAIN

Fatigue and pain have been suggested as mechanisms that may impact cognitive functions in SLE; however, few studies have been published. Fatigue and pain are commonly reported in patients with SLE (Bauman, Barnes, & Schrieber, 1989; Hall & Stickney, 1983; Liang et al., 1984; Middleton, McFarlin, & Lipsky, 1994; Schur, 1989; Taylor et al., 2000; Wysenbeek, Leibovici, Weinberger, & Guedj, 1993), and have been associated with self-report of cognitive problems (Alarcon et al., 2002). Fatigue has been described as the most chronic and debilitating symptom that SLE patients experience (Krupp, LaRocca, Muir, & Steinberg, 1990; Krupp, LaRocca, Muir-Nash, & Steinberg, 1989; Liang et al., 1984; Robb-Nicholson et al., 1989; Schur, 1989), and self-reported fatigue in SLE patients is extremely common, ranging from 46% to 100%. In one of our early pilot studies, declines in sustained attention were strongly associated independently with fatigue and depression in SLE patients (Kozora et al., 2001). In later research (Kozora, Ellison, et al., 2006) we reported a relationship between fatigue and cognitive dysfunction in SLE patients with overt NP manifestations. We have found higher levels of fatigue in SLE patients with and without NPSLE compared to controls using the Fatigue Severity Scale (Krupp et al., 1989), with more than 92% of the SLE patients reporting fatigue. However, only the NPSLE group demonstrated significant correlations between fatigue and measures of verbal learning and verbal recall, immediate and delayed recall of nonverbal material, and complex visuomotor functions. In addition, findings suggested that only the NPSLE group had significant associations between an overall cognitive index and measures of fatigue, pain, and depression. These preliminary findings might suggest that fatigue is related to aspects of cognitive dysfunction in SLE.

Pain has often been reported in SLE patients (Kewman, Vaishampayan, Zald, & Han, 1991) and there is some evidence that pain may reduce overall cognitive efficiency (Grigsby, Rosenberg, & Busenbark, 1994; Schwartz, Barth,

& Done, 1987). Relatively few data regarding this relationship are available and sample sizes are small. One of the first studies indicated that in ten SLE patients, pain was associated with cognitive deficits (Denburg, Carbotte, & Denburg, 1997). In our 2004 study, both the group of 29 NPSLE and that with 31 non-NPSLE patients had higher rates of pain on the McGill Pain Severity Scale (Melzak, 1975) compared to controls. Only the NPSLE patients, however, showed a significant correlation between higher self-reported pain and overall cognitive dysfunction. Notably, few studies include measures of pain and fatigue in studies of cognition despite the early positive relationship in SLE. As noted earlier, complex relationships between depression, pain and fatigue likely exist.

#### SLEEP

Preliminary studies indicate that more than 50% of SLE patients have sleep problems (Chandrasekhara, Jayachandran, Rajasekhar, Thomas, & Narsimulu, 2009; Greenwood, Lederman, & Lindner, 2008; Liang et al., 1984; McKinley, Ouellette, & Winkel, 1995; Palagini et al., 2014; Robb-Nicholson et al., 1989; Tench et al., 2002; Tench, McCurdie, White, & D'Cruz, 2000) that are likely to be related to cognitive dysfunction (Kozora, Zell, Swigris, Duggan, & Make, 2012). Valencia-Flores et al. (1999) reported respiratory and sleep-related movement disorders in 36% of 14 patients using polysomnography (PSG). These sleep disorders also resulted in greater daytime sleepiness. Disease activity was associated with decreases in sleep efficiency and delta sleep, and increases in sleep fragmentation. In a larger study, Laboni, Ibanez, Gladman, Urowitz, and Moldofsky (2006) studied 35 SLE patients complaining of overwhelming tiredness compared to 17 healthy controls. Results indicated that 26% had obstructive sleep apnea (OSA). Compared to controls, SLE patients had significantly impaired sleep efficiency, high arousal frequencies, increased Stage 1 sleep, decreased slow wave sleep and non-REM sleep, and excessive daytime sleepiness. There are a number of other studies in patients with OSA in which cognitive dysfunction, specifically aspects of attention and executive function, have been reported (Felver-Gant et al., 2007; Greenberg, Watson, & Deptula, 1987; Naegele et al., 1995). While sleep disorders are quite common in SLE, they have rarely been studied in relation to objective neuropsychological data. We have some pilot data suggesting a relationship between sleep problems (and sleep apnea) and cognitive dysfunction in SLE (Kozora et al., 2012) and continued assessment may expand our assessment and treatment options.

#### OBESITY AND EXERCISE ENDURANCE

Additional factors associated with cognition in general, such as obesity and exercise capacity, may be related to cognitive dysfunction in SLE. In one study of 138 SLE patients,

self-reported physical inactivity and obesity were associated with decline in cognition, specifically executive functioning (Katz et al., 2012). A recent study of 34 female SLE patients with relatively mild disease activity and no overt NP activity found lower levels of physical activity lower exercise capacity than matched healthy controls (Kozora, Swigris, et al., 2013). Among SLE subjects, there was a moderate association between a physical measure of exercise endurance (six-minute walk test) and cognition. Prior research suggested self-reported physical inactivity in SLE patients may negatively impact cognition, but ours are the first data documenting a relationship between objective measures of physical activity and cognitive dysfunction in this population.

### *Treatment of Cognitive Dysfunction*

Data are limited regarding the treatment of cognitive dysfunction in SLE. Few studies of pharmacologic therapy for SLE-associated cognitive dysfunction have been published. In one study (Denburg et al., 1994) the authors reported improved cognition in five of eight subjects who completed a trial of 0.5-mg/kg prednisone daily. It is not clear whether this beneficial effect was maintained when the corticosteroid was tapered and discontinued. An interesting volumetric MRI study of SLE patients, however, showed that those who received immunosuppressive medications had greater brain white matter (WM) volume than controls, implying a protective effect of standard SLE treatment on WM (Xu et al., 2010). Although there are no clinical trial data to support use of antiplatelet or anticoagulant therapy for cognitive dysfunction in SLE, patients with aPL but without thromboembolic phenomena were found in a longitudinal observational study to have better cognitive performance if they took regular aspirin than if they did not (McLaurin et al., 2005). Agents developed for the treatment of cognitive dysfunction in Alzheimer's disease (AD) (i.e., cholinesterase inhibitors, memantine) and attention deficit disorder (i.e., methylphenidate) are sometimes used, but the lack of trial data and biologic plausibility for such approaches in SLE are problematic. Memantine, a noncompetitive inhibitor of glutamate at the NMDA receptor, does have a more solid rationale in SLE patients, at least those with anti-NR2 antibodies. However, a randomized, double-blind placebo-controlled trial of memantine in 51 SLE patients, using the ANAM computerized battery and an extensive battery of tests recommended by the ACR, found no differences between the groups on the ANAM and a significant improvement on only one ACR test result (verbal fluency), suggesting that memantine produces no significant cognitive improvement in SLE (Petri, Nagibuddin, Asmpedro, Omdal, & Carson, 2011).

Cognitive rehabilitation, which involves intensive retraining of cognitive skills, is an alternative or complementary therapeutic approach. Rehabilitation programs in other conditions (stroke, dementia, traumatic brain injury, MS) teach patients with cognitive dysfunction the means by which they

may adapt to their impairments and maintain, if not regain, some level of independence. A novel psychoeducational group intervention targeted specifically at SLE patients with self-perceived cognitive dysfunction (Harrison et al., 2005) demonstrated that participation may result in improvement in memory self-efficacy, memory function, and ability to perform daily activities that require cognitive function. Further study is needed before these kinds of intervention can be recommended.

### *Neuroimaging*

Based on a variety of neuroimaging techniques, damage to both WM and gray matter (GM) of the brain occurs in SLE, and each kind of injury may underlie specific cognitive problems in this population (Appenzeller, Carnevalle, Li, Costalata, & Cendes, 2006; Kozora & Filley, 2011). A summary of neuroimaging abnormalities in SLE will be followed by a review of neuroimaging correlates of cognitive dysfunction in this population.

### *Neuroimaging Abnormalities*

#### MAGNETIC RESONANCE IMAGING

MRI has largely replaced its predecessor—computed tomography (CT)—and has been the most extensively studied brain imaging modality in SLE. MRI elegantly reveals a wide range of findings in SLE, including WM hyperintensities (WMHI), infarcts, and hemorrhages in either WM or GM, and cerebral atrophy, both in those with and those without NP presentations (Aisen, Gabrielsen, & McCune, 1985; Davie et al., 1995; Fields, Sibbitt, Toubbeh, & Bankhurst, 1990; Ishikawa, Ohnishi, Miyachi, & Ishizaka, 1994; Kozora & Filley, 2011; Kozora & Make, 1998). Whereas not all studies report MRI differences between SLE with and without NP activity (Haider, Zakarya, & Abu-Hegazy, 2012), NPSLE typically involves more florid MRI abnormalities. An important clue to the understanding of cognitive disorders in SLE is that the most common MRI abnormality in NPSLE is the presence of scattered hemispheric WMHIs (Castellino et al., 2008; Graham & Jan, 2003; Karassa et al., 2000; Sailer et al., 1997; Sanna et al., 2003; Sibbitt, Sibbitt, & Brooks, 1999; Toledano, Sarbu, Espinosa, Bargallo, & Cervera, 2013). In several well-designed studies with clearly defined characterizations of NP activity in adult SLE, the number of WMHI has been significantly higher in those patients with overt NP compared to those without (Ainiala et al., 2004; Appenzeller, Pike, & Clarke, 2008; Handa et al., 2003; Zivadinov et al., 2013). NPSLE patients with focal syndromes such as stroke and seizures are of course more likely to have destructive WM lesions, GM lesions, or both (McCune, MacGuire, Aisen, & Gebarski, 1988; Sewell, Livneh, Aranow, & Grayzel, 1989; Stimmler, Coletti, & Quismorio, 1993; West et al., 1995). Even in non-NPSLE, WMHIs occurred in 16% of patients

using clinical classification (Jarek, West, Baker, & Rak, 1994), and in up to 35% using quantitative techniques (Kozora & Make, 1998). In other studies, WMHI have been documented in 35%–50% of well-defined SLE patients without overt NP; but data on control subjects were not presented (Abreu et al., 2005; Appenzeller, Vasconcelos Faria, Li, Costallat, & Cendes, 2008). Importantly, however, not all studies have demonstrated MRI abnormalities in SLE patients without NP activity. Using a 3.0T MRI scanner, no differences were noted in total WM or GM volumes, or number and volume of WM lesions in well-defined non-NPSLE patients (Filley, 2009). This study suggested that MRI might not be sensitive to early microstructural WM disease in SLE, and set the stage for more detailed neurometabolic studies whereby the normal-appearing WM (NAWM) could be examined.

The MRI lesions of SLE have a variable course, with some being reversible and others irreversible (Sibbitt, Sibbitt, Griffey, Eckel, & Bankhurst, 1989). This variability reflects the complex nature of SLE, and many additional factors such as treatment effects. Some longitudinal studies in SLE have suggested resolution of WM lesions with high-dose corticosteroid therapy (Aisen et al., 1985; Bell et al., 1991; McCune et al., 1988; Sibbitt et al., 1989), but others have not (Griffey, Brown, Bankhurst, Sibbitt, & Sibbitt, 1990; Stimmler et al., 1993). Gonzalez-Crespo et al. (1995) reported MRI changes over three years in NPSLE, and some, but not all, of the WM lesions disappeared. In another MRI study (Chinn et al., 1997), 32% of SLE patients demonstrated increased atrophy over time, and abnormal MRI findings were more common in patients with a history of CNS events. Some studies have found stable MRI abnormalities over time (Appenzeller, Li, Costallat, & Cendes, 2005; Mortilla, Ermini, Nistri, Dal Pozzo, & Falcini, 2003) while other studies show increase MRI abnormalities. For example, Jennings, Sundgren, Attwood, McCune, and Maly (2004) reported that among 26 NPSLE patients followed for up to five years, eight of these patients had progression of abnormalities, three showed regression, and 15 had no change. Appenzeller et al. (2006) reported hippocampal atrophy in SLE patients at baseline, and after 19 months this volume loss has progressed significantly (43.9% at baseline and 66.7% at follow up); the hippocampal atrophy was associated with cumulative corticosteroid dose and number of CNS manifestations.

#### MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) is a neuroimaging technique that identifies and quantifies chemicals in living tissue. Creatine (Cr) is a storage form of high-energy phosphates and is used as a reference marker. N-acetyl aspartate (NAA) is produced by neurons and is a marker of neuronal health; levels decrease markedly with brain insult and axonal loss. Choline (Ch) is a precursor to acetylcholine, an essential chemical for neuronal membrane integrity and

synaptic transmission. Elevated Ch/Cr is associated with increased cell production (as occurs with brain tumors), and with increased membrane turnover related to inflammation, demyelination, ischemia, and gliosis. Most SLE studies have focused on NAA/Cr and Ch/Cr in an effort to assess neuronal and myelin integrity. A detailed review of MRS studies of Ch/Cr findings in SLE patients can be found in a recent review (Kozora & Filley, 2011). The studies considered generally reported decreased NAA and increased Ch/Cr in both the NAWM and abnormal-appearing WM (AAWM). The studies differed, however, in their methods, including variation in subject selection, sample size, and neuroimaging techniques. Higher Ch/Cr in SLE is postulated to be more likely due to inflammatory myelinopathy than ischemia or gliosis at this early disease stage (Filley et al., 2009). Studies with carefully characterized non-NPSLE patients suggest that increased Ch/Cr can occur without, and perhaps prior to, lowered NAA/Cr (Appenzeller, Li, Costallat, & Cendes, 2007; Filley et al., 2009; Sundgren et al., 2005). MRS studies have also documented NAA/Cr and Ch/Cr abnormalities before MRI discloses WMHI (Appenzeller, Bonilha, et al., 2007; Castellino et al., 2005). Castellino et al. (2005) found that non-NPSLE patients with high Ch/Cr at baseline had more MRI WM abnormalities at follow-up. Appenzeller, Li, et al. (2007) reported that SLE patients (both NPSLE and non-NPSLE) whose disease activity increased over the course of the study had a concomitant decline in NAA/Cr, that Ch/Cr increased in SLE patients compared to controls, and that patients with elevated Ch/Cr and normal MRI at baseline developed WMHI about one year later.

Studies further suggest that decreased NAA/Cr correlates with cerebral atrophy, focal lesions, aPL, and cognitive dysfunction in SLE, even in the absence of overt NP events (Brooks, Jung, Ford, Greinel, & Sibbitt, 1999; Brooks et al., 1997; Chinn et al., 1997; Davie et al., 1995; Rozell, Sibbitt, & Brooks, 1998; Sabet, Sibbitt, Stidley, Danska, & Brooks, 1998; Sibbitt, Haseler, Griffey, Friedman, & Brooks, 1997; Sibbitt et al., 1994; Sibbitt & Sibbitt, 1993). Reduced NAA in NPSLE may be largely due to microstructural lesions, including microinfarcts too small to discern with MRI (Friedman, Brooks, Jung, Hart, & Yeo, 1998; Sibbitt et al., 1999) that damage axons as well as myelin. NAA has also been found low in NPSLE patients with generalized seizures, psychosis, and confusional states, suggesting that cytotoxic effects of antineuronal antibodies, cytokines, or that small-molecule neurocytotoxins might also be involved (Sibbitt et al., 1999).

#### DIFFUSION TENSOR IMAGING

DTI provides an index of the structural integrity of WM by using quantitative directional diffusion properties of water molecules for each voxel. The technique is based on the principle of *anisotropy*, a term referring to the propensity for water in the normal state to diffuse along the direction of

WM tracts. Damaged WM, in contrast, is characterized by isotropic diffusion, which is correspondingly less directional and more random. Key DTI measures include fractional anisotropy (FA), mean diffusivity (MD), and the apparent diffusion coefficient (ADC). DTI is particularly sensitive to microstructural WM changes, including both myelin and axonal damage, and is an ideal tool for the study of WM because it can assess the structural integrity of specific tracts in relation to cognitive functions. DTI studies suggest WM damage in well-defined NPSLE patients and compared to controls (Bosma et al., 2004; Hughes et al., 2007; Jung et al., 2010; Zhang et al., 2007). In one controlled study of 37 non-NPSLE patients, no differences in WM, cortical GM, or the hippocampus were observed, but abnormalities were found in the amygdala (Emmer et al., 2006). Another controlled study of 34 NPSLE patients reported increased MD in the frontal lobe and the internal capsule, and decreased FA in the corpus callosum (CC) (Zhang et al., 2007). Abnormal findings were seen in patients with normal MRI scans, supporting the sensitivity of DTI to early WM changes. Use of a 3.0T scanner showed that FA was decreased in fronto-basal and temporal WM tracts of 12 SLE patients (NPSLE and SLE without overt NP; see Emmer et al., 2010), and increased ADC was reported in the frontal lobe as well as the CC splenium and genu in 15 SLE patients without overt NP compared to controls (Ulug et al., 2010). In a study of 26 SLE patients with one or more diffuse NP findings using a 3.0T scanner, increased ADC of NAWM was noted (Zivadinov et al., 2013).

#### POSITRON EMISSION TOMOGRAPHY AND SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) are functional brain imaging techniques that examine regional brain glucose metabolism. By their nature, these techniques are useful for the examination of GM areas only, as WM is generally less metabolic than GM. Overall, PET and SPECT studies in SLE patients demonstrate hypoperfusion across the cerebral cortex, and many studies have shown that these functional imaging abnormalities are increased compared to the prevalence of MRI abnormalities in these studies (Chen, Yen, Kao, Lin, & Lee, 2002; Otte et al., 1997; Weiner et al., 2000). Weiner et al. (2000) reported that PET showed hypometabolism in all of their SLE patients with NP manifestations, and also in 40% of the non-NPSLE patients. Studies have also demonstrated more specific hypometabolism in SLE, with abnormalities in the temporal (Csepany et al., 1997), parietal, and parietal-occipital regions (Otte et al., 1997; Weiner et al., 2000). Whereas PET and SPECT have potential utility in the study of cognition in SLE, it should be kept in mind that these techniques are intended primarily to assess cortical metabolism. Because this phenomenon is highly complex, and influenced not only by SLE but by many other unrelated

factors, the data gathered from PET and SPECT are relatively nonspecific with respect to the pathogenesis of SLE.

#### *Cognitive Correlates of Neuroimaging Abnormalities in SLE*

Across studies, consistent relationships between findings of traditional structural techniques of CT and MRI findings in relation to cognitive abilities have been intriguing but incomplete. Using CT, for example, Denburg et al. (1987) reported abnormalities in only 12% of the patients studied, and found that no CT findings were related to cognitive impairment. However, some of their specific neuropsychological case findings were associated with lateralized CT lesions. MRI has proven far more useful. Waterloo et al. (1999) used MRI in NPSLE and found cerebral atrophy in 47%, which was associated with decreased tactile problem solving, and furthermore, the number of infarcts was associated with impaired motor dexterity. Sailer et al. (1997) reported three or more WM lesions on 57% of their MRI scans in SLE. The number and size of WM lesions on MRI were correlated in this study with the presence of neurological deficits, but not with the severity of cognitive impairment. In contrast, another study showed that the number of WMHI was moderately associated with tests of attention, while cortical atrophy was not (Kozora & Make, 1998). Some studies have not found a relationship between global or specific cognitive dysfunction and WM or GM volume in SLE, either with or without NP activity (Filley et al., 2009; Haider et al., 2012).

Conventional brain imaging with MRI offered important initial information on the origin of cognitive decline in SLE, but findings have indicated that the structural analysis of MRI may not be the most sensitive approach to understanding brain-behavior relationships in this disease. More recent studies have identified more consistent abnormalities when the brain microstructure is examined in detail. The most helpful techniques permitting this kind of study are MRS, which enables measurement of brain neurometabolites; functional MRI (fMRI), which allows assessment of cortical and other GM function; and DTI, which increasingly offers a method of evaluating the microstructure of both WM and GM. The emerging studies using these and other techniques have been reviewed in this section, and important determinants of cognitive decline have been identified in both WM and GM. Rocca et al. (2006), for example, reported increased activation in the contralateral primary sensorimotor cortex, putamen, dentate, and fronto-parietal regions during a motor task in 14 SLE patients compared to 14 controls. In a study of ten pediatric SLE patients (mean age 17.1), working memory tasks resulted in increased activation (Difrancesco et al., 2007), with the pattern of abnormal fMRI activity suggesting disruption of WM connectivity that resulted in neuronal network dysfunction. In a more recent study, these authors examined seven pediatric SLE patients with and 14

without cognitive dysfunction, and noted greater brain activation during tasks of working memory and visuoconstruction (Difrancesco et al., 2013). Fitzgibbon et al. (2008) also examined working memory as well as attention and executive function using a working memory test in nine NPSLE patients compared to RA and healthy control subjects; they reported greater frontal and parietal activation that indicated abnormalities in frontal networks. In another study, a card-sorting task developed to assess executive function (strategic planning and goal directed task performance) indicated higher brain activation in 14 SLE patients compared to demographically matched controls (Mak, Ren, Fu, Cheak, & Ho, 2012).

Several studies further suggest that abnormal fMRI findings may occur in SLE patients with no history of overt NP activity and normal structural MRI. In 33 non-NPSLE patients, resting-state fMRI abnormalities were noted in many brain regions compared to healthy controls, primarily in the posterior cingulate cortex, the precuneus, and the neocerebellum (Lin et al., 2011). In another study of 13 SLE patients with no structural MRI abnormalities and no history of NP activity, greater cortical activation during working memory and emotional response was noted in the amygdala and superior parietal areas, and patients with less than two years of disease had increased activity in the cingulate gyrus, prefrontal cortex, and somatomotor cortex during working memory tasks compared to patients with greater than ten years of disease (Mackay et al., 2011). Another fMRI study, which involved 12 SLE patients with no history of NP activity, indicated increased brain activation in SLE patients during learning in the region of the intraparietal sulcus and around the junction of the precentral and superior frontal sulcus; a relationship between learning efficiency and greater hippocampal functional connectivity was also noted (Shapira-Lichter et al., 2013). Additional studies that suggest hippocampal abnormalities are related to memory impairment in NP and non-NPSLE, and in animal studies declines in learning and memory, as well as dendritic spine loss in the hippocampal pyramidal neurons, have been reported (Sakic et al., 1998; Tomita, Holman, & Santoro, 2001; Vogelweid, Wright, Johnson, Hewett, & Walker, 1994; Walker et al., 1997). In one study, 35 cognitively impaired SLE patients had reduced hippocampal when compared to 72 SLE patients without cognitive impairment (Appenzeller et al., 2006). In addition, the cognitively impaired SLE patients showed increased hippocampal volume loss over time. We further reported abnormalities of NAA/Cr and glutamate plus glutamine/Cr (Glu+Gln/Cr) in the hippocampus of 64 non-NPSLE patients that were directly related to memory impairment (Kozora et al., 2011).

PET and SPECT studies in SLE including a cognitive component are rare. Carbotte, Denburg, Denburg, Nahmias, and Garnett (1992) reported that in a longitudinal analysis of three SLE patients, PET abnormalities correlated with

cognitive deficits. Sailer et al. (1997) did not find cognitive differences in their SLE patients with abnormal global glucose utilization. Komatsu et al. (1999) reported that SLE patients with major psychiatric symptoms had decreased cerebral metabolic rates for glucose in prefrontal inferior parietal and cingulate regions, findings that they related to attentional deficits in this sample of patients. Waterloo et al. (2001) examined 52 SLE patients and reported that 55% had abnormal blood flow on SPECT, and 33% had one to ten focal areas of decreased blood flow. Specific regions of the brain demonstrating decreased blood flow included the frontal, temporal, and parietal regions. Seventy-seven percent of the SLE patients had significant decline in cerebral blood flow in the temporal lobe. These investigators failed to find any correlation between brain region and neuropsychological test findings after controlling for age and cerebral infarcts.

Neuroimaging techniques supporting an association between abnormal WM neuroimaging and cognitive deficits in SLE appear to be some of the strongest findings in the literature. Early MRI investigations demonstrated that the number of WMHI but not cerebral atrophy was associated with attention in 20 non-NPSLE patients, a finding suggesting WM changes associated with MCD-SLE (Kozora & Make, 1998). Subsequently, volumetric WM analyses were conducted, and CC volume was significantly lower in controls, and associated with a decline in measures of visuomotor reasoning and processing speed (Johnson, Pinkston, Bigler, & Blatter, 1996). In another study, CC volumes were significantly smaller (25%) in 115 SLE patients compared to controls (Appenzeller, Rondina, Li, Costallat, & Cendes, 2005); NPSLE had greater CC volume loss than SLE without overt NP. SLE patients with cognitive impairment had reduced CC sizes, but only a third of the patients were cognitively tested and no data were available for review. MRS has further identified WM changes in areas that are normal on MRI. Elevated Ch/Cr associated with cognitive impairment was reported in frontal WM of eight SLE patients without overt NP compared to eight controls (Kozora et al., 2005). In a later study, we did not find cerebral atrophy (based on volumetric analysis) or neuronal damage (based on NAA/Cr measurements) in SLE patients without overt NP compared to controls (Filley et al., 2009). However, higher Ch/Cr was found in the right frontal WM and left frontal WM in the SLE patients without overt NP compared to controls. A composite measure of attention and executive functioning was found to correlate positively with total WM volume and negatively with left frontal WM Ch/Cr (Filley et al., 2009). In a subsequent analysis of these patients, one selected measure (complex auditory information processing) was specifically associated with elevated Ch/Cr, further suggesting that WM changes were related to aspects of cognition (Kozora, Arciniegas, et al., 2013). The available MRS data in SLE indicate that early changes in WM,

particularly in myelin, may play an important role in cognitive impairment. Elevated frontal WM Ch/Cr may underlie MCD in SLE, which appears to be a precursor of more obvious brain pathology, advancing cognitive dysfunction, and clinical deterioration.

