Introduction

This, the fourth edition of "Knobil and Neill's Physiology of Reproduction," is a major departure from its first three editions by having Editors in Chief not previously involved in managing the production of this work. Before his death in the year 2000, Ernst Knobil and I had made plans for the transition to an Editor in Chief who had been trained at the postdoctoral level in one of our laboratories. Dr Tony M. Plant was chosen from among several excellent candidates who had the requisite characteristics needed to continue production of a work that would have the same high standards we hoped to have maintained in the earlier editions. I first met Tony in the early 1970s while I was a young faculty member at Emory University in Atlanta, Georgia, and he was employed at the Georgia Mental Health Institute also located in Atlanta. I received a letter from Ernst Knobil inquiring about my impression of Tony, who had applied for a postdoctoral fellowship in Ernst's laboratory where I had trained as a fellow but had recently relocated to Emory. My reply was a strong endorsement of Tony, which was borne out in subsequent years. Tony Plant chose Dr Tony Zeleznik as a Co-Editor in Chief to share with him the demanding tasks of editorship requiring a broad base of information in the field and a high level of academic rigor. My perusal of the list of authors and their chapter titles suggests that the information presented in this edition will rival in quality that presented in the first three editions, i.e., the work is a modern synthesis of reproductive physiology of mammals at the molecular, cellular, and organismic levels. This is not surprising given the excellent past records of the two Editors in Chief.

Ernst Knobil and I believed strongly that any work claiming to be comprehensive and hewing to the highest principles of scholarship must include a summary of the founding and the founders of the field. Because Dr Roy O. Greep was one of the leading founders of the field, we requested that he provide that information together with an overview of the future of the field in his Foreword for the first edition in 1988. Thus, the original Foreword had the great strength of being written by one of the last surviving founders in the field, and thus avoided the greatest weakness of all historical analysis, namely that history is defined as what professional historians define it to be.

A new Foreword has been prepared by Dr M. Susan Smith to address, in part, Greep's predictions of progress that might occur in the field in the succeeding years after his Foreword first appeared. Susan is a prominent leader in reproductive physiology due, for example, to her Presidency of the Endocrine Society, Directorship of the Oregon National Primate Research Center, and maintaining an National Institutes of Health (NIH)-funded laboratory running for several decades. I am pleased that her fellowship training occurred in my laboratory at Emory University during which we published the most highly cited paper of my career, of which she was the senior author.

Jimmy D. Neill

Preface

Having had the fortune of being mentored by Ernst Knobil in the early stages of our careers and serving as assistant professors in his faculty in the Department of Physiology at the University of Pittsburgh School of Medicine, we were greatly honored by the invitation to serve as Editors in Chief for the 4th edition of this book that has come to be recognized by many as the "Bible of Reproduction." At the same time, we undertook the task with considerable trepidation, being fully aware of how difficult it would be to fill the shoes of Professors Knobil and Neill, who, with their utmost attention to scientific rigor, had, together or individually, guided the previous three editions.

Given the foregoing challenge, we began by evaluating whether the structure and content of the previous edition needed to be refocused. It quickly became obvious that this was indeed the case because of the rapidly growing use of "omics" approaches in most, if not all, areas of reproductive biology. In this regard, it is noteworthy that the first edition of this text was published in 1988, a year before the first use of the "gene knockout" approach in mice was described. Over the course of the 25-year history of this text, the ability to delete or modify individual genes has increasingly and significantly added to the classical armamentarium of organ ablation/hormone replacement paradigms previously available to investigators studying reproduction. In addition, the application of genetics/genomics to elucidate the etiology of human disease has increased in parallel to the use of transgenesis in experimental animals. Collectively, these powerful approaches have provided new, and often serendipitous, information on the regulation of reproduction. For example, our view of the neuroendocrine control of the hypothalamic–pituitary–gonadal axis is now completely dominated by kisspeptin. This hypothalamic peptide, which, in the context of reproduction, was unheard of before 2003, surfaced because mutations of its receptor, then known as GPR54, were identified in individuals with delayed puberty.

Accordingly, our authors were confronted with the need to integrate information gleaned from "classical" whole animal studies with results generated by contemporary "omics" approaches in order to provide a holistic overview of reproductive processes. In keeping with this approach, we encouraged authors to discuss the historical underpinnings of their respective fields and to identify the burning questions that remain to be addressed.

In this 4th edition, Volume 1 focuses on basic processes of male and female reproduction while the thrust of Volume 2 is on the physiological control systems that govern reproductive processes, including those regulating sexual behavior. A chapter on meiosis has been included for the first time, and discussions of epigenetic mechanisms that are emerging as important regulators of reproduction, as well as fetal origins of adult diseases, have been expanded. New chapters on spermatogonial stem cells and hormone signaling in the testis that provide contemporary views of the control of testicular function replace the more classical approach to the control of spermatogenesis that was presented in prior editions of the text. We have also expanded the discussion of the regulation of reproductive behavior, which, having moved far away from its origins in ethology, is now dominated by genomic, epigenetic, cellular, and molecular approaches to the understanding of sexual motivation, partner preference, and parental behavior. For those chapters that have been updated, we are confident that these new versions present the most current discussion of the subject material.

Such restructuring of this book would not have been possible without the enthusiasm and commitment of our section editors, to whom we are greatly indebted. A feature of the 3rd edition that has been maintained is the inclusion of the Foreword by Professor Roy O. Greep that was written for the 1st edition, published in 1988. As recognized by Professor Neill, the Editor in Chief of the previous edition, Greep's account of the future of research on the physiology of reproduction continues to remain remarkably relevant, now 26 years after it was written. We are pleased to include a second Foreword that was written by Dr M. Susan Smith, who worked with Jimmy Neill as a postdoctoral scholar and was also a member of Ernst Knobil's Department of Physiology at the University of Pittsburgh School of Medicine. Dr Smith's broad understanding of both whole animal and molecular approaches used in the study of reproductive processes makes her uniquely qualified to comment on how the study of reproduction has progressed since Greep's original Foreword in 1988, as well as to identify the challenges to be met in future years.

This 4th edition of *Knobil and Neill's Physiology of Reproduction* will be the last available in a print version. While our purpose here is not to debate the loss of hard copy, electronic publishing will enable, on the one hand, the addition of new chapters covering important emerging fields and, on the other, the replacement or revision of outdated chapters, both with relative ease. In this way, we anticipate that the *Physiology of Reproduction* will continue to be highly contemporary and comprehensive and therefore remain, for the future, the authoritative text of the field.

It is our expectation that this 4th edition of *Knobil and Neill's Physiology of Reproduction* will continue to kindle the importance of physiology in the understanding of reproductive processes and, in the words of Neill and Knobil in their preface to the first edition, be "useful to all serious students of reproductive physiology be they scientists, teachers or physicians."

Tony M. Plant
Anthony J. Zeleznik

Foreword* by Roy O. Greep

I am pleased and honored to have been asked to prepare the Foreword to this volume of work depicting the progress in research on the physiology of reproduction as well as the resulting gains in understanding made over the past few years. The expertise that is represented by the numerous contributors to this work is so impressive that I am humbled even to contemplate adding anything of note. It is only by virtue of having personally witnessed a very large segment of twentieth century research on reproduction that I am emboldened to reflect on the byways and the trailblazings that have brought this field to its present proud state of enlightenment with regard to the long sought-after means of controlling the procreative process in humankind. Clearly, there are many important and knotty problems yet to be resolved, but the pace of progress over the past several years has quickened to the extent that one is left in expectant wonderment as to where and when the next revolutionizing development will occur.

The experimental method of studying reproduction was initiated in 1849 with Berthold's discovery of a blood-borne activity that came from the testis and stimulated growth of distant organs such as the comb and wattles. In so doing he utilized one of the most fundamental means of demonstrating the function of an endocrine organ, namely, surgical removal to determine what deficiencies follow, coupled with implantation or transplantation to ascertain whether the deficiencies were repaired. At that time it was not possible to take the next step, namely, preparation of an active extract of the testes, because nothing was known about the nature of the bioactivity. Forty years later, Brown-Séquard claimed to have prepared an active extract of dog testes; however, as is well known, his enthusiastic claims for restoration of his own sexual activity at an advanced age were not substantiated. Actually, these simple means of studying reproductive physiology persisted well into the twentieth century, including the studies of such pioneering stalwarts as Marshall, Heape, Prenant, Bouin, Ancel, Loeb, Cushing, and Aschner. Observations otherwise were limited to cyclic and seasonal changes in sexual behavior among common laboratory and small domestic animals. This type of eyeball research remained in vogue through the early 1920s and overlapped the extension of visualization to the microscopic level. The latter revealed, for the first time, the precise timing of events in the ovarian cycle through microscopically observable cellular changes in the vaginal fluid. My point in mentioning these early studies is to emphasize that although the tools and techniques were inordinately primitive by present standards, the results established a firm base of knowledge on which to build.

The study of cyclic changes in the vaginal smear in rats and the findings of estrogenic activity in follicular fluid during the early 1920s led to an explosion of interest in the study of reproduction. The field was fortunate in attracting to its ranks a small band of exceedingly able biologists and biochemists who, in 1932, were to become authors of the classic first edition compendium, Sex and Internal Secretions, a volume overwhelmingly devoted to reproductive endocrinology. It was this landmark of progress that finally gave propriety to the study of reproduction and put it on a par with the study of other major bodily systems. Incredible as it may seem, it was only a decade earlier that a distinguished panel of the National Research Council had declared that sex research was not a fitting topic for scientific study.

Lest our pride in today's spectacular pace of progress unduly bedazzle the mind, it should not be overlooked that the developments recorded in the 10-year span from 1926 to 1936 may never be equaled. Among those monumental achievements, all of the native sex steroid hormones were brought to light, their structures were determined, their functions were defined, and they were made available in pure form for research and therapy. Similarly, all of the pituitary, placental, and urinary tropic hormones were identified, and their functions were defined. Like today's competition for priority rights, publicity, and potential financial gain, these earlier periods also were times for intense rivalries, but rarely with prospects for financial rewards. It would be difficult to overstate the boost that was given to basic and clinical research in reproduction as a result of the availability of estradiol-17β, testosterone, and progesterone in pure form and of known potency. The replacement of

*This Foreword by Roy O. Greep is reprinted from the 1988 (first) 1994 (second) and 2006 (third) editions of this work (E. Knobil and J. D. Neill, The Physiology of Reproduction. Raven Press, New York. Copyright Elsevier). This now-deceased author wrote a remarkably prescient account of the future of research in the field that remains as relevant today as it did in the first three editions.

homemade extracts and such elastic entities as rat units, mouse units, capon units, and so forth, with micrograms of pure hormone was revolutionizing and allowed the study of reproduction on a quantitative basis.

Prior to World War II the thrust of research on reproduction dealt predominantly with the steroid hormones. This was the heyday of steroid biochemistry. After World War II the emphasis shifted to the protein and peptide hormones, where it still remains strong. This prolonged and difficult effort yielded many biochemical triumphs. Most notable among these were the isolation of the pituitary, placental, and urinary gonadotropins, as well as the determination of their primary structure as glycoproteins comprised of two dissimilar and covalently bonded subunits, the isolation and synthesis of the gonadotropin-releasing hormone (GnRH) of hypothalamic origin, and the isolation and structural characterization of relaxin.

The availability of pure protein and polypeptide hormones made possible the production of hormone-specific antibodies as well as the application of immunological techniques to the study of reproduction. An outcome of great consequence was the development of radioimmunoassay as the new means of measuring all of the hormones relating to reproduction. The sensitivity of this new technique was so great that it made possible, for the first time, the measurement of all these hormones in the body fluids. It had the further distinct advantage of requiring such a small amount of fluid that the monitoring of blood levels of the hormones of reproduction could be done throughout an estrous or menstrual cycle by close serial sampling. This revealed still another and most unexpected finding, the pulsatile pattern of secretion.

Identifying the homeostatic mechanism(s) responsible for maintaining a steady state in various physiologic systems of the body has been fraught with many challenging problems, but these pale in comparison with the difficulties encountered in trying to elucidate the mechanisms maintaining a constantly changing system, a characteristic of the reproductive system of female mammals. The earliest piece of evidence suggested the existence of a "push–pull" mechanism that later came to be known as negative feedback. It was based on the demonstration that an estrogenic extract administered to immature rats would maintain the ovaries in an infantile state. This was quickly followed by conclusive evidence that estrogen acted to inhibit pituitary follicle-stimulating hormone (FSH) stimulation of follicular growth and maturation; however, the effect on luteinizing hormone (LH), ovulation, and luteinization remained unsettled. Gaps continued to exist in all proposed explanations of reproductive cycles. None of these explanations took into account the influence of photoperiodicity on seasonal breeders, nor did they account for the role of the stimulus of mating in nonspontaneous ovulators. Following the discovery of the hypothalamic control of pituitary function, estrogen was shown to exert its action on both the pituitary and the hypothalamus; however, the problem of accounting for cyclicity remained. Adding to the complexity, radioimmunoassay revealed an unexpectedly high level of blood estrogen just prior to ovulation, an event not in keeping with the negative feedback concept.

Finally, after many years of searching for a way out of this frustrating situation, a glimmer of light appeared at the end of this long dark tunnel—light that soon turned to brilliance. In 1969, Goding and associates found that the administration of large doses of estrogen to ewes at the time of estrus did not block, but instead entrained, ovulation. Shortly thereafter, in more elaborate examination of the relationship of blood estrogen levels and ovulation in rhesus monkeys in Knobil's laboratory, it was revealed that elevated estrogen levels preceded and appeared to trigger ovulation. On further examination, Knobil and colleagues found that when blood estrogen reached a critical level, the feedback mechanism switched from a negative to a positive, or stimulative, action. This utterly new finding greatly advanced our understanding of the endocrine mechanism governing reproductive cycles. There still remain, however, some uncertainties: Why does the switch in feedback action occur; to what extent and at what stage of the cycle does estrogen act at the level of the pituitary or the hypothalamus, or both; and lastly, what role, if any, do the ovarian peptides, especially inhibin, play in controlling reproductive cycles?

The progress of research on reproduction has been chronicled in numerous review articles by individual authors. Many have appeared in Recent Progress in Hormone Research, Volumes 1–42. Other major sources include the multiple editions of such titles as: Marshall's Physiology of Reproduction, Fourth Edition (1990); Sex and Internal Secretions, whose third and last edition was issued in 1961; two volumes on the Female Reproductive System (1973), and one on the Male Reproductive System (1975) in Section 7 of the Handbook of Physiology, published by the American Physiological Society; and four serial volumes on reproductive physiology in the International Review of Physiology, the last one being issued in 1983. The present volume will provide comprehensive coverage and meet the current needs of the field of reproductive physiology, a field that is rapidly gathering momentum from the application of new and highly sophisticated tools and techniques.

In viewing the vast literature dealing with research on the male and female reproductive systems and considering the rate at which it is accumulating, one might ask whether this staggering proliferation of books and articles is essential to progress; the answer is an emphatic "Yes!" The yardstick by which progress is measured

in this or any other field is not in the number of articles published or the amount of financial support but in improved understanding. Such gains are generally marked by sharp peaks at indeterminate intervals, separated by avalanches of incremental gains, as recorded in an ever-growing list of journals. The point to remember is that without this persistent chipping away at a major problem there would be no solutions and no quantum leaps forward. In research very little comes from out of the blue. Part of the driving force in research is its adventuresome nature and ever-present possibility that one's efforts will pay off in an important manner. It may not be entirely fair, but in research (as in most human activities), the spoils go to the victor in the form of kudos, prizes, awards, public attention, and, increasingly in the present technological age, monetary gains—sometimes of great magnitude. What effect this latter may have, if any, on the long-cherished sanctity of science has not been determined, but it has become a matter of concern.

This volume bears the title The Physiology of Reproduction. Physiology, by traditional consensus, is that branch of science, which studies the functions of a living organism or any of its parts and includes the basic underlying processes. It will be understood that most of the studies reviewed here will be based more on holistic research than on research at the submicroscopic or molecular level. It is unfortunate that the excitement generated by recent fantastic advances in molecular biology and development has tended to downgrade the value of whole-animal research, and physiology in particular is sometimes looked upon as passé. Actually, the two categories of research are complementary, and both are essential for maximum advancement of knowledge. Whole-animal research cannot become outdated because it is the quintessence of biological relevance and the means by which molecular findings must ultimately be evaluated.

In the same vein, no one immersed in reproductive endocrinology can be unaware of the current tendency to regard research at the molecular level as representative of exceptional scientific talent. This is a common consequence of the opening of a new arena of investigation. I recall an incident that happened at a scientific meeting back in the 1930s. The first three papers in a session chaired by an eminent embryologist were on endocrine topics—mine was the third. That being ended, the chairman took pains to assure the audience that the meeting could now turn to considerations of more fundamental nature. One of the other three papers was given by Herbert M. Evans, who bristled noticeably but held his fire. There was also an earlier period when one either worked on steroid biochemistry or something of lesser appeal like biology. Anyone who remembers the 1950s will recall a flash in the pan ignited by cybernetics, a study of automatic control systems both neural and physical. The gurus of cybernetics captured the attention of the press and of audiences throughout the land, but eventually this obsession suffered the fate of other passing preoccupations. My own observation is that the closer one approaches the molecular level of research, the more one becomes dependent on highly sophisticated instrumentation to make the observations and to read out results that are often quite free of extraneous variables. Toward the obverse situation, one's dependence on an extensive background of experience and physiological increases as does the unavoidable complex of in vivo variables that must be taken into account. In either case we have today the availability of far more diverse approaches to a given problem in any field of biomedical research than has ever existed before. In Berthold's day there was only one experimental method available; today's number is untold but is probably in the hundreds, perhaps thousands. This is an exceedingly promising situation and one to which investigators of all persuasions must adjust. Open minds will experience exhilaration over substantive achievements at any point on this observational spectrum.

One of the major factors influencing research on reproduction has been the availability of funds or lack thereof. Prior to the institution of federal funding (i.e., prior to the middle of the twentieth century), reproductive research was sparsely supported by university departmental funds, industry, small grants from the Committee for Research in Problems of Sex within the National Research Council, and some aid from the Rockefeller Foundation. The National Institutes of Health were slow in providing significant support of research on reproduction because of restrictions on the support of work related in any way to birth control. This occurred despite the simultaneous postwar baby boom. What kept research afloat during this critical period was major support by the Ford Foundation plus lesser contributions by other major foundations. It was not until the establishment in 1968 of the Center for Population Research in the NICHD that major governmental funding in this area became available, but the boost was short-lived. As a result of the imposition of fiscal restraints in the early 1970s, federal support dwindled and has remained at a minimal level ever since. Support from all sources is woefully incommensurate with the distressing expansion of the human population and the need for safe, effective, economical, and readily available means of limiting human fertility.

The physiology of reproduction is predominantly under hormonal control. The first essential step in studying reproduction was identification of the hormones involved and the functions they serve. This having been accomplished, efforts turned to a detailed analysis as to how hormones act within the body. During the 1980s there has been a rising tide of interest

in the binding of steroid, protein, or peptide hormones to receptors on specific target cells. Much effort is currently being directed toward the isolation and chemical characterization of these receptors. They are known to be composed of a protein or proteins, and some information has already been gained as to their partial or provisional structure. This, however, is only a preliminary step in the complex process whereby hormone action results in an end response such as growth, secretion of a target cell hormone, or altered behavior. The curtain has already been raised on the climatic and final chapter of the story on how hormones act. This involves linkage of the hormone–receptor complex with the nuclear genetic apparatus leading through a now well-defined series of processes to the manifestation of a physiological response in the living organism. Genes that bring about the expression of certain hormonal signals are being isolated, modified, transferred between species, and also inserted into bacteria where they direct the biosynthesis of specific hormones in large quantity. Thus genes are being manipulated in ways that raise the potential of altering the reproductive process. It is largely as a result of developments in endocrinology at the molecular level that bewildering possibilities loom on the horizons of reproductive research—they are within reach; they are science, not fiction; and they stagger the imagination.

It being granted that nothing succeeds like success, then the new edition of this highly successful two-volume compendium on The Physiology of Reproduction is destined for an illustrious fate. This second edition will maintain the same high standards of the first and again fulfill an existing need in a field that is experiencing rapid growth and exhilarating progress. Like the first edition, this one will provide a critical assessment of the state of the art in every aspect of research on the physiology of reproduction by eminent authorities.

In the years intervening between this edition and the last, notable changes have taken place in the study of reproduction. These stem largely from major advances in technology. Remarkable new instruments, techniques, and methods have enabled investigators to probe ever deeper into the interaction between hormones and genes, thereby eliciting in vivo responses. New parameters are being added to the target tissues of the classical reproductive hormones as revealed by the presence of receptor sites in tissues, the physiologic significance of which often remains tantalizingly obscure. Similarly, newly identified substances of endocrine or paracrine nature are being added to this domain of research with persisting frequency. Some of these substances—the endothelins, interleukins, activins, inhibins, and prorenin, to name a few—also exhibit a puzzling array of effects on extraneous tissues. Their study is being aided by the fact that their structure is known and, though rare, they are available.

Great strides are also being made in many other aspects of research on reproduction. Much work is being done on the structure of receptors and the loci of binding sites on segments of the folded gonadotropic molecules. A full-scale effort is underway seeking an elucidation of the neural mechanism underlying pulsatile secretion. Neuroendocrinologists are closing in on an elusive pulse generator located in the central nervous system. This looms as another landmark discovery in reproductive biology.

Research on reproduction is flourishing and the future appears bright. The taboos are gone. All aspects of the reproductive process are an open book. One area that has taken a quantum leap forward is the clinical application of an important body of relevant new knowledge gained in both basic and clinical spheres. Expanded opportunities have been opened by greatly improved diagnostic procedures, more effective treatment of disorders, and new methods of controlling fertility. Contributing greatly to this explosive development is the dissemination of information on reproductive matters to the lay public by the mass media. Concerned individuals have been made aware of the existing new means of manipulating the male and female reproductive systems for enhancement or inhibition of fertility. The joys and comforts that accrue respectively to these opposing modes of fertility control have enriched the lives of a grateful public. To that end I may note that it was by virtue of these frontier reproductive measures that my own progeny includes a new grandson and namesake.

Roy O. Greep

Foreword by M. Susan Smith

I am truly honored to write the Foreword for the 4th edition of this book; it is a humbling task to follow in the footsteps of Professor Roy O. Greep, whose Foreword is herein reprinted from the 1st, 2nd, and 3rd editions of this work. His remarkable account of the field of the physiology of reproduction was written 26 years ago, yet as you read it, you will develop an overwhelming appreciation for how fortunate we were to have Professor Greep as one of the foremost leaders in our field. It is especially gratifying for me to be associated with this great work, since my scientific lineage is part of the Greep/Knobil/Neill 'family', having trained with Professor Neill and served as a faculty member in Professor Knobil's Department of Physiology at the University of Pittsburgh.

Since the publication of the 3rd edition of this book in 2006, there continues to be remarkable progress in the physiology of reproduction, reflecting the use of advanced technologies, such as those spurred by contemporary genetic and genomic approaches. However, the challenge today is to understand how this genetic and molecular information is integrated into the manifestation of a physiological response. Greep's thoughts on this are still prescient today, "Actually, the two categories of research are complimentary…." "Whole animal research cannot become outdated because it is the quintessence of biological relevance and the means by which molecular findings must ultimately be evaluated."

Professor Greep issued a challenge in his Foreword: "Developments recorded in the ten-year span from 1926 to 1936 may never be equaled." I posit that the 10-year span from 2004 to 2014 was, at the very least, equally important, as we have made a paradigm shift in how we conduct our science. In the more traditional way of science, experiments focused on understanding control systems; this then led to the discovery of new molecules. Today, in contrast, the use of massively parallel sequencing (exome sequencing, ChiP-seq, and RNA-seq) allows us to identify all the players, even though we may have no idea of their function. We then "reverse engineer" results from these studies to discover where a particular molecule is produced, how its production is regulated, and what its function is. These sequencing techniques were used in the groundbreaking studies that signaled the important role of kisspeptin and neurokinin B in regulating the pituitary–gonadal axis; subsequent studies located their sites of production in the hypothalamus and identified their critical function in controlling GnRH neuronal activity. All of these sequencing techniques generate massive amounts of data and necessitate application of the extensive bioinformatics infrastructure that goes with managing large databases. Greep was right when he stated, "the closer one approaches the molecular level of research, the more one becomes dependent on highly sophisticated instrumentation to make observations and to read out results that are often quite free of extraneous variables." As an example of the power of these databases that are available to the scientific community, there is one that identifies all the transcribed genes in the ovary of the nonhuman primate and maps changes in their individual activities throughout the duration of a menstrual cycle and into early pregnancy. Not too long ago it would have been impossible to imagine being able to follow the activity of one gene through such a time course. Importantly, these databases can be used for comparative analyses among species and should provide enlightenment about the evolution of different approaches to reproduction.

The material in the chapters of this 4th edition reflects advances that have been made at all levels of the hypothalamic–pituitary–gonadal axis and the reproductive tract; many of these advances have been made possible by the new tools available to scientists. The most notable is the discovery of kisspeptin in the hypothalamus that fundamentally changed our concept of the control of GnRH neurons and has expanded our knowledge of the neural networks that govern reproductive function. Significant advances have also been made in our understanding of how G-protein coupled receptors function; such as the insight gained by the discovery of GnRH receptor misfolding that results in a loss of trafficking of the receptor to the plasma membrane and, thus, functionality, a deficit that can be overcome by artificial chaperones. New areas of research have come forth, such as oncofertility, a term coined to signify the restoration or maintenance of fertility in cancer patients whose gonadal function is diminished or lost due to the side effects of their radiation treatment or chemotherapy. Studies using new techniques, such as 3-dimensional culture of follicles in an extracellular matrix and differentiation of gamete stem cells, have provided new insights into the processes controlling folliculogenesis and gametogenesis, with translational

opportunities for promoting or controlling fertility. In addition, there is an explosion of interest in stem cell biology, a field that was rooted in reproductive research and the practice of in vitro fertilization. There is also a new appreciation for the role of the environment in fetal development and this has led to the birth of a new area of medicine known as DOHAD (Developmental Origins of Health and Disease). Maternal under- and overnutrition both lead to epigenetic changes in the fetus that can have long-lasting consequences in the adult. Similarly, exciting new research shows environmental influences on epigenetic modifications of DNA in sperm that may result in paternal transmission of disease risk.

When considering all of this new research, some caveats need to be kept in mind. There appear to be significant species differences in a number of reproductive processes, including puberty, ovarian cyclity, and parturition, yet current research focuses primarily on the transgenic mouse model because of the ability to manipulate the expression of specific genes. Therefore, many of our current ideas about the control systems regulating reproductive processes are "mouse-centric" and may not be directly applicable to other species. This may create problems as we look to translate this information into new therapeutics for use in human and veterinary medicine.

What new advances can we look forward to in the near future? New technologies, such as optogenetic/pharmacogenetic tools, designer receptors, and advanced imaging, will likely contribute to the making of another "best decade" from 2014 to 2024. But it will be important to develop better methods, with increased specificity and sensitivity, for measuring hormones and other substances in the blood. There are also growing concerns over the use of sex steroids in clinical therapies. As a result, there is considerable interest in developing "nonhormonal", i.e., nonsteroidal, selective therapies that act at the local or intracellular levels.

Future studies must also focus on the still many critical unanswered questions in the physiology of reproduction. Just in the area of neural regulation of reproduction alone, there are numerous examples. Many external signals modulate reproductive function, such as stress, endocrine disrupters, diet, photoperiod, and pheromones. Yet we still do not know how these external signals are transmitted to directly alter kisspeptin or GnRH neuronal activity and thus, reproductive function. Perhaps, Greep's assertion that "The physiology of reproduction is predominantly under hormonal control," needs to be expanded to include nonhormonal factors that are important modulators. Another mystery is what heralds the onset of puberty. Detailed information is known about the regulation of kisspeptin gene expression and its upregulation at the time of puberty, but the specific signals that bring about these epigenetic changes are still completely unknown. Similarly, although neuroendocrinologists are closing in on the GnRH pulse generator located in the central nervous system, the actual mechanisms involved in pulse generation remain elusive. Greep recognized that "This looms as another landmark discovery in reproductive biology." The processes involved in the positive feedback effects of estrogen on gonadotropin secretion also remain a mystery. With the current recognition that there are likely species differences in these processes, negative and positive feedback of estrogen might be achieved through two different populations of kisspeptin neurons (rodent model) or two different populations of GnRH neurons (nonhuman primate model).

While the future for research in reproduction appears bright, with more landmark discoveries in the making, there is also cause for concern. Funding for basic research in reproduction at the federal level is declining, as the emphasis shifts to translational research relevant to human health and disease. In the bench-to-bedside continuum of research, it is critical to keep "bench" in the equation. There are still many areas in reproduction where we do not understand the basic underlying controlling mechanisms, making it difficult to devise therapeutics. Studies of various species will also be harder to support. This is regrettable, since comparative studies have revealed differences in how reproduction is regulated, and this collective information may be critical to solving long sought after questions, such as, what constitutes the GnRH pulse generator, how is puberty initiated, how is parturition initiated, and what is the impact of environmental factors on germ cells. A good example of the value of studying various species is the seasonal regulation of reproduction that led to a focus on photoperiod and how time-of-day signals are transmitted to GnRH neurons. These studies were instrumental in advancing the field of chronobiology to the recognition today that all cells appear to have clock genes that regulate their function. It is also regrettable that there are still constraints on contraception research even though the link between the ability to control fertility and the economic development of a country is well established. Finally, in this age of "big data," it is well to remember that analysis of large databases can detect correlations, but it cannot determine whether the correlations are meaningful or provide information about causality or mechanisms. This is the province of basic research: to discover the critical information about control systems that then provides the underpinnings for translational research and the development of new human therapeutics.

CHAPTER

26

Neuroendocrine Control of the Ovarian Cycle of the Rat

Jon E. Levine

Department of Neuroscience, School of Medicine and Public Health, Wisconsin National Primate Research Center, University of Wisconsin, Madison, WI, USA

INTRODUCTION

In all female mammals, fertility is maintained by hormonal signals conveyed between the brain, pituitary gland, and ovaries, functioning together as a hypothalamic–pituitary–ovarian hormone axis. Hypothalamic neurons in the basal forebrain secrete gonadotropin-releasing hormone (GnRH) into a hypothalamic–hypophysial portal vessel system to stimulate release of the pituitary gonadotropins, luteinizing hormone (LH) and follicle stimulating hormone (FSH), which circulate to regulate ovarian functions, including steroidogenesis, folliculogenesis, and ovulation. Ovarian hormones in turn exert negative feedback effects within the brain and pituitary gland to maintain homeostatic control within the axis. In addition, they convey special positive feedback actions that evoke a gonadotropin surge that triggers ovulation in mature ovarian follicles. These feedforward and feedback signals orchestrate the sequence of events that unfold during the course of each ovulatory cycle in spontaneously ovulating animals. More so than any other experimental animal, the laboratory rat has been studied to obtain a fundamental understanding of these physiological mechanisms that govern ovarian cyclicity.

The laboratory rat has also served as a reference point for the elucidation of species-specific aspects of ovarian cyclicity and its control by neuroendocrine systems (Chapter 33). Indeed, much of what is known about the control of the ovarian cycle of many spontaneously ovulating, nonseasonal estrual mammals is based on our knowledge of the controls of the estrous cycle of the rat. However, unlike the ovarian cycles of other spontaneous ovulating mammals (sheep and primates; also described in this section of the book), the rat as well as the mouse exhibit a cycle that is characterized by a brief luteal phase. Moreover, the events of the ovarian cycle of the rat are tightly coupled to the 24-h light–dark cycle. That is, the lighting periodicity plays a dominant role in the incidence and duration of the stages of the ovarian cycle.

This chapter will present a detailed description of the estrous cycle of the rat, with emphasis on the neuroendocrine control mechanisms that govern the ovarian cycle. The reader of this edition will note the increased frequency with which studies of genetically modified mice are cited to support the basic physiological principles that govern the ovarian cycle in both species. However, the reader should be aware that the neuroendocrine mechanisms regulating ovarian cyclicity in the two species overlap to a great degree, but are not identical. Rats and mice both exhibit spontaneous 4- to 5-day estrous cycles characterized by similar, if not identical, patterns of hormone secretion and cyclic ovarian function. Olfactory cues, however, can play a much more prominent role in regulating cyclicity in mice, while photic cues more robustly dictate the timing of ovulation in rats. These differences notwithstanding, I will remain true to the original intent of this chapter—to review the neuroendocrine regulation of the ovarian cycle of the rat—while incorporating into the discussion the newer findings obtained using the power of mouse genetics, specifically those observations that clearly support and further elucidate neuroendocrine principles common to both species, which are informative to the understanding of these processes in other species.

An understanding of the neuroendocrine regulation of ovarian cyclicity began with the recognition that the brain releases factors that direct the secretion of anterior pituitary hormones and that these, in turn, circulate to regulate ovarian function. Harris demonstrated in 1937 that electrical stimulation of the hypothalamus induces

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00026-0

ovulation in the rabbit.[1] In the same decade, the existence of a specialized hypothalamo-hypophysial portal vasculature was revealed in which blood flows from a primary capillary bed in the median eminence (ME) through long portal vessels that drain toward sinusoids in the anterior pituitary.[2,3] The description of the hypothalamo-hypophysial portal vessels led Harris to propose that they function to convey signals that mediate the ovulatory response to electrical stimulation of the hypothalamus.[4] Harris supported this view by demonstrating that restoration of reproductive function in stalk-transected rats was proportional to the degree of portal vessel regeneration.[5,6] Harris and Jacobsohn[7] also transplanted pituitary glands from neonatal donor rats to various neural and nonneural sites in hypophysectomized recipient rats. Only when the gland was transplanted to just beneath the ME and vascularized from the ME were full reproductive and other pituitary functions restored. With these and other observations, it was finally appreciated that hypothalamic control of reproductive function was due to a neurovascular link between the hypothalamus and pituitary gland.

The chemical nature of the molecules synthesized by neurons and transported by this specialized vascular link thus became the subject of studies attempting to identify the hypothalamic releasing factors that control the synthesis and secretion of the major anterior pituitary hormones,[8,9] including LH and FSH. An activity that is capable of releasing LH was found in extracts of ME by both McCann[10] and Harris[11] working independently. McCann later suggested that a luteinizing hormone releasing hormone (LHRH), now more commonly known as GnRH, exists in the hypothalamus, which activated the release of LH.[12] In 1971, Schally's laboratory and that of Guilleman successfully isolated the decapeptide from extracts of porcine and ovine hypothalamus, respectively, and identified its chemical structure.[13,14] With the synthesis of the decapeptide, antibodies were produced for purposes of radioimmunoassay,[15] and immunohistochemical localization of GnRH-neurons within the brain.[16,17] The peptide fulfilled all the expectations as a neurohormone: identification in neurons, release into portal blood, and activity correlated with release of LH and FSH into peripheral plasma. Decades of research have since established the primacy of GnRH as the neural effector of reproductive function in both sexes and in all mammalian species. In much of this chapter, the special importance of GnRH in the neuroendocrine regulation of the estrous cycle of the rat is considered.

The chapter begins with an overview of the estrous cycle and proceeds to build a hierarchical understanding of ovarian cyclicity by focusing in turn on ovarian, pituitary, and then neuroendocrine physiological controls. I consider the cyclic physiological processes that occur within the ovaries, the pituitary hormone secretions that control these cyclic ovarian phenomena, and then the neural mechanisms that register environmental and endocrine signals and transduce them into the GnRH release patterns that ultimately drive the pituitary and ovarian events of the ovarian cycle.

OVERVIEW OF THE ESTROUS CYCLE

The word *estrus* is a Latin adaptation of the Greek word *oistros* meaning gadfly, sting, or frenzy. This term was first used by Heape[18] to describe the "special period of sexual desire of the female" and distinguish it from rut in the male. Heape further described distinct stages of the cycle as it applied to mammals during the breeding season. He used the term *anestrus* to describe the nonbreeding season or period of rest in the female mammal when the ovaries and accessory reproductive organs are relatively quiescent and attempts of mating by the male are resisted. Heape also used the prefixes *pro-*, *di-*, and *met-* along with the suffix *-estrus* to describe the stages of the cycle between the periods of estrus during the sexual season. The first part of the cycle he termed *proestrus*, characterized as the time when an animal is "coming on heat." The next period, estrus, Heape described as "only at that time that the female is willing to receive the male, and fruitful coition rendered possible in most, if not all, mammals." In the absence of conception, estrus is succeeded by a short recovery period called metestrus, during which the estrus changes in the reproductive tract subside. The following period, diestrus, is of variable duration in different species and is analogous to the luteal phase observed in primates and sheep, but lasts only 1–2 days in the unmated rat or mouse before a return to proestrus and progression through the next cycle.

The laboratory rat is a nonseasonal, spontaneously ovulating, polyestrous mammal. That is, the ovarian cycle continues throughout the year (as opposed to ovarian cycles restricted to one season, as in many sheep). Ovulation is not dependent on overt nervous stimulation (as opposed to the requirement of the mating stimulus in rabbits). Ovulation occurs every 4–5 days throughout the year (the dog ovulates once in the spring and once in the fall). The mean length of approximately 2000 cycles in the rat was described by Long and Evans[19] to be 5.4 days with a range of 3–38 days. If cycles of greater than 8 days are excluded, the mean was 4.8 days, which compare favorably with 4.4 days of Blandau, Boling, and Young[20] and 4.5 days of Astwood.[21] The length of the individual phases of the estrous cycle based on vaginal smear pattern has also been described.[19,21–24] Proestrus lasts for 12–14 h; estrus, 25–27 h; metestrus, 6–8 h; and diestrus, 55–57 h.

The stages of the estrous cycle can be conveniently determined by monitoring, under low magnification, the cell types which appear in the vaginal smear. Proestrus is characterized by a predominance of nucleated epithelial cells. These cells are distinctly round, visibly nucleated and appear in clusters at the height of proestrus. Occasionally, a few cornified squamous epithelial cells may appear as well. On the next day, estrus, the dominant cell is the cornified squamous epithelial cell. This cell is without an observable nucleus, contains a highly granular cytoplasm, and is irregularly shaped. These also appear in large groups. During metestrus (often called diestrus-1) and diestrus (sometimes called diestrus-2), the dominant cell type is the leukocyte, which appears along with a significant number of nucleated epithelial cells. The leukocytes are small with granular cytoplasm and, if examined under higher magnification, usually contain a vesiculated nucleus. Once again, the following day, proestrus, is characterized by the complete absence of leukocytes in the vaginal smear and the predominance of nucleated epithelial cells. The 5-day cycle may appear as an additional day of cornification (estrus) or an additional day of leukocyte infiltration (diestrus).

OVARIAN EVENTS DURING THE ESTROUS CYCLE

Oogenesis

The oocyte develops during fetal life through the prophase stage to the dictyate or "resting stage" of meiosis I by 4 days after birth[25] (Chapter 1 and 2). This stage is characterized by the presence of a distinct germinal vesicle or nucleus, the faint appearance of the diploid number of chromosomes ($n = 42$), and a distinct nucleolus. The oocyte remains arrested at this stage of meiosis until ovulation occurs (see below). The timing of the resumption of meiosis has been reported with respect to the onset of sexual receptivity,[26] the phases of "natural" or artificial illumination,[25] and the timing of the ovulation inducing release of LH.[27] The resumption of meiosis I consists of a reduction division and is controlled by the preovulatory surge of LH[28] (Chapter 1 and 2). That is, the chromosome number is reduced from the diploid content of 42 to the haploid number of 21. The first signal that meiosis I has been re-initiated is breakdown of the germinal vesicle, the disappearance of the nuclear membrane, and chromosome thickening. This occurs between 17:00 and 18:00 h on proestrus[25] or approximately 2–3 h after the beginning of the ovulation-inducing release of LH and 7–9 h before the expected time of ovulation.[27] During the first metaphase, the paired chromosomes are aligned along a metaphase plate. They are attached to their respective centromeres by spindle fibers. At anaphase I, the chromosomes begin separating, with half the chromosomal material ($n = 21$) lost by polar body extrusion during telophase I. Extrusion of the first polar body has been variously reported to be complete by 4–8 h after the beginning of sexual receptivity,[26,29,30] by 21:00 h proestrus,[25] or by 22:00 h on proestrus to 03:00 h estrus.[27]

Once the first polar body is extruded, ovulation occurs. This occurs by 8–10 h after the beginning of sexual receptivity,[26,30–32] 9–10 h after the resumption of meiosis I,[25] or by 03:00 to 05:00 h on estrus.[27] The newly ovulated egg found in the upper third of the oviduct is now haploid, with one polar body extruded and the remaining chromosomes aligned along a new metaphase plate. The tubal ovum, now in metaphase II, is available for fertilization by the haploid sperm. The second meiotic division proceeds if the ovum is fertilized (Chapter 1,2 and 4).

Folliculogenesis

The maturational process of the oocyte described above occurs in association with the growth of the ovarian follicle. The control of folliculogenesis is described in detail in Chapters 2 and 21, and is briefly discussed here. During late fetal and early postnatal development,[33] a single layer of epithelial cells becomes arranged around the oocyte in a uniform capsule. Such follicles, with a single layer of flattened epithelial cells surrounding the oocyte, are called primordial follicles. Follicular growth begins upon the activation of primordial follicles, an event associated with the transformation of the flattened epithelial cells surrounding the oocyte into cuboidal granulosa cells and is triggered, at least in the mouse, by the AKT/PI-3 kinase pathway (Chapter 21). The primordial follicles then become primary follicles (Figure 26.1). The granulosa cell layer proliferates, first forming a double, and finally a multilayered, cuboidal follicular epithelium. At this stage, the follicles are identified as secondary follicles. The growth of the follicle from the primary to the secondary stage is thought to occur independently of FSH and LH; rather, communication between the oocyte and the granulosa cells by members of the transforming growth factor-β (TGF-β) family is primarily responsible for this phase of follicular development (see Figure 21.1 in Chapter 21).

Under the influence of FSH, LH, and TGF-β family members, multilayered secondary follicles are transformed into vesicular follicles with the formation of multiple fluid-filled intracellular spaces. These spaces eventually enlarge and coalesce into a single larger cavity, the antrum. The structure is now termed a tertiary follicle, which upon further growth to the preovulatory stage is known as a Graafian follicle. The oocyte, together with its attached granulosa cells (which once occupied the center of the secondary follicle), now become eccentric and form a hillock, the cumulus oophorus. The granulosa cells surrounding the encapsulated oocyte form a ring known

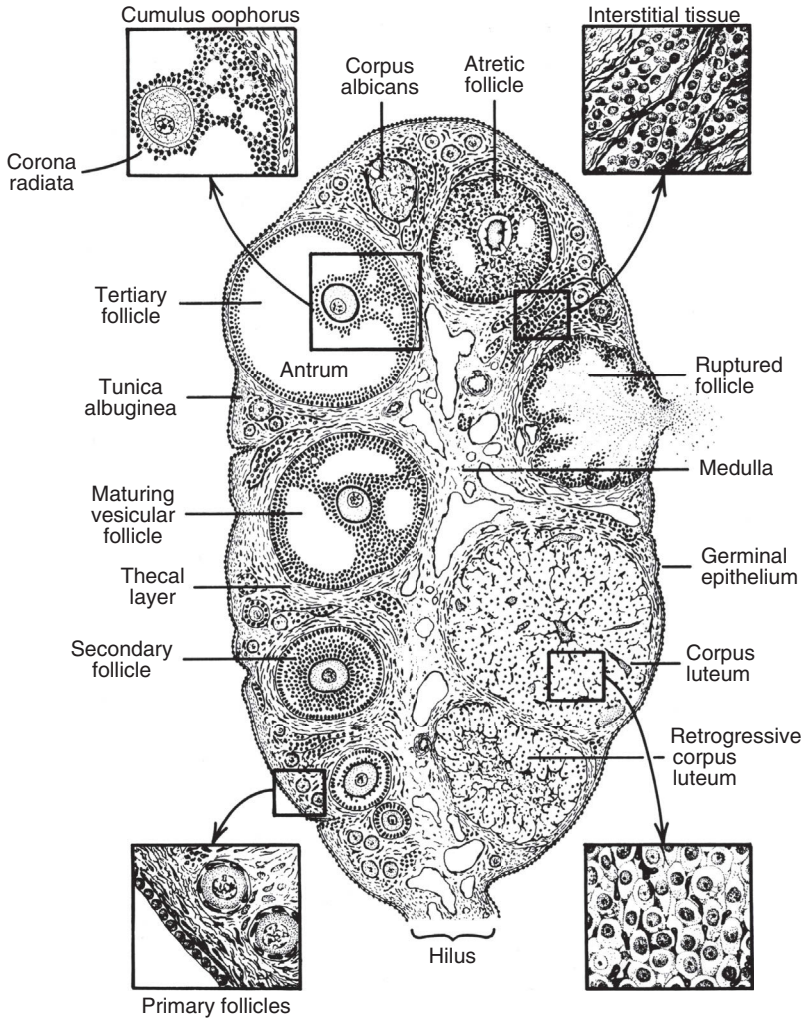

FIGURE 26.1 Composite stages of ovarian follicular development through ovulation, corpus luteum formation, and regression.

as the corona radiata. The fluid contents of the antrum, the liquor folliculi, increase in volume as ovulation approaches. The enlargement of the granulosa cell layer is accompanied by the development of an outer encapsulating sheath derived from the stroma. This constitutes the theca, which can be divided into a theca interna and theca externa. This division is first noted in the secondary follicle. The theca interna cells rapidly enlarge and assume a polygonal shape with vacuolated cytoplasm and vesicular nuclei. These cells are enmeshed in a reticular and fibrous network and contain a plexus of capillaries and lymphatics. This layer hypertrophies as proestrus approaches and is considered one of the major sites of steroid production during the cycle.[34,35] Indeed, owing to its glandular appearance, it has been referred to as the thecal gland.[36] The outermost follicular layer, the theca externa, contains contractile tissue, which is thought to play a role in ovulation.[37,38]

Very few of the follicles present on the ovary at the time of birth are destined to ovulate. Indeed, in the rat, Arai[39] calculated a decline in the total number of follicles from 35,000 at the time of birth to 11,000 at 20 days later. Thereafter, the rate of decline in the number of follicles decreases. This attrition of follicles, known as atresia, occurs throughout the reproductive lifespan. However, in contrast to primates, the supply of primordial follicles in rats and mice is not exhausted in aged animals. Rather, reproductive senescence in rats and mice is due to age-related alterations in the hypothalamic–pituitary axis (see Chapter 37).

Though some atresia of primordial and primary follicles occurs, atresia of secondary and vesicular follicles is most conspicuous during each cycle. The appearance of the atretic follicles differ depending upon the stage of the follicle at the time degeneration begins and the extent of the retrogressive changes at that time.[33] The questions of what determines which follicles ovulate and whether atresia begins in the oocyte or follicular epithelium have remained largely unanswered.[40] Also, the mechanism for maintenance of the viable follicle pool is not clear. Some

studies have suggested that adult mice have the capacity to generate new ova from adult germline stem cells originating from bone marrow and that transformation of these cells and incorporation into ovarian follicles can continuously replenish the ovarian follicle pool.[41] More recent studies have not provided support for adult neooogenesis as a replenishment mechanism,[42] and mathematical models for the kinetics of follicular development and atresia have reaffirmed that the classical model of a non-replenishable follicle pool adequately accounts for the observed follicle numbers throughout postnatal life.[42]

The first recognizable atretic changes are found in the epithelial cells lining the antral boundary of vesicular follicles and in the cells just external to the corona radiata of secondary follicles. Under conventional staining, the first sign of the process is a shrinking of the nucleus and condensation of the chromatin mass of the granulosa cells. This is known as pyknosis. In addition, the granulosa cell nucleus may rupture and the chromatin disintegrates into formless granules, which are extruded from the cell. This is known as karyorrhexis. In vesicular follicles, these nuclear fragments and pyknotic cells tend to slough off and float into the liquor folliculi and are readily noticeable. Such sloughing results in shrinkage of the cumulus oophorus and smoothing of its antral surfaces, a process that allows the ovum to eventually enter the liquor folliculi.[40] In the rat, the zona pellucida undergoes degeneration, followed rapidly by the oocyte. The granulosa cells also degenerate completely. However, the theca interna persists as interstitial masses, which eventually break up into small groups of cells scattered within the medulla of the ovary.

The growth and ultimate selection of follicles in the cycling rat ovary for preovulatory growth and maturation begin upon the transformation of the primordial follicle to a primary follicle, through a growth process that is independent of gonadotropin stimulation. Later stages of follicular growth are dependent upon gonadotropin support. Using a classification system for developing mouse follicles proposed by Pedersen and Peters,[43] Richards and Midgley[44] developed a model for follicular selection. For descriptive purposes, follicles are classified as (1) small preantral (primary) follicles just entering the pool of committed, growing follicles, which is distinguished from the large pool of quiescent, nongrowing primordial follicles; (2) large preantral (secondary) follicles; and (3) large antral (tertiary) preovulatory follicles. Some follicles begin to grow from the primordial stage each day of the cycle. This growth continues until either atresia or ovulation occurs. Those follicles that do ovulate on the morning of estrus actually began to grow 19 days earlier as a member of a larger group of growing primary follicles. These follicles continue to grow to large preantral stages. At this stage, the follicles either become atretic or, during the proestrus preceding the cycle in which they will ultimately rupture, are "committed" to the ovulatory pool. This model proposes that the follicles must arrive at the "pre-committed" stage in synchrony with the anticipated surge of FSH and LH from the pituitary gland. Those asynchronous follicles degenerate if gonadotrophin stimulation does not occur within a critical time.

By mapping the size distribution of large antral follicles (>390 μm diameter) on each day of the rat estrous cycle, one can observe a distinct variation on each day.[45,46] On late proestrus, preovulatory follicles are 500–750 μm in diameter just prior to rupture. On estrus, after ovulation and during metestrus, only follicles between 390 and 500 μm in diameter are present. During diestrus, follicles greater than 500 μm in diameter first appear. The absence of 390- to 500-μm diameter follicles on proestrus suggests that follicles of this size on late estrus and early metestrus are the ones that were selected to grow through diestrus and early proestrus and ultimately destined to ovulate.[45] Moreover, the absence of 390–500 μm diameter follicles on proestrus followed by their dramatic appearance on estrus further suggests that an event on proestrus selects these follicles to begin growth for the next estrous cycle. The hormonal control of this selection process will be described in another section.

Ovulation

The follicular events immediately preceding rupture and expulsion of the egg are easily visualized and were first described in the rabbit.[37,38] It is believed that the ovulatory event and its controls are generalizable to most mammals and are described in detail in Chapter 22. Rather than describe the changes from proestrus through ovulation, Blandau[29] treated immature rats with gonadotrophic preparations and observed the process of ovulation in over 300 follicles. The ovulatory follicles bulge from the ovarian surface and appear turgid and highly vascular. Within minutes after stimulation by gonadotrophic hormone, the macula pellucida or stigma forms at the apex of the preovulatory follicle. This is the first sign that the ovulatory process has begun. Beyond the periphery of the stigma, a dilated ring of blood vessels forms. As follicular rupture approaches, the superficial germinal epithelial cells covering the stigma break into small clumps. The underlying stroma thins and a delicate vesicle that may be a bleb of viscous follicular fluid forms. The actual escape of the ovum following breakdown of the stigma takes approximately 12 min. First, the granulosa cells begin to ooze through the plugged orifice, followed very quickly by the remaining egg mass. Once the egg is extruded, a great burst of follicular fluid follows. In the majority of cases, the cumulus and egg do not lie next to the rupturing stigma. Under these circumstances, the follicular fluid bursts through

as if under pressure. The cumulus and oocyte would be extruded subsequently in a stream. The oocyte rapidly finds its way to the ciliated fimbriated end of the oviduct. Within an hour after ovulation, eggs surrounded by cumulus masses can be recognized in the upper third of the oviduct. All ovulations are complete in 1.5 h.

Formation and Activation of the Corpus Luteum

During the estrous cycle of the rat, three or more generations of corpora lutea may be present on the ovary from the immediately preceding ovulatory cycles.[19] It appears that the cells of the corpus luteum have a dual origin. That is, based on anatomical and histochemical observations,[47] the corpus luteum arises from both the granulosa and thecal cells of the preovulatory follicle. Each set of corpora persist morphologically for 12–14 days. In the rat, each cyclic set of corpora lutea can be distinguished on the basis of size,[19,48] vascularity[49] and stain characteristics.[34,50,51] By diestrus, the newly formed corpora have attained their maximal size, which is maintained through metestrus of the following cycle. By diestrus of that second cycle, the corpora lutea abruptly regress. This regression coincides with closure of blood vessels, the appearance of areas of degeneration, leukocytic infiltration,[49] increase content of 20α-hydroxysteroid dehydrogenase,[50] and increase cholesterol content.[51] Such corpora lutea, if present in an unmated animal, are referred to as "nonfunctional" corpora lutea. That is, the corpora lutea do not secrete sufficient progesterone to support a decidual reaction (Chapter 23 and 24) induced by mechanical or chemical trauma of the uterine endometrium. Actually, the corpora are not completely nonfunctional because progesterone is secreted by the newly formed corpora lutea from metestrus through diestrus.[52] In the absence of luteotrophic support, however, they do secrete copious amounts of another progestin that is a metabolite of progesterone, 20α-hydroxyprogesterone. This steroid will not support a decidual reaction nor hold the hypothalamo–pituitary machinery controlling ovulation in check.

As the secretion of luteal progesterone declines through diestrus, a new ovulation takes place shortly thereafter. Thus, the "luteal phase" of rats (as well as hamsters and mice) is atypical. Other mammals have relatively long luteal phases (11–14 days) with extensive release of high levels of progesterone, while the corpora lutea of unmated rats secrete lower levels of progesterone for only 1–2 days. This serves as a basis for the short cycles in rodents. If, on the other hand, the animals are allowed to mate and become pregnant, the animals mate with infertile males, or the uterine cervix is stimulated artificially, the pituitary gland secretes sufficient quantities of a "luteotrophin" to "rescue" the corpus luteum and allow it to persist for a number of days, approximating a typical mammalian luteal phase.[52] If the mating is fertile, this luteal phase persists for the entire period of pregnancy, 20–22 days. If the mating is infertile or artificial, the corpus luteum persists for 12–14 days. This period is known as pseudopregnancy. The luteotrophin released by the mating stimulus is pituitary prolactin (PRL). The physiological basis for this extended luteal phase of the rat brought about by the mating stimulus will be described in a later section of this chapter.

In addition to support for luteal function provided by the pituitary gland, there is abundant literature to suggest that the placenta secretes a luteotrophin, which maintains the corpus luteum of the latter part of pregnancy. Moreover, compelling evidence leads us to believe that the decidual tissue may contain activity, independent of the well-established pituitary and varying placental activities,[53–57] that can serve as a luteotrophin.[58] Finally, although corpus luteum regression or luteolysis could be merely the consequence of withdrawal of luteotrophic support, there is ample evidence that the uterus may secrete "luteolysins," which directly or indirectly hasten luteal death[59] (Chapter 23).

Secretion of Ovarian Steroids during the Estrous Cycle

The preovulatory period of the estrous cycle is characterized by a growth of ovarian follicles and a concomitant enhanced secretion of estrogens, principally estradiol 17β. The secretion rate of estradiol into ovarian venous plasma is low on estrus, begins to rise significantly by late metestrus through the morning of diestrus and reaches peak concentrations by 12:00 h on the afternoon of proestrus.[59,60] The mean peripheral plasma concentration of estradiol (Figure 26.2) reflects the pattern found in ovarian vein blood.[52,61–64] That is, in the 4-day cycling rat, peripheral plasma levels of estradiol are basal through estrus. In late metestrus through early diestrus, plasma levels begin to rise. This increase continues through diestrus and early proestrus to reach peak values and plateau by mid-proestrus. During the early evening, shortly before the dark interval in the colony, estradiol levels fall rapidly, reaching basal values by the early morning hours of estrus. The cell types responsible for the secretion of estradiol throughout the cycle have been described in experiments by Falck.[65] Cotransplants of estradiol-sensitive tissue, the vagina, and various ovarian cellular compartments were made to the anterior chamber of the eye. Only transplantation of both theca interna and granulosa cells caused typical "estrogenic" changes in the cotransplanted vaginal tissue.

In rats with 4-day estrous cycles, peripheral plasma levels of testosterone and androstenedione are similar in pattern to estradiol.[66,67] The similar pattern of secretion of the androgens and estrogens reflect the fact that the synthesis, secretion, and controls of the two classes

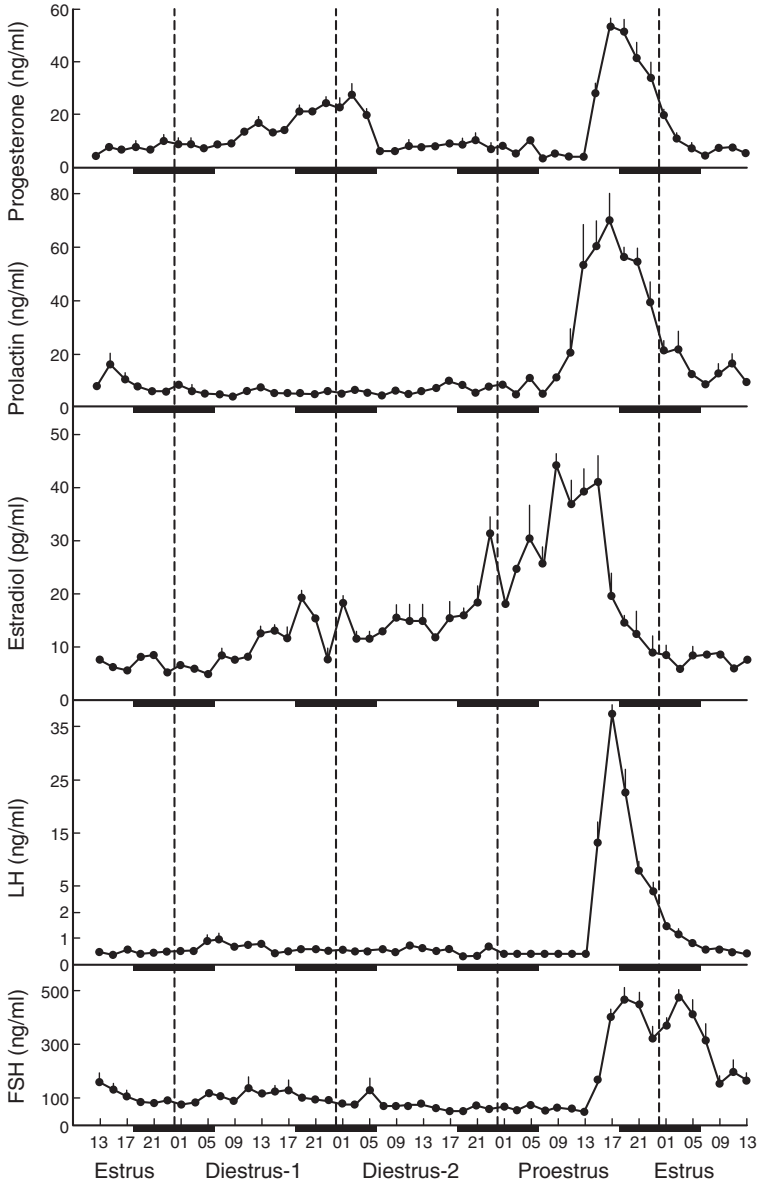

FIGURE 26.2 Concentrations of progesterone, prolactin, estradiol, LH, and FSH in peripheral plasma obtained at 2-h intervals throughout each day of the 4-day estrous cycle of the rat. Each point represents the mean hormone concentration (±SE) of five to six rats. Black bars represent the dark interval in the animal room (06:00–18:00) and the numbers below them represent the time-of-day (10–2) in terms of the 24-h clock. *From Ref. 52.*

of hormones are interrelated by the combined actions of FSH on granulosa cells and LH on theca interna cells, the so-called two-cell/two-gonadotropin model for estradiol biosynthesis (see Chapter 28).

In adult rats, the dominant progestin secreted into ovarian vein blood during the estrous cycle is 20α-hydroxypregn-4-en-3-one,[68–72] also known as 20α-hydroxyprogesterone (20α-OH-P). This progestin is a metabolite of progesterone, and its synthesis is catalyzed by the enzyme 20α-hydroxysteroid dehydrogenase.[73] 20α-hydroxyprogesterone is relatively inactive in classic progesterone bioassays. That is, it will not support the development of deciduomata in pseudopregnant rats.[74,75]

There are two peaks of both 20α-hydroxyprogesterone and progesterone secretion into ovarian vein blood during the cycle. The first peak occurs during the afternoon of metestrus and both steroids probably arise from the newly formed corpora lutea.[68,69] The second peak occurs during the late afternoon of proestrus.[68,69] The 20α-hydroxyprogesterone peak at this time probably comes from the corpora lutea, while the progesterone arises from the granulosa cells of the preovulatory follicle.[76] The secretion of these progestins into ovarian vein blood is mostly mirrored in their pattern of secretion in peripheral plasma.[52,62,64,77–79] In 4-day cycling rats, the secretion of 20α-hydroxyprogesterone into peripheral plasma appears to be quite variable. The lowest levels are observed during the morning of diestrus. However, peripheral levels rise during the evening of diestrus and the morning of proestrus to reach peak levels by 20:00 h on proestrus. The secretion of progesterone is more

regular (Figure 26.2). A large increase of follicular origin takes place during the afternoon and evening of proestrus. This increase occurs nearly simultaneously with the major ovulation-inducing increase of LH secretion. It reaches peak levels around the time of the LH peak in the early evening and returns to basal levels by the morning of estrus. A second major peak of luteal origin begins about midday on metestrus, is protracted through the early morning of diestrus, and falls to basal levels shortly after the onset of illumination on diestrus. This rise and fall represents the unsuccessful attempt of the newly formed corpus luteum to survive. The control of these patterns of progestin secretion during the estrous cycle as well as their physiological significance will be discussed in subsequent sections.

PATTERNS OF PITUITARY HORMONE SECRETION AND mRNA LEVELS DURING THE ESTROUS CYCLE

The predominant function of FSH is to stimulate estradiol secretion and growth of ovarian follicles, while LH induces ovulation and formation of corpora lutea and stimulates ovarian steroid hormone production. Both FSH and LH are each composed of two peptide subunits in virtually all mammals.[80] One subunit, designated α, is common to FSH, LH, and thyroid-stimulating hormone (TSH). The other subunit, β, is structurally specific for each gonadotropin. This specificity is responsible for the characteristic biologic activity of the intact (dimeric) molecules. Each gonadotropin has characteristic carbohydrate moieties, and these carbohydrate components may play a role in separate biologic activities.[80] The other hormone of the anterior pituitary gland of significance to the ovarian cycle of the rat is PRL, a single-chain peptide secreted from lactotropes (see also Chapter 12). Besides its well-known "pro-lactational" role shared by all mammals, pituitary PRL participates in maintenance of corpora lutea in rats, mice, and hamsters.

Control of the ovarian cycle of the rat by anterior pituitary hormones has been elucidated by various tools used to measure spontaneous release of the hormones during the estrous cycle. Prior to the advent of sensitive and specific radioimmunoassays, LH was measured by ovarian ascorbic acid depletion bioassay[81] and FSH by direct augmentation of the ovarian weight response to human chorionic gonadotropin (hCG)[82] or indirectly by uterine weight enhancement.[83] PRL activity was quantitated by the growth of the pigeon crop sac.[84] These early biological assays all had the distinct advantage of outstanding hormonal and tissue specificity, yet they shared the inherent disadvantage of lack of sensitivity such that cyclic patterns of pituitary hormone secretion into blood had to be inferred on the basis of changing content in the pituitary gland. Blood hormone levels were largely undetectable in samples obtained from individual animals. The concentration of hormone in the gland is the result of a balance between synthesis and release. Because these processes can vary independently of each other, declining levels of hormone in the gland may reflect decreased synthesis and release or release overtaking synthesis. Conversely, elevated levels may be the result of decreased release in the face of unchanging synthesis or acceleration of synthesis with or without compensatory increased release. For these reasons, the only definitive endpoint for hormone release is the concentration in blood. Sensitive radioimunoassays became available for rat FSH and LH[85] as well as rat PRL,[86] which permitted detection of basal serum levels of these hormones.

The development and availability of materials for these assays through the National Institutes of Health has represented a major milestone on our road to acquiring knowledge of the control of the ovarian cycle. The following descriptions of the pattern of pituitary hormone secretion are syntheses of the work of several laboratories[52,62,64,76,77] using these materials. All rats were housed under 14:10 or 12:12 light–dark cycles, with noon being the midpoint of the light period.[87,88] Under these conditions, the majority of the cycles are 4 days in length.[87] This description will be confined to animals with 4-day ovulatory cycles. The actual secretory patterns of LH, FSH, and PRL are shown in Figure 26.2 along with the circulating patterns of estradiol and progesterone. The interested reader is referred to the classic work of Nequin, Alvarez, and Schwartz[64] for a detailed description of differences in 4- and 5-day cycles.

Luteinizing Hormone

The serum levels of LH are at the lowest from early on the morning of estrus, shortly after ovulation, through metestrus, diestrus, and midday on proestrus (Figure 26.2). Although most studies report basal, unchanging levels of LH over this time,[52,62,64,76,77] one study reports slight but significant diurnal variation throughout the cycle.[89] This circadian pattern from estrus through diestrus consisted of a small elevation of LH each day at the midpoint of the light period and the lowest levels by midnight of each day. On the afternoon of proestrus, about 14:00 to 15:00 h, the circulating levels of LH begin to increase rapidly and ultimately reach peak levels by 17:00 to 19:00 h on that same evening (Figure 26.2). This rapid "surge" of LH induces follicular rupture and ovulation. Thereafter, these blood levels begin to decline and reach basal levels by early on the morning of estrus. When blood samples are obtained at 6- to 10-min-intervals during each day of the estrous cycle, a pulsatile or ultradian

pattern of LH secretion is observed.[90–93] Specifically, the pulses occur at periodicities of around 55–60 min and amplitudes, expressed in terms of the original NIDDK-LH-RP-1 standard, of 15–40 ng/ml whole blood from metestrus through the morning of proestrus (Figure 26.3).

During the afternoon of proestrus, the ovulation-inducing surge of LH has been characterized as composed of either declining pulse frequency with an amplitude of 600 ng/ml[92] or a single constant almost unvarying linear rise of LH secretion with an amplitude of nearly 200 times baseline in some animals (Figure 26.4).[89,90,94] This single surge declines through the early morning of estrus. By the late morning and throughout the day of estrus, pulses of LH are infrequent[91] or absent.[90] The circhoral pulses return by the morning of metestrus and continue through proestrus as before. The control of this unique pattern of LH secretion will be described in later sections.

Follicle Stimulating Hormone

The pattern of FSH secretion throughout the majority of the estrous cycle is similar to that of LH.[52,62,85,89] Specifically, basal levels of FSH are secreted from late estrus through metestrus, diestrus, and midday on proestrus (Figure 26.2). From mid-afternoon onward, proestrus FSH secretion increases simultaneous with that of LH. That is, by 14:00 to 15:00 h, the circulating levels of FSH begin to increase rapidly and ultimately reach peak levels by 17:00 to 19:00 h that same evening. Although both FSH and LH levels begin to decline to baseline after this time, during the early morning of estrus a secondary rise of FSH begins and peaks shortly thereafter. Circulating levels of FSH then begin to decline and reach baseline by the early evening of estrus. This early initial phase of FSH secretion shares some controls with the contemporaneous LH "surge" while the estrous phase of FSH secretion is under different controls, as described later.

Circadian and ultradian pulses of FSH similar to LH have not been described during the estrous cycle.[52,62,85,89] That is not to indicate that they do not exist, but merely that the available FSH radioimmunoassays are not sensitive enough to distinguish fluctuations in low levels of FSH secretion during the estrous cycle. On the other hand, pulsatile LH and FSH secretion does occur in the gonadectomized animal, but the interpulse interval of LH is significantly shorter than that of FSH.[95] The similarities and differences in control of FSH and LH secretion during the estrous cycle will be described in a later section.

Prolactin

The pattern of PRL secretion throughout the estrous cycle is also similar to that of LH[52,62,85,89] (see also Chapter 12). That is, basal levels of PRL are secreted from the evening of estrus through the early morning of proestrus (Figure 26.2). During the afternoon of proestrus, a "surge" of PRL, similar in timing to that of LH, is observed.[52,89] Although most laboratories have

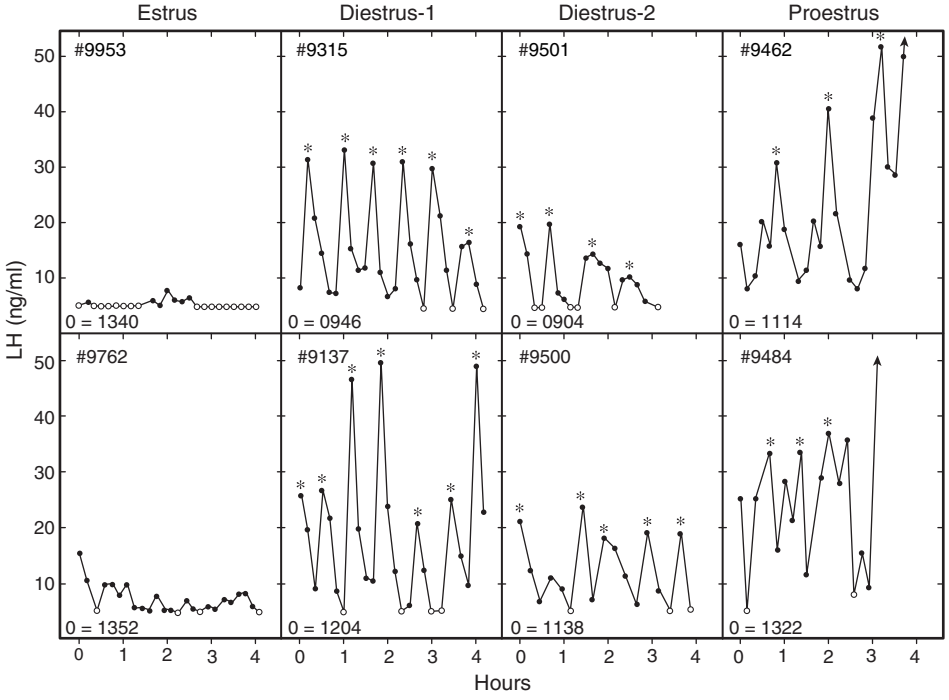

FIGURE 26.3 Concentrations of LH in peripheral plasma obtained at 10-min intervals for 4 h from each of two representative animals during each day of the 4-day estrous cycle of the rat. The animal numbers are presented in the upper left corner of each block and the time of sampling initiation is given as zero-time in the lower left. Statistically defined pulses are indicated with asterisks and the open circles represent values below the detection limits of the assay. *From Ref. 89.*

described a single surge of PRL on proestrus,[52,89,96] other laboratories have reported a secondary increase on estrus[62] or continuously elevated PRL levels on proestrus, estrus, and metestrus.[97] Because these latter patterns may have been due to method and frequency of blood collection, it is generally accepted that the afternoon of proestrus is the only time that a major "surge" of PRL secretion occurs.