### **Summary of Findings**

The literature regarding cognitive dysfunction in SLE is extensive, and despite differences in methodology, studies clearly suggest that over 50% of the SLE patients with overt NP activity demonstrate cognitive impairment across a broad range of areas (i.e., memory, attention, executive function visuomotor speed and visuoconstruction). Studies to date further suggest that there is a relatively large group of SLE patients (approximately 30%) where cognitive deficits alone are the primary NP feature. This group of patients, that we label MCD-SLE, has been the focus of multiple studies. Cognitive domains that consistently are impaired in this group include aspects of attention, memory, and executive function. Mechanisms of cognitive dysfunction in SLE continue to be unclear. Studies to date most strongly suggest that aspects of disease severity as well as the presence of specific autoantibodies (i.e., aPLs) and inflammatory markers (pro-inflammatory cytokines) are likely biological mechanisms. There is strong evidence that future studies investigating immune and autoimmune factors within the CSF are necessary to better identify mechanistic pathways. In addition, new studies investigating cardiovascular and cardiopulmonary disorders are promising, and suggest that many systemic aspects of SLE may have an indirect link to cognitive dysfunction. A variety of behavioral factors remain integral to cognitive dysfunction, primarily in the NPSLE subjects. Depression as a mediator of cognitive dysfunction is clear in the NPSLE population; however, few studies have incorporated additional potential factors such as pain, fatigue, sleep disorders, and exercise tolerance. Studies with advanced neuroimaging have allowed a more sophisticated evaluation of brain abnormalities underlying cognitive deficits in the NPSLE and MCD-SLE populations. Although studies continue to explore both GM and WM, it appears that WM abnormalities may occur early in the course of cognitive dysfunction and may be the essential feature underlying MCD-SLE. Studies that have focused on learning and memory dysfunction in SLE also indicate changes in the hippocampus, even in the MCD-SLE group. Although subject selection and descriptors have become more refined, continued controversy regarding assessment and definition of clinical improvement exists. In addition, relatively small sample sizes and lack of longitudinal studies clearly impact the generalizability of current findings and the ability of investigators to empirically model interactions between the various potential biobehavioral factors and cognitive outcomes.

## **Antiphospholipid Syndrome**

### **Definition and Epidemiology**

The Updated Sapporo Classification Criteria define APS as vascular thromboses (arterial, venous, or small vessel) and/or pregnancy morbidity occurring in persons with persistent aPL (LA, aCL (Jain & DeLisa, 1998), and  $\beta_2$ GPI (Miyakis et al., 2006). APS may present acutely or run a chronic course affecting multiple organ systems (Stanley & Ghosh, 2013) and is considered primary if no other connective tissue diseases are present (Keeling et al., 2012). Anticoagulation with heparin followed by long-term warfarin is the treatment for APS patients with thrombotic events, while aspirin or anticoagulation is generally used during the pregnancies of APS patients with or without a history of pregnancy morbidities. Risk factors for APS include a variety of genetic markers, race (Black, Hispanic, Asian, Native American), and a diagnosis of SLE, and like SLE and other autoimmune diseases, APS is more prevalent in women than men. It has been estimated that up to 50%–70% of SLE patients may develop APS (Love & Santoro, 1990b; Petri, 2000) when higher levels of aCL and LA are found in these patients (Cervera et al., 2002). Evidence of aPL has been found in between 1% and 5% of otherwise healthy control subjects (Petri, 2000), and, as with other autoimmune diseases, the risk of aPL prevalence increases with age. Any organ in the body can be affected by APS, including the brain, and the range of disorders possible for each system is diverse (Levine, Branch, & Rauch, 2002).

### **Neuropsychiatric Antiphospholipid Syndrome**

The prevalence of NP disorders in APS patients without other autoimmune diseases is unknown. Major overt NP syndromes that occur in aPL-positive patients include stroke, transient ischemic attack, seizures, chorea, Guillain-Barré-like symptoms, headaches including migraine, depression, and cognitive impairment (Brey, Muscal, & Chapman, 2011; Cervera et al., 2002; Rodrigues, Carvalho, & Shoenfeld, 2010; Roldan & Brey, 2007; Sanna et al., 2003). In a European cohort of 1,000 persistently aPL-positive patients, Cervera et al. (2002) found more than 20.2% experience migraine, 19.8% stroke, 11.1% transient ischemic attack, 7% epilepsy, 2.5% multi-infarct dementia, 1.3% chorea, and 0.4% transverse myelopathy. However, in this study it was not clear if the aPL was the cause of the neurological disorder. In the original observations of APS syndrome, Hughes (1988) highlighted the presence of cerebrovascular accident and myelitis in APS; but since the time of this report, neurological manifestations with APS have been noted in the absence of stroke, suggesting that other mechanisms beyond direct vascular thrombosis are active (Carecchio, Cantello, & Comi, 2014). In terms of the mechanism underlying NP activity in APS, aPLs may bind to CNS neurons, leading to permeabilization and depolarization of these cells (Chapman, Cohen-Armon,

Shoenfeld, & Korczyn, 1999). Animal models corroborate that NP performance is affected by aPL independently of the ischemic events (Ziporen, Shoenfeld, Levy, & Korczyn, 1997). In a recent review of the literature, pathological mechanisms by which aPL leads to neurological dysfunction have been summarized as including (a) induction of a proinflammatory or procoagulation state mediated by endothelial cells, and platelet and coagulation cascade activation, and BBB dysfunction that allows for the influx of aPL and cytokines into the brain with toxic impacts on neurons and glial cells; (b) impairment of the normal inhibition of cerebral atherogenesis, leading to an increase in atherosclerotic vascular disease in the brain; and (c) aPL-mediated complement activation leading to CNS toxicity and dysfunction (Brey et al., 2011). Few studies have clearly classified NP events, and the estimates of “cognitive dysfunction” are limited. Although data are limited, a number of clinicians suggest that 25%–50% of patients with APS may have identifiable cognitive dysfunction.

### **Cognitive Dysfunction**

#### *Neuropsychological Studies*

Studies in primary APS or in asymptomatic aPL positive patients have shown that cognitive deficits may be present, independent of any history of known CNS involvement, when compared to controls or other patient groups. Jacobson, Rapport, Keenan, Coleman, and Tietjen (1999) examined neuropsychological functioning in 27 nonelderly patients with elevated levels (> 10 IU) of aCL IgG, but without concurrent history of autoimmune disease or any history or report of neurological events. Compared with 27 age- and education-matched controls, there were group differences in domain scores of working memory, executive function, verbal learning, memory and visuospatial functioning. The overall frequency of impaired neuropsychological performance was greater among individuals with aPL than controls (33% vs. 4% respectively), suggesting subtle neurological involvement. Few studies have clearly classified NP events and the estimates of “cognitive dysfunction” are limited. Tektonidou, Varsou, Kotoulas, Antoniou, and Moutsopoulos (2006) examined 39 patients with primary APS, 21 patients with SLE-related APS, and 60 healthy controls using a three-hour neuropsychological battery measuring attention, learning and memory, executive function, visuospatial skills, and depression. In this study, the cutoff limits of aPL positivity are not reported. Results indicated that 42% of the 60 patients with APS (combined primary and SLE-related APS) had cognitive deficits compared with 18% of healthy controls, with deficits most commonly detected in complex attention and verbal fluency. There was no difference in cognitive performance between patients with primary APS and those with SLE-associated APS (although there was a significant association between cognitive dysfunction and WM

lesions). In one pilot study of 20 APS patients, 13 out of the 14 APS patients with CNS disorders demonstrated mild cognitive deficits compared to 10 controls (Aharon-Peretz, Brenner, & Amyel, 1995).

Studies to date regarding cognitive dysfunction in primary APS versus those with SLE-associated APS are inconclusive, but tend not to show major differences (Sanna et al., 2003; Tektonidou et al., 2006). In a recent study by our group comparing 20 aPL-positive non-SLE female patients to 20 aPL-negative SLE female patients with no history of overt NP manifestations, 40% of the aPL-positive patients had global cognitive impairment using a comprehensive cognitive battery (compared to 60% of the SLE). The pattern of cognitive difficulties was similar across the two groups, with impaired performance in visual and verbal learning and memory, visuomotor speed, attention and information processing, verbal fluency, and problem solving. This study was consistent with prior studies demonstrating that aPL patients also have a wide range of cognitive impairments, and suggests both have global versus focal cerebral changes. The careful selection and characterization of the two samples further suggests that unique mechanisms underlying cognitive deficits in these autoimmune diseases exist. Future studies that include a third control aPL-positive SLE group at baseline, and evaluate all groups over time, may be necessary to identify the most important risks and mechanisms associated with cognitive impairment in these patients.

Several studies have investigated the role of aPL in relation to dementia or cognitive decline in the aging population. One study reported that 56% of elderly APS patients had dementia based on diagnostic criteria (Chapman et al., 2002), and neuropsychological dysfunction in otherwise normal elderly people was associated with increased levels of aCL (Schmidt, Auer-Grumbach, Fazekas, Offenbacher, & Kapeller, 1995). It is likely that cognitive dysfunction in these patients is due to multiple mechanisms. The underlying pathophysiology may relate to small vessel ischemic events, often involving cerebral WM, or there may be a direct pathogenic role of aPL, which has implications in the treatment.

#### *Biobehavioral Mechanisms of Cognitive Dysfunction in APS*

The biobehavioral aspects underlying cognitive dysfunction in APS have not been systematically evaluated, and no studies have examined the potential effects on a large sample of patients. In Tektonidou et al. (2006) a relationship between cognitive dysfunction and one aspect of clinical disease (livedo reticularis) was reported in 39 APS and 21 APS-SLE patients, but no relationship was found with measures of thrombosis, CNS involvement, aCL, LA, a $\beta$ 2GPI, or depression. Jacobson et al. (1999) did not report any relationship between prior NP history or depression to cognitive dysfunction in 27 APS patients, but also did not present data and duration of disease or other health factors. In our pilot study

of 20 APS-only patients, there was no relationship between cognitive impairment and aspects of disease activity, disease duration, medication use, or symptoms of depression (Kozora, Erkan, et al., 2013). Studies suggest that both SLE and APS can result in cognitive dysfunction; however, direct comparison of cognition across these disorders is difficult due to methodological issues. Many prior studies of SLE have not specifically screened out or identified those patients with positive aPL. The prevalence of positive aPL in patients with SLE is approximately 30%–40% (Love & Santoro, 1990b). In SLE studies of cognition, the prevalence of aPL has ranged from 6% to 38% (Conti et al., 2012; Hanly & Harrison, 2005; Maeshima, amada, Yukawa, & Nomoto, 1992; Peretti et al., 2012; Sanna et al., 2003) and the presence of aPL in SLE patients has been associated with greater impairment in memory, visuospatial speed, and visuoconstruction (Conti et al., 2012; Denburg, Carbotte, Ginsberg, et al., 1997; Hanly et al., 1993; Leritz et al., 2002). Our latest study suggests that both SLE patients without aPL and aPL patients with no history of SLE have cognitive dysfunction with no evidence of more overt NP activity. Continued studies that assess and compare biobehavioral characteristics of patients with SLE, aPL and SLE with aPL who experience cognitive decline over time may be the next useful step in understanding these cognitive disorders.

#### *Treatment Studies With APS*

No large studies of pharmacological, behavioral, or rehabilitative treatment to improve cognitive function in APS are available. In a retrospective analysis of five aPL-positive patients who tolerated and responded to rituximab (an antibody that binds to CD20 antigen, resulting in a rapid and sustained depletion of peripheral B-lymphocyte lineage), there was some evidence that this drug may be effective for aPL-associated cognitive dysfunction. Four of the five patients showed a decline on the cognitive impairment index, representing cognitive improvement, at 24 weeks (complete response, three; partial response, one; see Erkan, Vega, Ramon, Kozora, & Lockshin, 2013).

#### *Neuroimaging*

Neuroimaging abnormalities have been reported in primary APS patients presenting with high levels of overt neurological and psychiatric syndromes, however, even in the absence of NP activity, abnormalities are noted. Infarcts and scattered WM lesions are the most common abnormalities seen on CT and MRI in APS patients. Provenzale, Barboriak, Allen, and Ortel (1996) reported that 54% of aPL patients (with and without SLE) had abnormal studies (large infarcts, cortical infarcts, lacunar infarcts, hyperintense WM foci, or dural sinus thrombosis) in subjects who underwent CT or MRI. Results showed that large infarcts were the most common abnormality (in 22% of patients), followed by

hyperintense WM foci (in 17% of patients). The frequency of abnormalities was 57% in the SLE group and 41% in the non-SLE group. Large infarcts were more common in the non-SLE group (26%). In a study of 24 APS patients, 29 SLE patients, and 31 healthy controls undergoing MRI scan, both APS and SLE groups demonstrated greater cortical atrophy and increased WM abnormalities (periventricular and deep WM hyperintensities) compared to controls after controlling for neurological syndromes and other demographic and health variables (Hachulla et al., 1998). Based on a score of two standard deviations below healthy controls, eight APS patients had cortical atrophy and nine had greater WM hyperintensities. Hachulla and colleagues (1998) found only a weak correlation between LAC and cerebral atrophy. Kim, Choi, Choi, Lee, and Suh (2000) also reported that in 11 APS patients with a majority demonstrating overt neurological disease (seven undergoing CT, eight undergoing MRI including some overlap), five had WM abnormalities, four had large infarct of the middle cerebral artery, and two had cortical atrophy. Gomez-Puerta et al. (2005) studied a combined APS/SLE group who underwent CT and/or MRI and reported cortical infarcts in 63% of patients, subcortical infarcts in 30%, basal ganglia infarcts in 23%, and cerebral atrophy in 37%. In the Tektonidou et al. (2006) MRI study, WM lesions were identified as “ill-defined” punctate hyperintensities on T2, proton density, and fluid attenuated inversion recovery (FLAIR) images without prominent T1 hypointensity, and lesions were classified according to location (subcortical, periventricular, and deep) and graded according to size. In 23 APS patients with CNS involvement, they report that 12 (52%) had WM lesions, with 100% in the periventricular regions. Of the 36 APS patients without CNS involvement, eight (22%) had punctate WM lesions, with 88% located in periventricular regions (Tektonidou et al., 2006). In our study of 20 aPL subjects with no other connective tissue disease or NP activity, 50% demonstrated abnormal MRI or incidental MRI findings of WM change or cortical atrophy.

No studies using DTI, fMRI, MRS, PET or SPECT in APS syndrome have been published. Other approaches to studying this disease, however, have been investigated. A recent study of 28 primary APS patients used carotid Doppler ultrasound and echocardiograph evaluations, and reported abnormal function in the middle and anterior cerebral arteries that was associated with LAC, history of stroke, and obesity. Lampropoulos et al. (2005) used EEG to study 57 patients with APS and/or SLE who had NP symptoms (those with a history of stroke, epilepsy, or encephalopathy were excluded). Fourteen patients had APS, 24 were positive for aPL, and 19 patients had SLE without aPL. The frequency of abnormal EEG findings (primarily bitemporal slow activity) of the combined aPL and APS groups was 82%, compared to 32% in the SLE group. An association between abnormal EEG and aPL positivity was found. Of the aPL-positive patients, 82.3% with abnormal EEG results had at least two positive results for aPL, while 28.5% with normal

EEG findings had at least two positive results. Patients with abnormal EEG findings were more likely to report memory problems; however, no formal cognitive testing was applied.

Few studies to date have evaluated cognitive impairment in relation to neuroimaging abnormalities in APS. The use of combined groups of SLE patients with high aPL has disclosed inconsistent relationships. Chapman et al. (2002) reported that only half of their demented APS patients had abnormal CT scans, and suggested that the demented APS patients with normal CT scans may have had micro-lesions or pathology (not necessarily vascular mediated) that might have been detected with MRI or other neuroimaging techniques. In contrast, eight of the nondemented subjects with APS showed diffuse slowing on EEG. Of those with dementia, six had generalized atrophy and seven had focal lesions consistent with vascular pathology. To date, there are only two studies of primary APS patients that report neuroimaging abnormalities in relation to cognitive dysfunction. In a pilot study using clinical procedures, 50% of the MRIs in aPL patients with no history of SLE or NP activity were abnormal, but no association between incidental or major MRI abnormalities and cognitive dysfunction were noted (Kozora, Erkan, et al., 2013). In another study, Tektonidou et al. (2006), of a significant correlation between cognitive deficits and presence of WM lesions was found. In a subgroup of eight APS patients without overt CNS involvement but with WM lesions, cognitive deficits were identified in seven of the patients (Tektonidou et al., 2006). They also noted a positive relationship between WM lesions, livedo reticularis, and cognitive dysfunction, suggesting the presence of microvasculopathy. It is likely that sophisticated neuroimaging techniques such as DTI and MRS, with the capacity to permit better depiction of WM abnormalities, will expand our understanding of cognitive dysfunction in APS (Erkan, Kozora, & Lockshin, 2011).

### **Summary of Findings**

Very few studies of cognitive functioning in APS without overt NP activity and other autoimmune disorders exist. Of those published and available for review, cognitive dysfunction occurred in 33%–42% of the patients. Methodological problems exist that are related to subject selection, test selection, definition of impairment, lack of control subjects, and small sample sizes (less than 30 subjects in largest study). A standardized definition of APS now exists that improves subject selection; however, classification of NP activity in APS is quite varied and may or may not include cognitive dysfunction. As with the early SLE literature, formal studies to facilitate classification of NP in diffuse or focal CNS activity, including cognitive dysfunction, are necessary. The cognitive studies reviewed included a wide range of cognitive domains, and impairments in attention and working memory, learning and memory, executive function, and visuospatial and visuomotor functions were impaired. Standardization and/or adaptation

of a test battery would improve future studies. Most existing studies do not include assessment of biobehavioral correlates, and in these studies, aspects of clinical disease and behavior were noted (but not consistently). Finally, the neuroimaging aspects of APS clearly suggest that in addition to the expected cerebral infarcts related to vascular-mediated aPL activity, there is evidence of atrophy as well as multiple WMHI. As with SLE, it is likely that WM abnormalities occur early in APS, are correlated with cognitive dysfunction, and may be detectable well before more obvious structural damage.

## **Rheumatoid Arthritis**

### **Definition and Epidemiology**

RA is an autoimmune disease in which the immune system attacks the body's own tissues, specifically the synovium. The synovium is a smooth, thin membranous lining between joints that produces lubricative synovial fluid. As a result of the body's attacks on the synovium, synovial fluid builds up within joint space and development of fibrous tissue causes systemic pain and inflammation. It may take some time for symptoms to occur, and the rheumatoid factors responsible for pathology are deposited in a different way than in SLE, resulting in inflammation via activated macrophages. Over time, RA can affect several other organ systems, including the integumentary, respiratory, cardiovascular, digestive, and nervous systems, among others. The etiology of RA is not completely known, although it is clear that the disease has a systemic autoimmune component. Risk factors include genetics (accounting for 50% of risk; see van der Woude et al., 2009), and smoking (RA is one to three times as common in smokers than nonsmokers; see Stolt et al., 2003). Once initiated, the disease may worsen over time. For some individuals, the abnormal immune response becomes permanent and chronic. Most people with RA experience intermittent periods of severe disease activity, called *flares*, which are generally treated with glucocorticoids. Otherwise, RA is generally managed with nonsteroidal anti-inflammatory drugs (NSAIDs) and COX-2 inhibitors (NSAIDs targeting the COX-2 enzyme, responsible for inflammation and pain). The prevalence of RA worldwide is surprisingly uniform at approximately 0.5% to 1% (Scott, Wolfe, & Huizinga, 2010), and in the United States the prevalence is approximately 2.5 million, or 0.6% of the population (Helmick et al., 2008). The incidence and prevalence are approximately two to three times greater in women than men. The usual age of onset is between the ages of 30 and 60 for women (with a later onset for men). The prevalence increases with age, with average onset in the third to sixth decade of life.

### **Neurologic Rheumatoid Arthritis**

The neurologic manifestations in RA are thought to be a consequence of local joint changes, extra-articular rheumatoid

nodules, and secondary vasculitis (Voss & Stangel, 2012). The most common manifestation in RA is peripheral neuropathy, which can be sensory or sensorimotor in its manifestations. Of particular interest for this chapter, complaints including cognitive dysfunction, depression, and fatigue have also been identified in RA, strongly suggesting the possibility of CNS disease affecting neurobehavioral function (Wolfe & Michaud, 2004).

### *Cognitive Dysfunction*

Several studies indicate that patients with RA may have subtle cognitive dysfunction (Dick, Eccleston, & Crombez, 2002; Kozora et al., 1996; Kutner et al., 1988; Wekking, Nossent, et al., 1991). As with the early studies in cognition in SLE and other autoimmune disorders, methodological issues such as subject inclusion and exclusion, diverse test selection, and varying definitions of cognitive impairment limit the generalizability of studies in RA. Several studies have also shown high rates of cognitive impairment in RA compared to controls. Kutner et al. (1988) indicated that while SLE patients were more impaired than RA patients, the RA group was significantly more impaired than controls on measures of non-verbal reasoning, visuospatial functions, language, and verbal memory. As they also reported impaired motor functioning in RA patients, motor deficits may have impacted some of their other cognitive findings. Wekking, Nossent, et al. (1991) reported that 40% of the RA patients were cognitively impaired and suggested that cognitive impairment may not be specific to SLE but related to autoimmunity in general. In one study of RA (Dick et al., 2002), 20 patients without major NP syndromes (mean age of 62.9) with chronic pain performed worse than pain-free controls on a global score of attention, as well as sustained attention and working memory tasks. In addition, more than 60% of the RA patients had at least one of three scales of attention in the impaired range using demographically corrected scaled scores.

In a study by our group, a high incidence of global cognitive impairment was reported in RA patients (Kozora et al., 1996). We found that 31% of 29 RA patients (carefully screened to exclude all patients with a NP history) were globally impaired (defined as two or more of eight domain scores in the impaired range) with specific deficits in attention and fluency when compared to controls. There was no relationship with disease duration or medication use. Bartolini et al. (2002) studied 30 RA patients (mean age of 55.6) who also had no history of major NP disease including depression, and found that they were impaired on measures of executive function (fluency, reasoning), visuomotor skills (constructive, speed), and learning and memory. Using demographically converted impairment scores, they reported that 71% of the RA patients were impaired in visuospatial construction, 47% in reasoning, 44% in verbal fluency, 50% in visual

learning and memory, 38% in mental flexibility, 35% in verbal learning, and 29% in motor function. They further noted that except for attention, disease severity but not duration had a relation to the cognitive profile. In a later study, Appenzeller, Costallat, and Condes (2004) reported cognitive impairment in 30% of RA patients ( $n = 40$ ) compared to 7.5% of controls ( $n = 40$ ). Verbal fluency, verbal memory, and short-term memory were significantly impaired in RA compared to controls, and no relationship between cognition, duration of illness, disability, or corticosteroid therapy was noted.

In a study of 55 patients with RA (screened for other autoimmune diseases and major NP symptoms) compared to 48 controls matched for socioeconomic status and education, 71% were impaired, with lower cognitive scores across multiple areas including aspects of memory, attention, reasoning, and verbal skill (Hamed et al., 2012). In addition, these investigators reported that standard measures of disease activity and severity were not related to cognitive dysfunction, and despite high levels of depressive symptoms, there was no correlation between these symptoms and cognition. In a recent well-designed study where 115 RA patients screened for NP completed a comprehensive neuropsychological battery, 31% of the patients were cognitively impaired (based on four of 12 tests in the impaired range; see Shin, Katz, Wallhagen, & Julian, 2012). Twenty percent or more of the RA patients were impaired in aspects of executive function (nonverbal fluency) verbal memory, visual memory, and visuomotor speed, and more than 15% were impaired in working memory. The cognitively impaired RA patients had a greater likelihood of having lower education, low income, use of oral glucocorticoids, and increased cardiovascular risk factor. In a subsequent study of 82 RA patients from this cohort, they report that 15% of the RA group was impaired on a cognitive screening measure (including verbal learning and memory, and phonemic fluency) that was sensitive to the larger comprehensive battery previously described (Julian et al., 2012). Notably, the self-report measure of cognitive functioning yielded low sensitivity.

Several studies have demonstrated that SLE patients performed worse than RA patients on neuropsychological tests (Carbotte et al., 1986; Denburg et al., 1987; Hanly et al., 1993; Julian et al. 2012; Koffler, 1987; Kutner et al., 1988; Yazdany et al., 2011). We also compared SLE and RA patients, and reported that 30% of the 51 non-NPSLE patients and 11% of the 27 healthy controls had global impairment (Kozora et al., 1996). Interestingly, the RA patients were similar to those with SLE, manifesting impairments in attention and fluency compared to controls. Despite global similarities in cognitive dysfunction in SLE and RA, 33% of the non-NPSLE patients had difficulty encoding material compared to 14% in the RA group. These findings might suggest a more general process associated with autoimmunity underlying cognitive dysfunction in RA and SLE, with additional factors specific

to SLE (as reviewed earlier). For example, both SLE and RA patients have difficulty with attention and executive function, suggesting that a more general “autoimmune” mechanism may be work and may impact frontal lobe WM.

### *Biobehavioral Mechanisms of Cognitive Dysfunction in RA*

As reviewed on earlier, there are few studies investigating specific biobehavioral mechanisms of cognitive dysfunction, although pain, fatigue, and motor dysfunction have been hypothesized. As with other autoimmune disorders, inconsistent associations between disease parameters in relation to cognitive dysfunction have been reported. In general, few studies have found a relationship between cognitive dysfunction and disease factors such as duration of illness, disease severity, or medication use. One study suggested that motor dysfunction in RA might impact cognitive tasks involving coordination (Kutner et al., 1988). Another study found that cardiovascular risk factors were associated with cognitive dysfunction in RA, and suggested that hypertension, hyperlipidemia, obesity, or current smoking could increase the prevalence of cognitive impairment in RA (Shin et al., 2012). This study also found a relationship between corticosteroids and cognitive dysfunction, and noted that most of the subjects were taking low doses of prednisone (of 115 RA patients, only 14 were taking more than 5 mgs per day). Their findings do suggest that in this population corticosteroid use may increase the risk of cognitive dysfunction. Notably, they did not find that chronic pain or psychological distress was associated with cognitive dysfunction in RA, nor was global disease severity or measures of inflammation such as CRP. Although one study reported an association between pain and cognitive dysfunction in RA (Dick et al., 2002) another study did not find that pain was related to cognitive dysfunction once depression was factored into the analysis of 121 RA patients (Brown, Glass, & Park, 2002). These investigators did report that depressive symptoms remained related to cognitive dysfunction. Notably, many studies reviewed above excluded any RA patients with major depression or psychiatric disorders.

### *Neuroimaging*

There have been several neuroimaging studies in RA patients identifying brain abnormalities. Specifically, preliminary findings are beginning to identify WM abnormalities (increased number of WMHI and abnormal neurometabolic functioning within WM). Some studies also suggest neurometabolic abnormalities of GM. Hamed et al. (2012) reported that seven of 48 MRIs performed on RA patients had WMHI; however when compared to controls, there was no statistically significant difference. A number of studies, however, have indicated increased WMHI occurring in RA patients that correlate with poor scores on attentional, executive, and frontal lobe tasks.

Bartolini et al. (2002) performed MRI and SPECT scans on 30 RA patients, and 35% showed “some alterations at the subcortical level in terms of WM hyperintensities (WMHIs) without leukoaraiosis.” In addition, the authors report that these 11 patients all had low scores on attentional, executive, and visuospatial tasks. Using SPECT data in particular, they also reported that cognitive deficits in RA were related to hypoperfusion of the frontal (85%) and parietal (40%) lobes.

In a study using MRS of the NAWM, Ch/Cr was elevated in the centrum semiovale of RA patients with active inflammatory disease (Emmer et al., 2009). These authors examined 35 RA patients with active disease and 28 healthy control subjects, none of whom had any neurologic symptoms or signs. Twenty RA patients (79% female, mean age of 51.8, disease duration mean of 7.7 years, mean disease activity score of 28, joint assessment of 4.4) with active disease and elevated erythrocyte sedimentation rates (ESR) had higher Ch/Cr ratio and lower NAA/Cr ratio compared to 20 demographically similar inactive RA patients. No relationships were noted between disease duration or medication use and metabolite ratios in the RA group. Emmer et al. (2009) did not report any difference between the total RA group and controls on neurometabolite values, and suggested that inflammation is the primary mechanism underlying the WM abnormalities. To date there are few studies investigating neuroimaging abnormalities in relation to cognitive functions in RA. One study showed increased WMHI occurring in RA patients with poor scores on attentional, executive, and frontal tasks (Bartolini et al., 2002). No other studies of this nature exist in RA, but the available findings would suggest WM abnormalities likely mediated by inflammation and may underlie cognitive dysfunction in this population.

### *Summary of Findings*

Across many well-designed studies, cognitive deficits have been found to occur in approximately 30% to 40% of RA patients. Notably, deficits in working memory and attention, executive function, learning and memory, visuomotor and visuospatial activity, and motor function were frequently reported. The neuropathology of cognitive deficits in this group of autoimmune patients is unclear. Motor function impairment in RA may impact some, but not all of the cognitive domains. Additional biological mechanisms related to inflammation and possible cardiovascular disease have been noted. Behavioral aspects of pain and depression are also likely mediators, although these have not been consistently noted across studies. Neuroimaging studies in RA indicate that WM abnormalities are the most common finding, and these have been associated with cognitive impairment. Few studies suggest damage to the GM in RA. Although the neuropathology of RA has rarely implicated active CNS disease, a review of the data suggests that there may be biological underpinnings, particularly in relation to inflammation, that

impact the brain and contribute to cognitive dysfunction in RA. As with other studies in autoimmunity, limitations exist regarding subject selection, test selection, and definition of impairment, and attention to these issues is likely to improve future studies.

## Primary Sjögrens Syndrome

### *Definition and Epidemiology*

PSS is an autoimmune disorder characterized by abnormal proteins in the blood associated with an immune attack against the patient's own tissue. This process causes inflammation and damage primarily involving the exocrine glands, specifically the salivary and lacrimal glands that produce saliva and tears. It is thought that the presence of serum anti-Ro/SSA and/or anti-La/SSB antibodies (specific to PSS) may set in motion a dysfunctional immune response (as evidenced by increased presence of regulatory T cell infiltration) resulting in inflammation, autoreactivity, and tissue destruction (Nocturne & Mariette, 2013). *Primary* Sjögren's syndrome (as opposed to *secondary* Sjögren's syndrome) is not associated with another autoimmune disease such as SLE. The presence of sicca complex (i.e., dryness syndrome) is one of the primary clinical symptoms and typically involves the eyes, mouth, and other mucous membranes. The disorder is marked by a triad of symptoms including keratoconjunctivitis sicca (dry eyes) with or without lacrimal gland enlargement, xerostomia (dry mouth) with or without salivary gland enlargement, and connective tissue disease. Due to relatively benign initial symptoms, PSS may not be considered as a diagnosis for several years. Similar to other autoimmune disorders, PSS can affect many organs, including the kidneys, blood vessels, lungs, liver, pancreas, and nervous system. The etiology of PSS is not well known, although a genetic contribution is thought to exist (Bolstad & Jonsson, 2002) that may make some individuals more susceptible to a distinctive pathogenic process (Voulgarelis & Tzioufas, 2010). Some patients may experience remission or sustained or worsening symptoms that may involve renal disorder development. PSS affects approximately 0.6% of the U.S. population, or approximately 2 million people (Jonsson, Moen, Vestrheim, & Szodoray, 2002). According to the Sjögren's Syndrome Foundation there are upwards of 4 million Americans with this diagnosis and approximately 90% are women (Jonsson et al., 2002). The usual onset of symptoms occurs between 45 and 55 years of age (Borchers, Naguwa, Keen, & Gershwin, 2003), and prevalence generally increases with age (Fox, Stern, & Michelson, 2000).

### *Neuropsychiatric Primary Sjögren's Syndrome*

Patients with PSS have been observed to develop both PNS and CNS disease. The span of overt neurological disorders in PSS includes brain and spinal cord disease that has been

described as ranging from transient and reversible to fixed and cumulative. There is no current consensus regarding NP classification in PSS, and the use of different classification criteria, differences in patient populations, and lack of criteria for classification of NP activity are notable (Lauvsnes et al., 2013)—a finding reminiscent to the SLE research prior to the 1980s. CNS involvement may be focal or diffuse, with problems such as strokes, movement disorders, cerebellar and brain stem dysfunction, myelopathy, encephalopathy, aseptic meningitis, seizures, headaches, psychiatric disturbance, and cognitive dysfunction (Fauchais, Magy, & Vidal; Streifler & Molad, 2014; Tobón, Pers, Devasuchelle-Pensec, & Youinou, 2012). The estimated prevalence of CNS manifestations in PSS varies considerably, with some estimates as high as 30% (Alexander, 1986; Tajima et al., 1997; Volk et al., 1994). In Volk et al. (1994), 70% of PSS patients had neurological complications, and PNS changes were twice as frequent as CNS manifestations. Of the 30% with CNS manifestations, cerebral atrophy, hemiparesis, and aseptic meningitis were common. In contrast, CNS manifestations were rare in other studies (Andonopoulos, Lagos, Drosos, & Moutsopoulos, 1990; Binder, Snaith, & Isenberg, 1988; Moutsopoulos, Sarmas, & Taland, 1993). The incidence of more subtle disorders of the CNS such as mood disorders and cognitive dysfunction may be higher, and may be under-represented due to methodological issues. One review has reported that up to 50% of PSS patients displayed cognitive dysfunction (Vitali et al., 2002). For example, a recent study identified high levels of CNS disorders in carefully screened PSS patients. Of 120 PSS patients, 81 (67%) had evidence of CNS or PNS symptoms, and CNS involvement was more common than PNS dysfunction with the use of neurological, psychological, and psychiatric evaluation (Morreale et al., 2014). These investigators further report that 68 patients (84%) had nonfocal and had 64 focal CNS deficits, and that headache was the most common manifestation (46.9%) followed by cognitive dysfunction (44.4%) and mood disorders (38.3%).

### *Cognitive Studies*

Cognitive dysfunction has been noted in studies to date of PSS patients. As with other studies in autoimmune populations investigating cognitive dysfunction, the methodological problems and variation in subject selection, type of cognitive tests, and definition of impairment have made comparison across studies difficult. Selnes, Gordon, Malinow, and Alexander (1985) reported that 46% of the PSS patients had abnormal cognition primarily in attention and concentration. Malinow et al. (1985) also reported cognitive abnormalities in 44% of 40 PSS patients using similar tests, and reported a correlation with depressive symptoms as well. In another study, incidence of psychiatric and cognitive impairment was found in up to 80% of 131 PSS patients with CNS symptoms (Spezialetti, Bluestein, & Alexander, 1995). Volk et al. (1994) reported cognitive impairment in 70% of 20 PSS patients

using measures of intelligence, visual memory, and perceptual speed. Specifically, one-fourth of their patients showed impairment on a visual memory test and up to 70% on a perceptual-motor speed test. Segal et al. (2012) studied 39 PSS (with no NP history) compared to 17 controls similar in premorbid IQ, age, and education and report lower cognitive performance in PSS on measures of psychomotor processing and verbal reasoning. There was no difference between PSS patients with high and low symptoms of depression on cognitive functions except for executive function (which was lower in depressed PSS). Pain also correlated with executive function and working memory dysfunction. Rodrigues et al. (2014) studied 18 PSS patients compared to 18 MS and 18 controls with measures of attention, fluency, visuomotor speed, verbal memory, and visuoconstruction. Group differences between PSS and controls existed on aspects of executive function/flexibility and verbal memory, but not on measures of fluency, visuoconstruction, or visuomotor speed. There was no relationship between depressive symptoms and cognitive functions. Epstein et al. (2014) studied 37 PSS and patients and 37 controls (matched for gender, IQ, education, and past NP history) and found few differences between the groups on measures of attention, visuomotor speed, executive functioning, and memory from a computerized test battery, but did report significantly lower recognition memory and visuomotor speed in PSS patients. Finally, Morreale et al. (2014) reported that 44% of PSS patients had cognitive deficits with abnormal scores reported in aspects of executive functioning (nonverbal reasoning), visuomotor sequencing, and verbal memory.

#### *Biobehavioral Correlates of Cognitive Dysfunction in PSS*

To date there are not enough studies to evaluate or comment on potential biobehavioral correlates of cognitive dysfunction in PSS. Most studies do not include correlations between disease factors, medications, and cognitive findings, and of the few that did report depressive symptoms, most detected no significant findings. Interestingly, one group studied 66 PSS patients compared to gender-matched healthy controls and did not report significant differences in performance across the groups on a comprehensive battery of cognitive tests, but did report that the patients with PSS and anti-NR2 antibodies in CSF and serum demonstrated worse performance in learning and memory (Lauvsnes et al., 2013). This study also reported that the patients with depression had serum anti-NR2 antibody levels above the cutoff. These studies suggest that autoimmune antibodies are likely associated with cognitive dysfunction and NP changes in PSS.

#### *Neuroimaging*

Neuroimaging studies have demonstrated a range of brain abnormalities in PSS. The major findings include increased

number of WMHI, small cerebral strokes, and cerebral volume loss. Alexander et al. (1988) reported that 12 of their 16 PSS patients with active CNS disease had abnormal MRIs (primarily because of focal lesions in the subcortical and periventricular WM) and two out of 22 PSS patients without active CNS disease had similar abnormalities. Notably, seven out of eight PSS patients with psychiatric or cognitive problems (documented with objective evaluations) had abnormal MRIs. In a Medline review of studies through 2003, MRI was found to reveal cerebral tissue damage even in neurologically asymptomatic PSS patients, and periventricular and subcortical WM changes were common. In PSS patients with CNS disease, cortical atrophy was also observed (Morgen, McFarland, & Pillemer, 2004). Compared to controls, higher WMHI numbers were noted in 38 of 53 PSS patients with no history of NP activity, and a relationship was found between disease duration and number of WM lesions (Tzarouchi et al., 2011). This study also reported that PSS patients had decreased GM and WM volume compared to controls, and atrophy of the CC was also significant. In another study, 22 PSS patients with tension headaches had a higher number and size of WMHI compared to 20 age-matched controls with tension headaches (Šarac et al., 2013). These investigators further reported that the increased number of WMHI in the PSS patients was related to disease duration, and with a marker of chronic inflammation.

Few studies using MRS or DTI in PSS exist, but findings to date suggest abnormalities. Of 81 PSS patients in one study, 47 were noted to have decreased NAA/Cr ratios using MRS analysis in subcortical frontal WM and basal ganglia (Morreale et al., 2014). Another study, using DTI analysis in 53 PSS patients with no history of NP activity, reported decreased FA in the corticospinal tract, superior longitudinal fasciculus, anterior thalamic radiation, inferior fronto-occipital fasciculus, uncinate fasciculus, and inferior longitudinal fasciculus (Tzarouchi et al., 2011). This study also found increased MD in many brain fiber tracts in PSS compared to controls.

Studies that integrate cognitive and neuroimaging data in PSS are also rare, but are beginning to emerge. In a study of 321 PSS patients presenting with neurological symptoms, 16% (51 patients) had at least one neuroimaging study, and of that group, 25 had WM abnormalities (Akasbi et al., 2012). WM abnormalities were classified as vascular changes in 21 patients, with ten showing multiple small focal lesions, seven with a confluence of lesions, and four having diffuse involvement. In addition, four patients were classified as having inflammatory/demyelinating lesions that were MS-like in nature. Of the 25 PSS patients, ten had cognitive impairment. Notably, with the subjects without WM abnormalities used as a comparison group, the patients with WM abnormalities were significantly older (mean age 70.3 vs. 58.3), were receiving less antimalarials, had lower leukopenia, lower anti-La/SS-Band, and higher frequency of cardiovascular risk

factors (i.e., diabetes, metabolic syndrome, hypertension, and HDL-c levels). Thus, it is unclear if PSS itself is an independent factor contributing to the WM abnormalities found in this study. One study that focused on hippocampal volumes reported that a group of 66 PSS patients had smaller hippocampi (adjusted for total intracerebral volumes) compared to healthy gender-matched controls (Lauvsnes et al., 2013). These investigators also report that higher hippocampal volume was related to higher scores on a majority of the memory tests administered.

### **Summary of Findings**

Although there are relatively few large comparable studies in PSS, findings to date suggest that up to 40% of PSS patients without NP activity or other autoimmune disorders have cognitive dysfunction. Notably, deficits in attention, memory, and executive function are common. As in other autoimmune diseases affecting cognition, methodological issues limit overall the generalizability of findings. Whereas a number of studies and reviews suggest an increasing awareness of NP activity, including cognitive dysfunction in PSS, a standard approach regarding NP classification has not yet emerged. Mediators of cognitive dysfunction in PSS are not consistently evaluated, and to date, clinical disease activity related to PSS has not been associated with cognitive dysfunction. However, there is some evidence that autoimmune activity may be an underlying mechanism for cognitive changes. Most autoantibodies (other than anti-NR2) or inflammatory measures have yet to be studied in this population. Behavioral factors may also be important, but no studies have yet included aspects of depression, pain, fatigue, sleep, and exercise. Neuroimaging abnormalities implicate both GM damage (cortical and hippocampal volume loss) and WM damage (increased WMHI, and MRS and DTI abnormalities).

### **Conclusion**

A thorough review of cognitive dysfunction in four autoimmune diseases for which substantial information is available—SLE, APS, RA and PSS—indicates that cognitive impairment is common. Even in the absence of overt neurologic or psychiatric features, cognitive dysfunction occurs in up to, or more than, 30% of patients with these diseases. SLE remains the most thoroughly studied autoimmune disease, with less information available in APS, RA, and PSS, but in all four diseases, impairments in attention, memory, executive function, and visuomotor/visuospatial functions are typical, suggesting a diffuse pattern of cerebral dysfunction. Underlying mechanisms related to cognitive dysfunction in the autoimmune diseases remain unclear, but there is evidence that biological features, including specific disease characteristics (severity of disease and associated organ involvement) and various autoimmune factors (especially

aPL, anti-NMDA antibodies, and proinflammatory cytokines), contribute to the development of cognitive dysfunction. Behavioral features (depression, pain, fatigue, sleep disorders, and physical inactivity) are not always included in studies of these diseases, but findings suggest that these factors also contribute to cognitive impairment, and likely interact with the inflammation that is characteristic of autoimmune diseases. Neuroimaging studies of cognitive dysfunction in these diseases suggest that WM abnormalities are the most common finding, and emerging evidence indicates that both macrostructural lesions (such as WMHIs) and microstructural WM damage are important in the pathogenesis of cognitive dysfunction. In particular, subtle WM damage early in the course of these diseases may be crucial in the early presentation of cognitive dysfunction. In this regard, the term MCD-SLE has been proposed as a descriptor for the insidious cognitive impairment that has been associated with microstructural WM involvement in SLE, and the MCD concept may be applicable to other autoimmune diseases as well, including APS, RA, and PSS. In SLE, APS, and PSS, diffuse GM abnormalities can also be found, and hippocampal volume loss may be important in producing learning and memory deficits. Thus it is clear that both WM and GM deserve study in these complex diseases. The investigation of WM dysfunction, however, offers a novel approach that could help identify a specific neuropathology that is common to all of these diseases. In addition, WM involvement could offer important insights into the processes by which distributed neural networks are disrupted by these diseases. Moreover, early WM injury could prove central to the understanding of the sequence of pathogenic events producing cognitive decline, and point the way toward effective treatments that could reverse or prevent cognitive impairment before more disabling problems develop. Future neuropsychological studies should employ uniform diagnostic criteria for subject selection, standardized classification, and reporting of NP features (for APS and PSS in particular), and standardized, uniform test batteries that at a minimum include attention and working memory, verbal and visual learning and memory, executive and problem solving, and visuomotor/visuospatial tasks. Larger sample sizes, using multisite studies, are also warranted to accommodate longitudinal designs that will lead to better understanding of disease course and potential treatments. The continued application of neuroimaging techniques that focus on WM (i.e., MRS, DTI) as well as GM (i.e., fMRI) will be highly informative, and the use of CSF analysis for measurement of autoimmune and inflammatory markers promises to yield useful data regarding the autoimmune processes underlying brain dysfunction. Whereas the high frequency of cognitive impairment in the autoimmune diseases is distressingly apparent, few treatment options exist for this problem, and future studies focusing on this area will likely improve the outcome for patients with these challenging diseases.

## 27 Sports-Related Concussion

*William B. Barr, Lindsay D. Nelson, and Michael A. McCrea*

### Introduction

Due to its extensive media coverage and public interest, sports-related concussion (SRC) continues as a major topic in the United States and worldwide (Pearce, Gallo, & McElvenny, 2015). The annual incidence of nonfatal traumatic brain injuries (TBIs) from sports and recreation activities in persons aged 19 years or younger is estimated to be more than 2.6 million per year in the United States and the numbers appear to be growing (Noble & Hesdorffer, 2013). A recent study indicated that from 1997 to 2007 emergency department visits for 8- to 13-year-old children affected by concussion in organized sports doubled and increased by more than 200% in the 14- to 19-year-old group (Bakhos, Lockhart, Myers, & Linakis, 2010). There are also indications that the reported incidence of SRC may even be higher than what was described in previous studies due to increased attention and awareness (LaBotz, Martin, Kimura, Hetzler, & Nichols, 2005; LaRoche, Nelson, Connelly, Walter, & McCrea, 2015; McCrea, Hammeke, Olsen, Leo, & Guskiewicz, 2004).

The increased incidence of SRC over the last several years may be driven, at least partially, by greater awareness and identification of SRC among current-era athletes relative to earlier generations (Hootman, Dick, & Agel, 2007). Because of the high incidence of concussion and concern for long-term neurologic consequences (DeKosky, Ikonomic, & Gandy, 2010; Gilchrist, Thomas, Wald, & Langlois, 2007; Langlois, Rutland-Brown, & Wald, 2006), nearly all states have now enacted SRC management legislation. These laws require athletes, coaches, parents, and school organizations to be educated regarding the recognition, evaluation, and management of SRC and to have predefined return-to-play protocols.

In spite of a growing body of empirical research, sports medicine professionals continue to view the diagnosis of SRC and projection of postinjury recovery patterns among their most difficult clinical challenges. From the beginning, clinical neuropsychology, through its emphasis on standardized clinical testing, has made significant contributions to understanding the nature, severity, and recovery of symptoms observed in SRC (Belanger, Curtiss, Demery, Lebowitz, & Vanderploeg, 2005; Belanger & Vanderploeg, 2005; Echemendia et al., 2013; Erlanger, Kutner, Barth, & Barnes, 1999; Nelson, Janecek, & McCrea, 2013). Given their

background in test construction and psychometrics, neuropsychologists have also been critically involved in developing new test methods for use exclusively in the sport setting. This chapter will provide a general review of the current status of SRC and provide an overview of the use of neuropsychological methods in sports, emphasizing an evidence-based approach to assessing and managing both acute and sub-acute symptoms.

### Diagnosis Acute Recovery From SRC

#### *Diagnostic Issues*

The initial identification and management of the athlete with a suspected SRC begins on the field of play. This initial stage of evaluation is conducted most appropriately by individuals with specialized training in emergency medicine, such as licensed physicians and certified athletic trainers (ATCs). The primary aims of the initial assessment are to (a) recognize whether or not an injury to the brain or any other part of the body has occurred, and (b) determine whether transport to a medical facility is needed (Bailes & Hudson, 2001; Kelly & Rosenberg, 1997a, 1997b). It is extremely important to rule out whether there are any medical or neurological signs that would signal the presence of severe intracranial pathology or possibly serious injuries to the spinal cord or other parts of the body (Kelly & Rosenberg, 1997a). In spite of some initial controversy on same-day return to play, the emphatic approach used today is that any athlete with a suspected concussion should not return to play on the day of the injury and should not return to any form of practice or competition until he or she is evaluated and cleared by a qualified professional.

Controversies in concussion begin with definitions and diagnostic classifications. Most of the standard guidelines for defining and classifying levels of TBI have been of little use for diagnosing SRC. Systems commonly used by clinicians including the American Congress of Rehabilitation Medicine (ACRM) guidelines for mild TBI (MTBI; see Kay et al., 1993) place too much emphasis on duration of loss of consciousness (LOC) and posttraumatic amnesia (PTA) considering the fact that results from controlled investigations have now demonstrated that LOC occurs in less than 10% of the subjects with SRC, with no signs of either

LOC or PTA observed in more than 70% (Guskiewicz et al., 2003). For similar reasons, while scores on the Glasgow Coma Scale (GCS; see Teasdale & Jennett, 1974) may be useful for reconstructing injury severity from ambulance records following motor vehicle accidents, they are clearly less useful for making a diagnosis of SRC in an athletic setting.

For clinical purposes, many neuropsychologists in the athletic setting are now using the injury definitions provided in the sports medicine literature. While over the past 20 years there has been a plethora of definitions and grading scales developed for use in an athletic setting, there has been some movement towards use of the evolving set of definitions included consensus statements developed through a series of International Conferences on Concussion in Sport (Finch, Clapperton, & McCrory, 2013).

The definition developed in the most recent conference, held in Zurich in 2012, is provided in Table 27.1. In this definition, concussion is defined as “a complex pathophysiological process affecting the brain, induced by biomechanical forces” and extends to a brief description of possible causes and effects in addition to the expected course of recovery (McCrory, Meeuwisse, Aubry, Cantu, et al., 2013). In conjunction with a number of assessment tools outlined in the consensus statement, the criteria specified in this definition can be used in a model emphasizing a more empirical and multidimensional approach to documenting the signs and symptoms of injury.

*Table 27.1* Definition of concussion: Consensus statement on concussion in sport from the the Third International Conference on Concussion in Sport held in Zurich, November 2012

Concussion is a brain injury and is defined as a complex pathophysiological process affecting the brain induced by traumatic biomechanical forces. Several common features that incorporate clinical pathologic and biomechanical injury constructs that may be utilized in defining the nature of a concussive head injury include:

- 1 Concussion may be caused either by a direct blow to the head face neck or elsewhere on the body with an “impulsive” force transmitted to the head.
- 2 Concussion typically results in the rapid onset of short-lived impairment of neurological function that resolves spontaneously. However in some cases symptoms and signs may evolve over a number of minutes to hours.
- 3 Concussion may result in neuropathological changes but the acute clinical symptoms largely reflect a functional disturbance rather than a structural injury and as such no abnormality is seen on standard structural neuroimaging studies.
- 4 Concussion results in a graded set of clinical symptoms that may or may not involve loss of consciousness. Resolution of the clinical and cognitive symptoms typically follows a sequential course. However it is important to note that in some cases symptoms may be prolonged.

(Used with permission from McCrory et al., 2013.)

### *Acute Clinical Effects and Recovery*

The scientific literature supports a functional rather than a structural etiology for SRC (Signoretti, Lazzarino, Tavazzi, & Vagnozzi, 2011). The model commonly used to understand the neurophysiological basis of SRC and other forms of mild head injury, developed on the basis of animal models, is conceptualized as a multilayered neurometabolic cascade, involving a complex of interwoven cellular and vascular changes that occur following trauma to the brain (Giza & Hovda, 2001; Giza & Hovda, 2014). According to this model, the pathophysiology of SRC represents a temporary disruption of brain function secondary to ionic fluxes, abnormal energy transmission, diminished cerebral blood flow, and impaired neurotransmission rather than any readily identifiable form of structural brain damage.

Extensive research over the last 10–15 years has advanced our scientific understanding of the true natural history of SRC. The results show, in general, that the clinical recovery is favorable. A 2003 report was the first to plot the continuous time course of acute recovery immediately and within several days after SRC, indicating that more than 90% of athletes exhibited recovery within one week. Figure 27.1 displays the recovery curves for symptoms, cognitive performance, and postural stability from that study (McCrea et al., 2003). Since that time, several other prospective studies have confirmed the fact that most athletes achieve a complete recovery of symptoms, cognitive functioning, postural stability, and other functional impairments within a period of approximately one to two weeks following SRC (Belanger & Vanderploeg, 2005; Broglio & Puetz, 2008; Collins et al., 1999; Macciocchi, Barth, Alves, Rimel, & Jane, 1996).

Limited research findings have suggested a lengthier recovery time in younger athletes (Field, Collins, Lovell, & Maroon, 2003), with some papers demonstrating that roughly half of all high school athletes require more than 14 days to recover (Henry, Elbin, Collins, Marchetti, & Kontos, 2015; Lau, Lovell, Collins, & Pardini, 2009; Lau, Collins, & Lovell, 2012). Unfortunately, these studies have not included control subjects and applied “recovery” criteria that may have resulted in high false-positive rates due to criterion contamination, complicating the interpretation of resulting data (Nelson et al., 2013). Other researchers have reported that female athletes experience more symptoms and greater cognitive impairment from SRC than male athletes, although findings from these studies are quite mixed (Covassin, Schatz, & Swanik, 2007; Dick, 2009; Zuckerman et al., 2012). Many of the studies reporting gender differences in recovery were hampered by small samples of female athletes, poorly matched groups, or lack of preinjury baseline data (Nelson et al., 2013).

Figure 27.1 Recovery curves for clinical recovery from SRC in sample of 94 injured athletes and 56 controls (used with permission by McCrea et al., 2003.)