Pituitary Gonadotropin Subunit and Prolactin mRNAs

Gene expression for the α subunit,[98] the β subunit of LH,[98] the FSH-β subunit[98] and PRL[99,100] have been described in the anterior pituitary gland throughout the estrous cycle of the rat (Figure 26.5). Alpha mRNA is heightened by 08:00 h diestrus-2 reaching maximal values by 20:00 h and declining abruptly by 24:00 h.[101] The content of α-mRNA remains low during proestrus, estrus, and diestrus-1. In contrast, LH-β mRNA is low during estrus and diestrus-1, increases at 08:00 h during diestrus-2, and then falls rapidly and remains low throughout the morning of proestrus.[101] By 14:00 h on proestrus, a second increase begins, which peaks at 17:00 h and then declines rapidly. This peak precedes the preovulatory surge of LH secretion. By 22:00 h proestrus, the levels are equivalent to estrus and diestrus-1. FSH-β mRNA increases from 20:00 h on proestrus to a peak value by 02:00 h estrus, returns to basal levels by 08:00 h, and remains low through 20:00 h estrus.[98] This peak corresponds to the surge of FSH secretion on proestrus. Another smaller increase begins by 23:00 h estrus, which remains elevated throughout the afternoon of diestrus-1, although FSH secretion remains basal over that time. The pattern of PRL mRNA during the estrous cycle is distinctly different than that of the gonadotrophin subunit messages.[99,100]

There is a striking increase of PRL mRNA content in the anterior pituitary gland at specific intervals during each day of the estrous cycle.[99,100] During proestrus and estrus, PRL mRNA is higher at 23:00 h than during any other time on each day. In contrast, PRL mRNA levels are highest at 08:00 h on diestrus-1. During diestrus-2, PRL mRNA values peak between 17:00 and 20:00 h. The only clear correlation between pituitary or plasma PRL and PRL mRNA is found on the afternoon of proestrus, when a morning rise in PRL mRNA precedes a morning increase in pituitary PRL content.[99]

NEURAL EVENTS DURING THE ESTROUS CYCLE

Circadian Control Mechanisms

As described above, frequent blood sampling reveals that LH secretion during the estrous cycle is largely pulsatile, with frequencies of less than one pulse per hour.[90–93] The pulses originate as the result of pulsatile release of GnRH presumably into the portal vasculature.[102] This is not the only patterned rhythmic control of the rat's ovarian cycle. Indeed, Everett and Sawyer[103] showed that the LH-release mechanism is under a 24-h photoperiodic control and thus can fall under the category of a circadian rhythm. These elegant classic studies (Figure 26.6) showed that administration of pentobarbital between 14:00 and 15:45 h on the afternoon of proestrus to animals under daily illumination from 05:00 to 19:00 h resulted in blockade of ovulation on estrus for 1 day (Figure 26.6(C)). Treatment with the same drug again the next day, estrus, blocked ovulation a further 24 h (Figure 26.6(E)). Treatment at times other than 14:00 to 15:45 h (Figure 26.6(B,D)) was much less effective in blocking ovulation on each day. These data led to the concept of a daily "critical period"—the interval during which a daily neural event leads to release of an LH surge and subsequent ovulation. The timing of the critical period can be shifted by altering the "zeitgeber" or time cue. That is, shifting of the phase but not the duration of the lighting period will shift the critical period by a corresponding time.[88] Thus, environmental light–dark cycles act to regulate ovarian cycles via entrainment of their circadian system. In fact, with prolonged exposure to the lack of a daily photoperiod, such as constant light, the rat will gradually become acyclic as manifested by constant vaginal cornification.[104]

A number of studies have implicated the paired suprachiasmatic nuclei (SCN) of the hypothalamus as the generators of the signal that is entrained to the light–dark rhythm. Neurons within the SCN function as a master circadian clock, consisting of a unified network of cells in which interlocked transcription-translation feedback loops generate 24-h rhythms. Retinohypothalamic pathways communicate photic signals that entrain these rhythms[105–107] and SCN efferents convey output signals that appropriately time the initiation of GnRH (and therefore LH) surges to occur during the critical period on the afternoon of proestrus. Lesioning or isolation of the SCN terminates the estrous cycle in rats,[108,109] presumably by preventing transduction of the signals for initiation of the surge. Similarly, mutation of the circadian locomotor output cycles kaput (*Clock*) gene, a core component of the molecular circadian pacemaker, renders female mice incapable of releasing LH surges at the expected time on the afternoon of proestrus (Figure 26.7).[110] Thus, one of the signals triggering release of the

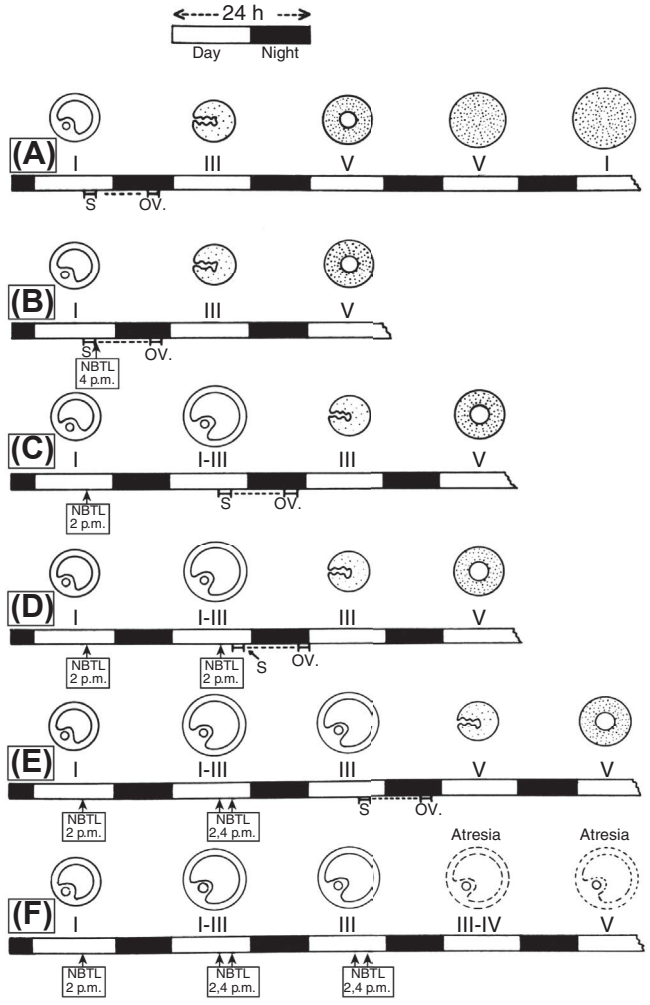

FIGURE 26.6 The classic experiments of Everett and Sawyer[103] illustrating the experimental basis for the 24-h periodicity in the LH-release mechanism during the estrous cycle of the rat. The light and dark bars represent a 24-h continuum; s defines the critical period and ov the time of ovulation. The Roman numerals represent vaginal smear stages: in each group (A–F) I represents the afternoon of proestrus. Group A represents the timing of the events of the normal cycle from ovulation through corpus luteum formation. Administration of the central anesthetic Nembutal (NBTL, sodium pentobarbital) at 4 p.m. on proestrus does not disturb the timing of the normal cyclic events (Group B). However, a single injection of NBTL at 2 p.m. on proestrus postpones the release of a surge quantity of LH and ovulation 24 h (Group C). Repetition of the treatment at the same time the following day, estrus, was insufficient to block LH release and ovulation and ovulation an additional 24 h (Group D). On the other hand, administration of NBTL at 2 p.m. on proestrus and at both 2 and 4 p.m. on estrus blocks the surge of LH and ovulation 48 h (Group E). The follicles cannot remain competent to respond to a delayed LH surge beyond 72 h. Consequently, atresia results from such a delay (Group F). These experiments have indicated that a hypothalamic signal occurs daily between 2 and 4 p.m., the critical period, which leads to LH release. However, the ovarian steroid milieu is appropriate for such release only on proestrus.[103]

LH surge and subsequent ovulation is provided by the circadian clock so that there is only a limited "window" during each day when the LH surge could potentially be initiated. This daily potential for LH release is determined by transduction of the lighting periodicity, the

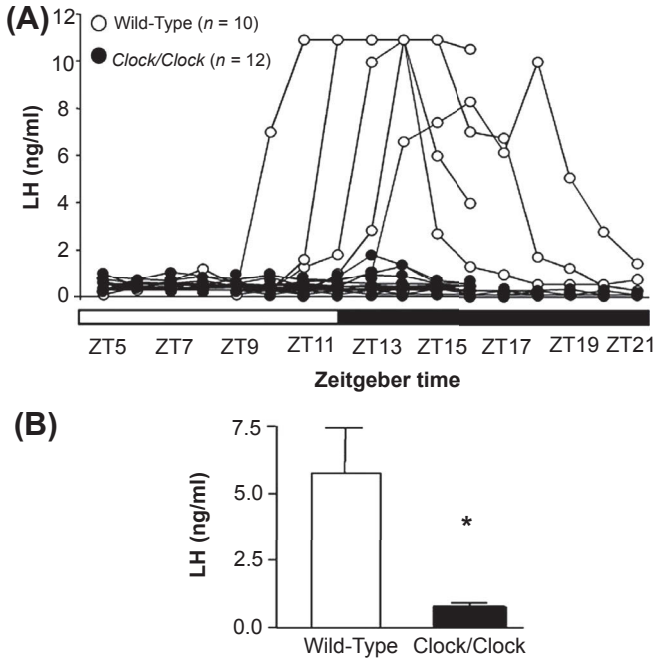

FIGURE 26.7 ***Clock/Clock*** **mutants fail to have a coordinated LH surge on the day of proestrus.** (A) Individual LH traces from all wild-type (open circles) and *Clock/Clock* (closed circles) females sampled from either 0500–1600 or 0900–2100. zeitgeiber, by the SCN. It is likely that the specification of the afternoon hours for release of LH surges serves the adaptive purpose of bringing into temporal register behavioral heat, which commences on the evening of proestrous, with ovulation in the early hours of estus. The interaction of ovarian hormones with circadian clock signals eventuating in LH, FSH, and PRL release will be described in the next sections.

Control by GnRH

GnRH is synthesized by neurosecretory neurons in the basal forebrain, transported along axons to neurovascular junctions in the ME, and released in a pulsatile fashion into the hypothalamic–hypophysial portal vasculature (Figure 26.8). The cellular substrates of pulsatile GnRH release have been referred to as the hypothalamic GnRH pulse generator.[111] Details of the molecular mechanisms that govern GnRH gene expression, as well as the electrophysiological and cellular events that may govern GnRH pulsatility, are discussed in depth in Chapters 11 and 27.

The pulsatile mode of GnRH release has been clearly shown to be required for the continued stimulation of "basal" LH and FSH secretions,[112] although in rats FSH secretion appears to have a GnRH-independent, and perhaps constitutive, component.[113] Basal secretions of the

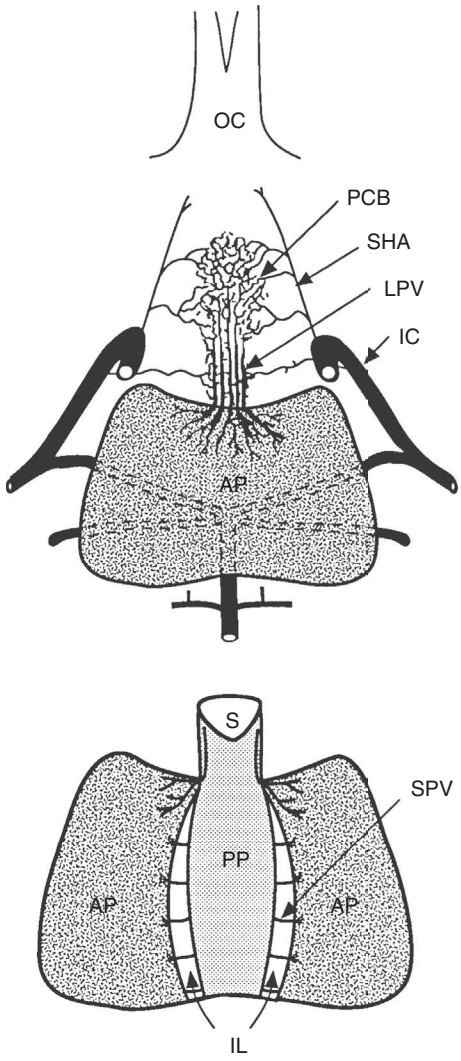

FIGURE 26.8 **Diagrammatic representation of the blood supply to the anterior pituitary (AP) gland through the long and short portal vessels.** Top is a ventral view and bottom is a dorsal view. The superior hypophysial arteries (SHA) arise from the internal carotid artery (IC). The SHA, in turn, supplies blood to the primary capillary bed (PCB) in the median eminence (ME). The long portal vessels (LPV) arise from the PCB and pass down the stalk (S) to the AP. The short portal vessels (SPV) arise from capillaries in the posterior pituitary (PP), pass through the intermediate lobe (IL) to the AP. Thus neurohormones can arrive at sites of action in the AP from axons which terminate in the ME or the PP. OC, optic chiasm.

gonadotropins continue throughout estrus, metestrus, diestrus, and the morning of proestrus in the female rat. On the afternoon of proestrus, this pulsatile release mode is interrupted by the neurosecretion of a surge of GnRH, which triggers the preovulatory gonadotropin surge. The regulation of these two modes of GnRH release—basal pulsatility and surge secretion—are essential to the normal progression by the female rat through the stages of the estrous cycle. An absence or excess of GnRH pulsatility disrupts follicular maturation and steroidogenesis, and failure to release a preovulatory gonadotropin surge

results in anovulation. Much of the subsequent discussion of GnRH release will focus on the mechanisms by which ovarian hormones exert homeostatic negative feedback regulation of basal GnRH pulsatility, and the positive feedback mechanisms that permit release of preovulatory GnRH surges.

GnRH has been localized in the rodent brain using a number of imaginative approaches. Wheaton and coworkers[114] measured GnRH by radioimmunoassay in frozen sections of rat brain and found the majority of the immunoreactivity in the infundibular stem and ME, the site at which axon terminals and the primary capillary bed of the hypophysial portal system meet (Figure 26.9). In addition, smaller but significant quantities of GnRH were measured in the anterior hypothalamus, the SCN, and rostrally in the preoptic area. Similar observations were made by Palkovits and collaborators[115–117] and Selmanoff and collaborators[118] using a technique of punching tissue from specific brain regions. In addition, GnRH is found in circumventricular organs particularly the organum vasculosum of the lamina terminalis (OVLT), the vascular structure at the tip of the third ventricle within the preoptic area.

Using various immunocytochemical approaches, GnRH neurons have been shown to be small, typically fusiform, and distributed rostro-caudally from the diagonal band of Broca (DBB) to the retrochiasmatic region and extend up to 2 mm on either side of the midline in the preoptic region and medial forebrain bundle[119–126] (see Chapter 11). Mapping of GnRH mRNA-expressing soma by in situ hybridization (ISH) has revealed the same GnRH neuronal distribution pattern.[127–130] GnRH-producing cells are concentrated in the DBB, stria terminalis, medial nucleus of the septum, medial preoptic area (mPOA), and the anterior hypothalamic area (AHA). GnRH-containing perikarya have also been found in the retrochiasmatic area of the medial basal hypothalamus.[125,126,131] GnRH neurons that project into the ME are concentrated basally in the midline regions from the mPOA rostrally and through the retrochiasmatic area caudally. These fibers terminate on capillaries of the primary plexus of the hypothalamo-hypophysial portal vasculature.[132]

There is reasonably good correlation between the location of GnRH cell bodies and axons and experimental manipulations at these sites, which affect the ovulatory surge of LH. Using an experimental model in which the proestrous preovulatory surge of LH has been blocked, Everett[133] mapped a funnel-shaped septal-preoptico-tuberal pathway that responds to electrochemical stimulation by releasing an ovulatory amount of LH. These fibers are fan-shaped in the septal complex, narrow through the mPOA-AHA, and converge as a compact band in the ME (Figure 26.10). Electrochemical stimulation along this band excites LH release.[134] However, despite the presence of GnRH fibers, stimulation of the lateral preoptic area, the median forebrain bundle, and dorsal or ventral medial hypothalamus fails to excite LH release.[133,134] These studies demonstrate that a core band of GnRH fibers originating from septal and preoptic GnRH neurons mediate neurosecretion of the decapeptide at neurovascular junctions in the ME, while the additional contribution of fibers coursing more laterally remain unconfirmed. Early lesion studies suggested that the mPOA may function as an integrative center for the generation of LH surges[135,136]—a contention later refuted by findings that dysregulated PRL secretion in lesioned animals may have been responsible for the absence of cyclicity in these animals.[136,137] However, the lesion of discrete midline sites through this area such as the OVLT,[138] the medial preoptic nucleus (mPN)[139] or more specifically the anteroventral periventricular nucleus (AVPv), or SCN[135] produced anovulation and anestrus or constant estrus.

As described in a subsequent section, it is now well accepted that the release of GnRH surges and ovulatory cyclicity depend upon the integrity of both the SCN and the AVPv. SCN delivers the daily neuronal signal for release of the surge, whereas AVPv receives these neural signals and integrates them with the positive feedback actions of ovarian hormones that permit the initiation of the GnRH surge. The circuit is then believed to be completed by projections from the AVPv to GnRH neurons, which prompt release of a preovulatory GnRH surge into the hypophysial portal vasculature.[140,141]

Neurosecretion of the GnRH Surge

The integration of circadian and endocrine signals on the afternoon of proestrus triggers a cascade of events within the hypothalamus, eventuating in a 2–4 h increase in GnRH release from neurovascular terminals within the ME. This, in turn, is the stimulus for the ovulation-inducing surge of LH. Just as the secretion of the LH surge on proestrus is reflected in altered pituitary levels of LH,[104] so too is a surge of GnRH release into portal blood on proestrus reflected by changing levels of the decapeptide in the hypothalamus. Using indirect estimates of bioactive GnRH activity in hypothalamic extract by assaying their LH-releasing capabilities from pituitaries in vitro, there appeared to be enhanced LH-releasing activity in hypothalami around the time of the LH surge on proestrus and a rapid decline in hypothalamic content associated with the surge.[142–144] GnRH concentrations have also been measured in the brain by immunohistochemistry or radioimmunoassay. In confirmation of the earlier studies, it seems that GnRH activity of the medial basal hypothalamus (MBH) declines as the proestrous surge of LH begins[145,146] or as peak peripheral levels of LH are approached.[147–149] There

The bars of each histogram represent the mean (+SE) GnRH content in sections projecting through parasagittal (panels A and B) or frontal (panel C) images of the hypothalamus of the rat. ar, arcuate nucleus; ha, anterior hypothalamic nucleus; hdv, dorsomedial hypothalamic nucleus; hpv, periventricular hypothalamic nucleus; hvm, ventromedial hypothalamic nucleus; pom, medial preoptic nucleus; posc, pars suprachiasmatic-preoptic nucleus; mmm, pars medialis-medial mamillary nucleus; sc, suprachiasmatic nucleus; CA, anterior commissure; CO, optic chiasm; I, infundibulum; OVLT, organum vasculosum of the lamina terminalis. Note that the greatest content of LHRH (GnRH) was in a broad band corresponding to the ar with lesser but significant amounts in the OVLT. *From Ref. 17.*

FIGURE 26.10 **Sagittal view of the rat brain diagramming the course of fibers which, when lesioned, affect ovulation.** Widely dispersed origins are in the septal complex where relatively large irritative lesions (large open circle) are required to activate the number of fibers that can be affected by small lesions (small open circles) in the preoptic area. *From Ref. 132.*

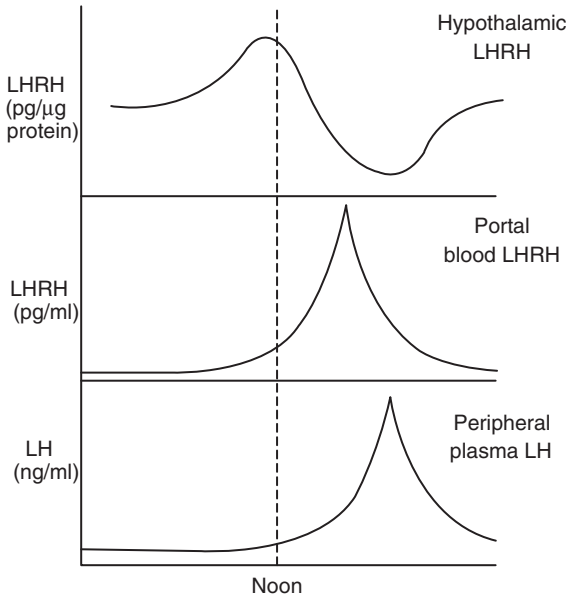

FIGURE 26.11 **Diagrammatic representation of the changes in hypothalamic concentration of LHRH (aka GnRH),[152] portal blood concentration of LHRH (GnRH),[154] and peripheral plasma concentration of LH[64] throughout proestrus in the rat.** Note that preceding the release of the ovulation inducing surge of LH there is a dramatic decline in hypothalamic concentration of GnRH and a corresponding increase in portal blood levels of GnRH.

does not appear to be general agreement on the increase in hypothalamic GnRH-content prior to the surge.[150–152] This may be due merely to variation in dissection technique of the various hypothalamic areas. In one study,[153] six areas along the preoptic-suprachiasmatic-tuberoinfundibular tract were dissected by the Palkovits' micropunch technique prior to and through the ovulation-inducing surge of LH on proestrus. Between 09:00 and 12:00 h on proestrus, there was a large increase in the concentration of GnRH in the ME as well as the SCN, mPN and anterior hypothalamic nucleus. Smaller, but significant, increases were observed in the retrochiasmatic area as well as the SCN. As with other studies, a large dramatic fall in GnRH concentration occurred in all areas between 12:00 and 15:00 h when the surge of LH begins. The pattern of GnRH mRNA expression levels as measured by ISH roughly mirrors these increases and then decreases in GnRH peptide concentrations in the mPOA and DBB.[130] Presumably, these changes are a reflection of GnRH gene expression and then release of GnRH into portal blood (Figure 26.11). Indeed, using a sophisticated surgical approach coupled with an anesthetic that does not appear to block the ovulatory surge of LH secretion on proestrus, Sarkar and collaborators[154] and later Ching[155,156] described an increase in radioimmunoassayable GnRH concentration in hypophysial blood, which shortly precedes the preovulatory surge of LH release on proestrus. Unfortunately, current methodologies as applied to rodents are such that it is difficult to obtain a reasonable amount of portal plasma frequently enough to determine if LH release on proestrus in the rat[90,92] is correlated with changes in GnRH pulse frequency and amplitude or merely the consequence of steroid-induced alteration in pituitary sensitivity to the decapeptide without a variation in GnRH frequency or amplitude.

In a larger mammal, the sheep, GnRH has been described as pulsatile in portal blood with a transition to a continuous mode of GnRH secretion during surge release (also see Chapter 27).[157] On the other hand, in the rat, by frequently perfusing the MBH with artificial cerebrospinal fluid and then sampling that fluid for assay of GnRH content (push–pull perfusion), Levine and Ramirez[102] described the patterns of release from GnRH terminals during the estrous cycle. Presumably, these are the neurons from which GnRH is secreted into hypophysial portal blood. Under these conditions, pulsatile GnRH release can be evaluated on proestrus. During proestrus, the average GnRH interpulse interval was 48 min. Pulses of increased amplitude and duration occurred throughout the afternoon hours, constituting a significant increase in the total GnRH release, with peak amount of GnRH release occurring between 1600 and 1800 h. It is this episode of release that presumably stimulates the release of the LH surge.[102] Using a microdialysis technique to monitor GnRH release, hormonally-induced GnRH surges have also been found to be comprised of pulses of increased amplitude in female rats[158] (Figure 26.12). These data, coupled with the observation that immunoneutralization of GnRH on proestrus blocks the surge of LH,[159] firmly establish the decapeptide as the physiological gonadotropin-releasing hormone that evokes the mid-cycle gonadotropin surge. The multiple pulses of GnRH likely serve a physiological role in the economy of LH release. Indeed, it has been shown that

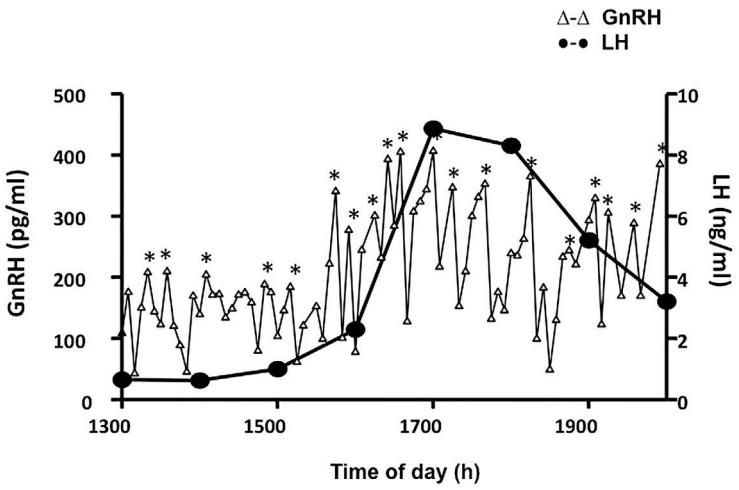

FIGURE 26.12 GnRH and LH surges in an ovariectomized, estradiol (E_2)-primed rat. GnRH release was measured by radioimmunoassay (RIA) in 5-min microdialysates of the mediobasal hypothalamus, and LH was measured by RIA in serum obtained hourly via an atrial catheter. The E_2 priming (30 μg E_2benzoate on the previous day) stimulated significant increases in GnRH pulse amplitude and mean level commencing at approximately 1600 h, accompanied by a concomitant 5-fold increase in LH. Asterisks represent significant pulses of GnRH release as determined by the ULTRA pulse analysis program. *Figure adapted from Ref. 158.*

small pulses of GnRH "prime" the gonadotroph cell to be maximally responsive to a subsequent release of a larger GnRH pulse on proestrus.[160,161]

Although the decapeptide has been unequivocally identified as the LH-releasing hormone in mammals, it is not clear that the termination of the LH surge is due exclusively to termination of GnRH secretion into hypophysial portal blood. Indeed, in sheep the GnRH surge significantly outlasts the duration of the LH surge.[157] It is possible that the termination of the LH surge reflects a limited capacity of gonadotropes to respond to heightened GnRH release. Alternatively, continued secretion of the LH surge may be actively suppressed by the pituitary actions of peptides of hypothalamic origins with gonadotropin inhibiting activity. One of these, the RF-amide orthologue of the avian gonadotropin inhibiting hormone (GnIH),[162] is considered more fully as a direct modulator of GnRH neurons later in this chapter. A second peptide of hypothalamic origin that inhibits GnRH-stimulated LH secretion has been partially characterized,[163] and administration of antisera to the peptide was shown to result in heightened release of LH on proestrus or in response to a challenge with estradiol.[164]

Other Neurohormones Controlling LH and FSH Secretion

Although GnRH occupies the primacy as the gonadotropin-releasing hormone, other neurosecretory products have been suggested to play complementary roles by regulating the responsiveness of gonadotropes to the stimulatory actions of GnRH. The list of putative "GnRH responsiveness factors" is headed by oxytocin (OT), neuropeptide Y (NPY) and galanin, each of which has been shown to have the capacity to regulate pituitary responsiveness to GnRH during the generation of preovulatory LH surges. There is evidence that OT acts at the anterior pituitary gland to augment the stimulatory effects of GnRH on LH secretion.[134,165–176] OT is found in portal blood[177,178] in highest amounts on the afternoon of proestrus.[178] Intravenous administration of an inhibitor to OT on the afternoon of proestrus blocks the preovulatory release of LH.[179] Passive immunization of OT, however, does not reduce the magnitude of the LH surge,[180] and OT- null mutant mice exhibit normal fertility.[181] Thus, the role of OT as a GnRH-responsiveness factor appears to be a supportive one, but not in itself obligatory for normal ovarian cyclicity. There is also abundant evidence that NPY acts a neurohormone to modulate GnRH-stimulated LH secretion.[182,183] NPY is found in the hypophysial portal circulation in high concentrations.[184,185] It regulates the binding of GnRH to its receptor on the gonadotroph cell membrane,[186,187] potentiates GnRH-stimulated LH surges,[188] and modulates calcium-transients in gonadotrophs.[189] These effects are probably mediated through the Y-1 receptor.[190] Hypothalamic NPY gene expression increases prior to the onset of the LH surge.[191,192] This suggests a role for NPY as a neurohormone participating with GnRH to regulate LH secretion at the gonadotroph. This idea has obtained direct support from the finding that genetic ablation of NPY in female mice results in a significant attenuation of both spontaneous and steroid-induced LH surges.[193] Finally, there is evidence for a neuromodulatory, neuroendocrine, and paracrine/autocrine role for galanin in the control of pituitary LH secretion. Galanin can stimulate LH secretion[194] and enhance GnRH-stimulated LH secretion in vivo.[195] It may act as a neurohormone since it is colocalized with GnRH[196] and has been found in portal blood.[197] Whether these actions of galanin are significant for the control of LH secretion is unknown at this time.

Though GnRH will release both FSH and LH,[198] there is still some uncertainty if one or possibly two releasing hormones exist. In the latter case, GnRH could release both LH and FSH while a distinct FSH-releasing factor

(FSH-RF) may exist. Early attempts to identify a separate FSH-RF provided some circumstantial evidence for such a molecule; however, no such factor has been isolated and identified. Radiofrequency lesions placed in the paraventricular nucleus-dorsal AHA (PVN-dAHA) were found to lower the plasma FSH levels of ovariectomized rats without disturbing the blood levels of LH or the concentration of GnRH in the ME.[199] Similarly, electrochemical stimulation of the DAHA caused FSH but no LH release.[200] Moreover, the posterior ME has greater FSH-releasing activity than can be accounted for by its content of GnRH.[201] Finally, a bioactive FSH-RF was isolated by size exclusion and ion exchange chromatography.[202,203] Fractions with greater FSH-releasing activity than could be accounted for by immunoreactive GnRH alone were detected prior to the immunoreactive GnRH peak. If indeed a distinct FSH-RF does exist, it may play an important role in the biphasic pattern of FSH secretion on proestrus through estrus. Administration of antiserum to GnRH[204,205] or a GnRH antagonist[206] blocks the preovulatory surge of LH, but the secondary surge of FSH on estrus is undisturbed by these treatments. These data, taken together, suggest one scenario in which a distinct FSH-RF may control the secondary surge of FSH on estrus. However, other studies (described later) argue that the secondary surge is largely independent of hypothalamic control.

The physiological control by peptidergic neurohormones of the secretion of PRL during the estrous cycle is less clear than that of LH and FSH. A number of neuropeptides have been demonstrated to stimulate PRL release. However, the most likely candidates as neurohumoral PRL-releasing hormones (PRHs) during the estrous cycle are thyrotropin-releasing hormone (TRH), vasoactive intestinal polypeptide (VIP), and OT. All three peptides are found in hypophysial portal blood[177,178,207,208] and stimulate PRL-release in vitro[209,210] and in vivo.[209] The indication that TRH plays a physiological role in the release of PRL during the estrous cycle comes from the observation that antiserum to TRH attenuates the basal secretion of PRL on diestrus and the surge on proestrus.[211] In TRH gene knockout mice, however, the absence of the peptide was not found to be associated with alterations in serum PRL levels or PRL content of the pituitary gland during proestrus.[212] The notion that VIP may be involved in the regulation of PRL secretion during the estrous cycle is supported by the fact that an antiserum to VIP administered on the afternoon of proestrus attenuates the peak phase of the PRL surge later that day.[213] However, the levels of VIP in the hypothalamus and anterior pituitary do not change during the surge of PRL on proestrus.[214] Therefore, a role for VIP in the cyclic release of PRL remains uncertain. The concentration of OT in hypophysial portal blood increases on the afternoon of proestrus just prior to the surge of PRL release into peripheral plasma.[178] Peripheral administration of an OT antagonist on the afternoon of proestrus completely blocked the proestrous surge of PRL.[179] Such data provide compelling evidence for a role of OT in the release of PRL on the afternoon of proestrus.

A member of the RF-amide family of peptides was originally shown to stimulate PRL secretion from cultured anterior pituitary cells and was therefore named PRL-releasing peptide (PrRP). Although PrRP has been implicated in a variety of other physiological functions, its importance in the physiological regulation of PRL in rodents has been questioned, especially in light of the finding that it is not detectable in the ME and has inconsistent PRL-releasing properties in vivo[215,216] (see also Chapter 12).

CONTROL OF PITUITARY HORMONE SECRETION

The cyclic release of LH, FSH, and PRL during the estrous cycle (Figure 26.5) is the result of positive (stimulatory) and negative (inhibitory) feedback control by the ovarian steroids acting at both the hypothalamus and pituitary gland. The positive feedback actions of ovarian steroids culminate in the release of the mid-cycle GnRH and LH surges that trigger ovulation. The negative feedback actions of ovarian steroids and additional ovarian protein hormones maintain homeostatic feedback control of basal (tonic), pulsatile GnRH, and LH secretion. The following is a description of this physiological interplay, which controls basal LH secretion from late estrus through early proestrus and the preovulatory surge pattern of this gonadotropin on late proestrus.

Luteinizing Hormone

Role of Ovarian Steroids

NEGATIVE FEEDBACK CONTROL OF LH SECRETION

In the intact female rat, the secretion of LH is low from late estrus to early proestrus due to the negative feedback provided by estradiol and progesterone secreted by the ovaries. This negative feedback was first recognized by Moore and Price in 1932.[217] Such inhibitory effects on LH secretion can be most easily demonstrated by removing the ovaries. Early observations using bioassay endpoints[104] showed that both pituitary and plasma levels of LH rise following gonadectomy of the rat. These observations were extended using the more sensitive radioimmunoassays. Plasma levels of LH rise slowly over a number of days following ovariectomy.[218–220] The earliest significant rise occurs by 18–24 h after ovariectomy, with diestrus being the most responsive day for removal of the inhibitory feedback response.[219,220]

As pointed out by Schwartz and McCormack,[104] the hundreds of attempts at restoring LH levels to pregonadectomy levels with estradiol and progesterone have presented varying experimental approaches, often without reference to the intact animal. It is now generally accepted that the most potent ovarian steroid for inhibiting LH secretion is estradiol.[104] In long-term ovariectomized rats, LH levels are significantly lowered by a single injection of as little as 0.2 μg of estradiol benzoate.[221] Progesterone administration alone is ineffective in lowering the elevated LH levels in ovariectomized rats.[220,222,223] However, administration of progesterone to estradiol-treated ovariectomized rats lowers LH levels below those of animals treated with estradiol alone.[222] Moreover, simulation of the basal levels of estradiol and progesterone secreted from metestrus through early diestrus prevents the postcastration rise of LH in animals ovariectomized on metestrus.[224] From these data, it can be inferred that the levels of estradiol and progesterone secreted from metestrus through diestrus are capable of restraining the hypothalamo–pituitary axis and leading to basal secretion of LH during this time. Now that the pulsatile manner of LH secretion is appreciated,[90–92] it is apparent that estradiol and progesterone differentially modify LH secretion by influencing the frequency and amplitude of the pulses. It is also apparent that these steroids affect pulse amplitude and frequency differently on the various days of the cycle as well as in long-term ovariectomized rats, in which estradiol suppresses mean LH levels by decreasing pulse frequency.[225] Using slightly different experimental approaches, both progesterone[226] and estradiol[227] have been assigned the role of inhibiting mean LH levels from metestrus through diestrus by suppressing pulse amplitude. During the interval from estrus to the morning of metestrus, however, mean LH increases slightly due to increased pulse amplitude and frequency which is independent of ovarian steroid negative feedback control.[228] It seems likely that the steroids exert their negative feedback on LH secretion by modifying the amplitude and frequency of the LH pulses. The effects on frequency and amplitude may be exerted at the hypothalamic level by directly or indirectly modifying the pulsatile release of GnRH into the hypophysial portal blood supply to the pituitary gland. Some negative feedback control of pulse amplitude also appear to be exerted at the pituitary level by suppression of the responsiveness of gonadotropes to pulses of GnRH.[229]

STIMULATION OF THE PREOVULATORY LH SURGE

There is voluminous literature indicating that ovarian estradiol, secreted on diestrus and the morning of proestrus, provides the positive feedback stimulus for the ovulation-inducing surge of LH. There are several experimental approaches that have attested to this fact. Specifically, under either a 14:10 or 12:12 light–dark cycle with noon as the midpoint of the light interval,[87,88,230] ovariectomized rats will respond to a dose of exogenous estradiol by generating a proestrous-like LH surge the following day with the same timing and duration as the intact rat.[231–239] However, the magnitude of this induced surge differs from the spontaneous surge on proestrus. That is, baseline values are not as low and peak values are not as high as those on proestrus. In addition, rather than secreting a surge of LH on the single day after estradiol administration, ovariectomized animals respond with initiation of LH surges at similar times on each of at least the following 3 days.[231–239] Thus, a daily neural event must be coupled with the presence of estradiol to eventuate in daily LH surges in the ovariectomized rat. This confirms Everett and Sawyer's[103] original proposal of a 24-h periodicity in the LH release apparatus. Other approaches have demonstrated that ovarian estradiol secreted on diestrus is required to activate the LH surge on proestrus. Specifically, administration of estrogen antagonists,[240] estradiol antiserum,[241,242] or ovariectomy[243] on diestrus blocks the proestrous surge of LH. On the other hand, administration of these agents or removal of the ovaries early on proestrus is ineffective in preventing this response later that same day. These data, taken together, suggest that the rising titer of estradiol secreted on diestrus is the major stimulus for the increased secretion of LH on proestrus.

The primary stimulus for the increased secretion of estradiol is the tonic pattern of LH and FSH secretion from metestrus through diestrus. Administration of sufficient antiserum to LH to neutralize tonic LH levels on diestrus-2 blocks the subsequent LH surge on proestrus.[244,245] Administration of that same dose of LH antiserum on early proestrus failed to block the LH surge late that afternoon.[244] LH antiserum preincubated with LH was without effect. Thus, the tonic levels of LH secreted on diestrus contribute to the stimulation of estradiol secretion by the ovarian follicle, which in turn stimulates the LH surge. It should also be noted here that tonic FSH secretion is also required to stimulate estradiol secretion, because an important action of this gonadotropin is to induce in granulosa cells the expression of aromatase, a critical enzyme responsible in the synthesis of estradiol from androgen that is produced by the theca cells in response to LH stimulation (see Chapter 28).

Unlike the long-term ovariectomized rat, which responds to a brief exposure to estradiol with daily LH surges, the intact rat presents LH surges only every 4–5 days in response to ovarian estradiol. Moreover, unlike the long-term ovariectomized rat, the acutely ovariectomized rat requires chronic exposure to estradiol to secrete daily LH surges.[237,238] Thus, some ovarian event associated with the LH surge on proestrus prevents expression of the daily neural signal eventuating in daily LH release. Indeed, it has been shown that

expression of the daily LH surge mechanism is limited to proestrus by the heightened secretion of progesterone on proestrus.[231,235] Interestingly, there is also every indication that the rise in progesterone on proestrus also facilitates the secretion of the surge of LH at this time. This idea first arose from Everett's observation in 1948[246] that injection of progesterone on the day prior to proestrus of a 5-day cycling rat would advance LH release and ovulation by 24 h. In fact, progesterone administered early on the morning of proestrus will advance LH release by several hours.[247] Similarly, progesterone administered to ovariectomized, estradiol-pretreated rats will induce an LH surge during the afternoon of that same day.[222] In addition, progesterone will enhance the magnitude of the estradiol-induced LH surge.[222] However, regardless of when injected, progesterone will not advance the LH surge beyond the early afternoon. Thus, LH release induced by progesterone is keyed to the time of day, not to the time the steroid was injected. Taken together, it seems that the proestrous surge of progesterone plays a dual role in controlling LH release during the cycle; specifically, it induces an initial early response that ensures the timeliness and increases the magnitude of the coincident LH surge induced by estradiol secretion during diestrus followed by a later extinction of the expression of the estradiol-induced 24-h periodic release of LH. At this time, there is no described role for the other major increase in progesterone secretion, which occurs from late metestrus through early diestrus, although it has been suggested that the duration of this secretion may determine whether a given cycle lasts 4 or 5 days.[248]

The stimulus for the increase in progesterone secretion on proestrus appears to be the proestrous surge of LH itself. Hypophysectomy on proestrus[72] or administration of pentobarbital to block the proestrous surge of LH[76,249] prevents the major ise in progesterone occurring later that day. Administration of LH reversed the effect of pentobarbital blockade of progesterone secretion.[76,249] Although the progesterone secreted on proestrus arises from the preovulatory ovarian follicle and is controlled by the proestrous surge of LH, the increase in progesterone from metestrus through diestrus is secreted ephemerally from the newly formed corpora lutea and appears to be autonomous of pituitary support. Indeed, Uchida and co-workers[72] found that hypophysectomy on estrus, shortly after corpus luteum formation, did not prevent the increase of progesterone on metestrus. Thus, this increase occurs independently of any continued pituitary luteotrophic support.

Interestingly, there appears to be a nonligand-dependent role for the progesterone receptor (PR) in the induction of a proestrus-like LH surge by estradiol.[250] Pharmacologic blockade of PR blocks the LH (and also primary FSH; see later) surge on proestrus in rats.[251–253] Ovariectomized PR knockout mice will not respond to an estradiol challenge or a self-priming paradigm of GnRH administration with significant LH secretion.[254] Peripheral administration of a PR antagonist blocks the estradiol-induced increase in GnRH levels in the ME and the proestrous surge of LH in plasma.[158] Moreover, implantation of an antisense PR oligonucleotide into the third ventricle prevented PR expression in the anteroventral periventricular region of the hypothalamus and blocked estradiol-induced LH surges.[158] Such PR activation requires cAMP.[255] Taken together, these data suggest expression of estradiol-induced LH surges requires ligand-independent PR activation. If this is the case, the precise role of the ligand, progesterone, must be more thoroughly evaluated. One possibility is that progesterone downregulates the activated PR to prevent LH surges on subsequent days.

STEROID RECEPTORS MEDIATING OVARIAN STEROID CONTROL OF LH DURING THE ESTROUS CYCLE

As discussed above, ovarian estradiol and progesterone secretions exert both negative and positive feedback actions in the brain and anterior pituitary gland, and thereby regulate the sequence of neuroendocrine events that in turn direct ovulatory cyclicity. The steroid receptors that convey these feedback actions have been identified largely through the study of the consequences of receptor gene knockout (KO) and knock-in (KI) in mice. Estrogen receptor α (ERα) knockout (ERαKO) mice exhibit hypergonadotropism and an absence of estrous cyclicity, and are refractory to both inhibitory and stimulatory actions of estradiol on LH secretion.[256–259] Null mutation of the ERβ isoform, by contrast, does not produce any such major defects[256] and studies to date have yet to document any major contributions of other physiological ERs to the regulation of gonadotropin secretion and control of the estrous cycle. Thus, ERα likely conveys most, if not all, of the negative and positive feedback actions of estradiol during the estrous cycle. Recent studies of tissue- and cell-specific ERα null mutant mice have also provided evidence that estradiol exerts feedback actions via ERα activation in both brain[259,260] and pituitary cells,[261,262] as discussed below. Moreover, the ERα signaling mechanisms that mediate steroid feedback actions have become clearer through the use of *ERα* gene mutant mice.

ERα can convey signals through classical genotropic pathways involving dimerization of ERα and binding to estrogen response elements in DNA to alter transcription of target genes. In nonclassical mechanisms, signaling proceeds in the absence of direct binding of ERα to DNA, through protein–protein interactions that alter transcription at non-ERE sites, or through signaling pathways activated by ERα complexed at the plasma membrane. A nonclassical ER knock-in (NERKI) mutant mouse has

been developed,[263] which isolates nonclassical ER signaling and permits analysis of the contributions that classical versus nonclassical signaling mechanisms may make to the manifestation of negative and positive feedback effects of estradiol during the estrous cycle. These studies have clearly demonstrated that classical ER signaling is an obligatory component of positive feedback regulation of LH secretion, while nonclassical mechanisms are sufficient for conveying the majority of the ERα-mediated negative feedback actions of estradiol on LH secretion.[258]

Progesterone receptor knockout (PRKO) mice have also been used to assess the importance of PRs in the regulation of cyclic LH secretion. The absence of estrous cyclicity and steroid feedback actions in these animals indicates that they play a primary role in the control of LH secretion during the estrous cycle.[254,264] The major importance of the PR_A isoform as opposed to the PR_B isoform in the control of LH secretion has also been confirmed in a study of PR isoform-specific KO mice 5.[265]

Sites at Which the Ovarian Steroids Act in Controlling LH Secretion during the Estrous Cycle

THE ANTERIOR PITUITARY AS A SITE FOR NEGATIVE FEEDBACK OF LH SECRETION BY OVARIAN STEROIDS

It is likely that the pituitary is a target for some of the inhibitory feedback effects of ovarian steroids on LH.[266,267] Ovariectomy increases[268,269] and estradiol decreases[266,269–271] the magnitude of LH released in response to GnRH administration, which suggests that the pituitary is indeed a locus of negative feedback by estradiol. These inhibitory actions can be observed within minutes following estradiol treatment, in contrast to the stimulatory actions of estradiol on LH secretion, which take 18–24 h to manifest. Although direct inhibitory effects of estradiol on LH secretion have been difficult to demonstrate using isolated anterior pituitary glands in vitro,[272] estradiol injections in vivo have been shown to suppress LH secretion from ectopic pituitary tissues exposed to chronic pulsatile GnRH stimulation.[229] Moreover, pituitary-specific ablation of ERα confers LH hypersecretion in female mice, indicating that some proportion of the negative feedback actions of estradiol occurs at the level of the pituitary, presumably the gonadotrope.[261,262] Increased serum LH levels in these mice are nevertheless much lower than levels noted in complete ERα knockout (ERαKO) mice, suggesting that the majority of the negative feedback actions of estradiol, or at least those mediated by ERα, are exerted at neural loci.

NEURAL SITES AT WHICH OVARIAN STEROIDS ACT TO INHIBIT LH SECRETION

Estradiol exerts central negative feedback actions, as first demonstrated by the finding that ovariectomy increases and estradiol treatment decreases GnRH concentrations in portal vessel blood of anesthetized female rats.[273,274] With the understanding that a neural GnRH pulse generator directs pulsatile LH secretion (see also Chapter 28), neural feedback actions of ovarian steroids were also inferred in studies documenting changes in the frequency of pulsatile LH secretion in peripheral blood. The frequency and amplitude of pulsatile LH secretion is increased following removal of the ovaries on metaestrus while replacement with estradiol and progesterone at physiological levels returns both parameters to ovary-intact levels.[226]

The brain has also been confirmed as a major locus of negative feedback mediated by ERα, as estradiol suppression of LH secretion was found to be absent in female mice bearing conditional deletion of ERα in neurons.[260] Confirmation of the specific sites of feedback in the brain has proven more challenging. Early studies used classic lesion[275] and steroid implantation[276] techniques in attempts to identify loci of these steroid negative feedback actions in the brain. In retrospect, this work was complicated by the inability of these approaches to discretely eliminate or activate specific neural networks without disabling the GnRH neurosecretory system itself, or impairing afferent networks required for its basic functioning. The persistence of estradiol negative feedback actions after complete hypothalamic deafferentation has been viewed as evidence that these effects are mediated by mediobasal hypothalamic neurons.[277] The complete and permanent separation of more rostral elements from the mediobasal hypothalamus must be questioned in these early studies, however, because LH pulsatility was found to continue in these animals, even after presumed transection of the majority of GnRH axons. At present, no studies have succeeded in identifying specific neuroanatomical locations containing cell populations that are necessary for conveying ovarian steroid negative feedback during the estrous cycle. The advent of cell-specific gene targeting in mice, however, is providing new clues as to the neurotransmitter cell phenotypes that may mediate some of these effects, as noted in subsequent sections.

THE ANTERIOR PITUITARY GLAND AS A SITE AT WHICH OVARIAN STEROIDS STIMULATE LH SECRETION

There is little doubt that the rising titers of estradiol through diestrus and the surge quantities of progesterone secreted on proestrus act at the gonadotrope to enhance its responsiveness to GnRH. Indeed, both basal and GnRH-stimulated LH release from cultured anterior pituitary cells are enhanced by the addition of estradiol to the culture medium.[278] Similarly, pituitary cells obtained during estradiol-dominated phases of the cycle are most responsive to GnRH.[279] In addition, within the first 3–8 h of introduction to the media, progesterone magnifies the estradiol-induced enhancement of the

LH-secretory response to GnRH.[280] However, by 48 h after introduction, progesterone significantly depresses the estradiol-induced enhanced LH secretory response to GnRH.[281] This effect of addition of steroids to pituitary cells in vitro mirrors the LH-secretory response to GnRH in vivo.[161] That is, from diestrus through early proestrus, rats secrete increasing amounts of estradiol and also respond to a challenge of GnRH with increasing maximal increments in plasma concentration of LH.

Coinciding with the proestrous surge of progesterone, the pituitary gland presents a larger acute increment in LH secretory response to GnRH, which is only present for approximately 2 h. After this time, the LH response to GnRH declines rapidly, reaching a nadir by the early morning of metestrus. These effects can be mimicked in vivo by appropriately timed administration of steroids to ovariectomized rats.[282] These data, and others, convincingly demonstrate that ovarian estradiol secreted from metestrus through early proestrus and ovarian progesterone secreted during the afternoon of proestrus sensitizes the pituitary gland to respond to GnRH. The later effects of the proestrous surge of progesterone are to blunt or completely inhibit the response to GnRH. These data suggest that the proestrous surge of LH is the consequence of two integrated actions brought about by the rising titers of estradiol from diestrus through proestrus: release of the GnRH surge on the afternoon of proestrous, and enhanced sensitivity of the pituitary gland to stimulation by the GnRH surge. A further increment in pituitary sensitivity is the result of the initial phases of the proestrous surge of progesterone. The relative insensitivity of the gland on estrus through diestrus may be the late response to the proestrous surge of progesterone.

Just how estradiol and progesterone modify cyclic response of the pituitary gland to GnRH is not known at this time. It had been rather widely suggested that the ovarian steroids enhance the pituitary response to GnRH by increasing GnRH receptor number,[262,283–285] while the diminished response induced by progesterone was a function of declining receptor number.[286] However, it now appears that the estrogen-induced heightened, or progesterone-regulated diminished, responsiveness may occur independent of a change in GnRH receptor number and may involve a postreceptor mechanism.[287–289] One likely postreceptor mechanism appears to involve the ability of estradiol to confer the capacity for gonadotropes to exhibit increasing LH secretory responses to successive pulses of GnRH—that is, the GnRH self-priming effect.[160] Estradiol may exert this permissive effect by inducing the expression of PRs in gonadotropes, which may then be activated by both ligand-dependent and ligand-independent mechanisms.[254,290] The latter appears to include activation of the PR_A isoform by GnRH receptor signaling via protein kinase A and/or protein kinase C–mediated pathways.[291] The mechanisms by which progesterone may thereafter exert delayed suppressive effects of on pituitary responsiveness remain unknown. Estradiol may also sensitize female rat pituitary cells to GnRH stimulation by regulating components of both PKC- and Ca^{2+}-dependent signaling pathways that are coupled to GnRH receptor activation.[292]

CONTROL OF LH SUBUNIT MESSAGE

Feedback actions of steroids may also be exerted through the regulation of gonadotropin subunit gene expression. There is little doubt that the gonads influence the expression of the LH subunit mRNAs. Ovariectomy dramatically enhances the expression of the α subunit mRNA and, to a lesser extent, LH-β subunit mRNA in the pituitary gland.[293] Moreover, treatment of ovariectomized rats with an estrogen and progesterone regimen that lowers serum levels of LH also lowers α subunit mRNA and LH-β subunit mRNA levels in the pituitary gland.[294] Ovariectomized rats treated with estradiol to induce a preovulatory-like surge of LH secretion presented a concomitant increase in α subunit mRNA without change in LH-β mRNA.[295] However, when rat pituitary fragments were incubated with estradiol for 2 or 6 h, LH-β subunit mRNA synthesis was increased.[296] LH-β gene promoter analysis in clonal LβT2 gonadotropes has revealed that estradiol may enhance GnRH-stimulated LH subunit expression through regulation of transcription of activators and repressors of the LHβ promoter.[297] These data suggest an additional subunit message control mechanism, wherein estradiol may differentially interact with frequency- or amplitude-modulated GnRH pulses to alter gonadotropin subunit gene expression. Indeed, in female rats, low-amplitude GnRH pulses elevate only LH-β subunit mRNA, whereas higher-amplitude pulses enhance both LH-β subunit and α subunit mRNAs.[296]

NEURAL SITES AT WHICH OVARIAN STEROIDS STIMULATE GnRH NEUROSECRETION

The evidence is overwhelming that estradiol acts at the diencephalon to stimulate release of a preovulatory GnRH surge, which in turn triggers secretion of an ovulation-inducing surge of LH on the afternoon of proestrus. As noted earlier, GnRH output by the MBH, as judged by push–pull perfusion, is pulsatile in nature with enhanced output prior to the expected surge of LH on proestrus.[102] Moreover, the concentrations of GnRH in hypophysial portal blood also increases dramatically just prior to the surge of LH on proestrus.[154] There is little doubt that the increased output of GnRH by the MBH is due to the enhanced secretion of estradiol on diestrus exciting peptidergic neurons in the preoptic-anterior hypothalamic area either directly or indirectly, to release a surge quantity of GnRH into portal blood.

That is, exogenous estradiol stimulates release of GnRH from neurovascular terminals in the ME, into hypophysial portal blood in a pattern equivalent to that secreted spontaneously on proestrus (Figure 26.12).[262] Most of the evidence points to rostral hypothalamic sites as the location for these stimulatory effects on GnRH secretion. Specifically, estradiol implanted directly into the POA-AHA elicits LH release,[262,298,299] while implantation of the ER antagonist, keoxifen, into the same area suppresses estradiol-induced LH surges.[300] Progesterone implanted in the preoptic area also exerts a stimulatory effect on LH secretion in estrogen-primed animals.[299] Implantation of steroids in other regions of the brain are largely without stimulatory effect on LH secretion. In addition, destruction of rostral inputs to the medial basal hypothalamus, while having no influence on the LH secretory response to ovariectomy or the negative feedback of ovarian steroids on LH secretion,[264] prevents the stimulatory effects of ovarian steroids on release of a surge-like pattern of LH secretion.[151,262,301–303] Also, direct implantation of progesterone within the mPOA blocked the expression of the 24-h periodic stimulus for release of a surge quantity of LH.[233] Placement of the steroid in other neural areas was ineffective. These and other data have served the argument that the LH "surge center" responsive to the positive feedback of estradiol and progesterone as well as the inhibitory effect of progesterone lies within the rostral hypothalamus.

Studies utilizing discrete lesions have more specifically implicated the AVPv as a critical target of the positive feedback actions of estradiol and progesterone.[139] Ablation of the AVPv renders animals incapable of maintaining estrous cycles or responding to LH surge-inducing regimens of estradiol and progesterone.[139] There is a sexual dimorphism in the volume of the AVPv in rats, with the larger nuclear phenotype in females[304] associated with the capacity of the female, but not the male, to respond to steroid feedback stimulation. The AVPv receives afferent inputs from the SCN that presumably convey a daily afternoon signal for release of the GnRH surge.[305] Vasopressin[306,307] and VIP[308,309] are among the neurotransmitters that likely mediate delivery of these circadian signals from the SCN to the AVPv. Estradiol appears to exert a major positive feedback action in AVPv neurons by coupling these afferent neural signals to the generation of efferent signals for the stimulation of the preovulatory GnRH surge. There is evidence that the cellular integrative mechanism that mediates this coupling process involves estradiol induction of PR expression in AVPv neurons, because knockdown of PR expression within the AVPv blocks steroid induction of the LH surge and treatment with the PR antagonist, RU486, blocks the release of GnRH and LH surges.[158,255] Moreover, estradiol treatments fail to evoke LH surges in PRKO mice,[254] revealing an absolute dependency of LH surge generation on the induction of PRs, most likely in the foregoing AVPv region.

It has been proposed that the daily neural signals conveyed by SCN afferents activate cAMP-PKA signaling pathways that initially prompt ligand-independent activation of PRs in AVPv neurons,[255] thereby activating AVPv neurons to deliver stimulatory signals via synaptic connections with GnRH neurons.[305] Additionally, the rising phase of the progesterone surge,[250] as well as estrogen-induced progesterone synthesis in hypothalamic astrocytes[310,311] likely contribute to the activation of these PRs and the amplification of GnRH surges. Supporting this idea are the observations that in vivo[312] and in vitro[313] measurements of GnRH release from hypothalamic tissues of adult ovariectomized rats treated with estrogen and progesterone in vivo results in enhanced release of GnRH relative to that from hypothalami of rats treated with estradiol alone. The expression of the immediate early gene product cFOS, which signifies neuronal activity, has been used to confirm that PR stimulation ultimately activates GnRH neurons in estradiol primed animals to a similar extent to that observed on the afternoon of proestrus.[314] Figure 26.13 depicts the sequence of events that are hypothesized to occur in AVPv neurons that culminate in the release of GnRH surges on the afternoon of proestrus. As described below, the phenotypes of AVPv neurons in which this integrative process occurs likely includes those that express kisspeptin.

Neurotransmitters and Neuropeptide Modulators Controlling GnRH and LH Secretion during the Estrous Cycle

The GnRH neuronal system functions as a final effector of neuroendocrine mechanisms that govern the reproductive axis and ovarian cyclicity. As such, it receives regulatory signals conveyed synaptically by afferent neural connections. Peripheral signals may also be directly registered by GnRH neurons, or these humoral cues may be delivered to the afferent circuitries that in turn regulate GnRH neuronal activity and secretion. Considerable progress has been made in identifying the neuronal cell groups that may integrate and communicate neural and peripheral signals to GnRH neurons, and thereby orchestrate the neuroendocrine control of ovulatory cyclicity. The advent of transgenesis and gene targeting approaches has facilitated this process, inasmuch as they have provided more definitive tests of the physiological relevance of mechanisms classically identified by pharmacological and anatomical approaches.

In general, neurotransmitters may contribute to the physiological control of estrous cyclicity by modulating basal pulsatile GnRH release, conveying synaptic signals that culminate in the release of the preovulatory

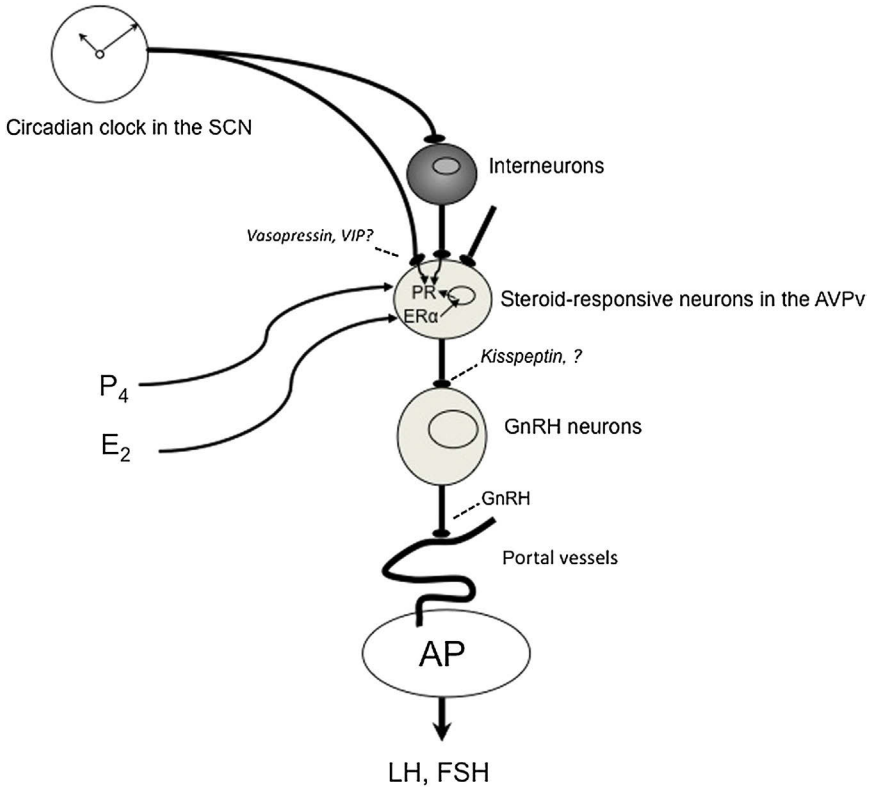

FIGURE 26.13 A model for the neuroendocrine integrative mechanisms that mediate release of preovulatory GnRH and gonadotropin surges. A daily neural signal is emitted on each afternoon of the estrous cycle from the master circadian clock in the suprachiasmatic nucleus (SCN), and conveyed to steroid-sensitive neurons in the anteroventral periventricular nucleus (AVPv). Vasopressin and vasoactive intestinal polypeptide (VIP) may function as neurotransmitters conveying the daily neural signal. In the absence of the preovulatory surge of estradiol (E_2), the signal is not coupled to the activation of AVPv neurons. The rising tide of E_2 on the evening of diestrus and morning of proestrus activates ERα in kisspeptin neurons and possibly other cells types in the AVPv, resulting in increased expression of progesterone (P_4) receptors (PRs) and other proteins that permit coupling of the incoming synaptic signals to the activation of the AVPv neurons. Excitation of AVPv kisspeptin neurons in turn stimulates release of the peptide at synapses on GnRH neurons, activating kisspeptin receptors and evoking excitation and release of a GnRH surge into the hypothalamic–hypophysial portal vasculature. The GnRH surge evokes an LH surge from the E_2-sensitized anterior pituitary (AP) gland. P_4 secretion evoked during the GnRH-induced LH surge functions to amplify the GnRH surge, and uncouple the AVPv neurons from the daily neural signal on the next day, effectively limiting the occurrence of the surge to the afternoon of proestrus.

GnRH surge, or simultaneously modulating both processes. Both positive and negative feedback regulation of GnRH release are believed to be exerted through actions in these afferent neurotransmitter cell groups, and not directly in GnRH neurons, because GnRH neurons do not to exhibit appreciable ER binding,[315] or detectable ERα protein.[316] The identities of those afferent neuronal populations that do express ERs, and thus may indirectly convey negative and positive feedback actions of the steroids to GnRH neurons, have remained the focus of intense research efforts for several decades. Below I note the neurotransmitter cell groups that have been most strongly implicated in the transmission of feedback actions of ovarian steroids, and more generally as modulators of either mode of GnRH release during the ovarian cycle. We focus in particular on neurotransmitter cell groups that express ERs and are known to function as monosynaptic modulators of GnRH neurons.

KISSPEPTIN

With the discovery that inactivating mutations of the kisspeptin receptor, KISS1R (also known as GPR54), are associated with hypogonadotropic hypogonadism in humans,[317,318] kisspeptin was identified in a variety of species as a powerful GnRH secretagogue that plays an important role in the regulation of pulsatile GnRH release in puberty, basal GnRH pulsatility in adulthood, and release of GnRH and LH surges during the estrous cycle (see also Chapters 11, 27, 28, and 30–32).[319,320] In rodents, kisspeptin-expressing neurons are concentrated in the ARN and in rostral periventricular regions that include the AVPv.[321] Co-expression of kisspeptin, neurokinin B, and dynorphin occurs within neurons of ARN,[322,323] prompting their designation as kisspeptin-neurokininB-dynorphin (KNDy) neurons.[324] Complete kisspeptin- or KISS1R deletion in transgenic mice results in infertility associated with hypogonadotropism and absent puberty and ovarian cyclicity in adulthood.[318,325–328] In *Kiss1R*

gene knockout mice, fertility can be completely restored by GnRH neuron-specific expression of KISS1R,[329] indicating that kisspeptin neurons serve as a final common afferent pathway controlling GnRH neurons and their neurosecretory activity during reproductive development and adult reproductive cycles.

Infusion of a kisspeptin receptor antagonist into the arcuate nucleus (ARN), but not the mPOA, retards GnRH pulse generation,[330] suggesting that ARN kisspeptin neurons and kisspeptin-KISS1R signaling function either as substrates of the GnRH pulse generator itself or as monosynaptic modulators of GnRH pulsatility.[329] One current hypothesis[322,324,331,332] holds that KNDy neurons function as an integrated and interconnected network, in which neurokinin B excites and dynorphin inhibits the activity of other KNDy neurons to produce and then transmit an intermittent, pulse-generating pattern of excitatory signals to GnRH neurons.

More than 90% of kisspeptin neurons in both the AVPv and ARN express ERα,[321] and thus it has been proposed that they play important roles in estradiol feedback regulation of GnRH release. Ovariectomy reduces and estradiol increases kisspeptin expression in the AVPv, whereas ovariectomy increases and estradiol reduces kisspeptin gene expression in the ARN.[333–337] It has therefore been hypothesized that estradiol exerts positive feedback through actions in AVPv kisspeptin neurons and negative feedback through effects on ARN kisspeptin neurons.[338] Evidence that AVPv neurons play a role in the generation of GnRH surges is compelling. Kisspeptin gene expression in the AVPv is increased at the time of the LH surge.[339] Localized passive immunoneutralization of kisspeptin in the POA, moreover, blocks the release of LH surges,[339,340] as does infusion of a KISS1R antagonist.[341] Estradiol treatments fail to stimulate kisspeptin gene expression in the AVPv of ERαKO mice,[333] consistent with the idea that ERα in these neurons mediates estradiol positive feedback actions. Observations of acyclicity and near absence of corpora lutea in kisspeptin cell-specific ERα knockout (KERKO) mice strongly suggest that ERα signaling in kisspeptin neurons is required for normal GnRH surge generation.[342] It remains to be determined if selective ablation of ERα in AVPv, but not in ARN, kisspeptin neurons produces the same result—a finding that would more specifically implicate AVPv kisspeptin neurons in the stimulation of GnRH surges. Nevertheless, the foregoing studies collectively provide strong support for the idea that kisspeptin neurons in the AVPv play an important role in conveying the positive feedback actions of estradiol.

A role for kisspeptin neurons in negative feedback has not yet been convincingly established. Consistent with this idea, nevertheless, is the observation that estradiol's negative feedback actions and its capacity to suppress kisspeptin gene expression in the ARN can both be mediated by nonclassical ERα signaling mechanisms.[333] In KERKO mice, elevated LH secretion occurs during the juvenile period, indicating that ERα in kisspeptin neurons mediates an estradiol negative feedback mechanism that functions to restrain GnRH release prior to puberty.[342] However, LH levels in KERKO mice decline to levels observed in wild-type animals during puberty, suggesting that a prepubertal ERα dependent negative feedback mechanism is supplanted in the adult by an ERα-, and perhaps kisspeptin, independent mechanism. It is not known if this reflects the normal activation of a postpubertal kisspeptin-independent negative feedback mechanism or if abnormal mechanisms are elicited in these animals to compensate for the absence of ERα signaling in kisspeptin neurons. The hypothesis that ARN neurons mediate steroid-negative feedback has not been supported by electrophysiological studies of identified kisspeptin neurons in hypothalamic slices from kisspeptin-GFP expressing transgenic mice; predictions that spontaneous firing of ARN kisspeptin neurons would be increased after ovariectomy and decreased with estradiol treatments have not been met.[343] Toxin-mediated ablation of KNDy neurons has been found to reduce the postovariectomy rise in LH secretion, but estradiol treatments of these animals were nevertheless effective in reducing serum LH to basal levels.[344] The latter effects may be due to the activity of 5% of KNDy neurons that survive the cell ablation procedures or to a pituitary site of action. Whether KNDy neurons are the site of estradiol negative feedback thus remains to be confirmed or refuted using methods for selective deletion or blockade of ERα in this discrete cell population in adult animals.

γ-AMINO BUTYRIC ACID

Hypothalamic cells that produce the neurotransmitter γ-amino butyric acid (GABA) also express ERs.[345] Thus, numerous studies have focused on their roles in regulating GnRH release during the estrous cycle and in response to steroid hormones. GABA has long been viewed as an inhibitory neurotransmitter in the brain, activating both postsynaptic ionotropic $GABA_A$ and presynaptic metabotropic $GABA_B$ receptors. Numerous GABA neurons are located in the AVPv, and expression of GABA transporters (VGAT) has been characterized in synaptic contacts on GnRH neurons;[346] many of these GABAergic neurons have also been shown to produce the excitatory amino acid neurotransmitter glutamate (see below).

Several in vivo studies have provided evidence supporting an inhibitory role for GABA in the regulation of GnRH release. GABA release, as measured by push–pull perfusion or microdialysis of the preoptic area, is reduced during estradiol-induced LH surges,[347–349] and GABA levels are increased during estradiol suppression of LH pulsatility.[350] Infusions of GABA into the preoptic area block the preovulatory LH surge in proestrous

rats,[351] whereas preoptic injections of a $GABA_A$ receptor agonist inhibit pulsatile LH secretion in ovariectomized rats.[352] However, blockade of $GABA_A$ receptors in the preoptic area by the receptor antagonist bicuculline also reduces, rather than stimulates, pulsatile LH secretion.[352] It was not found to have an effect on the LH surge in one study,[351] while another showed that it advanced its timing.[353] These contradictory results likely reflect the heterogeneaity of GABAergic neuronal influences on GnRH release that are difficult to parse with these in vivo, organ-level experimental manipulations.

More recent electrophysiological studies in tissue slices from GnRH-GFP transgenic mice have permitted direct and discrete analysis of direct synaptic regulation of GnRH neurons by afferent GABAergic neurons. Considerable evidence now supports the contention that GABAergic neurotransmission activates $GABA_A$ receptors in GnRH neurons to depolarize their membranes and increase the frequency of firing in these cells,[354–356] although some have questioned whether this is the predominant endogenous GABAergic control mechanism under all physiological and developmental circumstances.[357] Elevated chloride levels in GnRH neurons likely confers stimulatory responses to GABA through $GABA_A$ receptors, which function as chloride ion-selective pores. The stimulatory nature of this synaptic drive to GnRH neurons is supported by observations that the frequency of GABA neurotransmission and the postsynaptic responses of GnRH neurons to GABA in tissue slices are positively associated with GnRH neuron activity and LH release.[358–362] Recordings from GnRH neurons in an in vivo recording paradigm have provided a more complicated picture of GABAergic regulation of GnRH neurons, as responses to $GABA_A$ agonist are heterogeneous among GnRH neurons.[363] Nevertheless, $GABA_A$ receptor antagonism consistently reduces GnRH neuronal activation in this experimental paradigm. Surprisingly, partial GnRH neuron-specific knockdown of $GABA_A$ receptors does not impair ovulatory cyclicity, fecundity, or fertility[364]—a result that may indicate that few functional receptors are sufficient to mediate GABA effects or that one or more other synaptic inputs may compensate for the loss of $GABA_A$ mediated tone. See also Chapter 11 for further discussion of GABAergic regulation of the GnRH neuron.

Estradiol treatments that evoke daily LH surges evoke diurnal alterations in the frequency of GABA transmission to GnRH neurons, with reduced frequency in the morning correlated with negative feedback suppression of LH and increased frequency in the afternoon correlated with release of the GnRH surge.[365] These findings implicate GABAergic afferents in the transmission of both negative and positive feedback influences on GnRH release that operate before and then during the generation of preovulatory LH surges. It is not known at this time whether ERα in GABAergic neurons induces this synaptic signaling pattern, or if ERα signaling in higher-order afferents to GnRH neurons indirectly convey negative and positive feedback signals through these GABAergic interneurons. The locations of the GABA neurons that may function in this manner, and their functional relationship with kisspeptin neurons and other likely mediators of steroid hormone feedback actions, are not completely understood. Parallel kisspeptin and GABAergic pathways from the AVPv to GnRH neurons have been demonstrated and found to be sensitive to electrical stimulation of differing frequencies.[366] Other data demonstrate that kisspeptin increases GABA and glutamate (see below) transmission to GnRH neurons in an estradiol-dependent manner.[367] Thus, kisspeptin may influence GnRH neurons by multiple pathways, including direct actions via KISS1R signaling in GnRH neurons, as well as through modulation of fast GABAergic and glutamatergic neurotransmission to GnRH neurons.

GLUTAMATE

A considerable body of evidence exists that supports a stimulatory role for glutamate neurons in the regulation of GnRH release and ovulatory cyclicity.[368–370] Studies have implicated direct glutamatergic neurotransmission onto GnRH neurons in mediating these effects. GnRH neurons express both ionotropic glutamate receptors, the α-amino-3-hydro-5-methyl-4-isoxazole-propionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) receptors,[371–373] and postsynaptic currents mediated by receptors of both types have been recorded in GnRH neurons.[374] Peripheral and central administration of NMDA stimulates GnRH and LH release in a variety of species including the monkey,[375,376] and NMDA has been used as a reliable GnRH secretagogue in the study of puberty.[377] NMDA has also been shown to directly stimulate GnRH release from hypothalamic explants,[378] and spontaneous pulsatile GnRH release from hypothalamic tissues is suppressed by NMDA receptor blockade. In female rats, systemic challenge with NMDA evokes LH secretion in metestrus and proestrus rats but inhibits LH secretion in ovariectomized animals,[379] consistent with the findings that estradiol augments LH responses to NMDA stimulation.[380] One action of estradiol may therefore be to increase neuronal responsiveness to endogenous glutamate neurotransmission, possibly by increasing expression of receptors in GnRH neurons or other afferent circuitries. Glutamate release is increased in the preoptic area in association with estradiol- or estradiol and progesterone-induced LH surges[348,381] and antagonism of NMDA or AMPA receptors blocks estradiol-induced or preovulatory LH surges,[197,382,383] providing evidence that the positive feedback actions of steroid may also include stimulation of glutamate release.

Recordings of glutamatergic excitatory postsynaptic potentials (EPSCs) in GnRH cell bodies have not confirmed that glutamatergic activation of GnRH neurons is increased during the estradiol-induced LH surge,[374] although suppression of EPSC frequency was noted during the morning negative feedback phase. It is possible that increased glutamatergic neurotransmission may occur in dendritic synapses in GnRH neurons and would not be evident in this recording paradigm. Alternatively, estradiol may increase glutamatergic transmission at synapses on afferents to GnRH neurons. Further studies are required to more clearly characterize the cellular mechanisms by which estradiol may engage glutamate neurons in the service of feedback regulation of GnRH release.

MONOAMINES

The catecholamine neurotransmitters, principally norepinephrine (NE), have been known to be involved in the regulation of estrous cyclicity since the earliest days of neuroendocrine research.[384] The first indication was the demonstration that the α-adrenergic receptor antagonists dibenamine and SKF-501 blocked ovulation, presumably by preventing the release of an ovulation-inducing surge of LH.[262,385–387] Furthermore, blockade of the α-adrenergic postsynaptic receptor with chlorpromazine or depletion of catecholamines from presynaptic nerve terminals with reserpine also blocks ovulation.[388] Decades of subsequent research have provided evidence that NE and epinephrine-producing neurons in the brain stem are targets of ovarian hormone feedback signals, and can convey stimulatory synaptic signals for the release of GnRH and LH surges. For example, most catecholaminergic neurons in the caudal brainstem express the immediate early gene *cFos*, a correlate of excitation, coincident with the initiation of LH surges.[389] Subsets of these neurons also express ERα and send neural projections to preoptic and hypothalamic areas involved in surge generation.

Various measures of catecholamine turnover and release have been applied to assess the functional relationships between catecholaminergic neurotransmision in hypothalamic and preoptic areas and ovarian cyclicity. For example, with the semiquantitative microfluorometric assay, Lofstrom[390] observed that NE turnover is high in the subependymal layer in the ME of the rat during proestrus and low on all other days, while dopamine (DA) turnover rates in the lateral palisade zone of the ME are low on proestrus and high on other days of the cycle. While measuring the catecholamines by the more sensitive and specific radioenzymatic assay, Rance and co-workers[391] were able to thoroughly describe turnover rates of catecholamines in microdissected brain areas during the afternoon and early evening in proestrous rats. These were correlated with changes in GnRH concentrations in the ME and plasma concentrations of LH, FSH, PRL, estradiol, and progesterone. The concentrations of GnRH in the ME rose during the morning of proestrus (900–1200 h). At this time, plasma estradiol levels were elevated but both progesterone and FSH and LH remained basal. During this same time, both NE and DA turnover rates in the mPN, SCN, ARN, and the ME were low. Correlated with the beginning of the FSH and LH surges on proestrus, the ME concentrations of GnRH declined (1200–1400), while a significant rise in ME NE and DA turnover rates occurred. The decline in GnRH was probably a reflection of GnRH release into portal blood[154] and is correlated with the release of LH and FSH into peripheral plasma. During the time of enhanced GnRH, LH, and FSH release (1500–1700), turnover rates of NE in the ME remain elevated while those of DA decline. DA turnover rates also decline in the ARN but not the MPN. This decline in turnover of DA in the ME is correlated with enhanced release of pituitary PRL and is a reflection of the physiological inhibitory control the hypothalamus exerts over the secretion of PRL from the pituitary gland. Norepinephrine turnover rates remain elevated in the mPOA, SCN, and ARN and may be a reflection of the dynamic stimulatory control that NE exerts over the activity of GnRH neurons and subsequently the LH surge on proestrus.

In other studies, NE release in the POA has been monitored directly using push–pull perfusion[392] and more recently by microdialysis;[393] it was found to be increased in association with the initiation of LH surges. Moreover, selective lesioning of catecholaminergic terminals reduces LH surges, while reverse dialysis of NE stimulates LH secretion. Taken together, these findings reveal that caudal brain stem catecholaminergic neurons provide stimulatory signals for release of the LH surge, and hence for the progression of the estrous cycle. These signals may be modulatory in nature, however, and not obligatory for the release of LH surges; this idea is derived from the findings that depletion of hypothalamic catecholamines by transection of ascending noradrenergic pathways does not permanently impair ovarian cyclicity or release of LH surges.[394] That NE and epinephrine are not essential regulators of estrous cyclicity can also been inferred from the finding that dopamine β hydroxylase (*Dbh*) null mutant mice are fertile, and if treated during pregnancy with NE give birth to relatively normal progeny.[395] The caveat must be noted, however, that compensatory mechanisms may be engaged in both the foregoing pharmacological and gene targeting studies that obscure an essential role for NE in regulating ovulatory cyclicity under normal circumstances.