## Assessment of Acute Injury Effects

### Sideline Testing

The consensus opinion from a recent panel of experts in the field of sports injuries is that the sideline evaluation serves as an “essential component of the protocol” (Aubry et al., 2002). The timeline for formal assessment of an athlete using validated instruments begins right at the time of the injury. A comprehensive evaluation requires a multimodal approach, including information regarding subjective symptoms, examination of vestibular functions, and an assessment of neurocognitive status (McCrorry, 1997). The immediate goal of the initial evaluation is to determine whether or not symptoms of SRC are present and to provide a means to track the course of recovery. For years, this critical evaluation was performed through informal examination methods, without any empirical evidence to support their validity (Maddocks, Dicker, & Saling, 1995; McCrea, Kelly, Kluge, Ackley, & Randolph, 1997; McCrorry, 1997).

Over the years, a number of investigators have developed and validated a series of screening measures for use in evaluating athletes for SRC on the sideline (Collins & Hawn, 2002; Guskiewicz, Riemann, Perrin, & Nashner, 1997; McCrea et al., 1997). The requirements of these instruments are that they are portable, can be administered briefly, and can be used on multiple occasions. Since neuropsychologists are not typically present on the sideline for the initial assessment, it is important to utilize methods that can be administered and interpreted by team physicians and athletic trainers who have not received formal training in psychometric assessment. In the following, we present a multidimensional model of sideline assessment, comprised of measures that have been validated empirically for assessing symptoms, balance, and cognitive functioning.

### Symptom Checklists

The subjective symptoms resulting from SRC are either reported spontaneously or are elicited through an examiner’s questioning on the sidelines. Lovell and Collins (1998) introduced the Post-Concussion Scale–Revised (PCS-R) as a formal method of evaluating these symptoms in athletes, and this has gained rather wide acceptance for routine clinical use. The PCS-R consists of 21 symptoms commonly reported by individuals who have sustained a MTBI. The symptoms are rated individually on a 7-point Likert scale ranging from 0 (nonexistent) to 6 (severe). Ratings for each symptom are summed to obtain a total symptom score. Normative data on the original form of the instrument have been published (Lovell et al., 2006). Results from other investigations using modified versions of the instrument have demonstrated its utility in documenting symptoms of SRC (Guskiewicz & Broglio, 2011; McLeod & Leach, 2012).

The Concussion Symptom Inventory (CSI) is another brief 12-item instrument developed through psychometric methods that has proven to be sensitive to the effects of SRC (Randolph et al., 2009). This measure was developed from data obtained on more than 16,000 athletes receiving baseline testing and more than 600 athletes following SRC. A total of 12 of 27 symptoms were found to be most sensitive to detection of SRC in injured athletes. Each symptom is rated on a 7-point Likert scale ranging from 0 (nonexistent) to 6 (severe). Ratings for each symptom are summed to obtain a total symptom score. Studies on the validation sample indicated that this 12-item scale was as sensitive as prior measures composed of a larger number of items. At this point, this is the only empirically derived scale in existence for tracking SRC symptoms in injured athletes.

*Neurocognitive Testing*

The Standardized Assessment of Concussion (SAC) was developed by McCrea and colleagues as a brief and valid measure of neurocognitive functioning for use on the sideline for evaluating the immediate effects of SRC (McCrea, 2001; McCrea et al., 1997; McCrea et al., 1998). The instrument takes approximately five minutes to administer. It includes five orientation questions, a five-word list-learning test, digits backward, reversing the months of the year, and delayed recall of the word list. Summing scores from all of these tasks yields a 30-point composite score that can be used for aid in diagnosis and to guide immediate decision making. It also includes a standard neurologic screening, exertional maneuvers, and means for assessing LOC and posttraumatic amnesia. There are numerous studies demonstrating this measure's psychometric properties and its sensitivity to detecting symptoms of SRC in high school and college athletes (Barr & McCrea, 2001; M. McCrea et al., 2003; McCrea et al., 1998).

*Balance Testing*

Individuals sustaining a SRC are known to experience dizziness and resulting difficulties with balance. Positive Romberg signs can be elicited in up to two-thirds of athletes after the injury, making balance one of the most sensitive indices for assessing acute effects of SRC (Guskiewicz, Weaver, Padua, & Garrett, 2000). The Balance Error Score System (BESS) is a method developed by investigators at the University of North Carolina as a standardized measure of postural stability for assessment on the sideline (Guskiewicz, Ross, & Marshall, 2001; Riemann & Guskiewicz, 2000). The procedure requires the injured athlete to maintain three stances (double, single, and tandem) while resting on a firm surface or on a piece of 10-cm thick foam. Subjects are instructed to maintain their stance while keeping eyes closed and maintaining hands on their hips for 20 seconds. They are instructed to make any necessary adjustment to maintain their balance but to return to the original position as soon as possible. Examiners are trained to identify six types of errors. Scoring is based on the total number of errors observed over the six test trials. Psychometric properties and data demonstrating the reliability of this instrument have been reported in several research investigations (Guskiewicz & Broglio, 2011; Guskiewicz et al., 2001; Riemann, Guskiewicz, & Shields, 1999).

*Other Sideline Instruments*

The sports medicine literature includes descriptions of other standardized approaches to sideline testing of neurocognitive functioning (Collins & Hawn, 2002). In contrast to the SAC, many of these instruments provided structured guidelines for assessing mental status without computing a final test score. The subjective nature of these instruments limits their applicability in research settings and places restrictions

on the ability to determine their validity and sensitivity to detecting the effects of SRC.

The Sports Concussion Assessment Tool, currently in its third revision (SCAT-3) is a measure that has been developed and modified over the years as part of the International Conference on Concussion in Sport (McCrory, Meeuwisse, Aubry, Cantu, et al., 2013). The intent has been to develop a standardized tool that could be used for patient education in addition to multidimensional clinical assessment of SRC. The original version included a combination of previously published tools, including lists of physical signs of concussion in combination with measures of clinical symptoms and cognitive functioning. More recent versions of this instrument (SCAT-2 and SCAT-3) incorporate a graded symptom checklist, SAC, modified (firm surface) BESS, and the Maddocks questions (Maddocks et al., 1995) in addition to providing a total score (Guskiewicz et al., 2013; Paul McCrory et al., 2009). While normative data on this instrument in its entirety were not available initially, a number of studies providing norms on subtests from various versions of the SCAT are appearing in the literature (Jinguji et al., 2012; Putukian et al., 2015), which should lead to more widespread adoption of this instrument in the sports medicine community.

Another measure used increasingly for assessment of acute concussion effects is the King-Devick test (KDT; see King, Clark, & Gissane, 2012). The KDT is a brief and portable test of visual functions that can be performed in less than one minute. The respondent reads a series of numbers whose placement on three cards requires saccadic (fast alternating) eye movements to fixed targets. Consistent with other standardized assessments that have been advocated recently for the assessment of SRC (e.g., the SCAT-2, SAC, BESS), there is evidence that the KDT is sensitive to the effects of SRC, although published samples have been small (Galetta et al., 2011; Galetta et al., 2013). However, at this point there is a relative lack of normative data on the KDT and limited information on its psychometric properties, such as test-retest reliability, when applied to athlete samples.

**The Role of Neuropsychological Assessment**

Neuropsychological assessment in the sports setting is utilized optimally for providing an objective basis for evaluating the effects of SRC, particularly at a point when athletes are no longer reporting subjective symptoms. The original intention was to use neuropsychological testing as the measure to officially mark when an otherwise "symptom free" individual is ready to return to play. Unfortunately, the data have not supported the use of neuropsychological testing for that purpose (Nelson et al., in press). While there is no doubt that neuropsychological testing has made a contribution to our ability to diagnose and manage SRC, valid questions regarding its usage for tracking acute injury effects have emerged over the past ten years (Broglio, Ferrara, Macciocchi,

Baumgartner, & Elliott, 2008; Guskiewicz et al., 2005; Guskiewicz et al., 2003; Randolph, McCrea, & Barr, 2005; Resch, McCrea, & Cullum, 2013). The aim of this section of the chapter is to critically evaluate the current use of neuropsychological assessment in a sports setting with the goal of moving towards an evidence-based model of practice.

### *Utility of Baseline Testing*

At this point, many neuropsychologists have participated in baseline neuropsychological testing programs in the sports setting in a manner that is consistent with the model established by Barth, Alves, Ryan, Macciocchi, Rimel, and Jane (1989) with further refinement made by others for use with professional, collegiate, and high school athletes (Lovell & Collins, 1998). The overwhelming trend over the past several years has been to use computerized test batteries with team data obtained at preseason baseline, followed by testing performed on injured athletes within 48 hours of the injury. Additional testing is performed subsequently until the athlete has demonstrated a “return” to his or her baseline level of performance. While this model holds much in terms of intuitive appeal, its success and wide acceptance appears to be based more on the effects of professional recommendations and opinion than the results of empirical research. Empirical findings supporting the utility of neuropsychological testing during the early stage of recovery from SRC are sorely lacking.

There are, indeed, a number of apparent advantages to the concept of performing neuropsychological testing on injured athletes when baseline test data are available for use as a comparison. The availability of this “within-subject” design enables the clinician to control for what might amount to confounding factors associated with premorbid intelligence, cultural factors, and the individual’s neurodevelopmental background. However, what is tantamount to this model is an assumption that the clinician has a measure that is sensitive enough to detect a change in performance associated with the injury that can be detected over and above the noise associated with practice effects and the inherent reliability of the instrument. There are now a number of questions as to whether the neuropsychological tests currently used in the sport setting do indeed meet these criteria.

Over the past several years, a number of experts have begun to question whether the neuropsychological tests employed in most sports settings are actually sensitive enough to detect the effects of brain dysfunction underlying concussion. Randolph, McCrea, and Barr (2005) were the first to raise the issue of whether the neuropsychological tests used in both paper-and-pencil and computerized test batteries possessed the requisite reliability, validity, and sensitivity to the effects of SRC to warrant their use as part of a serial testing battery. Many of the arguments raised in this chapter have been supported by research findings published by other investigators demonstrating that tests contained in many of the

commercially available computerized test batteries lacked the level of reliability needed to be sensitive to the effects of SRC (Broglia et al., 2008; Resch et al., 2013; Resch et al., 2013).

There is no doubt that obtaining baseline neuropsychological test data on a team of athletes requires large commitments of time, effort, and finances. The questions addressed regarding the reliability and sensitivity of the test instruments, raise further questions about whether baseline testing is actually necessary and essential to diagnosing the effects of SRC. At this point, there are no evidence-based research findings indicating that baseline neuropsychological testing provides a more sensitive means for detecting impairment associated with SRC in comparison to the “standard” clinical approach using a single cross-sectional assessment point combined with a psychometric definition of impairment based on a deviation from test norms (Echemendia et al., 2012; Schmidt, Register-Mihalik, Mihalik, Kerr, & Guskiewicz, 2012). Given the existing state of affairs, clinicians should consider revisiting the use of “standard” testing in conjunction with test norms in the sports setting.

### *Timing of Postinjury Testing*

Another major question that arises with the use of neuropsychological testing is when to perform the postinjury assessment. Management models calling for routine assessment of the athlete within 24–48 hours of the injury run the risk of providing information that is redundant with data obtained through other sources such as the athlete’s reporting of symptoms. There is also a potential for these results to introduce extra confounds in terms of practice effects.

Findings from a study performed on a large sample of collegiate athletes (see Figure 27.2) demonstrated that neuropsychological testing provides little unique information regarding abnormal test findings in relation to results obtained from sideline assessment methods used during the initial period of recovery (McCrea et al., 2005). Results from testing performed at seven days, in turn, provided some additional information regarding impairment relative to information from traditional sideline measures, although the overall contribution was rather small. These findings suggest that postinjury neuropsychological testing provide nothing unique in terms of information for tracking initial recovery from SRC, raising questions about whether this form of testing might be utilized most optimally when it is reserved for assessment of recovery in cases of a complicated pattern of recovery from SRC or a history of multiple previous concussions.

### *Computerized Versus Paper-and-Pencil Testing*

The final question is whether computerized neuropsychological testing provides a more sensitive and efficient manner to assess cognitive functioning in injured athletes as compared to standard paper-and-pencil testing. Developers of

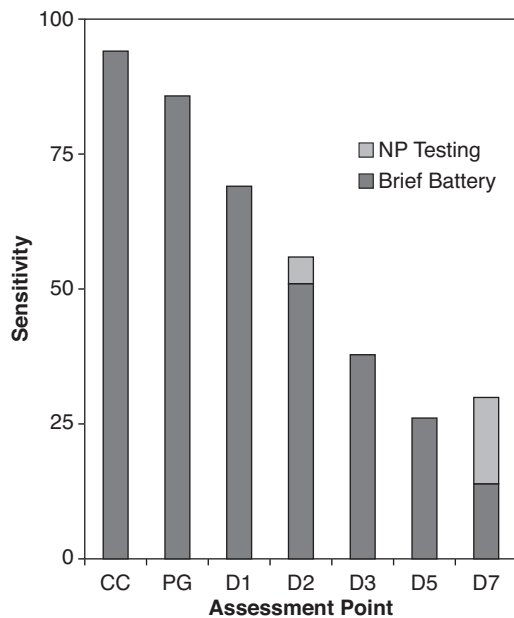

Figure 27.2 Percentage of concussion and control participants classified as “impaired” from time of injury through Day 7 on Brief Battery (GSC, BESS, and SAC) and NP Testing. GSC = Graded Symptom Checklist; BESS = Balance Error Scoring System; SAC = Standardized Assessment of Concussion; and NP Testing = Neuropsychological Test Battery. Assessment points: CC = time of concussion; PG = post-game/post-practice; D1 = postinjury Day 1, D2 = postinjury Day 2, etc. (adapted from by McCrea et al., 2005).

computerized test batteries have argued that the automated test platforms provide more efficient and accurate means for collecting data than standard paper-pencil batteries. The use of reaction time indices and randomized presentation of test items has been alleged to provide means for obtaining more reliable test data. However, those marketing claims have not been supported by results of empirical research.

At this point, the only study examining the sensitivity of computerized testing using prospective research designs has demonstrated no advantage to that form of testing relative to symptom checklists on injured athletes and matched controls compared with serial testing from baseline through the recovery of symptoms (Nelson et al., in press). There are no “head to head” studies demonstrating that any computerized test battery is more effective than standard paper-and-pencil testing for evaluating symptoms of SRC in this or any other population. The lack of empirical evidence supporting the use of neuropsychological tests of any kind in assessment of concussion symptoms raises questions about whether these measures should be used on a routine basis as part of a SRC management system.

Regarding other proposed advantages of computerized testing, there are no data supporting initial claims that these

methods offer financial advantages to standard methods of testing. While the emphasis on reaction time as a dependent measure may be attractive from a theoretical standpoint, its proposed advantage over data obtained from traditional testing has not been demonstrated empirically. In fact, any claims of the precision added by the use of computers must be tempered by numerous technological questions that arise when using these test paradigms across different computer platforms and in varying conditions of traffic in local area networks and on the Internet (Rahman-Fillipiak & Woodard, 2013). There is a major disadvantage to testing memory on a computer, as the focus must be on recognition rather than recall, which research has been demonstrated to be among the most sensitive tasks for assessing the effects of concussion (Collins et al., 1999; Echemendia, Putukian, Mackin, Julian, & Shoss, 2001).

Finally, there are also concerns about the quality of data obtained when young athletes are tested on a computer in groups or under minimal supervision and when athletes are making an attempt to look bad on baseline testing (e.g., “sandbagging”) in an attempt to mask detection of performance decline following injury (Erdal, 2012; Moser, Schatz, Neidzski, & Ott, 2011). There is also an increasing sentiment that the growth of computer testing may lead to a decline in the role that neuropsychologists play in evaluating and tracking the effects of SRC (Echemendia, Herring, & Bailes, 2009).

### Search for the Concussion “Biomarker”

Concussion causes temporary changes in brain function. The changes cannot be observed directly. They are typically inferred indirectly by scores from measures of behavior, symptoms, cognition, balance, and other functional abilities. Given the diagnostic difficulties associated with SRC, several lines of research are exploring the viability of using advanced imaging, electrophysiological techniques, and blood and cerebrospinal fluid (CSF) indices to arrive at a better understand of the physiologic effects of SRC. However, the clinical diagnosis of a SRC continue to be based on description of the acute injury characteristics, reported symptoms following the injury, and clinical measures of cognition or other functional activities. More recently, there is avid pursuit in the scientific community toward finding a definitive “biomarker” from a neurodiagnostic test or a blood sample that could enable a more objective diagnosis of SRC and indicate conclusively when an athlete has achieved a complete physiologic recovery and, therefore, is fit to safely return to play. To date, no such biomarker exists for clinical use, although some are considered viable candidates, as summarized below.

### Structural Brain Imaging

The presence of structural brain pathology after concussion can have important diagnostic and prognostic implications.

To begin with, positive neuroimaging findings may signal the need for rapid intervention to avoid a catastrophic outcome. Additionally, when clinical neuroimaging reveals the presence of an observable abnormality, such as the presence of subdural or subarachnoid blood collection, the classification of the injury may change from a simple “concussion” to a more complicated form of MTBI. The expected course of recovery and return to play becomes very different when one experiences the effects of a complicated MTBI, as opposed to an uncomplicated form of concussion (Kashluba, Hanks, Casey, & Millis, 2008).

It is generally accepted that computed tomography (CT) scans have great value in detecting neurosurgical emergencies but also have the poorest sensitivity in detecting underlying abnormalities associated with milder forms of brain injury, including concussion (Yuh, Hawryluk, & Manley, 2014). The absence of focal findings on a CT scan is often equated incorrectly and inappropriately with a complete lack or nonexistence of brain injury, which then creates confusion amongst health care providers that often follows the patient throughout his or her clinical management after injury. There is a continual pursuit in the neurosciences to develop imaging techniques sensitive to detecting structural and functional abnormalities following milder forms of brain injury, even in the absence of traumatic abnormalities on head CT scan (Yuh et al., 2014).

When looking at all levels of TBI severity, magnetic resonance (MR) imaging provides a more sensitive means for detecting structural abnormalities associated with TBI than CT. MR methods has been found to be up to 25%–30% more sensitive than CT scanning in revealing diffuse axonal injury (Mittl et al., 1994) but both imaging modalities are found to be normal in most cases and have very weak correlation with clinical outcome after concussion (Hammoud & Wasserman, 2002). Cortical contusions, subdural hematomas, and hemorrhagic changes in the white matter are the most common findings on brain MRI after concussion, but as mentioned, are rarely seen as a result of SRC.

The potential utility of more sensitive imaging techniques is especially intriguing in cases where a patient remains symptomatic despite negative conventional imaging (e.g., CT, MR). Recent studies have investigated the utility of diffusion tensor MR imaging (DTI) in TBI, particularly in an attempt to detect and characterize underlying diffuse axonal injury (DAI) with more severe forms of injury. DTI is an application of MRI that capitalizes on the diffusion of water molecules for imaging the brain. While diffusion-weighted MR imaging measures the diffusion of water molecules in a particular direction, DTI extends this technology by imaging diffusion in several different directions (Belanger, Vanderploeg, Curtiss, & Warden, 2007). Many believe that DTI may be in a unique position to predict recovery in TBI patients, with particular relevance to concussion that results in axonal injury (not death) not identified on normal CT/MRI scans (Belanger et al., 2007). However, results from more recent

reviews have demonstrated a range of disparate findings from DTI studies on concussion (Aoki, Inokuchi, Gunshin, Yahagi, & Suwa, 2012), indicating that its use for diagnosing brain effects of concussion on a clinical basis remain premature at this point.

### *Functional Brain Imaging*

It has been suggested that functional MRI (fMRI) might be more sensitive to detecting brain changes in MTBI in symptomatic patients, in the absence of deficits on objective cognitive testing, as suggested by (McAllister et al., 1999). However, results from studies using fMRI in concussion subjects have varied widely, with findings across studies sometimes going in opposite directions. Some studies have reported decreased activation following the subacute phase of recovery in injured athletes (Gosselin et al., 2011) and still others have not shown any difference in brain activation patterns as measured by fMRI following the subacute recovery period (Elbin et al., 2012; Terry et al., 2012).

Hammeke and colleagues (2013) used an event-related fMRI design with a working memory task to investigate brain activation patterns in high school football players who had sustained two or three concussions. Injured athletes and control teammates (matched on a number of variables) were initially tested approximately 13 hours postinjury and then again during the subacute phase of the injury approximately seven weeks later. During the acute phase, the injured group showed the expected postconcussive symptoms and cognitive decline when compared to the healthy control subjects. Brain activation patterns showed decreases in the injured group compared to the control subjects in attention networks during this acute phase. During the subacute phase, the injured athletes showed the expected improvement in symptoms and cognitive performance. Brain activation patterns showed the reverse of the acute-phase activation patterns, in that the attention network of the concussed athletes was greater than the activation in the healthy control subjects. These results suggest that there is less activation during the acute symptomatic phase, which is indicative of underlying brain dysfunction. Conversely, after a period of recovery, the increase in brain activation is likely due to compensatory increases in brain activity to support normal behavioral performance.

The fMRI studies mentioned previously used a task-state fMRI design. The participant actively engages in a cognitive task, which is correlated with brain activity. Resting-state fMRI (R-fMRI) is another method to investigate brain function. R-fMRI involves data collection while the participant is at rest, rather than while the participant is performing a cognitive activation task. Work that began in the early 1990s showed that an individual’s brain at rest demonstrates important information about functional organization (for a review, see Biswal, 2012). In that respect, there is a specific network of brain regions referred to as the *default network* that is consistently active during rest and has shown to be sensitive to

a number of neurologic and psychiatric disorders (Buckner, 2012; Raichle et al., 2001). Further work is needed to determine whether a profile exists that can reliably distinguish R-fMRI abnormalities in concussion from those associated with a range of developmental neuropsychiatric conditions.

### *Electrophysiological Methods*

While electrophysiological abnormalities can be demonstrated in a minority of concussed individuals through the use of routine EEG, the clinical significance of these findings have not been demonstrated in any reliable or scientifically rigorous manner (Nuwer, Hovda, Schrader, & Vespa, 2005).

A number of investigators have turned to the use of evoked related potentials (ERP) for the study of SRC. Some studies using small samples of athletes have demonstrated abnormalities of the P300 component with a suggestion that the abnormality corresponds in some way with symptom severity (Lavoie, Johnston, Leclerc, Lassonde, & Dupuis, 2004). Other findings have suggested abnormalities of certain ERP components extending beyond the athlete's reported recovery of symptoms (De Beaumont, Brisson, Lassonde, & Jolicoeur, 2007). Results from these studies indicate that electrophysiological indices hold promise as a means of identifying possible abnormalities in underlying brain function following concussion at a point when findings from other measures are negative.

Quantitative EEG (QEEG) investigations of concussion have reported abnormalities in many features reflecting changes in brain function, including reduced mean frequency of alpha, reduced power in the alpha and beta frequency bands, hypercoherence between frontal regions, and decreased gamma frequency (Tebano et al., 1988; Thatcher et al., 2001; Thatcher, Walker, Gerson, & Geisler, 1989; Thompson, Sebastianelli, & Slobounov, 2005; Watson et al., 1995). Using these features, normal controls have reportedly been discriminated from MTBI patients with high levels of sensitivity. The variables contributing to this discrimination include measures of coherence, phase and amplitude differences. It has been noted that frontal and fronto-temporal regions contributed more than other regions to such discrimination, suggesting increased vulnerability of these areas (Thompson et al., 2005). Much more work needs to be done in this area to demonstrate the specificity of the findings before these and other electrophysiological methods are ready for use in detecting abnormalities resulting from SRC.

The use of QEEG as a clinical tool to measure possible physiological vulnerability following concussion is of interest, but there are limited data on use of this methodology during the course of recovery following SRC. QEEG measures were recently used in a series of studies in conjunction with a number of clinical measures (Concussion Symptom Inventory, SAC, BESS, and Automated Neuropsychological Assessment Metrics) with athlete samples at the time of injury, at recovery Day 8 and recovery Day 45 (Barr, Prichep,

Chabot, Powell, & McCrea, 2012; McCrea, Prichep, Powell, Chabot, & Barr, 2010; Prichep, McCrea, Barr, Powell, & Chabot, 2013). As expected, athletes with SRC demonstrated impairments on clinical measures at the time of injury, but these impairments resolved by Day 8 postinjury. The QEEG measure, however, showed abnormal findings in the concussed group when compared to control subjects on the day of injury that persisted through Day 8 (and resolved by Day 45). These data support the notion that a period of physiologic recovery persists beyond the point of full recovery on clinical measures.

### *Laboratory Biomarkers*

Potential laboratory biomarkers include measures of a biological or pathological processes involving the brain that can be measured objectively in samples of blood or CSF. The theory behind the use of these measures in TBI research is based on a hypothesis that an injury to the brain causes a series of cellular processes affecting neurons and glia that result in a release of specific proteins and other biochemical products into the bloodstream, after crossing the blood-brain barrier (Mondello et al., 2014). The assumption is that these measures are associated with pathological processes induced by brain trauma and correlate in some manner with the magnitude of the underlying injury. Given the lack of any consistent imaging or electrophysiological findings associated with SRC, it is no surprise that there has been a surge of interest in finding a reliable biological index that can be used to determine the presence of SRC through a simple blood test.

The search for blood biomarkers has concentrated thus far on strategies for identifying disturbances of glial or neuronal processes. Most attention has focused on studies of S100B, a protein associated with neuronal and microglia processes that has been shown to be present in elevated levels in association with a number of neurological conditions (Zetterberg, Smith, & Blennow, 2013). While S100B has been demonstrated to be sensitive to the effects of TBI, its specificity has been questioned, as the protein is also present in a number of cell types independent of the central nervous system (CNS) (Schulte, Podlog, Hamson-Utley, Strathmann, & Struder, 2014). Its utility as a biomarker in athletic settings remains questionable, as elevations of S100B are commonly observed in athletes who have not sustained an SRC, indicating that its levels might be influenced by all types of bodily injuries, rather than injuries specific to the brain.

Other efforts to define a blood biomarker for SRC have examined the use of Neuron-Specific Enolase (NSE), a neuronally based enzyme that has been thought to provide a sensitive indicator of neuronal cell death. In contrast to the S100B protein, the issue with this enzyme has been its sensitivity, rather than specificity (Mondello et al., 2014). Studies on Glial Fibrillary Acidic Protein (GFAP) and Ubiquitin C-Terminal Hydrolase (UCH-L1) have generated

some interest due to the fact that those compounds are found exclusively within the CNS and have been demonstrated to have associations with severity and outcome in more severe levels of TBI (Zetterberg et al., 2013). Substantial interest has also been placed on identification of the tau protein, a marker of axonal damage and degeneration (Gatson & Diaz-Arrastia, 2014). However, despite its purported association with neurodegenerative changes following SRC, there has been no consistent evidence that the tau protein has any diagnostic value in studies of MTBI or SRC or any sensitivity to detecting a risk for negative long-term outcome (Castellani, Perry, & Iverson, 2015; Mondello et al., 2014).

Many challenges thus remain to the identification of a blood biomarker that is sensitive and specific to the effects of SRC, and can be used effectively for diagnosis and prediction of outcome. Some argue that studies of CSF will provide measures of brain biochemistry that are less confounded than those obtained from blood samples (Neselius, Brisby, Granholm, Zetterberg, & Blennow, 2015). However, the more invasive methods of collecting such samples do not appear feasible in the athletic setting.

Other questions remain as to whether there will ever be any success in identifying a single biomarker that would be sufficient for diagnosis of SRC in addition to being useful for predicting clinical outcome and/or risk for subsequent injury. Due to variability in the biochemical processes underlying brain injury recovery, it appears very likely that a strategy based on use of a variety of different biomarkers will need to be developed, depending on whether one is attempting to study acute, subacute, or chronic stages of injury recovery (Mondello et al., 2014). In the meantime, there remain no empirical data to indicate that any identified blood or CSF biomarker is suitable for diagnosing or making predictions about long-term outcome of SRC.

### **Potential Complications in Recovery From SRC**

Clinical strategies for management of SRC are based on an attempt to maintain the athlete's safety, by minimizing the possibility of sustaining a repeat injury, persistent symptoms, or more catastrophic or long-term effects. While it is known that the vast majority of athletes recover from concussion within a period of seven to ten days, there are beliefs that a window of cerebral vulnerability may extend beyond the point of clinical recovery after SRC, during which the brain remains physiologically compromised and athletes are at heightened risk of repetitive injury or complications (Nelson et al., 2013). The primary risk associated with repeat concussion is thought to be a slowed clinical recovery characterized by persistent symptoms or functional impairment. There are also significant concerns about prediction and prevention of more catastrophic effects of SRC, which appear to be exceedingly rare, and longer-term effects such as late-life dementia, which has been described in some individual athletes but has

an incidence that remains unknown (Karantzoulis & Randolph, 2013).

### ***Susceptibility to Repeat Injury and Catastrophic Outcome***

There are indications that an athlete's risk of repeat concussion in the same sports season is essentially equivalent to the risk of a single concussion. In a large sample of collegiate football players investigated over three seasons (over 4,000 player seasons), it was found that 6.3% of players sustained a single concussion and 6.5% sustained a repeat concussion within the same season (Kevin M. Guskiewicz et al., 2003). Results from an expanded analysis of that sample demonstrated that 75%–90% of the same-season concussions occurred within seven to ten days of an initial concussion, during the period when there is a presumed increase in cerebral vulnerability (McCrea et al., 2009).

Prospective scientific studies on the effects of multiple concussions are difficult to perform, given the relatively low incidence of repeat injury. However, an emerging literature has begun to show that repeat concussions produce more severe symptoms, such as disorientation, LOC, and amnesia (Collins & Hawn, 2002; Guskiewicz, et al., 2003). Given the report of more severe symptoms, it is logical to expect longer periods of recovery postinjury following repeat concussions. Guskiewicz et al. (2003) showed that players with a self-reported history of multiple prior concussions take longer to recover, and there is also some evidence that athletes' performance on balance testing and some cognitive measures (e.g., verbal memory and reaction time) may recover more slowly after repeat concussions (Bruce & Echemendia, 2004; Covassin, Stearne, & Elbin, 2008). However, data capturing initial and repeated concussions prospectively have not revealed increased symptom duration between first and second concussions (McCrea et al., 2009).

There is also evidence to suggest that sustaining a concussion might increase an athlete's risk for subsequent injury. Studies have shown that individuals reporting a prior history of concussion are at three to six times the risk for sustaining subsequent concussions (Schulz, 2004; Zemper, 2003) in a given sports season and that there may be a dose-response type relationship, such that individuals reporting more concussions prior to study onset are at progressively increased risk for further injury (Guskiewicz, et al., 2003). There are also indications that a history of attention deficit/hyperactivity disorder (ADHD) or learning disability render one more susceptible to repeat concussion (Nelson et al., 2015).

Historically, the greatest concern linked to repetitive concussion centered on the risk of catastrophic outcomes (i.e., death or permanent disability) associated with diffuse cerebral swelling or second-impact syndrome (Cantu, 1998; Kelly, 1991; Saunders & Harbaugh, 1984). Occurrences of catastrophic outcome remain extremely rare and are presumed to be caused by a second injury event encountered

while the brain is still in a state of vulnerability from an initial concussion days earlier. However, the pathophysiology of delayed cerebral swelling remains the subject of great debate and it remains unclear whether closely spaced injuries are the true underlying mechanism (Paul McCrory, 2001; McCrory & Berkovic, 1998; Randolph & Kirkwood, 2009).

### *Postconcussion Syndrome*

There is little information regarding the rates of postconcussion syndrome (PCS) in athlete samples. Existing data indicate that concussed athletes, as a group, do not exhibit any significant differences from controls on neuropsychological testing performed at 90 days following the injury (McCrea et al., 2003). While injury factors such as LOC, posttraumatic amnesia, and more severe acute symptoms are found to predict prolonged recovery time (> seven days) in a minority of athletes (McCrea et al., 2013), there are no indications that any known injury factor, including LOC, renders an athlete at risk for development of more prolonged forms of PCS (Tator & Davis, 2014).

In spite of the relatively low number of complicated recoveries from SRC predicted by that study, persistent symptoms are believed to occur in 10%–15% of athletes (Makdissi, Cantu, Johnston, McCrory, & Meeuwisse, 2013; Morgan et al., 2015). Similar to what is estimated from studies of MTBI nonathlete samples, this prevalence estimate and factors responsible for the presence of PCS following SRC remains a topic of contention in head injury research. At this point, strategies for managing persistent PCS symptoms in athletes, as a group, are based primarily on anecdotal evidence or extrapolation of data from studies performed on more severe levels of TBI (Makdissi et al., 2013).

Based on reviews of the general literature, preinjury risk factors identified for development of PCS in adults include a number of personality variables and a prior history of psychiatric disturbance (Broshek, De Marco, & Freeman, 2015; Silverberg & Iverson, 2011). Predictive factors for PCS in children include learning difficulties, behavioral problems, and a previous history of head injury (Zemek, Farion, Sampson, & McGahern, 2013). Thus far, similar findings have been reported among the few studies examining PCS in athlete samples. One recent study found the risk of PCS to be increased in athletes with a personal and/or family history of mood disorder, other psychiatric illness, or migraine (Morgan et al., 2015). Interestingly, this study also found the rate of PCS to be increased in association with a postinjury risk factor, namely delayed symptom onset. Other researchers reported that more than 80% of their PCS cases in athletes had a history of at least one prior concussion (Tator & Davis, 2014). A high percentage of these cases reported a history of a premorbid psychiatric condition, ADHD, learning disability, and migraine.

There has been much interest over the past 20 years in identifying the psychological factors (e.g., misattribution,

nocebo effect, “good-old-days” phenomena) underlying the tendency to report persisting symptoms following concussion in a range of settings, including sports (Gunstad & Suhr, 2001; Mittenberg, DiGiulio, Perrin, & Bass, 1992). As a group, athletes have been found to underestimate the level of baseline symptoms present before the injury and to overestimate changes in symptoms occurring after the injury, consistent with a model of expectation as etiology (Ferguson, Mittenberg, Barone, & Schneider, 1999; Mittenberg, DiGiulio, Perrin, & Bass, 1992). Another study found that athletes have a general expectation for a healthy recovery from concussion, which differs from the types of expectations observed in other groups (Gunstad & Suhr, 2001).

### *Chronic Traumatic Encephalopathy*

Based on extensive media coverage, the public is now acutely aware of cases of former athletes who have died tragically and prematurely and have been reported to have exhibited features of a clinical syndrome labeled as Chronic Traumatic Encephalopathy (CTE; see McKee et al., 2009; Omalu, 2014). Features of this syndrome were initially described in retired boxers nearly a century ago, using the terms “punch drunk syndrome” or “*dementia pugilistica*” (Corsellis, Bruton, & Freeman-Browne, 1973; Critchley, 1957; Iverson, Gardner, McCrory, Zafonte, & Castellani, 2015; Jordan, 2000; Maroon et al., 2015; Martland, 1928; Millspaugh, 1937). The recent interest in this condition is based on results of autopsy reports on professional athletes following retirement from careers in American football, ice hockey, and other contact sports. The relationship between CTE and SRC remains unclear, leading to conclusions that the condition is the result of cumulative exposure to subconcussive blows to the brain over the course of one’s career as an athlete, now referred to as repetitive brain injury (RBI) (Saigal & Berger, 2014; Stein, Alvarez, & McKee, 2015). The reported identification of CTE in a handful of younger athletes (< 25 years old) raises questions about the degree of exposure to RBI needed to produce CTE (McKee et al., 2009).

Proponents of CTE characterize it as a neurodegenerative disease distinguished from other forms of dementia by its widespread accumulation of hyperphosphorylated tau (p-tau; see McKee et al., 2009). Individuals with CTE have been described as exhibiting a number of characteristic behavioral features including mood changes, explosive behaviors, and cognitive disturbance (Stern et al., 2013). Based on results of autopsy studies, these individuals have been observed to exhibit extensive tau-immunoreactive neurofibrillary tangles throughout the brain, with a preferential involvement of superficial cortical layers and other characteristics that reportedly make it distinctive from all other known forms of dementia (McKee et al., 2009).

A number of reviews critical of the CTE literature have been published, with conclusions that there are no empirical data demonstrating a definitive association between

concussion in sports and increased risk for late-life cognitive and neuropsychiatric impairment, including CTE (Castellani et al., 2015; Iverson et al., 2015; Karantzoulis & Randolph, 2013; Maroon et al., 2015; McCrory, Meeuwisse, Kutcher, Jordan, & Gardner, 2013; Wortzel, Brenner, & Arciniegas, 2013). The primary criticism is that the CTE studies are based on autopsy series of cases identified with a risk of ascertainment bias. Based on results from epidemiological studies, there are no indications of any conclusive link between concussion and any emerging late life conditions, including dementia, and no increased risk for dementia in retired athletes has been in studies examining larger numbers of retired athletes (Baron, Hein, Lehman, & Gersic, 2012; Savica, Parisi, Wold, Josephs, & Ahlskog, 2012).

In terms of clinical characteristics, it has been argued that many of the behavioral and cognitive features attributed to CTE can be seen in other forms of neurodegenerative and mood disorders common to individuals from similar age groups (Karantzoulis & Randolph, 2013). From a neuropathological standpoint, there has been a lack of consensus among CTE proponents regarding the observed pattern and location of histopathological abnormalities, raising questions on whether the existing data warrant identification of a new clinical disorder (Randolph, 2014). Studies examining neuropsychological performance and neuroimaging findings in retired football players have been unable to demonstrate any test findings that would distinguish that group from individuals exhibiting features of mild forms of neurocognitive or mood disorder (Hart et al., 2013; Randolph, Karantzoulis, & Guskiewicz, 2013; Strain et al., 2013; Strain et al., 2015).

There is no doubt that the identification of neurodegenerative conditions in association with long-term sports participation has raised legitimate concerns about long-term safety issues for professional athletes. However, based on the existing science, there are no indications that younger athletes playing contact sports in recreational leagues, high school, or at the collegiate level are at any increased risk for development of neurodegenerative changes in later life. In the meantime, the topic of CTE will remain one of most publicized and controversial topics in the neurosciences until definitive findings are obtained from more scientifically rigorous longitudinal and epidemiological studies.

## Practice Recommendations for Neuropsychologists

### *Assessment and Management of Initial Recovery From SRC*

As discussed in the initial sections of this chapter, the initial assessment and management of the athlete with a suspected SRC begins on the field of play and is conducted in most instances by ATCs or team physicians. While neuropsychologists are rarely called into action on the sideline, those who find themselves posted in those settings should nonetheless

be equipped with methods for evaluating acute symptoms in addition to being aware of the team's protocol for dealing with emergency situations.

It is much more common for neuropsychologists consulting to sports teams to receive a call for evaluation of an athlete more than 48 hours after sustaining a SRC. For assessment of athletes during that time frame, we advocate a model using a multidimensional sideline battery consisting of a set of instruments discussed in this chapter, including a symptom checklist, testing of postural stability, and a screening of neurocognitive functions. All of those instruments can be found in the SCAT-3, the most recent revision of the sideline assessment tool (Guskiewicz et al., 2013). Over the course of the first week, symptoms should be evaluated on a daily basis by relevant staff members with the symptom checklist, until the athlete reports that he or she is symptom-free for a 24-hour period. Once the athlete is found to be symptom-free at rest, one can move on to a graduated return-to-play protocol.

As outlined in the most recent Zurich Consensus Statement on Concussion in Sport (McCrory, Meeuwisse, Aubry, Cantu, et al., 2013), a graduated return to play protocol is recommended, in which the athlete returns to full participation. According to the guidelines (listed in Table 27.3), athletes progress to subsequent stages of rehabilitation when they have been asymptomatic for at least 24 hours. There are a total of five stages, with the first stage being symptom-limited physical and cognitive rest. The second stage is

*Table 27.2* Graduated return-to-play protocol from the consensus statement on concussion in sport: the Third International Conference on Concussion in Sport, held in Zurich, November 2012

<i>Rehabilitation Stage</i>	<i>Functional Exercise at Each Stage of Rehabilitation</i>	<i>Objective of Each Stage</i>
1 No activity	Symptom limited physical & cognitive	Recovery rest
2 Light aerobic exercise	Walking, swimming, or stationary cycling keeping intensity < 70% maximum permitted heart rate. No resistance training.	Increase heart rate
3 Sport-specific exercise	Skating drills in ice hockey, running drills in soccer. No head impact activities.	Add movement
4 Noncontact training drills	Progression to more complex training drills, e.g., passing drills in football and ice hockey. May start progressive resistance training.	Exercise, coordination, and cognitive load
5 Full-contact practice	Following medical clearance, participate in normal training activities.	Restore confidence and assess functional skills by coaching staff
6 Return to play	Normal game play.	

(Used with permission from McCrory et al., 2013.)

light aerobic activity, then sport-specific exercise (e.g., skating drills in hockey, running drills in soccer), noncontact training drills (e.g., passing drills in football), full contact practice, and then finally return to play. If at any time the athlete becomes symptomatic, he or she is to return to the previous stage until asymptomatic for a 24-hour period. As each step in this process should take approximately one day, the whole process is expected to take approximately one week (McCroly, Meeuwisse, Aubry, et al., 2013).

The issue of complete cognitive and physical rest has become a controversial topic in the clinical management of SRC (Craton & Leslie, 2014; Schneider et al., 2013). Recommendations for rest are based loosely on concepts obtained from animal studies where it is known that a premature activation of physiological activity during a period when the brain is undergoing a restorative process can have a negative effect on many of the neural factors important for recovery (Griesbach, 2011; Griesbach, Gomez-Pinilla, & Hovda, 2007). Based on this information, it makes sense to recommend a few days rest following an injury. However, the neuropsychologist must be careful not to overextend recommendations of rest, which could have the potential of placing the recovering athlete at risk for developing a maladaptive focus on their symptoms. In fact, the results of a recent randomized controlled trial on 88 athletes assigned to conditions of extreme rest (five days) or usual care (one to two days rest, followed by stepwise return to activity) found no difference in neurocognitive or balance outcome between the groups (Thomas, Apps, Hoffmann, McCrea, & Hammeke, 2015). However, the extreme rest group reported more symptoms and slower resolution times than the group receiving usual care, indicating that symptom reporting was somehow affected by the period of extreme rest.

A naturally occurring question is whether neuropsychological testing should be performed routinely with athletes during the initial stages of recovery from SRC. Whether testing is conducted with standard (paper-pencil) methods or through computers, there are an increasing number of questions about the validity of neuropsychological testing with athletes and whether the information provided by neuropsychological testing during the stage of initial recovery provides incremental value to what might otherwise be obtained through multidimensional evaluations using an instrument like the SCAT-3.

As stated earlier in this chapter, the routine use of neuropsychological testing during the first week of the injury runs the risk of providing redundant information and a potential for confounding the results of subsequent testing. For these reasons, we recommend against the routine use of neuropsychological testing during the initial stages of recovery from SRC, with the aim of reserving this form of testing for those cases exhibiting atypical patterns of recovery.

While the sports culture calls for athletes to remain “tough” in the face of injury, there is an increase in the appreciation of the level that psychological and motivational factors

can influence prolonged symptom presentation in athletes as well as in other types of patients. With those factors in mind, neuropsychological consultation can add crucial information to developing plans for the athletes’ return to play and to school. Psychoeducational sessions aimed at athletes and their families should focus significantly on a review of the evidence-based literature to help counteract much of the information they are likely to have received through the media and from clinicians who have apparently not kept up with the vast majority of findings indicating that recovery from SRC proceeds in a relatively uncomplicated manner in most athletes.

### *Assessment and Management of Longer-Term Effects of SRC*

Clinicians involved in the diagnosis and treatment of sports concussion will undoubtedly encounter cases of complicated recovery, characterized by symptoms persisting beyond the period associated with a “normal” resolution of symptoms (Makdissi et al., 2013). In some cases, one might find that the prolonged recovery is attributed to underlying neurophysiological causes, including histories of recent or multiple concussions. In other cases, there will be no obvious physical causes, raising questions about the presence of a persistent PCS.

A focused approach to neuropsychological assessment can be very helpful to guide interventions aimed at athletes reporting symptoms for more than 14 days for SRC, which would take them beyond the window of vulnerability associated with physiological causes (Barr & McCrea, 2010; Nelson et al., 2013). Not faced with time constraints found in the setting of acute recovery, testing of cognitive functioning in patients with prolonged effects of SRC can be accomplished effectively with a medium-sized neuropsychological test battery focusing on assessment of a combination of cognitive and psychological symptoms. A test battery recommended for this purpose is listed in Table 27.3.

*Table 27.3* Test battery for assessment of SRC symptoms

- 
- Wechsler Abbreviated Scale of Intelligence (WASI-2)
  - Test of Premorbid Functioning (TOPF)
  - Digit Span (WAIS-IV)
  - Symbol Digit Modalities Test (SDMT)
  - Trail Making Test (TMT)
  - Stroop Color Word Interference Test
  - Controlled Oral Word Association Test (COWAT)
  - Hopkins Verbal Learning Test (HVLT-R)
  - Test of Memory Malingering
  - Reliable Digit Span (RDS)
  - Symptom Checklist (SCAT-3)
  - Minnesota Multiphasic Personality Inventory (MMPI-2-RF)
-

While athletes might end up reporting a wide range of symptoms following SRC, findings from the evidence-based literature indicate that attention, processing speed, and memory are the functions most commonly affected and these are the functions that should receive the most attention through neuropsychological testing (Belanger et al., 2005). The tests recommended in Table 27.3 for assessment of these functions were chosen on the basis of their previous use in sports concussion assessment protocols and the availability of normative data for athletes across the age spectrum (Barr, 2003; McCrea et al., 2003; Oliaro, Guskiewicz, & Prentice, 1998; Solomon, Lovell, Casson, & Viano, 2015).

As mentioned throughout this chapter, the available evidence from controlled research studies does not support the existence of long-term effects on cognitive functioning directly resulting from the physiological effects of any lasting brain injury. In fact, given the effect sizes reported in meta-analyses, cognitive impairment attributable to the effects of SRC (Belanger & Vanderploeg, 2005), if present, would be undetectable using neuropsychological testing or any other known methodology.

Ironically, when assessing the chronic effects of SRC, the neuropsychologist should be more in a position of providing assurance and communication that the results of testing indicate no long-term cognitive consequences of brain injury, contrary to what might be reported by other health care professionals. The goal would be to provide the patient with evidence-based information on recovery that will help him or her return to school, sports, and other activities. The end result of the neuropsychological evaluation will be to provide the athlete, family, and others an explanation of factors other than the physiological effects of “brain damage” that are likely to be playing a role in the maintenance of persisting symptoms and how those factors can be addressed through appropriate psychological intervention or other forms of rehabilitation.

Symptom reporting is an important component of any evaluation of a patient following SRC, particularly since there are no independent means to confirm the presence of injury through other neurodiagnostic methods. A formal evaluation of symptoms through standardized and validated assessment methods is thus an essential component of the neuropsychological evaluation so that the clinician can determine whether symptom magnification might be playing a role or whether the reporting of postconcussion symptoms is affected by any comorbid conditions such as chronic pain, somatization, or mood disorder. A combination of brief illness focused measures of symptom reporting and larger scale psychological inventories, such as the Minnesota Multiphasic Personality Inventory (MMPI-2-RF) (Ben-Porath & Tellegen, 2008), are recommended for use in test batteries designed for assessment of athletes presenting with reported prolonged effects of SRC.

A formal evaluation of validity and response bias is critical in any test battery, particularly in one focusing on

a condition such as SRC, where a combination of many physical, psychological, and motivational factors are likely to be in play. Evaluation of patients with prolonged effects of SRC requires tests of both performance and symptom validity (Larrabee, 2012). It is important to note that these measures are not only used for detection of malingering, which appears to be somewhat rare in athlete samples, but are also useful in helping to identify the influence that somatization, mood disorder, and other psychological disorders are having on the athlete’s ability to maintain the level of effort that is necessary to obtain valid results on neuropsychological testing.

Researchers involved in studies of sports concussion are only beginning to address the problem of prolonged recovery and the issue of PCS (Morgan et al., 2015). One positive feature of making a diagnosis of PCS in athletes is that the clinician will have more information regarding the initial injury than what is typically available in nonathletes. The challenge is in how to evaluate and attribute the athlete’s subjective symptoms, which are often nonspecific in nature and may represent the effects of other conditions, notably those involving disorders of mood and anxiety. This is the situation where neuropsychological testing can be most useful.

Research on effective intervention strategies for PCS in athletes is sorely lacking. While there is increasing evidence on the effectiveness of using cognitive behavioral therapy (CBT) for treatment of PCS (Al Sayegh, Sandford, & Carson, 2010), no controlled trials of this treatment modality have been attempted in a sports setting. Based on conclusions from a recent review, there is emerging evidence supporting the use of some forms of vestibular and oculomotor rehabilitation, although recommendations on these treatments remain at the consensus level (Broglia, Collins, Williams, Mucha, & Kontos, 2015). There is also some evidence that a graded approach to increasing exercise accompanied by close monitoring of physiological functions and symptoms can be useful in some athletes experiencing long-term effects of PCS (Leddy et al., 2013; Leddy, Sandhu, Sodhi, Baker, & Willer, 2012).

## Conclusions

Major advances in the study of concussion have been made over the past 20 years and neuropsychologists, in particular, have made significant contributions to science and the practices established for assessment and management of SRC. The field’s most valuable contributions have been in the development and validation of instruments for measuring symptoms and neurocognitive functions. Furthermore, based on the field’s emphasis on science and methodology, neuropsychology has also played an essential role on establishing which methods and approaches are most effective for enabling an athlete to return to play and other activities in a safe and successful manner.

Over the past several years, protocols for assessment of early symptoms and return to play guidelines have become relatively well established, although these practices continue to be based on consensus recommendation rather than as a result of controlled clinical trials. While neuropsychologists play a critical consultative role to the management of SRC over the entire course of recovery, the issue of how and when to use neuropsychological testing in the sports setting remains somewhat controversial. Based on empirical findings, the current conclusion is that neuropsychological testing is used most effectively with those athletes who are reporting symptoms persisting for more than 14 days, at a point when the test findings can help identify whether prolonged symptom reporting is the result of previously unidentified psychological factors.

With continuing media coverage on the potential negative consequences of SRC and medical attempts to identify a biomarker for concussion effects, the view provided in this chapter is that neuropsychologists can play a major role in the sports setting by providing education to athletes, families, and other providers on the range of other “nonbiological” factors that can affect symptom reporting and recommendations for treatment. Keeping that role in mind, the goal in the coming years will be to further refine and develop methods for assessing the atypical long-term consequences of SRC and developing more effective methods for its treatment.

## 28 The Three Amnesias

*Russell M. Bauer and Breton Asken*

During the past six decades, our understanding of memory and its disorders has increased dramatically. In 1950, very little was known about the localization of brain lesions causing amnesia. Despite a few clues in earlier literature, it came as a complete surprise in the early 1950s that bilateral medial temporal resection caused amnesia. The importance of the thalamus in memory was hardly suspected until the 1970s and the basal forebrain was an area virtually unknown to clinicians before the 1980s. An animal model of the amnesic syndrome was not developed until the 1970s. Thus, our understanding of amnesia is relatively recent, and is a remarkable testament to the power of translational research.

The famous case of Henry M. (H.M.), published by Scoville and Milner (1957), marked the beginning of what many have called the “Golden Age of Memory.” Since that time, experimental analyses of amnesic patients, coupled with meticulous clinical description, pathological analysis, and, more recently, structural and functional imaging, has led to a better understanding of the nature and characteristics of the human amnesic syndrome. We now know that the amnesic syndrome does not affect all kinds of memory, and, conversely, that memory-disordered patients without full-blown amnesia (e.g., patients with frontal lesions) may have less severe impairment in critical cognitive processes that normally support remembering. It is now known that the amnesic syndrome can follow damage to three major functional systems of the brain: the medial temporal lobe/hippocampal memory system (Milner, 1972; Squire & Zola-Morgan, 1991), the diencephalon (Aggleton, 1986; Butters, 1981; Graff-Radford, Tranel, Van Hoesen, & Brandt, 1990), and the basal forebrain (Damasio, Graff-Radford, Eslinger, Damasio, & Kassell, 1985; DeLuca & Diamond, 1995; Hashimoto, Tanaka, & Nakano, 2000). In this chapter, we review the characteristics and anatomic bases for these “three amnesias.” In a concluding section, we consider whether these three different disorders, or variations on a core amnesic syndrome.

### **Clinical Characteristics of the Amnesic Syndrome**

The term *amnesic syndrome* describes patients with profound inability in day-to-day remembering and with varying

degrees of remote or retrograde memory impairment whose memory-related disability exists in the context of comparatively spared cognitive and intellectual function. The disorder exists separately from generalized dementia, and from language or attentional disturbance, and has three distinct characteristics.