Most of the early data suggesting a role of the catecholamines in directly controlling GnRH release is inferential. That is, neurophysiological and neuropharmacologic manipulations within the diencephalon release LH, whereas application of pharmacologic agents directly

to the pituitary gland, in most cases, does not affect LH release. These data, along with a few direct measurements of GnRH in vitro[396] and in vivo,[397] have served to support the voluminous literature indicating that the catecholamines affect LH release by modifying the activity of GnRH neurons.[398] NE appears to be the most important of the catecholamines in controlling LH release. However, this catecholamine has a dual effect on LH release. Specifically, in the untreated ovariectomized rat, infusion of NE or adrenergic agonists into the third cerebral ventricle inhibits pulsatile LH release.[399,400] In addition, stimulation of the noradrenergic cell group in the locus coeruleus blocks the release of LH on proestrus.[401] Presumably, NE inhibits neurons in the mPOA responsible for pulsatile GnRH release into portal blood.[402] This inhibition is mediated by excitation of β-adrenergic receptors[403,404] since the effects can be blocked with propranolol, a β-blocker, but not phenoxybenzamine, an α-blocker. On the other hand, in ovariectomized rats in which serum LH was maintained at basal levels by ovarian steroids, NE or α- (but not β-) adrenergic agonists induced GnRH[405] and LH release.[400,406,407] Moreover, treatment with α-antagonists blocked the release of the preovulatory "surge" of LH on proestrus.[408] The noradrenergic fibers responsible for stimulation of GnRH and subsequently LH secretion also appear to arise from cell bodies in the locus coeruleus.[409–412] These data, taken together, suggest that LH release may be inhibited by a β-adrenergic mechanism in the preoptic area and stimulated via excitation of α-adrenergic receptors on GnRH neurons or unknown afferents to GnRH neurons.

Electrophysiological studies have revealed that the direct effect of NE on GnRH neurons is hyperpolarizing,[413] a response that occurs through both α1 adrenergic and β-adrenergic receptors in tissues obtained from ovarectomized and ovary-intact mice. These data suggest that noradrenergic facilitation of GnRH release during the ovulatory cycle is exerted indirectly, through synaptic intermediates to GnRH neurons. Clarification of the physiological roles of noradrenergic control of GnRH and LH secretion awaits further study in new rodent models that enable signaling analyses in complex, defined neural circuitries.

Older studies also implicated central epinephrine in the regulation of GnRH release.[398] For example, blockade of the proestrous surge of LH with pentobarbital[414] or LY78335, an inhibitor of phenylethanolamine-*N*-methyltransferase (PNMT; the enzyme that converts NE to epinephrine[415]), could only be reversed by administration of epinephrine in the cerebral ventricles. Administration of DA or NE was ineffective. Moreover, selective pharmacological suppression of epinephrine synthesis delayed the proestrus-like afternoon accumulation of GnRH in the ME and the resultant proestrus-like LH surge in ovariectomized estrogen–progesterone-treated rats.[416] These experiments, together with others, suggest a facilitating role for epinephrine in stimulating GnRH and subsequently LH release on the afternoon of proestrus. That *Dbh* gene knockout mice and *Pnmt* gene knockout mice are fertile[417] suggests that the role of epinephrine, like that ascribed to NE, is not an obligatory one in the regulation of estrous cycle.

Most of the literature provides an uncertain role for DA in control of the cyclic release of LH in the rat. DA turnover in the ME declines prior to the LH surge on proestrus.[391] Moreover, activation of central DA receptors inhibits the pulsatile release of LH.[418–420] These studies imply that DA may be a physiological inhibitor of GnRH and consequently LH release. However, DA has also been shown to stimulate GnRH release from ME fragments in vitro.[421] This suggests a stimulatory role for DA in cyclic LH release. Although it was shown that intraventricular injection of DA will cause LH release in ovariectomized steroid-treated rats,[422,423] this has not been confirmed in other laboratories.[400,406] Therefore, at the moment, a role for DA in control of the cyclic release of LH has not been unequivocally established. It is clear, nevertheless, that DA can exert powerful inhibitory effects on GnRH neuron excitabiity, and that these actions are mediated by both presynaptic and direct actions on GnRH neurons through both D1 and D2 receptor subtypes. It is possible that these effects serve to modulate both transmission and responsiveness to surge-induced signals from neurons in the AVPv.[424]

There are a large number of studies implicating 5-hydroxytryptamine (5-HT), or serotonin, derived from cell bodies in the dorsal and median raphe nuclei as both inhibitory or stimulatory to GnRH and consequent LH release. Enhancement of serotonin activity in regions of GnRH neurons along the preoptic-tuberal pathway depresses episodic LH release.[425–427] On the other hand, a large number of studies also indicate a stimulatory role for serotonin in the LH surge mechanism on proestrus. Indeed, the timing role of the SCN in the circadian nature of the LH release apparatus may be a function of its serotoninergic innervation from the raphe,[428–430] because there appears to be a diurnal rhythm of serotonin metabolism within the SCN.[428] Moreover, pharmacologic blockade of this rhythm disrupts the proestrous surge of LH[431] as well as the estrogen-induced daily surge of LH in ovariectomized rats.[430] However, lesions of the midbrain raphe, which reduce hypothalamic levels of serotonin, also diminish the estrogen-induced surge of LH in ovariectomized rats.[429,430] Taken together, these data imply that serotonin plays a dual role in release of LH: inhibitory to the GnRH pulse generator and stimulatory to the daily periodicity of the circadian oscillator. A study provided evidence that these dual actions of serotonin may be exerted in part by direct postsynaptic actions on GnRH neurons to regulate their electrical

excitability.[432] Thus, most GnRH neurons were found to exhibit a biphasic response to serotonin comprised of a rapid inhibition and slower excitation mediated respectively by the 5-HT1A and 5-HT2A subtypes of the serotonin resceptor. The physiological significance of this dual control remains to be clarified.

ENDOGENOUS OPIOID PEPTIDES

The endogenous opioids have been shown to play a physiological inhibitory role in the release of LH during the estrous cycle. Much of our understanding arises from the use of opioid receptor agonists such as morphine sulfate, analogs of the opiates, or opioid receptor antagonists such as naloxone or naltrexone. Morphine and the endogenous opioids block the proestrous surge of GnRH and subsequently LH,[433] as well as the LH surge induced by ovarian steroids in ovariectomized rats.[434,435] Early studies suggested that these effects may be due to the suppression of NE and epinephrine release from neurons that control GnRH secretion.[434,435] Through use of the μ opiate receptor blocker, naloxone, it is apparent that endogenous opioid tone is greatest on the days of metestrus, diestrus, and estrus and diminished immediately before and during the LH surge on proestrus.[436/437] In addition, the opiate tone is also reduced around the time of LH release in ovariectomized[438] or ovariectomized, steroid-treated rats.[437] These data, taken together, suggest that the endogenous opioids may play a physiologically significant restrictive role in control of LH secretion. The changes in opioid tone may be controlled, in turn, by the ovarian steroids.

Perhaps the most widely studied endogenous opioid peptide that may regulate LH secretion (and that of FSH and PRL) during the ovarian cycle is β-endorphin, which inhibits both pulsatile[439–441] and preovulatory[433–442] release of the gonadotrophins. β-endorphin, along with α-melanocyte-stimulating hormone (MSH) and other biologically active peptides, are derived via posttranslational proteolytic processing of the precursor protein, proopiomelantocortin (POMC), which is expressed at highest levels in the central nervous system (CNS) in a discrete neuronal population within the ARN. The POMC neurons in the ARN send projections to the rostral POA[443] and sites within the hypothalamus, through which they presumably act to suppress GnRH release in portal blood.[433,444] The actions of β-endorphin are mediated by μ opioid receptors[436,437] and may in part be exerted directly on GnRH neurons,[445] although one study failed to detect μ opioid receptor gene expression in GnRH cells.[446]

It has been hypothesized that POMC neurons convey negative feedback actions of estradiol during the ovulatory cycle because concentrations of the peptide in the POA, ARN, and ME are highest in diestrus and lowest in hours leading to the preovulatory GnRH and LH surges.[447] Estradiol can directly activate POMC neurons in hypothalamic tissue slices from guinea pigs, at least in part by desensitizing (uncoupling) $GABA_B$ receptors from their G-protein-gated inwardly rectifying K^+ channels.[448] A subset of POMC neurons expresses ERα, and POMC cell-specific deletion of these receptors results in reproductive deficits, including altered estrous cyclicity and reduced litter size.[449] Interestingly, however, estradiol failed to suppress LH secretion in these animals following ovariectomy, although it should be noted that postovariectomy LH levels were attenuated to the extent that suppression by the steroid may have not have been observable.

There is also evidence that prodynorphin-derived peptides, especially dynorphin A, may regulate GnRH and LH secretion on the afternoon of proestrus. Reduced expression and release of the peptides may serve to disinhibit GnRH neurons at the time of the proestrus surge,[450] as suggested by experiments in which infusions of the peptide were shown to block the LH surge, while local, passive immunoneutralization of the peptides in the MPOA advances the release of the LH surge.[451] These actions appear to be mediated by activation of kappa opioid peptide receptors.

RFAMIDE-RELATED PEPTIDE 3

RFRP-3, like kisspeptin, is a member of the arginine-phenylalanine-amide (RFamide) family of neuropeptides, but their effects on reproductive hormone secretions are diametrically opposed, with RFRP-3 inhibiting LH secretion. RFRP-3, which is the avian orthologue of GnIH identified by its ability to inhibit gonadotropin release from quail pituitaries in vitro,[452] is found in rodents to be produced by neurons located in the hypothalamic dorsomedial nucleus (DMN).[453] These neurons have been found to co-express ERα and form close appositions with GnRH neurons in hamsters.[453] In ovariectomized hamsters, systemic as well as intracerebroventricular injections of RFRP-3 rapidly suppress LH secretion, implying both central and pituitary actions of the peptide in this species. Similar studies in rats have not provided as clear a picture of the peptide's actions. One group has found that RFRP-3 decreases LH secretion when injected peripherally but not intraventricularly;[454] another found no effect of intravenous injections of RFRP-3 on serum LH.[455] Support for a central regulatory role for RFRP-3, however, comes from the observations that a subset of GnRH neurons express GPR74, a high-affinity receptor for the peptide, and that RFRP-3 exerts a direct postsynaptic inhibitory effect on GnRH neuron firing by activation of an inwardly rectifying K^+ conductance.[456,457] To date, there have been no direct tests of the hypothesis that RFRP-3 neurons directly or indirectly convey feedback effects of ovarian steroids on GnRH and LH secretion. That RFRP-3 neurons modulate a subset of kisspeptin cells in mice[455] adds to the possible scenarios by which this may occur.

NEUROPEPTIDE Y, OXYTOCIN, GALANIN, AND OTHER CENTRAL PEPTIDERGIC MODULATORS

A neurohumoral role for NPY, OT, and galanin in the control of LH secretion was identified above. Most of the literature shows that NPY enhances the LH and FSH-secretory responses to GnRH in vivo,[182,185,188,458–461] yet the data are equally compelling for a neuromodulatory role of this peptide. NPY stimulates the release of GnRH from the medial basal hypothalamus in vitro,[460] and synaptic contacts have been identified between GnRH and NPY-containing axonal fibers in the septo-POA.[462] LH surges are attenuated in NPY-knockout mice.[193] These neuromodulatory effects are probably mediated by Y1 receptors.[463] Estradiol induces NPY1 receptor expression through nonligand-dependent activation of PR.[464,465] The stimulatory actions of NPY on GnRH release are heightened on proestrous,[464] suggesting that the preovulatory surge of estradiol may upregulate responsiveness to NPY stimulation through Y1 receptors by stimulating expression of these receptors in the mediobasal hypothalamus. Taken together, the foregoing findings support a role for NPY and Y1 receptors in mediating a portion of the positive feedback action of estradiol.

Although the bulk of the evidence suggests that NPY exerts stimulatory effects on GnRH neurosecretion, there are also data to suggest that NPY may inhibit GnRH neurosecretion by acting centrally at a Y-5 receptor.[466] Thus, it appears quite likely that NPY enhances the surge mode of GnRH neuronal activity through Y-1 receptors yet inhibits basal GnRH neuronal activity through a Y-5 receptor. On the other hand, stimulation of basal GnRH release may be attributed to a Y-4 receptor.[467] Taken together, it seems that summoning the well-known link between undernutrition and the loss of fertility, the stimulation of NPY activity by negative energy balance may also lead to an inhibitory effect on GnRH neurons.[468,469] OT may also act as a neuromodulator. Central but not peripheral administration of an antiserum to OT blocks the proestrous surge of LH,[470] suggesting a neuromodulatory role for this peptide in the control of GnRH secretion. Excitatory effects of OT may occur at GnRH axon terminals,[471] stimulating the activity of nitric oxide synthase via NE and resulting in an increased release of nitric oxide, which increases prostaglandin-E2 release that in turn induces GnRH release.[472,473]

Galanin may also act as a neuromodulator because it stimulates NE release from hypothalamic slices.[474] Because galanin has been found to be an estrogen-inducible secretory product of the anterior pituitary,[475,476] it could subserve a paracrine/autocrine role in that gland.[477] Moreover, because galanin genes are expressed in hypothalamic GnRH-containing neurons, there is a possibility of autocrine regulation at the hypothalamic level.[478]

Other neuropeptides have been shown to affect release of LH under a variety of experimental conditions. However, to date, none have been shown to play a physiological role in control of cyclic release of LH. Those neuropeptides shown to inhibit LH release include arginine-vasotocin,[479] cholecystokinin,[480] neurotensin,[481] and gastrin.[482] The neuropeptides that have been shown to stimulate LH release include substance P.[481] In contrast, angiotensin II,[483,484] VIP[485–487] by a hypothalamic site of action on GnRH neurons,[308] and human pancreatic peptide[488] have been shown to have dual effects on LH secretion: the peptides are inhibitory in untreated ovariectomized animals and stimulatory in steroid-treated ovariectomized rats.

Circulating Orexigenic and Anorexigenic Factors Regulating the Estrous Cycle

Circulating adipocytokines, which were originally described for their orexigenic or satiety properties, have more recently been implicated in control of reproductive events such as puberty and the estrous cycle. It is not surprising that these peptides may have a critical role in reproduction because it has been well known that reproduction and reproductive development is optimally tied to feeding state. Although the adipocyte-derived satiety hormone, leptin, is not the primary signal that initiates the onset of puberty and estrous cyclicity, it acts in a permissive fashion, as a metabolic gate, to allow pubertal maturation to proceed if and when metabolic resources are deemed adequate.[489,490] In the adult, leptin stimulates LH, FSH, and PRL release in vitro[491] and in vivo.[492] Leptin also stimulates GnRH secretion in vivo[492] and in vitro.[493] This is not terribly surprising because leptin receptors have been found in the anterior pituitary gland,[494] in areas of the hypothalamus known to control secretion of these hormones,[495] and on hypothalamic neurons containing ERs.[496] However, the physiological significance of such observations should be tempered with caution because acute immunoneutralization of endogenous leptin in circulation is without effect on the proestrous as well as the estrogen/progesterone-induced surges of LH and PRL.[497] On the other hand, cycling rats treated with leptin antiserum for 8 days become anestrus.[498]

Studies have demonstrated that the ventral premammillary nucleus functions as an important target for leptin in the manifestation of its stimulatory effects on reproduction.[499] Lesions of this area disrupt estrous cycles, reduce LH levels, and prevent the ability of leptin to restore LH secretion during fasting. Moreover, re-expression of leptin receptors in the ventral premammillary nucleus is sufficient to induce puberty and improve fertility in female leptin receptor knockout mice.[500]

Central orexigenic neuropeptides also affect reproductive cyclicity. The orexins,[501] also known as

hypocretins,[502] are cleaved from a common precursor, prepro-orexin (130 aa residues), to form orexin A (residues 33–36; hypocretin 1 28–66) and orexin B (residues 69–96; hypocretin 2 residues 69–97). Orexin receptors are widely distributed throughout the hypothalamus. A subtype of the receptor, orexin 1, is found on GnRH neuronal cell bodies in the hypothalamus but not on GnRH terminals in the ME.[503] Orexin A fibers are also found in close apposition to 75–85% of these GnRH cell bodies.[503] Orexin A peptide is a potent stimulator of GnRH release from hypothalamic explants obtained from proestrous rats with diminished effects on explants obtained at other stages of the estrous cycle.[504] Similarly, intracerebroventricular injection of orexin A into estrogen/progesterone-treated ovariectomized rats, stimulates LH release in a dose-dependent manner.[505] However, the actions of orexin A on LH release may be site-specific. Indeed, injection of the peptide into the rostral preoptic area stimulates LH secretion; injection into the mPOA or the ARN/ME area inhibits LH secretion in ovariectomized estrogen/progesterone-treated rats.[506] Finally, hypothalamic content of orexin A is greater on proestrus than any other day of the estrous cycle in rats.[507] These data, taken together, suggest a potentially important role for the orexins in regulating the ovarian cycle of the rat.

The Gas Nitric Oxide as a Possible Regulator of the Estrous Cycle

Though the role of peptide and amine neurotransmitters in the regulation of the estrous cycle have been appreciated for some time, it is only recently that the neuroendocrine community has found that the gas nitric oxide (NO) plays a role as a neurotransmitter regulating the hypothalamo–pituitary axis. Unlike classical peptide and amine neurotransmitters, NO is not released from synaptic vesicles, does not interact with discrete receptor proteins, and does not function exclusively at synapses. NO is synthesized from the substrate L-arginine catalyzed by the enzyme nitric oxide synthase (NOS). There are three major isoforms of NOS that have been identified: neuronal NOS (n-NOS or type 1), macrophage NOS (m-NOS or type 2), and endothelial NOS (e-NOS or type 3).[508] n-NOS and e-NOS are constitutive, calcium- and calmodulin-dependent enzymes; m-NOS is an inducible calcium- and calmodulin-dependent enzyme. NOS has been found in the PVN, SON, OVLT, mPOA, SCN, ME, and ARN.[509–513] However, n-NOS is not co-localized in GnRH neurons obtained from rats[514,515] but is found in neurons bearing NMDA receptors.[509] Blockade of NO synthesis suppresses the LH surge in ovariectomized, steroid-treated rats,[516] and stimulation of NO release in cultured mediobasal hypothalamic tissues increases GnRH release.[517] However, stimulation of NO release in the POA suppresses GnRH neuronal firing,[518] indicating that NO effects on GnRH secretion are site specific.

Currently, it is believed that NO modulates GnRH release indirectly by influencing the GnRH secretory response to a host of stimulatory factors. These include the mediation of the GnRH secretory response to estradiol,[516,517,519–522] NPY,[523–525] and leptin.[526,527] Finally, NO has been found in gonadotrophs of the anterior pituitary gland[528] and is stimulated[529] or inhibited[530] by estradiol and stimulated by GnRH.[531] A precise role for NO of pituitary origin has yet to be described.

Growth Factors as Possible Regulators of the Estrous Cycle

Among the growth factors, epidermal growth factor (EGF), insulin-like growth factors (IGF), and nerve growth factor (NGF) may be implicated in the neuroendocrine control of the ovarian cycle of the rat.[532] Much of the data suggest a supportive role in the facilitation of LH and FSH secretion. Prior to the preovulatory release of LH during the late afternoon of proestrus, there is a significant increase in the proportion of gonadotrophs in the anterior lobe of the pituitary gland.[533–536] During this same period, there is an increased expression of EGF and EGF receptor on gonadotrophs to reach a peak on the afternoon of proestrus.[537,538] Both EGF itself and GnRH independently increased the expression of EGF receptor on gonadotrophs.[532] In addition to its mitogenic effect,[539] EGF may also be responsible for differentiation of gonadotrophs bearing GnRH receptors.[540,541] EGF release from gonadotrophs appears to be controlled by estradiol[542] as well as GnRH.[542] Taken together, it seems that EGF subserves an important autocrine or paracrine role by increasing the proportion of gonadotrophs responsive to GnRH, which will produce the ovulation-inducing surge of LH.

Studies have suggested that IGF-1 and the IGF-1 receptor may serve an important role in coordinating somatic development with the pubertal initiation of cyclicity and its maintenance in adulthood. Mice with the deletion of the IGF-1 receptor, but not the insulin receptor, in GnRH neurons exhibit delayed pubertal development with normal fertility. Administration of IGF1 advanced puberty in normal females but was ineffective in the GnRH-IGF-1 receptor knockout mice.[543] Blockade of IGF-1 receptors attenuates steroid-induced LH surges and reduces the percentage of GnRH neurons expressing cFOS in the preoptic area.[544] Long-term IGF-1 gene therapy in the MBH preserves estrous cyclicity in middle-aged female rats, suggesting that this growth factor may additionally play a role in the maintenance of adult GnRH neuronal function and protection against premature aging associated declines in activity.[545] During the estrous cycle of the rat, the number of synaptic

inputs to neuronal somas in the ARN decreases between the morning of proestrus and the morning of estrus. This decline in synaptic input and the accompanying increase in glial ensheathing of neuronal somas are blocked by an IGF-I receptor antagonist. In contrast, the IGF-I receptor antagonist did not affect the basal number of synapses or the morphology of synaptic terminals or length of the synaptic contacts. These findings indicate that IGF-I receptor activation may be involved in the phasic remodeling of ARN synapses during the estrous cycle.[546] Both IGF-I and IGF-II may additionally regulate LH secretion at the level of the pituitary gland, as both enhance basal and GnRH-stimulated LH release in vitro.[547–549]

Nerve growth factor (NGF) is a 26-kd protein found colocalized in virtually every cell of the anterior pituitary gland[550–553] and secreted.[550] Many of these same cells also contain the high affinity form of the NGF receptor.[551] NGF is also found in the ovary[554] as well as in the CNS.[555] However, the levels of the protein or the message do not appear to differ throughout the estrous cycle of the rat.[555] Although there are no data to suggest a direct neuroendocrine control of the ovarian cycle, its importance may lie in a potential role in differentiation of somatomammotrophs into mammotrophs.[552,556,557]

Follicle-Stimulating Hormone

It is apparent from the earlier discussion (Patterns of Pituitary Hormone Secretion and mRNA Levels during the Estrous Cycle) that the pattern of secretion of FSH bears some basic similarities to that of LH. The basic differences are the bimodal pattern of FSH secretion on proestrus through early estrus[52,62,85,89] and the longer interpulse interval of FSH than LH in gonadectomized animals.[95] It will be apparent from the following discussion that these differences may be attributable to differential control of FSH and LH secretion by the hypothalamus as well as by ovarian steroidal and nonsteroidal hormones. Because the common control of basal FSH and LH secretion by GnRH has been discussed, most attention is focused on the ovarian factors that regulate FSH secretion and their potential interaction with GnRH stimulation.

Role of Ovarian Steroid and Nonsteroidal Hormones Secreted Throughout the Estrous Cycle

The similarities in control of FSH and LH secretion by ovarian steroids abound. For example, just as the most potent negative feedback for LH is mediated by estradiol secreted from late estrus through early proestrus, the same relationship obtains for inhibition of FSH secretion.[104] Moreover, secretion of progesterone during this same interval potentiates the inhibitory effect of estrogen on secretion of FSH. However, not all of the inhibition of FSH secretion can be attributed to the ovarian steroids. Much of the physiological literature favors a major role for inhibin, a protein hormone originally designated as such in the male[558] and as folliculostatin[559] in the female. The hormone is primarily synthesized by the granulosa cells of the ovarian follicle[560] and appears in high concentration in follicular fluid. In fact, porcine follicular fluid (pFF) orignially served as a reliable source of inhibin bioactivity. In addition, the bioactivity or immunoreactivity is found in ovarian venous plasma,[561–563] the corpus luteum of pseudopregnancy[564] and the anterior pituitary gland within the gonadotroph[565] of the rat.

The initial evidence for the existence of a nonsteroidal ovarian factor regulating cyclic FSH secretion was indirect. Simulation of the patterns of estradiol and progesterone circulating throughout the estrous cycle are

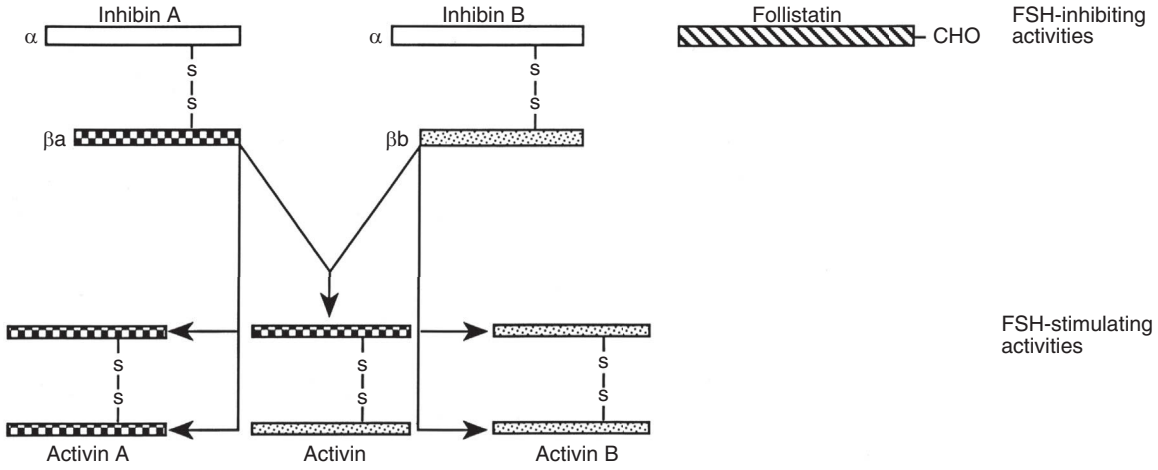

FIGURE 26.14 Diagrammatic representation of the three FSH-inhibiting proteins (inhibin A, inhibin B, follistatin) and three FSH-stimulating proteins (activin AB, activin A, activin B) found in the gonads of the rat. Similar patterned bars represent similar amino acid sequences in the respective subunits. Arrows point to proposed structural relationships between the inhibins and activins. See text for details.

sufficient to maintain basal and induce surge quantities of LH in ovariectomized rats.[566] However, both basal levels and surge concentrations of FSH are 2–3 times higher in these steroid-treated ovariectomized rats than comparable secretory states in intact cycling animals.[566] Such observations argued for another ovarian factor that selectively inhibits excessive secretion of FSH and thus prevents uncontrolled follicular maturation. When administration of inhibin-containing porcine follicular fluid was superimposed upon the steroid treatments, both basal and peak concentrations of FSH were lowered to levels similar to those seen in intact cycling rats.[566] Interestingly, there was an inverse relationship between the amount of inhibin-like bioactivity in ovarian venous plasma and the secretion of FSH throughout the estrous cycle.[563] That is, during periods of basal secretion of FSH, inhibin-like activity in ovarian venous plasma is high; during the proestrous-estrous surge of FSH, the activity declines.

The activity of pFF attributed to inhibin was originally isolated and partially characterized as a 32-kd protein of 2 chains of 18 (designated as the α-subunit) and 14 kd (the β-subunit), respectively.[567] Two forms of 32-kd inhibin, designated inhibin A and B (Figure 26.14), were actually isolated.[567] The two forms share the same α-subunit but their β-subunits, though similar, are distinguishable by N-terminal microsequencing (Figure 26.14). The cDNA clones of the α- and β-subunits of inhibins A and B were isolated from a porcine cDNA library and the N-terminal sequences of α-, βA-, and βB subunits used to design oligonucleotide probes.[568] The three rat inhibin subunits were subsequently isolated using the porcine cDNA clones.[569,570] The inhibins of the various species are highly conserved. During the course of purification of inhibin, two separate and distinct FSH-regulating activities were also found.[567] One of these, designated activin (Figure 26.14), showed potent FSH-releasing properties in the inhibin bioassay.[567] When the amino acid sequence of the inhibins was deduced, it was found that they bore striking similarities to TGF-β.[568] Although TGF-β will enhance FSH release in vitro,[571] the FSH-releasing activities in the preparation were found to be dimers of the β subunits of the inhibins (Figure 26.14).

Activin A and B are dimers of βA and βB, respectively[572] Activins are expressed in most tissues, including the pituitary gland, and act via local paracrine/autocrine actions to effect a variety of developmental and cellular processes.[572] In the pituitary gland, the major actions of activin include the stimulation of FSHβ gene expression and FSH secretion. A third FSH-inhibitory activity distinct from the inhibins was also isolated from pFF (Figure 26.14) during the original search for inhibin.[567] This single-chain glycosylated polypeptide has an MW of 35-kd and was designated follistatin.[573] It was subsequently shown that follistatin exists as 32, 35, and 39-kd glycoproteins,[574] the varying forms accounted for by varying degrees of glycosylation. Follistatins are extracellular binding proteins that function to sequester, and hence inactivate, activins and thereby inhibit FSH release from rat pituitary cells in vitro.[575] In general, follistatin is produced locally, whereas inhibin functions as an ovarian feedback signal, to counterregulate the stimulatory actions of activins on FSH synthesis in and secretion from pituitary gonadotropes.

Like other ligands in the TGFβ family, activins signal through binding to a type II receptor, which recruits and phosphorylates a type I receptor. The type I receptor then phosphorylates receptor-regulated signaling molecules called SMADs[576,577] and other downstream pathways that convey signals ultimately regulating gene transcription and cell function. Activin signals are transmitted through two type II receptors, ActRII or ActRIIB, and one type I receptor, ActRIB/ALK4.[576,577] Beta-glycan functions as an inhibin co-receptor which, when bound by inhibin, induces the formation of ternary complex with the ActRII or ActRIIB, and thereby prevents signaling by activins.[578] Circulating and local inhibins act through this mechanism, in parallel with the local effects of follistatin, to antagonize activins stimulatory effects on FSHβ gene expression and FSH release. These actions appear to be of major importance in differentially regulating FSH production during the estrous cycle.

Much of what we have learned about inhibin, activin, and follistatin actions in vivo[572] is due to the purification of reasonable quantities of these materials as well as the advent of recombinant technology. Using recombinant technologies, the peptides can be synthesized and used for biological studies as well as antibodies produced for immunoneutralization or radioimmunoassay. Recombinant inhibin will suppress FSH but not LH release in ovariectomized rats[579] but suppress both LH and FSH release on proestrus without an impact on ovulation rate 5 days later.[580] Similarly, recombinant activin A[581] or purified activin A[582] stimulates FSH synthesis and secretion in vivo,[581] stabilizes[583] and enhances[581] FSH-β mRNA in vitro, and enhances estradiol secretion in hypophysectomized rats.[582] Thus, activin A may not only stimulate FSH secretion, but it may also play an autocrine or paracrine role in controlling ovarian estradiol secretion. Administration of antisera to the inhibin preparations not only enhances FSH release during the estrous cycle but also increases ovulation rate during the next estrous cycle.[584,585] Measurements of immunoreactive inhibin-α subunit in peripheral plasma throughout the estrous cycle of the rat[584,586,587] confirms the measurements of bioactive inhibin in ovarian venous plasma.[563]

Serum concentrations of inhibin are high during the morning of proestrus and then decline sharply to the lowest levels by 24:00 h on proestrus after the preovulatory LH and FSH surges. Peripheral plasma levels of inhibin then returned to peak levels by 15:00 h on the afternoon of estrus from which they again rapidly declined to another low level by 24:00 h on estrus. Thus, serum levels of immunoreactive inhibin are inversely correlated with those of FSH.[52] Although both inhibin A and inhibin B are inversely correlated to FSH, they are discordant during the follicular phase of the cycle; inhibin A is low on the morning of metestrus and rises steadily to a peak on proestrus, while inhibin B is elevated elevated on the mornings of metestrus, diestrus, and proestrus. The differing patterns of inhibin A and inhibin B during the period of follicular development on metestrus and diestrus suggest different follicle sources or regulation of these molecules during this period.[588]

The estradiol-induced proestrous surge of GnRH is responsible for increased pituitary follistatin gene expression that is associated with the primary FSH surge on proestrus.[589–590] At the time of the trough between the primary and secondary surge of FSH on proestrus (Figure 26.2), there is decline in pituitary follistatin, an increase in free circulating activin A and pituitary content of FSH-β mRNA,[565] and a fall in ciruclating inhibin concentrations. These three events lead to the subsequent secondary surge of FSH secretion.

Much of the in vitro evidence points to a stimulatory effect of ovarian steroids on FSH secretion directly. Estradiol appears to stimulate LH and FSH secretion by acting on the pituitary directly.[281] Moreover, progesterone potentiates this stimulatory effect of estradiol on gonadotrophin secretion.[281] However, unlike its direct stimulatory effect on LH secretion, the apparent effect of progesterone on FSH secretion may be secondary to its stimulatory effect on FSH synthesis.[281]

Interrelationship of Steroid and Nonsteroidal Hormones and GnRH in Controlling the Cyclic Release of FSH

As previously described, the rising titers of estradiol by early diestrus have excited specific neurons within the hypothalamus to release a surge of GnRH into the portal vasculature during the afternoon of proestrus.[109,272] Concentrations of GnRH reach an initial peak in the late afternoon hours on proestrus, begin to decline and then reach a second lower peak at 0200 h on the morning of estrus. The second peak of GnRH release was originally proposed as a signal for release of the secondary phase of FSH secretion on estrus.[154] However, the selective release of FSH in the absence of continued LH secretion strongly suggests that GnRH-independent mechanisms must predominate in the regulation of the secondary FSH surge. Indeed, several lines of evidence suggest that the secondary (estrus) phase of FSH secretion may be independent of hypothalamic support. When spontaneous FSH release on proestrus is blocked with phenobarbital, infusion of GnRH reinstitutes the proestrous phase of FSH release.[591] Moreover, administration of an antiserum to,[204] or an antagonist of, GnRH on the early afternoon of proestrus[206,592] was effective in blocking the proestrous phase of FSH release. However, these same treatments were ineffective in preventing the estrous phase of FSH release when given on late proestrus. In addition, complete hypothalamic deafferentation on late proestrus does not prevent the estrus phase of FSH release.[593] Such data emphasize the fact that the proestrous phase of FSH secretion is dependent on direct hypothalamic stimulation while the estrous phase may be independent of direct support.

The secondary phase of FSH secretion, however, can be eliminated by blockade of the primary gonadotropin surge.[594] This observation suggested that the secondary phase of FSH secretion on estrus results from the ability of the primary gonadotropin surge to trigger an acute alteration in the selective ovarian feedback regulation of FSH secretion. It is now known that the secondary phase of FSH secretion is mediated in large part as a consequence of the withdrawal of negative feedback regulation by ovarian inhibin, which in turn appears to be dependent upon the release of the primary gonadotropin surge. Thus, the preovulatory surge of LH directs a precipitous drop in inhibin production by inducing transcriptional inhibitors of inhibin α in granulosa cells.[594] The acute reduction in serum inhibin, together with a drop in local follistatin production in the pituitary gland, likely disinhibits activin signaling and hence increases FSHβ expression and FSH secretion. Schwartz and colleagues have also provided evidence that progesterone and/or PR activation in pituitary gonadotropes may also contribute to the selective release of FSH on estrous.[595]

The additional contribution of a neurohormonal stimulator of FSH secretion during the estrous cycle, independent of GnRH, remains possible. The identity of separate FSH-releasing factor has been sought for decades, yet as of the writing of this review no such hypophysiotropic factor has been found.

Prolactin

As noted earlier, the pattern of secretion of PRL during the estrous cycle is quite similar to that of LH (Figure 26.2). That is, it is secreted in low basal amounts for the major portion of the cycle except for a "surge" quantity on the afternoon of proestrus. This surge begins approximately 2 h prior to the preovulatory surge of LH on proestrus but reaches peak values coincident with that of LH on proestrus. Enumeration

of the similarities and differences in controls of the two surges follow.

Role of Ovarian Steroids in Control of the Cyclic Secretion of Prolactin

There is overwhelming literature which clearly states that the dominant and perhaps sole stimulus for the proestrous surge of PRL is the rising titer of estrogen on diestrus through early proestrus. Indeed, just as neutralization of the circulating levels of estradiol with an antiserum blocks the proestrous surge of LH, it also blocks the proestrous surge of PRL.[242] Similarly, just as estrogen will induce daily afternoon surges of LH in ovariectomized rats, it will also stimulate daily surges of PRL.[239] These data, taken together, clearly show that the proestrous surges of LH and PRL are both linked to a 24-h clock wherein expression is closely linked to the presence of estradiol. Moreover, progesterone administered on diestrus-3 of a 5-day cycle will advance the proestrous LH[246] and PRL[596] surges 24 h. However, unlike the same effects on LH, progesterone neither enhances magnitude of estrogen-induced PRL surges nor extinguishes the estrogen-induced diurnal rhythm of PRL release (M. E. Freeman, unpublished). Although estrogen administration will elevate basal levels of plasma PRL in male rats, surge levels of PRL do not result from such administration.[239] Such a sexually differential response results from androgenization of the hypothalamo–pituitary axis of the males during neonatal life[239] (see also Chapter 47). It is not known if the larger AVPv in the female is functionally linked to the capacity for estradiol-induced PRLsurges, as it is for estradiol-induced LH surges.

Sites and Mechanisms Whereby Ovarian Steroids Control Prolactin Secretion during the Estrous Cycle

There is little doubt that one locus for the stimulatory action of estradiol is the lactotroph cell of the pituitary gland. Indeed, incubation of enzymatically dissociated pituitary cells with estradiol enhances both the basal- and TRH-stimulated release of PRL[597] Moreover, co-incubation with progesterone prevents the stimulatory effect of estradiol while progesterone alone exerts no effect.[597] Estradiol exerts its excitatory effect in part by blocking the inhibitory influence of DA. The DA agonist, CB-154, is less effective in inhibiting basal or TRH-stimulated PRL secretion in the presence of estradiol.[597] This antidopaminergic action of estradiol is probably not due to antagonism of the DA receptor[597] but may act at a postreceptor calcium- or cyclic AMP-dependent step.[597,598] In a sense, estradiol functions as a PRL responsiveness factor; decreasing responsiveness to DA and allowing some spontaneous PRL release as well as increasing responsiveness to TRH.[599] The molecular mechanisms that mediate these effects of estradiol during the estrous cycle are not fully known. On the day of proestrus, but not on other days of the cycle, DA activates an inwardly rectifying K+ current that rapidly hyperpolarizes the lactotroph membrane,[600] due to activation of G protein-coupled inwardly rectifying K+ channels (GIRKs). It has been hypothesized that the preovulatory estradiol surge confers signaling through this mechanism on this day, thereby engendering a PRL secretory rebound in association with the abrupt reduction of DA concentrations in portal blood on the afternoon of proestrus. Estradiol additionally stimulates PRL gene expression, likely through an ERα-mediated mechanism.[601]

Estradiol also stimulates the proestrous surge of PRL by acting at the hypothalamic level. Earlier studies revealed that a cut placed immediately behind the optic chiasm blocked the induction of a proestrous-like surge of PRL by exogenous estradiol.[602] Because this retrochiasmatic cut transected caudal efferents from the mPOA as well as the SCN, and the latter is a timing regulator,[105] one cannot be absolutely certain, on the basis of transection studies, of the exact site of estrogen action in inducing the proestrous surge of PRL. It is more certain, however, on the basis of focal lesion as well as localized implantation studies, that both the mPOA and the SCN play a role. For example, lesions of the mPOA prevented the estrogen-dependent proestrus surge of PRL[603] and the estrogen-induced afternoon surge of PRL in ovariectomized rats.[604] In addition, lesions of the SCN blocked the estrogen-induced afternoon surge of PRL in ovariectomized rats.[605–607] These data suggest that both the MPOA and the SCN are involved in the cyclic PRL secretory response to ovarian estradiol. They do not indicate if one or both sites respond directly to estrogen or indirectly through synaptic influence with other estrogen-responsive areas. On the other hand, implantation of cannulae containing sufficiently dilute crystalline estradiol into hypothalami of ovariectomized rats revealed sites that responded to such implants with proestrous-like surges of PRL.[605]

The possibility that the implanted estradiol gained access to the systemic circulation was monitored by vaginal smears and uterine weight patterns. This study revealed that the mPOA and the ventromedial nucleus (VMN) of the hypothalamus were most sensitive to estradiol implantation, while placement in other sites involved in the estradiol-response, the SCN and anterior pituitary, did not induce proestrus-like surges of PRL.[605] Although this study suggested that the SCN is probably not estrogen-responsive directly, more recent studies have suggested that estradiol acts within the SCN ensuring the fidelity of each PRL surge. Indeed, administration of estradiol increased the expression of the mRNA for the clock gene Cry 2 within the SCN but was without affect on the expression of Cry 1 mRNA.[608]

More recent data implicate cell bodies in the locus coeruleus (presumably noradrenergic) in the elaboration of the estradiol-induced surge of PRL on proestrus.[609] Specifically, lesion of the locus coeruleus blocked both the proestrous surge and the estradiol-induced surge of PRL without influencing basal secretion. Such an observation suggests the involvement of NE in the surge of PRL.

Dopamine and Candidate Prolactin-Releasing Hormones of Hypothalamic Origin

The chemical identity of the neurotransmitters and neurohormones regulating this estrogen-dependent proestrous surge of PRL is partially known. We now appreciate the fact that though the dominant hypothalamic input regulating pituitary PRL release is inhibitory, the release of the proestrous surge of PRL probably results in a delicate balance of acute removal of inhibitory input coupled with simultaneous stimulatory input from the hypothalamus.[610] It has been shown, though not without contradiction, that dopaminergic binding sites,[611] the turnover of DA,[612] the activity of dopaminergic neurons,[613] and DA levels in portal blood[614] are depressed on the day of proestrus, corresponding to an increased secretion of PRL into peripheral plasma. DAreceptors in the anterior pituitary gland have been reported to increase[611] and decrease[615] during the afternoon of proestrus. The source of DA controlling PRL secretion is believed to be tuberoinfundibular neurons (TIDA), with cell bodies in the ARN of the hypothalamus and axons terminating upon capillary tufts in the external layer of the ME (see Chapter 12). Long portal vessels emanating from these tufts deliver DA to the anterior lobe of the pituitary gland.[616,617] There is also ample evidence to suggest that DA arrives at the anterior lobe of the pituitary gland from the posterior lobe that contains axon terminals of tuberohypophysial dopaminergic (THDA) neurons, where cell bodies are found in the rostral part of the ARN.[618,619] Finally, DA may arrive from the intermediate lobe that contains axon terminals of periventricular hypophysial dopaminergic (PHDA) neurons where cell bodies are found in the periventricular nucleus.[620–622] The short portal vessels connecting the three lobes of the pituitary gland may serve as the vascular pathway through which DA is transported to the anterior lobe from the neural and intermediate lobes. Indeed, the fact that posterior lobectomy[623] or neurointermediate lobe denervation[619] results in chronic elevation of PRL secretion implicates both THDA and PHDA neurons in the control of PRL secretion.

The issue of the control of the activity of these dopaminergic neurons on proestrus is far from settled. The content of DA in the ME and portal blood declines prior to the onset of the surge of PRL secretion on proestrus.[614–616] The proestrus surge of progesterone has been implicated in the decline in dopaminergic tone in vivo,[624] while estradiol has been implicated in the short-term decline in the in vitro activity[625] and gene expression[626] of the rate-limiting enzyme in DA synthesis, tyrosine hydroxylase. Not only does the proestrous surge of progesterone suppress the expression of tyrosine hydroxylase mRNA in the ARN,[627] but it inactivates the enzyme by inducing dephosphorylation.[628] It is quite likely that both steroids play a role in the PRL-releasing decrease in DA synthesis and neurosecretion: estradiol initiating[625] and progesterone prolonging[629] the decline in tyrosine hydroxylase gene expression on proestrus. The signal for the reactivation of the dopaminergic neurons and the resultant decline in PRL secretion at the end of proestrus are the peak levels of PRL on proestrus.[630] Indeed, immunoneutralization of circulating PRL on proestrus prevents the elevation of DA concentration[631] and activation[613] of all three populations of hypothalamic dopaminergic neurons. These "short-loop" feedback actions of heightened PRL levels are likely manifest through the activation of PRL receptors coupled to signaling via signal transducer and activator of transcription 5 (STAT5) in TIDA neurons.[632]

The induction of an estrogen-stimulated proestrus-like surge of PRL is associated with a decline of DA levels in portal blood.[633] Such evidence suggests that DA is the physiological PRL inhibitor prior to the afternoon of proestrus and that a diminution of the levels of this neurohormone in portal blood is requisite for a surge of PRL secretion during the afternoon. Based on pharmacologic approaches,[599] candidates for the converse stimulatory hormones are many. The earliest physiological evidence pointed to the tripeptide TRH as the stimulatory neurohormone on the afternoon of proestrus. Indeed, TRH is a potent stimulator of PRL release.[599] The concentration of TRH in hypophysial portal plasma increases on the afternoon of proestrus, corresponding to the times of the PRL surge.[634] However, a concomitant surge of TSH does not accompany the proestrous surge of PRL,[635] and suckling, a potent stimulus for PRL release, does not evoke release of TSH.[635] It is possible that during the estrous cycle, receptors on lactotrophs are more abundant or have a higher affinity for the peptide than receptors on thyrotrophs, thus allowing the lactotroph the most sensitive secretory response to minute changes in levels of TRH in portal plasma. Immunoneutralization of TRH during proestrus has resulted in attenuation[211] or merely altered the timing[636] of the proestrous surge of PRL. Nevertheless, it is now inferred from studies in ovariectomized, estrogen-treated rats[633] and lactating rats[637–639] as well as in vitro studies[640] that optimal PRL release on proestrus in response to estrogen and progesterone or during lactation in response to suckling requires a diminution in DA release in concert with an increase in a PRH release into portal blood.

Studies have provided renewed interest in OT actions on the proestrus pituitary gland as an important determinant of the proestrous PRL surge. Plasma concentrations of OT are increased in response to estradiol,[641] and OT concentrations in portal blood reach peak values on the afternoon of proestrus.[178] Both passive immunoneutralization of OT[180,642] and administration of an OT receptor antagonist[179] inhibit release of the proestrus PRL surge. In addition, estradiol secretions may increase the responsiveness of pituitary lactotropes to the stimulatory actions of OT.[643] Thus, lactotrophs are significantly more responsive to OT and show enhanced intracellular Ca^{++} responses when tissues are harvested on proestrus versus diestrus. These effects may be mediated by upregulation of both OT receptor levels and enhancement of downstream signaling pathways.[644] Though not as thoroughly documented, there is abundant evidence that VIP may play a physiological role as a PRH on the afternoon of proestrus (see Ref. 645 for references). On the other hand, somatostatin, GABA, atrial natriuretic hormone, vasopressin, calcitonin, NPY, galanin, substance P, bombesin-like peptides, neurotensin, and even DA itself have been implicated as PRHs, but their physiological significance has not been satisfactorily unmasked at this time (see Ref. 645 for references).

As noted in a previous section, peptides isolated from bovine hypothalamus,[646] when synthesized,[647] specifically stimulated the release of PRL from pituitary cells of lactating rats. Two peptide sequences of 20 and 31 amino acids were isolated and quickly named prolactin-releasing peptide (PrRP). The PrRP mRNA for each is most abundant in the medulla oblongata,[648–650] whereas only moderate amounts are found in the hypothalamus and the anterior lobe of the pituitary gland.[649,651,652] Neither the 20- nor 31-aa peptide will stimulate PRL secretion from pituitary cells obtained from male rats; those obtained from random cycling female rats respond only to the highest dose of either peptide.[653] When administered intravenously, the 31-aa peptide stimulated PRL secretion in male as well as female rats in a dose-dependent manner with females responding in a more sensitive manner, particularly during proestrus.[654]

Immunocytochemical approaches have revealed PrRP-positive fibers in the paraventricular and supraoptic nuclei of the hypothalamus and in the neural lobe of the pituitary gland, with cell bodies found in the DMN and VMN of the hypothalamus.[652,655] Interestingly, the presence of PrRP-positive fibers in the neural lobe and the ability of the peptide to release OT[656] suggests that PRL-releasing properties of PrRP may be mediated through OT. Alternatively, the absence of PrRP-positive fibers in the external layer of the ME and presence in the posterior lobe of the pituitary gland[652,655,657] suggest the PrRP may reach the anterior lobe through the short rather than the long portal vessels. Though meager, some studies suggest that PrRP may play a role in the preovulatory release of PRL and even LH on proestrus.[658–671] In contrast, emerging literature illustrates the role of PrRP in autonomic homeostasis.[662] Indeed, PrRP has been implicated in regulation of cardiovascular function,[663–665] stress responses,[666–669] ingestive behavior and energy balance,[670–672] and sleep.[673–675] Taken together, it is clear that the rush to (mis-) name this peptide has not led to an unambiguous conclusion as to a physiological role.

Possible Roles for Prolactin Secreted during the Estrous Cycle

Although it is quite clear that PRL is luteotrophic during pseudopregnancy and early pregnancy, an indispensable role for PRL in control of the hypothalamo–pituitary–ovarian events of the estrous cycle has not yet been firmly established. It was initially suggested that the proestrous surge of PRL plays a luteolytic role during the estrous cycle.[676,677] However, the corpora lutea are already secreting relatively small amounts of progesterone by proestrus, so it seems unlikely that such input is necessary. On the other hand, a role for the proestrous surge of PRL in control of female sexual behavior has been suggested.[678] Inhibition of the proestrous surge of PRL with a DA agonist attenuates the lordosis quotient (LQ) on proestrus, while replacement with ovine PRL restores the LQ to normal. The enhanced LQ is also associated with the estrogen-induced PRL surge in ovariectomized rats. However, it is not certain at this point if PRL has a direct physiological role in enhancing female sexual behavior or if it may act by stimulating adrenal progesterone secretion[678] (see also Chapter 50). Finally, both pituitary and ovarian roles have been attributed to PRL secreted during the estrous cycle. Specifically, the proestrous surge of PRL may attenuate the pituitary GnRH-receptor level.[679] This would explain the decline in GnRH receptor that occurs on proestrus. Secondly, within the granulosa cells of the rapidly developing ovarian follicle on proestrus, the surge of PRL may be responsible for inhibiting estrogen-synthesizing aromatase enzyme activity,[680] as reflected in the rapid decline in blood estrogen levels on the early afternoon of proestrus after the PRL surge begins.[52] However, interference with either of these activities does not appear to have a major impact on the regular expression of the normal estrous cycle in the rat.

REGULATION OF THE CORPUS LUTEUM

Rescue of the Corpus Luteum

Earlier in this chapter, it was noted that the corpora lutea formed during the estrous cycle of the rat were only ephemerally active structures. That is, except for a brief interval shortly after ovulation, the corpora lutea do not secrete sufficient progesterone to maintain a

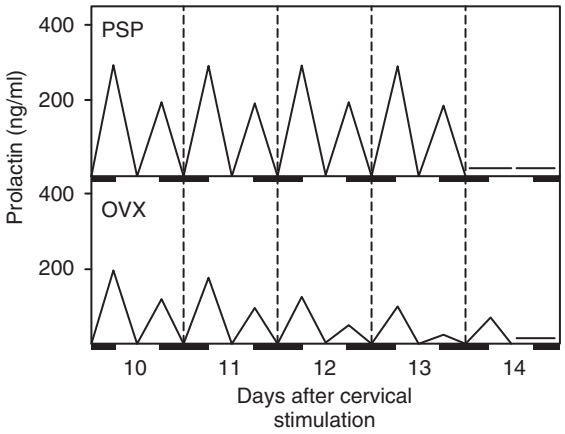

FIGURE 26.15 Diagrammatic representation of the nocturnal and diurnal surges of prolactin on days 10–14 after cervical stimulation in animals with intact ovaries (PSP, upper panels) and long-term ovariectomized rats (OVX, bottom panels). Values on the ordinate are approximate serum hormone concentrations (ng/ml NIAMDD-PRL-RP-1). Black bars on abscissa are the dark intervals in the animal quarters (18:00–06:00 h). During PSP the larger nocturnal and smaller diurnal surges persist for 12–13 days and end abruptly. The surges of prolactin in OVX rats are smaller than those of PSP rats. Moreover, as the days following cervical stimulation elapse, the magnitude of the surges gradually wanes. However, the surges themselves persist beyond a normal PSP.

decidual reaction in the uterus. Thus, the luteal phase in the rat is relatively brief, unlike that in species with spontaneous prolonged functional luteal phases of 14–16 days duration, such as guinea pigs, sheep, cows, pigs, monkeys, and humans (Chapter 23). However, the corpora lutea can be "rescued" from the quiescent state and transformed to the active state[52,681] by injection of PRL or transplantation of pituitary glands beneath the kidney capsule, which secrete copious amounts of PRL when removed from hypothalamic restraint.[682] In addition, corpora lutea may be rescued on diestrus by mating with a male rat on the previous proestrus. The corpora lutea of pregnancy persist for 20–22 days. Finally, mating with a sterile male or artificial stimulation of the uterine cervix results in a period of extended luteal function lasting 12–14 days. This interval is known as pseudopregnancy and is characterized by a period of heightened PRL secretion from the pituitary gland in response to the mating stimulus.[683,684] It is this PRL secretion that initially "rescues" the corpus luteum on diestrus[52] and allows it to respond to other luteotrophic factors.[58]

The Unique Pattern of Prolactin Secretion

Rather than being constantly elevated, the pattern of PRL secretion in response to mating is characterized by two daily surges.[683–685] One of these surges, called diurnal, begins in the afternoon (13:00–15:00 h), reaches peak values during the early evening (17:00–19:00 h), and returns to basal levels by 24:00 h. The other surge, called nocturnal, begins by 01:00 h, peaks by 03:00 to 07:00 h, and approaches baseline values by 11:00 h. This recurrent pattern (Figure 26.15) of PRL secretion continues throughout pseudopregnancy but ends abruptly by day 12 or 13.[686,687] This does not represent the typical neuroendocrine response to an acute stimulus. On the contrary, the PRL secretory response to suckling exemplifies the typical neuroendocrine reflex. Temporally, the response is tightly coupled to the stimulus. Within minutes of introduction of hungry pups, the nursing mother's blood levels of PRL increase. In addition, the magnitude of the increase is related to the intensity of the stimulus. That is, larger litters induce release of more PRL from lactating mothers than do smaller litters. The response is tightly stimulus-bound in that each subsequent secretory episode requires reinforcement by reapplication of the suckling stimulus provided by the pups. In contrast, the PRL secretory response to mating has some unique features not shared with other neuroendocrine reflexes.

Unlike the constantly elevated PRL secretion induced by suckling, mating-induced PRL secretion is surge-like, coupled to the time of day,[688] and is repetitive even without reapplication of the stimulus.[683,684] It should be noted that the requirements for mating-induced PRL secretion and the characteristics of this phenomenon are somewhat different in mice. In contrast to the induction of pseudopregnancy in rats, this process requires receipt of an ejaculate from the male.[689] Furthermore, mice exhibit a single diurnal PRL surge on day 6 of pseudopregnancy.[689] Differences in the pattern of FOS expression in the brains of pseudopregnant mice versus rats[689] suggest that the neural mechanisms that mediate the mating-induced PRL release patterns are also not identical in these two species.

Control of Mating-Induced Prolactin Secretion

Ovarian and Uterine Controls

The PRL surges in rats are somewhat independent of the ovaries in that they continue in an attenuated form if the ovaries are removed within hours of cervical stimulation or can be initiated by and continue for several days after brief cervical stimulation of long-term ovariectomized rats.[686,690] Thus, the basic neuroendocrine reflex remains in the absence of ovarian steroids. However, ovarian steroids do play a role in the control of mating-induced PRL surges. Progesterone magnifies the nocturnal surge and prolongs the recurrent nature of both the nocturnal and diurnal surges of PRL.[686,690] Moreover, estradiol magnifies the diurnal surge and abolishes the nocturnal surge. Though the steroids are not required for initiation or maintenance, they seem to play a role in the termination of these surges on a timely basis. The surges end abruptly by day 12–13 in

pseudopregnant rats (Figure 26.15) but wane gradually in ovariectomized, cervically stimulated rats through day 14.[686] This result implies an ovarian role in their abrupt termination. Indeed, the diurnal surge is terminated by the gradual withdrawal of progesterone as the corpus luteum wanes at the end of pseudopregnancy, whereas the nocturnal surge is terminated by the rising level of estradiol secreted by the newly developing follicle at this time.[686]

Just as the disappearance of PRL surges at the end of pseudopregnancy is associated with a decline in luteal activity,[686,691,692] the presence of the surges beyond day 13 is associated with lengthening of the functional lifespan of the corpus luteum. Specifically, in hysterectomized rats, regression of the corpus luteum is prevented[693] and the surges of PRL continue for several days beyond a normal pseudopregnancy.[596,694] Although it is possible that the PRL surges are terminated indirectly because of regression of the corpus luteum induced by a uterine luteolytic agent,[693] the uterus may also secrete a substance that acts directly at the hypothalamo–pituitary axis to terminate PRL surges. Indeed, the nocturnal surges of PRL are still present 16 days after cervical stimulation in long-term ovariectomized rats in the absence of the uterus but not when the uterus is in place.[694] Because there is no luteal tissue to be maintained in these animals, the continuation of the surge must be due not to persistent progesterone secretion, but to direct restraint provided by the uterus. In fact, the uterus must be present for the ovarian steroids to effectively inhibit the surges of PRL secretion.[695] This implies that the nonpregnant uterus may secrete a substance that acts at the hypothalamo–pituitary axis to modify PRL secretion.

Prolactin-inhibitory activity has been extracted from the uterus and shown to be specific for its tissue of origin and hormone on which it acts.[696] Moreover, it has been demonstrated that uterine epithelial cells secrete the activity, while its presence in peripheral blood is correlated with the presence of the uterus.[697] Although there are many questions remaining unanswered regarding the PRL inhibitory activity of the uterus, these data suggest that the nonpregnant uterus may function as an endocrine organ regulating PRL secretion.

Neural Sites Mediating the Prolactin Secretory Response to Cervical Stimulation

The pelvic nerve is the primary sensory afferent from the cervix.[698] The message provided by cervical stimulation ascends to the brainstem through the anterolateral columns of the spinal cord. The central neural areas responsive to cervical stimulation include the lateral reticular nucleus, the central gray, the gigantocellular reticular nucleus, and the dorsal raphe nucleus.[699–701] The induction of nocturnal surges of PRL can be prevented by transections in the ventromedial and lateral part of the midbrain.[702]

Within the hypothalamus, three areas have been implicated in the control of PRL release in response to cervical stimulation. Lesions of the dorsal mPOA cause repetitive pseudopregnancies[135] characterized by nocturnal but not diurnal surges of PRL.[136] Moreover, the lesion will block the diurnal surge induced by cervical stimulation.[136] These studies suggest that the mPOA possesses two types of neurons: those tonically inhibitory to nocturnal surges and those potentially stimulatory to diurnal surges. Cervical stimulation acts by inhibiting the former and stimulating the latter.[703] Because destruction of the mPOA leads to consecutive spontaneous luteal phases approximating those of other mammals, one can speculate on the evolutionary significance of the primacy of the mPOA. The activation of repetitive luteal phases by destruction of the mPOA suggests that the rat has a short estrous cycle characterized by a quiescent corpus luteum due to the tonic inhibitory activity provided by the mPOA over secretion of the luteotrophic hormone, PRL. Perhaps phylogenetically, an active mPOA that stimulates ovulation-inducing LH surges and inhibits luteal-activating PRL surges in rodents is the more primitive form. The more advanced form may be mammals, which are not dependent on the mPOA for LH secretion, ovulation, and subsequent luteal activation. Indeed, rhesus monkeys secrete perfectly normal LH surges in response to estrogen when only their medial basal hypothalami are intact[704] (see also Chapter 28).

The second area implicated in mating induced PRL secretion includes the DMN and the VMN of the hypothalamus. Electrical stimulation of the DMN-VMN induces a pseudopregnancy characterized by nocturnal and diurnal surges of PRL.[136,705] However, a lesion of this area does not interfere with estrous cyclicity, the ability to mate and support a pregnancy to term, or secrete a nocturnal surge of PRL.[705–707] Such a lesion only interferes with the diurnal surge of PRL.[706] In fact, the intact DMN-VMN is required for the stimulatory but not the inhibitory control of the PRL surges by the mPOA.[708] The third area of the hypothalamus shown to be important in mating-induced PRL secretion is the SCN. When lesioned, both surges of PRL that had been induced by mating are completely abolished.[709] Because this area has been characterized as a master pacemaker for PRL release,[710] it is probably the timer involved in transducing the time-of-day signal for these regular PRL surges.[105] At the moment, the functional interrelationships between these areas is not yet fully appreciated.

Neuroendocrine Control of the Prolactin Secretory Response to Cervical Stimulation

Although there is a reasonably expansive literature describing the neuroendocrine control of suckling-induced

PRL secretion,[599] the same is not true describing control of mating-induced PRL release (see also Chapter 12). An early study described the relationship between DA levels in hypophysial portal blood and the release of PRL surges in cervically stimulated rats.[711] As expected, there was an inverse relationship between DA levels in portal blood and PRL surges in peripheral blood. That is, during the surges, DA levels were 36% lower in cervically stimulated than control ovariectomized animals, while during intersurge intervals there was no difference between DA levels in portal blood of control and cervically stimulated rats.

The reason for this periodic inhibition of DA release into portal blood has been studied using the accumulation of L-dopa in the ME as an index of TIDA nerve activity.[712] In this assay system, the amount of L-dopa accumulated in the ME is inversely related to the activity of dopaminergic neurons. The activity of these dopaminergic neurons, in turn, is inversely correlated with the PRL surges induced by mating and may indeed be controlled by them.[712] Thus, as the PRL surge occurs in response to diminution of DA secretion into portal blood, these high levels of PRL may feedback to stimulate the activity of these TIDA dopaminergic neurons, which results in DA release into portal blood and consequent inhibition of PRL secretion.[713] Such feedback loops result in phasic rather than enhanced basal secretion and may be the basis for the two daily surges of PRL secretion in mated animals. This issue, coupled with the possible involvement of a mating-induced PRL releasing factor, is currently under study.

To determine if the decrease in DA levels is solely responsible for release of PRL in cervically stimulated rats, the synthesis of DA was blocked with α-methyl para tyrosine in ovariectomized noncervically stimulated rats. Dopamine was then infused peripherally at rates that resulted in portal blood levels simulating those of cervically stimulated rats.[711] Dopamine concentration in physiologic ranges inhibited PRL secretion, but pharmacologic quantities were required to suppress PRL to basal levels characteristic of the intersurge intervals. Moreover, a 36% decrease of infused DA resulted in only a 1.5-fold increase in PRL levels, while a 36% spontaneous decrease in DA secreted into portal blood in the cervically stimulated rat was associated with a four- to fivefold increase in PRL secretion.[711] Such observations argue for the involvement of another additional inhibiting factor or more likely a PRL releasing factor activated by cervical stimulation.

Studies have revealed the basic components of the neuroendocrine mechanisms producing the mating-induced PRL secretory rhythm. These involve reciprocal interactions between PRL, DA, and OT, with VIP input from the SCN. As we have noted, hypothalamic DA inhibits lactotroph activity via activation of D2 receptors.[714] PRL exerts feedback control over its own secretion

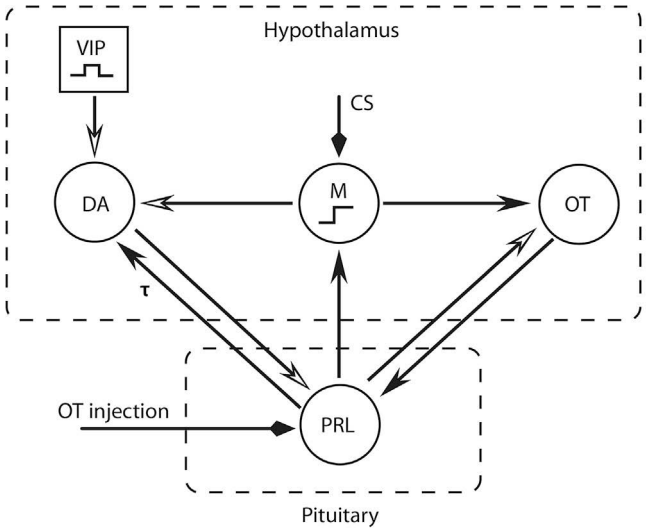

FIGURE 26.16 Proposed model for the prolactin (PRL) rhythm initiated by cervical stimulation (CS) or by oxytocin (OT) injection. Closed arrowheads indicate stimulatory actions, open arrowheads indicate inhibitory actions. The stimulation of dopamine (DA) neurons by PRL has a delay of τ hours. A pulse of vasoactive intestinal polypeptide (VIP) from suprachiasmatic neurons occurs every morning, setting the phase of the PRL oscillation. The memory, M, is switched on by CS or by PRL. *Adapted from Ref. 721.*

by activating its cognate receptors in hypothalamic DA neurons and stimulating the production and release of DA; these actions are likely mediated by phosphorylation and hence activation of tyrosine hydroxylase, as well as a more protracted increase in tyrosine hydroxylase gene expression.[715,716] A rhythm of PRL secretion would thus be predicted to occur as a consequence of the integration of these antiphasic, temporally locked feedforward and feedback actions. Additional findings have demonstrated that VIP neurons in the SCN, which innervate and inhibit dopaminergic neurons in the ARN in the morning hours,[717] appear to dictate the timing of the nocturnal PRL surge and amplify it relative to the diurnal surge.[718] The importance of this input has been confirmed by the finding that administation of VIP antisense oligonucleotides in the SCN alter PRL rhythms in cervically stimulated rats.[719] The actions of OT, functioning as a PRL-releasing factor in lactotropes, were also recently shown to be a requisite element of the PRL rhythm-generating mechanism. Administration of an OT receptor antagonist that does not penetrate the blood–brain barrier blocks the cervical stimulation-induced PRL rhythm.[720] Freeman and colleagues have thus proposed a model for the neuroendocrine mechanisms that govern the cervical stimulation-induced PRL secretory rhythm,[721] as depicted in Figure 26.16. The rhythm is mediated by reciprocal interactions between pituitary lactotropes and hypothalamic DA neurons, wherein DA suppresses PRL secretion and PRL stimulates DA release. Peaks of these two activities occur out

of phase. The rhythm is also facilitated by OT release from neurons of the paraventricular nucleus, at neurovascular junctions in the ME and posterior pituitary,[722] and its stimulation of PRL release from lactotropes.[179,642] Prolactin also exerts a rapid inhibitory feedback effect on OT neurons.[723,724] It is proposed that cervical stimulation initiates these cyclic events through induction of a "memory" or neural program that continues to operate for many days past the application of the cervical stimulus. The cellular basis for this memory is unknown, although a recent study showed that PRL itself is capable of programing the same mechanism.[725] Evidence suggests that PRL release does not mediate cervical stimulation induction of the rhythmic secretory program,[721] and thus its cellular basis remains to be clarified.

Significance of the Short Luteal Phase

As noted earlier, the corpora lutea of rats, mice, and hamsters secrete progesterone for only a brief period after ovulation. In the absence of spontaneous luteotrophic support, the waning corpora lutea marshal in new waves of ovarian follicles and hence new ovulation. Due to the brevity of the luteal phase in rodents, ovulation recurs every 4–5 days. One can speculate on the selective advantage of short cycles. In those cycles in which an ovulation is not associated with a fertile mating and conception, it would not be advantageous to have a protracted period, the luteal phase, in preparation for continuation of a pregnancy that did not take place. On the other hand, it seems most efficient if an active luteal phase that prepares the uterus for a conceptus is only associated with a mating stimulus. In that regard, a luteotrophic mechanism activated by a mating stimulus is an example of such an efficient system.

CONCLUSION

The neuroendocrine mechanisms that govern the rat estrous cycle share many essential features with neuroendocrine systems controlling ovulatory cycles in most other species. As in other animals, the tempo and sequence of events are orchestrated by hormone signals conveyed within the hypothalamic–pituitary–ovarian axis. A hypothalamic GnRH pulse-generating mechanism sustains basal gonadotropin secretions throughout the cycle, and FSH and LH secretions thereafter direct folliculogenesis and steroidogenesis, respectively. Ovarian hormones—principally estradiol, progesterone, and inhibin—exert negative feedback regulation of pulsatile GnRH release through effects on neuronal circuitries that control the GnRH pulse generator; they additionally exert direct inhibitory effects on gonadotrope synthesis and secretion, in part by modulating responsiveness to GnRH stimulation. Basal LH secretion prompts a sustained high level of estradiol release from ripening ovarian follicles at mid cycle. The increased level of estradiol then evokes a preovulatory gonadotropin surge through two integrated mechanisms—induction of an antecedent preovulatory GnRH surge, and massive priming of the pituitary gland to stimulation by the GnRH surge. An estradiol-dependent, GnRH self-priming effect constitutes part of this pituitary up-regulatory process. Ovulation is subsequently triggered by the LH surge.

Chief among the differences in rats versus other species is the tight control of the GnRH surge by the photic-entrained circadian clock. A daily neural signal specifies a temporal window on the afternoon of proestrus for the release of the preovulatory GnRH surge. A principal function of the estradiol surge is to couple the transmission of this daily neural signal to the GnRH release process. This coupling process may be mediated by ERα activation in neurons resident in the AVPv; evidence suggests these may be at least in part neurons that produce the GnRH secretagogue, kisspeptin. A direct afferent projection by kisspeptin neurons to GnRH neurons likely conveys at least a portion of this signal, resulting in KISS1R activation in GnRH neurons and release of the GnRH surge. The ensuing LH surge induces progesterone secretion on the evening of proestrus, which serves to further amplify the LH surge and to prevent its reoccurrence the next day. In parallel with the positive feedback actions of estradiol and progesterone on GnRH and LH, the sequential exposure of the hypothalamus to these hormones induces a behavioral heat that begins in the evening of proestrus. Thus, the timing of the GnRH and LH surges on the afternoon of proestrus ensures that ovulation occurs in temporal register with sexual behavior, an adaptive mechanism that greatly increases reproductive efficiency.

The secondary surge of FSH on the morning of estrous also represents a unique feature of the 4- to 5-day rodent estrous cycle. The biological role of this singular release of FSH is to recruit ovarian follicles destined for ovulation in the upcoming cycle. A drop in inhibin secretion, engendered by the primary LH surge, comprises one major signal for release of the secondary FSH surge. A role for PR activation in the gonadotrope has also been indicated in the stimulation of this secretory event.

The short luteal phase of the rat estrous cycle also stands in contrast to the protracted luteal phases in most other mammals. The recruitment of PRL as a luteotropic hormone in this species, and one that is engaged in full by mating, appears to be another adaptive mechanism that promotes reproductive efficiency in animals with short reproductive cycles. The circadian clock again appears to have been coopted as a mechanism that drives a characteristic PRL secretory mechanism that persists as a biphasic, daily pattern of release following mating.

Both similarities and differences between rats and other species will continue to invite further research. Major questions remain, for example, about the molecular and cellular basis of GnRH pulsatility and its regulation by ovarian steroids, mechanisms that appear to be common among the neuroendocrine control systems of most mammals. The cellular targets and mechanisms that engage negative feedback in the hypothalamus remain particularly unclear. Progress in understanding these phenomena will undoubtedly be made in the coming years, and will shed new light on the dysregulation of pulsatility and resistance to negative feedback that are associated with infertility syndromes in humans. The photoperiodic regulation of the proestous GnRH surge in rats reflects an inherent difference in the transmission of positive feedback signals in this species versus the sheep, monkey, and humans. A fuller understanding of the mechanisms that link the circadian clock to the GnRH release system will hopefully be gained, allowing dissection of mechanisms that impart circadian timing mechanisms from a more conserved "core" surge generating process that occurs in a wider variety of species. Future research will also hopefully clarify the molecular mechanisms that mediate the differential release of FSH and LH, a process that occurs most robustly during the morning hours of estrus. In addition to a drop in inhibin levels, the additional mechanisms by which activin, follistatin, and other pituitary factors may contribute to this process are far from resolved. Moreover, the cellular mechanisms that integrate these signals in these and other instances of singular FSH release remain to be determined. Likewise, the neural integrative mechanisms that control mating-induced PRL surges await further analysis.

Finally, I have not included in this chapter any discussion of the mechanisms that may mediate the effects of stress, illness, alterations in nutrition and/or energy balance, season, and changes in any other important neuroendocrine variables on the rat estrous cycle. As discussed in several other chapters, such studies are ongoing in numerous laboratories and continue to provide important information relative to human and animal reproductive cycles, fertility, and infertility. I hope that the body of fundamental knowledge about the neuroendocrine control of the estrous cycle, as updated and presented in this chapter, will continue to inform and guide these studies into the future.

Acknowledgments

The author is immensely grateful to Dr Marc Freeman, the sole author of the versions of this chapter in the three previous editions of this book. I thank Dr Freeman for graciously allowing me to update his work, and in the process retain many sections and re-use figures from the previous edition. I also thank Sharon Dubois and Robert Shapiro for their assistance in editing this work. Finally, I would like to express my sincere gratitude to all of my current and past trainees for their ingenuity, hard work, and adventurous spirit in research that has contributed to a better understanding of neuroendocrine mechanisms controlling the rat estrous cycle.

INTRODUCTION

Although significant progress has been made in some aspects of our understanding of the ovine estrous cycle, much of the information in the third edition of this volume does not need updating and remains substantially the same. We have indicated those areas where significant advances have occurred in the text, which include (1) the role of kisspeptin and neurokinin B in control of gonadotropin-releasing hormone (GnRH) secretion, (2) intraovarian mechanisms controlling follicular development and hormone secretion, (3) the regulation of follicular waves during the luteal phase, and (4) the importance of the episodic pattern of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), membrane progesterone receptors, and intracellular Ca^{++} to luteolysis. New information on mechanisms underlying seasonal breeding and pheromonal control of reproductive function discussed in more detail includes (1) a potential role for thyroid-stimulating hormone (TSH) from the pars tuberalis, and local conversion of T_4 to T_3 in mediating the actions of melatonin during the transition to anestrus; (2) identification of the components, including arcuate kisspeptin neurons, of the neural circuitry inhibiting GnRH in anestrus; and (3) determination of the olfactory pathways and the possible roles of learning and memory in the ability of males to induce ovulation in anestrous ewes. Because of space constraints, we have limited the number of references and, with the exception of classic historical citations, have generally included only more recent references; many important early references can be found in our previous chapter[1] (which can be obtained at http://www.sciencedirect.com/science/article/pii/B978012515400050049X), and we have cited it in the text where specific data from early work are particularly relevant. We have also had to rely on recent reviews more than we would like. Reviews that provide valuable coverage of major topics have been cited in the title of that section, while more focused reviews are cited in the text. We strongly encourage students to read the primary literature cited in these reviews rather than simply relying on the conclusions reached in the latter because the original work contains important experimental details, valuable data, and viewpoints not often found in reviews.