### ***Anterograde Amnesia***

The hallmark of the amnesic syndrome is a profound defect in new learning called *anterograde amnesia*. The deficit involves “recent” or “long-term” memory. The essential feature of the deficit is that that patient is impaired in the conscious, deliberate recall of information newly learned after illness onset. The defect primarily involves memory for events (episodic memory) and is apparent in practically any situation in which (a) the recall burden exceeds the immediate memory span, or (b) in which a substantial delay ensues between learning and retrieval. Amnesic patients are severely impaired in their daily functioning and their learning deficit is apparent on even casual observation. That is, the deficit is more than just a “memory problem.” Such patients may fail to recognize or learn the names of newly encountered persons after even brief delays. They may appear disoriented in place or time because they have failed to update the details of their location or have lost the ability to monitor and keep track of ongoing events. Amnesic patients are frequently capable of engaging in routine conversation, but their deficit becomes obvious when they are asked to recall an event that occurred only hours or minutes before. Instructions to remember such events for later recall rarely result in measurable improvement. Formal neuropsychological assessment is usually not needed to reveal the deficit, but such assessment often helps in characterizing the deficit in quantitative and qualitative terms (Squire & Shimamura, 1986).

### ***Retrograde Amnesia and Remote Memory Disturbance***

The amnesic patient usually also has some difficulty in recalling information learned prior to illness onset, an impairment that is often worse for relatively recent events than for events that occurred in the very remote past. The deficit usually

primarily involves “autobiographical” memories of the patient’s specific past (e.g., the personally experienced circumstances surrounding an important relative’s death), but also may involve memory for “public” information that has not been personally encountered (e.g., details about the most recent presidential election). Kapur (1999) suggests that autobiographical memory for past personal events is both anatomically and functionally distinct from remote semantic knowledge and fact memory, and some case studies, experimental data and recent functional neuroimaging studies (Cabeza & St Jacques, 2007; Soderlund, Moscovich, Kamar, Mandic, & Levine, 2012) support this distinction. Autobiographical defects are commonly seen after lesions to the medial temporal and diencephalic structures, while defects in remote semantic memory result more commonly from neocortical damage to the temporal lobe and other regions. Severity of retrograde and anterograde amnesia in the individual patient is typically correlated, and it has been argued that retrograde amnesia is often not measurable until anterograde amnesia reaches at least moderate severity (Smith, Frascino, Hopkins, & Squire, 2013).

Three patterns of remote memory impairment have been described in the literature (Albert, Butters, & Brandt, 1981). *Temporally limited remote memory disturbance* is an impairment that primarily involves the few years prior to the onset of amnesia with relative sparing of more remote time periods. This has been documented in the amnesic patient H.M. (Corkin, 1984; Marslen-Wilson and Teuber, 1974; Milner, Corkin, & Teuber, 1968), in patients receiving electroconvulsive therapy for depression (Squire, Slater, & Chace, 1975; Squire & Fox, 1980) and in recent cases of remote memory impairment after language-dominant temporal lobectomy (Barr, Goldberg, Wasserstein, & Novelly, 1990). This deficit pattern has been explained as a failure of consolidation. For example, H.M.’s remote memory defect is most severe for events taking place up to three years prior to his surgery in 1953. Consolidation accounts suggest that these more proximal remote memories are still in an unstable, not fully consolidated state, causing them to be more vulnerable to acquired brain injury than are more remote, firmly established memories. *Temporally graded remote memory disturbance* affects all time periods, with greater impairment of memories in the recent past. This pattern has been said to be typical of patients with alcoholic Korsakoff’s (AK) syndrome (Albert, Butters, & Levin, 1979; Cohen & Squire, 1981; Meudell, Northern, Snowden, & Neary, 1980; Seltzer & Benson, 1974; Squire, Haist, and Shimamura, 1989), and has also been reported in patients with basal forebrain damage (Gade & Mortensen, 1990). At least in AK patients, an increasingly severe anterograde learning deficit associated with years of heavy drinking, coupled with an acute decade-nonspecific deficit coincident with the onset of Wernicke’s encephalopathy, remain possible explanations of the temporally graded pattern. A recent study of remote episodic/autobiographical and semantic memory in AK and

postencephalitic patients showed clear temporal gradients in episodic memory, but no evidence of a temporal gradient in semantic memory (Kopelman et al., 2009). A third pattern, a *decade-nonspecific, or pervasive remote memory disturbance* that affects all time periods equally, has been described in patients surviving herpes simplex encephalitis (Butters, Milotis, Albert, & Sax, 1984; Cermak & O’Connor, 1983; Damasio et al., 1985; Kopelman, Stanhope, & Kingsley, 1999) and in certain other amnesic subjects (Sanders & Warrington, 1971) as well as in patients with Huntington’s disease (Albert et al., 1981). This decade-nonspecific pattern has been primarily attributed to a retrieval deficit that impairs access to information from all time periods equally.

As suggested in the preceding section, recent studies have shown rather convincingly that retrieval of remote autobiographical information is distinct from retrieval of remote semantic material and facts, a finding that has led to the development of Multiple Trace Theory (MTT) as an alternative to standard consolidation theory (Moscovitch et al., 2005; Nadel, Samsonovich, Ryan, & Moscovitch, 2000). Standard consolidation theory would suggest that the hippocampus is involved in consolidation of new memories, but only for a relatively short period of time. In contrast, MTT suggests that, as time passes and memories are continually retrieved in different contexts, their episodic or autobiographical character can be blurred and, as a result, the corresponding trace can become more “semantic” (context-independent), and cortically based in nature. However, MTT states that, as long as a memory trace retains distinctive autobiographic qualities, the hippocampus remains strongly involved in its retrieval, regardless of its age. Recent data (Urbanowitsch, Gorenc, Herold, & Schröder, 2013) are clearly in favor of MTT, a major development in our theoretical understanding of the role played by the hippocampus and related structures in human memory performance.

### *Spared Abilities in Amnesic Patients*

Despite significant impairments in new learning and remote memory, amnesics often perform normally or near-normally on psychometric tests of intelligence (e.g., Wechsler Scales) and on measures of immediate memory, provided that the amount of information is within their attention span (Drachman & Arbit, 1966) and that the recall test follows quickly after learning. Thus, amnesia cannot be explained on the basis of poor attention span or generalized intellectual loss. However, other cognitive deficits can be seen in some amnesic patients, and may contribute to their deficits in memory. Examples include visuoperceptual and executive skills deficits in AK syndrome (Kapur & Butters, 1977; Kopelman, 1995; Moscovitch, 1982; Squire, 1982b) and prominent frontal lobe-executive deficits in patients with basal forebrain amnesia (DeLuca & Diamond, 1995).

Remarkably, even densely amnesic patients show certain spared memory capacities. When memory is measured

indirectly by evaluating changes in performance rather than by assessing conscious recollection (“what do you remember?”), amnesics often show normal or near-normal performance. These intact capabilities are reflected, for example, in (a) the acquisition of new motor, perceptual, and cognitive skills (Beaunieux et al., 1998; Cohen & Squire, 1980; Cohen, Poldrack, & Eichenbaum, 1997; Schmidtke, Handschu, & Vollmer, 1996); (b) the intact facilitation (“priming”) of performance, as measured by increased accuracy or response speed when specific stimuli, or stimulus contexts, are repeated after initial presentation (e.g., Cermak, Talbot, Chandler, & Wolbarst, 1985; Gabrieli, Milberg, Keane, & Corkin, 1990; Hamann & Squire, 1997), and (c) intact “non-cognitive” forms of learning such as classical conditioning in some amnesics but not others (Gabrieli, Fleischman, Keane, Reminger, & Morrell, 1995; Myers et al., 2001; Schugens & Daum, 1999; Woodruff Pak, 1993).

### Anatomic Correlates of Amnesia

As indicated in the preceding section, amnesic syndrome can result from focal damage to the medial temporal lobes, the medial thalamus, or the basal forebrain. Anatomic, physiologic and behavioral studies in nonhuman primates have suggested why these regions may be important for memory. An understanding of the underlying circuitry provides a basis for understanding that these three regions are not discrete entities, but are parts of an integrated, distributed, memory system.

#### Temporal Lobe

The importance of the temporal lobes in memory was established in the 1950s by reports of severe and permanent amnesia after bilateral surgical resections of the medial aspects of the temporal lobes in humans (Scoville, 1954; Scoville & Milner, 1957). The aim of surgery was either to ameliorate psychotic behavior or to treat intractable epilepsy. H.M., who was treated for epilepsy, is the best studied of such patients, having been the subject of many reports and studies over nearly five decades.

H. M.’s intended lesions extended 8 to 9 CM back from the temporal poles, and included the amygdala, the hippocampus, and the parahippocampal cortex. An appreciation of the anatomic connections of these structures is key to understanding their role in memory function.

#### The Hippocampus and Parahippocampal Region

The hippocampus is a phylogenetically ancient cortical structure consisting of the dentate gyrus, the sectors of Ammon’s horn (cornu Ammonis (CA) 1–4), and the subiculum. The internal connections of the hippocampus were identified by Ramón y Cajal and his student Lorrente de Nó, who first described the *trisynaptic circuit* (Van Hoesen, 1985). Neurons

of the entorhinal cortex project via the *perforant pathway* to synapse on dendrites of granule cells in the dentate gyrus. Granule cell axons project to the dendrites of pyramidal cells in the CA3 region of Ammon’s horn (*mossy fiber projection*). These pyramidal cells have axons that bifurcate, one branch projecting subcortically via the fimbria-fornix, and the other (*Shaffer collateral pathway*) to CA1. CA1 neurons project subcortically via the fimbria, but also to the subiculum, which is the major source of hippocampal efferent projections (Rosene & Van Hoesen, 1977). Efferent fibers from the subiculum project either to subcortical targets (via the fimbria and fornix) or to other cortical regions. The subiculum also projects back to the entorhinal cortex, completing a circuit. The connections described are unidirectional, suggesting an orderly progression of information through the hippocampus.

Although there are direct cortical connections to the hippocampus, the majority of hippocampal cortical inputs are from the adjacent parahippocampal region. The parahippocampal region consists of rhinal (entorhinal and perirhinal) cortex, pre- and parasubicular cortex, and parahippocampal cortex (Scharfman, Witter, & Schwarcz, 2000). The parahippocampal region is hierarchically organized, with the entorhinal cortex being the final common pathway to the hippocampus (Van Hoesen and Pandya, 1975). The entorhinal cortex receives afferents from perirhinal cortex and the parahippocampal gyrus (Insausti, Amaral, & Cowan, 1987a; Irle & Markowitsch, 1982; Rosene & Van Hoesen, 1977; Van Hoesen, Rosene, & Mesulam, 1979). These regions in turn receive projections from unimodal and polymodal association cortex, thus providing entorhinal cortex with indirect access to a variety of highly processed information (Amaral, Insausti, & Cowan, 1983; Insausti et al., 1987a; Van Hoesen, 1985; Van Hoesen, Pandya, & Butters, 1972). Unlike the intrinsic hippocampal connections, which are unidirectional, the connections of the parahippocampal region are reciprocal (Rosene & Van Hoesen, 1977). Both perirhinal and parahippocampal cortices are connected with visual and polymodal cortical regions, and, to a lesser extent, with somatosensory cortex; but only the parahippocampal cortex receives substantial input from parietal polysensory and auditory cortices (Suzuki & Eichenbaum, 2000).

Subcortical projections from the hippocampus travel in the fornix, a white matter structure that arches through the lateral ventricle and descends medial to the foramen of Munro into the lateral wall of the third ventricle, where it divides at the anterior commissure. Fibers from CA1, CA3 and the subiculum project in the precommissural fornix to the lateral septal nucleus (Swanson & Cowan, 1979). Other subicular projections travel in the postcommissural fornix and terminate in either the anterior nuclear complex of the thalamus or the mammillary bodies (Swanson & Cowan, 1979; Van Hoesen, 1985). There are also hippocampal projections to the amygdala, nucleus accumbens, and other regions in

the basal forebrain, and to the ventromedial hypothalamus (Amaral & Insausti, 1990; Swanson & Cowan, 1979).

The hippocampal → post-commissural fornix → mammillary body projection was part of the “circuit” described by Papez in 1937 to explain how emotional expression and feeling, mediated by the hypothalamus, could be coordinated with cognition, mediated by the cortex. The hippocampus projects via the postcommissural fornix to the mammillary bodies, which, in turn, project via the mammillothalamic tract to the anterior nuclei of the thalamus. The circuit, which has since been referred to as the *medial limbic circuit*, is completed by thalamic projections to the cingulate gyrus and cingulate projections (via the cingulate bundle or cingulum) that extend back to the hippocampus.

The hippocampus also receives subcortical projections from the basal forebrain (medial septal nucleus and the nucleus of the diagonal band of Broca), from midline, anterior, and laterodorsal thalamic nuclei, and from the amygdala, hypothalamus, and brain stem, including the central gray, ventral tegmental area, raphé nuclei and locus coeruleus (Amaral & Cowan, 1980; Amaral & Insausti, 1990; Herkenham, 1978; Insausti, Amaral, & Cowan, 1987b; Van Hoesen, 1985).

### *The Amygdala*

The amygdala is situated immediately anterior to the hippocampus and deep to the periamygdaloid and perirhinal cortices. It has two main parts: a large basolateral group of nuclei, with extensive connections to limbic and association cortex and to dorsomedial thalamus, and a smaller corticomедial segment, which extends into the basal forebrain and has extensive connections with basal forebrain, hypothalamus, and brain stem (DeOlmos, 1990; Heimer & Alheid, 1991; Scott, DeKosky, & Scheff, 1991). In a very general sense, the connections of amygdala and hippocampus are similar: both are strongly interconnected with frontal and temporal limbic cortex, and thus both have indirect access to polymodal and supramodal neocortical association areas (Herzog & Van Hoesen, 1976; Rosene & Van Hoesen, 1977). Both project to basal forebrain and hypothalamus. The amygdala and hippocampus also have direct connections with each other (Insausti et al., 1987b; Poletti, 1986; Saunders, Rosene, & Van Hoesen, 1988).

Although in the brains of higher mammals the amygdala is adjacent to the hippocampus, it differs radically from the hippocampus in structure and derivation. The amygdala is a subcortical structure, intimately related with the basal forebrain, and often classified as one of the basal ganglia. The amygdala is more closely related to limbic and neocortical regions that are of paleocortical derivation, whereas the hippocampus is archicortical, and is more closely related to cortex of archicortical derivation (Pandya & Yeterian, 1990). Thus, the amygdala is more closely related to orbitofrontal and anterior temporal cortex (Porrino, Crane, &

Goldman-Rakic, 1981), and the hippocampus is more closely related to cingulate cortex. Abnormalities in emotional responsiveness and social interactions are associated with lesions in the amygdala and related anterior temporal and orbitofrontal cortex (Butter & Snyder, 1972).

The subcortical connections of the amygdala also differ from those of the hippocampus. Whereas the hippocampus is related through Papez’s medial limbic circuit with the mammillary bodies and the anterior thalamic nuclei, the amygdala has projections (via the ventral amygdalofugal pathway) to the dorsomedial nucleus of the thalamus (Nauta, 1961). Basal forebrain connections also differ: The hippocampus is related to more ventral portions of the septal nuclei, and the amygdala has more extensive connections with the bed nucleus of the stria terminalis. Cholinergic projections to the amygdala are from the nucleus basalis of Meynert, whereas the hippocampus receives input from the septal region and diagonal band of Broca (Mesulam, Mufson, Levey, & Wainer, 1983). Finally, the amygdala has connections with brain stem autonomic centers (nucleus of the tractus solitarius), providing a direct pathway for limbic-autonomic interaction. In contrast to Papez’s medial limbic circuit, the amygdala can be thought of as participating in a “lateral” limbic circuit: amygdala → dorsomedial nucleus of the thalamus → orbitofrontal cortex → uncus → amygdala.

### *The Anatomical Basis of Temporal Lobe Amnesia*

Early studies of patients with bilateral temporal lobectomy supported the idea that damage to the hippocampus was necessary for medial temporal lesions to produce amnesia. Scoville and Milner (1957) reviewed ten patients with bilateral medial temporal resections. Removal of the uncus and amygdala (in one patient) caused no memory loss, but resections that extended posteriorly to involve the hippocampus and parahippocampal gyrus were associated with amnesia. Also, amnesia was more severe with more extensive resections. Scoville and Milner concluded that amnesia would not occur unless the surgery extended far enough back to involve the hippocampus.

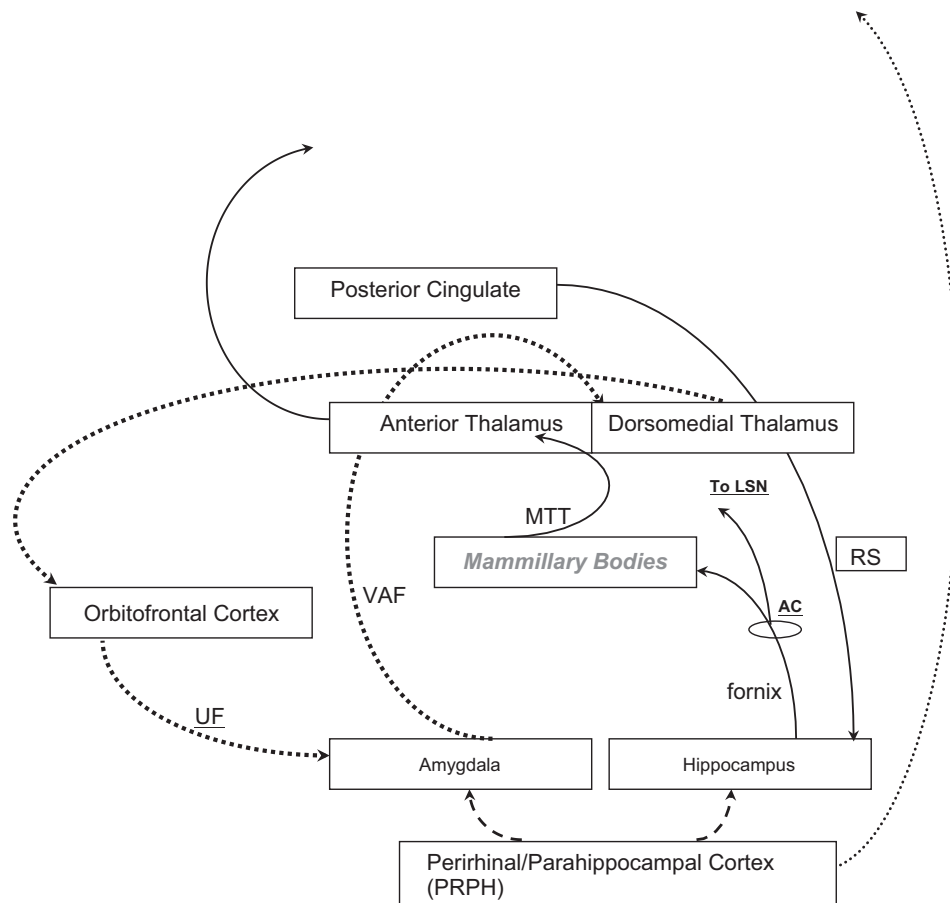

The case for the importance of the hippocampus in memory was subsequently made even more convincingly by the study of patients who survived cardiopulmonary arrest with well-documented deficits in memory, and whose brains were examined after they died from other causes (Cummings, Tomiyasu, Read, & Benson, 1984; Victor & Agamanolis, 1990; Zola-Morgan, Squire & Amaral, 1986). In each case, damage was restricted almost entirely to the hippocampus, where the pyramidal neurons of CA1, exquisitely sensitive to hypoxia, were selectively destroyed. Global ischemia in monkeys causes similar lesions, with scores on memory tasks comparable to those of monkeys with surgical lesions restricted to the hippocampus (Squire & Zola-Morgan, 1991). It should be noted, however, that in these cases, memory loss was not as severe as that seen in H.M.

Our basic understanding of the anatomic substrate of temporal lobe amnesia was greatly enhanced in the 1970s by numerous investigations motivated by the original Scoville and Milner report on H.M., which eventually led to the development of animal models of amnesia. This advancement was facilitated by the development of tasks, including delayed matching-to-sample (DMS; Gaffan, 1974) and delayed nonmatching-to-sample (DNMS; Mishkin, 1978) that provided meaningful analogues to human memory paradigms. DNMS was learned more readily than DMS by normal monkeys, who presumably were drawn to novelty. Hundreds of different objects were used so that habits (or “familiarity”) could not be used as a basis for recognition.

Monkeys with extensive medial temporal lesions, involving both amygdala and hippocampus, were more impaired on the DNMS task than were monkeys with damage to the hippocampus or amygdala alone. This critical observation led to the notion that *two parallel systems subservise memory, one involving the hippocampus and the other the amygdala* (Mishkin, 1978; Mishkin and Saunders, 1979; Mishkin, 1982;

Mishkin, Spiegler, Saunders, & Malamut, 1982). Because either system can subservise memory in large part, lesions in both systems are required to produce severe amnesia. This has come to be known as the *dual system theory of amnesia*, and forms a core principle of understanding memory disorders regardless of lesion location. In a series of experiments, Mishkin and colleagues extended their observations to the subcortical projections of these two medial temporal structures, focusing on the circuits (medial and lateral limbic circuits) described in Figures 28.1 and 28.2.

The general principle that damage to both the medial and lateral limbic circuits is necessary for amnesia serves as a basis for understanding diencephalic and basal forebrain amnesias as well. Figure 28.2 depicts the basic anatomy of memory with a rudimentary representation of the basal forebrain contributions to the two limbic circuits added. Thus, for example, lesions that interrupt both the fornix (disrupting Papez’s circuit) and the ventral amygdalofugal pathways (disrupting the lateral circuit) cause severe amnesia, whereas lesions restricted to either pathway alone cause

**Figure 28.1** The dual-system theory of amnesia. The hippocampally based “medial” system is depicted by solid lines, while the amygdala-based “lateral” system is depicted by dotted lines. Perirhinal-parahippocampal cortex contributes to both systems by projecting to both amygdala and hippocampus, as well as to dorsomedial nucleus of the thalamus (right-most projection in the figure). AC, anterior commissure; LSN, lateral septal nucleus; MTT, mammillothalamic tract; VAF, ventral amygdalofugal pathway; RSA, retrosplenial area; UF, uncinate fasciculus.

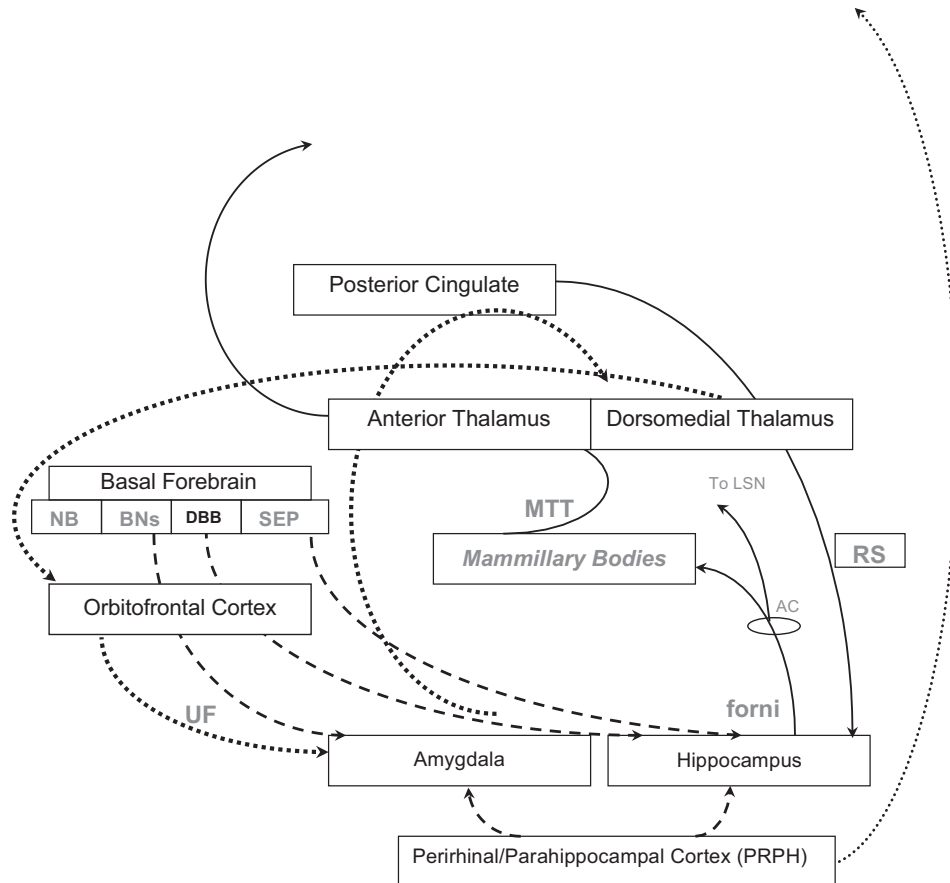

Figure 28.2 Dual system with basal forebrain inputs. Not all inputs from the basal forebrain are shown. Abbreviations within the two limbic circuits are as in Figure 28.1. NBM, nucleus basalis of Meynert; BNst, bed nucleus of the stria terminalis; DBB, diagonal band of Broca; SEP, septal nucleus.

less memory disturbance (Bachevalier, Saunders, & Mishkin, 1985; Bachevalier, Parkinson, & Mishkin, 1985). Many other combinations on this general theme are possible and have been documented in the literature.

Lesions that affect either the posteromedial or antero-medial aspect of the thalamus cause little memory disturbance; severe amnesia, comparable to that associated with medial temporal ablations, occurs only when *both* anterior and posterior medial thalamic regions are involved (Aggleton & Mishkin, 1983). Finally, lesions that affect the frontal projections of both Papez's circuit (anterior cingulate gyrus) and the lateral circuit (ventromedial frontal lobe) produce greater memory loss than lesions of either alone (Bachevalier & Mishkin, 1986). This series of studies on primates suggests (a) that structures within each memory system are highly interdependent, since damage to different parts of each system can cause apparently equivalent deficits; and (b) that each system can, to some extent, carry on the function of the other, since lesions affecting only one system result in memory loss that is far less severe than if both systems are damaged.

The dual-system theory, as first proposed, had to be modified when it was definitively shown that collateral

damage to the perirhinal cortex was responsible for the memory deficits seen after amygdala lesions. In fact, stereotactic lesions of the amygdala sparing perirhinal cortex do not add to the memory deficit of animals with hippocampal and parahippocampal gyrus lesions (Zola-Morgan, Squire, & Amaral, 1989a). Zola-Morgan, Squire, Amaral, and Suzukiet al. (1989b) found that lesions involving both perirhinal and parahippocampal cortex *but not the hippocampus* cause severe memory impairment in the monkey. This is not explained entirely by interruption of cortical input to the hippocampus, because monkeys with this lesion had *more* severe memory deficits than monkeys with lesions that involved only the hippocampus and parahippocampal gyrus (Zola-Morgan & Squire, 1986; Squire & Zola-Morgan, 1991). This suggests that the perirhinal cortex not only conveys information to the hippocampus via entorhinal cortex, but that it also contributes to memory in its own right. Because both the amygdala and the perirhinal cortex project to dorsomedial thalamus, the dual-system theory could be easily modified by substituting perirhinal cortex for the amygdala (this connection is signified by the right-most line in Figure 28.1).