Overview

Patterns of reproductive function in the ewe are dominated by two distinct rhythms.[2] The first of these is a 16- to 17-day estrous cycle. The duration of this cycle is remarkably constant, with an estimated 95% of ewes showing estrous cycles within the normal range of 14–19 days.[3] There are some differences in cycle lengths among breeds and with age, but these differences are relatively small (~1 day).[3,4] The other major rhythm in ovine reproduction is an annual cycle of ovarian activity. In most breeds of sheep,[2–4] normal estrous cycles occur in the fall and winter (breeding season), but ovarian cycles cease in the spring and summer (anestrus). From an adaptive point of view, this limited duration of fertility ensures that lambs are born in the spring, when environmental conditions are favorable for their survival. In contrast to the constancy of estrous cycle length, seasonal reproductive patterns vary dramatically; some primitive mountain sheep have only one estrous cycle during the breeding season, while Merino ewes show estrous cycles throughout most of the year.[2] This variability appears to reflect the environment in which the breeds were developed, with breeds originating in harsher conditions having shorter breeding seasons.[4] It should be kept in mind

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00027-2

that these breed differences in seasonality reflect differences in the degree of ovarian activity during spring and summer. The presence or absence of ovulation represents a somewhat arbitrary dividing line in what is, in fact, a continuum of ovarian function. Thus, seasonal variations in fertility are evident even in ewes capable of breeding throughout the year and, in seasonal breeders, considerable ovarian activity (e.g., follicular development) occurs during anestrus.

The estrous cycle of the ewe is essentially analogous to the ovarian cycles of other spontaneously ovulating species with functional luteal phases, although the follicular phase is relatively brief compared to that of primates (see Chapter 33). It is thus not surprising that the neuroendocrine mechanisms controlling the ovine ovarian cycle are similar in many respects to those in primates and rats. However, the seasonal aspect of reproductive function represents an additional challenge for any model of these control systems. Namely, in the ewe, it must be able to account both for the events occurring within the estrous cycle and for the annual cessation and re-initiation of ovarian cycles. In addition to these theoretical issues, the occurrence of a seasonal anovulatory period provides a natural experimental model for examining the control of ovulation. Consequently, experiments examining the control of the estrous cycle and the annual reproductive cycle of sheep became intertwined over the years so that our understanding of each has developed in parallel. Nevertheless, it is useful for didactic reasons to consider these two cycles separately, and we will first consider the control of the estrous cycle. We will provide a historical perspective on the field after consideration of the current model for the ovarian cycle.

Methods of Analysis

The ovine estrous cycle results from the coordinated interaction of four tissues: brain, pituitary, ovary, and uterus. To understand the control of this cycle, we must analyze the communication among these tissues, which occurs largely via seven hormones: GnRH from the hypothalamus; luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary; estradiol, inhibin, and progesterone from the ovary; and $PGF_{2\alpha}$ from the uterus and corpora lutea. In analyzing the physiological interactions of these hormones, two factors are of paramount importance. First, for the action of a particular hormone to be important in controlling ovarian cyclicity, it must be evident at physiological concentrations of the hormone. Thus, particular emphasis will be placed on those studies that have avoided pharmacological hormone treatments or artificial manipulations with little relevance to physiological events. Second, changes in circulating concentrations of these hormones occur in a specific sequence at very predictable times during the estrous cycle. As a result, examination of the temporal relationship between two specific hormones provides a useful indication of the causal linkage between the two. Because of the importance of these two factors, this chapter will begin with a detailed description of the behavioral and hormonal patterns that occur throughout the estrous cycle. We then dissect the cycle into its functional components and consider the control of each component individually. The third step will be synthesis of these components into a model that can account for the events of the estrous cycle. Finally, we will briefly consider how these mechanisms are modified by photoperiod and pheromonal input to produce seasonal alterations in reproductive function.

DESCRIPTION OF THE OVINE ESTROUS CYCLE

The 16–17-day estrous cycle can be divided into a 2–3-day follicular phase and a 13–14-day luteal phase. The demarcation between a follicular and subsequent luteal phase is ovulation, whereas there is a more prolonged transition between a luteal phase and the next follicular phase because luteolysis is a gradual process. Because this is a cycle, one can theoretically start at any point in its description. However, because estrous behavior is the only outward manifestation of the ovine ovarian cycle (and can be easily monitored using vasectomized rams with marking devices), the onset of estrus is used to time the events of the cycle and, by convention, the first day of estrus is commonly designated day 0 of the ovarian cycle.

Estrous Behavior[5]

Traditionally, estrous behavior is divided into three distinct activities: attractivity, proceptivity, and receptivity. Attractivity consists of passive characteristics and behaviors that make a ewe attractive to rams, proceptivity involves activities in which the ewe is actively seeking a mate, and receptivity consists of a ewe allowing the ram to mount.[5,6] While attractivity can be identified under experimental conditions,[7] it is difficult to distinguish from proceptivity under natural conditions, so it is usually subsumed under the latter. Proceptivity is evident as an increase in motor activity at the start of estrus and can be accompanied by tail fanning and the ewe looking over her shoulder at the ram as he approaches and nudges her flank and/or anogenital region. Receptivity, which is the most common index used to monitor estrous behavior, consists of simply standing still during copulation. Copulation is fairly brief, but several copulations usually occur during a single estrous period. In general, behavioral estrus lasts 24–36 h in the ewe, but its

duration is reduced by continuous contact with males.[5,6] The start of estrus is coupled with the preovulatory LH surge so that ovulation occurs, on average, 24–30 h after the onset of estrous behavior.[3,8]

Hypothalamo–Hypophysial Unit

LH and GnRH Patterns

The ability to monitor GnRH secretion in the hypophysial portal blood of unanesthetized sheep has produced a wealth of information on the normal pattern of endogenous GnRH secretion and its control that is not available in any other species. These data demonstrated a very close correlation between GnRH and LH secretion, so we have chosen to describe secretion of these two hormones in tandem. Historically, two functionally distinct modes of LH secretion were identified in the ewe, as in other mammals (see Chapter 33). These two modes of LH, and parallel secretion of GnRH, are regulated by different feedback mechanisms and control different aspects of ovarian function. Tonic LH secretion is controlled by the negative-feedback actions of ovarian hormones, occurs in a pulsatile pattern at a low level throughout the cycle, and is important for ovarian steroidogenesis; the LH surge is triggered by high circulating concentrations of estradiol late in the follicular phase and induces ovulation and formation of the corpus luteum. As discussed in this chapter, the negative and positive feedback actions of ovarian hormones occur at both the hypothalamic and hypophysial portions of this unit.

Tonic LH secretion during the cycle (Figure 27.1) is inversely correlated to luteal function so that LH concentrations decline from days 1–9 as progesterone secretion from the corpus luteum increases,[13] remain low until day 14, and then increase during the follicular phase following luteolysis.[13–15] In contrast, when averaged over several hours, tonic GnRH secretion does not vary markedly throughout the cycle (Figure 27.1),[9,16] but these means mask a marked variation in the pattern of pulsatile GnRH release (Figure 27.2). During the midluteal phase, low-frequency, high-amplitude GnRH pulses are observed; following luteolysis, the frequency increases and the amplitude decreases.[9,16] Because GnRH pulses drive LH pulses, LH pulse frequency follows the same pattern (Figure 27.2): it is high in the early part of the cycle, decreases to a nadir late in the luteal phase, and then increases progressively throughout the follicular phase. LH pulse amplitude either does not differ between the midluteal and follicular phases or decreases during the follicular phase, so mean LH concentrations correlate with LH pulse frequencies, not amplitudes, during the estrous cycle.

The LH surge represents a brief, massive outpouring of LH from the pituitary (Figure 27.1). LH concentrations rise rapidly within 4–8 h to a peak that is 50–100 times basal levels, and then decline just as rapidly so that the surge lasts approximately 12 h. The onset of the LH surge is usually coupled to the onset of estrous behavior,[5] and the interval between the LH surge and ovulation (22–26 h) is remarkably constant. At the same time, there is a dramatic 20- to 40-fold increase in the GnRH secretion rate (Figure 27.1),[9] which reflects a change in the pattern of GnRH release from episodic to continuous.[17] This change occurs gradually, starting with increased GnRH secretion between pulses, followed by an increase in both interpulse GnRH secretion and GnRH pulse amplitude, and then continuous release during peak secretion.[17,18] Although the initial phases of the preovulatory surges of GnRH and LH are relatively synchronous, elevated GnRH secretion is maintained for many hours after the termination of the LH surge (Figure 27.1).[9]

FSH Secretion

As illustrated in Figure 27.1, FSH concentrations decline during the follicular phase to a nadir on the day before the preovulatory LH surge.[10,11,19] There is an FSH surge coincident with the LH surge, and FSH concentrations fall in parallel with LH to a nadir at 8–12 h after the preovulatory peak. FSH then increases to a second peak 20–28 h after the first, followed by a second nadir between 36 and 48 h. A gradual increase in FSH concentrations is often observed sometime between days 4 and 6 of the luteal phase,[11,19,20] which correlates with the second "wave" of follicular development (discussed later in this chapter). Small increments in FSH, lasting about a day, occur at 3- to 6-day intervals throughout the luteal phase, each preceding a wave of follicular development.[20,21]

Ovary

Follicular Dynamics[22]

Because of space limitations and the availability of an excellent review on all aspects of folliculogenesis in ruminants,[22] we have chosen to rely primarily on that publication with only selected references to the primary literature. Formation of primordial follicles begins in the ovigerous cords near the interface of the cortex and medulla of the fetal ovary around day 75 of gestation,[23] coincident with maximal germ cell numbers in the fetal ovary. Initially, each primordial follicle consists of an oocyte, surrounded by a single layer of granulosal cells; the number of these per follicle is highly variable, but correlates with the diameter of the oocyte. Granulosal cells come from pregranulosal cells that arise primarily in the surface epithelium of the developing ovary and segregate the oocytes within the ovigerous cords before these cords regress.[23] More than 75% of the germ cells are lost by day 90 of gestation, presumably by apoptosis. The ovaries of young ewes contain from 40,000 to 300,000 primordial follicles. Numbers of antral follicles

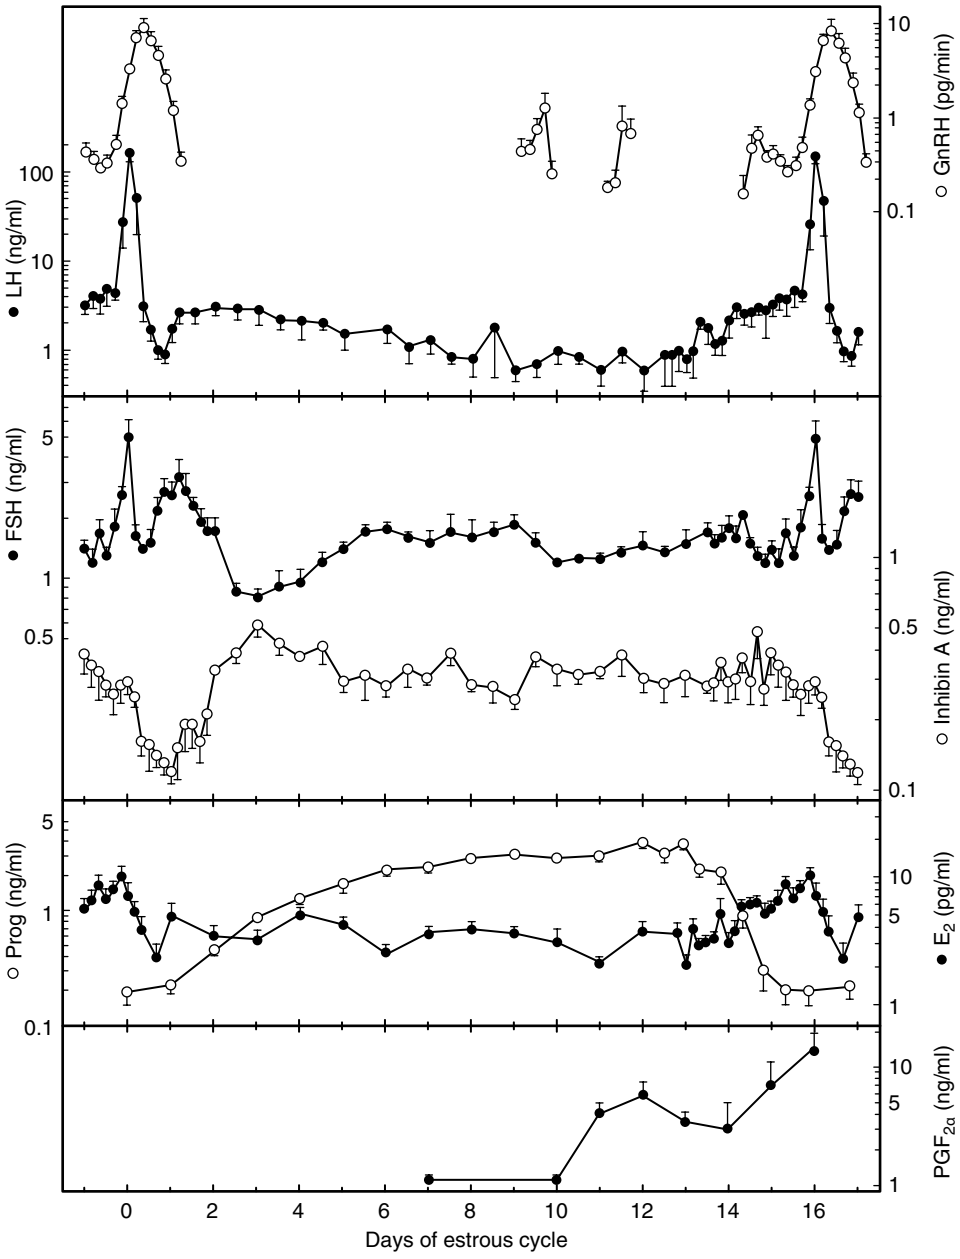

FIGURE 27.1 Hormonal patterns during the ovine estrous cycle. Changes in mean (± standard error of the mean) secretion rate of GnRH into hypophysial portal blood, peripheral concentrations of gonadotropins and major ovarian hormones, and uterine vein concentrations of $PGF_{2\alpha}$ throughout the ovine estrous cycle. Data for all hormones (except $PGF_{2\alpha}$) during the periovulatory period (days −1 to +2 and 13–17) are normalized to the peak of the LH surge (day 0 and day 16) and represent values monitored every 4 h. During the remainder of the cycle, data collected every 12 or 24 h are presented. By convention, the day of estrous behavior is designated Day 0; this is also the day of ovulation and thus the start of the luteal phase. The follicular phase begins with the first sustained fall in progesterone concentration (on Day 14 in this figure), but the transition between luteal and follicular phases occurs over the next 24 h as progestrone concentrations fall to a minimum. *Source: GnRH values were calculated from data in Moenter et al.,[9] and LH and ovarian steroid concentrations are from Goodman et al.[10] (Copyright 1981, The Endocrine Society.) FSH and inhibin A from Knight et al.,[11] and $PGF_{2\alpha}$ values are derived from data in Inskeep and Murdoch.[12]*

in ewe lambs are high at birth and fluctuate randomly during the prepubertal period, with no obvious follicular waves or correlation with FSH concentrations.[24]

Whether follicular waves, similar to those in cows, occur in adult ewes has been an ongoing controversy. In an analysis of 15 laparoscopic and ultrasonographic studies, it was concluded that waves can be demonstrated if one defines a wave on the basis of follicles that arise at 3 mm in diameter and grow to at least 5 mm in diameter (Figure 27.3).[25] However, numbers of waves ranged from two to six among studies, waves sometimes overlapped, and ovulatory follicles arose from both the penultimate and ultimate waves[26] and as early as day 9 or as late as day 14 of the cycle.[27] Interestingly, cycle length did not vary between cycles with three or four waves,[28] in contrast to cattle, in which cycles with three waves were longer than those with two waves. Detailed hormonal analyses indicated that each follicular wave was preceded by a transitory increase in FSH concentrations[1,20,21,26] and that recruitment into the growing cohort required the presence of some LH. Follicular waves continued during anestrus and were often,[29] but not always,[30] associated with increments in FSH; as in the luteal phase, the presence of some LH appeared to be essential for recruitment by FSH.[29]

Follicular selection or dominance[31] has been difficult to demonstrate in ewes, although it is supported by observations during the follicular phase.[25,32] It has been

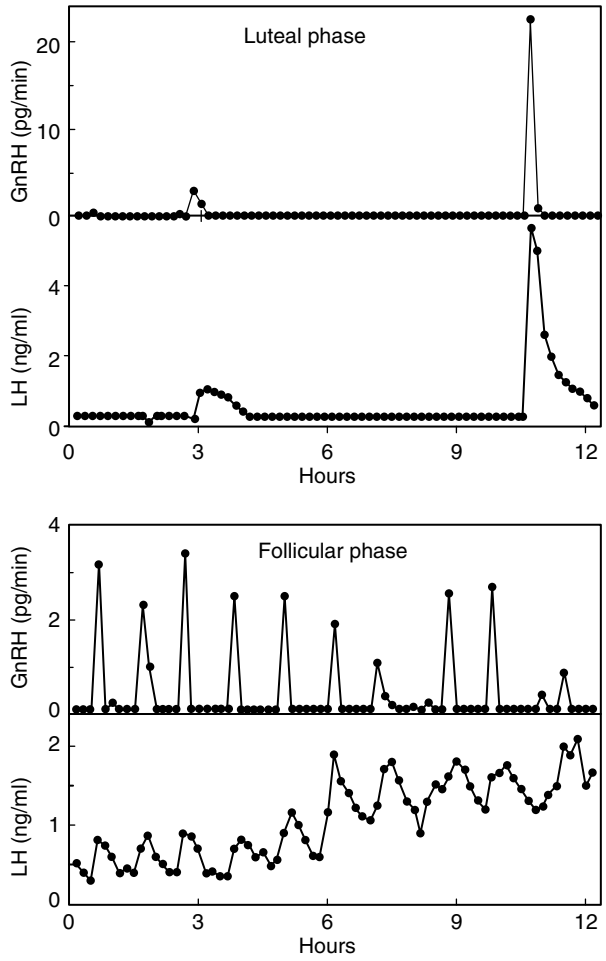

FIGURE 27.2 Episodic GnRH and LH secretion varies with stage of estrous cycle. Pulsatile patterns of hypophysial portal GnRH secretion and jugular concentrations of LH during the late luteal phase (days 12–13) and late-follicular phase (39–51 h after progesterone withdrawal). Note the difference in the scale of the *y*-axis between the luteal and follicular phases. *Source: Drawn from data provided by F. J. Karsch from work described in Moenter et al.*[9]

suggested that "potentially ovulatory" is a better term than "selected" or "dominant" for the most advanced class of follicles,[22] and the concept of follicular dominance in the ewe has recently been questioned.[33] It is thus not surprising that in many breeds of sheep, twinning occurs in a significant percentage of animals. In ewes with twins, ovulatory follicles arose over a greater range of days than in ewes with single ovulations, and twin ovulations appeared to result from reduced atresia of both smaller and larger follicles.[34] That is consistent with ovulations from both the ultimate and penultimate waves; that is, larger follicles from the penultimate wave were retained and smaller ones in the ultimate wave grew to ovulatory size and competence. More follicles from the penultimate wave ovulated in breeds of ewes with lower progesterone and more frequent pulses of LH.[26] The most rapid apparent turnover of follicles was reported in the Merino del Pais, a monovulatory breed in Spain, in which seven different follicles became the largest during an estrous cycle.[32] A subsequent analysis in three other Spanish breeds concluded that patterns of follicular turnover were not affected by breed.[35] Readers are referred to the review by Scaramuzzi et al.[22] for models that illustrate the processes of recruitment and selection of follicles in relation to patterns of FSH and LH secretion.

Ovulation (Follicular Rupture)[36,37]

The process of ovulation in the ewe does not differ particularly from that described in other species, but work in ewes has contributed to greater understanding of the role of the ovarian surface epithelium and of the involvement of tumor necrosis factor alpha (TNFα) in rupture of the follicle. Therefore, we will focus this description on these events; a more detailed description of this process can be found in Chapter 22. Key steps in the ovulatory cascade in ovine follicles (Figure 27.4) begin with an initial effect of the LH surge to increase 3′5′ cyclic adenosine monophosphate (cAMP), which blocks synthesis of estradiol from progesterone via androgens. The resulting increase in progesterone in the follicular tissue contributes to increases in secretion of PGE_2 and $PGF_{2\alpha}$, which contribute sequentially to hyperemia of the follicle and proteolytic activity (PGE_2) and to contractions of smooth muscle–type cells in the follicular wall ($PGF_{2\alpha}$). LH stimulates secretion of urokinase-type plasminogen activator (uPA) from the ovarian surface epithelium. The uPA stimulates conversion of interstitial plasminogen to plasmin, which activates latent collagenases in the apical follicular wall and releases TNFα from the thecal endothelium. Collagenolysis, potentiated by increases in transcription of matrix metalloproteinases (MMPs) in response to TNFα, and further supported by progesterone and prostaglandins, weakens and thins the apical follicular wall, leading to stigma formation and rupture. Tissue inhibitors of MMPs limit the degree of proteolytic damage and contribute to collagen remodeling during the folliculo–luteal transition.

Ovarian Hormone Secretion

The primary steroids secreted by the ovary are progesterone, estradiol, and androstenedione. Although circulating androstenedione does not appear to play a physiological role in ewes,[1] immunization against it has been used successfully to increase the ovulation rate.[38] Progesterone is secreted into the blood exclusively by the corpus luteum, whereas estradiol is secreted only by follicles.[1] Progesterone concentrations are virtually undetectable early in the cycle and then rise gradually, in parallel with increases in the volume of luteal tissue, determined using ultrasound,[39] from days 2 to 8 to reach a maximal concentration ranging from 1.5 to 4 ng/ml, depending on the breed.[1,13] Progesterone

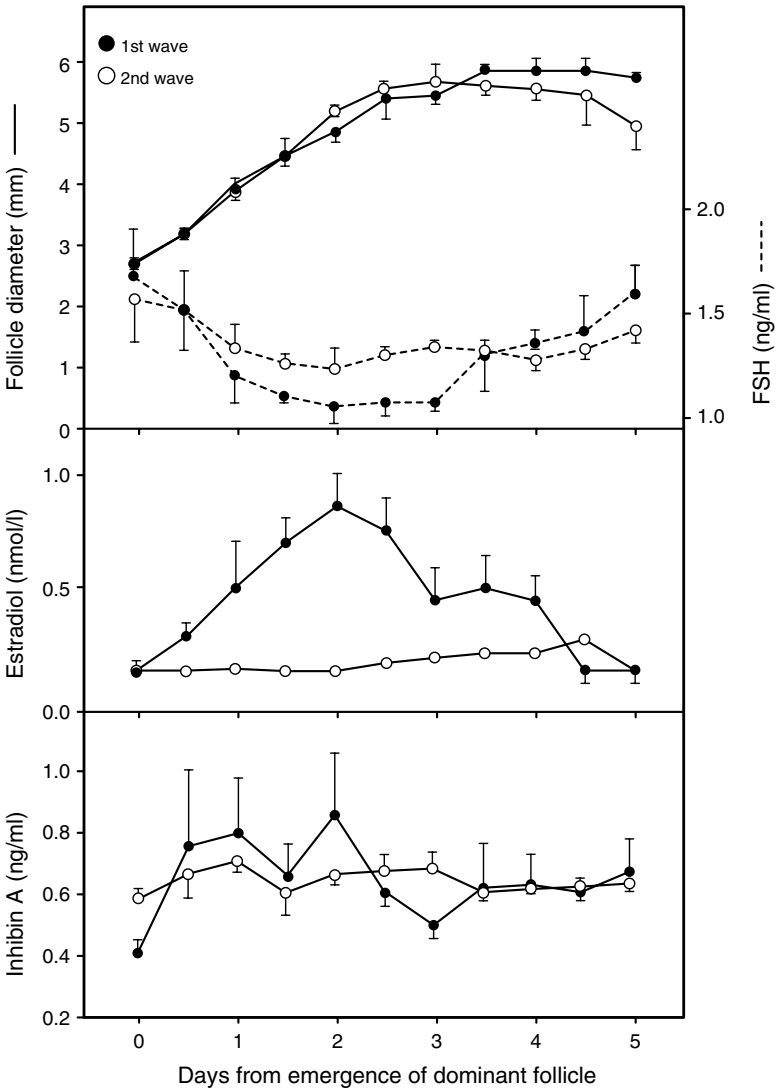

FIGURE 27.3 Follicular waves and hormonal patterns early in the luteal phase. Relationships among the diameter of the largest follicle (*top panel*, solid lines), peripheral FSH concentrations (*top panel*, dashed lines), and concentrations of estradiol (*middle panel*) and inhibin A (*lower panel*) in ovarian venous plasma during the first and second follicular waves of the estrous cycle. Values (mean ± standard error of the mean) are normalized to the day of first emergence (diameter >2.5 mm) of the largest follicle, for waves 1 (from days 1 to 4 of the cycle) and 2 (from days 5 to 9 of the cycle). *Source: Data replotted from Souza et al.[20]; reproduced by permission of the Society for Endocrinology.*

concentrations remain relatively constant from days 8 to 14, and then rapidly fall to undetectable levels over the next 1–2 days (Figure 27.1). In contrast to the rat and primate (see Chapters 26 and 28), peripheral progesterone concentration does not increase in response to the preovulatory LH surge in the sheep,[40] but it does increase within the preovulatory follicles and plays an important role in the ovulatory process (see Figure 27.4). This pattern of progesterone concentrations is remarkably constant across breeds, but there are modest breed differences in maximum progesterone concentrations. Surprisingly, breeds with high ovulation rates do not always have higher progesterone concentrations than those with low ovulation rates,[39] indicating that less progesterone is produced per corpus luteum in the former.

The principal estradiol rise occurs during the 2–3-day follicular phase of the estrous cycle (Figure 27.1): estradiol secretion begins to rise after the first drop in progesterone concentrations at luteolysis[40] and increases five- to 10-fold over the next few days.[13,14] This estradiol increment peaks at the start of the preovulatory LH surge (Figure 27.1) and then rapidly declines to basal concentrations. Estradiol secretion during this period appears to come largely from the follicle destined to ovulate, which is growing rapidly at this time. In most studies, a second peak in estradiol secretion was observed around day 4 of the cycle that correlated with the first follicular wave (Figure 27.3)[13,20,40]; mean estradiol concentrations remained relatively low during the rest of the luteal phase and showed no consistent pattern during this period (Figures 27.1 and 27.3). When measured at frequent intervals in individual sheep, both progesterone and estradiol show marked fluctuations, indicative of an intermittent secretory pattern analogous to tonic GnRH and LH secretion.[1] The episodic secretion of estradiol, but not progesterone, is temporally correlated with preceding LH pulses.

Inhibin is produced by follicles, but not the corpus luteum, in sheep,[41] and it comes primarily from granulosal cells, although low levels of mRNA for both the

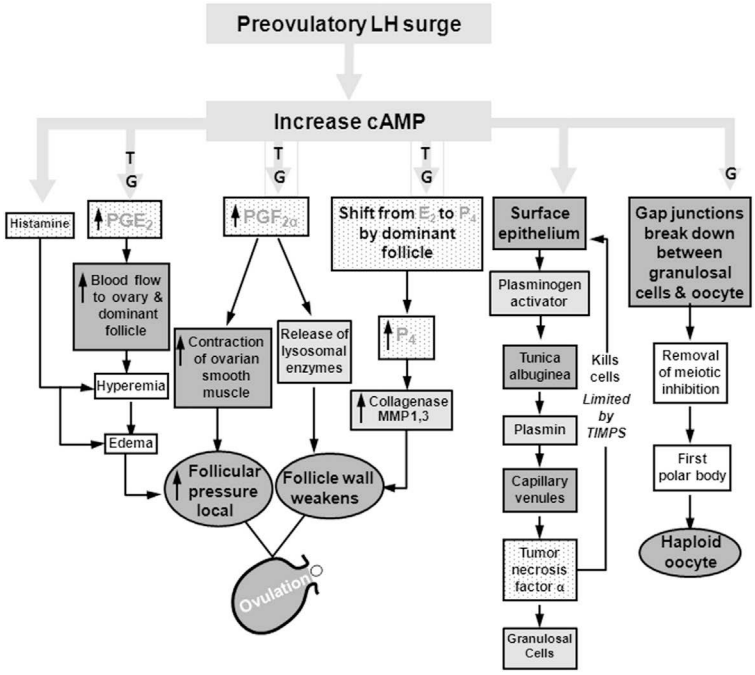

FIGURE 27.4 Sequence and sites of the process of follicular rupture and ovulation in the ewe in response to the preovulatory surge of luteinizing hormone. Hormones and cytokines are in light gray print in stippled boxes, tissues are in dark gray boxes, enzymes are in light gray boxes, and results are in dark gray ovals or structures. Hormonal and enzymatic changes in granulosal (G) and thecal (T) cells are indicated on arrows. *Source: Adapted from Murdoch et al.[36] and information provided by E. K. Inskeep from work described in Senger PL Pathways to Pregnancy and Parturition, 3rd Ed., Current Conceptions Inc., Redmon, OR; 2012: 173.*

α and β_A subunits have recently been detected in thecal cells using quantitative reverse-transcriptase (qRT)–polymerase chain reaction (PCR).[42] Although mRNA for both β_A and β_B can be found in ovine follicles, inhibin A appears to be the only form of inhibin secreted by the ovary,[11] and inhibin B could not be detected in ovine plasma or follicular fluid.[22] Large follicles are an important source of inhibin, but smaller follicles also appear to contribute significantly to ovarian inhibin secretion.[41] Because the latter are not an important source of estradiol, the ovarian secretion of these two follicular hormones is not always coupled.[11,19,41]

The development of two-site enzyme-linked immunosorbent assays was critical for accurate estimates of circulating inhibin and provided relatively consistent estimates of inhibin A secretion throughout the ovine estrous cycle (Figure 27.1). In contrast to estradiol secretion, there is no change in either peripheral inhibin concentrations[19] or inhibin secretion rate from the ovary[11] during the follicular phase. Inhibin begins to decline within a few hours after the peak of the LH surge, reaching a nadir about 24 h later that coincides with the peak of the second FSH surge. There is then an increase in inhibin secretion between days 1 and 3 of the luteal phase, followed by a slight decline over the next 1–2 days.[11,19] No further consistent changes in inhibin are seen throughout the rest of the luteal phase, although transitory decreases sometimes correlate with increases in FSH secretion and initiation of follicular waves (Figure 27.3). At this time, there is little evidence that inhibin is secreted episodically and, in any case, episodic fluctuations in secretion would be damped by the 50 min long half-life of this hormone.

Uterine Prostaglandins

Assessment of uterine $PGF_{2\alpha}$ secretion in vivo is complicated by two factors. First, it must be measured in the utero-ovarian or uterine vein because prostaglandins are metabolized almost completely in one passage through the lungs and because some metabolism occurs locally in the uterus and/or ovary.[43] Second, $PGF_{2\alpha}$ is secreted episodically,[12,40] so that blood samples must be collected relatively frequently to determine the actual secretory pattern. When these technical issues are taken into account, a consistent picture of $PGF_{2\alpha}$ secretion emerges. From days 2 to 10 of the estrous cycle, there is little secretion of $PGF_{2\alpha}$ from the uterus.[40,44] Episodes of $PGF_{2\alpha}$ secretion first appear between days 11 and 13 of the cycle, and the frequency of these episodes then increases over the next 2–3 days.[12,44] These changes in episodic prostaglandin release are reflected in mean concentrations of $PGF_{2\alpha}$ in the uterine vein, which increase late in the luteal phase, plateau during the early follicular phase, and then increase again to a peak after progesterone declines (Figure 27.1).[12,40,44]

ANALYSIS OF THE OVINE ESTROUS CYCLE

In this section, we will consider the hormonal control of each component of the ovine estrous cycle. This is not intended to be a complete review of each component, but instead will focus on those aspects of control directly relevant to events of the estrous cycle and recent mechanistic observations.

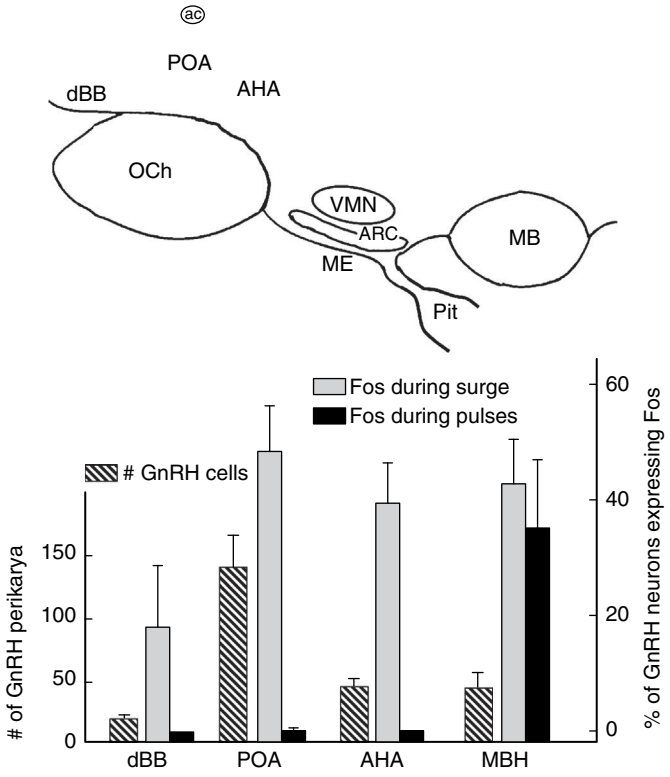

FIGURE 27.5 Diencephalic areas important for reproductive function in the ewe. *Top panel*: Schematic drawing of a parasagittal section through the ovine preoptic area and hypothalamus illustrating the major areas involved in the regulation of estrous behavior and GnRH secretion. ac: anterior commissure; AHA: anterior hypothalamic area; ARC: arcuate nucleus; dBB: diagonal band of Broca; MB: mammillary body; ME: median eminence; OCh: optic chiasm; POA: preoptic area; Pit: pituitary; VMN: ventromedial nucleus. *Bottom panel*: Distribution of GnRH perikarya (striped bars) and GnRH neurons activated (percentage containing Fos) during the preovulatory GnRH surge (gray bars) and during pulsatile GnRH secretion (black bars). Control of Hypothalamo–Hypophysial Function

Neuroanatomy

As in many other species (see Chapter 11), GnRH neurons are scattered throughout the ovine diencephalon (Figure 27.5),[45] with about 50% of them located in the preoptic area (POA) and the rest found in the diagonal band of Broca (dBB), anterior hypothalamic area (AHA), and mediobasal hypothalamus (MBH), which extends from the posterior border of the optic chiasm to the rostral edge of the mammillary body and includes the arcuate nucleus (ARC), dorsomedial hypothalamus (DMH), and ventromedial nucleus (VMN). Most of these cells are multipolar with extensive dendritic processes, but some bipolar cells can be seen. Interestingly, in contrast to nearby non-GnRH cells, the soma and dendrites of ovine GnRH neurons are almost entirely ensheathed by astroglia[48]; over 90% of the cell membrane is in direct apposition with astroglia processes in both breeding and anestrous seasons.[49] Although there is good evidence for anatomical and functional subpopulations of GnRH neurons (discussed below), there are no regional differences in the percentage of GnRH neurons projecting to the median eminence.[50] Thus, GnRH fibers arising from cells in the dBB, POA, and AHA, which travel either periventricularly or laterally at the base of the brain, are responsible for most of the GnRH terminals in the external zone of the median eminence.

The first obvious step in identifying mechanisms by which steroids act within the hypothalamo–hypophysial unit is to determine the location of steroid receptors. Thus, one can infer from the presence of receptors for ovarian steroids in gonadotropes[51] that these steroids exert feedback actions at the level of the pituitary, and, as discussed later, there is also direct evidence for this conclusion. In contrast, GnRH neurons do not contain estrogen receptor alpha (ERα)[52,53] or progesterone receptors (PRs),[54] but about 50% of them contain ERβ.[55] This dearth of steroid receptors, and the lack of evidence that ERβ is important for the control of GnRH, have led investigators to search for neuronal populations likely to mediate the feedback actions of gonadal steroids. Work over the last decade has added four new candidates to the pantheon of neurotransmitters implicated in the control of GnRH in the ewe. Thus kisspeptin,[56] galanin,[57] orphanin-FQ (OFQ),[58] and RF-amide related peptide 3 (RFRP3; sometimes called gonadotropin inhibitory hormone)[59] join the four classical neurotransmitters (dopamine (DA),[52,60] gamma-aminobutyric acid (GABA),[53] glutamate,[61] and norepinephrine[62,63] (NE)) and five neuropeptides (dynorphin,[64] β-endorphin,[52] neurokinin B (NKB),[65] neuropeptide Y (NPY),[60] and somatostatin[66]) previously identified (Table 27.1). Also of considerable interest was the report that three of these peptides (kisspeptin, NKB, and dynorphin) are co-localized in the same population of ARC neurons.[77] Because this combination is unique to the ARC (kisspeptin and dynorphin neurons elsewhere in the hypothalamus do not contain either of the other two peptides), the ARC population is now referred to as KNDy neurons.[73] Each of these 13 transmitters has been identified in boutons in close contact with GnRH neurons in the POA using light microscopy,[49,57,58,65,67,69,75,76,78] and synaptic contacts containing three of them (dynorphin, β-endorphin, and NPY) have been identified with electron microscopy.[1,69] Some of these signaling molecules are found in the same synaptic terminals; in addition to the KNDy peptides, there is a 50–60% overlap of NPY and NE,[67] and glutamate is found in 15% of the NE terminals.[61] It should be kept in

TABLE 27.1 Neurons Implicated in the Control of GnRH in Ewes

Neurotransmitter or Neuropeptide	% POA GnRH Cells Contacted	Area of Cell Bodies	% Cells Containing ERα	Afferents to POA	Effect on GnRH Release
Dopamine	12–18%	POA/AHA (A14)	3–17%[a,52,60]	No	Inhibit and stimulate
		ARC (A12)	3–13%[a,b,52,60]	No	Inhibit and stimulate
	0%[68]	RCh (A15)	0%[52]	No	Inhibit in anestrus

mind that ERα-containing neurons in the ARC (but not elsewhere) also project to the median eminence,[79] as do KNDy neurons,[80] where they may contact GnRH terminals; DA synapses on GnRH terminals in the median eminence have been identified with electron microscopy.[1]

All but one of these transmitters (RFRP3) have been co-localized with either ERα and/or PR in neuronal cell bodies in the hypothalamus or, in the case of NE, in A1 and A2 groups in the brain stem (Table 27.1). These steroid-responsive populations are likely candidates for mediating the feedback actions of estradiol or progesterone, but there is little evidence on which of them project to GnRH neurons. Co-localization of KNDy peptides in boutons contacting GnRH neurons has been used to demonstrate that this population projects to one-third of GnRH neurons in the POA and about 40% of those in the MBH,[71] but this approach is not available for other potential afferents. Retrograde tract-tracing studies have demonstrated projections to the POA from ERα-containing neurons in the ARC and VMN[81]; from ARC neurons containing glutamate,[61] dynorphin, β-endorphin, DA, and NPY[82,83]; and from A1 NE neurons,[84,85] but have not demonstrated that these projections contact GnRH neurons. Anterograde tract-tracing studies have produced conflicting results, with one finding projections to GnRH neurons from the VMN[86] while the other did not.[87] The

latter study also found no input from the ARC,[87] which is not consistent with recent data using KNDy peptides as markers (as discussed above). This difference may reflect the location of the tract tracer injection, which appeared to be in the anterior portion of the ARC where there are few KNDy neurons. It should also be kept in mind that steroid-responsive neurons can influence GnRH secretion indirectly via interneurons, as has been recently suggested for A1 and A2 NE cell groups,[88] and that other neurotransmitters may well contribute to steroid negative feedback. For example, nitric oxide synthase (NOS) is co-localized with PR-containing neurons in the ARC and VMN,[89] but NOS-positive synaptic contacts on GnRH neurons have yet to be identified.

Most of the work in this field over the last decade has focused on kisspeptin, although there is now considerable new information on galanin and OFQ as well. Kisspeptin neurons in the sheep, as in other species (see Chapter 11), are found in the ARC and POA. Essentially, all of the ARC population, which also express NKB and dynorphin, contain ERα[72] and PR,[64] while about 50% of the POA kisspeptin neurons contain ERα.[72] Galanin and OFQ share several characteristics in common: (1) they are both found in all GnRH neurons (although antigen retrieval is needed to visualize galanin)[57,58,90]; (2) another population of neurons containing each peptide, but not GnRH, are distributed throughout the hypothalamus (e.g., in the PVN, AHA, and anterior portions of the ARC), and some of these contain ERα (OFQ and galanin)[70,74] and PR (OFQ)[74]; and (3) they both co-localize with known neuropeptides in the ARC (galanin with DA,[91] and OFQ with β-endorphin[74]). Galanin can act via Gal-R1, Gal-R2, and Gal-R3, and mRNA for all three are found in the POA, PVN, and ARC and increase during the luteal phase[92]; Gal-R1 protein is found in ovine GnRH neurons (5–20%, with the highest percentage in the luteal phase),[93] but Gal-R2 protein is not.[94] OFQ is considered one of the endogenous opioid peptides (EOPs), but acts via its own receptor, ORL1, which has yet to be characterized in ovine tissue. Neurons containing RFRP3 are found only in the region adjacent to the third ventricle within the PVN and DMH.[95,96] RFRP3-positive boutons contact GnRH neurons in the POA[75] and β-endorphin- and NPY-containing cell bodies in the ARC,[78] but the one study that examined expression of the putative RFRP3 receptor in sheep (by in situ hybridization) found little expression in the ARC, and none in the POA.[95] As noted earlier, no studies have looked for the presence of steroid receptors in ovine RFRP3 neurons at this time.

The location of steroid receptors and determination of relevant neural circuitry lay the anatomical foundation for analysis of the feedback actions of gonadal steroids, but provide no information on the function of these systems. The latter requires determination of the actions of the neurotransmitters using receptor agonists and antagonists, and of changes in neuronal function under different physiological conditions. Neuronal function is usually assessed in one of three ways: (1) measurement of mRNA (RT–PCR and in situ hybridization) and/or protein (immunocytochemistry) expression for peptide transmitters, or more indirect indices (e.g., transporters or synthetic enzymes) for the smaller neurotransmitters; (2) monitoring expression of the early immediate gene product, Fos, which has been used extensively as an index of increased activity and/or other intracellular signaling molecules; or (3) measurement of transmitter concentrations in samples collected by push–pull perfusion or microdialysis in the vicinity of nerve terminals.

Based on the effects of receptor agonists and/or antagonists, there is general agreement that dynorphin,[69] β-endorphin,[97] GABA,[98] somatostatin,[99] and OFQ inhibit,[58] while glutamate,[100] kisspeptin,[101] and NKB[102] stimulate, GnRH release in the ewe (Table 27.1). NPY usually inhibits GnRH,[103] but stimulatory effects have been reported under some circumstances.[104] Dopamine can have both inhibitory[105] and stimulatory[106] effects depending on the site of administration, and NE has either inhibitory or stimulatory effects depending on the endocrine condition of the ewe.[107,108] Because interest in RFRP3 is a fairly recent development, there have been only a few studies on its potential role, and the results to date are inconsistent. RFRP3 inhibited the response of ovine gonadotropes to GnRH in vitro,[96,109] and RFRP3 was found in the external zone of the median eminence[96] and in hypophysial portal blood.[110] Although in vivo inhibitory effects of intravenous (IV) administration of RFRP3 on LH secretion have been observed by one group,[96,110,111] the doses used produced RFRP3 concentrations far in excess of those found in portal blood.[110] Another group reported that RFRP3 given either IV (at similar doses to those used by others) or into the third ventricle had no inhibitory effects on LH secretion in ovariectomized (OVX) ewes.[112] Thus, any conclusions as to the physiological actions of RFRP3 in the ewe await further studies. The effects of galanin, agonists, or antagonists for its receptors have not been reported in ewes, and there is no direct evidence at this time that galanin or RFRP3 mediates any feedback effects of ovarian steroids in this species. Similarly, the possibility that glial cells play a role in steroid feedback, as they may in other species (see Chapter 11), has yet to be tested in sheep.

Control of Tonic GnRH and LH Secretion by Ovarian Steroids

Because tonic gonadotropin secretion always occurs in an episodic pattern, the negative-feedback actions of both estradiol and progesterone require direct or indirect interactions with the neural mechanisms driving pulsatile GnRH secretion. Therefore, we will first consider

recent information on these neural elements, and then discuss the effects of ovarian steroids on them.

THE GnRH PULSE GENERATOR[73,113]

The episodic pattern of GnRH release implies that the GnRH neurons controlling tonic LH secretion must function in synchrony, an inference supported by detailed analysis of pulsatile GnRH secretion rates.[114] Specifically, episodic GnRH secretion occurs essentially as a square wave, with very rapid onsets and offsets and no secretion between pulses (Figure 27.6), indicating tight coupling of the responsible GnRH neurons. Thus, a key first step in understanding the mechanisms of steroid negative feedback is to identify the neural systems responsible for the generation of GnRH pulses, and significant progress has been made during the last few years toward this goal. Early work that de-afferented input to the MBH with knife cuts indicated that the neural elements necessary for episodic LH secretion reside within this area in sheep,[115,116] as in other species (see Chapter 33), and bursts of multiunit electrical activity (MUA) that correlated with LH pulses were recorded in this area in OVX ewes.[117]

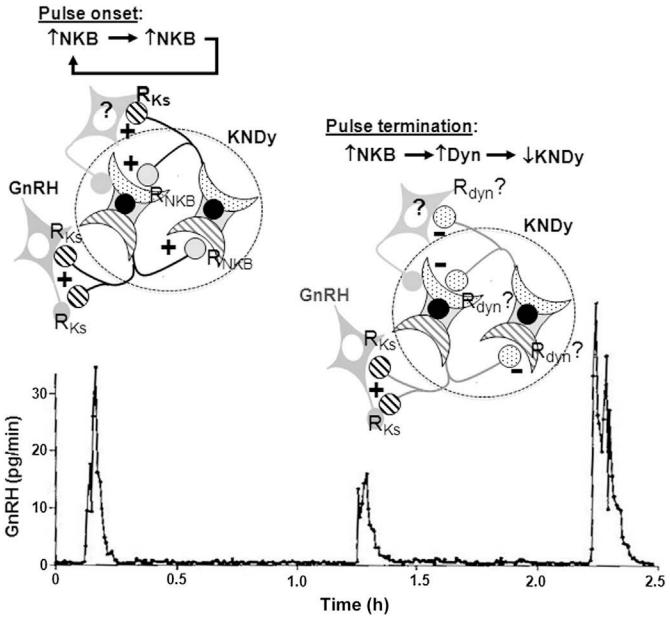

FIGURE 27.6 Model for role of KNDy neurons in driving episodic GnRH secretion. Representative GnRH pulse pattern is presented in the *bottom panel*, which depicts the GnRH secretion rate into hypophysial portal blood samples collected every 30 s for 2.5 h in OVX ewes. The model proposes that each pulse is triggered by an initial release of NKB (gray terminals) within the KNDy circuit, which increases the activity of these neurons. This initiates a positive-feedback loop that further increases NKB release onto KNDy neurons and kisspeptin (striped terminals) release that stimulates GnRH neurons, which have kisspeptin receptors (R_{Ks}) Within 1–2 min, the inhibitory effects of dynorphin (stippled terminals) within the KNDy circuit dominate, possibly due to a decrease in NK3R (R_{NKB}) or an increase in κ-receptor (R_{Dyn}) expression. Dynorphin inhibits KNDy neural activity, breaking the positive-feedback loop and suppressing kisspeptin and, thus, GnRH release to terminate the pulse; see the text for further details. Note that the pattern in each terminal indicates the biologically active transmitter (e.g., due to selective expression of postsynaptic receptors), not selective transport of that peptide to the terminal. *Source: Revised from Lehman et al.*[73]

More recently, several lines of evidence have led to the hypothesis that KNDy neurons in the ARC play an important role in driving episodic GnRH secretion,[73,113] including the following: (1) kisspeptin is needed for episodic LH secretion in OVX ewes,[105,118] (2) KNDy neurons form an extensive interconnected network capable of firing synchronously[119,120] and project to GnRH neurons in the ovine MBH and POA,[71] and (3) bursts in MUA activity that correlate with LH pulses in OVX goats appear to be recorded from KNDy neurons.[121] Moreover, a coherent model for the synchronous firing of KNDy neurons during episodic GnRH secretion has been developed that appears to be applicable to sheep and goats. This model postulates specific roles for each of the KNDy neuropeptides (Figure 27.6). First, the primary role of kisspeptin is to provide the output signal from KNDy neurons that drives each GnRH pulse; supporting evidence is that (1) GnRH neurons contain KISS1R (kisspeptin receptor, aka GPR54),[122] (2) KNDy neurons do not,[80] and (3) exogenous kisspeptin increased LH secretion without altering MUA in the ARC.[121] Second, the stimulatory effects of NKB on KNDy cells trigger a positive-feedback loop within the KNDy network to initiate each GnRH pulse; supporting evidence is that (1) KNDy neurons contain NK3R (tachykinin NK3 receptor), while GnRH neurons do not[123]; (2) intracerebroventricular (ICV) administration of an NK3R agonist increased MUA activity[124] and Fos expression in KNDy neurons[125]; and (3) local administration of an NK3R antagonist to the ARC disrupted episodic LH secretion.[126] Third, increased release of dynorphin dampens and eventually terminates KNDy neural activity and thus each GnRH pulse; supporting evidence is that (1) IV infusion of naloxone increased GnRH pulse amplitude and prolonged pulse duration,[127] (2) ICV administration of a κ-opioid receptor antagonist increased the frequency of MUA in the ARC,[124] and (3) the same κ-opioid receptor antagonist increased LH pulse frequency when given locally into the ARC.[126] The recent report that local administration of a KISS1R antagonist to the ARC of OVX ewes decreased LH pulse frequency indicates that endogenous kisspeptin also has effects on the activity of the KNDy neural network.[126] Because these actions must be via non-KNDy KISS1R-containing neurons found in the ARC,[80] we have modified our original proposal to include an unidentified interneuron that can interact with this circuit (Figure 27.6).

The possible interaction of specific GnRH neurons with this putative pulse generator are still under investigation, but GnRH neurons within the MBH are likely to be its

primary target, based on knife cut data[115] and the selective expression of Fos in MBH GnRH neurons when episodic LH secretion was stimulated.[46] The latter contrasts with the LH surge, during which GnRH neurons in all areas were activated (Figure 27.5).[47] It has been suggested, based on systemic administration of a GnRH receptor antagonist, that ultrashort loop feedback may contribute to the generation of GnRH pulses,[128] but other data in sheep are not consistent with this hypothesis,[129] and local administration of acyline to the ARC had no effect on pulsatile LH release in OVX ewes.[126] Thus, at this time it appears as if the activity of the three KNDy neuropeptides may be sufficient to largely account for GnRH pulse generation in sheep. Interestingly, two of these peptides have also been implicated in the feedback actions of ovarian steroids.

ACTIONS OF ESTRADIOL AND PROGESTERONE

Careful replacement studies reproducing normal progesterone and estradiol concentrations in acutely OVX ewes produced tonic LH concentrations in steroid-treated OVX animals that were virtually identical to those seen during the normal estrous cycle, while treatment with progesterone or estradiol alone modestly reduced tonic LH secretion, but not to normal levels.[130] Thus, estradiol and progesterone are both necessary and sufficient to account for the pattern and mean concentrations of tonic LH during the ovine estrous cycle. Quantitatively, progesterone is more important than estradiol because the latter is a weak negative-feedback hormone during the breeding season.[131] Progesterone produces a dose-dependent inhibition of LH and GnRH pulse frequency, while estradiol inhibits GnRH and LH pulse amplitude, but also stimulates pulse frequency.[107] Each of these individual actions is dose dependent, but because they tend to offset each other, basal estradiol concentrations are as effective as peak concentrations in suppressing mean LH. Estradiol also enhances the inhibitory actions of progesterone, but this action is not dose dependent.[107] Consequently, the inhibitory effects of estradiol are relatively constant throughout the cycle, and tonic LH secretion and GnRH–LH pulse frequency are inversely correlated with progesterone concentrations during the estrous cycle (Figures 27.1 and 27.2).

MECHANISMS MEDIATING PROGESTERONE NEGATIVE FEEDBACK[107]

Progesterone has one primary negative-feedback action: inhibition of GnRH pulse frequency. Although progesterone can have inhibitory effects directly on the pituitary,[1] the physiological relevance of these remains unclear, because pituitary effects were not always observed in vivo[132] and this steroid specifically inhibits LH pulse frequency, an action that reflects inhibition of GnRH pulse frequency. There is some evidence that progesterone increased GABA[133] and decreased glutamate[134] release in the POA, but knife cuts between the POA and MBH did not disrupt progesterone negative feedback,[107] so these systems probably do not play a critical role in the inhibitory actions of progesterone. Progesterone also partially inhibited *Kiss1* mRNA expression in the ARC based on in situ hybridization data,[135] but this has not been confirmed using qRT–PCR (Figure 27.7). Thus, the

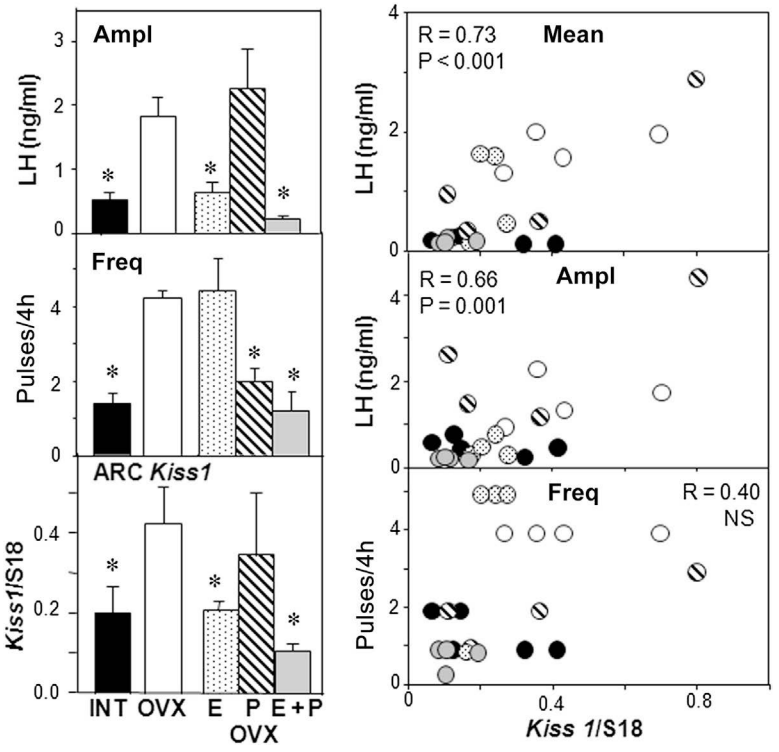

FIGURE 27.7 Effects of ovarian steroids on episodic LH secretion and *Kiss1* mRNA expression in the caudal ARC of ewes. Ewes ($n = 4$–5/group) were ovariectomized (OVX) and given either no implants (clear symbols) or implants that produced luteal-phase levels of estradiol (stippled symbols), progesterone (striped symbols), or both (shaded symbols). Eight days later, LH pulse patterns were monitored for 4 h, and tissue was immediately collected and frozen. Samples from ovary-intact (INT) luteal-phase ewes (black symbols) were collected at the same time. The caudal ARC was then microdissected, mRNA extracted, and *Kiss1* mRNA determined by qRT–PCR. Bars on the right depict mean ± standard error of the mean values for LH pulse amplitude (*top panel*), LH pulse frequency (*middle panel*), and *Kiss1* mRNA (*bottom panel*). *$P < 0.05$ versus OVX. Right panels present correlations of the mean LH (*top*), LH pulse amplitude (*middle*), and LH pulse frequency (*bottom*) with *Kiss1* mRNA expression in individual ewes. *Source: From Goodman RL, Rao A, Smith JT, Clarke IJ. Negative feedback control of Kiss-1 gene expression by estradiol and progesterone. Program: 1st World Congress on Kisspeptin Signaling in the Brain, Cordoba, Spain, 2008.*

general consensus is that EOPs are the primary mediators of progesterone negative feedback because several studies have demonstrated that EOP antagonists increased LH (and GnRH) pulse frequency in the presence, but not the absence, of progesterone.[1,107] More recent work points to dynorphin from KNDy neurons as the EOP mediating the negative-feedback actions of progesterone: (1) all KNDy neurons contain PR,[64] the receptor mediating progesterone negative feedback[136]; (2) local administration of a κ-receptor antagonist to the MBH increased LH pulse frequency in luteal phase ewes[69]; (3) OVX decreased expression of pre-prodynorphin mRNA in the ARC[137]; and (4) local microimplantation of RU486 into the region containing KNDy neurons blocked the negative-feedback action of systemic progesterone.[138] It should be noted, however, that microimplants containing progesterone had no effect when placed in the region containing KNDy neurons,[138] indicating that other neural systems act in concert with KNDy neurons to mediate progesterone negative feedback. Both dynorphin[69] and β-endorphin[97] can act in the POA to inhibit LH pulse frequency during the luteal phase but, as noted earlier, data from de-afferentation studies indicate that these other systems are likely in the MBH.[107] One possible system is the OFQ-containing neurons concentrated in the rostral ARC, which contain ERα and PR,[74] because an antagonist to the OFQ receptor increased LH secretion in OVX ewes treated with estradiol plus progesterone, but not those treated only with estradiol.[74]

MECHANISMS OF ESTRADIOL NEGATIVE FEEDBACK[107]

These are much more complex than those of progesterone because estradiol produces four different effects on episodic GnRH–LH secretion. During the luteal phase, it increases the ability of progesterone to inhibit GnRH pulse frequency.[136,139] During the follicular phase, estradiol (1) decreases GnRH and LH pulse amplitude,[140] (2) increases pulse frequency,[140,141] and (3) alters the shape of GnRH pulses and increases GnRH release between pulses.[142] The mechanisms underlying these actions are not well understood, in part because direct assessments of GnRH secretion are necessary to monitor most of them.

The primary negative-feedback action of estradiol is to inhibit LH pulse amplitude. Most evidence indicates that this reflects estradiol actions at both the pituitary and hypothalamus. Acutely (within a few hours), estradiol treatment decreased the response of the pituitary to GnRH, both in vivo and in vitro,[143] and completely suppressed LH pulses without disrupting GnRH secretion into the portal circulation under some circumstances.[1] The cellular mechanisms of this inhibitory action have not been completely elucidated, but early work demonstrated that estradiol acutely decreased expression of mRNA for the α and LH-β subunits.[143] More recent work has implicated membrane estrogen receptors in the acute negative-feedback actions of estradiol.[144–146] Binding of estradiol to these receptors activated the same second messenger systems as GnRH, but inhibited GnRH-induced increases in intracellular Ca^{++} concentrations,[147] so the latter most likely accounts for the acute negative-feedback actions of this steroid. Estradiol-induced increases in GnRH pulse frequency may also indirectly decrease LH pulse amplitude, because increasing the frequency of GnRH administration decreased LH pulse amplitude in response to each GnRH injection.[1,143,148]

Estradiol also decreased the amount of GnRH released per pulse,[142] an action that may occur in both the POA and MBH.[1] Of the 12 neural systems identified to contain ERα and project to GnRH neurons (Table 27.1), the possible roles of EOP, GABA, NE, and kisspeptin in estrogen negative feedback have been examined.[107] Although initial work monitoring LH pulse amplitude indicated that EOPs mediate this action of estradiol, direct measurement of GnRH ruled out a role for EOPs,[127] and it is unlikely that GABA mediates estrogen negative feedback.[98] There is evidence that NE may mediate this action of estradiol because estradiol rapidly induced Fos in A1 NE neurons[84] and microimplants of an α-adrenergic antagonist into the POA increased LH pulse amplitude in the presence, but not the absence, of estradiol.[107] On the other hand, knife cut data point to the MBH as the most important site of estrogen negative feedback,[115] and more recent studies have implicated KNDy neurons in this action. Specifically, OVX increased, and estradiol treatment decreased, kisspeptin peptide and mRNA expression in the ARC,[75,135] and OVX increased Fos expression in these neurons.[149] Moreover, a KISS1R antagonist decreased LH pulse amplitude when given ICV to OVX ewes[118] and kisspeptin mRNA expression in the caudal ARC, measured by qRT–PCR, correlated with LH pulse amplitude, but not pulse frequency, under a variety of endocrine conditions (Figure 27.7). Thus, KNDy neurons may mediate the negative-feedback actions of both estradiol and progesterone, but do so via different neurotransmitters. This hypothesis is consistent with the proposed roles of kisspeptin and dynorphin in the generation of GnRH pulses. If kisspeptin is primarily the output signal, then inhibition of kisspeptin expression would be expected to inhibit GnRH pulse amplitude. Likewise, if dynorphin terminates each GnRH pulse and prevents activity between pulses, then a progesterone-induced increase in dynorphin would inhibit pulse frequency.

Little is known about how estrogen exerts its other three actions on pulsatile GnRH secretion in breeding-season ewes. The ability of estradiol to increase progesterone inhibition of GnRH pulse frequency most likely involves dynorphin in KNDy neurons that contain both ERα[72] and PR,[64] and could reflect the well-established ability of this steroid to increase expression of PR. The

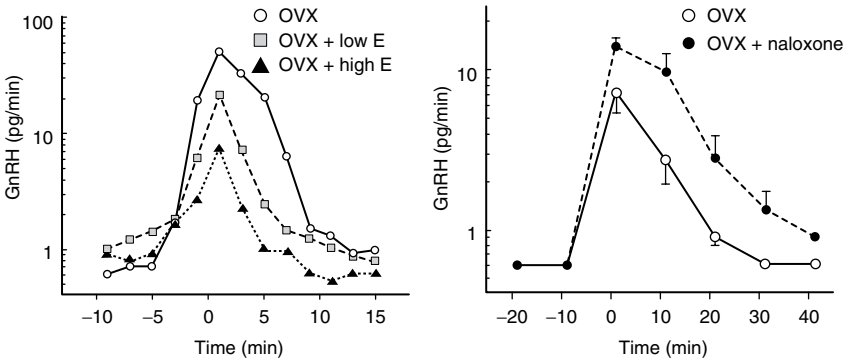

FIGURE 27.8 Effects of estradiol (E) and an EOP antagonist (naloxone) on the shape of GnRH pulses in OVX ewes. *Left panel*: Mean GnRH secretion rate, normalized to the peak of each pulse, in samples collected every 2 min from acutely OVX ewes treated with either no steroid or estradiol implants to produce luteal-phase (low E) or peak follicular-phase (high E) concentrations of E. *Right panel*: Mean GnRH secretion rate, normalized to the peak of each pulse, in samples collected every 10 min from ewes OVX 2 weeks earlier, before (OVX) and during (OVX + naloxone) intravenous infusion of naloxone. Note the difference in axes between two panels. *Source: Reprinted from Goodman et al.*[107]

mechanisms by which estradiol increases GnRH pulse frequency are completely unknown. It is unlikely that they involve EOPs or NE because antagonists to these neurotransmitters had no effect on pulse frequency in OVX+E ewes.[107,127] On the other hand, EOPs may be involved in the ability of estradiol to alter GnRH pulse shape because naloxone and estradiol produced opposite effects on GnRH pulse shape (Figure 27.8). This raises the possibility that the increase in β-endorphin release that occurs in the follicular phase[150,151] may mediate effects of estradiol on GnRH pulse shape. In contrast, both estradiol and naloxone increased the release of GnRH between pulses, so that this action of estradiol cannot be due to an increase in EOP. Finally, as discussed in the next section, these changes in GnRH pulse shape and in release between pulses are greatly magnified at the start of the preovulatory GnRH surge[18] so that these effects of estradiol most likely reflect positive, rather than negative, feedback actions of this steroid.

Control of the GnRH and LH Surges

HORMONAL CONTROL

It is now well established that the follicular-phase estradiol rise is the ovarian signal that induces the preovulatory surges of GnRH and LH,[1] while neither progesterone nor PR acutely contributes to the LH surge because (1) circulating progesterone concentrations do not increase during the periovulatory period of the ovine estrous cycle[14]; and (2) the PR antagonist, RU486, does not block the estradiol-induced surges of GnRH and LH in the ewe.[152] Induction of the LH surge does not require the full preovulatory estradiol rise[153]; an increase to midfollicular phase concentrations is sufficient. However, greater amounts of estradiol do increase the magnitude of the LH surge[153] and synchronize it with the onset of estrus,[1] so peak estradiol concentrations are required to mimic events during the estrous cycle. The most obvious action of progesterone is that chronically elevated concentrations block the ability of estradiol to induce an LH–GnRH surge.[130,152] Progesterone pretreatment and withdrawal also delay the onset of the GnRH–LH surge,[130,154] contributing to its synchronization with estrus, and augment the amplitude of the GnRH surge.[155]

MECHANISMS OF ACTION OF ESTRADIOL

The sites of estradiol action in triggering the LH surge include both the hypothalamus and pituitary. The amount of LH released in response to exogenous GnRH is maximal just before the onset of the LH surge,[143] and studies in which endogenous GnRH secretion was blocked and replaced with exogenous GnRH pulses have demonstrated that approximately 10–20% of the surge can be accounted for by estrogen actions at the pituitary.[1,143] The stimulatory effects of estradiol on the gonadotrope appear to be multifaceted and mediated primarily by nuclear ER. Acting in concert with increased GnRH pulse frequency, estradiol increased expression of both ERα[156] and GnRH receptors[132] in gonadotropes, both of which were maximal during the late-follicular phase.[51,132] Estradiol also increased the synthesis of LH and the number of Ca^{++} channels, and enhanced the movement of secretory granules toward the cell membrane.[1,143] All of these actions enhance pituitary responsiveness to GnRH, but the relative importance of each remains to be determined.

Direct measurements of GnRH have clearly demonstrated that estradiol produces a dramatic increase in mean GnRH release and alters the pattern of GnRH secretion so that it moves progressively from episodic to continuous.[17,18,142] As illustrated in Figure 27.9, GnRH secretion between pulses begins to increase just prior to the start of the LH surge; there is then a dramatic increase in both GnRH pulse amplitude and interpulse

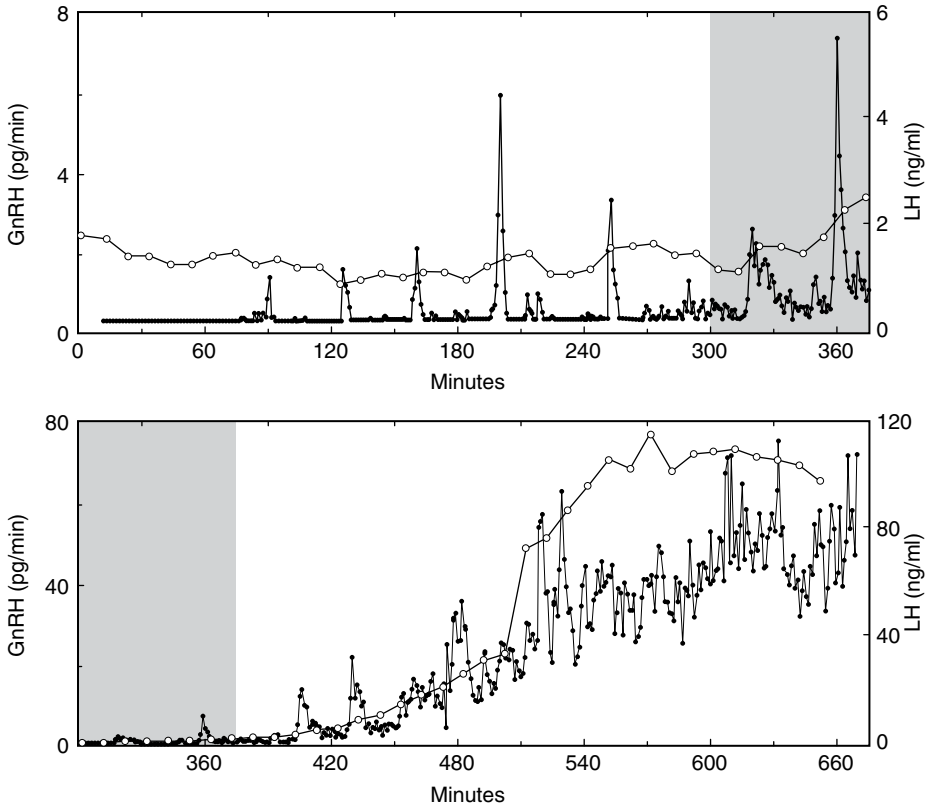

FIGURE 27.9 Time course of changes in the pattern of GnRH secretion leading up to and during the estradiol-induced preovulatory surges of GnRH and LH. GnRH secretion rates (solid circles) monitored every minute and peripheral LH concentrations (open circles) monitored every 10 min in an individual ewe are presented. Note the differences in the *y*-axis between the top and bottom panels. The shaded area depicts the time of overlap of values from the top and bottom graphs. *Source: Reproduced from Evans et al.[18] (Copyright 1995, The Endocrine Society).*

GnRH secretion during the ascending phase, which eventually leads to sustained erratic GnRH release during peak secretion. The mechanisms by which estradiol produces these effects are still poorly understood, but two questions have been resolved. First, studies using local administration of estradiol have demonstrated that it acts in the VMN–ARC region to induce the surge.[157] Second, there is no anatomically distinct subpopulation of GnRH neurons involved; approximately 40% of GnRH neurons in all hypothalamic areas (Figure 27.5) expressed Fos during the surge.[47] These data are consistent with the observation that knife cuts between the POA–AHA, where most of the GnRH perikarya are found, and the MBH decreased the amplitude, but did not completely block, the estrogen-induced LH surge.[115]

Early work implicated seven different neurotransmitters in the control of the GnRH surge, while more recent work has focused on the role of kisspeptin and NKB (Table 27.2). In analyzing this information, we have made use of a conceptual model[152] that divides the surge induction process into three stages: (a) activation, a period lasting between 4 and 14 h, during which estradiol must be present; (b) transmission, which lasts for 6–8 h and does not require the presence of estradiol; and (c) GnRH release, which also does not require the presence of estradiol (Figure 27.10). Of the nine potential transmitters, four have received significant attention: the inhibitory actions of β-endorphin and the stimulatory actions of NE, kisspeptin, and NKB. Levels of mRNA for the precursor of β-endorphin decreased during the activation stage,[160] while concentrations of β-endorphin in the median eminence increased during the transmission phase,[150,151] and then fell during the GnRH surge.[150] This pattern of release raises the possibilities that withdrawal of EOP inhibition contributes to the onset of the surge and EOP agonists did delay the surge.[162,163] However, EOP antagonists did not advance the surge,[162,172] so an EOP brake is unlikely to be the last limiting factor before the onset of GnRH release. Estrogen treatment acutely stimulated A1 NE neurons[84] and there is evidence for increased NE release in the POA during the transmission phase,[164,167] and in the median eminence during the GnRH surge.[150] However, an α-adrenergic antagonist did not consistently block the estrogen-induced LH surge,[158] so this transmitter may play only a facilitating role.

Kisspeptin contributes to, but is not solely responsible for, the GnRH surge in sheep because a KISS1R antagonist was able to reduce the LH surge by only approximately 50%,[80] even though it completely inhibited LH secretion in OVX ewes[80,105] and blocked the LH surge in rats.[173] However, which kisspeptin neurons (POA or KNDy) are responsible remains under debate. Estrogen stimulated kisspeptin expression in the POA,[75] and levels of *Kiss1* mRNA in these neurons increased during the follicular phase.[122] There is also agreement that Fos

TABLE 27.2 Evidence for Roles of Transmitters Implicated in Induction of GnRH Surge

Transmitter	Activation Phase (Estradiol Required)	Transmission Phase (Estradiol Not Required)	GnRH Release (Estradiol Not Required)	Caveates
Dopamine		Antagonist blocks[106,158]	Increased turnover in VMH[106]	Agonist did not advance[159]
β-endorphin (ARC)	Decreased mRNA[a,160] No change in Fos[161]	Increased in ME[b,150,151] Agonist delays[162,163]	Fall in ME[b,150]	Antagonist did not advance[162]
Glutamate (ARC)	Increased Fos[61]			Limited data
GABA	Increased release in POA[164]	Gradual decline in POA[164]		Limited data
Kisspeptin (POA)		Increased mRNA[a,122] Antagonist reduced amplitude[80]	Increased Fos[149,165]	Antagonist did not completely block[80]
Kisspeptin (ARC KNDy)	Increased Fos[122]	Increased mRNA[a] in some areas[122,149,166] Antagonist reduced amplitude[80]	Increased Fos[149]	Antagonist did not completely block[80]
Norepinephrine (A1 cells)	Increased Fos[84]	Increased pulses[164] and DBH[c] release in POA[167]	Increased in ME[b,150]	Antagonist did not consistently block[158]
Neurokinin B (ARC KNDy)	Decreased mRNA[a,168] Increased Fos[122]	No change in mRNA[a,65] Antagonist in RCh reduced amplitude[169]	Increased Fos[149] No change in mRNA[a,65]	Agonist induced surge[102] Antagonist did not completely block[169]
Neuropeptide Y (ARC)	No change in Fos[161] or mRNA[a,160]	Increased in ME[b,104]	Increased in ME[b,104]	Inconsistent effects of agonist[104,170] and antibodies[1]
Somatostatin (VMN)	Increased mRNA[a,99] Fos: No change at 1 h,[161] and increased at 6 h[171]		Increased Fos[66]	Limited data

expression in this POA population increases at the time of the LH surge,[149,165] so this population likely participates in the secretory phase of estrogen action. There are two reports of increased Fos expression in KNDy neurons at the time of the surge,[149,174] and Kiss expression was also elevated in some of these neurons late in the follicular phase.[122,149,166] An increase in Fos was not observed in KNDy neurons in a third study,[165] possibly for technical reasons.[149] KNDy, but not POA kisspeptin, neurons were also activated 1 h after a surge-inducing estrogen injection,[122] so they are most likely involved in both the activation and release phases of the GnRH surge.

Initial interest in the possible role of NKB in the surge was dampened by observations that mRNA for the NKB precursor did not increase before or during the estrogen-induced surge,[65] and that estradiol acutely inhibited levels of this mRNA.[168] However, NKB in KNDy neurons may be involved because these neurons express Fos at the time of the LH surge[149] and local administration of the NK3R agonist, senktide, to the retrochiasmatic area (RCh) induced a surge-like LH pattern in ewes.[102,169] Moreover, recent evidence that local administration of a NK3R antagonist to the RCh decreased the amplitude of the estrogen-induced LH surge[169] provides strong evidence that NKB actions in this region are another component of the neural mechanisms responsible for the preovulatory GnRH surge. The NKB input to this region most likely arises from KNDy cells, and we have preliminary data that RCh neurons provide input to KNDy neurons, so this reciprocal circuit may be important during the transmission or secretory phases of estrogen positive feedback.