More recently the specific roles of these temporal lobe structures has been increasingly elucidated. The perirhinal cortex receives substantial cortical input from ventral temporal and occipital cortex concerned with the processing of objects. In contrast, the parahippocampal cortex receives widespread input from frontal and parietal association cortex that collectively code spatiotemporal context. It has been proposed that the perirhinal cortex codes item (object)-based memory, while the parahippocampal cortex codes contextual aspects of memory. By this view, both of these regions project to the hippocampus via separate pathways in the entorhinal cortex. The hippocampus then binds item and context through relational memory processing, producing an episodic memory trace.

In summary, the temporal lobes play a significant role in memory; however, the relative contribution of different temporal lobe structures remains to be worked out. At this point, one can argue on the basis of animal models that the hippocampus has a particular role in spatial memory, and that object memory may be more dependent upon perirhinal cortex. It is suggested that the hippocampus in humans may subserve episodic memory, and the perirhinal cortex may be necessary to establish semantic memories. The ability of children with hypoxic damage to the hippocampus to acquire semantic information (Vargha-Khadem et al., 1997) and of amnesic patients to acquire new vocabulary words (Verfaellie, Koseff, & Alexander, 2000) suggests some degree of independence between these kinds of memory; however, there is presently not enough evidence to support a neat anatomic parcellation of these functions. A related distinction between episodic recall and recognition memory is made by Aggleton and Brown (1999), who attribute the former to the hippocampal/diencephalic circuit of Papez, and the latter to the perirhinal cortex and dorsomedial thalamus. In humans, it has been proposed that the hippocampus mediates conscious, deliberate recall ("recollection"), while perirhinal cortex mediates "familiarity" based on item-based recognition (Diana, Yonelinas, & Ranganath, 2007; Eichenbaum, Yonelinas, & Ranganath, 2007). However, this viewpoint is controversial and considerable data from humans and animals suggest that the perirhinal-parahippocampal-entorhinal-hippocampal system is an integrated memory system that does not differentially represent these two subjective states of remembering (Squire & Wixted, 2011; Wixted & Squire, 2011).

#### *Amnesia From Damage to Other Elements of the Medial Limbic Circuit*

Having considered the importance of temporal lobe structures in amnesia, we now turn to consideration of whether amnesia can occur after damage to other components of the medial limbic circuit.

#### FORNIX

It was once widely held that surgical section of the columns of the fornix would not result in memory loss (Cairns &

Mosberg, 1951; Dott, 1938; Garcia Bengochea, De La Torre, Esquivel, Vieta, & Fernandez, 1954; Woolsey & Nelson, 1975), although there was some early evidence to the contrary (Hassler & Riechert, 1957; Sweet, Talland, & Ervin, 1959). Heilman and Sybert (1977), reporting on a patient who had a tumor affecting fornix projections, argued that lesions of the fornix posterior to the anterior commissure affect not only fibers destined for the mammillary bodies, but also disrupt connections between the hippocampus and the basal forebrain and direct projections from the hippocampus to the anterior thalamic nuclei (Aggleton, Desimone, & Mishkin, 1986; Veazey, Amaral, & Cowan, 1982). They suggested that section of the columns of the fornix ventral to the anterior commissure might not cause amnesia, as it affects only projections to the mammillary bodies. Fornix damage usually results in some degree of amnesia both in animals (Bachevalier et al., 1985; Bachevalier et al., 1985; Carr, 1982; Gaffan, 1993, 1974; Moss, Mahut, & Zola-Morgan, 1981; Owen & Butler, 1981) and humans (Aggleton et al., 2000; Calabrese, Markowitsch, Harders, Scholz, & Gehlen, 1995; D'Esposito, Verfaellie, Alexander, & Katz, 1995; Gaffan, Gaffan, & Hodges, 1991; Gaffan & Gaffan, 1991; Grafman, Salazar, Weingartner, Vance, & Ludlow, 1985; McMackin, Cockburn, Anslow, & Gaffan, 1995; Moudgil, Azzouz, Al-Azzaz, Haut, & Guttmann, 2000; Park, Hahn, Kim, Na, & Huh, 2000). In primates, fornix damage, like hippocampal lesions, impairs spatial memory and memory for objects in a scene, a paradigm that Gaffan (Gaffan & Parker, 1996) suggests is related to episodic memory. In humans, fornix lesions have been found to affect recall more than recognition memory (Aggleton & Brown, 1999), and to cause anterograde but not retrograde amnesia (but see Yasuno et al., 1999).

#### MAMMILLARY BODIES

The anatomy of mammillary body connections is summarized by Aggleton and Sahgal (1993). This paired hypothalamic nucleus receives substantial input from the hippocampus. There are projections from the subicular complex of the hippocampus through the fornix to the medial mammillary nucleus, which is more affected than the lateral mammillary nucleus in Wernicke-Korsakoff disease. There are also hippocampal projections to the lateral mammillary nucleus and tuberomammillary nucleus. These hippocampal-mammillary body connections are not reciprocated. Mamillothalamic projections are also unidirectional. The mammillary bodies also project to the medial septum and midbrain.

The presence of prominent mammillary body damage in Wernicke-Korsakoff syndrome first suggested their importance in memory (Gamper, cited by Victor, Adams, & Collins, 1989). Victor et al. (1989) examined the mammillary bodies and the dorsomedial thalamic nucleus of 43 alcoholics. Five had suffered Wernicke's encephalopathy but had recovered without evidence of memory loss; 38 had Wernicke-Korsakoff disease, with persistent amnesia. At autopsy, all had lesions of the mammillary bodies; but only

the 38 patients with persistent memory loss had concurrent lesions of the dorsomedial thalamic nucleus. Victor and colleagues concluded that memory loss could not be attributed solely to mammillary body damage, but was more likely to be associated with thalamic lesions. Mair, Warrington, and Weiskrantz (1979) and Mayes, Meudell, Mann, and Pickering (1988) each report two cases of Wernicke-Korsakoff syndrome with lesions in the thalamus restricted to a thin band of gliosis adjacent to the third ventricle affecting the midline nuclei but not the dorsomedial nucleus. Based on this, Mair et al. (1979) suggested that the mammillary body lesions (present in each of these patients) may account for the memory loss. Lesions restricted to the mammillary bodies have not been associated with deficits on DNMS tasks in monkeys (Aggleton & Mishkin, 1985). However, deficits on spatial memory tasks have been reported in monkeys (Parker & Gaffan, 1997) and in rats (Sziklas & Petrides, 1998). Human cases with selective mammillary body lesions are rare. Dusoir, Kapur, Byrnes, McKinstry, and Hoare et al. (1990) reported amnesia in a patient with MRI evidence of mammillary body lesions following a penetrating injury from a snooker cue. Loesch, Gilman, Del Dotto, and Rosenblum (1995) report memory deficits in a patient with a cavernous malformation of the mammillary bodies, and Tanaka, Miyazawa, Akaoka, and Yamada (1997) report memory loss with mammillary body damage following removal of a cystic craniopharyngioma. It is difficult to exclude extramammillary lesions in these cases, especially to adjacent portions of the hypothalamus or basal forebrain.

#### ANTERIOR THALAMIC NUCLEI

The anterior thalamic nuclei consist of anteromedial (am), anteroventral (av), anterodorsal (ad), and lateral dorsal (ld) nuclei. The medial mammillary nucleus projects ipsilaterally to am and av; whereas the lateral mammillary nucleus projects bilaterally to ad (see Aggleton & Sahgal, 1993). The anterior thalamic nuclei also receive a substantial direct projection from the hippocampus. Pre- and parasubiculum project to av, and subiculum to am, and the hippocampus also projects to ld. All of these hippocampal-thalamic projections are reciprocated.

The anterior thalamic nuclei project to the cingulate and retrosplenial cortices, among other locations. The lateral dorsal nucleus projects strongly to retrosplenial cortex, and shows specific degeneration in Alzheimer's disease (Xuereb et al., 1991).

Parker and Gaffan (1997) demonstrated deficits on a delayed-matching-to-place task in monkeys with anterior thalamic lesions. Ghika-Schmid and Bogousslavsky (2000) report a series of 12 patients with anterior thalamic infarcts, all of whom demonstrated anterograde amnesia (verbal with left and nonverbal with right hemisphere lesions) in combination with perseveration, transcortical motor aphasia, apathy, and executive dysfunction. The lesions involved the anterior thalamic nuclei and not the dorsomedial or ventrolateral

nuclei. They also extended to involve the mammillothalamic tract and the internal medullary lamina. More often, thalamic lesions in humans associated with severe amnesia spare the anterior thalamic nuclei. DNMS deficits are reported only with more extensive thalamic involvement.

#### CINGULATE AND RETROSPLENIAL CORTEX

The major cortical connections of the anterior thalamic nuclei are with the cingulate gyrus. Bachevalier and Mishkin (1986) suggest that combined lesions of orbitofrontal and anterior cingulate cortex in monkeys damages both memory circuits, the orbitofrontal cortex being connected to the lateral limbic circuit, and the anterior cingulate to the medial circuit. But extensive frontal lesions in humans (Eslinger & Damasio, 1985) do not typically result in the classical amnesic syndrome. Meunier, Bachevalier, and Mishkin (1997) describe a spatial memory deficit in monkeys with anterior cingulate lesions; studies in rats (Aggleton, Neave, Nagle, & Sahgal, 1995) suggest that this may be due to damage to the underlying cingulate bundle. The anterior cingulate region appears to play a role in initiating movement, in motivation, and in goal-directed behaviors (Devinsky, Morrell, & Vogt, 1995), but anterior cingulate gyrus lesions have not been associated with amnesia in humans.

The principal projections of the anterior thalamic nuclei, however, are to posterior cingulate cortex, and especially retrosplenial cortex. These cortical regions are also interconnected with the hippocampus (Morris, Petrides, & Pandya, 1999). Lesions in humans that involve retrosplenial cortex can result in a classical amnesic syndrome (Valenstein et al., 1987) but there remains some debate whether the cause of the amnesia is interruption of cingulate/hippocampal connections via the cingulate bundle, damage to the retrosplenial cortex itself, or damage to hippocampal-thalamic, hippocampal-basal forebrain (septal nuclei) or frontal lobe connections traveling in the fornix (Rudge & Warrington, 1991; von Cramon & Schuri, 1992). Additional cases of amnesia with retrosplenial lesions have been reported in the Japanese literature by Arita et al., 1995; Iwasaki et al., 1993; Takayama, Kamo, Ohkawa, Akiguchi, & Kimura, 1991; Yasuda, Watanabe, & Ono, 1997). Takahashi et al. (1997) report pure topographic amnesia with a right retrosplenial lesion. Valenstein et al.'s case (1987) was left-sided, and the memory loss was predominately verbal.

#### *Summary of Temporal Lobe Amnesia*

The bulk of the evidence reviewed suggests that (a) damage to cortical and subcortical structures within the temporal lobe, whether focal or extensive, can result in amnesia; (b) amnesia most likely results from simultaneous damage to both the hippocampally based medial limbic circuit and the amygdala-based lateral limbic circuit; and (c) that damage to individual elements of these circuits can result in amnesia provided that it sufficiently impairs the functional integrity of this distributed memory system.

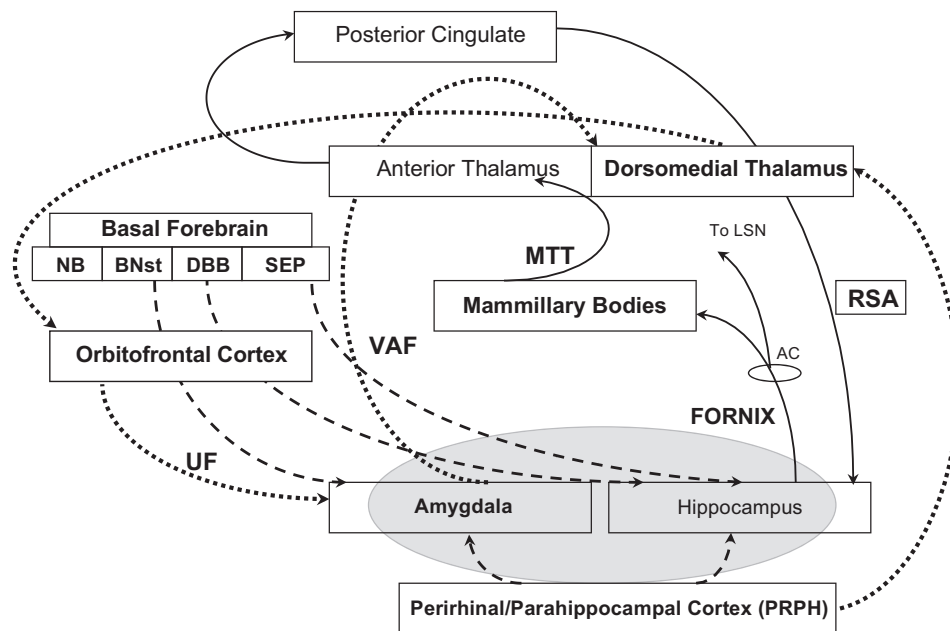

Figure 28.3 Two possible lesion Scenarios for bitemporal amnesia. In Panel A, a large lesion affects both amygdala and hippocampus and their connections with their respective circuits. In Panel B, a more restricted lesion affecting the PRPH affects inputs to both circuits including PRPH inputs to the dorsomedial thalamus.

Figure 28.3 depicts two possible lesion scenarios for bitemporal amnesia. In Panel A, an extensive lesion affects both hippocampus and amygdala, and their respective connections to the medial and lateral limbic circuits. In Panel B, a more restricted lesion of the perirhinal-parahippocampal (PRPH) region affects intrinsic functioning of this region and impairs its connectivity to amygdala, hippocampus, and dorsomedial thalamus. Both lesions would be expected to result in clinically significant amnesia.

### Thalamic Amnesia

Amnesia associated with tumors in the walls of the third ventricle (Grünthal, 1939; Lhermitte, Doussinet, & Ajuriaguerra, 1937; Sproffkin & Sciarra, 1952; Williams & Pennybacker, 1954) provided early evidence that medial thalamic structures may be important in memory. The advent of neuroimaging made it possible to correlate memory deficits with restricted thalamic lesions in patients with thalamic strokes. Although initial reports appeared to confirm evidence from Wernicke-Korsakoff disease that dorsomedial thalamic lesions were associated with memory loss, subsequent studies cast doubt upon this. Early reports had suggested that N.A., a patient who became amnesic after a fencing foil passed through his nose into the brain (Teuber, Milner, & Vaughan, 1968), had a restricted lesion involving the left dorsomedial thalamic nucleus on CT scan (Squire & Moore, 1979), and that amnesic patients with thalamic strokes had CT evidence of restricted dorsomedial lesions (Bogousslavsky, Regli, & Assal, 1986; Choi, Sudarsky, Schachter, Biber, & Burke, 1983; Speedie &

Heilman, 1983). High-resolution imaging in N.A., however, revealed that his lesion not only affected the ventral aspect of the dorsomedial nucleus, but also severely damaged the intralaminar nuclei, mammillothalamic tract, and internal medullary lamina (Squire et al., 1989). Such lesions impair connectivity between the mammillary bodies and the anterior nucleus, as well as between the amygdala and the dorsomedial nucleus. N.A. also had lesions affecting the postcommissural fornix, mammillary bodies, and the right temporal tip. More restricted lesions in patients with thalamic infarctions suggest that thalamic amnesia best correlates with anterior thalamic lesions affecting the internal medullary lamina and mammillothalamic tract (Gentilini, DeRenzi, & Crisi, 1987; Graff-Radford et al., 1990; Malamut, Graff-Radford, Chawluk, Grossman, & Gur, 1992; Winocur, Oxbury, Roberts, Agnetti, & Davis, 1984; von Cramon, Hebel & Schuri, 1985). More posterior lesions that involve portions of the dorsomedial nucleus but spare the internal medullary lamina and mammillothalamic tract do not produce amnesia (Graff-Radford et al., 1990; Kritchevsky, Graff-Radford, & Damasio, 1987; von Cramon et al., 1985). The association between anterior thalamic lesions and amnesia is entirely consistent with the dual-system theory. Graff-Radford et al. (1990) provided a clear anatomic demonstration in the monkey of the juxtaposition of components of both systems (the mammillothalamic tract and the ventral amygdalofugal pathway) in the internal medullary lamina.

Alternative explanations of thalamic amnesia suggest a role for the midline thalamic nuclei. These nuclei have connections with the hippocampus (Amaral & Cowan, 1980; Herkenham, 1978, Insausti et al., 1987b; Van Hoesen,

1985), and are quite consistently damaged in patients with Wernicke-Korsakoff disease (Mair et al., 1979; Mayes et al., 1988). Another proposal is that thalamic lesions may disconnect thalamic interactions with the frontal lobes. Warrington (Warrington and Weiskrantz, 1982; Warrington, 1985) proposed that restricted thalamic lesions found in their cases of Wernicke-Korsakoff disease (Mair et al., 1979) might disconnect mediadorsal-frontal connections important for coordinating posterior cortical regions subserving semantic memories with frontal structures that impose cognitive structure upon these memories.

Figure 28.4 depicts two possible lesion scenarios for diencephalic amnesia. In Panel A, an extensive lesion of the thalamus

affecting both anterior and dorsomedial nuclei impairs both circuits. In Panel B, a more restricted lesion, meant to depict pathway disconnection in the internal medullary lamina, affects both the mammillothalamic tract (MTT), an intrinsic component of the medial circuit, and the ventral amygdalofugal (VAF) pathway, a component of the lateral circuit.

**Basal Forebrain Amnesia**

The basal forebrain is at the junction of the diencephalon and the cerebral hemispheres, and has, at minimum, the following components: the septal area, diagonal band of Broca, nucleus accumbens septi, olfactory tubercle, substantia

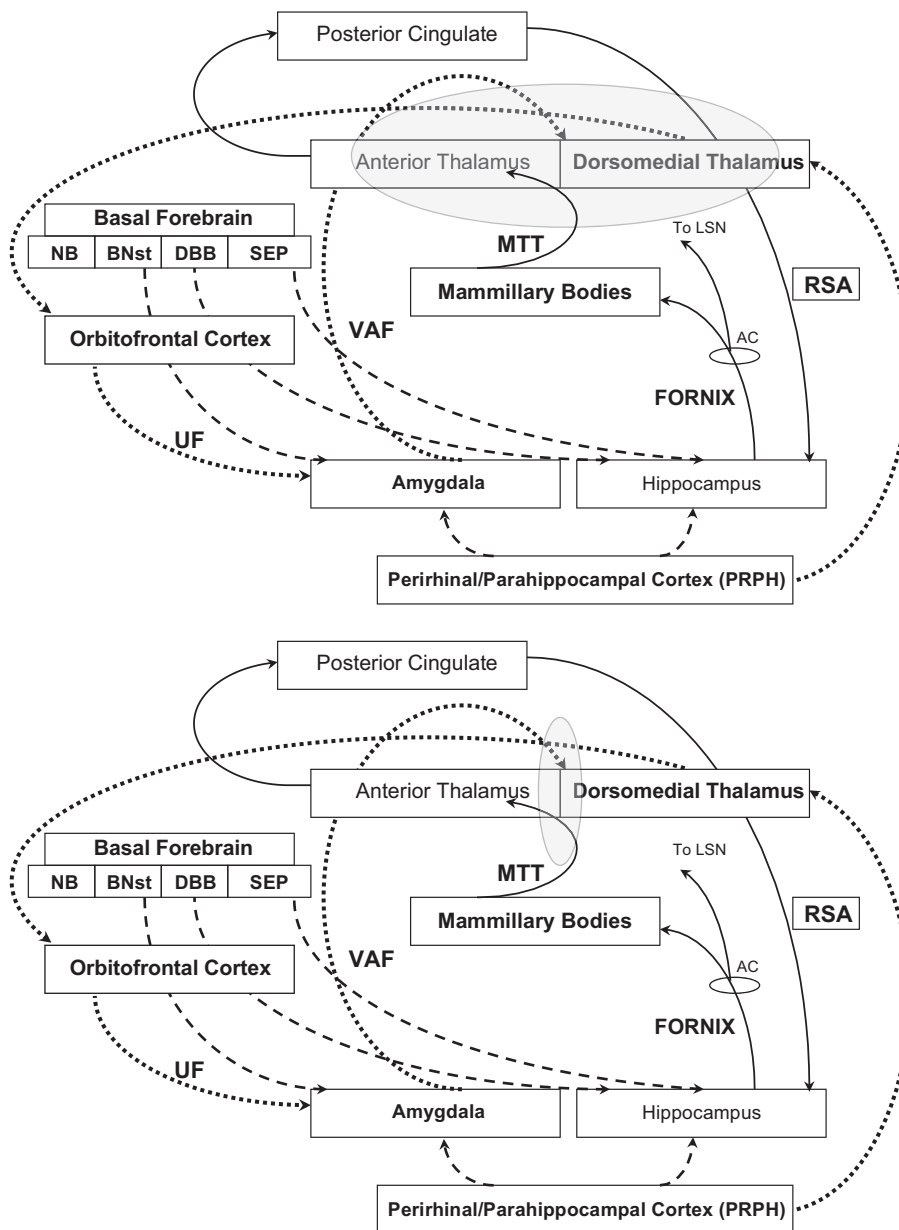

Figure 28.4 Two possible lesion scenarios for diencephalic amnesia. In Panel A, a large lesion affects both anterior and dorsomedial thalamic nuclei, thus impairing both circuits. In Panel B, a more restricted lesion affects the internal medullary lamina within the thalamus, impinging upon both the mammillothalamic tract and the ventral amygdalofugal pathway, thus impairing both circuits.

innominata (containing the nucleus basalis of Meynert), bed nucleus of the stria terminalis, and the preoptic area. It is the third major region, after the temporal lobes and diencephalon, to be considered essential for normal memory function in humans. It was known for many years that some patients developed memory loss after hemorrhage from rupture of anterior communicating artery aneurysms (Lindqvist & Norlen, 1966; Talland, Sweet, & Ballantine, 1967), but the pathogenesis of this amnesia was not understood.

One theory suggested that cholinergic neurons in the basal forebrain were involved in memory. Lewis and Shute (1967) documented a cholinergic projection from the medial septal region of the basal forebrain to the hippocampus. For many years, scopolamine, a centrally acting anticholinergic agent, had been used in obstetrics, in conjunction with analgesics, to induce a "twilight" state, after which women would have little recall of their deliveries. Drachman and Leavitt (1974) demonstrated that normal subjects had difficulty with free recall of words when given scopolamine, and that this effect was reversed by physostigmine, a centrally acting anticholinesterase agent that prevents inactivation of acetylcholine. Mesulam and Van Hoesen (1976) documented a cholinergic projection from the basal nucleus of Meynert, and in subsequent studies Mesulam and his colleagues (Mesulam et al., 1983; Mesulam & Mufson, 1984) defined the connections of basal forebrain cholinergic neurons. Neurons in the medial septal nucleus and diagonal band of Broca project strongly to the hippocampus, as had been documented by Lewis and Shute (1967). Cholinergic neurons in the substantia innominata (nucleus basalis of Meynert), however, project widely to limbic system and neocortex. In 1981, Whitehouse Price, Clark, Coyle, & DeLong documented selective loss of neurons in the nucleus basalis of Meynert in patients with Alzheimer's disease. Cell loss in cholinergic neurons of the basal forebrain (Arendt, Bigl, & Arendt, 1983) has also been found in Wernicke-Korsakoff syndrome (Butters, 1985; Butters & Cermak, 1980; Butters & Stuss, 1989). All of these lines of evidence suggested a role for the basal forebrain in memory, and more specifically, suggested that the cholinergic projections of the basal forebrain might be of particular importance. In this way, the structures of the basal forebrain can be thought of as key contributors to both the medial and lateral limbic circuits described earlier.

This "cholinergic hypothesis" (Bartus, Dean, Beer, Poncorvo, & Flicker, 1985; Kopelman, 1986) has generated a large volume of research, but poses some continuing difficulty (Fibiger, 1991). Cholinergic medication provides only a very modest improvement in memory in patients with Alzheimer's disease (Johns, Greenwald, Mohs, & Davis, 1983; Peters & Levin, 1979, 1982; Thal, Fuld, Masure, & Sharpless, 1983). It may be the case, however, that acetylcholine replacement does not have the dramatic effect that dopamine treatment has in Parkinson's disease, since patients with Alzheimer's disease have degeneration in many other areas thought to be of importance in memory, including the

target areas of basal forebrain cholinergic projections (the hippocampus, amygdala, and neocortex).

The complexity of basal forebrain anatomy makes it difficult to arrive at firm conclusions about the pathophysiology of amnesia associated with basal forebrain lesions. In addition to its role in cholinergic neurotransmission, the basal forebrain encompasses additional pathways and systems that could conceivably participate in memory. The anterior commissure crosses the midline just posterior to the septal nuclei. The columns of the fornix descend through the basal forebrain on their way to the hypothalamus. The ventral amygdalofugal pathway both projects to the basal forebrain and traverses it on its way to the thalamus. Thus structural lesions of the basal forebrain, if properly situated, may disrupt one or both of the pathways critical for memory. The medial forebrain bundle, which interconnects brain stem, hypothalamic and forebrain structures, travels through the lateral hypothalamus and the basal forebrain. Noradrenergic and dopaminergic pathways are represented in the median forebrain bundle. The *extended amygdala* refers to groups of neurons within the basal forebrain, including neurons in the bed nucleus of the stria terminalis and portions of the nucleus accumbens septi, that are anatomically considered to be related to the corticomedial amygdala, with which they are laterally confluent (Heimer & Alheid, 1991). The core of the nucleus accumbens and the olfactory tubercle closely resemble the caudate-putamen and form the *ventral striatum*, which, in turn, projects to the region of basal forebrain beneath the globus pallidus (the *ventral pallidum*). The *preoptic area* receives projections from amygdala, hippocampus, and other areas of the basal forebrain. It is involved in self-regulatory and species-specific behaviors (Swanson, 1987). It is not known if these areas contribute to memory function.

Most basal forebrain lesions reported in human cases of amnesia have been large, and probably affect all or many of the structures listed here. Often, they also affect areas outside the basal forebrain, such as the orbitofrontal and medial frontal cortices, and the caudate nucleus. Irle et al. (1992) studied 30 patients with brain lesions associated with anterior cerebral artery aneurysm rupture. Severe memory loss was associated with combined lesions in the striatum (caudate) and basal forebrain, whereas lesions restricted to basal forebrain were not associated with memory disturbance. Morris, Bowers, Chatterjee, and Heilman (1992), however, reported a patient with amnesia following removal of a very small glioma in the lamina terminalis, just posterior to the right gyrus rectus. Post-operative MRI scans demonstrated a lesion restricted to the diagonal band of Broca, anterior commissure, nucleus accumbens, and preoptic area. They postulated that destruction of the cholinergic projection to the hippocampus, most of which originates in the nucleus of the diagonal band of Broca, probably accounted for the amnesia, but they could not rule out contributions from other damaged areas. Although the cholinergic hypothesis has been popular, other neurotransmitter pathways (e.g.,

dopamine) may be of importance, and their contribution to memory remains to be elucidated.

Figure 28.5 depicts two possible lesion scenarios for basal forebrain amnesia. In Panel A, a large basal forebrain lesion affects both intrinsic information-processing within the basal forebrain as well as cholinergic input and fibers of passage that are components of both the medial and lateral limbic circuits. In Panel B, a more restricted lesion affects the cholinergic inputs to both circuits, thus impairing functional capacity of these two systems simultaneously.

**Summary of the Anatomy of Memory**

Earlier conceptions that memory was a localized function subserved by a specific structure such as the hippocampus or dorsomedial thalamus have given way to the view that memory is a distributed function of the human brain. The bulk of the evidence suggests that two functionally and anatomically integrated circuits, one involving the hippocampus and the other involving the amygdala form the basis of this distributed system. Amnesia is associated with medial temporal, thalamic, and basal forebrain damage to the extent that such

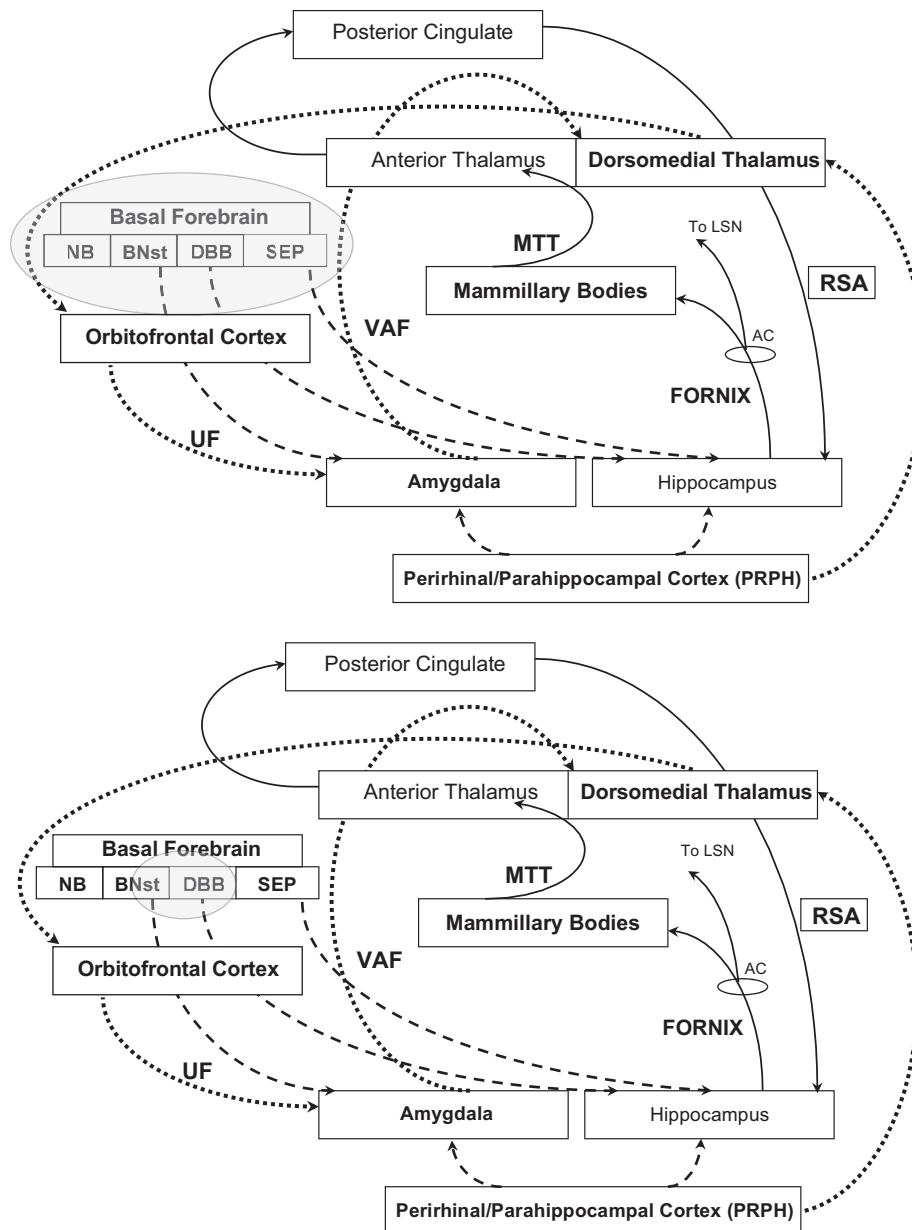

Figure 28.5 Two possible lesion scenarios for basal forebrain amnesia. In Panel A, a large lesion affects both structures within the basal forebrain (and their cholinergic projections to the two limbic circuits) as well as adjacent components of the limbic circuits themselves. In Panel B, a more restricted lesion affects cholinergic projections to both hippocampus and amygdala, thus functionally impairing both circuits.

damage either directly or indirectly impairs the functional integrity of these systems. Most existing evidence suggests that functional impairment of both circuits is necessary for full-blown amnesia to occur.

### **Amnesia Subtypes: Similarities and Differences Among Amnesics**

The view that memory relies on a distributed system suggests the presence of a “core” amnesic syndrome that results when this system is damaged. Nonetheless, the clinical and neuropathologic heterogeneity in amnesics has suggested that profound memory loss following temporal, diencephalic, and basal forebrain damage may represent different *subtypes* of amnesia (Huppert & Piercy, 1979; Lhermitte & Signoret, 1972; Squire, 1981). Can these anatomic subtypes be distinguished on neuropsychological grounds? Data on this issue come from two main sources: studies evaluating rates of forgetting from long-term memory in diencephalic and bitemporal amnesics, and studies evaluating cognitive deficits specific to diencephalic amnesia, particularly AK syndrome.

#### ***Rate of Forgetting From Long-Term Memory***

Rate of forgetting from long-term memory has been commonly assessed in experimental studies of amnesic patients. Using retention intervals from ten minutes to seven days, several authors have argued that bitemporal amnesics (e.g., H.M., herpes encephalitic, bilateral electroconvulsive therapy [ECT]) may show a more rapid rate of forgetting than diencephalic amnesics or controls (Huppert & Piercy, 1979; Martone, Butters, & Trauner, 1986; Squire, 1981). In most of these studies, diencephalic patients were given longer stimulus exposures than controls or bitemporals (to counteract an encoding deficit) in order to achieve comparable recognition performance at the shortest delays. This, coupled with faster forgetting for bitemporals, initially led to the conclusion that bitemporal amnesia involves a defect in “consolidation,” while diencephalic amnesia involves an earlier defect in stimulus “registration” or encoding (Huppert & Piercy, 1979; Squire, 1982a; Winocur, 1984). By this reasoning, once the encoding deficit is circumvented by increased exposure to the stimuli, the normal forgetting in diencephalic amnesics has been taken to mean that their consolidation ability is intact, thus distinguishing them from bitemporals.

However, the view that bitemporal amnesia is distinctively characterized by abnormally rapid forgetting has been questioned by the results of more recent studies. One of the problems with the Huppert and Piercy study is that procedures for matching initial recognition levels (which required repeated exposures for the diencephalic group) resulted in longer study-test intervals in the bitemporal group than in the diencephalic group (Mayes, Downes, Symons, & Shoqeirat, 1994). Freed, Corkin, and Cohen (1987) retested H.M.’s

recognition memory over intervals of 10 minutes, 24 hours, 72 hours and one week with two recognition paradigms, taking pains to precisely equate his 10-minute recall with that of normals. The first was a modified Huppert and Piercy (1979) rate-of-forgetting paradigm in which H.M. was given increased exposure to pictorial stimuli (10 sec. compared to one sec. for controls) and in which yes–no recognition was probed at the four retention intervals. H.M.’s performance was normal after 10 minutes, but dropped significantly below controls after 24 hours and remained at that level through the one-week recognition probe. The normal controls continued to forget over the entire week such that their recognition performance declined to H.M.’s level, and was not significantly better than his at 72 hours or one week. Freed et al. (1987: 467) suggested that their findings indicated a “normal rate of forgetting over a 1-week delay interval,” though as Crosson (1992) has indicated, an alternative explanation of these results is that H.M.’s lowest level of performance for the one-week interval was raised above previous levels reported by Huppert and Piercy (1979) by virtue of additional stimulus exposure. That is, although Freed et al. focused on the equivalence between H.M. and normals at the 72-hour and one-week delays, the fact that H.M.’s performance leveled off more rapidly than controls may, in fact, be taken to support, rather than refute, the notion that bitemporal amnesics forget at an abnormally rapid rate (Crosson, 1992). In the second task reported by Freed et al., forgetting rate was assessed at the same intervals by a forced-choice recognition test rather than a yes–no recognition test. On this task, H.M.’s performance was not significantly different from controls at any interval, and in fact was slightly above that of the controls at 72 hours and one week. This is a more convincing demonstration that abnormally rapid forgetting caused by a consolidation defect does not necessarily characterize bitemporal amnesia.

McKee and Squire (1992) directly compared rate-of-forgetting from long-term memory in bitemporal and diencephalic amnesics equated for amnesia severity. Both groups of amnesics received eight seconds of exposure to each of 120 target pictures, while normal controls received one second of exposure. Ten minutes, two hours, and 30–32 hours after study, subjects were tested with four different recognition probes, including human analogues to paradigms (delayed nonmatching to sample, delayed matching to sample) used in the animal literature. There were no group differences for any of the recognition tests at any retention interval.

Thus, although initial studies differentiated bitemporal and diencephalic amnesia on the basis of long-term forgetting rate, recent studies have tended to emphasize the similarities, rather than the differences, in rate of forgetting in these two groups. Recent evidence suggests that rapid forgetting exists in many amnesics and may vary with the extent to which the memory test taps intentional (“recollection”) versus automatic (“familiarity”) aspects of memory (Green & Kopelman, 2002). Some recent studies suggest that there

may be subtle differences in the shape of the forgetting curve when recognition probes are concentrated in the first 30 minutes, but there is little evidence of substantial differences thereafter (Downes, Holdstock, Symons, & Mayes, 1998; Mayes et al., 1994). McKee and Squire (1992: 3771) suggest that, although it is reasonable to suppose that the medial temporal lobe and diencephalic systems should have different contributions to normal memory, “each region might also be an essential component of a larger functional system such that a similar amnesia might result from damage to any portion of that system.”

### *Patterns of Retrograde Amnesia*

The three patterns of retrograde amnesia described in the “Retrograde Amnesia and Remote Memory Disturbance” section have been attributed at least in part to impairments in consolidation or retrieval that also produce anterograde learning deficits. Squire (1984) initially suggested that temporally limited retrograde amnesia was due to a defect in consolidation specifically related to dysfunction of the hippocampus (Zola-Morgan & Squire, 1990b), thus linking it specifically to bitemporal amnesia. However, Squire et al. (1989), using an updated version of Cohen and Squire’s (1981) remote faces and events tests, found extensive, temporally limited retrograde amnesia in both AK patients ( $n = 7$ ) and a group of patients with presumed medial temporal pathology secondary to anoxia or ischemia ( $n = 3$ ). Although there were differences in the specific pattern exhibited by individual patients, their retrograde amnesia spanned a period of about 15 years and was not detectible in the more remote time periods. Gade and Mortensen (1990) found graded retrograde memory loss, supposedly typical of patients with bitemporal amnesia, in patients with basal forebrain and diencephalic amnesia (including five patients with AK syndrome). It is thus unlikely that differences in the degree or pattern of retrograde amnesia can reliably distinguish among basal forebrain, diencephalic, or medial temporal amnesics, though there may still be reason to distinguish between temporally graded, temporally limited, and decade-nonspecific patterns in the individual case. Some recent clinical and experimental evidence suggests that the degree and pattern of retrograde deficit may depend on concomitant involvement of temporal (Kapur & Brooks, 1999; Reed & Squire, 1998) or frontal (Kopelman, 1991; Kopelman et al., 1999; Winocur & Moscovitch, 1999) cortex that is regionally associated with temporal or diencephalic damage per se. (Kapur, 1999) suggests that, while lesions of the hippocampus and diencephalon can produce limited retrograde amnesia, more extensive episodic (autobiographical) or semantic (fact-based) retrograde amnesia generally requires neocortical damage. Kapur argues that those cases with extensive retrograde amnesia from ostensibly localized damage must be interpreted in light of the more widespread metabolic effects on brain function that result.

### *Deficits in the Spatiotemporal Context of Memory*

Several studies have suggested that certain cognitive abilities might be disproportionately impaired in diencephalic amnesia, particularly in patients with AK syndrome. Early research on AK patients suggested that they may display disproportionate impairments in the spatiotemporal aspects of memory. A critical issue is whether such impairments are an obligatory part of the amnesia seen in these patients, or whether they result from concomitant frontal involvement.

### *Memory for Temporal Order*

The ability to discriminate when a target item occurred in a study sequence is a critical memory function necessary to maintain order in the flow of events (Hirst & Volpe, 1982; Huppert & Piercy, 1976; McAndrews & Milner, 1991). In a typical temporal-order judgment paradigm, subjects are given a list discrimination task in which a target list is initially shown, followed after a brief delay by a second target list. During later testing, subjects are asked whether they had seen each stimulus before (recognition judgment) and, if so, whether it belonged to the first or second list (temporal order judgment). It is now clear that bitemporal and diencephalic amnesics can both show defects in temporal order judgments, but the issue of whether the underlying mechanisms are the same has not been fully resolved (Downes, Mayes, MacDonald, & Hunkin, 2002; Shimamura, Janowsky, & Squire, 1990). In an early study of this phenomenon, Squire, Nadel, and Slater (1981) examined temporal order judgments in bilateral ECT (bitemporal) patients, patient N.A. (diencephalic), and controls. They found that, though impairments in temporal order judgments were seen in both ECT patients and N.A., recognition judgments were also poor. When recognition performance was subsequently equated with normals, no temporal ordering deficit remained. Thus, in these patient groups, impaired temporal order judgments appeared to be similar and due to poor recognition memory. Hunkin, Awad, and Mayes (2015) compared temporal and diencephalic patients on within-list and between-list discrimination tests of temporal order memory and found that, while both groups performed poorly relative to controls, the diencephalic group was more impaired. Temporal order judgment correlated significantly with a composite measure of recognition memory.

However, the impairment in temporal order judgments exhibited by AK patients cannot, in most studies, be accounted for on the basis of their poor recognition performance (Bowers, Verfaellie, Valenstein, & Heilman, 1988; Meudell, Mayes, Ostergaard, & Pickering, 1985; Shuren, Jacobs, & Heilman, 1997; Squire, 1982b). Several authors (Moscovitch, 1982; Schacter, 1987b; Squire, 1982b) have attributed the temporal ordering impairment in these patients to concomitant frontal lobe pathology known to coexist with diencephalic damage (Jernigan et al., 1991a, 1991b;

Shimamura et al., 1990). By this view, impairments in judging temporal order is a “neighborhood sign” rather than a core symptom of amnesia. Indeed, *nonamnesic* patients with frontal lesions and basal ganglia disease show impairment in temporal order judgments (McAndrews & Milner, 1991; Milner, Petrides, & Smith, 1985; Sagar, Sullivan, Gabrieli, Corkin, & Growdon, 1988; Shimamura et al., 1990). Although the link to frontal lobe damage has been relatively consistent, there may be reasons to keep the book open on this issue. Results from a temporal-ordering study with a retrosplenial amnesic suggest that a defect in temporal ordering can exist independently of both recognition ability and frontal lobe dysfunction (Bowers et al., 1988, Parkin & Hunkin, 1993). Interestingly, this patient was dramatically impaired in temporal order judgments for newly acquired information, but had no difficulty judging the temporal order of remote events. He performed normally on tests of frontal lobe function, as did another patient with a hypothalamic glioma but no concomitant frontal damage (Parkin & Hunkin, 1993). These findings provide an initial clue that it may be important to distinguish between two kinds of temporal ordering deficits: (a) one which is a part of a more general, frontally mediated strategic deficit (as in AK syndrome; Shimamura et al., 1990; Squire, 1982b), and (b) another that reflects an anterograde impairment in “time tagging” new information that is independent of frontal pathology (Bowers et al., 1988; Parkin & Hunkin, 1993; Yasuno et al., 1999).

#### *Source Monitoring and Source Amnesia*

Successful retrieval from episodic memory has an autobiographical quality and is characterized by direct recollection of both the content and source of remembered information (Johnson, Hashtroudi, & Lindsay, 1993). The phenomenon of *source amnesia* illustrates that the content and source of recollected information are potentially dissociable (Shimamura & Squire, 1987). In source amnesia, recollection of the informational source of a memory item is lost despite intact memory for item content. For example, we might remember specific information about the *Hunger Games*, but be unable to recollect where that information was learned. Source attributions differentiate autobiographical event memories from more general factual knowledge.

Schacter, Harbluck, and McLachlan (1984) presented bogus facts (e.g., “Bob Hope’s father was a fireman”) to their patients and then gave a recall test. If a fact was recalled, patients were asked where they had learned it. Many patients demonstrated recall of at least some of the facts, but frequently asserted that they had learned them from a source other than the experimental session. This finding could not be explained by poor memory, since normal subjects whose recall was lowered by a one-week study-test interval did not commit source errors. Shimamura and Squire (1987) taught obscure (true) facts to a small group of AK patients and a smaller group of patients with amnesia secondary to anoxia.

Severe source amnesia, in which recall was attributed to sources other than the experiment, was observed in three of the six AK patients and in one of the three anoxic patients. The level of fact memory performance did not predict the degree of source amnesia. Furthermore, patients with bitemporal amnesia (including H.M.) who display severe defects in fact memory often perform *better* at tests of recency and temporal order than do nonamnesic frontal patients (Milner, Corsi, & Leonard, 1991; Sagar, Gabrieli, Sullivan, & Corkin, 1990).

Some evidence suggests that, like temporal ordering, the severity of source amnesia varies as a function of frontal lobe impairment in both amnesic and nonamnesic subjects (Schacter et al., 1984; Janowsky, Shimamura, & Squire, 1989). Source monitoring tasks make variable demands on retrieval and cognitive estimation (Shallice & Evans, 1978), reality monitoring (Johnson, 1991), attribution (Jacoby, Kelly, & Dywan, 1989), and temporal order memory (Hirst & Volpe, 1982; Olton, 1989). Evidence suggests that distinctions between bitemporal and diencephalic amnesics that have emerged are due to the variable demands on such functions imposed by tests of source memory.

#### *Deficits in Metamemory and “Feeling of Knowing”*

Another cognitive domain that some have thought to be differentially impaired in AK syndrome has been referred to as *metamemory*. Metamemory involves knowledge about one’s own memory capabilities, the memory demands of particular tasks or situations, and potentially useful strategies relevant to given tasks or situations (Flavell & Wellman, 1977; Gruneberg, 1983). It encompasses people’s beliefs (e.g., “I will [or will not] be able to remember these words”) as well as their knowledge about the memory system (e.g., rehearsal strategies that enhance recall). Hirst and Volpe (cited in Hirst, 1982) were among the first to report differentially impaired metamemory in AK patients when compared to other etiologies of amnesia. Based on interviews, they found that AK patients had less knowledge of mnemonic strategies than did patients with amnesia from other causes.

The most widely studied metamemorial capacity in amnesic patients is the feeling-of-knowing (FOK) phenomenon (cf. Gruneberg & Monks, 1974; Hart, 1965, 1967; Nelson, Leonesio, Shimamura, Landwehr, & Narens, 1982; Nelson, Gerler, & Narens, 1984). In a typical FOK experiment, subjects are asked to freely recall the answers to general information questions of varying difficulty (e.g., “What is the tallest mountain in South America?”) until a certain number of failures occur. For these unrecalled items, subjects are then asked to judge the likelihood that they would be able to recognize the correct answer if it was presented along with other likely but incorrect choices. FOK predictions are then validated by a subsequent recognition test. In normal, recognition performance is better for questions eliciting strong FOK than for questions eliciting weak or no FOK.

Shimamura and Squire (1986) evaluated the ability of FOK judgments to predict subsequent recognition performance in patients with Korakoff's syndrome, psychiatric patients undergoing bilateral ECT, a mixed group of amnesics that included the diencephalic fencing victim N.A., and controls. Using general information questions (Study 1) and a sentence memory paradigm that assessed newly learned information (Study 2), they found that only the AK patients (and not the other diencephalic cases) displayed impairment in making FOK judgments. From these results, it appears that metamemory dysfunction is not an obligatory aspect of amnesia (or even diencephalic amnesia), since both can occur without any measurable impairment in FOK. The authors speculated that the disturbed FOK in AK patients might be a function of their frontal pathology, which would be expected to impair their ability on a variety of judgment and planning tasks.

### *Unique Characteristics of Basal Forebrain Amnesia*

Amnesia due to basal forebrain lesions most commonly results from vascular lesion or aneurysm surgery in the region of the anterior communicating artery (Alexander & Freedman, 1983; Damasio et al., 1985; DeLuca & Cicerone, 1989; Gade, 1982; Okawa, Maeda, Nukui, & Kawafuchi, 1980; Volpe & Hirst, 1983; Vilkki, 1985; Phillips, Sangalang, & Sterns, 1987). After basal forebrain damage, the patient exhibits extensive anterograde but variable retrograde amnesia. Temporal gradients similar to that seen in AK syndrome have been described (Gade & Mortensen, 1990; Lindqvist & Norlen, 1966). Some authors have also described impairment in placing memories in proper chronological order (Damasio et al., 1985; Lindqvist & Norlen, 1966; Talland et al., 1967). Free, and sometimes wild, confabulation appears to be characteristic, particularly in the acute period (Alexander & Freedman, 1983; Damasio et al., 1985; Lindqvist & Norlen, 1966; Logue, Durward, Pratt, Piercy, & Nixon, 1968; Okawa et al., 1980; Talland et al., 1967) and probably relates to the extent of concomitant orbitofrontal involvement, particularly in those patients who show spontaneous or unprovoked confabulation (Damasio et al., 1985; DeLuca & Cicerone, 1989; Fischer, Alexander, D'Esposito, & Otto, 1995; Phillips et al., 1987; Turner, Cipolotti, Yousry, & Shallice, 2007; Turner, Cipolotti, Yousry, & Shallice, 2008; Vilkki, 1985). Some patients have difficulty distinguishing reality from dreaming. Although these behavioral abnormalities are distinctive, they may not be functionally related to the amnesia per se. Often, basal forebrain amnesia persists after dream-waking confusion and confabulation have subsided (Hashimoto et al., 2000; Morris et al., 1992).

Cueing seems to differentially improve memory performance in these patients, and anecdotal evidence suggests that many of these patients can recall specific information in one retrieval attempt, but not the next. These data have suggested that these patients have a problem in accessing information

that does exist in long-term memory. However, further data is needed before accepting this proposition confidently. It has frequently been noted that these patients appear apathetic and unconcerned about their memory impairment (Alexander & Freedman, 1983; Phillips et al., 1987; Talland et al., 1967). Interestingly, Talland and colleagues regarded basal forebrain amnesics to show striking behavioral similarities to patients with AK syndrome, and Graff-Radford et al. (1990) saw similarities between these amnesics and those with memory loss secondary to paramedian thalamic infarctions. It may be that such similarities arise because the large, vascular lesions that characterize these cases also involve structures or pathways destined for components of the medial temporal or diencephalic memory systems (Gade, 1982; Crosson, 1992). Myers and colleagues (2001) have compared the performance of medial temporal and basal forebrain amnesics on delay eyeblink classical conditioning and found impairment in the basal forebrain (ACoA) patients but not the medial temporal (hypoxic) patients. In a subsequent study, these two groups were compared on performance in conditional discrimination and reversal tasks (Myers, DeLuca, Hopkins, & Gluck, 2006). The medial temporal patients showed spared acquisition but impaired reversal, while the ACoA patients showed the opposite pattern. Although quite suggestive, these studies did not rule out the possibility that such differences arose from differential involvement of neighborhood regions rather than damage to the memory system per se.

### **Conclusion**

Four decades of research with amnesic subjects has led to an increased understanding of the role that specific brain regions and brain systems play in normal and disordered memory functions. It could be said that we now have a good understanding of the fundamental components of the brain's distributed memory system, and decades of experience with amnesic patients has led to an increased appreciation of the anatomic and symptomatic heterogeneity within the amnesic population. The focus of the next decade will likely be on building and testing more comprehensive models of memory function at the network level.

For now, we return to our original question: Are there really "three amnesias" or do the amnesias of medial temporal, diencephalic, or basal forebrain origin represent variations on a "core" amnesic syndrome? In our view, the weight of the current data favors the latter interpretation. To be sure, there are clinically significant differences between these three groups of amnesics, but many of these differences can be attributed to concomitant damage to cortical and subcortical structures adjacent to the integrated memory circuits. Distinctions among patients (and patient groups) on the basis of forgetting rates, encoding versus consolidation deficits, or on the basis of impairments in contextual or metamemorial aspects of memory are important on both clinical and experimental grounds, even though such distinctions do

not thus far appear reliably reflective of lesion localization. Although the behavioral distinctions among amnesic subtypes are not that reliable or impressive, it still is reasonable to hypothesize that the different components of the distributed memory system have different functional contributions to memory performance and that such functions can be measured if sufficiently sensitive and specific behavioral probes are developed and implemented in clinical research.

The interprofessional neuroscientific study of memory and its disorders can be thought of as one of the most remarkable translational science love stories of our time. Surely our understanding of normal and impaired memory will continue to advance dramatically as increasingly sophisticated behavioral paradigms and neurodiagnostic technologies are brought to bear on this critically important area of brain function.