Of the other five neurotransmitters, two of them (glutamate[61] and GABA[164]) have been implicated in only one report (Table 27.2), and no consistent picture has emerged for NPY. Agonists to NPY receptors have been reported to advance[104] and delay the LH surge,[170] and NPY antisera can either delay or advance the surge.[1] Another two (DA and somatostatin) may be involved in estrogen actions in the VMN. Dopaminergic activity increased in the VMN coincident with the surge, and blockade of DA (and thus also NE) synthesis in this area delayed the surge.[106] These results are consistent with the early report that systemic administration of a DA D2 receptor

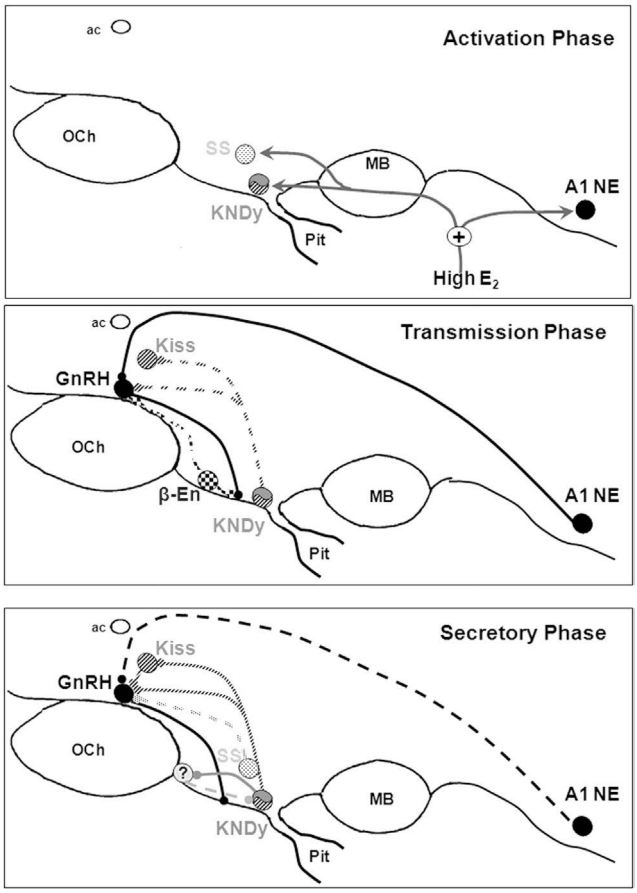

FIGURE 27.10 Neural systems postulated to participate in the estrogen-induced LH surge in the ewe. Note that solid connections are supported by direct evidence, and dashed ones by indirect evidence. This model proposes that these mechanisms are activated by estradiol acting on ARC KNDy and VMH somatostatin (SS), and, possibly, A1 noradrenergic (NE) neurons (*top panel*). During the transmission phase (*middle panel*), stimulatory NE and possibly kisspeptin inputs to GnRH neurons are counterbalanced by the inhibitory effects of β-endorphin at GnRH cell bodies and terminals. Sometime after β-endorphin release falls, GnRH secretion is initiated by kisspeptin from KNDy and POA kisspeptin neurons and maintained by a positive-feedback loop between KNDy and NK3R-positive neurons in the RCh (*bottom panel*). NE and somatostatin may also contribute to the stimulation of GnRH neurons at this time. Note that for simplicity, two aspects of this system have not been depicted here: (1) GnRH neurons in the AHA and MBH that participate in the surge, and (2) stimulatory inputs to GnRH terminals in the median eminence.

(D2R) antagonist disrupted the surge,[158] but not with the report that administration of a D2R agonist to the VMN during the transmission phase failed to advance the surge.[159] Estrogen treatment increased somatostatin mRNA levels at 4 h[99] and Fos expression at 6 h[171] (but not 1 h post injection[161]) in the VMN, and induced Fos in 81% of these neurons during the GnRH surge.[66]

In summary, one can propose the following speculative model for the estrogen-induced GnRH surge in the ewe (Figure 27.10). Estradiol acts on ARC kisspeptin neurons, and probably VMN somatostatin and A1 NE neurons, to activate the surge mechanism. During the transmission phase, there is an increase in stimulatory NE input to GnRH neurons, but this is balanced by an increase in inhibition by β-endorphin. At sometime during or after removal of the EOP brake, the reciprocal circuit between KNDy cells and NK3R-containing neurons in the RCh is activated and soon acts as a positive-feedback loop to maintain the kisspeptin release from KNDy neurons that drives GnRH secretion during the surge. These primary inputs are supplemented by kisspeptin from POA neurons, somatostatin from the VMN (driven by local DA release), and NE from the A1 in either a redundant or cooperative manner.

MECHANISM OF ACTION OF PROGESTERONE[152]

Much less is known about the mechanisms of the two actions of progesterone. The mechanism of the priming action of progesterone pretreatment that increases the amplitude of the GnRH surge has not been investigated extensively, probably because it was discovered fairly recently and is not reflected in the preovulatory LH surge, so GnRH must be measured.[155] Progesterone pretreatment did not increase Fos expression in GnRH neurons during the estradiol-induced GnRH surge, but did increase Fos in non-GnRH POA neurons.[175] This raises the possibility that the latter neurons may provide stimulatory input that augments GnRH release, although they also could be involved in behavioral estrus (discussed further in this chapter).

The ability of progesterone to block the LH surge is due to inhibition of the GnRH surge, not inhibitory effects of this steroid at the pituitary.[176] It is mediated by the classical PR[152,177] and prevented both the activation[178] and transmission[179] phases of the estradiol-induced surge. Progesterone treatment throughout these two phases blocked Fos expression in GnRH neurons, but did not consistently affect Fos expression in other POA neurons.[175] This is consistent with the report that progesterone acted in the VMN, not the POA, to block the LH surge.[180] Progesterone did inhibit Fos in the VMN during activation and in the ARC at the end of the transmission phase.[181] Which neurotransmitters are involved in this action of progesterone remains unclear. Studies with the EOP antagonist, naloxone,[182,183] indicated that EOPs are not involved in progesterone blockade of activation and play only a minor role in the disruption of transmission.

Control of FSH Secretion

The only new information on the control of FSH secretion since the previous version of this chapter (in the third edition of this book) comes from a few studies on the role of anterior pituitary paracrine factors, so we will briefly summarize the discussion that was presented in that previous version,[1] and then consider the latter in more detail.

The preovulatory FSH surge is controlled by the same neural mechanisms that produce the coincident LH surge: the follicular-phase rise in estradiol secretion acting in the brain triggers the FSH surge, which can be blocked by a neural action of progesterone. Tonic FSH secretion throughout the remainder of the estrous cycle is controlled largely by estradiol and inhibin secretion from the ovary and paracrine effects of activin within the pituitary. Based on the patterns of estradiol and inhibin during the cycle (Figure 27.1), one can infer that the follicular-phase estradiol rise is responsible for the fall in FSH concentrations at this time, while changes in inhibin concentrations probably account for the "second FSH surge" on day 1 on the cycle.[11] It is less clear how ovarian hormones control the FSH fluctuations associated with follicular waves during the remainder of the cycle; as illustrated in Figure 27.3, estradiol and inhibin can account for changes in FSH associated with the first wave, but concentrations of these ovarian hormones did not change during the second wave in this study (probably because of decreasing LH release, as discussed later), so they cannot account for FSH changes seen during the second wave.[20] Similarly, periodic increases in FSH release observed in anestrus do not correlate with changes in either inhibin or estradiol.[30] There is one report of waves in FSH secretion occurring every 3–4 days in the absence of ovarian hormones,[184] but these observations need to be confirmed, and how such a rhythm could be generated is completely unknown. Evidence for a distinct hypothalamic FSH-releasing factor was reviewed in the third edition's version of this chapter, but no new information has been developed since then and interest in this possibility appears to have waned.

It is generally agreed that the ovine pituitary produces activin, inhibin, and follistatin, but the physiological functions of these locally produced peptides are less clear. Although several studies have demonstrated that inhibin can decrease FSH release in vitro,[1] no changes have been observed in hypophysial mRNA for inhibin receptors[185] or in local levels of mRNA or protein for the α-subunit of inhibin[186] in the pituitary at times during the estrous cycle when FSH secretion varies markedly. Similarly, pituitary inhibin-A expression did not change in response to variations in GnRH that stimulated FSH secretion,[187] and follistatin concentrations actually increased in response to a GnRH treatment that increased FSH release.[187] Activin can stimulate FSH synthesis and release in vitro,[188,189] and in vivo data support a physiological role for this peptide. The most consistent in vivo evidence comes from the strong positive correlations of FSHβ mRNA with the mRNA levels of three activin receptors[185] and of activin-βB (but not βA)[186] at the time of the second FSH surge. The mechanisms responsible for these changes in activin expression in the ovine pituitary remain to be determined, particularly in light of recent data that expression of activin B protein was unaffected by changes in GnRH pulse frequency.[187] There has been some recent work on the possible roles of bone morphogenetic proteins (BMPs) that are members of the same large protein family as activin and are found in the pituitary, but support for an important role for these peptides is not compelling. Early work indicated that BMP6 and BMP7 could stimulate FSH release,[190] but subsequent studies reported an inhibitory action of BMP4,[188] or that BMP2 and BMP6, but not BMP4, inhibited FSH release in vitro.[189] However, the inhibitory effects of BMP2 and BMP6 were observed at only one of the doses tested in the latter study. Moreover, a careful examination of expression of receptors and signaling molecules for BMPs found little change during the estrous cycle, and the authors concluded that it was unlikely that these proteins played an important role in regulation of FSH secretion in the ewe.[186] Thus, it appears at this time that activin is the only pituitary paracrine factor important to changes in FSH synthesis and secretion during the ovine estrous cycle.

Control of Estrous Behavior[5]

Hormonal Control

Under physiological conditions, both progesterone and estradiol are necessary for the induction of estrous behavior in the ewe.[5] Estradiol treatment alone can produce estrus, but in the absence of progesterone pretreatment, pharmacological doses are required.[1,5,130] Progesterone pretreatment for several days increases the sensitivity to estrogen and the intensity of both proceptive and receptive behavior.[191] There are breed differences in sensitivity to estradiol[192] but, in general, low concentrations can induce estrus in virtually all ewes, with higher concentrations decreasing the latency to estrus and increasing the proceptive activity of the ewe.[1,5,153,193]

The temporal relationship between progesterone and estradiol during the estrous cycle is also important for initiation of estrus. In contrast to the facilitating effects of pretreatment with progesterone, when progesterone was given simultaneously with estrogen it blocked estrous behavior,[5] and estrogen treatment was most effective if given a few days after progesterone withdrawal. Thus, the ideal steroid pattern for induction of estrus in the ewe is a prolonged period of elevated progesterone followed by a fall in progesterone and a rise in estradiol over the next few days, a pattern very similar to that observed during the ovine follicular phase (Figure 27.1). This pattern also synchronized estrus with the preovulatory LH surge; progesterone decreased the latency to estrus,[5] but increased that to the LH surge,[130,154] moving the two events closer together, and the full preovulatory E_2 rise completes this synchronization.[1] The fall in estradiol at the time of the LH surge is important for termination of

estrus, because prolonged estrogen treatment doubled its duration.[193] The physiological importance of both steroids is further emphasized by the absence of estrus at the transitions between the anestrous and breeding seasons.[1] At the start of the breeding season, the first ovulation is not accompanied by estrous behavior, because of the lack of progesterone priming. At the end of the breeding season, estrus does not occur after luteolysis, because estradiol concentrations fail to rise.

Neural Control

In contrast to the wealth of information on the hormonal control of estrous behavior in the ewe, the neural substrates for this behavior remain largely unknown. Based on lesions and local administration using microimplants,[194] estradiol acts in the VMN to induce estrous behavior.[1,5] Interestingly, progesterone increased expression of ERα in this region[195] which might explain the mechanism of progesterone priming. In contrast, progesterone microimplants blocked the ability of systemic estrogen treatment to induce sexual receptivity when placed in either the POA or VMN.[180] To date, three neurotransmitters have been implicated in the control of estrous behavior in the ewe: DA, GnRH, and oxytocin.[5] DA release in the VMN was stimulated by progesterone withdrawal, and then fell rapidly only if estradiol was administered to induce estrus.[196] These data led to the hypothesis that DA first acts in the VMN to stimulate the neural systems responsible for estrous behavior, but then inhibits this activity. This proposal is supported by the effects of local administration of a DA D2R agonist to the VMN, which increased the intensity of estrous behavior when given before systemic estradiol treatment, but decreased it when given after estradiol.[159] Interestingly, these treatments had no effect on the onset or duration of estrous behavior, indicating that other neurotransmitters are involved in triggering and terminating this behavior; both GnRH and oxytocin have been implicated in the latter. During the preovulatory GnRH surge, GnRH is released into both the portal circulation and the cerebrospinal fluid (CSF) in the third ventricle.[197] Administration of a GnRH antagonist into CSF during the latter part of the GnRH surge prematurely terminated estrous behavior, providing strong evidence that GnRH in CSF helps ensure that estrous behavior lasts for 36 h in the ewe.[198] Conversely, coitus-stimulated oxytocin release in the region of the VMN and infusion of oxytocin in this region suppressed receptivity.[5] This inhibitory effect of coitus-induced oxytocin release may account for the shortening of receptivity that occurs when ewes are exposed continuously to rams.[5]

Control of Ovarian Function

A complete review of the control of ovarian function in the ewe is beyond the scope of this chapter. Instead, this section will focus on factors responsible for follicular development, luteal development and regression, and hormone secretion throughout the ovine estrous cycle.

Control of Follicular Development[22]

Major workers in this field summarized the literature and proposed a model for follicular development in 1993, and have updated that model in a recent review.[22] In this section, we have used this review as a framework for our discussion, adding relevant newer data from ewes where appropriate. Movement from the primordial to primary and small preantral follicles (up to approximately 2 mm in diameter) occurs continuously throughout the estrous cycle because it is independent of gonadotropins. Instead, it is controlled by intrafollicular factors, primarily those coming from the oocyte. Atresia is low during these stages, but rates of atresia increase progressively as the follicles become more and more reliant on gonadotropic support. Under conditions of low concentrations of FSH and LH, thecal cells differentiate and express LH receptors, and follicles become responsive to gonadotropins. With continued growth and increases in LH and FSH, the gonadotropin-responsive follicles acquire aromatase and become gonadotropin dependent. Because of the requirement for gonadotropic support, gonadotropin-dependent follicles are susceptible to a high rate of atresia if that support is withdrawn, a characteristic that likely leads to follicular waves. If gonadotropin-dependent follicles continue to develop, they acquire LH receptors on granulosal cells and high levels of aromatase, and thus become potential ovulatory follicles. The latter will usually become atretic if an LH surge does not occur within about 72 h.

During the ovine estrous cycle, movement of follicles through their developmental trajectory is controlled by changes in concentrations of FSH and LH. During most of the luteal phase when LH pulse frequency is low, FSH plays a critical role because suppression of endogenous FSH peaks blocked emergence of follicular waves,[199] and exogenously produced FSH increments consistently initiated new follicular waves.[33,184] FSH concentrations simply have to be above a critical threshold for the development of gonadotropin-dependent follicles because neither fluctuations in the amplitude of FSH peaks during the luteal phase nor increases in the amplitude of an FSH peak affected the characteristics of the subsequent follicular wave.[21,184] Thus, a small rise in FSH above this threshold allows emergence of a cohort of follicles at the start of a follicular wave. As one or more of these become "potentially ovulatory follicles", they produce increasing amounts of estradiol and inhibin, and suppress FSH concentrations to below the threshold required by the other gonadotropin-dependent follicles so that they eventually become atretic. Thus, ablation of the largest follicle significantly lengthened the lifespan

of the second largest follicle in a monovulatory breed.[200] The secretory activity of the largest follicle may also control timing of the next follicular wave. According to this hypothesis, in the luteal phase these potentially ovulatory follicles eventually undergo atresia in the absence of an LH surge, which allows FSH concentrations to rise and initiate the next follicular wave. Although this is an attractive hypothesis, recent data do not appear to support it because an extra follicular wave, induced with exogenous FSH, did not delay the normal timing of the next endogenous increment in FSH secretion and follicular wave.[33] It should be noted, however, that inhibin, which appears to be important to the suppression of FSH,[200] was not measured in that study, and follicles in the extra wave produced abnormally low peak estradiol concentrations. The inability of ablation of all large follicles midway through a wave to advance the onset of the next wave also argues against this hypothesis, but estradiol concentrations were already declining at the time of ablation in that study.[200] Thus, there is now strong evidence for follicular dominance within a wave, but not that atresia of one wave is critical for the FSH increment that induces the next wave. Although the hypothesis that an ovarian-independent rhythm in FSH release drives follicular waves during the ovine luteal phase is intriguing,[33,184] more work is needed to rule out a role for inhibin and estradiol and to identify a mechanism for such a rhythm.

During the follicular phase of the cycle, the final stages of follicular development require both gonadotropins. During the early follicular phase, when LH pulse frequency is still relatively slow, elevated concentrations of FSH are required for the development and maintenance of potential ovulatory follicles. If these FSH concentrations were maintained throughout the follicular phase, they would be sufficient for the development of preovulatory follicles (Figure 27.11).[201] However, FSH concentrations fall as estradiol rises, so the preovulatory follicles must switch their dependence from FSH to LH during the follicular phase. Both the FSH induction of LH receptors on the granulosal cells of preovulatory follicles and the increasing LH pulse frequency seen in the follicular phase are critical for this switch, and thus ultimately for ovulation of a mature ovum. The importance of the latter is evident by the ability of high-frequency LH pulses produced exogenously in the luteal phase to maintain potentially ovulatory follicles[202] and the inverse correlation of progesterone concentrations and ovulation rates in Barbados blackbelly ewes.[203] It should be noted that episodic LH secretion is not essential; constant infusion of LH was capable of supporting ovulatory follicles in GnRH antagonist–treated[204] or prepubertal[205] ewes.

As noted elsewhere, only modest progress on our understanding of gonadotropic support of follicular development has occurred over the last decade.[22] In contrast, major new information is available on the molecular changes, oocyte–follicle interactions, and other intrafollicular factors involved in follicular development, including growth differentiation factor 9 (GDF9) and BMP15 from the oocyte, components of the insulin-like growth factor (IGF) system, and endothelial cell mitogens such as vascular endothelial growth factor (VEGF) and fibroblast growth factor 2 (FGF2). The reader is referred to Chapter 21, and two recent reviews for discussions of possible roles of intraovarian factors in follicular development.[22,206]

Control of Ovulation Rate[22]

Ovulation rate is influenced by hormonal, genetic, and environmental factors. One important hormonal influence is progesterone, with low concentrations in peripheral blood increasing ovulation rate, independent of nutritional management. In studies of the effects of low progesterone on the persistence of follicles, there was a trend toward an increased ovulation rate[27] and a prolific breed of ewes had lower concentrations of progesterone than a nonprolific breed.[26] Similarly, in a prolific breed of sheep, ovulation rate was negatively linearly correlated with concentrations of progesterone but lower progesterone did not increase lambs born.[203] Anestrous ewes pretreated to produce lower progesterone before ram introduction than seen in the luteal phase had a greater ovulation rate than ewes with ram introduction alone.[207] Consequently, treatment at progesterone withdrawal and ram introduction with low dosages of FSH, which had been shown to increase ovulation rate in anestrous ewes induced to ovulate with ram introduction, did not increase ovulation rate or litter size beyond that obtained in progesterone-pretreated ewes.[207]

There are several instances in which single-gene mutations in BMP15 in the oocyte; its receptor in the oocyte, granulosa, or corpora lutea; or GDF9 in the oocyte have a major influence on ovulation rate (reviewed by Montgomery et al.,[208] Fabre et al.,[209] and Otsuka et al.[210]). Immunization against either BMP15 or GDF9 increased ovulation rate in Romney ewes, with fewer single ovulations and more cases of three or greater ovulations,[211] but immunization against BMP15 did not increase response to a superovulatory treatment.[212] Six different sites of mutation have been identified in the BMP15 gene on the X chromosome, and they occur in five different breeds: two in Romney, two in Belclare, and one each in Cambridge, Lacaune, and Rasa Aragonesa. The Galway mutation in BMP15 occurs in Belclare and Cambridge, which also share a mutation in GDF9 on chromosome 5. The Icelandic Thoka has a different mutation in GDF9. The Booroola mutation in BMP receptor 1B, originally found in Merino on chromosome 6, has been identified in four other breeds. Finally, there is evidence for a maternally imprinted gene on the X chromosome, the

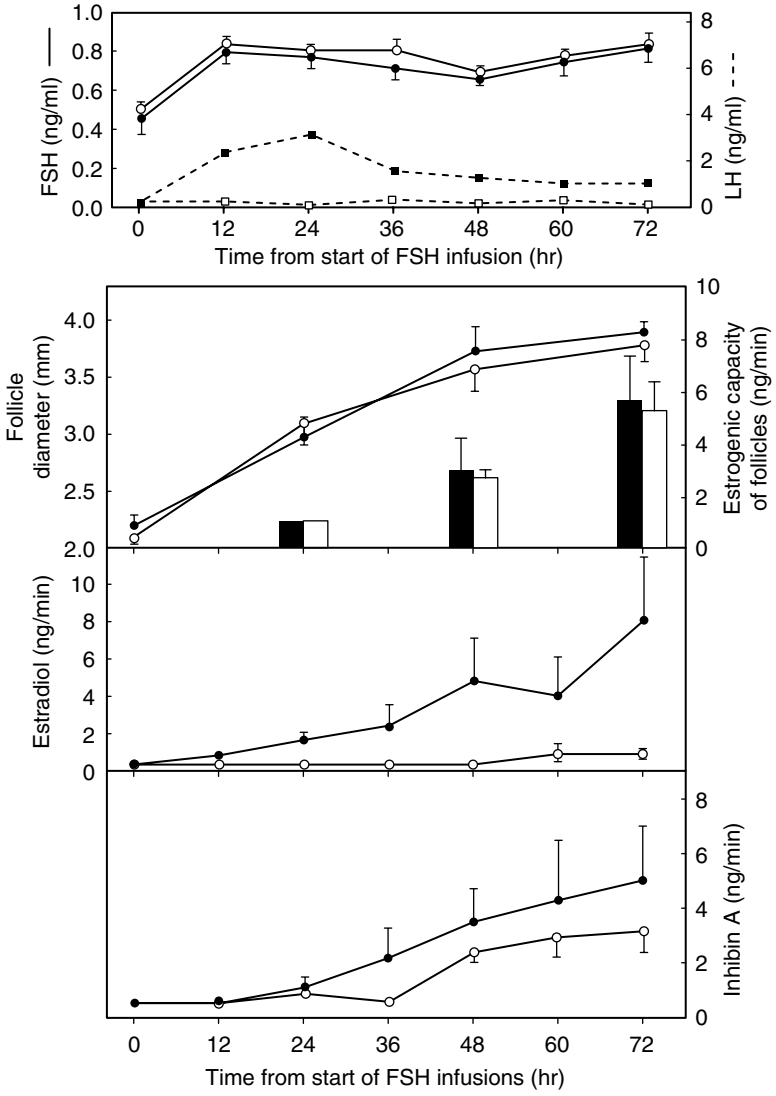

FIGURE 27.11 Effects of FSH, with and without LH, on the development of, and hormone secretion from, follicles in ewes with an ovary autotransplanted in the neck. Gonadotropin secretion was suppressed by long-term treatment with a GnRH antagonist. FSH was infused intravenously (IV) for 72 h, with (closed symbols) and without (open symbols) episodic LH injections (every 4 h). *Top panel* depicts FSH (circles) and LH (squares) concentrations; *bottom panels* present follicular diameter and secretion rates of estradiol and inhibin. Estrogenic capacity of the follicles (peak estradiol secretion rate in response to a single IV injection of LH) was determined daily. *Source: Data redrawn from Campbell et al.*[201]*; reproduced by permission of the Society for Endocrinology.*

Woodlands gene, which increased ovulation rate by 0.4 oocytes in the daughters of carrier rams.[213]

The genes related to BMP15 and GDF9 vary in the amount by which ovulation rate is increased by the effective allele (from one to 10 oocytes), and in physiological characteristics influenced by the gene. The heterozygous (single-copy) mutations in BMP15 and GDF9 described above increase ovulation rate, but homozygosity leads to sterility with no ovulation.[214,215] However, in Brazilian Santa Ines sheep with another polymorphism in GDF9, homozygosity increased ovulation rate by 82% and prolificacy by 58%.[216] Similarly, the Booroola gene ($FecB^B$) is maximally effective in increasing ovulation rate when homozygous. Crawford et al. found lower expression of mRNA for BMP15, but not of GDF9, in oocytes of homozygous Booroola ewes, and an earlier onset of responsiveness of the follicles to LH, which they proposed was similar to the effect of heterozygous BMP15 mutations.[217] The Booroola gene increases secretion of FSH, but most often the effects are in follicles; they have fewer granulosal cells, acquire LH receptors earlier, mature at a smaller size, and produce smaller corpora lutea than in noncarriers. Older ewes with $FecB^B$ maintained higher ovulation rates than noncarriers despite the fact that the numbers of developing follicles did not differ between genotypes, and concentrations of FSH increased and those of inhibin A decreased in older ewes, regardless of genotype.[208] Thus, the suggested action of the $FecB^B$ allele is to reduce the rate of follicular atresia. Current knowledge of the mechanisms of action of these genes and their mutations in sheep and other species has been reviewed.[22,210]

The effects of nutrition on ovulation rate have been recognized for almost a century and have been used extensively in attempts to increase fertility. Early work on nutritional "flushing" of ewes to increase the ovulation rate indicated that it required an increase in nutrition for at least the length of an estrous cycle to be

effective and that energy from a high-grain diet had a greater effect than protein from soybeans[218] when either or both were increased above a maintenance regimen. Coop[219] and others advanced the concept of different effects of static (due to body condition) and dynamic (temporary increases, i.e., "flushing") nutritional signals, a hypothesis that continues to provide a useful structure for interpreting contemporary data. A recent thorough review on nutritional influences on folliculogenesis and ovulation concluded that flushing effects occur mainly at the ovary.[22] Negative energy balance affects multiple levels within the hypothalamic–pituitary–ovarian axis,[22] but extremely severe restrictions are required to produce these effects.[1] The effects of flushing reflect regulatory mechanisms, not simply an increase in available energy, and recent work has focused on identification of systemic nutrient and metabolic signals and intrafollicular sensors and signaling pathways.[22] These have established that glucose and insulin act as mediators of short-term influences, while body condition is signaled primarily via the growth hormone–IGF system and leptin. These signals then have important regulatory roles in the oocyte and follicle. Notably, the oocyte influences its own fate (ovulation or loss via follicular atresia) through its effects on the follicle via BMP15 and GDF9, as described in this chapter. A useful model integrating nutritional and metabolic inputs that affect ovulation rate is provided in the review by Scaramuzzi et al.[22]

While the early work had indicated that flushing required nearly a cycle to have an effect, a more rapid action has recently been observed by synchronizing a follicular wave.[220] The first wave of an ovulatory cycle was synchronized among ewes in either high or low body condition with two injections of $PGF_{2\alpha}$ (7 days apart), and supplementation with lupin grain started (on day 0) during the growing phase of the postovulatory wave (2 days after the second $PGF_{2\alpha}$ injection); follicles from this wave were then allowed to ovulate by inducing luteolysis on day 5. Lupin supplementation for just 6 days in this model increased emergence of a second follicular wave 4 days later, and tended to increase the rate of ovulation of follicles in this wave in ewes in high (1.7 versus 1.3 ova) but not low (1.1 versus 1.2 ova) body condition. In three of seven supplemented high-condition ewes, ovulations occurred from both the first and second waves, despite the short interval for development of the second wave. Thus, nutritional effects may be possible in a shorter time frame than was previously thought.

Control of Follicular Hormone Secretion

Of the two major follicular hormones, the control of estradiol secretion has received considerably more attention than control of inhibin secretion, and several lines of evidence support the conclusion that LH pulses are the primary stimulator of estradiol release during the cycle. Early work demonstrated that (1) there is a positive correlation between tonic LH secretion and estradiol during the cycle, (2) an LH pulse precedes each episode of estradiol release into the ovarian vein, (3) blockade of LH secretion prevents the follicular-phase rise in estradiol, and (4) mimicking the follicular-phase LH increment in anestrous ewes produces a preovulatory-like estradiol rise in the presence of unchanging or decreasing FSH concentrations.[1] The hypothesis that LH was the sole driver of the preovulatory estradiol rise was challenged by a series of studies in the early 1990s using a GnRH agonist to suppress gonadotropin secretion.[221] In this model, FSH administration in vivo, even in the absence of LH pulses, stimulated follicular development and increased estradiol production by these follicles in vitro. However, in subsequent work using chronic treatment with a GnRH antagonist that markedly suppressed both gonadotropins, FSH infusion alone stimulated the growth of ovulatory follicles, but little or no estradiol secretion occurred (Figure 27.11).[201] When the follicular-phase pattern of episodic LH secretion was added to FSH, it had no effect on follicular growth but markedly stimulated steroid secretion. Thus, although FSH secretion clearly plays an important role in controlling follicular development and ovulation rate, it appears to be largely permissive for the preovulatory estradiol rise because FSH concentrations are declining at this time. Similarly, LH is most likely the primary hormonal driver for estradiol secretion during the luteal phase. This critical role for LH is illustrated by the different estradiol secretion patterns during the first and second follicular waves[20]; during the first wave, when LH pulse frequency is high (because of low progesterone), there is a progressive increase in estradiol secretion, but in the second wave when LH pulse frequency is suppressed there is no increase in estradiol secretion, despite the same rate of follicular growth (Figure 27.3). In addition to FSH and LH, progesterone can modulate estradiol secretion, and it does so by two mechanisms: (1) by inhibiting tonic LH secretion, progesterone indirectly suppresses estradiol production; and (2) progesterone directly inhibits the response of the follicle to exogenous LH.[1] The latter effect may account for the observation that higher LH pulses during the luteal phase produce similar or smaller estradiol increments than those during the follicular phase.

With the hormonal regulation of preovulatory estradiol rise largely resolved, more recent work has turned toward determining which intrafollicular factors control synthesis of this steroid. At this time, there is growing evidence for local stimulatory actions of IGF1,[22] inhibin A,[222] BMP2,[223] and BMP6[224] on estradiol synthesis, while leptin,[225] activin A and B,[42] and anti-Müllerian hormone[226] inhibit estradiol production. However, these data must be interpreted cautiously because some of these effects

may reflect an action on follicular development, and the relative importance of each factor remains unclear.

The hormonal control of inhibin A secretion has been more difficult to unravel, in part because secretion of this hormone is closely coupled to changes in follicular development, so independent hormonal effects on its release are difficult to identify. Early work, summarized in this chapter in the third edition of this volume, led to the conclusion that neither LH nor FSH stimulated inhibin secretion. Although exogenous FSH did increase inhibin production, this was thought to reflect its stimulation of follicular development, and additional LH treatment did not further augment inhibin release (Figure 27.11). However, more recent studies have provided strong evidence that FSH is a potent stimulator of inhibin secretion from follicles in vitro[222] and that an LH pulse frequency seen late in the follicular phase (once per hour) stimulates inhibin secretion in vivo.[204] In light of these stimulatory effects of LH and FSH, it seems likely that inhibin concentrations remain relatively stable during the follicular phase because FSH concentrations fall as LH concentrations rise. As noted earlier for estradiol, the absence of an increase in inhibin during the second follicular wave of the luteal phase (Figure 27.3) also argues for an important role for LH in stimulating inhibin secretion at this time of the cycle.

In contrast to the stimulatory effects of tonic LH secretion on estradiol production, the LH surge terminates estradiol secretion.[1] The LH surge appears to directly inhibit aromatase activity so that estradiol concentrations fall before any changes in androgen production are evident. Likewise, an ovulation-inducing dose of human chorionic gonadotropin inhibits inhibin secretion from the preovulatory follicle,[204] producing a fall in inhibin concentrations similar to that seen after the normal LH surge (Figure 27.1). Whether these changes reflect direct effects of the LH surge or indirect effects via luteinization remains to be determined.

Control of Luteal Progesterone Secretion[227,228]

As reviewed in detail in the previous versions of this chapter, the functional activity and demise of the corpus luteum during the ovine estrous cycle are controlled largely by luteotropic factors from the pituitary (LH and GH) and luteolytic factors from the uterus ($PGF_2\alpha$) and ovary (estradiol and $PGF_2\alpha$). Both LH and uterine $PGF_2\alpha$, in turn, are regulated by progesterone. Actions of these hormones on corpora lutea in sheep,[229] in cattle,[230] and on a comparative basis[231] have been reviewed recently and are addressed in Chapter 23. Here, we will focus on other new information raised in the last decade, with an emphasis on intraluteal factors.

LUTEAL DEVELOPMENT

The steroidogenic cells of the corpus luteum form by transformation of granulosal cells into the large cells and of thecal cells into the small cells; important studies of their characteristics were cited in the reviews by Niswender et al.[228,229] A key factor in luteal development is angiogenesis, because of the extensive vascular supply required for this active gland.[230] Cytokines involved include VEGF and FGF2. VEGF is a potent mitogen for vascular endothelial cells that stimulates migration of endothelial cells. VEGF mRNA was greatest in ovine corpora lutea early in the estrous cycle and least during luteal regression. VEGF protein was localized to capillary pericytes and vascular smooth muscle cells in the early corpus luteum. Because FGF2, which was localized to endothelial cells in the early corpus luteum, enhanced expression of endothelial platelet-derived growth factor receptor in pericytes and smooth muscle cells surrounding vasculature, Miyamoto et al.[230] concluded that FGF2 may be more important than VEGF in luteal angiogenesis in the cow. As pointed out in the previous edition's version of this chapter, estrogen, acting locally via ERα, may also play a role in activating secretion of progesterone by the early corpus luteum, which is consistent with the finding that blockade of aromatase delayed the initial rise in secretion of progesterone early in the estrous cycle.[232]

LUTEAL SUPPORT

Although LH is the primary luteotropic hormone during the ovine estrous cycle, it appears to play largely a permissive or supportive role in progesterone secretion. This conclusion comes in part from the inverse correlation of LH and progesterone concentrations during the cycle; because progesterone secretion is maximal when LH concentrations and LH pulse frequency are minimal, this gonadotropin is unlikely to be the primary factor controlling progesterone secretion rates (Figure 27.1). The relative independence of progestrone secretion from LH occurs because most progesterone secretion derives from large luteal cells that are unresponsive to LH, as they normally function at maximal capacity. Growth hormone (GH) interacts with LH to serve as a supplementary luteotropin in ruminants. The ovine corpus luteum expresses GH receptors and IGF-I and its receptors,[233,234] and treatment with a combination of LH and GH restored luteal weight to near normal in hypophysectomized ewes.[233] Treatment with LH restored concentrations of mRNA for GH receptor in the corpora lutea of the hypophysectomized ewes, while treatment with GH restored mRNA for IGF-I. However, neither mRNA for IGF-I nor for GH receptor changed after a luteolytic dose of $PGF_2\alpha$. Perhaps regulation of the action of GH through IGF-I is achieved by changes in the IGF binding protein 1, which was increased in response to $PGF_2\alpha$ in cattle.[235]

The biochemical steps in stimulation of progesterone synthesis by LH in luteal cells, the details of which are

available in Chapter 23 and have been reviewed elsewhere,[229] include activation of protein kinase A, transport of cholesterol through the cytoplasm, and transport of cholesterol from the outer to inner mitochondrial membrane. Phosphorylation of steroidogenic acute regulatory protein (StAR) by protein kinase A, which appears to be the primary effect of the protein kinase pathway on activity of the StAR protein, enhances cholesterol transport. Large luteal cells had sixfold more StAR than small luteal cells in ovine corpora lutea, and concentrations of StAR were correlated with serum concentrations of progesterone throughout the estrous cycle. Similarly, endozepine, another protein involved in transport of cholesterol across the mitochondrial membrane, was 2.4-fold greater in large cells, leading those authors to propose that these proteins played a constitutive role in large luteal cells, which, as mentioned in this chapter, secrete most of the progesterone but are unresponsive to LH.[236]

In luteal cells from ewes on days 5, 10, and 15 of the cycle, secretion of progesterone in vitro was positively correlated with expression of mRNA for the gap junctional protein, connexin 43 (Cx43), and rates of observed gap junctional communication.[237] When Cx43 mRNA expression was decreased by Cx43 gene-target small interfering RNA, progesterone secretion by cells from days 5 and 10 was decreased as well. These authors thus suggested that intercellular communication may play some role in luteal secretion of progesterone and raised the possibility that findings from separated large or small luteal cells may not fully reflect the factors involved in the function of an intact corpus luteum.[237]

LUTEAL REGRESSION[1,238]

The major new findings in the ewe since our previous chapter include (1) the effects of progesterone via receptors in membranes of the endoplasmic reticulum of steroidogenic luteal cells and the plasma membranes of lymphocytes, (2) the elucidation of an intraluteal role of oxytocin in the process of luteal regression, and (3) the controversial evidence that interferon tau produced by the conceptus can exit the uterus and act directly on the corpus luteum to upregulate genes and prevent luteal regression, as a part of maternal recognition of pregnancy. Rather than reiterate the details reviewed in the previous edition, we will briefly review that information and concentrate on work since 2004 in the current discussion.

Luteolysis is defined as structural demise of the corpus luteum, which is preceded by loss of the capacity to synthesize and secrete progesterone. Natural luteolysis is dependent upon secretion of a uterine luteolytic factor, $PGF_{2\alpha}$, that acts locally, at least in part, because unilateral hysterectomy maintained luteal function on the ipsilateral, but not contralateral, ovary. It was postulated that $PGF_{2\alpha}$ enters the ovarian artery from the utero-ovarian vein via a countercurrent exchange mechanism that allowed $PGF_{2\alpha}$ to reach the ovary without entering the pulmonary circulation, where it would be enzymatically inactivated in the lungs.[1] However, Bonnin et al.[239] later presented strong evidence for a re-interpretation that the process involves both rapid systemic transport (12% of $PGF_{2\alpha}$ was not oxidized by the lungs) and a slower local diffusion pathway that utilizes the utero-ovarian veins and lymph vessels. Luteal-phase progesterone is a major determinant of the timing of uterine secretion of $PGF_{2\alpha}$, with low concentrations of estradiol playing a permissive role in both that secretion and the luteolytic response.[1] Specifically, increased secretion of $PGF_{2\alpha}$ on days 11 through 14 is programmed by rising concentrations of progesterone early in the luteal phase; this was demonstrated by the ability of progesterone treatment beginning at estrus to advance secretion of $PGF_{2\alpha}$ by 4 days and shorten the cycle.[44] The fall in progesterone at luteolysis and subsequent follicular-phase rise in estradiol prevent premature release of $PGF_{2\alpha}$ early in the next cycle, thus ensuring a normal-length luteal phase. As was the case with the priming effect of progesterone on estrous behavior, this priming action may reflect progesterone-induced ERα in the uterine endometrium.[240] More recently, Banu et al.[241] characterized a prostaglandin transporter (PGT) in ovine endometrium that is highly expressed between days 14 and 16 of the estrous cycle. They provided evidence that its action within endometrial cells involved protein kinases A and C, epidermal growth factor receptor, ERK1/2, and Jun kinase–stress-activated protein kinase cell-signaling pathways. Intrauterine infusions of a PGT inhibitor twice daily on days 11 through 15 prevented luteolysis, maintaining progesterone and extending interestrous intervals beyond 35 days.

The other new work of interest in regard to uterine secretion patterns in relation to luteolysis induced by $PGF_{2\alpha}$ comes from a series of studies in heifers in the laboratory of O. J. Ginther at Wisconsin.[242,243] Their work has pointed to differences in responses to the episodic secretion of $PGF_{2\alpha}$, mimicking natural luteolysis, in comparison with effects seen with bolus injections that are considered to be overdoses. Large bolus dosages of $PGF_{2\alpha}$ produced initial increases in progesterone secretion in sheep and cattle in several studies cited. However, in agreement with earlier work in the ewe,[244] a secretory-equivalent pattern of doses of $PGF_{2\alpha}$ initially inhibited progesterone secretion, and yet did not induce structural luteolysis. However, it caused a transient reduction in progesterone, which led to an LH pulse during the decline in $PGF_{2\alpha}$, and these events were followed by a rebound in progesterone. This sequence was repeated during the period that Ginther designated as preluteolysis. The transition to luteolysis began from a point at which progesterone was at its original concentration.

Beyond that transition point, as further episodes of secretion of $PGF_{2\alpha}$ occurred, rebounds in progesterone were incomplete, but partial rebounds continued to be associated with increases in blood flow to the corpus luteum. Reduction in progesterone is a key step in structural luteolysis, because it has recently been shown that intraluteal progesterone protects the steroidogenic cells from apoptosis,[245] which will be discussed later in this chapter.

It has been well documented that $PGF_{2\alpha}$ has at least four major actions in the corpus luteum.[228,229] The temporal sequence of these major, and many other, effects of a luteolytic dose of $PGF_{2\alpha}$ is illustrated in Figure 27.12. First, $PGF_{2\alpha}$ stimulates luteal secretion of oxytocin within 2–5 min after an intramuscular injection[246] or within 15 min after beginning infusion into a uterine lymphatic vessel.[253] Second is a rapid decrease in luteal blood flow (detected by 4 h), concomitant with the third action of $PGF_{2\alpha}$, a decrease in the secretion of progesterone (detected as early as 1–2 h and usually by 4 h) due to activation of the protein kinase C (PKC) second messenger pathway. Fourth, $PGF_{2\alpha}$-induced increases in intracellular calcium appear to cause cell death via apoptotic mechanisms and structural luteolysis. Much of the research in the ruminant corpus luteum in recent years has been directed to the mechanism by which $PGF_{2\alpha}$ induces these effects, including the involvement of a fifth action, stimulation of luteal production of the vasoactive factors, prostaglandins, endothelin, angiotensin II, and nitric oxide (NO), as intermediates or collaborators in a luteolytic cascade (reviewed by Skarzynski and Okuda).[254]

In our previous version of this chapter, evidence that changes related to structural luteolysis began even before completion of functional luteolysis was discussed in some detail. Specifically, changes expected to alter the structure of the extracellular matrix, and to be associated with cell death and structural luteolysis, preceded the nadir in progesterone concentrations.[244,247,248] These changes may play a role in functional as well as structural luteolysis, as indicated by the observation that subluteolytic infusion of $PGF_{2\alpha}$ induced precipitous declines in tissue inhibitor of metalloproteinase 1 and 2 (TIMP1 and TIMP2) proteins lasting 8 or 24 h, respectively,[248] and by the decline in mRNA for TIMP2 in corpora lutea during the late luteal phase.[255] In contrast, mRNA in ovine corpora lutea increased for MMP14 on day 4 and was greatest for MMP2 on day 10, associated with increases in gelatinolytic activity.[256] MMP2 and MMP9 were localized primarily in large luteal cells, but MMP2 appeared to be present in endothelial cells on day 15. These authors concluded that remodeling of the extracellular matrix occurs throughout the luteal phase and may "facilitate processes important to luteal development, maintenance and regression".[256]

A further understanding of intraluteal regulation of luteal regression began with the demonstration of membrane receptors for progesterone in the endoplasmic

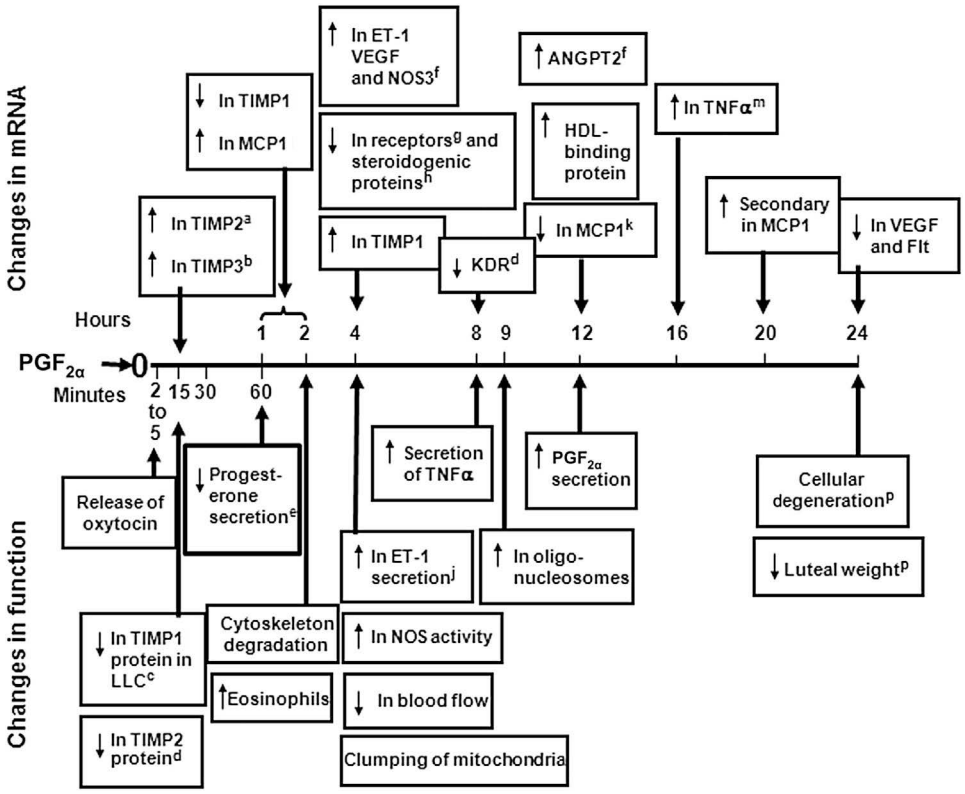

FIGURE 27.12 Time course of intraluteal events in response to a bolus injection of $PGF_{2\alpha}$. Data on messenger RNA are presented above the timeline, and data on functional and structural changes are presented below the timeline. [a]Continues through 48 h. [b]Continues through 6 h. [c]Continues through 8 h. [d]Continues through 24 h. [e]More often detected by 2–4 h because of sampling at same times as for blood flow. [f]Continues through 12 h. reticulum of both large and small steroidogenic ovine luteal cells.[229,257] The intracellular nature of these receptors was indicated by the lack of effectiveness of a progesterone–BSA conjugate. Localization to the endoplasmic reticulum was demonstrated with fluorescent protein conjugates to the receptor in transfected Chinese hamster ovarian cells. In a 1981 review,[258] Rothchild had summarized evidence that progesterone is an intracrine regulator of luteal function, but it was largely ignored until evidence surfaced for membrane receptors for steroids. This included a report of membrane receptors for progesterone in the rat corpus luteum,[259] and that progesterone was able to oppose functional and structural luteal regression in the absence of classical nuclear progesterone receptors in this species.[260] Membrane receptors also were shown to allow intracellular mobilization of Ca^{++} from the ovine luteal endoplasmic reticulum in response to either progesterone or 17α-hydroxy-progesterone.[257]

Early work[261] showed an ability of oxytocin to increase secretion of $PGF_{2\alpha}$ by the uterus, and the concept of a positive-feedback loop between luteal oxytocin and uterine $PGF_{2\alpha}$ gained wide acceptance.[1] The upregulation of oxytocin receptors in the endometrium was considered key to that loop, with the initial stimulation of secretion of $PGF_{2\alpha}$ by oxytocin from the posterior pituitary. Evidence related to that concept was discussed in our previous review, including some that questioned its importance, such as the indication that increased uterine responsiveness to oxytocin did not precede initial decreases in progesterone secretion and depended upon estrogen being the dominant steroid. In a recent study, an inhibitor of PGT in ovine endometrium, infused into the uterus, blocked oxytocin from inducing pulses of $PGF_{2\alpha}$ on day 15.[241] Considered in relation to the discussion in the previous edition, it remains likely that oxytocin stimulates the final secretion of $PGF_{2\alpha}$ that contributes to structural luteolysis.

A new concept for the role of luteal oxytocin in luteal regression has emerged from the work of Gordon Niswender and colleagues at Colorado State University.[229] The large steroidogenic luteal cells have receptors for $PGF_{2\alpha}$ and produce more prostaglandin in response to the initial stimulation by uterine $PGF_{2\alpha}$. To test whether luteal secretion of $PGF_{2\alpha}$ is required for luteolysis, this group placed implants containing indomethacin in the corpus luteum of ewes on day 11 of the estrous cycle. Serum progesterone declined by day 17 and ewes returned to estrus, but luteal weights on day 18 were heavier in ewes treated with indomethacin than in control ewes. Because peaks of the inactive metabolite of $PGF_{2\alpha}$ (15-keto,13,14-dihydro-$PGF_{2\alpha}$), observed after initiation of luteolysis, did not differ between intact and hysterectomized ewes, the $PGF_{2\alpha}$ secreted in response to treatment was not of uterine origin. In addition to secreting $PGF_{2\alpha}$, the large cells respond to $PGF_{2\alpha}$ by releasing stored oxytocin. The small luteal cells have oxytocin receptors, and the binding of the locally secreted oxytocin elicits increases in PKC and release of intracellular Ca^{++}, which initiates apoptosis of the small cells. Meanwhile, uterine and luteal $PGF_{2\alpha}$ elicits decreases in progesterone and increases in PKC in the large cells, followed by increased intracellular Ca^{++} and apoptosis of those cells.

The evidence that intraluteal regulatory mechanisms are key to life or death of the corpus luteum became increasingly complicated with further studies of ovine luteal cells.[245] As mentioned earlier, the luteoprotective actions of progesterone involve increased intracellular Ca^{++} via the membrane progesterone receptors in the endoplasmic reticulum in both large and small steroidogenic cells.[257] In contrast, $PGF_{2\alpha}$ increased intracellular Ca^{++} to cause apoptosis of large steroidogenic luteal cells, while oxytocin increased intracellular Ca^{++} in causing apoptosis of small steroidogenic cells.[245] Moreover, progesterone blocked these effects of $PGF_{2\alpha}$ and oxytocin on intracellular Ca^{++}. When these results are considered in relation to the protective effect of progesterone against luteolysis[229,245] and the fact that the steroidogenic effect of LH also increases intracellular Ca^{++},[228] it becomes apparent that increases in intracellular Ca^{++} can have a myriad of different effects, depending up the conditions and stimuli.

Another component of luteal regression appears to be the influx of immune cells into the tissue, which is important for structural luteolysis. In our previous review, we emphasized the role of monocyte chemoattractant protein 1 (MCP1, now known as CCL2) in recruiting macrophages in sheep, but most recent work has been in the bovine corpus luteum. Because of evidence for important mechanistic effects of episodic $PGF_{2\alpha}$,[242,243] Atli et al. used two or four episodic low-dose treatments of $PGF_{2\alpha}$ in nonlactating Holstein cows to examine gene expression for factors that activate the immune system.[262] Specifically, the second pulse of $PGF_{2\alpha}$ increased mRNA for interleukins 1B and 8 (IL1B and IL8), FAS, and FAS ligand. Recent reviews provide more detail on the immune cells and cytokines involved in luteal regression, including T lymphocytes of several types, γδ, $CD4^+$, and $CD8^+$.[263,264] Based upon these studies of bovine corpora lutea,[265] $CD8\alpha\alpha^+$ and $\gamma\delta^+CD8\alpha\alpha^+$ T cells that migrate into spaces between steroidogenic cells in the corpus luteum increase during luteal regression. In contrast to the steroidogenic luteal cells, the membrane receptors for progesterone on these lymphocytes are located on the plasma membrane.[266] These membrane receptors appear to account for the ability of progesterone to inhibit luteal cell–induced proliferation of T lymphocytes. The T lymphocytes also have oxytocin receptors[267] and, like small steroidogenic cells, responded to oxytocin with increased intracellular Ca^{++} via the phospholipase

C (PLC)–PKC pathway. Thus, a part of the effect of the intraluteal action of oxytocin in luteal regression may occur by regulation of the resident immune cells.

In the study with dairy cows discussed above, the first pulse of $PGF_{2\alpha}$ increased mRNA for steroidogenic acute regulatory protein and VEGFA, but these mRNAs were decreased by subsequent treatments, which also induced pathways for the production of $PGF_{2\alpha}$. Corpora lutea collected from superovulated ewes were examined at 0, 4, 8, 12, and 24 h after a single luteolytic injection of $PGF_{2\alpha}$ on day 10 of the cycle.[249] They observed similar initial increases in mRNAs for the VEGF and one of its receptors (Flt) at 4 h, decreases in another VEGF receptor (KDR) at 8–24 h, and increases in FGF and angiopoetin 2 at 8 h (Figure 27.12), followed by decreases in the stimulated factors at later times as apoptosis increased and the endothelial component of the vascular bed decreased. In contrast, smooth muscle cell actin remained high during luteal regression, which was considered to indicate a role for pericytes and vascular smooth muscle cells in the process.

Three other vasoactive substances have been shown to increase in ruminant corpora lutea in response to $PGF_{2\alpha}$: endothelin 1 (EDN1),[268] angiotensin II,[249] and NO.[254] Shirasuna et al.[269] observed positive correlations of concentrations of $PGF_{2\alpha}$, EDN1, and oxytocin by microdialysis in bovine corpora lutea during spontaneous luteolysis, but a low relationship to angiotensin II. Oxytocin and $PGF_{2\alpha}$ increased together in ovarian venous plasma in that study. Observations in sheep and cattle indicate that intraluteal secretion of $PGF_{2\alpha}$, oxytocin (both discussed earlier), EDN1, and angiotensin II in response to uterine $PGF_{2\alpha}$ is integral to the luteolytic cascade during the estrous cycle in ruminants.

EDN1 has received detailed study in the ewe; a luteolytic dose of $PGF_{2\alpha}$ stimulated gene expression for EDN1 in ovine corpora lutea,[250] and in a study using microdialysis in vivo,[251] perfusion of $PGF_{2\alpha}$ increased secretion of EDN1 over a period of 12 h (Figure 27.12). EDN1 inhibited basal and LH-stimulated secretion of progesterone in dispersed ovine luteal cells, and the effect was blocked by an antagonist specific for the receptor for endothelin, endothelin receptor type A (EDNRA).[250] The EDNRA antagonist also delayed the decrease in plasma progesterone in response to $PGF_{2\alpha}$. In another study,[268] chronic infusion of the inhibitor into the sheep corpus luteum by an osmotic minipump did not prevent the initial decrease in progesterone in response to $PGF_{2\alpha}$, but restored progesterone to luteal-phase concentrations by 48 h. This result led to the conclusion that the initial action of $PGF_{2\alpha}$ on progesterone secretion was direct, while later stages of luteolysis may be mediated in part by EDN1. In a repeat of that study, the effect was confirmed in three of 12 ewes, and treatment maintained greater expression of mRNA for 3β-hydroxy-steroid dehydrogenase and TIMP1, while it decreased expression of pre-pro-EDN1 and EDNRA.[270] In contrast to the above results, chronic infusion of EDN1 into the ovarian pedicle or intrauterine infusion on days 10 through 18 prevented luteal regression and increased the ratio of PGE_2 to $PGF_{2\alpha}$.[271] Injection of 100 μg EDN1 alone did not regress ovine corpora lutea, but regression was observed in ewes treated with 100 μg EDN1 in combination with a subluteolytic dose of $PGF_{2\alpha}$.[250] Likewise, $PGF_{2\alpha}$ followed by EDN1, simultaneous perfusion of $PGF_{2\alpha}$ and EDN1, two successive perfusions of EDN1, or EDN1 followed by TNFα decreased progesterone secretion and caused a massive release of oxytocin in the study using microdialysis of ovine corpora lutea.[251] TNFα, which is secreted by luteal cells and macrophages, was elevated in regressing ovine corpora lutea after progesterone secretion had decreased[252] (Figure 27.12).

There are different responses of ovine and bovine corpora lutea to NO at various stages of the cycle, and in various in vivo or in vitro conditions, but the authors of a review of this literature concluded that reduced concentrations of NO may facilitate the upregulation of the EDN1 system in older or regressing corpora lutea.[254] Responses of NO appeared to differ in regard to functional and structural regression. For example, activity of endothelial NOS increased at 4 h after treatment with PGF_2 at midcycle.[249] In contrast to reports that NO is luteolytic, uterine infusion of NO donors during days 8–18 of the ovine estrous cycle produced heavier corpora lutea, greater progesterone in the jugular vein, and a greater ratio of PGE_2:$PGF_{2\alpha}$ in the inferior vena cava in ewes that received the NO donor.[272] That interpretation could fit with the conclusion that decreased NO contributed to structural luteal regression.[254]

Overcoming or preventing luteal regression during maternal recognition of pregnancy, although not germane to the estrous cycle per se, provides insight into luteal regression in relation to changes that are prevented. Interferon tau, produced by the trophoblast of the conceptus, is a major signal in the maternal recognition process,[264,273] and evidence for the involvement of prostaglandins E_1 and E_2 in this process has existed since the 1970s (reviewed by Weems et al.[274–276]). It was considered that interferon tau acted in the uterus to alter the ratio of PGEs to $PGF_{2\alpha}$, but evidence has developed that interferon tau may in fact leave the uterus and act directly on the corpus luteum. This possibility initially arose from observations that intrauterine and subcutaneous injections of interferon tau were equally effective in inducing the expression of two proteins in the corpus luteum.[277] Subsequently, it was found that infusion of interferon tau into the uterine vein extended the luteal lifespan in ewes,[278] and a series of studies summarized by Hansen et al.[279] provided evidence that interferon tau is released into the uterine vein and may exert direct

effects on the corpus luteum. However, Lee et al. were unable to detect transport of interferon tau through the utero-ovarian plexus.[280] Instead, they found transport of uterine PGE_2 to the ovary by that route and upregulation of intraluteal biosynthesis of both PGE_2 and its receptors, EP2 and EP4. Moreover, PGE_2 acted through EP2 receptors to increase mRNA for LH receptors, LH receptors, and circulating progesterone.[281] In that same study, the luteolytic action of $PGF_{2\alpha}$ was mediated via prostaglandin F and EP3 receptors. Overall, the mechanisms of maternal recognition remain controversial, but new possibilities for points of disruption of luteal regression have been identified.

FACTORS AFFECTING LUTEAL SENSITIVITY TO $PGF_{2\alpha}$

An interesting research area for several years has been the effort to understand differences in luteal sensitivity to regression by $PGF_{2\alpha}$. These studies have been conducted in cattle, sheep, and pigs, and as discussed in detail in our previous chapter, there appears to be a great deal of commonality among the species. In the ewe, a single injection of $PGF_{2\alpha}$ usually does not cause luteolysis before day 5, but longer acting analogs of $PGF_{2\alpha}$ were effective as early as day 3 of the cycle. Because most studies have been conducted with single bolus injections of $PGF_{2\alpha}$, results will have to be re-evaluated in view of the recent studies using episodic pulses of $PGF_{2\alpha}$,[243] because repeated treatments upregulated luteolytic mechanisms in the early corpus luteum.[235] Luteal sensitivity to $PGF_{2\alpha}$ could not be accounted for by changes in concentrations of receptor for $PGF_{2\alpha}$, but differences were observed between the early and midluteal phases in mRNA for prostaglandin-endoperoxide synthase 2 (PTGS2), CCL2, and TIMP1 protein in response to $PGF_{2\alpha}$.[1] Similarly, mRNA for and activity of prostaglandin dehydrogenase in the corpus luteum decreased later in the cycle, as did mRNA for two inhibitors of PKC.

In bovine corpora lutea, there is greater expression of mRNA for PKC-ε on day 10 than on day 4,[282] and differential expression of several genes associated with signal transduction pathways, including calcium–calmodulin kinase kinase 2.[283] The latter observation led to further studies of Ca^{++} channels[284] that should eventually help to elucidate how the signal transduction pathways in luteolysis induced by $PGF_{2\alpha}$ differ with stage of the estrous cycle. Two recent studies in the pig also may shed light on stage differences in luteal sensitivity to regression by $PGF_{2\alpha}$. First, intraluteal progesterone may play a protective role against $PGF_{2\alpha}$-induced regression, because blocking progesterone synthesis in early corpora lutea allowed treatment with $PGF_{2\alpha}$ to upregulate mRNAs for PTGS2, phospholipase A2, aromatase (CYP19A1), and caspase 3.[285] In a subsequent study, similar effects were found for chemokines (including IL8 and CCL2) and chemokine receptors.[286]

RESYNTHESIS: A MODEL FOR THE OVINE ESTROUS CYCLE

Model for Cycle

In this section, we will use the previous analysis on the control of the individual components to describe how these components interact to produce the ovine estrous cycle. This systems analysis approach as well as space constraints preclude inclusion of some of the detailed mechanisms described in other sections of this chapter. In this synthesis, it is useful to make a distinction between ovarian events controlled by LH from those controlled by FSH because they function largely independently of each other.

The estrous cycle can be viewed as a sequence of causally related endocrine events, with each step in the sequence initiating the subsequent hormonal change. Because the estrous cycle is a recurring chain of events, the description of these events can begin, in theory, at any point in the cycle. However, the preovulatory LH surge is a particularly appropriate starting point because it initiates formation of a new ovarian structure and occurs on what is conventionally taken as day 0 of the ovine estrous cycle.

The LH surge produces ovulation and luteinization of the follicular remnants, and as the corpus luteum develops, progesterone concentrations begin to rise (Figure 27.13). Because the luteotropic actions of LH are permissive in the ewe, the pattern of progesterone throughout the luteal phase (from ovulation to just before luteolysis) reflects internal factors within the corpus luteum and its secretory capacity; it is thus an indirect consequence of the luteinizing actions of the LH surge. The elevated progesterone concentrations during the luteal phase have several major actions that are critical to the estrous cycle. Progesterone primes the centers in the brain, controlling estrous behavior and the GnRH surge so that the follicular-phase estradiol rise induces estrus and a maximal GnRH surge. The early increase in progesterone (days 3–5) inhibits uterine $PGF_{2\alpha}$ secretion, but also programs the uterus to begin episodic secretion of $PGF_{2\alpha}$ 7–8 days later. It also modifies uterine function so that no premature secretion of $PGF_{2\alpha}$ occurs early in the next estrous cycle, ensuring a normal-length luteal phase in that cycle. Interestingly, two of these three priming actions of progesterone may reflect its ability to induce ERα,[195,240] so the ability of progesterone pretreatment to amplify the GnRH surge may induce ERα as well. Finally, progesterone inhibits tonic LH secretion by suppressing GnRH pulse frequency, so that circulating LH concentrations decrease to a nadir at midcycle and remain low until luteolysis. The low concentrations of LH are necessary for follicular waves, and the minimal support for luteal function allows the increase in $PGF_{2\alpha}$ that occurs between

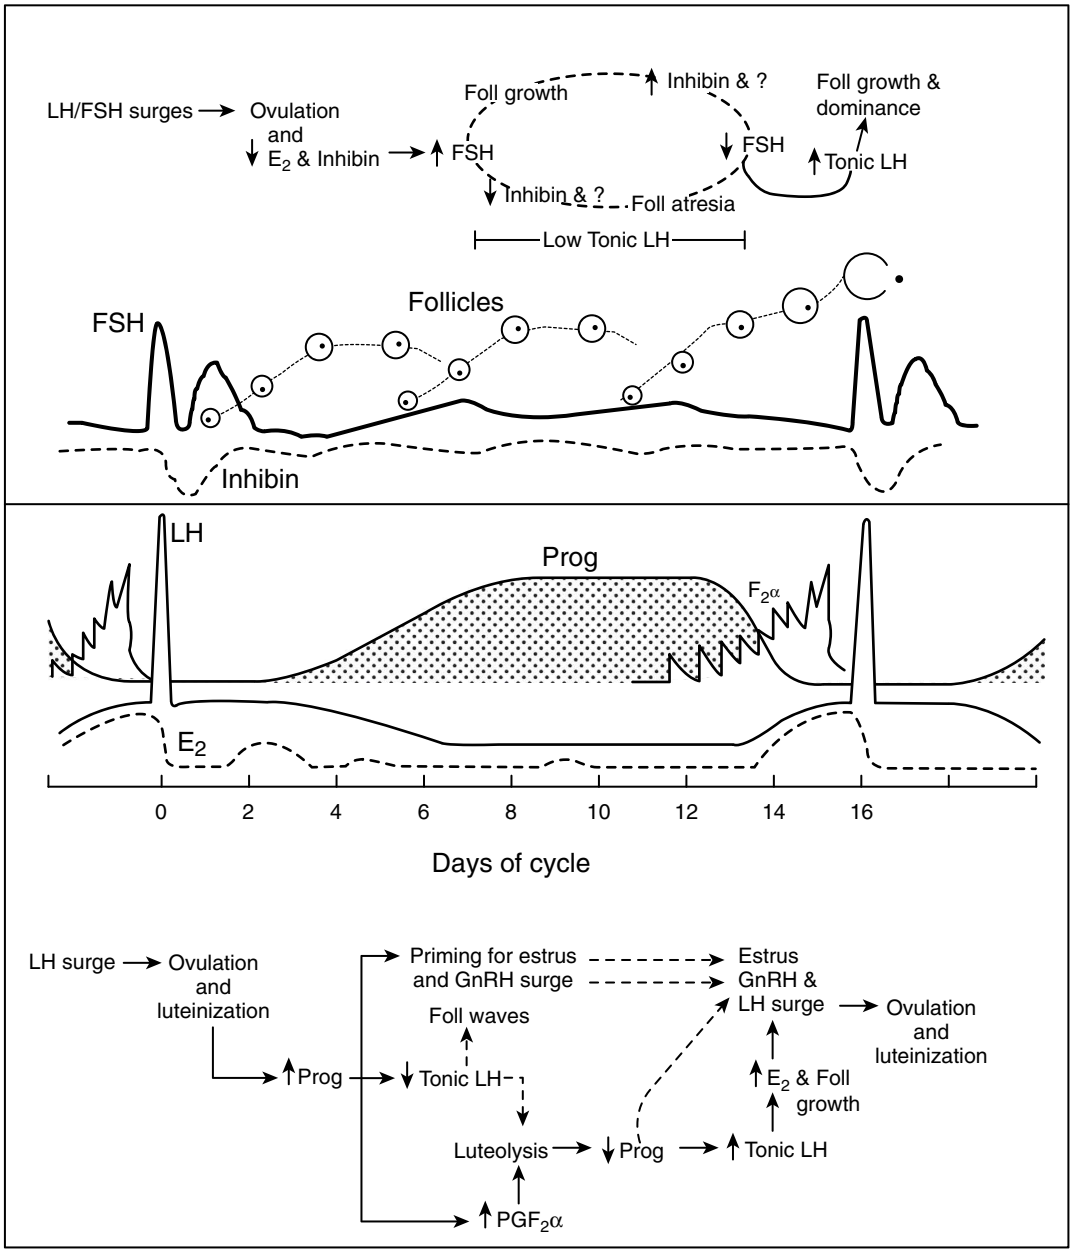

FIGURE 27.13 Model for the two major feedback systems controlling the ovine estrous cycle. The *top half* of the figure presents a schematic depiction of circulating concentrations of FSH and inhibin, the feedback cycle thought to be responsible for waves of follicular development during the luteal phase, and the role of tonic LH secretion in the final stages of follicular growth in the follicular phase. The *bottom half* of the figure depicts a schematic pattern of progesterone (Prog), LH, estradiol (E_2), and $PGF_{2\alpha}$ secretion, and the sequence of causal relationships that determines the timing of major events during the estrous cycle. In the latter, solid arrows represent direct effects, and dashed arrows represent permissive actions. See the text for further details.

days 11 and 13 to induce luteolysis, and consequently progesterone concentrations fall precipitously. The fall in progesterone at luteolysis releases three hypothalamic neural systems from the inhibitory effects of this steroid. It allows the centers controlling the GnRH–LH surge and estrous behavior to respond to estradiol, and allows the GnRH pulse generator to increase in frequency. The resulting rise in tonic LH concentrations helps to maintain follicular growth and stimulates estradiol secretion from the ovary. The sustained follicular-phase elevation in circulating estradiol triggers estrous behavior and the preovulatory GnRH and LH surges, and is also important for programing the uterus for normal $PGF_{2\alpha}$ secretion during the next estrous cycle. The LH surge, in turn, terminates estradiol secretion and induces ovulation and luteinization so that the next cycle begins.

At the same time that these events are occurring, a feedback loop between developing follicles and FSH

secretion helps determine follicular dynamics. The preovulatory LH surge terminates secretion of both estradiol and inhibin from the ovary, and the fall in these two hormones allows FSH concentrations to increase on day 1. This increase in FSH stimulates follicular development and, in the presence of elevated tonic LH, both estradiol and inhibin concentrations increase as a cohort of follicles develops (Figure 27.3). These ovarian hormones in turn inhibit FSH secretion, which eventually causes atresia of these follicles if tonic LH secretion is also low. As follicular function wanes, the fall in their negative-feedback signal allows FSH concentrations to increase again, and a second wave of follicles begins to develop. This temporal sequence is postulated to recur throughout the luteal phase (except that there is little, if any, increase in peripheral estradiol concentrations), producing several waves of follicular development. It should be noted, however, that the limited data now available do not support a role for inhibin in controlling the changes in FSH secretion associated with later follicular waves, so that either an unidentified follicular hormone or ovarian-independent fluctuations in FSH secretion may be critical for some of the follicular waves during the luteal phase. Regardless of the signals involved, the characteristics of the feedback loop between FSH and follicular hormones, and the low concentrations of LH, prevent the development of strong follicular dominance in the ewe. This, in turn, ensures that the ovaries always contain follicles ready to begin the final phase of preovulatory development if luteolysis occurs, which accounts for the short duration of the follicular phase. When luteolysis occurs, the resulting increasing frequency of LH pulses maintains follicular growth in the face of falling FSH concentrations and promotes follicular dominance within that wave so that, in most breeds, only one to two ova are ovulated.

The feedback loop between follicles and FSH secretion functions in parallel with, and relatively independent of, the progesterone feedback loops controlling luteolysis and the events of the follicular phase. Consequently, changes in FSH concentrations play little role in timing the events of the estrous cycle. It is thus not surprising that changes in ovulation rate have little influence on the control of ovarian cycles; estrous cycles in multiple ovulators are very similar to those in ewes ovulating a single ovum.

One important characteristic of this model is the major role of ovarian steroids in control of the estrous cycle. Perhaps the three critical events timing the estrous cycle are luteolysis, estrous behavior, and ovulation–luteinization, and the occurrence of all three is ultimately controlled by ovarian steroids. Progesterone, by ensuring that $PGF_{2\alpha}$ secretion increases late in the luteal phase, controls luteolysis, while the follicular-phase estradiol rise is responsible for estrous behavior and, by triggering the LH surge, ovulation. It is interesting to note that the secretory products of the corpus luteum and preovulatory follicle initiate events leading to the destruction of each structure. The function of both tissues is thus self-limiting, a characteristic that allows for the cyclic nature of ovarian activity. While the preovulatory estradiol rise is critical for events during the follicular phase, it is in turn controlled by progesterone. If progesterone concentrations are high, tonic LH secretion is suppressed, and consequently the estradiol rise cannot occur; if progesterone falls, tonic LH secretion increases and stimulates the preovulatory estradiol increment. One can thus infer that in the ewe, as in the rhesus monkey,[287] a "pelvic clock" controls the estrous cycle, but in the case of sheep, the corpus luteum represents a larger component of this clock than in primates.

Retrospective Historical Analysis

That the corpus luteum plays a primary role in timing the events of the ovine estrous cycle is not a new concept. Indeed, it was first suggested in the 1930s following the experimental observation that lutectomy at mid-cycle resulted in estrous behavior and ovulation within 2–3 days,[3] and a critical role for progesterone was incorporated into the first model for control of estrus and ovulation in the ewe.[8] This model, developed by Robertson prior to the general availability of radioimmunoassays, accurately predicted most of the critical events leading from the demise of the corpus luteum to the induction of ovulation[8]; its only inaccurate prediction was that an increase in FSH was the stimulus for the preovulatory estradiol rise. The importance of progesterone to the ovine estrous cycle was further confirmed by the first measurements of circulating hormonal concentrations throughout the cycle, so that Hansel and Echternkamp concluded in their 1972 review[288] that "the dominant event in the cycle…seems to be the rapid regression of the corpus luteum at the appropriate time." The emphasis on the importance of luteolysis to the control of the estrous cycle sparked interest in the mechanisms controlling luteal lifespan and led to the discovery of the luteolytic effects of $PGF_{2\alpha}$.[289] This discovery, in turn, enabled Goding and associates to develop a model encompassing the complete estrous cycle,[290,291] a model that set the groundwork for many of our current ideas. This model emphasized the role of estradiol, so it was not until the discovery of the negative-feedback actions of progesterone and the importance of these actions to control of the timing of follicular-phase events[13,14] that investigators came back to including a major role for progesterone in models for the estrous cycle.[292,293] This, in turn, led to the model presented in the first edition of *The Physiology of Reproduction*, which we then updated in the third edition to include new information on FSH and follicular

dynamics. Although many important mechanistic aspects of the feedback relationships controlling events during the ovine cycle have been highlighted in the current chapter, the basic relationships between systems have not changed, so the model presented in Figure 27.13 has not been modified from the previous edition.

There is one other important characteristic of this model that is relevant to the control of seasonal reproductive patterns in the ewe. Because the estrous cycle is a sequence of hormonal events, with each step depending on the previous one, disruption of a single step will prevent all subsequent events and thereby cause anovulation. A good example of this phenomenon is pregnancy. As noted in this chapter, the presence of a conceptus in utero blocks luteolysis, probably by stimulating uterine secretion of the luteotropin PGE_2 and possibly by uterine and ovarian actions of interferon tau. Consequently, progesterone does not fall, tonic LH secretion and estradiol do not increase, and ovulation does not occur. This anovulatory condition will then continue until removal of the embryo and fetus by death or parturition allows progesterone concentrations to fall. Similarly, disruption of a single endocrine event accounts for the anovulatory condition of anestrus, although in this case the blockade occurs at a different step in the chain of events comprising the ovine estrous cycle.

SEASONAL CONTROL OF OVARIAN CYCLICITY IN THE EWE

Seasonal Breeding[68,294]

So far, the model described here has considered only the role of endogenous hormonal signals in the control of the ovine estrous cycle. However, as noted in the introduction, reproductive function in ewes is characterized by a marked seasonal variation in fertility that has been a subject of scientific investigation for almost a century. That the annual reproductive cycle of the ewe is controlled by photoperiod was first proposed by Marshall[295] and verified experimentally by Yeates over 60 years ago.[296] The effects of photoperiod in the ewe reflect a complex interaction between day length (hours of light per day) and an endogenous circannual rhythm.[297] This interaction and other aspects of seasonal breeding in sheep and other mammals are considered in detail elsewhere in this book (see Chapter 34) and in recent reviews on seasonal breeding in the ewe.[68,294] Therefore, we will present an overview of this topic, emphasizing the underlying changes in hypothalamic function and their effects on events within the estrous cycle, and recent advances, which include (1) melatonin effects on deiodination of thyroid hormones, (2) characterization of the neural circuitry inhibiting GnRH in anestrus, and (3) the contributions of RF-amides in general, and kisspeptin specifically, to seasonal changes in fertility.

The key observation that laid the foundation for our understanding of these events was the demonstration of a dramatic seasonal variation in the negative-feedback actions of estradiol (Figure 27.14).[131] During anestrus, estradiol suppresses GnRH and LH pulse frequency and thereby strongly inhibits tonic LH secretion, whereas during the breeding season this steroid cannot inhibit pulse frequency and thus produces only a modest inhibition in mean LH concentrations. There is also a modest decrease in LH pulse frequency that is evident during anestrus in ovariectomized ewes, but the physiological significance of this "steroid-independent" effect of photoperiod is unclear.[1]

How Does the Annual Variation in Estradiol Negative Feedback Account for Seasonal Breeding?

As noted in the section Resynthesis: A Model for the Ovine Estrous Cycle, because the estrous cycle is a chain

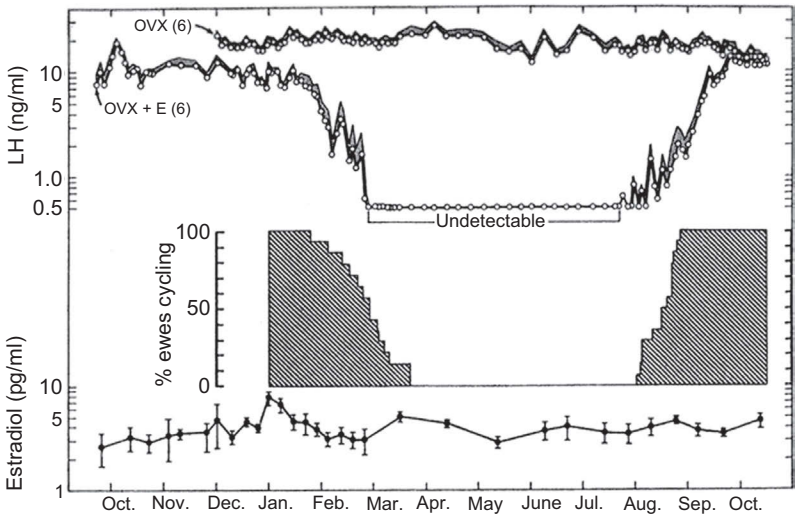

FIGURE 27.14 Seasonal changes in response to estradiol negative feedback. *Top graph*: Mean ± standard error of the mean (shaded area) LH concentration throughout the year in ovariectomized (OVX) or estradiol-treated ovariectomized (OVX + E) ewes. *Bottom graph*: Estradiol was administered with silastic capsules that produced relatively constant serum estradiol concentrations throughout the year. Histogram in the *middle graph* indicates the breeding and anestrous seasons in a separate group of 14 ovary-intact ewes. *Source: Reproduced from Legan et al.[131] (Copyright 1995, The Endocrine Society).*

of causally related events (Figure 27.13), disruption of any step will break the chain and produce anovulation. In terms of seasonal breeding, the critical step is the follicular-phase increase in tonic LH secretion or, more specifically, LH pulse frequency, which drives the preovulatory estradiol rise.[298] During the breeding season, progesterone is the primary inhibitor of GnRH pulse frequency. Hence, when progesterone concentrations fall at luteolysis, GnRH and LH pulse frequencies increase, and the latter stimulates ovarian estradiol secretion; the estradiol rise then triggers the LH surge, and ovulation occurs (Figure 27.15, left panel). At the transition into anestrus, however, the inhibitory neural systems activated by long-day photoperiods allow estradiol to become the primary negative-feedback steroid controlling GnRH pulse frequency. Consequently, following regression of the last corpus luteum of the breeding season, GnRH and LH pulse frequencies do not increase. Without the increase in tonic LH secretion, there is no preovulatory estradiol rise to induce an LH surge and estrous behavior, and anovulation and anestrus result (Figure 27.15, middle panels). Ewes then remain in anestrus as long as estradiol negative feedback holds LH pulse frequency in check. In the autumn, however, the negative-feedback actions of estradiol wane, and, in the absence of progesterone, pulsatile LH secretion increases and stimulates an estradiol rise, which triggers an LH surge, and the first ovulation of the breeding season occurs (Figure 27.15, right panel).

It should be noted that the mechanism controlling tonic LH secretion is not the only hormonal system to show seasonal variations in sheep. A variety of other seasonally related changes has been observed in anestrous ewes, including a decrease in the ability of estradiol to induce estrous behavior, a slight reduction in ovarian responsiveness to LH, and a marked increase in circulating prolactin concentrations.[1] Although these changes may modulate ovarian function and thereby contribute to the maintenance of anestrus, none is sufficient to account for seasonal breeding in the ewe. In contrast, the photoperiod-controlled alterations in tonic LH secretion can explain both the cessation of ovarian cycles in the spring and their reinitiation in the fall.[298]

Neuroendocrine Mechanisms Mediating Seasonal Change in Response to Estradiol Negative Feedback

The mechanisms by which a change in photoperiod is transformed into an alteration in estradiol negative feedback can be divided into three major steps.[68] First, photoperiodic information is received by the retina, and a neural signal is transmitted via the suprachiasmatic nucleus, paraventricular nucleus, and superior cervical ganglion to the pineal gland. Second, the pineal gland transduces the neural signal into an endocrine signal: the serum and CSF melatonin patterns. The pineal secretes melatonin only at night, so the duration of the daily increment in melatonin concentrations is a hormonal analog of the external photoperiod. Third, the melatonin pattern is translated in the hypothalamus to produce a change in its response to estradiol negative feedback.

The exact mechanisms by which melatonin alters hypothalamic function to produce changes in estradiol negative feedback are still under investigation, and there is growing evidence that it acts at different sites to control the two transitions between breeding and anestrous seasons (Figure 27.16). Work focused initially on the transition into the breeding season, with results strongly implicating an area just rostral to the mammillary bodies (the premammillary region) as the site of melatonin action.[299] More recent work raises the possibility that melatonin acts in the pars tuberalis to control the transition into anestrus.[300] The latter studies grew out of data indicating that thyroid hormones are necessary, albeit permissive, for the transition to anestrus.[294,301] However, the hypothesis that these hormones are permissive was based on peripheral administration of thyroxine (T_4), and several lines of evidence indicate that an increase in the local conversion of T_4 to T_3, the biologically active form of thyroid hormone, is critical for the transition into anestrus. As described in detail in Chapter 34, this model proposes that a long-day melatonin pattern acts in the pars tuberalis to induce synthesis and release of TSH.[300] TSH then acts in adjacent neural tissue to increase synthesis of type II deiodinase, the

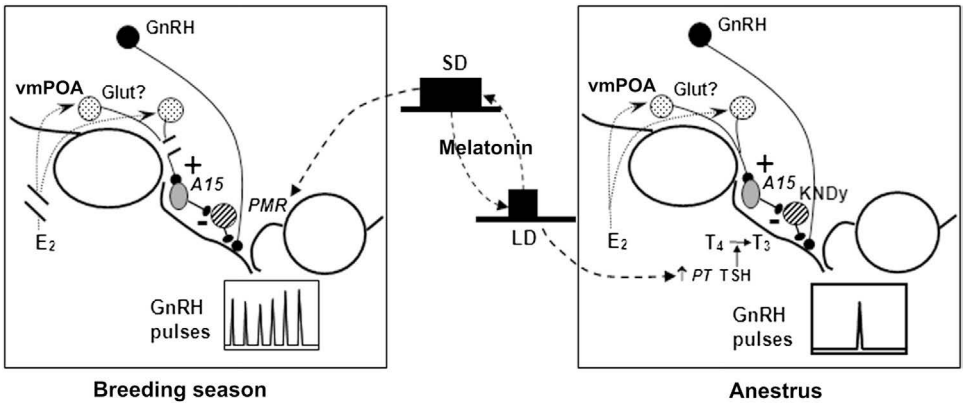

FIGURE 27.16 Model for the seasonal changes in response to estradiol (E_2) negative feedback in the ewe that postulates that an E_2-responsive inhibitory neural system is active only during anestrus. During the breeding season (*left panel*), this system is inactive so that E_2 cannot inhibit GnRH pulse frequency and progesterone is the primary regulator of tonic GnRH secretion. During anestrus (*right panel*), this system is active, allowing E_2 to act on ERα-containing neurons (stippled) in the vmPOA and retrochiasmatic area (that may contain glutamate), which in turn stimulate activity of A15 DA neurons (gray). These DA neurons act in the ARC to inhibit kisspeptin (striped) release from KNDy neurons and thus decrease GnRH and LH pulse frequency. Possible seasonal changes in this circuitry include an increase in responsiveness of the ERα-containing neurons and/or in their ability to stimulate A15 DA neurons. These changes are induced by a long-day (LD) melatonin pattern that increases synthesis and release of TSH in the pars tuberalis (*PT*); TSH then acts locally to increase conversion of T_4 to its active form, T_3, which initiates changes that activate the anestrous neural circuit. The short-day (SD) melatonin pattern, in turn, acts in the premammillary region (PMR) to inactivate this system during the transition to the breeding season.

enzyme that converts T_4 to T_3, and the increasing local T_3 concentrations, in turn, drive hypothalamic changes that shut down GnRH secretion and initiate anestrus. It should be noted that this hypothesis needs to be reconciled with data indicating that T_4 acts in the premammillary region or ventromedial POA, but not in the MBH, to induce anestrus in thyroidectomized ewes.[302] Although further work is thus needed to test this intriguing hypothesis in sheep, these mechanisms may also apply to reproductive transitions induced by long-day photoperiods in hamsters[303] and Japanese quail,[304] indicative of an important evolutionary conservation. Moreover, peripheral administration of T_4 can induce anestrus in thyroidectomized ewes only during a restricted time of the year extending from late breeding season through mid-anestrus,[305] an observation that provides indirect support for the hypothesis that there are important changes in local conversion of T_4 to T_3 during the annual reproductive cycle of sheep.

While the exact mechanisms by which melatonin and/or T_3 control the timing of transitions between breeding and anestrous seasons are yet to be determined, there is now a great deal of information on the neural circuitry within the hypothalamus responsible for the seasonal changes in response to estradiol negative feedback (Figure 27.16). Early work, using pharmacological approaches, led to the hypothesis that an inhibitory DA system suppressed GnRH secretion in anestrus.[1,68] The actual DA neurons involved were identified as the A15 group in the RCh by lesion studies,[306] and subsequent work demonstrated that these neurons are stimulated by estradiol in anestrus, but not in the breeding season, and mediate estradiol negative feedback during anestrus.[1] Thus A15 DA neurons were postulated to play a central role in the hypothalamic changes underlying the seasonal changes in response to estradiol negative feedback. Because A15 neurons do not contain ERα,[52,60] it was inferred that estrogen-responsive afferents are an important part of this circuit, and studies using local administration of estradiol identified such afferents originating from the ventromedial POA (vmPOA)[307] and the ventral RCh.[308,309] These data, together with the observation of an increase in synaptic contacts onto A15 neurons in anestrus,[310] raise the possibility that changes in afferent innervation of these DA neurons are responsible for their selective stimulation by estradiol only in anestrus. More recent work using local administration of receptor agonists and antagonists to the A15 has provided strong evidence that inhibitory GABAergic[311] and stimulatory glutamatergic[312] synapses control A15 DA tone during anestrus, with estradiol inhibiting GABA and stimulating glutamate release at this time of year. Interestingly, there are more glutamatergic-containing close contacts on A15 neurons in anestrus,[312] so that plasticity in estrogen-responsive glutamatergic afferents may account for seasonal changes in estradiol negative feedback. There are no seasonal alterations in GABAergic close contacts onto these DA neurons,[311] but this does not preclude an important role for these inputs in controlling A15 activity. For example, because estradiol inhibits GABAergic tone in anestrus, a loss of ERα expression in these neurons during the breeding season would result in continuous inhibition

of A15 DA activity and thus could account for seasonal changes in response to estradiol.

As with many other aspects of reproductive neuroendocrinology, work during the last decade on seasonal reproduction in sheep has focused on the possible role of kisspeptin and, to a lesser extent, RFRP3. Kisspeptin expression in ARC KNDy neurons was lower in anestrus, largely due to a stronger inhibition by estradiol, and there were parallel changes in kisspeptin-positive contacts onto the more posterior populations of GnRH neurons.[75] No changes were observed in the number of kisspeptin neurons in the POA,[75,313] although there was a small increase in their density in this region during exposure to short-days.[313] These data led to the hypothesis that seasonal changes in kisspeptin are critical to seasonal breeding in the ewe. Subsequent support for this hypothesis came from the observation that exogenous kisspeptin induced ovulation[314] by stimulating tonic LH, and thus estradiol, secretion in anestrus,[315] which demonstrated that inadequate kisspeptin limits fertility at this time of year. The kisspeptin and A15 DA systems may well be coupled based on a report that ARC KNDy neurons contained the DA D2 receptor (with higher expression in anestrus) and that a KISS1R antagonist blocked the ability of an antagonist to the D2 receptor to stimulate LH secretion.[105] These data, together with evidence that A15 DA neurons project posteriorly,[68] led to the hypothesis that the A15 neurons inhibit GnRH pulse frequency in anestrus by limiting kisspeptin release from the ARC KNDy neurons that normally drive GnRH pulses. In summary, the current model for seasonal changes in estradiol negative feedback (Figure 27.16) proposes that in anestrus, estradiol stimulates glutamatergic input in the vmPOA and/or RCh to increase the activity of A15 DA neurons. These neurons, in turn, inhibit the release of kisspeptin from ARC KNDy neurons that are necessary for episodic GnRH secretion, thus inhibiting GnRH pulse frequency. Seasonal changes in this circuitry that prevent its activity during the breeding season most likely occur at multiple levels, and may well include a decrease in ERα in estrogen-responsive afferents,[60] a decrease in stimulatory synaptic input to the A15, decreased responsiveness of ARC KNDy neurons to DA from the A15, and fewer kisspeptin-positive synapses onto GnRH neurons.

Other systems have been implicated as contributing to the seasonal changes in GnRH release, but their physiological significance remains unclear. There is a decrease in synaptic contacts onto POA GnRH perikarya in anestrus,[49] which appears to reflect a shift from stimulatory inputs in the breeding season to inhibitory inputs in anestrus, but these changes are independent of thyroid hormones,[310] so they are unlikely to be critical for seasonal breeding. Changes in RFRP3 may also play a role because the number of RFRP3-immunoreactive cell bodies in the DMH and synapses onto the more rostral GnRH neurons increased in anestrous ewes.[75] There is also one report that RF9, a putative antagonist to the RFRP3 receptors, produced larger increases in LH secretion in anestrous, than in breeding-season, ewes,[112] but these workers were unable to inhibit LH secretion with RFRP3 and concluded that the effects of RF9 were not related to endogenous release of RFRP3. Thus, more work is needed to determine what role, if any, this RF-amide peptide plays in seasonal breeding in the ewe.

Effects of Pheromones and Social Interactions[316–318]

One of the most striking examples of the reproductive impact of social interactions in general, and olfactory input specifically, is the induction of ovulation in anestrous ewes by exposure to rams, which is often referred to as the "male effect". Although this phenomenon has been recognized for more than 60 years and has been put to practical use to induce out-of-season breeding,[319] most of the earlier work has been largely descriptive in nature.[1] However, work during the last decade has provided important new information on underling mechanisms, including the olfactory pathways involved, the importance of learning and memory, and possible changes in hypothalamic function.

It is well established that the exposure of anestrous ewes to a novel ram produces an immediate increase in LH pulse frequency (Figure 27.17), which is followed by follicular growth and a preovulatory LH surge.[1] Ovulations usually occur within 2–3 days of ram introduction, but can sometimes be delayed so that they occur 4–6 days later.[319] These endocrine responses are induced, in part, by androgen-dependent primer pheromones from the head and neck region of the male; the exact chemical nature of these pheromones remains to be determined,[317] but they must be sufficiently complex so that ewes can distinguish between individual rams (as discussed below). It should be noted that estrous females produce similar increases in episodic LH secretion in response to rams, although the functional significance of these effects is less clear.[321]

Olfactory signals from males could theoretically affect GnRH secretion in females via two pathways: (1) the olfactory epithelia that project to the main olfactory bulb, which in turn projects to the cortical amygdala, the piriform cortex, and the entorhinal cortex; or (2) the vomeronasal organ that projects to the accessory olfactory bulb, which in turn projects to the medial amygdala, an area with direct connections to hypothalmic nuclei. The vomeronasal organ and accessory olfactory systems mediate many pheromonal effects on reproduction in rodents,[316] but several lines of evidence implicate the main olfactory system in the responses

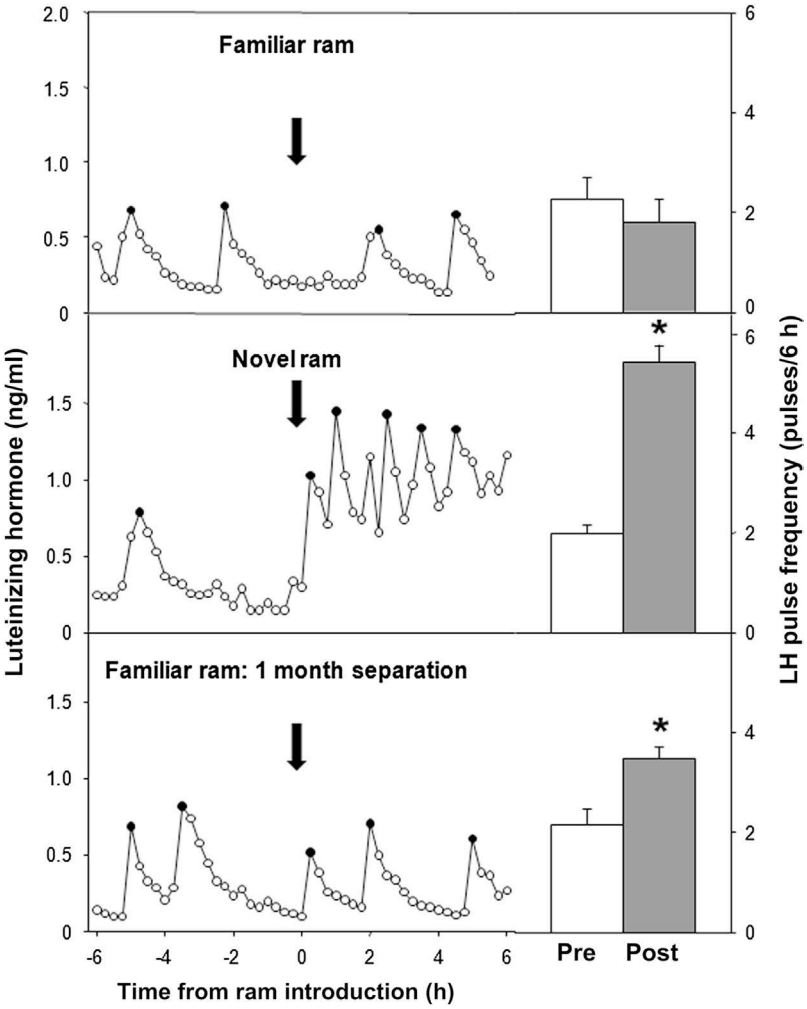

FIGURE 27.17 Effects of introduction of a novel or familiar ram on pulsatile LH secretion in ovary-intact anestrous ewes. Reintroduction of a familiar ram (*top panels*) had no effect on episodic LH secretion, whereas a novel ram (*middle panels*) produces a dramatic increase in LH pulse frequency. Ewes can remember a familiar ram for at least 2 weeks, but by 1 month pheromonal and social signals are able to induce a modest increase in episodic LH secretion (*bottom panels*). Rams introduced at time 0 (arrows). *Source: Adapted from Jorre de St Jorre et al.*[320]

of ewes to male odors. First, male fleece that increased episodic LH secretion also stimulated neural activity (Fos expression) in the main olfactory bulb, the cortical amygdala, and the dentate gyrus of the hippocampus above that induced by female fleece.[322] In contrast, differences in Fos expression between male and female fleece were not seen in neurons of the accessory olfactory system.[322] Second, lesions of the olfactory epithelia blocked the effects of male odor in ewes,[323] but lesions of the vomeronasal organ did not.[324] Finally, inactivation of the cortical amygdala, but not the medial amygdala, prevented male odors from increasing LH secretion in anestrous ewes.[325] It should be noted that the ram provides a much stronger stimulatory signal than that produced by male fleece; rams activated both primary and accessory olfactory systems,[322] and the ram-induced increase in episodic LH secretion could not be blocked by lesions of the olfactory epithelia[323] or inactivation of the cortical amygdala.[325] Moreover, complete disruption of both olfactory systems did not block the ability of rams to induce LH pulses,[323] although the nature of the nonpheromonal signals is still under investigation. Thus rams normally stimulate episodic LH secretion in anestrous ewes via the main olfactory system, with other sensory systems, including the accessory olfactory system and visual input,[326] acting in synergy with the primary olfactory pathway.

It has been proposed that the main olfactory system mediates pheromonal effects in the ewe because it provides olfactory information to cognitive centers and that learning and memory play important roles in this response in sheep.[316] Strong evidence for the involvement of learning was provided by work demonstrating that sexually naïve ewes did not respond to male fleece with an increase in episodic LH secretion.[327] There was a corresponding decrease in activated neural systems in these naïve ewes, with Fos expression increased only in portions of the main olfactory bulb,[328] but not in the amygdala or dentate gyrus, as seen in sexually experienced ewes described above.[322] Apparently naïve ewes have to learn to associate odors with rams because a specific scent (lavender) induced episodic LH secretion if anestrous ewes had been exposed to rams scented with lavender the previous breeding season.[327] An important

role for memory in this process can be inferred from early observations that a novel ram is required to induce this response[1] and has been clearly demonstrated by recent studies.[320] As illustrated in Figure 27.17, a novel ram induced a dramatic increase in LH pulse frequency, whereas a familiar ram had no effect. After exposure, a ewe recognized a ram as "familiar" for at least 2 weeks, but this memory began to fade after a month, although the stimulatory effect at 1 month was not as robust as that of a completely novel ram (Figure 27.17). The mechanisms underlying learning and memory of specific ram odors are unclear, but it is interesting to note that exposure to novel males rapidly stimulated cell proliferation in the dentate gyrus,[329] an area implicated in learning and memory.

While there is thus interesting new information on the afferent pathways and role of learning in the male-induced increase in LH secretion, the changes in hypothalamic function are less clear. Novel males did increase Fos expression in VMN neurons.[322,328] However, male fleece was no more effective than female fleece in this regard,[322] so these neurons are unlikely to be critical for the increase in LH pulses induced by male odors. Novel males were reported to increase Fos expression in a few POA GnRH neurons in one study,[322] but this effect was not observed in a later experiment from this same group.[328] One new relevant observation is that novel males also increased LH pulse frequency during the breeding season.[330] While the impact of this effect on events of the estrous cycle is unclear (see the excellent discussion in Hawken et al.[330]), these data have important mechanistic implications. Previous work had led to the hypothesis that neural systems activated by novel males during anestrus indirectly increase pulsatile LH secretion by disrupting the neural circuitry responsible for estradiol negative feedback,[1,331] but these new data raise the possibility of a more direct effect on the GnRH pulse generator. This possibility is supported by the recent report that exposure of anestrous ewes to rams induced Fos in KNDy neurons and that the increased pulsatile LH secretion in these ewes was blocked by a KISS1R antagonist.[332] It is also consistent with a series of studies in OVX goats in which brief exposure to male odors rapidly (within seconds) induced a single burst of MUA from KNDy neurons.[318,333,334] Interestingly, there was a refractory period after an endogenous MUA burst during which male odors were ineffective,[333] and the burst induced by the male odor delayed the next endogenous MUA burst so that it appeared to reset the pulse generator.[333] These data support a direct interaction of the male stimulus with pulse generation, but caution is needed in applying them to sheep because novel males did not increase LH pulse frequency in OVX ewes, even in anestrus.[331]

CONCLUSION

The ovine estrous cycle is controlled by a complex interaction between cues from the external environment and internal hormonal signals. Environmental factors determine whether or not estrous cycles occur, but are not directly involved in the events of the estrous cycle. Instead, these endocrine events reflect a coordinated hormonal communication among the brain, pituitary, ovaries, and uterus. The primary coordinator of this communication within the ewe is progesterone, which controls the timing of the major endocrine events of the estrous cycle (Figure 27.13). Superimposed on these internal events are two major environmental cues: photoperiods and social interactions with males. Long-day photoperiods, by activating inhibitory neural systems, actively suppress ovarian cycles, but these inhibitory effects of photoperiod can be disrupted by the introduction of pheromones and other signals from the ram.

Although the overall regulation of the ovine estrous cycle involves a large number of hormonal interactions, if one focuses on just the control of ovulation, an important unifying principle emerges. Namely, it is the frequency of pulsatile LH release that determines whether or not ovulation occurs. LH pulse frequency is critical because a relatively fast frequency is required for the sustained estradiol rise that triggers the preovulatory LH surge. Consequently, the activity of the hypothalamic GnRH pulse generator is a pivotal control point under a variety of conditions (Figure 27.18). During the breeding season, estradiol does not inhibit pulse frequency, but progesterone does. Thus, at this time of year, the pattern of progesterone determines the timing of ovulation. When progesterone is high, pulse frequency is low, and anovulation results; when progesterone falls at luteolysis, pulse frequency increases because estradiol can only inhibit pulse amplitude at this time of year, and ovulation occurs within 2–3 days.

During anestrus, estradiol gains the capacity to suppress the hypothalamic pulse generator, so that LH pulse frequency remains low in the absence of progesterone (Figure 27.18). As a result, the animals remain anovulatory as long as estradiol is able to hold episodic LH pulses in check. Exposure of ewes to pheromones from rams may well act via an unknown neural pathway to directly increase GnRH pulse frequency, and hence LH pulse frequency, so that introduction of rams induces ovulation in anestrous ewes (Figure 27.18). Alternatively, the negative-feedback action of estradiol is lost as the effects of long-day photoperiods wane in autumn. Thus, LH pulse frequency increases, which initiates ovulation and the start of the breeding season. With the

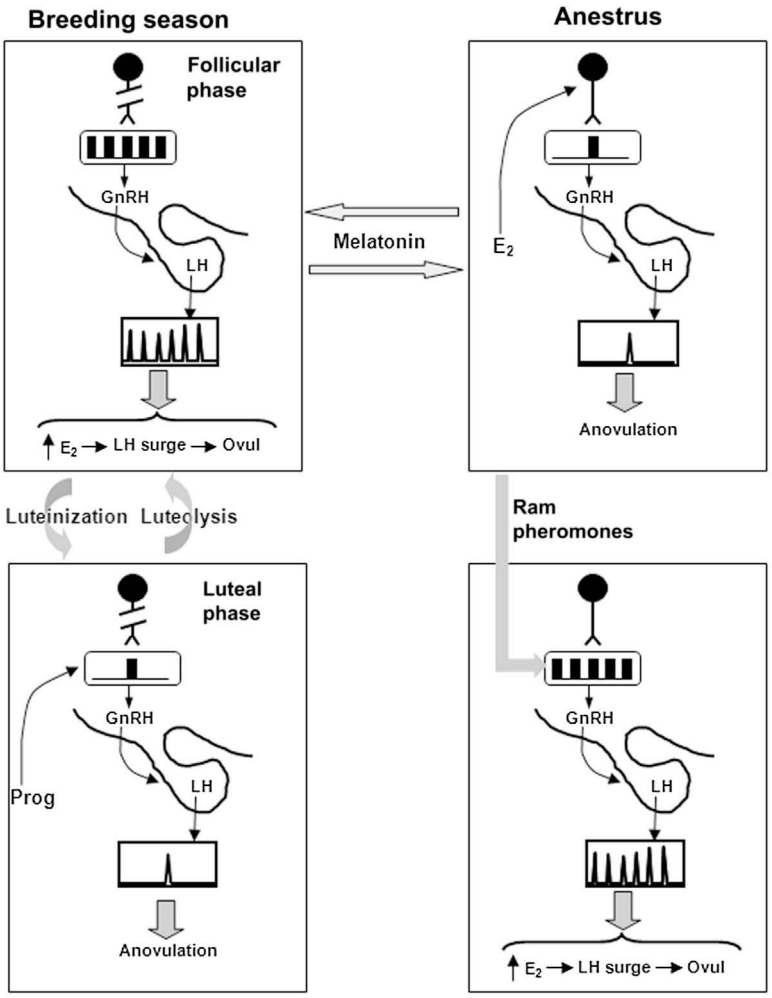

FIGURE 27.18 Control of ovulation in the ewe. The frequency of pulsatile LH secretion, by controlling the preovulatory estradiol (E_2) rise, determines whether or not ovulation occurs. *Left panels*: During the breeding season, progesterone (Prog) is the primary regulator of LH pulse frequency. *Bottom left*: During the luteal phase, Prog inhibits the hypothalamic pulse generator, producing anovulation. *Top left*: Following luteolysis, LH pulse frequency increases and initiates the follicular-phase events leading to ovulation. *Right panels*: During anestrus, the long-day melatonin pattern activates an E_2-sensitive inhibitory neural system. *Top right*: In anestrous ewes isolated from rams, E_2 stimulates the inhibitory neural system, which inhibits GnRH and LH pulse frequency and ensures anovulation. *Bottom right*: Pheromones and social signals from a novel ram activate a neural pathway that directly stimulates the GnRH pulse generator, increasing LH pulse frequency and producing ovulation during anestrus.

return of ovulatory cycles, progesterone concentrations increase, and this steroid resumes control of the hypothalamic pulse generator and hence the occurrence of ovulation.

In updating this chapter, we have identified several unresolved issues that remain to be addressed. In the area of neuroendocrinology, these include (1) testing the hypothesis for the role of KNDy neurons in episodic GnRH secretion; (2) determining the physiological roles, if any, of NKB and RFRP3; and (3) integrating the actions of kisspeptin with those of other neural systems controlling GnRH release. In terms of ovarian function, future work is needed to (1) understand the mechanisms responsible for follicular waves, (2) evaluate the interactions of intraovarian factors in the control of follicular development and estradiol and inhibin secretion, (3) assess the complex interactions of intraluteal factors ($PGF_{2\alpha}$, oxytocin, resident immune cells and cytokines, vasoactive substances, and intracellular Ca^{++}) in the demise of the corpus luteum, and (4) test recently developed hypotheses for the disruption of luteolysis by the embryo. Finally, areas for future work in seasonality include (1) determining the mechanisms by which melatonin and T_3 alter the neural circuitry responsible for seasonal breeding at the transitions into the breeding and anestrous seasons, respectively; and (2) identifying the changes in hypothalamic neural systems by which pheromonal and social cues from the ram increase the activity of the hypothalamic pulse generator.

In conclusion, the basic endocrine interactions among the hypothalamus, pituitary, ovary, and uterus responsible for ovarian function in the ewe are, with a few exceptions, now well understood. Our understanding of these basic mechanisms has led to practical applications in animal husbandry, including the synchronization of estrus for artificial insemination and out-of-season breeding protocols. More recently, significant progress has been made in elucidating mechanistic aspects of these interactions at several levels. Our understanding of critical

neural mechanisms has increased dramatically, as has our knowledge of intraovarian factors controlling follicular and luteal function. This new information provides important conceptual details for, and a richer contextual picture of, the model describing the function of the ovine hypothalamo–pituitary–ovarian axis and may lead to the future development of treatments to improve fertility in domestic livestock.

Acknowledgments

We thank Gloria Nestor for preparation of Figures 27.4 and 27.11. This work was supported by grants from the National Institutes of Health (NIH) (RO1 HD017864, RO1 HD039916, and NIH F33 HD055789), Hatch 476 (Multistate Project Northeast 1027), and a grant from the West Virginia Legislature for economic development of the sheep industry.

Control of the Menstrual Cycle

Anthony J. Zeleznik, Tony M. Plant

Department of Obstetrics, Gynecology and Reproductive Sciences, University of Pittsburgh School of Medicine, and Magee-Womens Research Institute, Pittsburgh, PA, USA

INTRODUCTION

Although the regulation of the primate menstrual cycle has been addressed in previous editions of this text, the ovarian events that comprise the menstrual cycle were discussed in isolation from the neuroendocrine control mechanisms that govern these ovarian processes. In this current version of the regulation of the menstrual cycle, we have attempted to integrate the neuroendocrine control mechanisms that govern follicular development, ovulation, and the corpus luteum during the menstrual cycle. We will highlight the importance of the physiological signaling processes that occur between the ovaries and the hypothalamic-pituitary unit that result in a remarkable orchestration of perfectly timed events that culminate in the production and ovulation of a mature oocyte, the formation of the corpus luteum with the concomitant preparation of the uterine endometrium for the implantation of a fertilized oocyte, and the establishment and maintenance of pregnancy. The overall goal of this chapter is to provide a focused review of the extant literature that emphasizes the physiological control mechanisms that govern the timing of the events that occur during the menstrual cycle. The molecular and cellular processes that underpin these events are presented in detail in Chapters 20–23,25.

The history of the ovary as a reproductive and endocrine gland is summarized in contributions by Short and Corner.[1,2,3] The anatomical presence of the ovary has been recognized since the time of Aristotle (384–322 BCE), and the great anatomists of the sixteenth and early seventeenth centuries—Vesalius, Fallopius, and Fabricius—described the vesicular nature of the ovary. In his text *De mulierum organis generationi inservietibus*, de Graaf not only described the ovarian (Graafian) follicle but also surmised that the corpus luteum, previously named by Malphigi, participated in reproduction. De Graaf noted that the presence of a corpus luteum within the ovary was associated with the presence of a fetus in the uterus and that there were a corresponding number of corpora lutea and fetuses in species that bore more than one young. Having deduced the role of the ovarian follicle in the production of the egg (although he concluded that the follicle was the egg itself), de Graaf proposed that the function of the corpus luteum was to squeeze the egg out of the ovary.[3] The correct anatomical relationship between the ovarian follicle and the oocyte was identified by von Baer in 1827.[1]

The endocrine functions of the ovary began to be recognized in the mid-nineteenth century as the result of clinical descriptions on the effects of ovariectomy in humans. In his 1856 text, Ludwig noted that removal of the ovaries in humans led not only to the cessation of menstruation but also to the shrinkage of the uterus.[3] As presented by Corner,[3] the initial thoughts regarding the atrophy of the uterus after ovariectomy were that either the blood or nerve supply to the uterus was disrupted by the surgery. The finding by Knauer in 1896 that castration in guinea pigs followed by grafting ovaries at different sites within the body prevented uterine atrophy indicated that blood-borne chemicals were produced by the ovaries and acted upon the uterus.[3] The description by Allen in 1922 of the cyclic changes in the vagina of rodents and the association of these changes with the presence of mature follicles led to the hypothesis that the uterine development associated with estrus was due to secretions of the maturing follicle, which was subsequently confirmed by the findings that injections of small amounts of follicular fluid into castrated mice and rats led to changes in the vaginal epithelium typical of estrus.[4,5,6] Armed with this sensitive bioassay for the hormone of estrus, Doisy and colleagues purified estrone from human pregnancy urine and porcine follicular fluid.[7,8]

During the early 1900s, research on ovarian secretions progressed on two fronts. In addition to the knowledge that removal of the ovary led to atrophy of

the uterus, the role of the corpus luteum in the maintenance of pregnancy was documented when Fraenkel demonstrated that ablation of the corpus luteum in rabbits after mating resulted in the failure of the animals to establish pregnancy.[9,10] The link between the secretions of the corpus luteum and the endometrium was made in 1910 by Ancel and Bouin when they described the histological changes of the rabbit endometrium associated with pregnancy and demonstrated that the removal of corpora lutea prevented the development of the gestational endometrium.[11] In 1928, Corner, after a decade of research on the anatomy and physiology of the corpus luteum, invited Allen, a medical student skilled in organic chemistry, to take a year of sabbatical from his studies to work with him on the corpus luteum. This collaboration led to the isolation of a progestational agent from pig corpora lutea and the demonstration that this material maintained pregnancy in castrated rabbits.[12,13] Research on the chemical nature of the progestational hormone was continued by Allen and others, and progesterone was obtained in crystalline form in 1934.[14,15]

In addition to producing steroid hormones, the ovary was shown to produce a number of peptide hormones including relaxin, oxytocin, and a number of growth factors (see elsewhere in text and Chapters 21 and 23) as well as the peptide hormones inhibins and activins[16] that participate in both the regulation of follicle-stimulating hormone (FSH) secretion in a species-dependent manner and the local (paracrine and autocrine) control of ovarian function (as described later).

The first half of the twentieth century was also the period in which the role of the pituitary gland in controlling ovarian function was defined. As elegantly chronicled by Greep,[17] these years were a period of intense efforts to identify the hypophysial hormones responsible for follicle growth and luteinization. The clinical findings that disorders of the pituitary gland in humans were sometimes associated with sexual immaturity suggested that the pituitary secreted a gonad-stimulating substance, observations that were confirmed when Smith demonstrated that the effects of hypophysectomy on the reproductive organs could be counteracted by extracts of pituitary tissue.[18] In the 1920s, Ascheim and Zondek extracted urine from pregnant and postmenopausal women and identified the presence of two distinct gonadotropic activities: urine from postmenopausal women stimulated follicular development, whereas urine from pregnant women stimulated luteinization.[19,20] Isolation and biological characterization of two distinct pituitary gonadotropic hormones, FSH and luteinizing hormone (LH), was accomplished in the mid-1940s.[21]

The first direct evidence for adenohypophysial control of ovarian function in primates was the independent studies of Allen in 1928[22] and Hartman in 1930[23] that demonstrated that treatment of immature and adult monkeys with pituitary extracts resulted in stimulation of ovarian function. Thereafter, investigations by others demonstrated that follicular development in monkeys could be initiated by pituitary extracts but not by extracts obtained from urine of pregnant women.[24–26] The proof of two distinct anterior pituitary gonadotropic hormones in the 1940s led to rational approaches in the stimulation of ovulation in primates, and the work of van Wagenen and Simpson in the early 1950s demonstrated that follicular growth could be stimulated in monkeys with purified preparations of macaque gonadotropins.[27] Knobil et al.[28] were the first to report that follicular development and ovulation could be elicited in hypophysectomized monkeys with purified gonadotropins, findings that were subsequently confirmed in humans.[29,30]

The notion that the central nervous system (CNS) regulates gonadal function emerged at the turn of the twentieth century, largely as the result of the recognition by Marshall that many environmental cues (termed exteroceptive factors by Marshall) such as food availability, photoperiod, and temperature had a profound impact on reproduction.[31] In humans, the recognition by clinicians that menstrual cycles can be altered by environmental and social stresses, such as those associated with new jobs and failed relationships, also contributed to the idea that the CNS was an important component of the control system regulating ovarian function. Although it was apparent from the early studies of castration and gonad transplantation in cockerels by Bethold in the mid-nineteenth century that the peripheral nervous system was not critical for gonadal function, definitive evidence that the pituitary was the link between the CNS and gonad did not emerge until the ovary stimulating properties of the pituitary were recognized in the late 1920s.[18] The finding that electrical stimulation of the hypothalamus, but not of the pituitary, caused the release of gonadotropins directed attention on this region of the forebrain by those investigating the CNS control of ovarian function.[32,33] The idea that the CNS control of the gonadotropins, and other anterior pituitary hormones, was likely mediated by the liberation of humoral substances released from the hypothalamus into the primary plexus of the hypophysial portal circulation in the median eminence was formulated by Harris in the 1940s.[34] In a key experiment, Harris and Jacobson[35] found that when pituitary glands where placed in the subarachnoid space beneath the median eminence of hypophysectomized female rats, estrous cyclicity was observed in the recipient animals. This did not occur when the donor pituitaries were transplanted to a site distant from the median eminence and hypophysial portal circulation, although the transplanted pituitaries were well vascularized in both locations; it was concluded that the hypophysial

portal blood supply must have a specific property that is capable of activating pituitary gonadotropin secretion.[35] Harris's hypothesis was finally confirmed beyond doubt by the near simultaneous isolation and characterization of a hypothalamic gonadotropin-releasing peptide, now known as gonadotropin-releasing hormone or GnRH (aka LRF, luteinizing hormone releasing factor or LHRH, luteinizing hormone releasing hormone), by the laboratories of Schally and Guilleman in 1971.[36,37] That GnRH was released from the hypothalamus into the portal circulation in an intermittent mode was inferred by Knobil and his colleagues in 1969 from the moment-to-moment changes ("pulses") they observed in LH concentrations in the peripheral circulation of ovariectomized monkeys.[38] Although the critical importance of such a pulsatile pattern of hypothalamic GnRH release in sustaining gonadotropin secretion was established by the same laboratory in 1978,[39] it wasn't until more than a decade later that the intermittent release of GnRH into the hypophysial portal circulation was demonstrated empirically by Clarke and Cummins.[40]

The finding that selective lesions of the arcuate nucleus (a group of neurons immediately dorsal to the median eminence) in ovariectomized monkeys was associated with loss of LH and FSH secretion[41] led Knobil and his colleagues to conclude that the arcuate nucleus was the likely hypothalamic site where the signal for pulsatile GnRH release originated, thus spawning the concept of the hypothalamic GnRH pulse generator. Most recently, findings from human genetics that loss of function mutations of a G-protein coupled receptor, GPR54 (aka, kisspeptin receptor—KISS1R), are associated with hypogonadotropic hypogonadism and absent or delayed puberty[42] have led to an explosion of studies demonstrating that the ligand to the receptor, kisspeptin, which is expressed in neurons in the arcuate nucleus, is of fundamental importance in driving pulsatile GnRH release.[43]

That ovarian hormones were involved in a "push–pull" servo system with gonadal factors serving as circulating inhibitory signals to pituitary gonadotropin secretion emerged from studies rodents by Moore and Price in 1932.[44] That estradiol also exerted a stimulatory or positive feedback action on gonadotropin secretion, triggering the ovulatory LH and FSH discharge at the midpoint of the menstrual cycle, was later demonstrated in the human and monkey female.[45,46]

OVERVIEW OF THE MENSTRUAL CYCLE

Pattern of Gonadotropins, Ovarian Steroids and Inhibin Levels during the Menstrual Cycle

The ovarian cycle may be divided into three stages: the follicular phase, ovulation, and the luteal phase. Figure 28.1 illustrates the circulating concentrations of FSH and LH (top panel), estradiol and progesterone (center panel), and inhibin A and inhibin B (lower panel) throughout the human menstrual cycle.[47] Because of differences in the duration of the follicular phase, values are standardized to the day of the mid-cycle LH surge (Day 0).

The follicular phase commences upon the initiation of menstrual bleeding from the previous cycle and lasts until the mid-cycle LH surge. The early part of the follicular phase is characterized by elevated concentrations of FSH and low concentrations of LH. Concentrations of the ovarian hormones estradiol and progesterone are also low. Inhibin A concentrations are low while inhibin B concentrations rise, lagging slightly behind those of FSH. Approximately 7–10 days before the mid-cycle gonadotropin surge, serum estradiol and inhibin A concentrations begin to rise and continue to increase thereafter. Coincident with the progressive rise in estradiol and inhibin A concentrations is a decline in FSH concentrations, while LH concentrations are maintained or continue to increase gradually. The rise in estradiol and

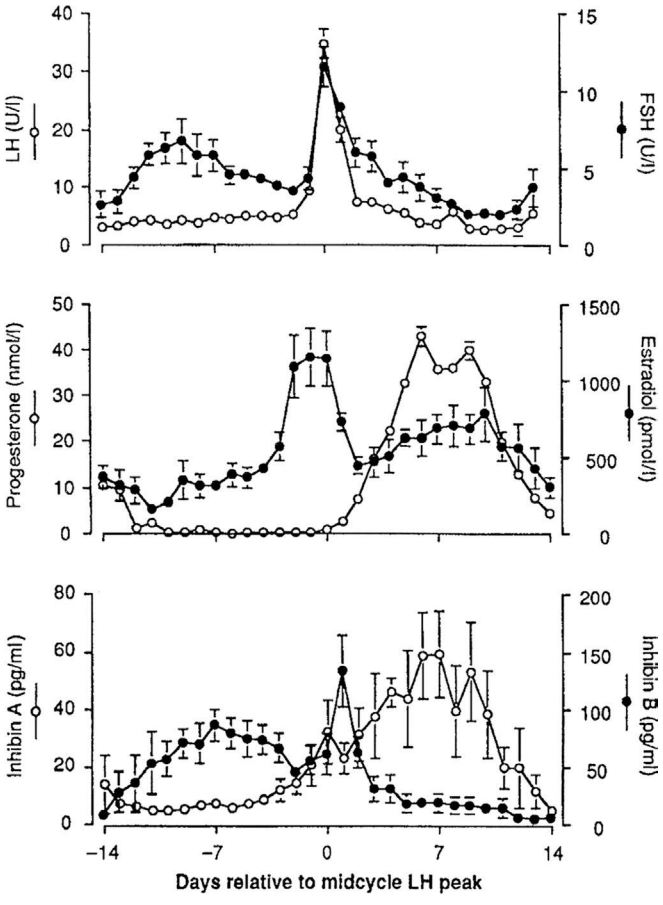

FIGURE 28.1 Profiles of the concentrations of follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol, progesterone, and inhibins throughout the human menstrual cycle. *Source: Redrawn from Ref. 47 with permission, Copyright 1996, The Endocrine Society.*

inhibin A production during the mid-follicular phase onwards reflects the emergence of the follicle destined to ovulate. At this time, asymmetrical estradiol secretion, as assessed by direct sampling of ovarian venous blood, becomes evident, and mechanical destruction of the largest visible follicle within the ovaries delays ovulation by the two weeks required for the maturation of a new preovulatory follicle.[48,49] The follicular phase, in addition to producing an oocyte that is capable of being fertilized and establishing a pregnancy, is also a period during which the uterine endometrium is stimulated to proliferate under the influence of the estradiol that is produced by the developing follicle.

The follicular phase ends with the abrupt elevation of serum LH (and FSH) levels that causes the rupture of the follicle and the release of its mature oocyte (ovulation). As part of the dramatic structural and functional changes that accompany ovulation, there is a marked fall in estradiol and inhibin B production from the follicle. Thereafter, blood levels of progesterone begin to rise, heralding the transformation of the ovulated follicle into a corpus luteum and the beginning of the luteal phase of the menstrual cycle. Inhibin A concentrations continue their late follicular phase rise and then fall in parallel with those of progesterone. The primate corpus luteum also secretes estradiol so concentrations of this steroid parallel those of progesterone during the luteal phase. The progesterone that is produced by the corpus luteum transforms the proliferative endometrium to a secretory one in anticipation of the implantation of a fertilized oocyte. In the absence of pregnancy, the corpus luteum has a 14–16 days lifespan following which production of progesterone and other luteal hormones ceases, menstruation commences, and another ovarian cycle starts anew. However, in the event that successful fertilization and implantation occurs, the lifespan of the corpus luteum and its resultant production of progesterone are prolonged until the placenta develops the capacity to produce sufficient amounts of progesterone to maintain the established pregnancy.

The Concept of a Pelvic Clock

It is apparent in Figure 28.1 that precise timing and communication is required between the ovary and the pituitary gland to ensure that the mid-cycle surge in gonadotropins occurs at the point in time of the menstrual cycle when an ovarian follicle that is capable of ovulating and forming a corpus luteum is present within the ovary. The classical studies of Knobil and his colleagues in rhesus monkeys investigated the effects of ovariectomy plus replacement of steroid hormones on the generation of an LH surge. These studies convincingly demonstrated that the ovarian hormone estradiol was the principal regulator of the timing of the LH surge and that peripheral estradiol concentrations must be elevated to ~1000 pmol/l (275 pg/ml) for 24–36 h in order for an LH surge to occur.[50] As can be seen in Figure 28.1, in women this concentration of estradiol is seen during the late follicular phase and immediately precedes the spontaneous LH surge. On the basis of these observations, Knobil concluded that the clock that times the onset of the LH surge, and therefore ovulation, lies within the pelvis and its zeitgeber (synchronizer) is the ovary through its production of estradiol. As will be discussed later, not only is estradiol responsible for the timing of the LH surge and ovulation but it is also involved in the process by which a single follicle is selected to mature during the follicular phase of the menstrual cycle.

The Hypothalamic GnRH Pulse Generator

In the primate hypothalamus there are some 1000 to 2000 diffusely distributed GnRH neurons (see Chapter 11), many of which send their projections to the median eminence where they synchronously and intermittently discharge their peptide into the primary plexus of the hypophysial portal circulation, thereby providing the pituitary gonadotropes with the pulsatile stimulation that is obligatory for maintaining gonadotropin secretion.[39] While routine assessment of GnRH concentrations in portal blood is not feasible in primates, studies of the ewe indicate that discharges ("pulses") of GnRH into the hypophysial portal circulation are robustly correlated with episodes ("pulses") of LH secretion from the pituitary.[40,51] Moreover, in several species including the rhesus monkey volleys of multiunit electrical activity (MUA) that are tightly coupled to pulses of LH secretion (Figure 28.2) can be recorded in the medial basal hypothalamus (MBH),[52,53] and it is thus generally recognized that hypothalamic MUA provides a robust correlate of GnRH pulse generator activity.[54] In the absence of ovarian negative feedback on gonadotropin secretion, the primate GnRH pulse generator operates at a frequency of approximately 1 pulse/h.[38,52]

The early finding by Knobil's laboratory in the female rhesus monkey that pulsatile LH secretion was maintained after all neural inputs to the MBH had been surgically interrupted using a bayonet-shaped "Halasz" knife[55] suggested that the neurobiological network necessary for pulsatile GnRH secretion was resident in this basal aspect of the hypothalamus that lies between the optic chiasm and mammillary bodies. The later finding by the same laboratory that discrete lesions of the arcuate nucleus in the MBH of ovariectomized monkeys abolished gonadotropin secretion without compromising the pituitary's response to GnRH, while much larger lesions in this region of the hypothalamus that spared the arcuate nucleus had little impact on LH and FSH secretion,[41] led Knobil to propose that the origin of GnRH

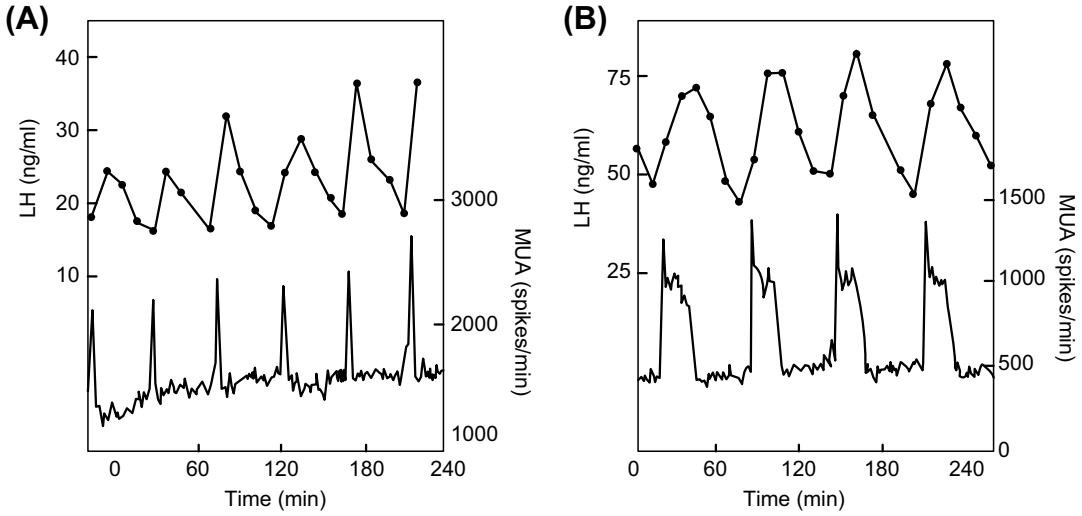

FIGURE 28.2 Multiunit electrical activity (MUA) recorded from the mediobasal hypothalamus in a normal monkey on day 5 of the follicular phase of the menstrual cycle (A) and in an ovariectomized animal (B). Note the association of the MUA volleys with the initiation of luteinizing hormone (LH) pulses and the shorter duration of the volleys in the presence of the ovary. *Source: Reproduced from Ref. 52 with permission, Copyright 1991, S. Karger AG, Basel.*

pulse generation in the primate hypothalamus resides within the arcuate nucleus.[56] Since the vast majority of GnRH neurons in the monkey MBH are found lateral to the midline arcuate nucleus surrounding the base of the third ventricle,[57] they would have likely remained intact in the arcuate lesioned animals (Figure 28.3). This would suggest that pulse generation is actively imposed upon the network of GnRH neurons rather than reflecting an intrinsic property of the GnRH neurons per se. The concept of the GnRH pulse generator remained that of a black box for essentially 30 years. With the landmark discovery in 2003 that loss of function mutations of the kisspeptin receptor (KISS1R, aka GPR54) in man were associated with hypogonadotropic hypogonadism and delayed or absent puberty,[42,43] a neurobiological basis to account for GnRH pulse generation by the arcuate nucleus has begun to emerge.

Within the MBH in primate and nonprimate species, expression of kisspeptin at both the mRNA and protein levels is restricted primarily to neurons in the arcuate nucleus[57–59] (see also Chapter 11). Kisspeptin fibers project throughout the arcuate nucleus and to the median eminence where they mingle intimately with GnRH fibers targeting the primary plexus of the hypophysial portal circulation[57] (Figure 28.3). That kisspeptin provides an attractive candidate to account for the intermittent signal relaying the output of the GnRH pulse generator to the GnRH neuronal network is suggested by the following observations. First, GnRH neurons in nonprimate species have been shown to express KISS1R,[60,61] and application of microdialysis to assess peptide release in the median eminence of the female monkey suggests that both GnRH and kisspeptin release in this region of the MBH is pulsatile and that the discharge of these neuropeptides can occur synchronously.[62] Second, concomitant application of a KISS1R antagonist in the dialysate perfusing the monkey median eminence results in a suppression of pulsatile GnRH release.[63] Third, single IV bolus challenges with kisspeptin throughout the human menstrual cycle invariably evoke an LH discharge,[64] and in the juvenile monkey where spontaneous pulsatile GnRH and LH secretion is minimal, chronic repetitive IV infusions of kisspeptin at 1 pulse/h (the open loop frequency of the GnRH pulse generator in the adult) elicits, as reflected by LH release, a sustained train of GnRH pulses comparable to that generated spontaneously by the hypothalamus of the adult.[65] Fourth, continuous infusions of kisspeptin (kisspeptin-10) at various low doses (0.3–4.0 μg/h/kg) in the latter nonhuman primate model failed to stimulate any parameter of LH secretion (Ramaswamy and Plant, unpublished observations), while high dose infusions (approximately30–40 μg/h/kg) of the neuropeptide resulted in initial stimulation of GnRH release that is followed by desensitization of KISS1R and a hypogonadotropic state.[66]

It should be noted that there are reports in the human literature that are difficult to reconcile with the hypothesis that the output of the pulse generator to the GnRH neurons is provided by intermittent kisspeptin signaling. Studies of normal and hypogonadotropic men have reported that continuous kisspeptin infusions (kisspeptin-10, 1.5–4.0 μg/kg/h for 12–22.5 h) were associated with an increase or restoration, respectively, in frequency of pulsatile LH secretion,[67,68] and a pulsatile pattern of low amplitude LH release has been reported in one female patient with a loss of function mutation of KISS1R.[69] Identification of LH pulses, however, is somewhat subjective, and transfection of cell lines in vitro to

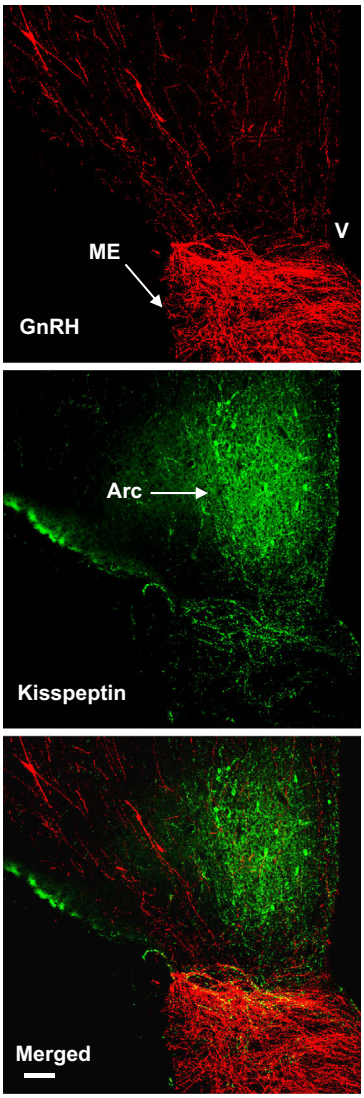

FIGURE 28.3 A hemi-coronal section through the mediobasal hypothalamus of a castrated rhesus monkey at the level of the arcuate nucleus (Arc), the posited site of the gonadotropin-releasing hormone (GnRH) pulse generator. This figure is reproduced in color in the color plate section. The section was doubled labeled by immunofluorescence for GnRH and kisspeptin. Top panel, a confocal image of the distribution of GnRH cell bodies and fibers; middle panel, also a confocal image of the same section showing the corresponding distribution of kisspeptin cell bodies and fibers. The lower panel shows the merged image. Castration results in an upregulation of kisspeptin expression that is associated with robust GnRH pulse generator activity. Note that GnRH cell bodies at this level of the hypothalamus are found lateral to the kisspeptin perikarya in Arc: both sets of neurons send projections to the median eminence (ME) where they closely intermingle. The ependymal lining of the third ventricle (V) may be seen on the right-hand side of the section. Scale bar 100 μm. *Source: Rearranged from Ref. 57, with permission, Copyright 2008, The Endocrine Society.*

examine signal transduction by mutated receptors may not fully reflect the situation in the in situ GnRH neuron. Further examination of these questions is therefore required, because if the observations in man were to be substantiated they would challenge the model for GnRH pulse generation that we have developed here.

Whether the posited intermittent kisspeptin output of the arcuate pulse generator drives pulsatile secretion of GnRH by an action on the GnRH fibers in the median eminence or by targeting GnRH cell bodies and dendrites is not clear. However, the dense field of GnRH terminals in the median eminence throughout which kisspeptin axons transverse (Figure 28.3) would appear to be an ideal site at which synchronized activity of a diffusely distributed network of GnRH perikarya could be established. The potential for such control has been demonstrated by the findings that retrochiasmatic explants of rat hypothalami containing few if any GnRH cell bodies continue to release GnRH in a pulsatile mode,[70,71] and kisspeptin stimulates GnRH release directly from GnRH terminals in MBH explants from mice.[72] Axoaxonic synapses to GnRH neurons in the median eminence are rare,[73] but volume transmission by diffusion of kisspeptin in extracellular fluid to extrasynaptic KISS1R on GnRH terminals in the median eminence is possible. Consistent with this notion is the general finding across species that IV-administered kisspeptin (kisspeptin-10) is a potent stimulator of GnRH release (see Chapter 11), in spite of the fact that this form of kisspeptin does not appear to cross the blood–brain barrier[74] and is therefore unlikely to gain access to the majority of GnRH cell bodies in the hypothalamus.

A study of sheep in 2007 was the first to demonstrate that many kisspeptin neurons in the arcuate nucleus also express neurokinin B (NKB),[75] a member of the tachykinin family of peptides.[76] In most species including the monkey and human, the majority of kisspeptin neurons in the arcuate nucleus also appear to express NKB,[77,78] although the relative number of kisspeptin and NKB immunopositive cell bodies in the arcuate nucleus has been reported to differ markedly across species.[79–81] The full significance of the coexpression of kisspeptin and NKB in arcuate neurons, however, went largely unrecognized until Topaloglu and his colleagues reported in 2009 that loss of function mutations in either this ligand or its receptor (NK3R) were associated with a phenotype similar to that reported earlier for inactivating mutations of KISS1R, i.e., hypogonadotropic hypogonadism and delayed puberty.[82] As is to be expected from the clinical observation, IV bolus injection of NKB to the juvenile monkey elicits a GnRH-dependent LH discharge.[78] This action of NKB on GnRH release is upstream from that of kisspeptin as demonstrated by the finding in the monkey that LH discharges induced by an NKB agonist (senktide) are abolished by desensitization of KISS1R, but antagonism of NK3R does not interfere with kisspeptin-induced LH release.[83] The realization that two neuropeptides, each seemingly critical for driving gonadotropin secretion, were expressed by the same arcuate neurons

further focused attention on the arcuate nucleus as the critical hypothalamic regulator of GnRH release.

A third peptide, the endogenous opioid dynorphin, is also expressed in kisspeptin/NKB neurons, and therefore the acronym KNDy is commonly used to describe these unique arcuate neurons.[84] Dynorphin signals primarily at the kappa opioid receptor,[85] and, interestingly, it has been known for more than two decades that administration of naloxone, a general opiate antagonist, results in an acceleration in LH pulse frequency during the luteal phase of the menstrual cycle in women and monkeys (see later), indicating that endorphin signaling is involved in the control of GnRH pulse frequency.[86,87] The appreciation of the importance of these specific arcuate neurons in GnRH pulse generation in the rat has been cemented by the elegant finding from Rance's laboratory that ablation of KNDy neurons following NK3R-mediated uptake of the ribosome inactivating toxin, saporin, results in a loss in hypothalamic drive to LH secretion.[88]

In the hypothalamus of men, only a very small percentage of arcuate neurons that dual label for kisspeptin and NKB have been found to also express dynorphin.[80] The functional significance of this and other species differences in the relative immunoexpression of these three arcuate peptides is difficult to ascertain because staining intensities depend on many aspects of the immunohistochemical procedures employed and, in particular, on the relative characteristics of the primary antibodies used. For these reasons, it would seem reasonable to conclude from the extant data that the role of KNDy neurons in GnRH pulse generation is likely to be fundamentally similar across mammalian species.

The neurobiological mechanisms within the arcuate nucleus that underlie the pulsatile kisspeptin output from KNDy neurons to the GnRH neuronal network remain the subject of speculation. Based on studies primarily in mice and sheep, however, it is posited that GnRH pulse generation is achieved by reciprocating stimulatory (NKB) and inhibitory (dynorphin) connections between KNDy neurons within the arcuate nucleus.[79,81,89] The evidence for this contemporary model of hypothalamic GnRH pulse generation within the arcuate nucleus has been presented in detail in Chapter 27. It should be noted, however, that this model is likely to be modified in the future. In this regard, substance P, also a tachykinin, has recently been reported to be colocalized with NKB in KNDy neurons in the human hypothalamus,[90] and studies utilizing hypothalamic slices from transgenic mice indicate that this neuropeptide, like NKB, is able to depolarize KNDy neurons.[91,92] Moreover, the stimulatory action of NKB on KNDy neurons occurs via activation of all three tachykinin receptors (NK1R, NK2R, and NK3R)[91]—a finding consistent with the in vivo observation in ovariectomized rats that pulsatile LH secretion was inhibited by central injection of a nonselective tachykinin antagonist but not by single administration of specific antagonists to the three receptor subtypes.[93] Thus, the intermittent intra-KNDy neuron stimulus that is posited to be responsible for pulsatile GnRH release in the current model of pulse generation may involve multiple and redundant tachykinin signaling pathways.

FOLLICULOGENESIS

Preantral Follicular Development

Figure 28.4 illustrates the stages of follicular development from the primordial to the preovulatory stages. Folliculogenesis begins with the transition of primordial follicles, which are formed during fetal life and may remain dormant within the ovaries for as long as 50 years, to a primary follicle. This transition is characterized by the expansion of the epithelial-like granulosa cells to a cuboidal appearance, the initiation of proliferation of the granulosa cells, and the onset of the growth of the oocyte. Up until the past few years, the mechanisms responsible for the activation of primordial follicles were a mystery. The serendipitous finding that knockout of the forkhead transcription factor, FOXO3, in mice leads to global activation of primordial follicles[94] has focused attention on the role of the phosphoinisitol 3-kinase (PI3-K) pathway as an important regulator of follicle activation. Pharmacological stimulation of the PI3-K pathway in human ovaries leads to activation of primordial follicles indicating that this pathway may also be involved in this aspect of folliculogenesis in primates.[95] A role for the PI3-K pathway specifically in preantral folliculogenesis in the human has been investigated in a recent study performed in women with premature ovarian insufficiency (POI).[96] Ovarian tissue was collected from women with POI and the PI3-K pathway was pharmacologically activated in combination with cutting the ovary into small fragments, a procedure that inactivates the Hippo signaling pathway, which in turn stimulates the growth of the ovarian fragments. Following autotransplantation of the ovarian fragments and gonadotropin therapy, mature oocytes were collected and fertilized, and embryo transfer resulted in a pregnancy and a live birth. Although very preliminary, these findings indicate that the rapidly advancing knowledge base regarding the signaling pathways involved in preantral folliculogenesis may lead to novel treatment for infertility. However, the recent observation that FOXO3 does not appear to be expressed in rhesus monkey, baboon, chimpanzee, or human oocytes questions the role of this factor in primordial follicle activation in primates.[97] Whether there are redundancies in the roles of the individual FOXO transcription factors between rodents and primate oocytes or

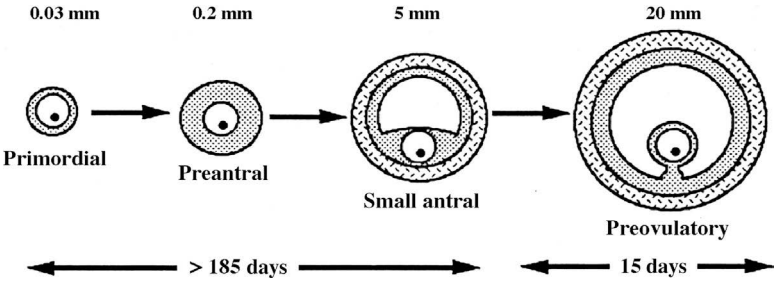

FIGURE 28.4 Pattern of human follicular development. Growth of follicles from the primordial (approximately 0.03 mm diameter) to the small antral stage (4–5 mm diameter) is characterized principally by proliferation of granulosa cells and takes greater than 120 days to complete. The maturation of a small antral follicle to a preovulatory follicle (approximately 20 mm diameter) takes approximately 15 days. See Ref. 98 for more details.

whether other downstream targets of the PI3-K pathway may control primordial follicle activation in primates remains to be established.

The role of the PI3-K pathway and other potential regulators of primordial follicle activation and preantral folliculogenesis are discussed in greater detail in Chapter 21.

After the preantral follicle acquires six to seven layers of granulosa cells, the antral cavity begins to form and the theca cell layer begins to develop. Based on measurements of mitotic indices and granulosa cell doubling times, Gougeon[98] estimated that the growth of a follicle from the primordial to the early antral stage in humans takes at least 120 days, whereas the final stages of follicular growth occur during the follicular phase of the menstrual cycle, which lasts approximately 14 days.

Histological studies have demonstrated the presence of preantral and early antral follicles in ovaries removed from hypophysectomized and prepubertal monkeys, indicating that the early stages of follicular development up to and including the formation of early antral follicles are independent of the secretion of the pituitary gonadotropins FSH and LH.[28,99,100] Similarly, morphological studies in humans and macaques identified all stages of preantral follicles throughout the entire menstrual cycle.[101,102] Use of [^{3}H]-thymidine to label dividing granulosa cells in monkeys revealed that all stages of preantral follicles undergo DNA synthesis during the luteal phase of the menstrual cycle as well as during the mid- through late follicular phases after the selection of the dominant follicle,[103] and are therefore presumably growing.

Granulosa cells from early antral follicles isolated during the human menstrual cycle do not produce substantial amounts of estradiol under basal conditions, but the secretion of estradiol can be stimulated by prolonged incubation of the cells with FSH and androgen substrate, whereas they do not respond to LH, either acutely or after prolonged incubation.[104] The responsiveness of developing monkey follicles to the gonadotropins parallels the distribution of cell surface receptors for FSH and LH because it has been demonstrated that, like that of other subprimate species, granulosa cells of preantral and early antral follicles possess cell surface receptors for FSH but not for LH.[105] Because early antral follicles are responsive to FSH and are present throughout the menstrual cycle as a result of the continuous entry of primordial follicles into the pool of developing follicles, it is generally accepted that the process of preantral follicular development serves to provide a constantly available source of maturing follicles for final development to the preovulatory stage when provided with appropriate gonadotropic support. This is best evidenced by the observations that preovulatory follicular development is rapidly stimulated in hypophysectomized monkeys and humans by the administration of exogenous FSH and LH[28–30] as well as in prepubertal monkeys by the administration of pulsatile GnRH.[106]

Antral Follicular Development

The maturation of follicles beyond the early antral stage is under obligatory gonadotropic control. During this phase of development, striking structural and functional changes occur within the follicle that result in its ability to produce steroid hormones and the ability to undergo ovulation and luteinization in response to the mid-cycle gonadotropin surge. Because preantral follicles possess only FSH receptors, it is this gonadotropin that is responsible for the initiation of preovulatory follicular development and the associated biochemical changes within the follicle that accompany this process. Microarray analysis of rat granulosa cells stimulated by FSH for 48 h revealed that over 400 mRNA transcripts are increased at least two-fold by FSH.[107] Included among the mRNAs induced by FSH are cholesterol side chain cleavage cytochrome P450 (P450scc), aromatase cytochrome P450 (P450arom), steroidogenic acute regulatory protein (StAR), and the LH receptor. The coordinated expression of P450arom results in the ability of the follicle to produce estradiol, whereas the acquisition of the LH receptors on granulosa cells confers LH responsiveness to the follicle that results in its capacity to ovulate and luteinize in response to the mid-cycle gonadotropin surge.[108]

As reviewed in detail in Chapter 20, the cAMP/protein kinase A (PKA) intracellular signaling pathway is activated by FSH in granulosa cells and appears to be sufficient to account for the dramatic increase in gene expression that accompanies granulosa cell differentiation. Thus, transduction of undifferentiated rat

granulosa cells with a lentiviral vector that expresses a constitutively active catalytic subunit of PKA indicated that a majority of genes induced by FSH were also induced to a similar extent by PKA.[107] However, a subset of genes, including those that encode for the LH receptor and P450AROM, were induced to a greater extent by FSH than by PKA, suggesting that additional signaling pathways activated by FSH may contribute to optimal gene regulation that accompanies preovulatory follicle differentiation. One likely candidate is the PI3-K/AKT signaling pathway (Chapter 20).

Control of Follicular Estradiol Biosynthesis

Gonadotropic Hormones

The classical studies of Greep et al.[21] demonstrated in hypophysectomized rats that although highly purified FSH was able to stimulate follicular growth, estradiol secretion, as measured by increases in uterine weights, was not stimulated unless LH was also administered. Administration of LH alone to hypophysectomized rats stimulated the repair of interstitial tissue but did not stimulate follicular growth or estradiol secretion. These results, published over 70 years ago, provide the framework for virtually all of our fundamental knowledge regarding the hormonal control mechanisms that govern preovulatory follicular development in primates and subprimate species.

The production of estradiol by the maturing follicle requires the interaction between the theca cells and the granulosa cells.[109] As revealed from studies conducted initially in subprimate species, theca cells under LH stimulation produce C19 androgens (testosterone and androstenedione). Because theca cells lack significant quantities of P450AROM, theca cells cannot metabolize androgens to estradiol.[110] By contrast, granulosa cells lack the 17α-hydroxylase, C17, 20 lyase activities (P450c17) that are required to metabolize C21 steroids to C19 androgens but under FSH stimulation acquire P450AROM that converts C19 androgens to estradiol.[104] Thus, Greep's original observations that both FSH and LH are required for estradiol production can be explained by the requirements for theca cell production of androgens under the influence of LH as well as granulosa cell aromatization of androgens to estradiol under the influence of FSH.

This "two-cell, two-gonadotropin" model for estradiol biosynthesis is also operative in primates. Autoradiographical studies have demonstrated that theca cells of early antral and antral follicles possess LH receptors, whereas granulosa cells contain FSH receptors.[105] Immunocytochemical analysis has demonstrated that theca cells, but not granulosa cells, possess P450c17, whereas granulosa cells from preovulatory follicles, but not theca cells, stain positive for P450AROM.[111] In vitro studies using radiolabeled steroids demonstrated minimal production of estradiol when theca cells or granulosa cells were incubated alone, whereas combining the two cell types resulted in significant production of estradiol.[112] The requirement for androgen as a substrate for estradiol production by granulosa cells was demonstrated by the findings that addition of testosterone or androstenedione to isolated human granulosa cells resulted in estradiol secretion, whereas granulosa cells incubated in the absence of androgen produced minimal amounts of estradiol.[113,114]

In humans, the FSH-mediated induction of P450AROM is the rate-limiting step in follicular estradiol secretion. Granulosa cells collected from immature follicles throughout the follicular and luteal phases produced negligible quantities of estradiol when incubated in the presence of androgen substrate unless they were exposed to FSH for 48 h.[104] In contrast, granulosa cells collected from mature preovulatory follicles were able to metabolize androgens to estradiol immediately upon removal from the follicle in the absence of added FSH.[115] In vivo, thecal androgen production does not appear to be limiting for the secretion of estradiol because androgen concentrations in the follicular fluid of early antral follicles whose granulosa cells lack P450AROM are similar to those of mature follicles whose granulosa cells possess this enzyme.[116–118]

Autocrine and Paracrine Factors

Although FSH and LH are the primary regulators of ovarian cellular function, it has become increasingly apparent that the ovarian cellular responses to the gonadotropins can be modified either in a positive or a negative manner by factors that are produced and have actions within the follicle. Those factors that have received the most attention with respect to the primate ovary include steroid hormones (androgens and estradiol), insulin-like growth factor (IGF) I, and the inhibins and activins.

STEROID HORMONES

The ability of estradiol to augment the actions of FSH on granulosa cells is well recognized, and it has been postulated that elevated estradiol concentrations present within the maturing follicle may contribute to the selection of the preovulatory follicle. This thesis is based largely on studies in rodents that demonstrated that treatment of hypophysectomized rats with estradiol or diethylstilbestrol greatly enhanced the responses of the ovary to exogenously administered FSH.[119–121] However, rigorous studies in macaques failed to demonstrate a synergistic effect of diethylstilbestrol on FSH-stimulated follicular development in vivo.[122] Messenger RNA for the estradiol receptor (ER) and immunoreactive ER protein

has been identified in baboon granulosa cells.[123] Specific antibodies that distinguish between the alpha and beta forms of the ER demonstrated that ERβ is localized to the granulosa cells of the follicle while the ERα is present in the theca cells.[124,125] Despite the presence of ERs in the follicle, it does not appear that estradiol is absolutely required for gonadotropin-dependent antral follicular development. Women with inactivating mutations of P450AROM cannot convert androgens into estradiol, and as a result, serum FSH levels are elevated due to a lack of estradiol negative feedback (see following).[126,127] Studies on the morphology of ovaries of a P450AROM-deficient girl have revealed the presence of numerous large antral follicles with intact oocytes and normal-appearing granulosa cells that regressed after the suppression of FSH secretion by the administration of low doses of estradiol.[128] These findings indicate that lack of estradiol production does not inhibit FSH-stimulated antral follicular development. However, it remains to be determined whether the large follicles present in the ovaries of P450AROM-deficient humans are functionally normal and can ovulate in response to exogenous LH or human chorionic gonadotropin (hCG).

As mentioned above, androgens are produced by theca cells under LH stimulation and are metabolized to estradiol by granulosa cells. In addition to serving as the obligatory substrate for P450AROM, androgens potentiate FSH-stimulated induction of P450AROM activity and inhibin production by primate granulosa cells in vitro.[129,130] Androgen receptor (AR) has been identified by immunocytochemistry in granulosa cells of follicles in the primate ovary, with preantral and early antral follicles exhibiting higher levels of AR than preovulatory follicles.[131] In humans, it does not appear that androgens are absolutely essential for follicular growth because successful ovarian stimulation by FSH was achieved in a woman with P450c17 deficiency, and granulosa cells isolated from this woman were able to produce estradiol when provided with an androgen substrate.[132,133]

Although androgens may not be obligatory for follicular development, studies in macaques have suggested that androgens appear to be positive regulators of this process because treatment of rhesus monkeys with testosterone or dihydrotestosterone increases the abundance of mRNA for the FSH receptor in granulosa cells and increases the growth of small follicles.[134,135] However, when the actions of androgens on gonadotropin-stimulated ovarian function were tested in vivo in rhesus monkeys, no apparent stimulation of ovarian function was observed.[136] The ability of androgens to augment FSH-stimulated follicular growth in humans has been investigated in the context of ovarian stimulation for assisted reproductive technologies, particularly in women who previously exhibited a suboptimal response to ovulation induction therapy. The results of one study did not show a beneficial effect of androgen pretreatment on FSH-stimulated follicle growth,[137] while others demonstrated that androgen pretreatment either increased the number of recruited follicles[138] or improved the apparent ovarian sensitivity to FSH, based upon the amount of exogenous FSH necessary to stimulate follicle development.[139] An inherent difficulty in evaluating potential effects of androgens on follicular development is that it is not known to what extent peripheral administration of androgens results in physiologically relevant androgen levels within the follicle. To circumvent this problem, women were pretreated with LH prior to initiating ovarian stimulation with FSH, the rationale being that LH pretreatment would stimulate endogenous androgen production by theca cells and thereby provide a more physiologically relevant intrafollicular androgen environment to the developing follicle. The results of one study[140] indicated that the number of small antral follicles and the number of normally fertilized oocytes was increased by LH pretreatment, while the results of another study[141] indicated that LH pretreatment decreased the daily amount of FSH necessary to stimulate follicle growth (improved the sensitivity to FSH) and increased estradiol concentrations but did not increase the number of maturing follicles. Collectively, the aforementioned studies suggest that androgens, although perhaps not essential for FSH-induced follicular development, may function to increase the sensitivity of follicles to FSH thereby augmenting follicular growth, as might be predicted by the findings in macaques that androgens increase FSH receptor mRNA levels in developing follicles.[134]

INSULIN-LIKE GROWTH FACTORS 1 AND 2

IGF1 synergizes with FSH in the induction of P450AROM activity in primate granulosa cells as well as with LH in the production of androgens by theca cells.[142–145] As such, IGF1 could contribute to the regulation of estradiol biosynthesis and follicular development. Although IGF1 is produced by rat granulosa cells,[146] evidence to date in primates suggests that IGF1 is not produced in human granulosa cells.[147] However, IGF1 is present in follicular fluid, presumably derived from ultrafiltration of plasma, and could thus serve as a regulator of gonadotropin action on the maturing follicle.[148]

The hypothesis that IGF1 augments the actions of FSH and/or LH on the maturing follicle was tested in a nonhuman primate animal model. Rhesus monkeys received an intravenous infusion of IGF1 for 5 days before and continuing throughout a 15-day regimen of pulsatile infusion of FSH and LH.[149] Serum estradiol and serum androstenedione concentrations were measured as an index of FSH and LH actions, and ovarian weights were measured at the end of the FSH/LH infusion. Results demonstrated that there was no augmentation of

FSH/LH-stimulated estradiol or androstenedione production by IGF1 and there was no increase in ovarian weights compared with FSH/LH treatment alone. The lack of effect of IGF1 in this in vivo setting is consistent with results from an IGF1-deficient Laron dwarf, which indicated that these subjects respond normally to ovulation induction with exogenous gonadotropins.[150]

Messenger RNA for IGF2 is present in human granulosa cells, and human granulosa cells secrete IGF2 in vitro,[151,152] suggesting that this peptide could also fulfill the role of an autocrine/paracrine agent. As reviewed by Kwintkiewicz and Giudice,[153] the biological activity of IGF2 within follicles is governed by both its production as well as its sequestration by IGF binding proteins (IGFBPs). Studies with follicular fluid isolated from healthy and atretic human follicles revealed that atretic follicles have low levels of IGF2, high levels of IGFBPs, and low levels of IGFBP protease activity. Conversely, dominant follicles have high levels of IGF2, high levels of IGFBP-4 protease activity, and low levels of IGFBPs. Collectively, these differences would result in a greater bioavailability of IGF2 in dominant follicles when compared with atretic follicles. Enhanced IGF2 signaling in the dominant follicle could amplify the biological actions of FSH and LH and therefore participate in the process of follicular development and selection. However, it should be noted that both IGF1 and IGF2 signal through the type 1 IGF receptor and, as noted above, studies in monkeys failed to reveal a significant effect of IGF1 on FSH/LH-stimulated estradiol levels and ovarian weights. Clearly, additional in vivo studies are necessary to determine if IGF1 and/or IGF2 play a major role in primate folliculogenesis.

INHIBIN/ACTIVIN

The inhibins and activins are proteins composed of two of three peptide subunits, an α subunit, a β_A subunit, and a β_B subunit. Assembly of an α subunit with a β_A subunit results in the formation of inhibin A, and assembly of an α subunit with a β_B subunit results in inhibin B. Assembly of two identical β subunits results in the formation of the homodimeric activins (activin A and activin B), whereas assembly of a β_A subunit and a β_B subunit results in activin AB.[16] The expression of inhibin and activin in the primate ovary is developmentally regulated. In cynomolgus monkeys, neither the α subunit nor the β subunits are present in preantral follicles, whereas granulosa cells in early antral follicles intensely express mRNA for the β_B subunit. As early antral follicles mature to the preovulatory stage, the expression of the β_B subunit is extinguished, whereas the expression of the α and the β_A subunits is stimulated.[154] These observations suggest that the early stages of antral follicular development may be influenced by activin, whereas the final stages of preovulatory follicle development may be influenced by inhibin. Similar findings have been reported in humans.[155] One potential role for the inhibin/activin system in the primate ovary may be the coordination of the functional activities of the theca and the granulosa cells in the production of estradiol. As mentioned above, the production of estradiol requires the synthesis of androgens by the theca cells under LH control and the metabolism of androgens to estradiol by granulosa cells in which P450AROM activity is induced by FSH. Studies with isolated human theca cells have revealed that activin antagonizes the stimulatory effects of LH on androgen production, whereas inhibin potentiates the ability of LH to stimulate androgen production.[144,156] These actions may serve to ensure that appropriate amounts of androgen are produced by the theca cells relative to the extant P450AROM activity. Before stimulation by FSH and before the induction of P450AROM, granulosa cells may produce activin, which would suppress theca androgen production and prevent excessive androgen secretion. As the follicle is stimulated by FSH, P450AROM is induced as is the ability of the follicle to produce inhibin. The increased demand for androgens by granulosa cells of the maturing follicle for subsequent aromatization to estradiol could thus be met by the actions of inhibin, which augment LH-sensitive theca androgen production. In addition to its actions on theca cell androgen production, activin also amplifies FSH-stimulated P450AROM activity in granulosa cells from immature marmoset follicles,[157] which would further enhance the ability of the developing follicle to produce estradiol. These results with primate ovarian cells showing that activin amplifies the stimulatory actions of FSH on P450AROM are similar to results obtained in rats that demonstrated that activin synergizes with FSH to stimulate DNA synthesis, as well as the induction of P450AROM and LH receptors on granulosa cells.[158,159] Collectively, these findings indicate that activin, which is expressed in FSH-dependent early antral follicles, amplifies the effects of FSH during preovulatory follicle development.

Gonadotropic Control of Preovulatory Follicular Development

Follicle-Stimulating Hormone

The essential role for FSH in preovulatory follicular development in primates was first demonstrated unequivocally by Rabin et al.[160] in their investigations of a woman with an isolated deficiency of FSH. This "experiment of nature", a 22-year-old with primary amenorrhea, had undetectable concentrations of FSH (<3 mIU/ml), elevated levels of LH (50–90 mIU/ml), estradiol levels less than 10 pg/ml, and no evidence of antral follicular development assessed by laparoscopy

and ovarian biopsy. Although initial attempts to restore ovulation in this individual with exogenous human menopausal gonadotropins were unsuccessful due to the production of anti-FSH antibodies in response to the "foreign" antigen, subsequent studies in which increasing amounts of FSH were administered to overcome the binding of the hormone to anti-FSH antibodies resulted in follicular development, estradiol production, ovulation, and successful pregnancy.[161] The low estradiol concentrations and lack of follicular development in the presence of elevated LH supports the findings of Greep et al.[21] that LH, in the absence of FSH, is unable to initiate preovulatory follicular development and estradiol secretion. The failure to observe follicular development until FSH concentrations were restored despite the presence of LH in the circulation confirmed the absolute requirement of FSH for preovulatory follicular development and estradiol secretion. Further confirmation of the absolute role for FSH in preovulatory follicular growth was revealed by the identification of additional women with isolated FSH deficiencies as well as women with inactivating mutations of the FSH receptor that are associated with the failure of ovarian follicles to advance beyond the early antral stages of maturation.[162,163]

Luteinizing Hormone

In patients with gonadotropin deficiency (low FSH and low LH), treatment with pure FSH obtained by recombinant DNA technology[164] has permitted investigations of actions of FSH in vivo in the apparent absence (or very low circulating levels) of LH. As would be predicted from Greep's observations,[21] in these hypogonadotropic patients administration of pure FSH promoted large antral follicular development but did not result in the stimulation of estradiol secretion[165] underlying the role of LH in driving thecal androgen production. In addition, inactivating mutations of the LH receptor have been identified in humans.[162,163,166] The ovarian phenotype in these individuals is exactly what would have been predicted from the extant knowledge of the effects of LH on the maturing follicle. Thus, women with inactivating mutations of the LH receptor are hypoestrogenic and anovulatory.

SELECTION OF THE PREOVULATORY FOLLICLE

The fact that numerous follicles can be stimulated to mature in humans and nonhuman primates when exogenous gonadotropins are administered eliminates the possibility that only a single follicle is available for maturation as the follicular phase commences. Although it is indisputable that the pituitary gonadotropins are indispensable for preovulatory follicular growth, why is it that a single follicle usually matures in view of the fact that FSH and LH are presumably provided to all follicles by the circulatory system? The process of follicular selection must require the operation of a highly stringent regulatory process, the function of which is to ensure that only one of the many follicles with the potential to mature to the preovulatory state actually does so. In simple terms, follicle selection must involve a mechanism by which the presence of a maturing follicle in some manner inhibits the growth of other follicles without compromising its own development.

Cessation of Preovulatory Follicular Development during the Luteal phase of the Menstrual Cycle

During the luteal phase of the menstrual cycle, preantral follicles continue to develop, but the maturation of follicles beyond the early antral stage does not occur.[101–103] Upon the regression of the corpus luteum, antral follicle growth resumes and ovulation occurs approximately 14 days later. That the hiatus in preovulatory follicular development during the luteal phase of the menstrual cycle is due to the presence of the corpus luteum has been demonstrated by the observations that removal of the corpus luteum before the expected time of luteal regression resulted in the prompt resumption of preovulatory follicular development and ovulation approximately 14 days later.[167–169] The nature of inhibitory influences imposed by the corpus luteum upon preovulatory follicular development has been the subject of debate. In monkeys, because restoration of preovulatory follicle development after luteectomy was not necessarily followed by a statistical increase in FSH and LH secretion, it was proposed that the corpus luteum directly inhibited follicular development by reducing the ability of follicles to respond to gonadotropins.[167] In humans, however, resumption of follicular development after the removal of the corpus luteum was preceded by a clear elevation of FSH concentrations.[168,169] Although the hypothesis that the corpus luteum directly inhibits follicular growth has not been disproved, the available evidence to date suggests that the corpus luteum indirectly inhibits preovulatory follicular development by way of its secretions of estradiol, progesterone, and possibly inhibin, which suppress FSH secretion (see later). Thus, as mentioned above, preantral follicular development continues throughout the luteal phase, and hence the inhibitory influences imposed by the corpus luteum must be confined to the final stages of preovulatory folliculogenesis. The observations in monkeys that preovulatory follicular development can be readily stimulated during the luteal phase of the menstrual cycle either by direct administration of exogenous gonadotropins or by interfering with the feedback inhibition of estradiol and

progesterone upon gonadotropin secretion is consistent with the hypothesis that the failure of follicles to mature beyond the early antral stages during the luteal phase is due to insufficient gonadotropin concentrations.[170,171] Finally, although systemic administration of progesterone, with its resultant feedback effects on gonadotropin secretion, after luteectomy in monkeys prolonged the interval until the next ovulation, local elevation of intraovarian progesterone concentrations by progesterone-imbedded Silastic wafers, which presumably was insufficient to restrain gonadotropin secretion, was without effect.[172]

Initiation of Preovulatory Follicular Development

Primates are unique with respect to the long duration required for the maturation of the preovulatory follicle when compared with other species, such as sheep and cows. Baird et al.[173] proposed that the lengthy follicular phase of primates is because the primate corpus luteum, unlike that of sheep and cows, produces estradiol that suppresses FSH secretion below the level necessary to advance the development of early antral follicles. Both sheep and cows display waves of follicular development during the luteal phase in which antral follicles develop but do not ovulate, presumably because the secretion of progesterone by the corpus luteum blocks the ability of estradiol that is produced by these follicles to initiate a preovulatory LH surge[173–175] (and Chapter 27). In these species, upon the regression of the corpus luteum and the removal of the feedback inhibition of progesterone on LH secretion, follicles rapidly produce estradiol, which triggers an LH surge and ovulation. By contrast, because of the suppression of FSH secretion during the luteal phase of the primate menstrual cycle, follicular development does not progress beyond the very early antral stages, hence more time is required for follicles to undergo FSH-dependent differentiation. It should be noted however that the notion that primates do not exhibit waves of follicle growth has recently been challenged by serially monitoring human ovaries using high resolution transvaginal ultrasonography throughout the menstrual cycle.[176] These studies revealed the existence of two or three waves of antral follicle growth as reflected by the periodic presence of a follicle (or follicles) with diameters equal to or greater than 5 mm (Figure 28.4). In women with two follicle waves, one wave occurred during the early follicular phase and produced the follicle destined to ovulate, and the second wave occurred during the luteal phase of the cycle, shortly after the mid-cycle gonadotropin surge. Women with three follicle waves exhibited, in addition to the wave of follicle growth during the luteal phase, two waves of follicle growth during the early follicular phase with the second wave producing the follicle destined to ovulate. The overall significance of follicle waves in humans remains uncertain in view of the observations that removal of the corpus luteum in both monkeys and humans is followed by ovulation approximately 14–17 days later,[168,169] while in sheep, ovulation can occur within 3 days of induced luteal regression.[177,178]

Upon the demise of the corpus luteum and the clear elevation in plasma FSH and LH concentrations (Figure 28.1), the maturation of the follicle that is destined to ovulate is initiated. Although the perimenstrual rise in serum FSH concentrations was recognized by Ross et al.[179] in their original descriptions of the hormonal profiles of the human menstrual cycle, the extent to which such a slight (30–50%) rise in FSH concentrations during the early follicular phase participated in follicular development was not fully appreciated until Brown[180] demonstrated that changes in FSH concentrations on the order of 10–30% are sufficient to initiate follicular development in anovulatory women.

During the follicular phase of the menstrual cycle, there are dynamic changes in the patterns of the plasma concentrations of FSH, estradiol, and inhibins A and B (Figure 28.1). The early to mid-follicular phase, before the emergence of a stimulated follicle, is characterized by elevated serum FSH concentrations and inhibin B concentrations. Serum estradiol and inhibin A concentrations are low. Approximately 7 days before the mid-cycle gonadotropin surge, serum concentrations of estradiol and inhibin A begin to increase, while inhibin B and FSH concentrations decline. The rise in serum estradiol and inhibin A concentrations during the mid through late follicular phase is likely due to the emergence of a maturing preovulatory follicle and its associated expression of P450AROM and the β_A subunit of inhibin.[110,154] Serum levels of inhibin B fall slightly, possibly due to the decline in the expression of the β_B subunit that accompanies preovulatory follicle development as well as atresia of small antral follicles.[154] Associated with this gradual increase in estradiol and inhibin A concentrations is a progressive fall in FSH concentrations due to the feedback actions of estradiol and/or inhibin A on gonadotropin secretion (see later). This classical negative feedback relationship between developing follicle and the secretion of FSH by the pituitary gland is the essential component in the process of follicular selection. Because of the steady exit of follicles from the primordial pool, there is always a maturational distinct population of early antral follicles within the ovaries ready for development to the preovulatory stage under the influence of FSH. When a growing follicle acquires sufficient P450AROM activity and/or inhibin biosynthetic capacity as a result of FSH stimulation, FSH levels are suppressed to below those necessary to promote the further development of less mature follicles, which then undergo atresia.

How Does the Maturing Follicle Inhibit the Development of Other Follicles?

As noted before, the classical negative feedback effects of estradiol and/or inhibin provide a mechanistic explanation of how the presence of a maturing follicle could curtail the maturation of other follicles by suppressing FSH secretion. Because both estradiol and inhibin A plus B concentrations are elevated during the follicular phase (Figure 28.1), it has been difficult to determine the relative importance of estradiol and the inhibins in the negative feedback regulation of FSH secretion. The ensuing sections summarize the evidence in favor of either estradiol or inhibin as being the principal ovarian feedback regulator of FSH secretion.

Estradiol

The hypothesis that the maturing follicle inhibits the development of less mature follicles by suppressing FSH secretion by way of its production of estradiol has been tested directly in humans and nonhuman primates by manipulating the pattern of estradiol concentrations during the follicular phase of the menstrual cycle. In rhesus monkeys, subcutaneous insertion of estradiol-containing capsules on days 3–6 of the follicular phase of the menstrual cycle prematurely elevated estradiol concentrations by 50–80 pg/ml and resulted in a slight but significant fall in the plasma concentration of FSH and an interruption of spontaneous follicular development. When the estradiol capsules were removed, FSH concentrations once again became elevated, whereupon follicular development began anew and ovulation occurred 14 days later.[181] Analogous studies in humans demonstrated that oral administration of ethinyl estradiol (the major component of oral contraceptives) during the early follicular phase of the menstrual cycle resulted in a fall in FSH concentrations and a lengthening of the follicular phase, an effect that was negated either by concurrent administration of an anti-estrogen[182] or by the administration of exogenous FSH.[183]

This feedback model for follicle selection would also predict that negating the gonadotropin-suppressing effects of estradiol during the mid through late follicular phases of the menstrual cycle should prevent the fall in FSH concentrations and result in the maturation of more than one preovulatory follicle. Indeed, passive immunization of rhesus monkeys with anti-estradiol antibodies during the mid through late follicular phases of the menstrual cycle prevented the fall in FSH concentrations and caused the maturation of more than one preovulatory follicle.[184] In humans, it is well known that antagonizing the biological actions of estradiol with the anti-estrogen clomiphene or inhibition of P450AROM results in an augmentation of FSH secretion and maturation of more than one preovulatory follicle.[185,186]

Inhibin

Although the aforementioned studies are consistent with the hypothesis that feedback inhibition of FSH secretion by estradiol is a major mechanism by which the maturing follicle suppresses the development of less mature follicle, as can be seen in Figure 28.1, concentrations of inhibin A and B, parallel those of estradiol during the follicular phase. Inhibin B is produced by small antral follicles and has an in vivo biopotency in ovariectomized rats that is approximately 1.45-fold greater than inhibin A, which is produced by the dominant follicle and the corpus luteum.[154,187] Because both inhibins are present in the circulation during the follicular phase, it is possible that inhibin A and/or inhibin B may also be an important regulator of FSH secretion and hence follicle selection. There are two lines of evidence that support a possible role for inhibin in the feedback regulation of FSH secretion during the follicular phase. First, a number of studies have shown that administration of porcine follicular fluid (that was treated with charcoal to remove steroid hormones) during the follicular phase of the menstrual cycle suppresses FSH secretion and interferes with the timely development of a preovulatory follicle.[188,189] However, the limitation of these studies is that it is not known whether resultant inhibin levels achieved by this treatment were within the physiological range. In addition, follicular fluid would also contain follistatin, which could interfere with activin-stimulated FSH secretion by the pituitary.[190] Administration of inhibin A during the follicular phase of the menstrual cycle was shown to suppress FSH secretion in monkeys.[191] However, because the resultant plasma inhibin level was 10 ng/ml, about 100 times greater than the combined concentrations of inhibin A and inhibin B seen during the follicular phase (Figure 28.1), it is likely that these observations reflect a pharmacological action of inhibin. It should also be noted that while inhibin B concentrations fall during the mid to late follicular phase, inhibin A concentrations rise during that interval such that the total inhibin concentrations (inhibin A + inhibin B) do not change dramatically during the mid through late follicular phase when FSH levels are declining (Figure 28.1).

A second line of evidence in support of inhibin as an important regulator of FSH secretion is the observation that FSH levels are elevated during the follicular phases of older women.[192,193] That these women have normal levels of LH and estradiol but reduced levels of inhibin B is suggestive that diminished inhibin B, reflecting the reduction in follicle number that accompanies ageing (Chapter 37), may be causal to the elevated FSH levels observed. However, in older women there is a reduction in the sensitivity to estrogen-negative feedback on FSH secretion, which could also play a role in the elevated FSH levels in these subjects.[194]

In the passive immunization studies with anti-estradiol antibodies described previously,[184] neutralization of circulating estradiol in monkey resulted in an elevation of FSH and maturation of more than one preovulatory follicle, presumably in the presence of elevated inhibin

concentrations that would have resulted from the increased number of maturing follicles.[195] In humans, administration of the anti-estrogen clomiphene resulted in an increase in both estradiol and inhibin B concentrations, but FSH levels were not suppressed.[196] These observations therefore suggest that when the negative feedback effect of estradiol is interrupted, inhibin alone is not able to suppress FSH secretion.

As mentioned above, humans with P450AROM deficiency have elevated levels of FSH in the presence of multicystic ovaries with macroscopically normal large antral follicles, which are the primary source of circulating inhibin A.[127,128] Yet despite the presumption of increased circulating inhibin A concentrations, FSH levels in these subjects were not suppressed. Moreover, when these subjects were treated with exogenous estradiol, serum FSH levels declined and the multicystic ovaries resolved.[128] In addition to knowledge gained from women with P450AROM deficiency, the recent identification of a woman with an inactivating mutation of ERα,[197] which has been shown in genetically modified mice to regulate estrogen-dependent negative feedback of gonadotropin secretion[198] has provided important additional insight into the relative roles of estradiol and inhibin in the control of FSH secretion in humans. This patient exhibited markedly elevated levels of estradiol and inhibin A and pelvic ultrasonographic analysis revealed the presence of enlarged multicystic ovaries, consistent with excessive stimulation of follicular development. Not surprisingly, this patient also had elevated levels of FSH, the presumptive cause of the excessive folliculogenesis, despite elevated levels of estradiol and inhibin A. Thus, in the absence of estrogen-mediated negative feedback, elevated levels of inhibin A were unable to adequately suppress FSH secretion to levels seen during the mid through late follicular phase of the menstrual cycle and therefore limit the number of preovulatory follicles that develop. These compelling observations from this subject indicate that estradiol, rather than inhibin A, is the principal ovarian hormone that is responsible for feedback inhibition of FSH secretion and the resultant control of mono-ovulatory follicular development in humans. However, it is also important to note that serum levels of FSH in this subject were only moderately elevated in comparison to those seen in postmenopausal women that lack both ovarian estradiol and inhibin production.[199] The novel phenotype of this subject could therefore be interpreted to indicate that inhibin may act to set the upper level of FSH secretion while estradiol regulates FSH production to achieve the additional control of serum concentrations of FSH needed to ensure that levels fluctuate within the window necessary for mono-follicular development. It is also possible that other ERs may be involved in the negative feedback control of FSH secretion (see following), which could explain why FSH levels do not rise into the postmenopausal range in this woman with ERα deficiency.

Although we conclude that the extant evidence favors a more important role for estradiol than for inhibin in regulating FSH secretion during the follicular phase of the menstrual cycle, a conclusion that was also reached by mathematical modeling (Chapter 29), in the context of the physiology of the menstrual cycle the important take-home message is that the maturing follicle inhibits the maturation of other follicles by depriving them of adequate FSH support.

How Does the Maturing Follicle Survive Its Self-imposed Suppression of FSH Secretion?

Given that FSH is absolutely required for preovulatory follicle growth and that the maturing follicle inhibits the development of other follicles by suppressing FSH secretion, how is it that the maturing follicle continues to develop in the presence of FSH concentrations that are unable to maintain the development of less mature follicles? The only explanation for this paradox is that as the follicle matures, it becomes less dependent on FSH such that the concentration of FSH necessary to initiate preovulatory follicular development is greater than the concentration of FSH necessary to maintain preovulatory follicular growth. This hypothesis was tested directly by infusion of highly purified human FSH and human LH into cynomolgus monkeys whose endogenous gonadotropin secretion was blocked by a GnRH antagonist.[200] As shown in Figure 28.5, when plasma FSH levels were maintained at approximately 10 mIU/ml, there was no evidence of estradiol secretion. Elevation of plasma FSH concentrations to approximately 20 mIU/ml resulted in the initiation of preovulatory follicular development as reflected by increasing concentrations of estradiol. Once preovulatory follicular growth was stimulated by FSH, reduction of plasma FSH concentrations to 8–10 mIU/ml over a five-day period was associated with a continued rise in estradiol production, and histological examination of the ovary revealed the presence of mature preovulatory follicles. That estradiol secretion continued to rise despite the progressive fall in FSH concentrations demonstrates that the maturing follicle, as a consequence of FSH simulation, exhibits a diminished requirement for FSH such that it continues to mature in the presence of FSH concentrations that are unable to initiate the development of less mature follicles. Similar findings have been observed in humans.[201,202] These data support the hypothesis developed by Brown[180] of a threshold concentration of FSH that must be achieved to initiate preovulatory follicle development. Not surprisingly, this experimentally determined threshold concentration of FSH is very close to the actual concentration of FSH measured during the early follicular phase of the human menstrual cycle when the initiation of preovulatory follicular development occurs.[179] Once this threshold concentration of FSH is reached, follicles readily enter the final stages of preovulatory development.

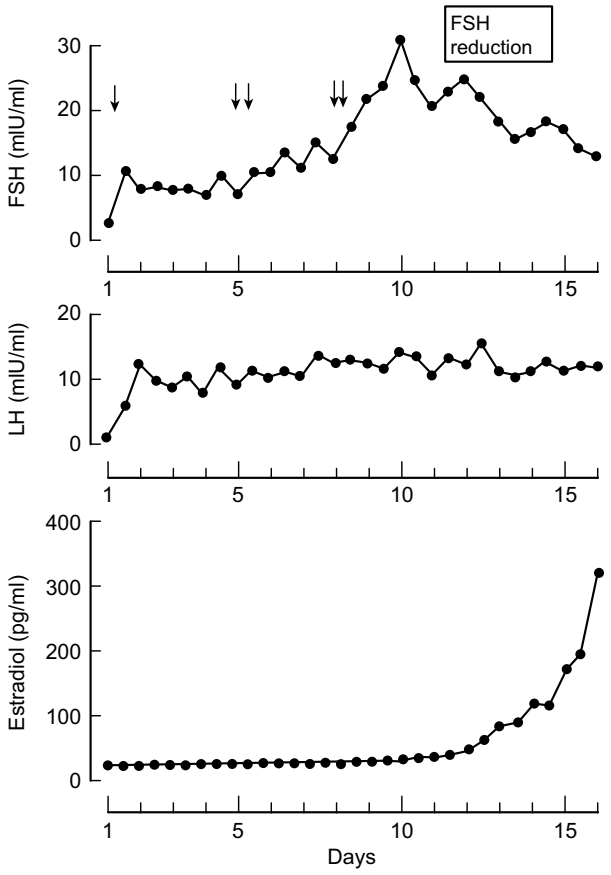

FIGURE 28.5 Ovarian responses in a cynomolgus monkey that received hourly pulses of purified human follicle-stimulating hormone (FSH) and human luteinizing hormone (LH). The concentration of FSH in the infusate was increased every 4–5 days until estrogen secretion became evident; thereafter, the concentration of FSH in the infusate was reduced by 12.5% per day for 5 days. Estrogen secretion, reflecting the presence of a maturing follicle, was stimulated when plasma concentrations reached ~20 mIU/ml. When plasma FSH concentrations were reduced to levels that were unable to initiate estrogen secretion (10–15 mIU/ml), the production of estrogen by the stimulated follicle continued to increase in an exponential manner. *Source: Reproduced from Ref. 200, with permission, Copyright 1986, The Endocrine Society.*

The number of follicles that develop to the preovulatory stage is dependent on the duration that FSH concentrations are maintained above threshold.[200,203] During spontaneous menstrual cycles, the operation of the negative feedback loop between estradiol and FSH secretion provides moment-to-moment communication between the ovary and the hypothalamic-pituitary axis that results in the suppression of FSH secretion and the cessation of secondary follicular development upon the emergence of a maturing follicle.

Although a single follicle is usually selected during the human menstrual cycle, dizygotic twinning (fertilization and implantation of two oocytes) does occur in about 1% of human pregnancies. Although it has been proposed recently that mutations in the FSH receptor that lead to increased sensitivity of the receptor to FSH could be one factor responsible for dizygotic twinning,[204] this hypothesis has been disputed because these amino acid substitutions do not confer enhanced FSH responsiveness as assessed by hormone binding and cAMP production in transfected COS7 cells.[205] There are, however, two interesting "experiments of nature" that point to increased FSH levels being associated with dizygotic twinning. The first example is that the rate of dizygotic twinning increases in women with maternal age, despite the paradoxical fact that the number of ovarian follicles declines significantly with age (Chapter 37). Beemsterboer et al.[206] used ultrasound examinations to assess the incidence of multiple periovulatory follicles (>1 follicle with a diameter of >14 mm) in women and found that basal levels of FSH obtained on the third day of the menstrual cycle were greater in 30–41 year-old women that exhibited multifollicular growth compared with those with monofollicular growth. They proposed that these elevated FSH levels may have resulted in overshooting the threshold, which could result in selection of more than one ovulatory follicle, perhaps by lengthening the time that FSH levels were maintained above threshold values.[200,203] A second example is that of Yoruba women in western Nigeria who have an incidence of dizygotic twinning that is nearly five times the average rate of other women. Serum FSH levels in these women are higher than those of a control group.[207] It has been speculated that increased consumption of local white yams that may contain estrogen-like substances could act in a similar fashion to ovulation-inducing agents (such as clomiphene) and elevate FSH levels and thereby stimulate multifollicular development.

Mechanisms by Which the Maturing Follicle Becomes Less Dependent on FSH

The final solution to the question of follicle selection requires the elucidation of the mechanism(s) by which the maturing follicle escapes its requirement for elevated FSH concentrations. During preovulatory follicular development, there are changes in the cellular functions of the FSH-stimulated follicle that may contribute the selective maturation of a preovulatory follicle. These development-dependent changes may occur at different levels, and the advantages that each may provide to the follicle are not mutually exclusive but rather could likely provide a variety of "fail safe" mechanisms that ensure the maturing follicle is spared from the reduction in FSH concentrations.

LH and FSH Receptors

Increases in the density of cell surface receptors for FSH and LH enhance the sensitivity of target cells to the hormone, as predicted by the law of mass action.

In rats, the density of FSH receptors on granulosa cells increases during preovulatory follicular development.[208] Although comparable studies have not been reported in women or monkeys because of the difficulty in obtaining sufficient amounts of granulosa cells from unstimulated follicles, analysis of the dose–response relationship between FSH concentrations and estradiol production by marmoset granulosa cells revealed that cells collected from preovulatory follicles were nearly four times more sensitive to FSH when compared with granulosa cells harvested from less mature follicles.[209] A four-fold increase in responsiveness to FSH would more than compensate for a 50% decline in plasma FSH concentrations.

In addition to changes in the number of FSH receptors on granulosa cells, a hallmark action of FSH is to induce cell surface receptors for LH.[210] The presence of LH receptors on granulosa cells of developing follicles could also serve to protect the follicle from the fall in plasma FSH concentrations by providing the follicle with the ability to respond to LH. Because preovulatory follicles are responsive to both FSH and LH with respect to increases in cAMP production, whereas early antral follicles are responsive to only FSH[104,115] (and Chapter 20), a reduction in FSH concentrations would reduce the only source of gonadotropic support to early antral follicles. By contrast, the FSH-mediated induction of LH receptors on granulosa cells could protect the mature follicle from reduced FSH concentrations by providing it with the ability to respond to both FSH and LH.

The hypothesis that the selected follicle has reduced dependence on FSH because of its acquisition of LH responsiveness was first tested in humans.[211] In this study, women whose spontaneous gonadotropin secretion was suppressed by a GnRH agonist received recombinant human FSH until at least one follicle attained a size of 14 mm. Thereafter, subjects were then randomized into three groups for a two-day period during which either FSH treatment was continued or FSH treatment was discontinued and replaced with either recombinant LH or saline. Results demonstrated that serum estradiol levels continued to rise in the women that received either FSH or LH, whereas in those receiving saline estradiol levels declined over the two-day treatment interval indicating that LH can replace FSH in the final stages of preovulatory follicle development. Subsequent studies in humans demonstrated that following FSH treatment, LH alone can maintain the maturation of a preovulatory follicle and, moreover, stimulate the formation of a single preovulatory follicle more effectively than either FSH alone or FSH given in combination with LH.[212] Studies in sheep, horses, and cows, as reviewed in Refs 213 and 214, have also indicated that a shift in responsiveness from FSH to LH likely plays a role in continued development of the dominant follicle in the presence of declining FSH concentrations. Thus, the FSH-mediated induction of LH receptors on granulosa cells may be a common mechanism that many mammalian species employ to select the preovulatory follicle.

Angiogenesis

In addition to increases in gonadotropin responsiveness, preferential delivery of gonadotropins to the maturing follicle could protect it from a fall in FSH concentrations. In rhesus monkeys, the density of the capillary network that supplies the preovulatory follicle is at least three times greater than that supplying other less mature follicles, and this increased density of capillaries results in a greater delivery of radioiodinated gonadotropin to the selected follicle.[105] The finding that extracts of follicle cells or conditioned tissue culture media from granulosa cells were able to stimulate the proliferation of endothelial cells in vitro suggested that the maturing follicle may produce diffusible angiogenic factors that cause selective vascularization of the theca layer.[215] A family of heparin-binding endothelial growth factors has been identified. The first members of the family, vascular endothelial growth factor (VEGF) and vascular permeability factor, were isolated, respectively, from bovine pituitary cell–conditioned medium and a guinea pig tumor cell line.[216,217] Human VEGF is a glycoprotein of 165 amino acids, whereas the structure of human vascular permeability factor is nearly identical to that of VEGF except it contains an additional internal amino acid sequence.[217] Additional forms of VEGF have now been identified and appear to be derived from alternate exon splicing.[218] VEGFs are secreted proteins that specifically stimulate endothelial cell proliferation, and receptors for VEGF are ubiquitous on capillary endothelial cells.[219] In situ hybridization studies on ovaries from cynomolgus monkeys have demonstrated that mRNA for VEGF was expressed strongly by the maturing follicle but not by other antral follicles, indicating this protein could be responsible for the selective vascularization that accompanies preovulatory follicular development.[220] Studies by Zimmermann et al.[221] tested the hypothesis that VEGF plays a role in follicular selection by treating rhesus monkeys with an antibody directed against the VEGF receptor and observed that administration of anti-VEGF receptor antibody, but not a control antibody, inhibited preovulatory follicular development despite the presence of elevated FSH concentrations. Similar findings in marmosets indicated that VEGF plays an essential role in preovulatory folliculogenesis.[222]

Neuroendocrine Control of FSH and LH Secretion by the Maturing Follicle

As described above, the suppression of FSH secretion during the second half of the follicular phase of the cycle, most likely mediated by the ovarian production

of estradiol, underlies the mechanism whereby the presence of the maturing follicle inhibits the development of others but does not succumb to its own inhibitory influences. In women, this decline in FSH secretion is monotropic, i.e., it is not accompanied by a reduction in circulating LH levels, whereas in the female monkey there is parallel suppression in the secretion of the two gonadotropins during the late follicular phase.[47,50] Here, we discuss the neuroendocrine bases of the negative feedback action of ovarian estradiol responsible for suppression of FSH secretion during the late follicular phase of both the human and monkey menstrual cycle. Four major aspects will be considered. First, the essential features of the negative feedback loop whereby the primate ovary restrains gonadotropin secretion throughout the greater part of the menstrual cycle will be briefly stated. Second, the relative importance of pituitary versus hypothalamic sites of feedback action by estradiol on gonadotropin secretion will be discussed. Third, the molecular and cellular mechanisms underlying the negative feedback action of estradiol will be examined. Fourth, the cell biology underlying the differential secretion of FSH and LH from the human gonadotrope will be briefly and speculatively examined.

The Classic Negative Feedback Loop between Gonadotropin Secretion and Ovarian Hormones

As described before the ovarian cycle is directed by the gonadotropins, the secretion of which is in turn governed by classic negative and positive feedback loops between the ovary and pituitary (see Chapter 33). During the menstrual cycle, the negative feedback loop restrains the secretion of both FSH and LH throughout most of the follicular and luteal phases. Thus, when this loop is opened either by ovariectomy or following menopause, circulating levels of the gonadotropins increase progressively to plateau at values an order of magnitude higher than those observed during the early follicular phase of the cycle. Reclosing the negative feedback loop in the ovariectomized monkey by replacement with estradiol that produces follicular phase levels of the circulating steroid restores gonadotropin concentrations to the low values typically observed in the early follicular and luteal phases (for full details, see Chapter 45 in the third edition).

Hypothalamic and Pituitary Sites of Negative Feedback Action of Estradiol

Theoretically, the suppression of gonadotropin secretion by estradiol may be achieved by an action of the steroid either directly at the level of the pituitary to inhibit the response of the gonadotropes to GnRH stimulation or indirectly at the level of the hypothalamus to decrease the secretion of GnRH, or by a combination of the two. In women with hypogonadotropism due to a deficiency in GnRH and in monkeys bearing hypothalamic lesions that abolish gonadotropin secretion by preventing GnRH release, menstrual cyclicity may be induced by administration of a constant intermittent infusion of GnRH[223–225] (Figure 28.6). Since the GnRH input to the pituitary gonadotropes is invariant in these experimental models, known as "hypophysiotropic clamps", the negative feedback action of estradiol responsible for the approximately normal levels of gonadotropin in the follicular phase must be exerted directly at the pituitary. Similarly, in hypogonadotropic women, estrogen administration that resulted in follicular phase levels of circulating estradiol suppressed FSH and LH in response to pulsatile GnRH stimulation for 5 days.[226] Again, in these experiments, the negative feedback action of estradiol must be exerted at the pituitary because the GnRH drive to the gland was exogenous and invariant. In a complex human model employing postmenopausal women in whom the pituitary was acutely emancipated from hypothalamic input by administration of a GnRH

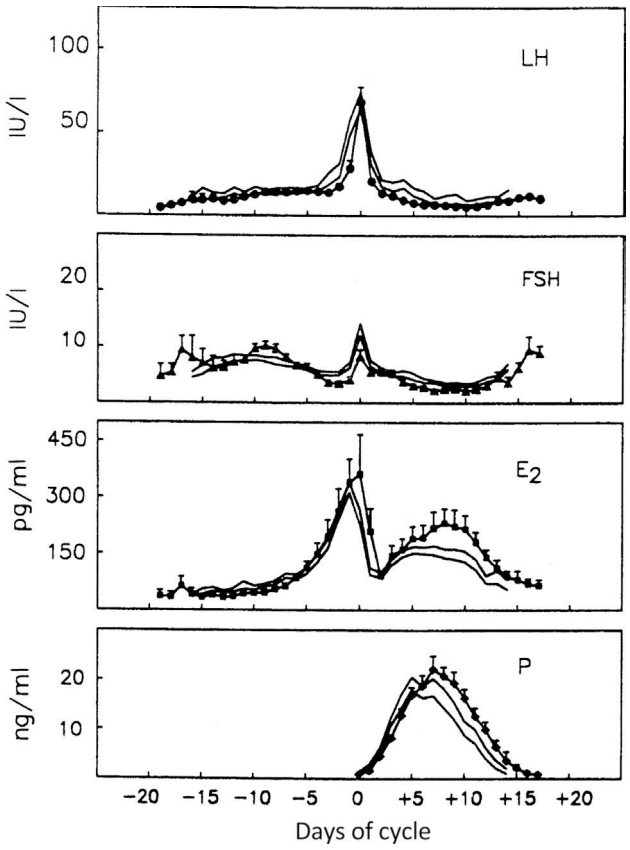

FIGURE 28.6 Induction of ovulatory menstrual cycles in women with primary hypothalamic amenorrhea with an unvarying pulsatile gonadotropin-releasing hormone (GnRH) treatment (5.0 μg GnRH pulse IV every 60 min). Note the close similarities in hormonal profiles of the women with amenorrhea and treated with GnRH and normal controls depicted by the area between the broken lines. antagonist (at a dose that did not block LH responses to large doses of exogenous GnRH), Hall and her colleagues demonstrated that the response of FSH and LH to exogenous GnRH was reduced by chronic exposure to follicular phase levels of estradiol indicating negative feedback directly at the pituitary.[194]

While the foregoing studies provide strong support for negative feedback actions of estradiol at the pituitary, there is also evidence that this steroid can inhibit gonadotropin secretion indirectly by suppressing hypothalamic GnRH release. Microinjections of estradiol into the hypothalamus or third cerebroventricle suppressed LH secretion in ovariectomized rhesus monkeys.[227,228] Peripheral administration of the steroid to ovariectomized or estrogen-replaced ovariectomized monkeys led to a rapid suppression of GnRH release in the region of the pituitary stalk and median eminence,[229] and to a deceleration or interruption in the volleys of MUA in the MBH[230,231]: episodes of hypothalamic electrical activity that are tightly coupled with pulsatile LH release (Figure 28.2) and thereby provide a robust indicator of GnRH pulse generator activity.[54] The physiological significance of the observed estradiol-induced changes in GnRH pulse generator activity in the ovariectomized monkey, however, are unclear. This is because GnRH pulse generator frequency, as reflected by MUA (monkey, Figure 28.7) and episodic LH release (monkey and human) during the last half of the follicular phase of the cycle before initiation of the LH surge is held constant at approximately 1 pulse/h, despite the progressive rise in circulating estradiol at this time.[53,232,233] It therefore seems reasonable to propose that any indirect negative feedback action of estradiol on gonadotropin secretion during the late follicular phase is mediated by a hypothalamic mechanism that results in amplitude modulation of pulsatile GnRH release. This view is supported by the finding that in ovariectomized monkeys estradiol administration leads to a reduction in GnRH pulse amplitude in the absence of a change in pulse frequency[229] and by studies of the ewe (see Chapter 27).

The relative importance of hypothalamic versus pituitary sites of negative feedback action of estradiol that underlie the restraint of gonadotropin secretion during the menstrual cycle, including the suppression of FSH secretion in the latter half of the follicular phase, is unclear. What is clear, however, is that as may be anticipated for a control system governing reproduction, a high degree of redundancy is likely to exist as indicated by the finding that gonadotropin secretion throughout the follicular phase of the menstrual cycle may be controlled by solely ovarian negative feedback directly to the pituitary, as compellingly demonstrated in hypophysiotropically clamped paradigms employing both women and female monkeys as experimental subjects[223–225] (Figure 28.6).

Cellular and Molecular Mechanisms Underlying the Negative Feedback Action of Estradiol

The cellular and molecular mechanisms underlying the direct and indirect negative feedback actions of estradiol at the level of the pituitary and brain, respectively, have not been extensively studied in primates, but as in other species are presumably mediated by activation of ER signaling pathways in either the gonadotrope or in neuronal circuits regulating the secretion of GnRH. As noted above, there are two forms of nuclear ER (ERα and ERβ), (also see Chapters 9 and 25). Targeted independent deletion of these proteins in mice has led to the view that ERα mediates the negative feedback action of estradiol on gonadotropin secretion (see Chapter 26). Recent studies of a woman with a loss

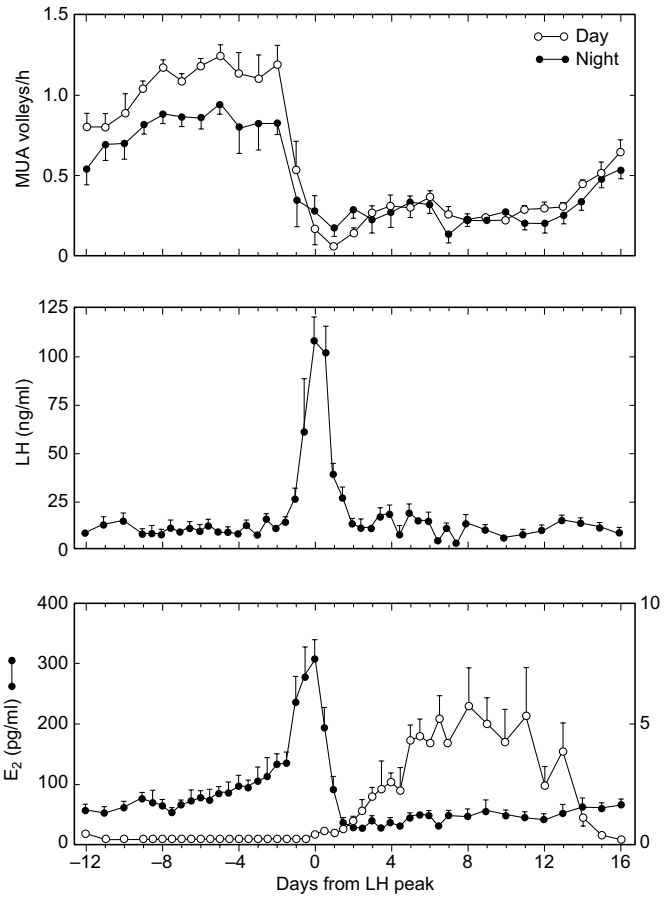

FIGURE 28.7 Frequency of gonadotropin-releasing hormone (GnRH) pulse generator activity (MUA volleys per hour) monitored by radiotelemetry during the menstrual cycle of unrestrained rhesus monkeys, with accompanying time courses of luteinizing hormone (LH), estradiol, and progesterone. Data are normalized to the day of the mid-cycle LH peak (day 0). Each point represents the mean ± standard error of the mean ($N = 5–12$ observations). Note the slower frequency of the GnRH pulse generator at night during the follicular phase, the abrupt reduction in pulse generator activity with the onset of the LH surge, and the slower frequency of the pulse generator during the luteal phase in comparison with its activity during the follicular phase. (MUA, multiunit electrical activity.) *Source: Reproduced with permission from Ref. 53, Copyright 1991, The Endocrine Society.*

of function mutation in ERα (see above) also suggest that this receptor mediates, at least in part, the negative feedback action of estradiol in the human female. Interestingly, studies of transgenic mice indicate that ERα utilizes both the classical genomic and the more rapid membrane initiated pathway (nonclassical) to modulate function of target cells mediating the negative feedback action of estradiol on gonadotropin secretion.[234]

In the context of a direct pituitary site of estradiol negative feedback, the finding in the rat that the predominant ER expressed in the anterior pituitary is ERα[235] is consistent with our understanding of the molecular basis of this action of estradiol. The relative importance of classical genomic versus nonclassical membrane-initiated ER signaling pathways in the pituitary is unclear. In this regard, a second putative membrane ER, GPR30, has been reported in anterior pituitary of rat and cow,[236,237] and further study of membrane-initiated ER signaling in the context of negative feedback action of estradiol is merited. This is because of the rapidity of this action of estradiol, which may lead to an immediate block of the hourly episodes of LH secretion in ovariectomized monkeys following the peripheral administration of the steroid.[238,239]

In the case of hypothalamic sites of estradiol negative feedback it is now generally recognized that ERα is not expressed by GnRH neurons (see Chapter 11), and this has led to the proposal that the action of the steroid in this regard must be exerted on neural and or glial systems, which are afferent to the GnRH neuronal network. While there are several such estrogen-responsive systems that can modulate GnRH secretion (see Chapters 26 and 27), attention is currently focused on the kisspeptin neurons in the arcuate nucleus. Data are at hand to support the view that these neurons represent a major hypothalamic site for the negative feedback action of estradiol on gonadotropin secretion in primates, as in other species (see Chapters 26, 27, and 33). In the hypothalamus of postmenopausal women, Rance and her colleagues in 2007 demonstrated using in situ hybridization that *KISS1*-expressing neurons were hypertrophied,[58] a neuronal phenotype previously shown by this group to express *ERa* (see Ref. 240). Moreover, the use of immunohistochemistry and in situ hybridization has shown that ovariectomy in the rhesus macaque results in an increase in kisspeptin mRNA and peptide content in neurons in the arcuate nucleus, while replacement with estradiol leads to a reduction in *KISS1* expression.[58,59] The estrogen-induced suppression of *KISS1* expression in the MBH of ovariectomized monkeys has been confirmed by RTPCR.[241] The foregoing changes in kisspeptin mRNA and peptide content in neurons of the arcuate nucleus appear to directly reflect their neurosecretory activity as ovariectomy in the pubertal monkey results in an increase in the release of kisspeptin into the region of the median eminence.[62] Studies of transgenic mice have implicated an important role of nonclassical ERα signaling in arcuate kisspeptin neurons in mediating the negative feedback action of the estradiol.[242]

The estrogen-responsive kisspeptin neurons in the arcuate nucleus are likely to be KNDy neurons, which are considered to be a fundamental component of the GnRH pulse generator (see above). In the hypothalamus of the human female, the majority of arcuate kisspeptin neurons also coexpress NKB, and NKB neurons in the arcuate nucleus also exhibit hypertrophy in postmenopausal women.[243] Similarly, the hypertrophic arcuate neurons in postmenopausal women also express the mRNA encoding for prodynorphin.[244] Taking the foregoing considerations together, it seems reasonable to propose that amplitude modulation of the GnRH pulse generator is the major mechanism underlying the negative feedback action of estradiol at the hypothalamic level: the estrogen-dependent change in pulse generator activity being relayed to the GnRH neuronal network by variation in the intermittent delivery of kisspeptin to the median eminence.

Although membrane actions of estradiol on primate GnRH neurons have been described,[245] to date these have been excitatory and are therefore unlikely to play a role in mediating negative feedback action of this steroid at the hypothalamic level.

Differential Negative Feedback of Estradiol on FSH and LH in Late Follicular Phase of the Human Menstrual Cycle

It is generally recognized that LH and FSH are synthesized together in the same gonadotropes, the amount of LH stored in the pituitary is greater than that for FSH, and there is a greater tonic or constitutive (GnRH-independent) secretion of FSH than that for LH[246] (see also Chapter 10). Regardless, to achieve differential release of the gonadotropins, as occurs during the late follicular phase of the human menstrual cycle, it would seem that LH and FSH must be differentially distributed in at least a cohort of granules/vesicles that are destined for exocytosis. Ultrastructure examination of the anterior pituitary of the ewe revealed that the gonadotropin immunopositive granules contained either LH only or LH and FSH in combination, with the LH-only cells predominating.[247]

The frequency of the GnRH pulse generator does not appear to change during the late follicular phase of the human menstrual cycle when circulating FSH levels are declining at a greater rate than those of LH (see above), and therefore the differential secretion of the gonadotropic hormones during this phase of the cycle must be achieved at the level of the anterior pituitary, as a result of either a decline in GnRH pulse amplitude and/or an increase in estradiol concentrations to which the gonadotropes are exposed. Since the relative changes in circulating FSH and LH levels during the latter half of the follicular phase in

women that are hypophysiotropically clamped are essentially identical to those in normal women,[248] it would seem that any role of decreased amplitude of the intermittent GnRH input to the pituitary is dispensable. This view is consistent with other findings from hypophysiotropically clamped women. Marshall et al.[226] found that estradiol administration to hypogonadotropic women, which resulted in follicular phase levels of the circulating steroid, profoundly suppressed the FSH response to invariant pulsatile GnRH stimulation with lesser suppression of LH. Moreover, in postmenopausal women in whom the pituitary was acutely emancipated from hypothalamic input by administration of a GnRH receptor antagonist (see above), chronic exposure to follicular phase levels of estradiol blunted the response of FSH to exogenous GnRH to a greater extent than that of LH.[194]

The question therefore becomes how is the negative feedback action of estradiol on gonadotropin secretion during the late follicular phase of the human menstrual cycle able to produce a suppression of FSH that is greater than that of LH? The most compelling hypothesis at the present time is that estradiol inhibits the activin tone within the pituitary and therefore reduces the paracrine drive for constitutive release of FSH. Activin B is the major activin in the pituitary and synthesis of this paracrine factor occurs in the gonadotropes themselves, which also express the repertoire of membrane receptors necessary for activin signaling (details of which may be found in Chapter 10). Support for the foregoing hypothesis has been provided by Nett and his colleagues, who demonstrated in primary culture of pituitary cells from the ewe that addition of physiological estradiol concentrations (0.01–1.0 nM) produced a dose-dependent suppression of activin β_B mRNA.[249] Interestingly, in the same study, estradiol did not influence the expression of follistatin, another pituitary factor that selectively modulates FSH secretion by its ability to bind to activin and abrogate its action.[250]

The reason for the difference in the extent to which the secretion of FSH and LH is differentially regulated during the late follicular phase of the human and monkey menstrual cycle is unclear, but it is conceivable that the characteristics of the assays used to measure monkey and human gonadotropin levels in blood may contribute to this apparent species difference. Regardless, in both women and the female monkey the decline in FSH secretion produced by the negative feedback action of increasing estradiol production by the follicle destined to ovulate is the critical component underlying the ovulation of a single follicle during the primate menstrual cycle.

Summary of Follicular Development and Clinical Implications

The selection of the preovulatory follicle in primates is best explained by the concept of a critical "threshold" concentration of FSH that must be achieved to stimulate the development of early antral follicles to the preovulatory stage. As depicted in Figure 28.8, during the luteal phase of the menstrual cycle the corpus luteum restrains FSH secretion (by mechanisms to be discussed later). Upon the regression of the corpus luteum, plasma FSH concentrations rise and early antral follicles undergo FSH-dependent growth and differentiation. The number of follicles that develop to the preovulatory stage depends on the duration that FSH concentrations are maintained above threshold values. By way of the FSH-dependent production of estradiol, the leading follicle suppresses FSH secretion below the threshold and further maturation of follicles is prevented, whereas the maturing follicle continues to develop because the FSH-mediated induction of LH receptors on the maturing follicle protects it from its self-imposed reduction of FSH secretion.

The concept that continued maturation of the preovulatory follicle in the face of declining FSH levels is due,

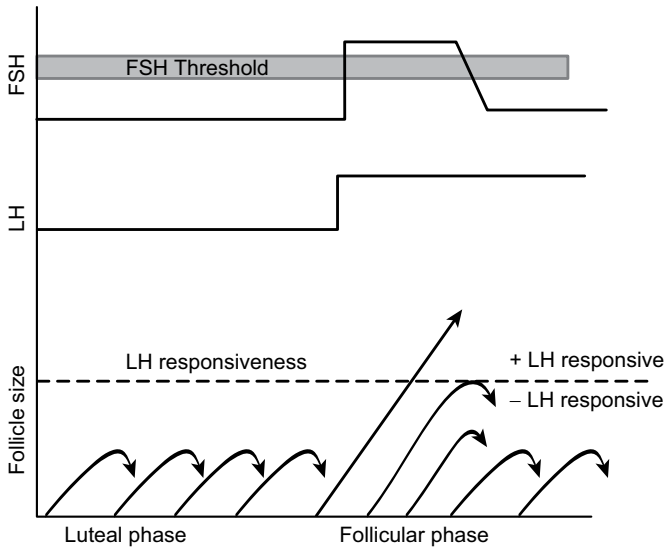

FIGURE 28.8 The follicle-stimulating hormone (FSH) threshold model for the selection of the preovulatory follicle. During the luteal phase of the menstrual cycle, circulating FSH concentrations are held below the FSH threshold by secretions of estrogen, progesterone, and inhibin by the corpus luteum and growing follicles do not advance beyond the preantral stage and undergo atresia. Upon the regression of the corpus luteum at the end of the menstrual cycle, the negative feedback restraint on FSH secretion is released and FSH concentrations rise above threshold levels. One (or occasionally more) of the maturing preantral follicles is stimulated in response to the elevation of FSH and develops both the P450AROM enzyme and luteinizing hormone (LH) receptors. The acquisition of P450AROM produces a rise in systemic levels of estradiol that results in the suppression of FSH secretion, which, in turn, prevents the maturation of less mature follicles. The FSH-stimulated induction of LH receptors and the acquisition of LH responsiveness of granulosa cells of the stimulated follicle permit the FSH-stimulated follicle to mature in the presence of FSH concentrations that are insufficient to stimulate the maturation of other less mature follicles that undergo atresia due to the lack of sufficient FSH stimulation.

at least in part, to its acquisition of LH responsiveness has led to novel paradigms for ovulation induction in humans.[251] Traditional ovulation induction protocols typically involve the administration of recombinant FSH or human menopausal gonadotropins to stimulate follicular growth to the preovulatory stage, whereupon human chorionic gonadotropin is given to induce final oocyte maturation. The inherent problem with this approach is that the prolonged administration of FSH throughout the entire course of treatment would result in the asynchronous recruitment and maturation of follicles (Figure 28.9). The administration of hCG to promote the final maturation of the oocytes may thus result in the recovery of suboptimal oocytes from less mature follicles that may have diminished developmental potential when compared with oocytes from more mature follicles. Further, the continuous administration of FSH may also result in the maturation of smaller follicles, which could lead to the development of ovarian hyperstimulation following the administration of hCG.[251]

However, switching from FSH to LH during the latter period of ovulation induction could result in the maturation of a more synchronous cohort of follicles and thereby produce a greater percentage of mature oocytes as well as reduce the number of smaller, less mature follicles and thereby reduce the incidence of ovarian hyperstimulation (Figure 28.8). Filicori and colleagues were the first to apply this strategy in the clinic.[252] Instead of using LH to support the final maturation of follicles, they administered a low dosage of hCG as a surrogate for LH to sustain the final maturation of FSH-stimulated preovulatory follicles. Their results indicated that switching from FSH to hCG did not reduce the number of large preovulatory follicles but did reduce the number of smaller developing follicles. Further, the fertilization rate of oocytes collected from these follicles was greater than that observed in women who received FSH alone, and pregnancy rates were comparable in both groups of patients. In a larger randomized control trial, Blockeel et al.[253] demonstrated that substitution of FSH by low-dose hCG in the final days of ovarian stimulation produced comparable yields of oocytes and pregnancy rates when compared with subjects that received FSH alone, although they were unable to confirm a reduction in small antral follicles in the hCG-treated group. However, as would be expected, both studies reported a significant reduction (approximate 25%) in the amount of FSH necessary to achieve successful ovarian stimulation, which would result in a substantial reduction in the cost of treatment.

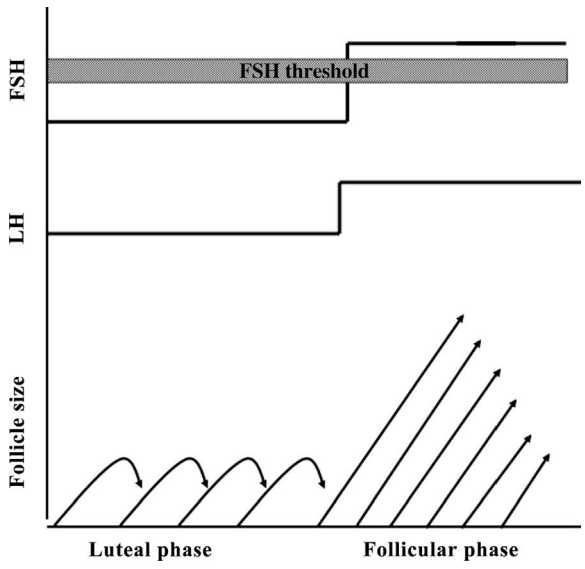

FIGURE 28.9 Conventional controlled ovarian stimulation protocol. Recombinant FSH or human menopausal gonadotropins are administered to elevate blood follicle-stimulating hormone (FSH) concentrations above the threshold level, which results in the stimulation of preovulatory follicular development. Prolonged treatment with FSH may result in asynchronous recruitment and maturation of follicles, which may lead to recovery of suboptimal oocytes from less mature follicles as well as increasing the number of smaller follicles, which could result in ovarian hyperstimulation.

OVULATION

The follicular phase ends with an abrupt rise in blood levels of LH and FSH (Figure 28.1). The role of the midcycle surge of LH in initiating the processes of ovulation and luteinization was first explored in primates by Moudgal et al. who demonstrated that injection of antiserum that neutralized circulating LH on days 10–13 of the menstrual cycle blocked ovulation and the expected rise in progesterone secretion in cynomolgus monkeys.[254] Weick et al.[255] performed daily laparotomies in rhesus monkeys beginning at the peak of estrogen levels and noted that the time of ovulation, as reflected by the presence of an ovulatory stigmata on the surface of the ovary as well as newly formed corpora luteum, occurred approximately 37 h after the estimated time of the LH peak. The ovarian events associated with the control of ovulation and oocyte maturation are described in detail in Chapters 2 and 22 and in a comprehensive review of the molecular control of ovulation and luteinization in primates.[256] The foregoing is a brief summary of the major factors that are thought to play a role in LH-induced ovulation in primates.

Epidermal Growth Factor-like Ligands

As described in detail in Chapter 22 and elsewhere,[257] studies in rodents have shown that the ovulatory surge of LH, acting through its receptors on mural granulosa cells, stimulates the production of the epidermal growth factor (EGF)-like proteins amphiregulin, epiregulin, and betacellulin, and that these ligands mediate the actions

of LH in the process of cumulus-oocyte expansion, resumption of meiosis of the oocyte, prostaglandin synthesis, and expression of proteolytic enzymes involved in follicle rupture. In monkeys and humans, amphiregulin (AREG) appears to be the primary EGF-like ligand stimulated by an ovulatory gonadotropin stimulus and is able to stimulate the cumulus expansion and resumption of oocyte meiosis.[258–260] The extent to which AREG mediates other ovulatory effects of LH remains to be established.

Prostaglandins

A role for prostaglandins in the process of ovulation in primates was identified by Wallach et al.[261] who demonstrated that the prostaglandin synthesis inhibitor indomethacin was capable of blocking gonadotropin-induced (hMG + hCG) ovulation, as assessed by laparotomy, in the rhesus monkey. Similarly, ultrasonic scanning demonstrated that inhibition of prostaglandin synthesis resulted in luteinized unruptured follicles in humans.[262] Studies by Duffy and Stouffer demonstrated that an ovulatory hCG stimulus produced an elevation in cyclooxygenase-2 and prostaglandins E_2 and $F_{2\alpha}$ in the ovulatory follicle.[263] A local role for prostaglandins in the process of ovulation was confirmed by the demonstration that an intrafollicular injection of indomethacin in rhesus monkeys blocked ovulation but did not inhibit the process of luteinization as reflected by a normal pattern of progesterone levels during the posttreatment luteal phase and histological identification of luteinizing granulosa cells. Simultaneous intrafollicular injection of indomethacin plus prostaglandin E_2 restored ovulation.[264] Although the evidence that prostaglandins are required for ovulation in primates is strong, the precise mechanisms by which prostaglandins govern the process of ovulation remain to be identified. Recent studies[265] have identified the distribution of PGE_2 receptor subtypes in the macaque ovulatory follicle and found that the PGE_2 receptor EP1 was stimulated in mural granulosa cells following hCG-induced ovulation, while EP2 and EP3 were present in cumulus cells to a greater extent than mural granulosa cells following hCG, and EP4 levels were uniformly low in all granulosa cell subtypes. These results are consistent with the notion that the EP1 receptor regulates follicle rupture by way of its stimulation of proteolytic enzymes, while the EP2 and 3 receptor subtypes are involved in cumulus cell expansion.

Progesterone

Early studies in rodents demonstrated that inhibition of steroid biosynthesis blocked ovulation and that supplementation with progesterone restored the ovulatory response.[266] Moreover, as discussed in detail in Chapter 22, genetically modified mice that lack the progesterone receptor (PR) fail to ovulate.[267] A role for progesterone in the process of ovulation in primates was identified by the observation that systemic treatment of rhesus monkeys with the steroid biosynthesis inhibitor trilostane blocked gonadotropin-stimulated ovulation and oocyte maturation and that this inhibition was reversed by coadministration of the progestin agonist R5020.[268] The mechanisms by which progesterone participates in ovulation may involve, at least in part, the stimulation of a variety of proteolytic enzymes involved in ovulation (see below).

Proteolytic Enzymes

The classic studies of Rondell[269] demonstrated in rabbits that, contrary to expectations, ovulation was not an explosive event due to increased intrafollicular hydrostatic pressure but rather to a weakening of the follicle wall as a result of proteolytic degradation of the extracellular matrix. He further demonstrated that the production of progesterone was essential for the increased distensibility (weakening) of the follicle wall and proposed that, in response to the LH surge, progesterone activates an enzymatic cascade that leads to weakening and rupture of the follicle wall. A number of proteolytic enzymes, including matrix metalloproteinases (MMPs) disintegrin and metalloproteinases with thrombospondin-like repeats (ADAMTSs) and plasminogen activators (PAs), involved in tissue remodeling are induced by the ovulatory stimulus in monkeys and ovulation can be blocked by the intrafollicular injection of a metalloproteinase inhibitor.[270,271] As noted before, one role of progesterone in the ovulatory process appears to be related to the regulation of these proteolytic enzymes as inhibition of steroidogenesis blocks ovulation and the expression of ovulation-associated proteolytic enzymes.[270]

Neuroendocrine Control of the Mid-cycle Gonadotropin Surge

The preovulatory gonadotropin surge is initiated by the positive feedback action of the rising levels of circulating estradiol that are produced as a result of increased secretion of the steroid by the follicle that is destined to ovulate. For estradiol to exert a positive feedback action on pituitary gonadotropin secretion it must be maintained above a threshold serum concentration for a duration of several hours. In the monkey, Knobil and his colleagues systematically varied these two parameters of the circulating estradiol signal by the administration of square wave increments of exogenous steroid during the early follicular phase: a premature LH surge was only elicited when an estradiol threshold of 200–400 pg/ml was maintained for a minimum of 36 h.[45]

This relationship was termed the strength-duration characteristic of the positive feedback action of estradiol.

Small quantities of progesterone are secreted prior to ovulation by the ovary in both women and female monkeys,[255,272,273] and this preovulatory release of the steroid has been implicated in the genesis of the LH surge. However, the findings in both species that LH surges may be prematurely elicited in the early follicular phase[45,46,274,275] and triggered in ovariectomized monkeys by administration of estradiol alone[50] has led to the view that progesterone's role is limited to amplifying the magnitude of the gonadotropin surge that is initiated by the positive feedback action of estradiol. This action of progesterone and other stimulatory effects of the steroid on gonadotropin secretion were discussed in full in the previous edition of this book.

As in the case of the negative feedback action of estradiol on pituitary gonadotropin secretion, the site of the positive feedback of the steroid may also be exerted directly at the pituitary, or indirectly at the level of the hypothalamus, to increase GnRH stimulation of the gonadotropes or at both these sites. The finding with hypophysiotropically clamped models employing GnRH-deficient women and hypothalamic-lesioned female monkeys that the preovulatory gonadotropin surge and ovulation were restored when the pituitary was stimulated by invariant GnRH administration (Figure 28.6) provides convincing evidence that positive feedback of estradiol solely at the pituitary is sufficient to elicit a functional LH surge.[223–225,233] The results obtained from the human models are particular compelling for two reasons. First, the pulse doses of GnRH selected to drive the pituitary–ovarian axis were in many cases chosen because they induced episodes of LH secretion that mimicked those observed spontaneously in normal women. Second, subjects with Kallman syndrome, when employed, guaranteed that the hypothalamic GnRH deficiency was absolute as migration of GnRH during embryonic development in these patients is arrested in the forebrain.[276] During normal embryonic development in primates and other species, GnRH neurons migrate from the olfactory placode through the forebrain to the hypothalamus and in the adult brain are found in relatively large numbers in both the rostral hypothalamus and more caudal regions including the MBH (see Chapter 11).

During spontaneous menstrual cycles in the monkey, however, a positive feedback action of estradiol is also evident at the hypothalamus, as demonstrated by the finding of Spies and his colleagues that the preovulatory LH surge in this primate is associated with a corresponding and unequivocal discharge of GnRH, as measured in perfusates of the median eminence collected during the LH surge.[277] The heightened release of GnRH at the time of the mid-cycle LH surge in the monkey does not appear to be triggered by an action of estradiol on the GnRH pulse generator, since hypothalamic MUA appears to be arrested during the spontaneous preovulatory LH surge in this species[53] (Figure 28.7). Thus, it becomes necessary to posit a GnRH surge generator in the monkey hypothalamus, as is the case for nonprimate species (see Chapters 26 and 27). In contrast to the rodent, however, the LH surge in the monkey is not tightly coupled to the circadian system, as indicated by the finding that the timing of the LH surge may be advanced by up to 12 h when the strength of the estradiol positive feedback signal is increased to a supraphysiological level.[45]

Whether a GnRH surge generator is resident in the human hypothalamus is unclear. In contrast to the monkey, GnRH pulse generator activity, as reflected by pulsatile patterns of circulating LH, continues unabated during the spontaneous preovulatory gonadotropin surge in women.[278] In postmenopausal women, metabolic activity in the MBH and pituitary as determined by monitoring [^{18}F]2-fluoro-2-deoxy-D-glucose uptake using positron emission tomography was increased only in the pituitary during an estradiol-induced LH surge.[279] Moreover, Hall and her colleagues have argued that the amount of GnRH secreted at this stage of the human menstrual cycle is actually decreased[280]: a view based on the finding that the amount of GnRH receptor antagonist required to effect a particular level of LH and FSH suppression during the mid-cycle surge is less than that needed to effect the same level of suppression during the follicular phase. This observation also indicates that the pituitary gonadotrope becomes more sensitive to GnRH during the LH surge, as would be predicted by the pituitary being a primary site of action for the positive feedback of estradiol (see above). The spontaneous initiation of the preovulatory LH discharge in the human female generally occurs in the morning[281–283] in association with high cortisol levels.[283] This temporal relationship, however, appears to be independent of an endogenous circadian rhythm, as recently demonstrated by the finding that amplitude and frequency of pulsatile LH secretion do not vary over a 24 h period in premenopausal women studied under a rigidly controlled environment of constant lighting, activity, posture, wakefulness, and nutritional intake.[284]

While the GnRH surge generator in the rodent is located in the preoptic area (POA) of the rostral hypothalamus (see Chapter 26), the situation in the monkey is less clear. A series of studies by Knobil's group in the 1970s led to the proposal that the neuroendocrine mechanisms governing the LH surge in the monkey were resident entirely within the MBH. Application to the monkey of the Halasz knife (a bayonet-shaped knife that may be lowered to the base of the brain using stereotaxic and imaging techniques) to surgically isolate the MBH from the rest of the brain, including more anterior aspects of the hypothalamus such as the POA, and placement of large lesions in the POA that destroyed the suprachiasmatic nucleus neither abolished ovulatory menstrual cycles nor blocked estradiol-induced LH surges.[55,285]

In addition, estradiol-induced LH surges in ovariectomized monkeys were observed in an acute decerebrate preparation, in which all hypothalamic tissue dorsal to the optic chiasm had been removed by aspiration.[286] These findings[a] indicate that in the monkey the hypothalamic GnRH surge generator (like the pulse generator) is localized in the MBH.

The classic view of the neuroendocrine mechanism underlying the preovulatory LH surge in the monkey, which is based largely on studies by Knobil's laboratory more than 30 years ago, merits reexamination in light of the recognition of the critical importance of kisspeptin neurons in regulating GnRH release. This is for two reasons: first, in the rodent, the positive feedback action of estradiol, that together with a circadian signal from the suprachiasmatic nucleus trigger the preovulatory GnRH surge in these species, is mediated, at least in part, by activation of kisspeptin neurons of the AVPV in the POA (see Chapters 26 and 27); and second, although neuroanatomical studies of the primate hypothalamus are limited, in both female monkeys and women *KISS1* and kisspeptin neurons are also located in the POA[58,77,288] in areas that are likely to be analogous to the AVPV of rodents. Moreover, high levels of *KISS1* expression in the POA of the female monkey have been reported using quantitative real-time-PCR (qRT-PCR).[289] The regulation of *KISS1* expression by estradiol in the primate POA, however, has only been scantly studied. In contrast to rodents, *KISS1* mRNA levels in the POA of the monkey as determined by qRT-PCR did not decrease following ovariectomy.[289] However, an increase in *KISS1* mRNA/neuron was observed by in situ hybridization in the POA of female monkeys during the late follicular phase in association with elevated blood estradiol levels, and interestingly this was accompanied by a similar, albeit less marked, change in *KISS1* expression in the caudal third of the arcuate nucleus.[288] This finding led Smith et al. to propose that in the monkey both populations of kisspeptin neurons may be involved in mediating the positive feedback action of estradiol on gonadotropin secretion.[288] Such a conclusion may be reconciled with that of Knobil by proposing that the kisspeptin neurons in the POA of the monkey hypothalamus are not essential for the positive feedback action of estradiol and that the MBH-pituitary unit is sufficient for the generation of functional preovulatory LH surges (Figure 28.10). Moreover, if the proposal of Smith et al. is substantiated, it would seem reasonable to further propose that the arcuate nucleus of the monkey must contain two distinct populations of kisspeptin neurons: one involved in GnRH pulse generation and in mediating the negative feedback action of estradiol, and the other in transducing the positive feedback action of the steroid. Presumably, the activity of the first population as reflected by MUA activity will be inhibited during the positive feedback action of estradiol,[53] while that of the second population will be increased by an estradiol signal that exceeds the strength-duration characteristic necessary for induction of the LH surge. An alternative possibility is that the same neurons respond differentially to low (negative feedback) and high (positive feedback) levels of circulating estradiol.

Neural systems other than those comprised of kisspeptin neurons in the POA and arcuate nucleus have also been implicated in the modulation of the LH surge

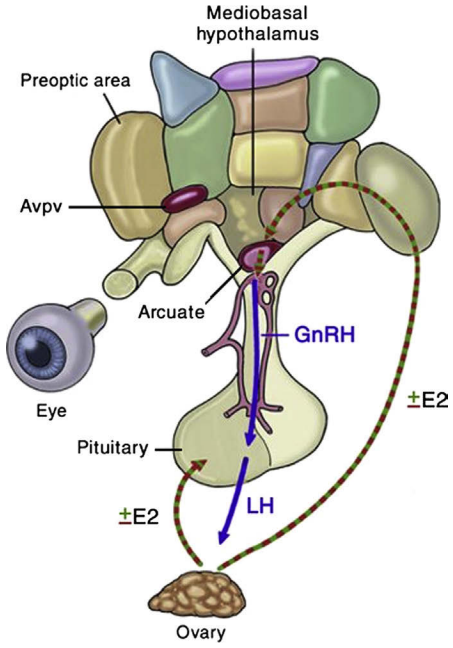

FIGURE 28.10 A model of the neuroendocrine mechanisms underlying the positive and negative feedback actions of ovarian estradiol (E2) on luteinizing hormone (LH) secretion during the menstrual cycle. In this model, the hypothalamic gonadotropin-releasing hormone (GnRH) pulse generator is located in the arcuate nucleus, which contains one of the two major hypothalamic populations of kisspeptin neurons (the second population of kisspeptin neurons is found in the anteroventroperiventricular nucleus (AVPV) in the preoptic area). The negative feedback action of E2 that regulates tonic LH secretion during the follicular phase and luteal phase (in combination with progesterone) is exerted on the GnRH pulse generator to primarily suppress GnRH pulse amplitude and on the pituitary to inhibit responsiveness to pulsatile GnRH stimulation. In the monkey, the positive feedback action of E2, which triggers the preovulatory LH surge, is also exerted within the medial basal hypothalamus (MBH) and at the pituitary. In the human female, the significance of the MBH in mediating the positive feedback action of estradiol is less clear: in both species positive and negative feedback actions of E2 solely at the pituitary level are sufficient for menstrual cyclicity and ovulation.

[a] In a contemporaneous study by Spies and his colleagues, anterior hypothalamic lesions were reported to block spontaneous and estrogen-induced gonadotropin surges, and this group concluded that the POA was necessary for induction of the preovulatory LH surge in the monkey.[287]

in primates. These have included the brainstem norepinephrine neurons,[290] which, as may be expected from their location, appear to play a nonessential role[50] (also see Chapter 33), and the MBH and pituitary tachykinin, substance P.[291,292] However, since 2003 the neuroendocrine community studying the hypothalamic control of the LH surge has become kisspeptinocentric as a result of the signal discovery in that year that loss of function mutations in *KISS1R* in man were associated with hypogonadotropic hypogonadism and delayed or absent puberty,[42,43] and few attempts have been made to incorporate other neurotransmitters/neuropeptides into contemporary models for generation of the LH surge.

While the precise neurophysiologic mechanisms underlying the spontaneous generation of the LH surge late in the follicular phase in primates remain to be fully delineated, the extant data permit several inferences/conclusions to be drawn. First, as may be anticipated from a process as important as ovulation, major redundancy is found in the control system that generates the preovulatory LH surge, the proximate trigger for ovulatory process. In this regard, the minimal hypothalamic input that is required for the surge to be generated is the pulsatile secretion of GnRH that permits, in turn, the positive feedback action of estradiol to be expressed at the pituitary. Under physiological conditions, however, an additional hypothalamic mode of GnRH release, not reflected by MUA, is engaged, at least in the monkey. Second, the control of the preovulatory LH surge in primates, and therefore ovulation in these species, has become relatively emancipated from regulation by the POA of the hypothalamus, which in the rodent dictates that ovulation is rigidly coupled to the light–dark cycle. A full discussion of differences in the neural control of the preovulatory LH surge in rodents and primates falls beyond the scope of this chapter, but this subject has been recently reviewed by one of us.[293]

CORPUS LUTEUM FORMATION AND FUNCTION

After years of investigation of the function and regulation of the corpus luteum, George W. Corner commented, "These yellow bodies of the ovary have been puzzling to scientists ever since they were first described by de Graaf."[3] In retrospect, this statement is particularly accurate regarding the quest for the understanding of the physiological regulation of this gland in mammals because the mechanisms that individual species have evolved to control the function of the corpus luteum exhibit marked variations[294] (and see Chapter 23). It appears, at least on the surface, that higher primates have developed a simpler solution to the regulation of the corpus luteum than most other species. As in other mammals, the primate corpus luteum plays a pivotal role in the control of reproduction and, in doing so, its functions must be regulated accordingly. In nonfertile menstrual cycles, the corpus luteum has a finite 14- to 16-day life span after which its secretions of steroid and protein hormones cease and the tissue is eventually removed from the ovary. The regression of the corpus luteum in the absence of conception is obligatory for the initiation of a new menstrual cycle because its secretions of estradiol, progesterone, and possibly inhibin A exert negative feedback effects at the hypothalamic-pituitary axis that prevents the rises in FSH and LH secretion that are essential for the development of a new preovulatory follicle.[170,173] On the other hand, during menstrual cycles in which conception occurs and implantation ensues, the prolongation of luteal function beyond its usual life span is obligatory for the maintenance of pregnancy until the placenta assumes the primary responsibility for the production of steroid hormones.[295,296] An explanation of luteal function must therefore account for the mechanisms by which the functions of the corpus luteum are governed to accommodate its dual responsibilities.

Development of the Corpus Luteum

Preovulatory Determinants of Luteal Function

The corpus luteum is formed upon the culmination of preovulatory follicular development and the rupture of the mature Graafian follicle. As shown in Figure 28.1, the mid-cycle gonadotropin surge marks the transition point at which the secretion of follicular estradiol is replaced as the major ovarian steroid by the production of progesterone by the corpus luteum. Although the corpus luteum is not formed until after ovulation, developmental events that transpire during the follicular phase under the control of FSH are essential for the appropriate functioning of the corpus luteum. Granulosa cells isolated from immature follicles are steroidogenically quiescent and require stimulation by FSH in vitro before the secretion of estradiol and progesterone becomes evident. By contrast, granulosa cells collected from preovulatory follicles of humans and subhuman primates are capable of producing both estradiol and progesterone immediately after isolation.[104,297] This FSH-dependent differentiation of the granulosa cell is responsible not only for the production of estradiol by the maturing follicle but also for the preparation of the granulosa–lutein cells to rapidly initiate progesterone secretion after ovulation. As noted above, studies in subprimate species have shown that FSH stimulation of granulosa cells during preovulatory follicular development is associated with increases in the cellular content of mRNAs and/or enzyme activities of P450scc, 3β-hydroxysteroid

dehydrogenase, Δ^{5-4} isomerase (3β-HSD), P450AROM, and the LH receptor, all of which are required for the secretion of steroid hormones by the corpus luteum. The importance of FSH on luteal function by way of its effects on the differentiation of the follicular granulosa cell was shown by in vivo studies in subhuman primates that demonstrated a disturbance in the normal pattern of FSH secretion during the follicular phase, resulting in abnormal luteal phases characterized by reduced progesterone production.[298,299]

Luteinization

Although the granulosa cells of preovulatory follicles manifest LH-responsive estradiol and progesterone secretion that is characteristic of luteal cells, the transformation of the granulosa cell into a luteal cell by the mid-cycle LH surge is associated with a further accretion of the steroidogenic capacity of the cell and a further increase in the steady state levels of mRNAs for enzymes involved in progesterone production. This increased steroidogenic capacity occurs in parallel with changes in the morphology of the granulosa–lutein cells. In the rhesus monkey, granulosa cells from preovulatory follicles have a diameter of approximately 10 μm, contain sparse amounts of endoplasmic reticulum, and possess mitochondria with lamelliform cristae. By contrast, luteal cells of newly formed corpora lutea measure approximately 25 μm in diameter and possess abundant smooth and rough endoplasmic reticulum and mitochondria with tubular cristae.[300] The structural remodeling of granulosa cells during luteinization is dependent on high levels of LH because granulosa cells collected from rhesus monkey follicles before the LH surge fail to produce substantial amounts of progesterone in vitro and fail to exhibit morphological signs of luteinization.[301] In addition to alterations in cellular morphology, the process of luteinization is associated with terminal cellular differentiation. Studies in rats have convincingly demonstrated that corpora lutea do not incorporate [^{3}H] thymidine into nuclei, a measure of DNA synthesis, whereas such incorporation is readily apparent in follicular granulosa cells.[302]

Although comparable in vivo labeling studies have not been performed in primates, analysis of rhesus monkey ovaries has indicated that the expression of markers of proliferation such as Ki67 and proliferating cell nuclear antigen are absent in the parenchymal cells of the corpus luteum.[303,304] The molecular mechanisms by which cellular proliferation is curtailed in the corpus luteum is not completely understood, although it is now known that luteinization is associated with the reduced expression of cellular proteins thought to be involved in the regulation of cell cycle dynamics[305] (and Chapter 23). The luteinizing stimulus generated by the LH surge thus results in a coordinated series of responses of granulosa cells that include intracellular remodeling, enhanced gene expression, and modulation of the cell cycle. Although the precise cellular mechanisms by which LH initiates the coordinated processes of luteinization is not known, it is likely that the large increase in cAMP or other intracellular signaling molecules triggered by the ovulatory LH surge either activates or represses signaling pathways that control cellular differentiation and proliferation[306] (and Chapter 20). The morphological events associated with luteinization are not completed until 5–6 days after ovulation; thereafter, the luteal cells exhibit all the cellular characteristics associated with steroid-producing cells.[307]

Angiogenesis

The granulosa cell layer of preovulatory follicles is not vascularized; the capillary network that supplies the follicle abruptly terminates at the basement membrane that separates the granulosa cells from the theca cells. As described by Corner,[3] after ovulation, as the luteinizing granulosa layer grows thicker, blood vessels creep in from the theca layer and form a network that supplies every one of the large luteal cells. Within a few days after ovulation, the corpus luteum becomes highly vascularized such that on a tissue weight basis, blood flow to this gland is among the greatest of any tissue in the body.[308] This increased vascularity, in addition to providing a conduit for the delivery of luteal steroids to the general circulation, is also necessary for the provision of cholesterol substrate in the form of low-density lipoproteins (LDLs) for progesterone biosynthesis.[309]

The incisive experiments of Gospodarowicz and Thakral[310] demonstrated that the newly ovulated follicle produces diffusible angiogenic substances that direct capillary proliferation into the luteinizing tissue. As described above, mRNA for the angiogenic factor VEGF is expressed intensely by the maturing follicle, and this intense expression continues after ovulation such that the newly formed corpus luteum also expresses mRNA for VEGF[154] (and Chapter 23). The expression of mRNA for VEGF in the corpus luteum, as revealed by northern analysis, correlates with luteal function in that it is extinguished during spontaneous luteal regression and declines prematurely after suppression of LH secretion by a GnRH antagonist, and stimulation of luteal function by administration of CG extends the expression of mRNA for VEGF beyond the expected time of luteal regression.[220] The localization of mRNA for VEGF to structures within the primate ovary in which angiogenesis plays an important role in development is consistent with the hypothesis that the VEGF family of angiogenic factors may be instrumental in the formation of capillaries that accompanies both the development of the preovulatory follicle and the neovascularization that

is essential for the functioning of the corpus luteum. Indeed, studies in nonhuman primates have shown that administration of VEGF antagonists at the time of ovulation or during the luteal phase of the menstrual cycle attenuates progesterone production by the corpus luteum.[311,312] Additional discussion of the complex process of angiogenesis that occurs during luteinization and its maintenance throughout the lifespan of the corpus luteum is presented in Chapter 23.

Endocrine Secretions of the Corpus Luteum

Steroid Hormones

The description of the corpus luteum as an endocrine gland is based on its capacity to secrete progesterone and estradiol.[3,313] The production of progesterone and estradiol by the primate corpus luteum likely is regulated by separate steroidogenic pathways. As described above, the secretion of estradiol by the developing follicle requires the participation of both the theca cells for the production of androgen substrates and the granulosa cells for the aromatization of androgens to estradiol. Although the basement membrane that separates theca cells from granulosa cells is dissolved after ovulation, the primate corpus luteum retains some of the structural organization that was present in the preovulatory follicle. Using specific antibodies to steroidogenic enzymes, it has been shown that P450c17, a theca cell marker, is confined to the outer borders of the corpus luteum, whereas P450AROM, a granulosa cell marker, is present within the central area of the corpus luteum.[111] Assuming that the "two-cell" model for estradiol secretion by the maturing follicle can be extended to the corpus luteum, the production of estradiol therefore would require the coordinated activity of both theca lutein and granulosa–lutein cells.

Progesterone production by the corpus luteum is dependent on cholesterol as a substrate. Although luteal cells can manufacture cholesterol de novo from acetate, as mentioned above, the corpus luteum relies extensively on serum LDL-associated cholesterol for use as a precursor for the synthesis of progesterone.[314,315] The dependence of normal luteal secretion of progesterone on LDL cholesterol is reinforced by the finding that progesterone concentrations during the luteal phase of the menstrual cycle in a woman with hypobetalipoproteinemia, a genetic disorder characterized by low plasma concentrations of LDL, were nearly ten-fold lower than those of normal subjects.[316] The control of luteal steroidogenesis is described in greater detail in Chapters 8 and 23.

Protein Hormones

In addition to steroid hormones, the primate corpus luteum also synthesizes and releases a variety of protein hormones, including relaxin,[317–319] oxytocin[320–322] and inhibin.[323–325] Enucleation of the corpus luteum of cynomolgus monkeys resulted in a rapid decline in serum inhibin concentrations, indicating that most inhibin in blood is of luteal cell origin.[326] The secretion of inhibin throughout the luteal phase appears to reflect a unique function of the primate corpus luteum because neither inhibin A nor inhibin B appears to be produced to any great extent by corpora lutea of rodents and domestic animals.[327–330]

Control of Luteal Function and Life Span

Luteotropic Hormones

LUTEINIZING HORMONE

As discussed in the section on follicular maturation, the early to mid-1900s was a period in which the nature and biological actions of the pituitary gonadotropins were revealed. The parallel studies on the identification and purification of prolactin and the demonstration that this hormone had stimulatory effects on the corpus luteum of rodents[331,332] confounded the identification of the anterior hypophysial hormone responsible for the regulation of the primate corpus luteum. Hisaw,[333] in his pioneering studies on the regulation of the rhesus corpus luteum, proposed that prolactin was the primary luteotropin responsible for the maintenance of the corpus luteum of the menstrual cycle, whereas CG was required to extend the functional life span of the corpus luteum of pregnancy. Although it was well established by the early 1960s that LH-stimulated progesterone production by human corpora lutea in vitro,[334,335] not until the early 1970s was it shown that LH acutely increased progesterone production by the corpus luteum in vivo.[336,337]

The requirement for LH in the control of progesterone secretion and the functional life span of the corpus luteum has been the subject of numerous debates. Gemzell[29] noted that induction of ovulation by hCG in hypophysectomized women who had been treated with FSH to induce follicular growth was followed by luteal phases of normal duration, suggesting that once formed, the human corpus luteum functioned independently of additional pituitary gonadotropin support. Subsequent studies by Vande Wiele et al.[30] demonstrated that the long half-life of hCG used to induce ovulation provided extended gonadotropic support to the corpus luteum; when LH was used to induce ovulation, the corpus luteum regressed after 5–6 days unless additional LH was given throughout the luteal phase. An obligatory requirement for LH in the maintenance of the corpus luteum was indicated when Moudgal et al.[254] passively immunized rhesus monkeys with antibodies against LH and found that immunized animals exhibited premature luteal regression, an observation later confirmed by others.[338]

The role of LH in the maintenance of the primate corpus luteum was subsequently questioned by the

observations that neither hypophysectomy nor treatment with a GnRH antagonist to suppress LH secretion truncated the luteal phase of macaques.[339,340] However, studies in rhesus monkeys in which pituitary gonadotropin secretion was controlled directly by pulsatile infusion of synthetic GnRH provided compelling evidence that pituitary secretion of gonadotropins absolutely is required for luteal function.[341] As first described by Knobil and colleagues[56] and shown in Figure 28.11 (top), rhesus monkeys rendered anovulatory by the placement of lesions in the MBH in which menstrual cycles are restored by hourly intravenous pulses of GnRH have luteal phases of normal 14- to 16-day duration. As shown in Figure 28.11 (bottom), when gonadotropin secretion was interrupted in this experimental model by terminating the GnRH infusions, a rapid and precipitous fall in serum progesterone concentrations occurred and premature menstruation ensued in all animals. The initial report[340] that GnRH antagonists fail to shorten the life span of the corpus luteum appears to be dose related because others have shown in both macaques and humans that GnRH antagonists rapidly suppress luteal progesterone secretion and concomitantly evoke premature menses.[342,343]

In addition to the secretion of progesterone, LH also is required for the production of estradiol and inhibin by the corpus luteum as plasma concentrations of both hormones decline after treatment with GnRH antagonists.[342] Further, plasma concentrations of estradiol, inhibin, and relaxin are elevated during early pregnancy and in nonpregnant subjects in response to the administration of exogenous CG, suggesting that synthesis of these hormones is also gonadotropin regulated.[344–349]

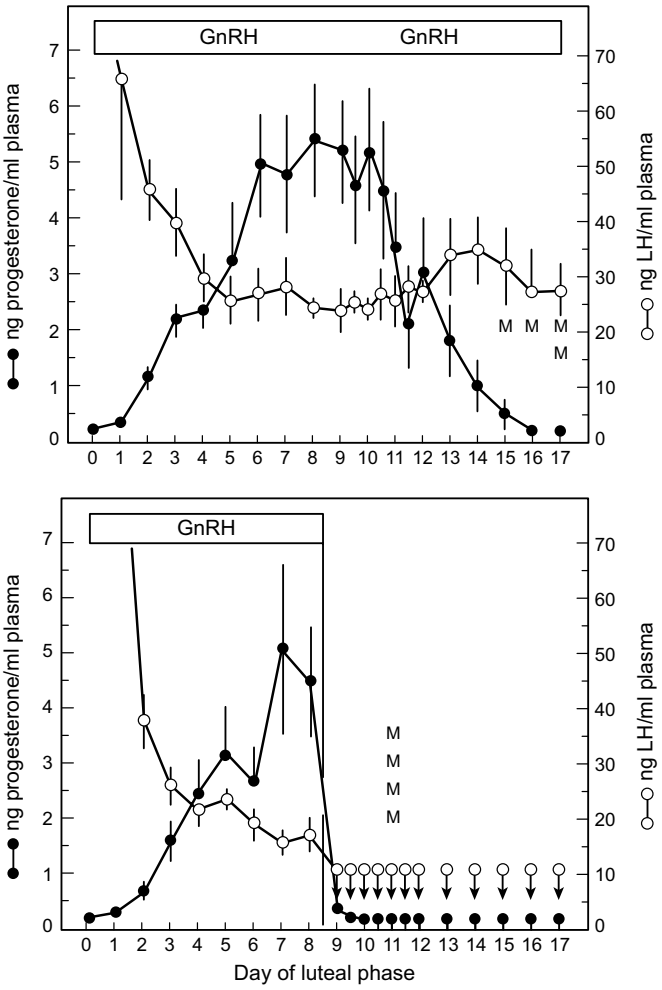

FIGURE 28.11 Serum luteinizing hormone (LH) and progesterone concentrations in medial basal hypothalamus (MBH)-lesioned rhesus monkeys whose menstrual cycles were restored by a pulsatile infusion of synthetic gonadotropin-releasing hormone (GnRH). The top panel illustrates serum LH and progesterone concentrations of animals that received GnRH at a frequency of 1 pulse/h throughout the menstrual cycle. Note that these animals have luteal phases of normal duration. The bottom panel illustrates data from animals in which the infusions of GnRH were terminated on day 8 of the luteal phase. Serum LH and progesterone concentrations fell rapidly upon the cessation of GnRH treatment and premature menses were observed in all animals. *Source: Reproduced with permission from Ref. 341, Copyright 1984, The Endocrine Society.*

FOLLICLE-STIMULATING HORMONE

Both FSH and LH secretion are reduced by GnRH antagonists, and the withdrawal of GnRH support to MBH-lesioned animals curtails both FSH and LH secretion.[350,351] Thus, experiments using these approaches to suppress LH secretion do not rule out the possibility that FSH may also participate in the regulation of the primate corpus luteum. FSH receptors have been identified in human corpora lutea,[352] but FSH does not stimulate adenylate cyclase activity in membranes prepared from macaque corpora lutea[353] and does not stimulate progesterone secretion in either human or macaque corpora lutea in vitro.[354,355] Although FSH has been shown to cause a slight (25%) increase in estradiol production by luteal cells isolated from human corpora lutea, this effect was observed in response to pharmacological concentrations of FSH,[356] and the possibility that the stimulatory effects of supraphysiological concentrations of FSH on luteal cell steroidogenesis are not a consequence of slight LH contamination of the FSH preparation cannot be ruled out. Further, the observations that exogenous hCG or LH alone is able to maintain luteal function in hypophysectomized women indicate that FSH does not play an obligatory role in the regulation of the primate corpus luteum in vivo.[29,30]

PROLACTIN

Prolactin is a principal luteotropin in rats and mice.[357] Whether this hormone exerts luteotropic effects on the primate corpus luteum is less clear, although it is known that the monkey corpus luteum expresses mRNA for the prolactin receptor.[358] Despite Hisaw's failure to extend the functional life span of the rhesus monkey corpus luteum with prolactin, he nonetheless concluded that

prolactin was the principal pituitary hormone responsible for the maintenance of lutea function until CG production by the implanting trophoblast commences.[333] Using the argument developed above against FSH as a luteotropin, the fact that normal luteal phases can be established in hypophysectomized women after FSH and hCG treatment argues against an obligatory requirement for prolactin in the maintenance of luteal function in primates.[29,30] Moreover, suppression of prolactin secretion during the luteal phase with a dopamine agonist does not interrupt normal luteal function in monkeys and humans.[359,360]

Although prolactin may not be an essential luteotropin in primates, elevated levels of prolactin may sustain luteal function beyond its typical life span of 14–16 days. Some rhesus monkeys rendered anovulatory by the placement of lesions in the MBH have elevated serum prolactin concentrations, presumably due to the destruction of the dopaminergic pathways that inhibit prolactin secretion. Although these hyperprolactinemic animals undergo ovulatory menstrual cycles in response to administration of exogenous GnRH, in some animals progesterone concentrations failed to decline to undetectable levels at the end of the luteal phase but rather were maintained at approximately 1 ng/ml for extended periods beyond the expected time of luteal regression.[361] That this extension of luteal function was due to prolactin was indicated by the findings that treatment of these hyperprolactinemic monkeys with the dopamine agonist bromocriptine resulted in a suppression in circulating prolactin concentrations and a prompt fall in serum progesterone levels. Similarly, lactation, which is associated with elevated prolactin concentrations, is known to stimulate progesterone secretion.[362] Treatment of suckling monkeys with bromocriptine suppressed prolactin secretion and reduced progesterone to undetectable levels.[361] Although the aforementioned results indicate that prolactin most likely does have stimulatory effects on the primate corpus luteum, it is unlikely that the corpus luteum is responsive to prolactin concentrations typically observed during the menstrual cycle, and that the responses of the corpus luteum during suckling and experimentally induced hyperprolactinemia reflects a response of the tissue to elevated concentrations of this hormone.

Autocrine and Paracrine Regulation of Luteal Function

STEROID HORMONES

The macaque and human corpus luteum contains PR, AR, and ERβ.[363–365] In vivo studies in monkeys have shown that blocking the production of progesterone with a 3β-HSD inhibitor shortens the luteal phase, suggesting that intraovarian progesterone may have an essential role in corpus luteum function.[366] Bishop et al.[367] used a microarray approach to identify mRNA transcripts that are regulated by LH and/or progesterone in the macaque corpus luteum. Results of this global analysis revealed that the greatest number of altered transcripts was observed when LH secretion was interrupted using a GnRH antagonist, while a smaller number of transcripts differed when progesterone biosynthesis was blocked with a 3β-HSD inhibitor. Of the approximate 1500 transcripts decreased by LH withdrawal, approximately 33% of these transcripts were also decreased by inhibition of steroid biosynthesis when LH levels were maintained by treatment of animals with exogenous LH. These findings indicate that whereas LH controls the vast majority of luteal transcripts, some of these LH-dependent genes are regulated indirectly by steroids produced by the corpus luteum. Exactly how LH and progesterone (or other steroids) interact to maintain luteal function remains to be established.

As described below, it has been proposed that estradiol may directly act at the level of the corpus luteum to promote luteal regression. There have been no systematic studies undertaken to identify a role of androgens on corpus luteum function, other than to serve as a substrate for estradiol biosynthesis by the corpus luteum.

PROTEINS

As noted above, although a number of proteins, including inhibin, activin, and IGFI, have been shown to influence steroid production by theca and granulosa cells of humans and subhuman primates, little information is available regarding the actions of these putative autocrine and paracrine agents on the primate corpus luteum. Studies have shown that activin reduced progesterone production by cultured macaque luteal cells, whereas inhibin had no effects.[368] In vivo, peripheral infusion of activin A suppressed progesterone production and shortened the luteal phase of rhesus monkeys.[369] However, in these studies, the infusion of activin also suppressed LH secretion. When activin was infused directly into the corpus luteum, neither progesterone production nor the length of the luteal phase was affected, indicating that the luteolytic effects of activin were most likely caused by a suppression of LH secretion rather than by a direct effect of activin on the corpus luteum.

Cellular Regulation of Luteal Function

The corpus luteum of nonfertile menstrual cycles has a finite 14- to 16-day life span during which time its functional presence is manifested by the secretion of progesterone and estradiol. Although serum progesterone concentrations are typically used to assess the functional status of the corpus luteum, studies in MBH-lesioned rhesus monkeys whose menstrual cycles are driven by pulsatile infusion of exogenous GnRH have shown that

the gonadotropic regulation of progesterone secretion can be dissociated from the control of luteal life span.[370] As shown in Figure 28.12, the termination of GnRH infusions in MBH-lesioned animals resulted in a rapid fall in serum progesterone concentrations, demonstrating that pituitary gonadotropin secretion is required for progesterone production by the corpus luteum. However, when LH secretion was restored 3 days later in these animals, serum progesterone secretion resumed and persisted for a time that effectively completed the duration of a typical luteal phase. Although the withdrawal of LH for a three-day period resulted in a suppression of progesterone secretion and premature menses, it did not compromise the functional life span of the corpus luteum. This suggests that although LH may be required for the acute stimulation of progesterone production, it may not be required for the long-term maintenance of the functional capacity of the corpus luteum. A complete investigation of the regulation of the primate corpus luteum must therefore address both the acute regulation of progesterone production and the long-term control of its steroidogenic capacity.

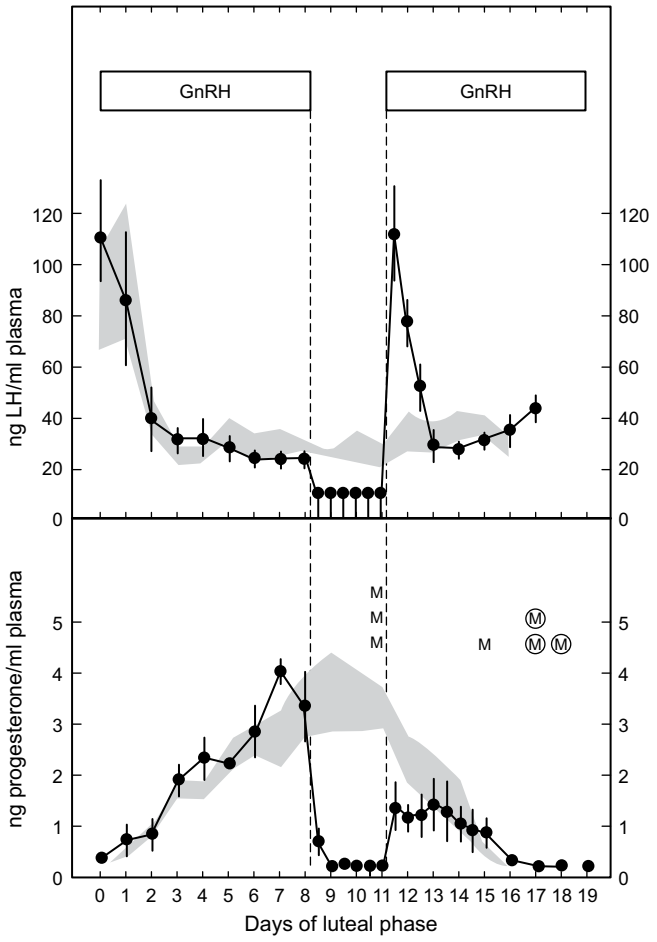

FIGURE 28.12 The primate corpus luteum is capable of recovering from a transient withdrawal of pituitary gonadotropin support. Medial basal hypothalamus (MBH)-lesioned rhesus monkeys whose menstrual cycles were driven by exogenous gonadotropin-releasing hormone (GnRH) were deprived of the GnRH infusion from days 8–11 of the luteal phase of the menstrual cycle. During the interval of deprivation of gonadotropins, serum progesterone concentrations fell to nondetectable levels and premature menstruations occurred. However, when luteinizing hormone (LH) secretion was restored by reinstating the GnRH infusions, progesterone production recommenced, and the corpus luteum regressed at its normal time, 16 days after ovulation. The shaded areas show data from animals in which GnRH was provided at a frequency of 1 pulse/h throughout the luteal phase. *Source: Reproduced with permission from Ref. 370, Copyright 1985, The Endocrine Society.*

Acute Actions of Gonadotropins

Studies in both macaques and humans have revealed a close temporal relationship between secretory pulses of LH by the pituitary gland and episodes of progesterone and estradiol production by the corpus luteum.[371,372] Elevations in plasma progesterone concentrations occur within minutes after individual pulses of LH. Because of the very rapid increases in steroid secretion in response to individual LH discharges, it is likely that the acute effects of LH on progesterone production by the corpus luteum reflect the channeling of cholesterol substrate through extant biosynthetic pathways rather than increases in the intracellular concentrations of enzymes responsible for progesterone synthesis. Addition of cAMP to dissociated luteal cells results in rapid increases in progesterone production,[373] indicating that the acute stimulatory effects of LH on luteal steroidogenesis are mediated by cAMP. The precise intracellular mechanisms responsible for the acute mobilization of cholesterol are unknown but likely include the intracellular transport of cholesterol and its access to P450scc at the inner mitochondrial membrane mediated by the steroidogenic acute regulatory protein, StAR[374] (and Chapter 8).

Long-term Actions of Gonadotropins

Although it is well established that LH is obligatory for the acute production of progesterone by the corpus luteum, the extent to which LH is involved in the longer-term regulation of the steroidogenic capacity of the corpus luteum has not been explored in great detail. The cloning of the genes for the enzymes involved in estradiol and progesterone biosynthesis has provided powerful tools for the investigation of luteal function at the cellular level.[375–378] Figure 28.13 illustrates serum progesterone concentrations and the cellular expression of mRNAs for P450scc and 3β-HSD in corpora lutea at defined stages of the luteal phase of cynomolgus monkeys.[379] Surprisingly, the highest concentrations of both mRNAs are seen shortly after ovulation. mRNA for P450scc remained relatively constant throughout the luteal phase until regression, whereas mRNA for 3β-HSD declined throughout the entire luteal phase. Similar findings were observed with human corpora lutea

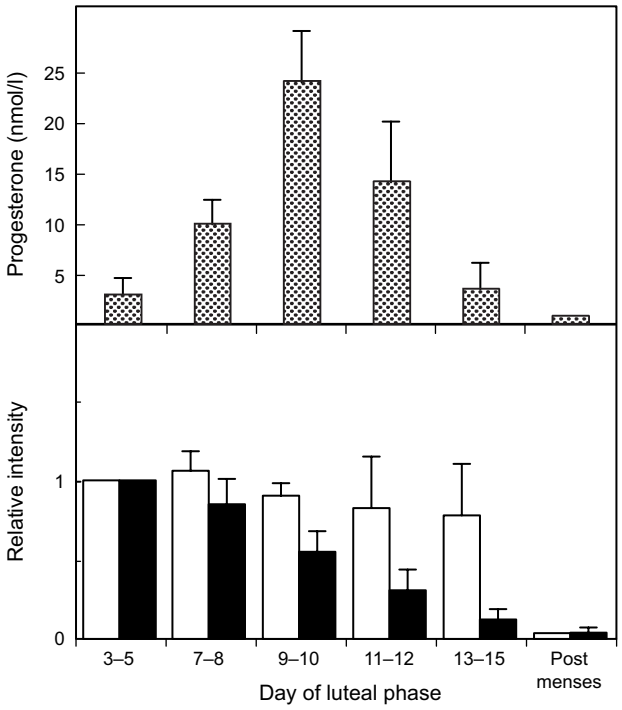

FIGURE 28.13 Expression of mRNAs for P 450scc and 3β-HSD throughout the luteal phase of cynomolgus monkeys. Corpora lutea were collected at defined stages of the luteal phase, as defined on the *x* axis. The top panel illustrates serum progesterone concentrations of the animals immediately before removal of the corpora lutea. The bottom panel illustrates levels of mRNAs for P450scc (open bars) and 3β-HSD (solid bars). *Source: Reproduced with permission from Ref. 379, Copyright 1991, The Endocrine Society.*

in that mRNAs for P450scc, 3β-HSD, and StAR were at their highest levels during the early luteal phase.[380,381] The progressive fall in these mRNAs throughout the luteal phase parallels the steroidogenic capacity of isolated luteal cells because it has been shown that luteal cells collected from newly formed human corpora lutea have greater basal and gonadotropin-stimulated progesterone production than cells obtained during the mid-luteal phase, when serum progesterone concentrations are maximal.[354,355] The discrepancy between progesterone biosynthetic capacity in vitro and the in vivo secretion of progesterone by the newly formed corpus luteum likely reflects the fact that the newly formed corpus luteum has yet to establish an extensive microvascular network, and therefore the delivery of precursor via LDL cholesterol to luteal cells is limited.[309]

The progressive decline in mRNAs for enzymes involved in steroid secretion and steroidogenic capacity of isolated luteal cells in vitro throughout the luteal phase suggests that the absolute steroidogenic capacity of the corpus luteum is set by the mid-cycle gonadotropin surge and declines thereafter independently of the overall pattern of gonadotropin secretion. A similar observation was reached in the investigation in the rat corpus luteum, which demonstrated that after luteinization, the expression of mRNA for P450scc does not require continued gonadotropin support.[382,383] However, the notion that LH does not directly participate in the long-term regulation of mRNAs for steroidogenic enzymes in the primate corpus luteum was dispelled when it was shown in cynomolgus monkeys that suppressing LH secretion during the luteal phase with a potent GnRH antagonist resulted in a decline in mRNA concentrations for P450scc and 3β-HSD to undetectable levels over a three-day period.[384] As noted above, global analysis gene expression profiles in the monkey corpus luteum following curtailment of LH secretion with a GnRH antagonist revealed that approximately 1500 transcripts were decreased following withdrawal of LH support.[367] Thus, LH, in addition to its obligatory role in the acute stimulation of progesterone production, is also required for the long-term maintenance of the functioning of the primate corpus luteum.

Regression of the Primate Corpus Luteum

Alteration of the Pattern of LH Secretion

Given that LH is required for both the acute and long-term regulation of luteal function, it would not be illogical to surmise that changes in LH secretion during the luteal phase could be responsible for the initiation of luteal regression. The most striking change in LH secretion during the luteal phase of both human and subhuman primates is the progesterone-mediated reduction of the frequency of LH pulses from approximately 1 pulse/h during the early to mid-luteal phases to 1 pulse/4–8 h from the mid through late luteal phases.[371,372] However, as originally documented by Knobil and colleagues[56] and later by others as shown in Figure 28.11, maintenance of menstrual cycles in anovulatory rhesus monkeys and humans by unvarying GnRH pulse frequencies typical of the follicular and early luteal phases does not prolong the life span of the primate corpus luteum.[385–387] Moreover, as shown in Figure 28.14, when an LH pulse frequency of one pulse per eight hours, which is typical of the mid through late luteal phases of the menstrual cycle when luteal regression occurs, is provided shortly after ovulation, serum progesterone concentrations increased progressively and normal 14- to 16-day luteal phases were observed in three of four animals studied.[387]

Further evidence that luteal regression is not caused directly by a reduction of gonadotropic support to the corpus luteum has been obtained from MBH-lesioned monkeys in which plasma concentrations of LH were reduced during the luteal phase by limiting the amount of GnRH delivered per pulse.[360] Reductions in plasma LH concentrations during the early luteal phase of the menstrual cycle by 50–75% did not cause immediate luteal regression. Rather,

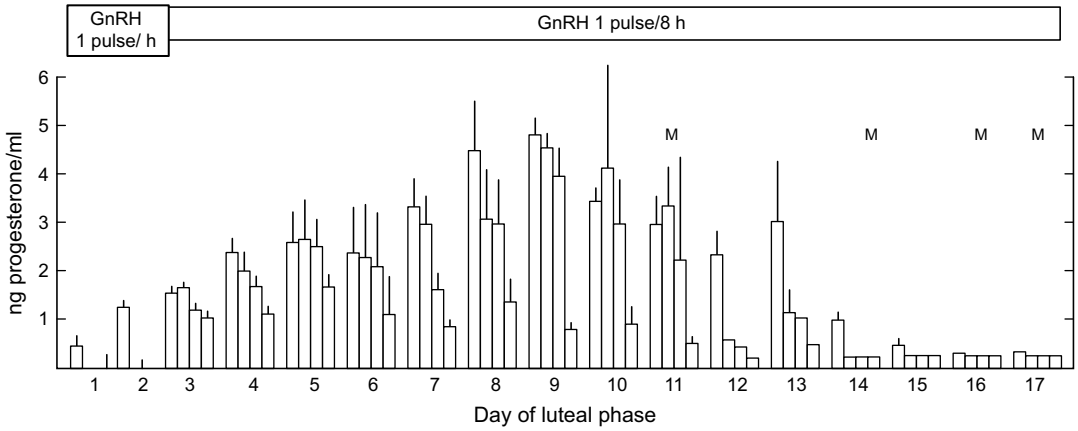

FIGURE 28.14 Response of the macaque corpus luteum to a decrease in the frequency of luteinizing hormone (LH) pulses. Medial basal hypothalamus (MBH)-lesioned rhesus monkeys received exogenous gonadotropin-releasing hormone (GnRH) at a frequency of 1 pulse/h to restore follicular development and ovulation. Shortly after ovulation, on days 2–3 of the luteal phase, the frequency of GnRH pulses was changed to one pulse every eight hours, which is typical of the mid through late luteal phase. The individual bars over each day, beginning on day 3, reflect plasma progesterone concentrations obtained 30, 60, 120, and 240 min after a GnRH pulse. Despite the reduced LH pulse frequency, normal luteal function was observed in three of four animals. *Source: Reproduced with permission from Ref. 387, Copyright 1986, The Endocrine Society.*

progesterone secretion was maintained for 6–7 days after the reductions in plasma LH concentrations. These findings suggest that during the early through mid-luteal phases of the menstrual cycle there is a surfeit of LH, whereas during the mid through late luteal phases of the menstrual cycle, an age-dependent alteration of the responsiveness of the corpus luteum to LH occurs such that a more intense gonadotropic stimulus is required to sustain luteal function. Extension of this hypothesis would predict that luteal regression at the termination of nonfertile menstrual cycles is not due to a reduction in LH secretion per se but rather to the failure of the corpus luteum to respond to ambient concentrations of LH, a conclusion that completely supports Hisaw's speculation, made 70 years ago, that "menstruation is not due necessarily to a lack or absence of pituitary gonadotropin but rather to a failure of the corpus luteum."[333]

Estradiol as a Luteolysin

Hoffman[388] noted that in humans direct injection of estradiol into the ovary containing the corpus luteum resulted in premature menstruation, whereas injection of estradiol either into the contralateral ovary or systemically did not shorten the menstrual cycle, an observation that has been confirmed by others in both humans and macaques.[389,390] These observations led to the suggestion of a "self-destruct" mechanism by which internally produced estradiol leads to the regression of the corpus luteum,[391] a hypothesis supported by the findings that concentrations of estradiol and estrone in macaque corpora lutea increase during the late luteal phase as progesterone concentrations decline.[392] The luteolytic effect of estradiol was proposed to occur directly at the level of the corpus luteum because in many instances, premature regression of the corpus luteum did not appear to be accompanied by a reduction in plasma LH concentrations.[389,393] The self-destruct hypothesis was supported further by the observation that the addition of estradiol to isolated macaque luteal cells inhibited both basal and gonadotropin-stimulated progesterone production.[394,395]

This attractive hypothesis, which would account for the observations that luteal regression does not appear to be due to a reduction in LH secretion, was questioned by subsequent observations in which sensitive bioassays were used to measure serum LH concentrations during estradiol-induced luteolysis. These studies revealed that estradiol-induced luteal regression was preceded by slight, but significant, declines in plasma LH concentrations during exposure to exogenous estradiol.[396] The physiological relevance of estradiol-induced luteal regression was also questioned by studies in MBH-lesioned monkeys, which demonstrated that exogenously administered estradiol, at dosages shown to be luteolytic in intact animals, failed to provoke premature luteal regression in monkeys in which hypophysial drive (LH support) was driven by pulsatile infusion of GnRH.[397] Unless there are totally different mechanisms responsible for luteolysis between GnRH driven and spontaneously cycling animals, a possibility that is unlikely because of the remarkable similarities of their luteal phases, it would appear that because of its failure to induce luteal regression in GnRH driven animals, estradiol is not a physiologically important luteolysin during the spontaneous luteal phase. This conclusion is supported by the findings that neither the administration of P450AROM inhibitors nor estradiol antagonists to spontaneously cycling nonhuman primates prolongs the duration of the luteal phase.[398–400]

Prostaglandins

In many subprimate species, luteal regression is caused by the production of prostaglandins by the nongravid uterus. This is clearly not the case in primates, including humans, because hysterectomy does not result in prolonged luteal phases.[401–403] However, numerous studies have shown that prostaglandins can affect luteal function. In vitro, prostaglandins E_2, I_2, and D_2 generally stimulate luteal function,[404–409] whereas prostaglandins of the F series inhibit luteal functions.[355,410–412] In vivo, infusions of prostaglandin $F_{2\alpha}$ directly into the corpus luteum have been shown to cause luteal regression.[413–416] These findings, together with the observations that luteal cells produce prostaglandins in vitro,[417–421] have led to the supposition that locally produced prostaglandins may exert direct luteolytic effects on the primate corpus luteum.

Although it is unequivocal that exogenously administered prostaglandins can induce premature luteal regression, it is uncertain whether the luteolytic effects of prostaglandins reflect physiological or pharmacological actions. Injections of indomethacin into rhesus monkeys at dosages that prevented the initiation of labor failed to prolong the life span of the corpus luteum.[422] In addition, it has been shown that direct infusion of the prostaglandin synthesis inhibitor meclofenamate into the rhesus monkey corpus luteum actually caused premature luteal regression, suggesting that prostaglandin synthesis may be required for normal luteal function as opposed to luteal regression.[423] In this regard, it has been demonstrated that direct infusion of prostaglandin E_2 into the corpus luteum inhibits prostaglandin $F_{2\alpha}$–induced luteal regression in monkeys.[424] However, infusion of prostaglandin E_2 alone during the time of luteal regression did not extend the life span of the corpus luteum, thus questioning the role of endogenous prostaglandin $F_{2\alpha}$ in the regression of the primate corpus luteum. As noted in Chapter 23, until specific antagonists of prostaglandin $F_{2\alpha}$ become available, a definitive role for this prostaglandin in the process of luteolysis in primates remains uncertain.

Cellular Correlates of Luteal Regression

Production of both estradiol and progesterone by isolated luteal cells under basal conditions and in response to tropic stimulation declines as the luteal phase progresses.[354,355] The decline in steroidogenic capacity in aging corpora lutea is accompanied by a reduction in the number of LH receptors on luteal cells, a decline in LH-sensitive adenyl cyclase activity, and a decline in LH-stimulated PKA activity.[425–428] However, it remains uncertain as to whether these changes in the transmembrane signaling system for LH are causes or consequences of luteal regression because reductions in serum progesterone concentrations may precede the decreases in LH receptors and postreceptor LH signaling. In addition to changes in LH responsiveness, luteal cells collected from corpora lutea during the late luteal phase also exhibit reduced progesterone production in response to cAMP as well as in response to the addition of pregnenolone, the immediate precursor to progesterone.[355] These data therefore suggest that the alterations in cellular function that accompany luteolysis are global in nature such that many aspects of luteal cell function are compromised. This is further supported by the results of microarray studies that the levels of hundreds of mRNAs decline during spontaneous and induced luteolysis.[367]

The histological studies of Corner describe the morphological correlates of luteal regression in macaque and human corpora lutea.[429] During the mid-luteal phase, approximately 9 days after ovulation when serum progesterone concentrations are at their zenith, the corpus luteum begins to exhibit signs of degeneration, including shrinkage of luteal cells and vacuolization of the cytoplasm. By day 11 of the luteal phase, 4–5 days before the expected time of menstruation, cell shrinkage becomes more pronounced and nuclear chromatin condensation and pyknosis are apparent. As mentioned above, the process of luteinization of granulosa cells in vivo is not completed until 5–6 days after ovulation.[307] On the basis of the morphological characteristics of luteal cells throughout the luteal phase, it would thus appear that luteolysis on a cellular level is a progressive phenomenon that may begin shortly after the process of luteinization is completed.

Stouffer and colleagues[430,431] (and Chapter 23) used flow cytometry to analyze the functional characteristics of luteal cells from rhesus monkey corpora lutea based on their sizes. At least two populations of luteal cells were distinguished, small luteal cells (15 μm diameter) and large luteal cells (>25 μm diameter). During the early luteal phase small luteal cells outnumbered large luteal cells by a ratio of 4:1, and although both small and large cells were responsive to hCG and cAMP, the absolute steroidogenic capacity of large cells exceeded that of small cells by 10- to 20-fold. As the luteal phase progressed, both the number of small and large cells declined, but the rate of decline of large cells exceeded that of small cells such that by the end of the luteal phase, the ratio of small to large cells was approximately 15:1.[431] In addition, from the mid-luteal phase onward, small cells were unresponsive to hCG and cAMP, whereas large cells retained responsiveness to both cAMP and hCG.[431] These observations indicate a gradual shift in population of steroidogenic cells as the corpus luteum ages. If the "small" luteal cells isolated by flow cytometry correspond to the shrunken granulosa–lutein cells described by Corners, it would then appear that luteal regression may be the result of a stochastic process in which individual luteal cells undergo a transformation from being gonadotropin responsive and steroidogenically competent to

gonadotropin-unresponsive cells and that at any given point in the luteal phase the functional status of the corpus luteum is determined by the relative proportions of each cell type. A progressive increase in the percentage of gonadotropin-unresponsive cells during the mid through late luteal phases of the menstrual cycle could provide a mechanism by which the corpus luteum regresses without a change in gonadotropin secretion. In this regard, the morphological changes in luteal cells that occur during the mid through late luteal phases are typical of apoptotic cell death[432] (and Chapter 23), and analyses of the human corpus luteum have revealed a progressive increase in the number of apoptotic cells during the mid through late luteal phases of the menstrual cycle.[433] The determination of whether apoptosis is the cause or the result of a loss of responsiveness to gonadotropins is not known. Neither is it known whether the diminution of gonadotropin responsiveness is due solely to a consequence of luteal cell aging, or whether it is due to the actions of other factors (such as $PGF_{2\alpha}$) that impinge on the luteal cell; this remains one of the major unanswered questions regarding luteal regression.

In summary, the formation of the corpus luteum represents the culmination of the ovarian events of the long process of gametogenesis and the beginning of the period in which the implanted embryo must be nourished and sheltered. The numerous cell divisions that granulosa cells undergo during preantral follicular development and their final differentiation into LH-responsive steroid-producing cells during the follicular phase of the menstrual cycle are not dissimilar to the morphogenesis of the elegant yellow monarch butterfly. The emergence of the corpus luteum from its follicular cocoon after ovulation begins the final episode of the ovarian cycle. Like a butterfly, the corpus luteum must fulfill a purpose that is essential for the preservation of the species, and when this function is completed, it dies. The data available to date entirely support Hisaw's conclusion, made 70 years ago, that the death of the primate corpus luteum is not due to a lack of pituitary gonadotropin secretion but rather to intrinsic changes within the corpus luteum. The simplest explanation for the regression of the primate corpus luteum is that there is an age-dependent diminution in its responsiveness to LH such that ambient concentrations of LH during the mid through late luteal phases of the menstrual cycle are no longer able to sustain its secretory activity. The final challenge continues to be the identification of the cellular mechanisms that are responsible for the age-dependent loss in the responsiveness of the corpus luteum to LH.

Neuroendocrine Control of Gonadotropin Secretion by the Corpus Luteum

During the mid-luteal phase of the human and rhesus monkey menstrual cycle, circulating progesterone is dramatically elevated and total inhibin (predominantly inhibin A) concentrations are at their highest.[47] Moreover, in the human female circulating estradiol concentrations during much of the luteal phase are approximately two-fold greater than those observed during the early follicular phase (Figure 28.1). Despite the increase in these circulating hormones of corpus luteum origin, all of which are potentially capable of inhibiting gonadotropin secretion, mean concentrations of circulating LH and FSH during the mid-luteal phase of the menstrual cycle are similar or only marginally lower than those observed at the beginning of the follicular phase.[47,434] This apparent paradox is not understood, although it has been proposed that the monkey ovary in some way is able to attenuate the profound negative feedback action of estradiol that is observed in the ovariectomized condition.[230] With the initiation of the demise in the corpus luteum late in the luteal phase, circulating levels of all three hormones decline dramatically, and the secretion of gonadotropins, in particular that of FSH, increases.

The relative importance of estradiol, progesterone, and inhibin A in relaying the ovarian negative feedback signal to pituitary gonadotropin secretion during the luteal phase of the menstrual cycle is not entirely clear. With the current data available, the least important in this regard appears to be inhibin A. Although the IV infusion of recombinant human inhibin A (1 μg/h) during the mid-luteal phase of the monkey cycle has been shown to suppress circulating FSH levels,[369] the physiological significance of this finding is difficult to evaluate because blood levels of inhibin A during treatment were not reported. Moreover, passive immunization against circulating inhibin during the luteal phase of the menstrual cycle in a closely related macaque was without effect on FSH secretion.[435] Twice daily SC injection of large doses of inhibin A at the time of the luteal–follicular transition in the rhesus monkey when FSH levels were rising resulted in selective suppression in the secretion of this gonadotropin.[191] However, the blood levels of inhibin A produced by the injections of this recombinant hormone were one to two orders of magnitude greater than basal levels, and therefore the inhibin effect must be viewed as pharmacologic.

That estradiol is a major component of the negative ovarian feedback signal during the luteal phase is suggested by the finding that, in women, continued maintenance of mid-luteal levels of this circulating steroid into the next follicular phase prevented the initiation of the rise in FSH secretion typically observed during the luteal–follicular transition.[436] This finding is consistent with another study in women, where daily administration of tamoxifen during the luteal–follicular transition resulted in a further increase in FSH secretion.[437] In the brain, tamoxifen is considered to be an ER antagonist.[438]

Although analogous approaches to address the importance of progesterone as a negative feedback regulator of gonadotropin secretion during the luteal phase has not been undertaken, a contributing role of progesterone in this regard may be inferred from our understanding of the role of this steroid in regulating LH/GnRH pulse frequency on the one hand, and the impact of changes in GnRH pulse frequency in mediating steroid feedback on gonadotropin secretion on the other. In contrast to the unremarkable changes in mean gonadotropin levels during the luteal phase of the menstrual cycle, the pulsatile mode of LH secretion is profoundly modulated at this stage of the cycle. Whereas an LH pulse frequency of approximately 1 pulse/h is observed during the greater part of the follicular phase, this may be reduced to as few as 1 pulse/8 h in the mid-luteal phase.[439–443] The deceleration of LH pulse frequency by progesterone may be readily demonstrated by experimentally imposing luteal phase concentrations of progesterone during the follicular phase of the menstrual cycle in normal women.[86] Maintenance of a low, mid-luteal phase GnRH pulse frequency during the luteal–follicular transition in GnRH-deficient women in whom the menstrual cycle is being driven by pulsatile GnRH replacement dampens the initial rise in FSH secretion normally observed at this stage of the cycle.[444]

The action of the progesterone to decelerate pulsatile GnRH release, which has been demonstrated empirically in the ewe (see Chapter 27), is unlikely to be mediated directly on GnRH neurons as there is little evidence for expression of the nuclear PR in these cells, including those of the African green monkey[445] (and Chapter 11). The finding that administration of naloxone, a generalized opioid receptor antagonist, during the luteal phase of the menstrual cycle in humans and monkeys results in an increase in LH pulse frequency,[87,446–448] and reverses the deceleration in LH pulse frequency induced by progesterone administration to women in the follicular phase,[449] provides compelling evidence for the view that signaling by endogenous opioids in the hypothalamus mediates the action of progesterone on GnRH release. In view of the emerging hypothesis that the arcuate KNDy neurons are the pivotal component of the GnRH pulse generator (see above), it is tempting to speculate that progesterone action in this regard may be directly on the GnRH pulse generator to upregulate dynorphin expression in KNDy neurons. In this regard, expression of PR in KNDy neurons has been reported for the ewe,[450] and evidence derived from studies of this species in support of progesterone action on KNDy neurons is accumulating (Chapter 27). In a study of the ovariectomized rhesus monkey, in situ expression of *KISS1* in arcuate neurons (presumably KNDy neurons) was downregulated by exposure to luteal phase blood levels of progesterone.[59] The significance of this finding is unclear, however, because (1) LH pulse frequency was not monitored, and (2) earlier studies of the monkey have shown that progesterone replacement alone to ovariectomized animals does not suppress mean levels of LH.[238] Another endorphin that has been implicated in the progesterone-induced deceleration of GnRH/LH pulse frequency in the rhesus monkey is β-endorphin, encoded by the *pro-opiomelanocortin* gene (*POMC*) that is also expressed by neurons in the arcuate nucleus (non-KNDy neurons).[451] β-endorphin levels in pituitary portal blood (and therefore perhaps also in the region of the arcuate nucleus and median eminence) of the monkey during the menstrual cycle are highest in the luteal phase.[452] β-endorphin, in contrast to dynorphin, has only low affinity for kappa opioid receptors,[85] and the mechanisms by which the putative action of these two EOPs retard GnRH pulse frequency are likely to be different. In this regard, GnRH neurons in the primate hypothalamus appear to be directly contacted by β-endorphin terminals.[453]

The negative feedback mechanisms utilized by estradiol to suppress FSH and LH secretion during the luteal phase are presumably the same as those discussed above that are operative during the follicular phase. As for the follicular phase, however, the relative importance of hypothalamic versus pituitary sites for the negative feedback action of this steroid during the luteal phase is unresolved. Nevertheless, it is clear from studies with hypophysiotropically clamped GnRH-deficient women and female monkeys that negative feedback by estradiol at the level of the pituitary is sufficient to regulate the secretion of both LH and FSH during the luteal phase of the cycle.[223–225]

Although the contribution of inhibin A to the control of gonadotropin secretion by the primate corpus luteum is unclear, any negative feedback by this ovarian peptide is likely to be exerted selectively on FSH secretion and primarily by a pituitary site of action. This view is based on studies of the hypophysiotropically clamped male rhesus monkey. Accordingly, castration in this model where the pulsatile GnRH drive to the pituitary is clamped at the male frequency of 1 pulse/3 h results in a marked monotropic rise in FSH that may be prevented by replacement with recombinant human inhibin A that maintains circulating inhibin A at levels observed for inhibin B prior to removal of the testis.[454] It should be noted, however, that circulating levels of inhibin B in the adult male monkey are approximately an order of magnitude greater than those observed for inhibin A in the luteal phase.[454,455] As established in nonprimate species, the action of inhibin to suppress FSH secretion is due to its abrogating an intrapituitary activin tone, which is stimulatory to FSH synthesis and release (see Chapter 10).

As with the mechanism underlying the initiation of the preovulatory LH surge, it appears from the foregoing considerations that there are likely to be major

redundancies in the negative feedback control system utilized by the primate corpus luteum to control gonadotropin secretion. In this regard, although the action of progesterone to robustly decelerate GnRH/LH pulse frequency is conserved across mammalian species exhibiting a prolonged luteal phase (see Chapter 33), a deceleration in GnRH/LH pulse frequency is not essential for either normal corpus luteum function or for preventing a premature FSH rise during the luteal phase of the cycle that would in turn advance the next wave of follicle differentiation. In both GnRH-deficient human and rhesus monkeys, the dynamics of menstrual cycles driven by pulsatile exogenous GnRH replacement at an unchanging frequency typical of the follicular phase (approximately 1 pulse/h) are essentially indistinguishable to those of cycles in normal subjects.[223–225] Notwithstanding, it has been suggested that a reduction of GnRH pulse frequency during the luteal phase may be necessary for optimal follicular development during the subsequent follicular phases. However, this thesis has not been investigated in great detail.

One other aspect of the neuroendocrinology of the luteal phase that needs to be mentioned is that during this phase of the cycle the hypothalamic-pituitary unit is unable to respond to the positive feedback action of estradiol.[456] That progesterone is responsible for this phenomenon was convincingly demonstrated in the monkey by the finding that estrogen-induced LH surges in the follicular phase of the cycle are blocked by prior exposure to luteal-phase levels of progesterone.[456] This action of progesterone would be brought into play in luteal phases where circulating estradiol levels exceed the strength-duration requirements for positive feedback of the steroid and may be particularly significant in the human female where luteal-phase levels of circulating estradiol are characteristically elevated. The mechanism underlying this action of progesterone remains to be established (for further details, see Chapter 45 in the previous edition).

MATERNAL RECOGNITION OF PREGNANCY

In the absence of a successful pregnancy, the primate corpus luteum has a finite 14- to 16-day life span, but its secretory activity is prolonged beyond this duration when successful conception occurs. Indeed, the abrupt increase in serum progesterone concentrations that was seen in pregnant rhesus monkeys when spontaneous luteal regression normally would have occurred led Neill et al.[457] to conclude that the corpus luteum of the menstrual cycle is "rescued" during early pregnancy.

The findings by Ascheim and Zondek in 1927[19] that urine of pregnant women contained a substance that stimulated luteinization in rats was the first evidence of a specific luteotropic factor associated with pregnancy, an observation that shortly thereafter resulted in the development of the first test for pregnancy. Because the biological activity of extracts of urine from pregnant women differed from that of extracts of urine from postmenopausal women, which also possessed the ability to stimulate follicular growth, Zondek[20] proposed the existence of two hormones, one with FSH activity and called prolan A at the time and the other with LH activity and called prolan B. Although Zondek initially proposed that both prolan A and B were of pituitary origin, the observations by Gey et al.[458] and Jones et al.[459] that cultured placenta trophoblast cells produced prolan B provided definitive evidence for the placental production and secretion of this gonadotropin, which subsequently became known as hCG.

As mentioned above, the insightful studies by Hisaw in 1944[333] demonstrated that injections of CG into rhesus monkeys during the luteal phase prolonged the functional life span of the corpus luteum, a seminal observation that was made without the benefit of chemical assays for either estradiol or progesterone. Based on careful monitoring of menstrual bleeding, coloration of sex skin, and characteristics of the vaginal mucosa, Hisaw correctly deduced that CG stimulated both estradiol and progesterone secretion by the corpus luteum. On the basis of these studies, he concluded that the newly formed corpus luteum is maintained by the pituitary gonadotropin, whereas the extension of the functional life span of the corpus luteum was a direct result of placental production of CG.

Role of CG in the Rescue of the Corpus Luteum

The requirement of CG for the prolongation of the life span of the corpus luteum was convincingly demonstrated by the findings that its neutralization by either active or passive immunization resulted in failure to support pregnancy.[460–463] Although early studies in both humans and nonhuman primates revealed a temporal association between rising concentrations of CG in peripheral plasma and progesterone and estradiol concentrations, a direct cause–effect relationship between the secretion of CG and the rescue of the corpus luteum was confounded by two observations. First, in some studies, increases in plasma concentrations of CG as indexed by elevated progesterone levels in the circulation occurred after the rescue of the corpus luteum.[464,465] Second, despite rising concentrations of CG, the heightened response of the corpus luteum was transient such that progesterone secretion declined in the presence of increasing concentrations of CG in blood.[391]

The lack of a precise relationship between the initial detection of CG in plasma and luteal rescue was most likely due to the insensitivity of early bioassays for CG. Using sensitive radioimmunoassays for rhesus CG, Hodgen et al.[466]

and Atkinson et al.[467] demonstrated that CG concentrations in plasma were detectable, on average, 10–11 days after ovulation (Figure 28.15). However, this rise occurred 1 day after the initial rise in progesterone secretion, making it difficult to establish a causal role for the appearance of CG in the blood and the rescue of the corpus luteum. Using a very sensitive immunoassay, Baird et al.[468] demonstrated that in humans hCG in urine can be detected 7–8 days after ovulation when increases in urinary excretion of estradiol and progesterone metabolites also become apparent. It is well documented that human and nonhuman primate blastocysts can produce CG in vitro.[469–471] Although it has been suggested that production of CG by preimplantation embryos and local delivery of the gonadotropin from the uterus to the ovary may contribute to the rescue of the corpus luteum,[472,473] direct injections of small amounts of hCG into the uterine cavity of rhesus monkeys failed to stimulate progesterone secretion.[474] As concluded by Ross,[475] the most likely explanation for the slight temporal discrepancy between enhanced progesterone secretion by the corpus luteum and the initial detection of CG in blood is that the corpus luteum is more sensitive to low concentrations of CG than are existing assays.

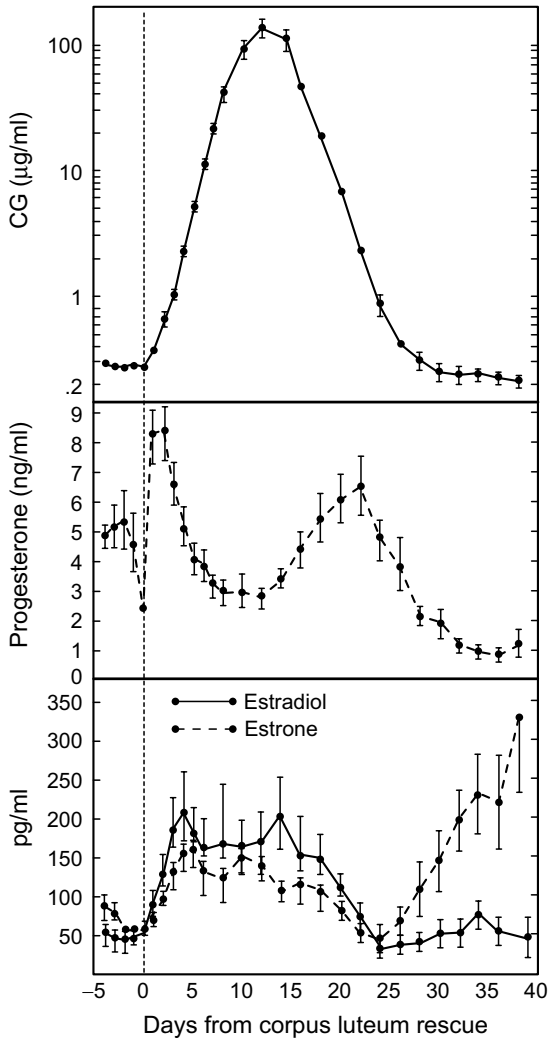

FIGURE 28.15 Patterns of serum chorionic gonadotropin (CG), progesterone, and estrogen concentrations during early pregnancy in the rhesus monkey. Results are standardized to the time of rescue of the corpus luteum (day 0) that occurs on average 10–11 days after ovulation. Note the decline in serum progesterone that occurs after the first week of pregnancy despite rising concentrations of CG. By contrast, estrogen concentrations parallel the temporal pattern of CG. *Source: Reproduced with permission from Ref. 467, Copyright 1975, The Society for the Study of Reproduction.*

More perplexing are the numerous observations that enhanced progesterone secretion by the corpus luteum is not sustained despite rising titers of CG in plasma,[476,477] a phenomenon that also occurs in response to the administration of exogenous CG.[345,478,479] Neill and Knobil[479] proposed that the decline in steroidogenesis after initial exposure to CG might be due to depletion of intracellular substrates required for steroidogenesis. More recently, it has been shown that prolonged stimulation of rhesus monkeys during the luteal phase by hCG in vivo results in a progressive decrease in the ability of hCG to stimulate adenylate cyclase activity in membranes isolated from corpora lutea.[480] This process of desensitization could account for the progressive decline in the secretion of progesterone by the corpus luteum in response to the progressive increases in plasma concentrations of CG that occur during early pregnancy. However, as deduced by Hisaw[333] and subsequently demonstrated later by others,[481,482] the progressive decline in progesterone production in response to hCG is not accompanied by a parallel decline in estradiol secretion. These observations indicate that individual CG-dependent biosynthetic pathways of the corpus luteum may be differentially affected by luteal cell aging, a hypothesis that is supported by the observation of an age-dependent attenuation of the responsiveness of selected mRNAs to CG stimulation[481] as well as differences in the temporal pattern of expression of mRNAs during hCG administration.[482] These findings indicate that luteal cell aging is associated with a selective loss of individual gonadotropin-sensitive biosynthetic pathways and agree well with the physiological data that luteal rescue (and exogenous hCG treatment) is associated with continuous stimulation of estradiol secretion but only transient stimulation of progesterone secretion and that the corpus luteum becomes less responsive to exogenous CG as the luteal phase progresses.[345,478] Diminished progesterone production by the corpus luteum therefore does not appear to be due to an absolute refractoriness to CG but rather to a selective loss in specific luteal cell functions.

Mechanism of Action of CG

CG and LH share identical α subunits, whereas their β subunits differ in size and pattern of glycosylation.[483]

The additional 30-amino acid sequence at the carboxyl terminal of CG-β together with the different glycosylation pattern results in a plasma half-life of CG that is substantially longer (36 h versus approximately 20 min) than that of LH.[484–486] Both CG and LH appear to occupy the same receptor[487] on luteal cells, both stimulate adenylate cyclase activity in luteal cell membranes,[353] and both stimulate progesterone secretion by isolated luteal cells.[488] The paradox regarding the rescue of the corpus luteum therefore is why the corpus luteum regresses in the presence of LH yet the similar molecule CG is able to prolong its functional life span.

Three hypotheses have been developed to account for the differential responses of the primate corpus luteum to LH and CG. One hypothesis is that the patterns of the secretory dynamics of LH and CG provide different gonadotropic stimuli to the corpus luteum. This hypothesis relates to the fact that whereas plasma concentrations of LH intermittently fall to very low values during the luteal phase due to the pulsatile nature of LH secretion by the pituitary gland, plasma concentrations of CG do not fall to these low levels due to both the continuous secretion of CG by the placenta and its longer circulatory half-life.[489] It is thus possible that continuous exposure of the corpus luteum to CG provides a more intense gonadotropic stimulus to the corpus luteum than does the episodic stimuli provided by LH. A second hypothesis is that although CG and LH are structurally similar, the amino acid differences in the β chains of CG and LH as well as differences in the extent of glycosylation and sulfation[490] could result in an inherent difference in biological activity between the two hormones. This hypothesis is based largely on studies of rodent and ovine systems that demonstrated that the time course of steroid production in response to hCG was significantly prolonged when compared with that of ovine LH, suggesting that the dynamics of the interaction of CG with the CG/LH receptor and/or the subsequent activation of intracellular signaling pathways may differ from that of LH.[491,492] More recent studies using recombinant hCG and LH in a variety of cell-based bioassays have indicated that although there is overlap in the activities of hCG and LH, on an equimolar basis, hCG was more effective in the stimulation of cAMP production while LH was more effective in the activation of ERK and AKT signaling pathways.[493] A third hypothesis is that the aging corpus luteum exhibits a diminished responsiveness to gonadotropins such that the ambient concentrations of LH present during the mid through late luteal phases of the menstrual cycle are unable to sustain its functions[360] and that the functional life span of the corpus luteum is prolonged in early pregnancy because the exponentially increasing plasma concentrations of CG transiently overcome the diminishing responsiveness of the aging corpus luteum to LH.

These hypotheses were tested in cynomolgus monkeys. In this study, monkeys received intravenous infusions of either LH or CG in a continuous or an exponentially increasing manner beginning during the mid-luteal phase of the menstrual cycle and continuing beyond the expected time of luteal regression.[494] As shown in the left panels of Figure 28.16, a continuous infusion of either LH (top) or CG (bottom), which resulted in bioactive LH/CG concentrations 10 times greater than endogenous LH concentrations, did not prolong the functional life span of the corpus luteum. These findings reinforce the notion that luteal regression at the end of nonfertile menstrual cycles is the result of a decrease in the responsiveness of the aging corpus luteum to LH because superimposition of exogenous LH or CG at ten-fold greater concentrations than endogenous LH concentrations did not prolong the functional activity of the corpus luteum. Also, these results do not support the hypothesis that a simple switch from pulsatile LH secretion to the continuous secretion of CG is sufficient to rescue the corpus luteum because timely luteal regression occurred in the animals that received a continuous (i.e., nonpulsatile) infusion of LH.

In contrast, exponentially increasing concentrations of LH or CG (Figure 28.16, right panels) prolonged progesterone production beyond the expected time of luteal regression. However, the responses to LH and CG were not identical because although the pattern of progesterone production in animals that received the exponentially increasing regimen of CG was similar to that of pregnant animals, the cumulative progesterone levels in response to the exponentially increasing LH infusion were 40% lower than those seen in the animals that received hCG, despite the fact that bioactive plasma concentrations of both gonadotropins were comparable throughout the duration of the infusions. Thus, it appears that luteal rescue requires CG rather than LH and that the corpus luteum be exposed to an exponential increase of this gonadotropin. The reason CG was more effective than LH in this experimental paradigm remains to be answered, although as noted above, on an equimolar basis hCG appears to be more effective than LH in stimulating cAMP production in cell-based bioassays.[493] Thus, hCG would be expected to produce a greater cAMP response and result in greater progesterone production in response to hCG when compared with that of LH, consistent with the findings shown in Figure 28.16.

Interestingly, the duration of CG production by the placenta differs among primate species.[495] In humans, hCG concentrations reach a maximum during the first trimester of pregnancy, decline thereafter, but remain detectable throughout the entire duration of pregnancy. A similar pattern of CG production is seen in apes, with the exception that the absolute plasma concentrations are an order of magnitude less than those seen in humans.

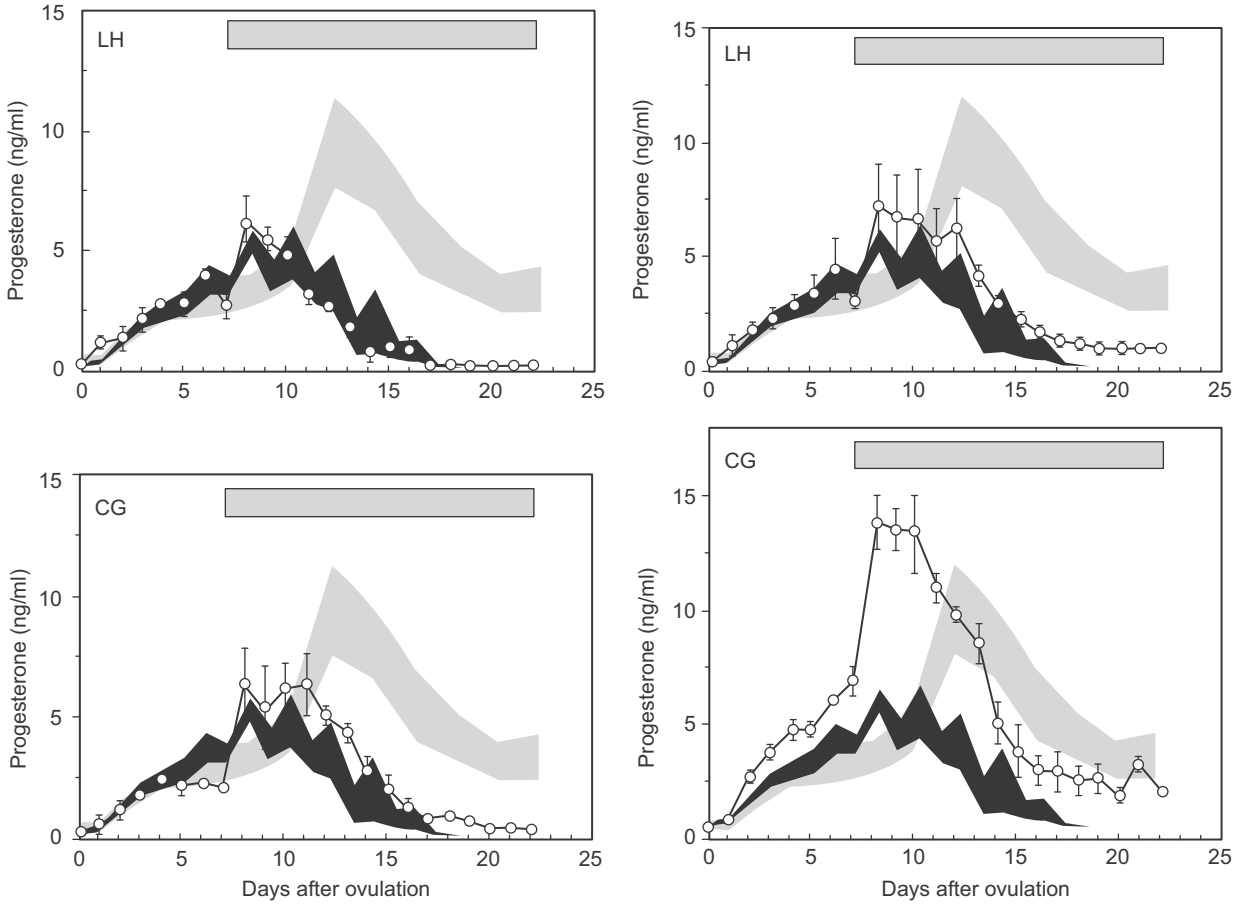

FIGURE 28.16 Responses of the primate corpus luteum to exogenous luteinizing hormone (LH) and human chorionic gonadotropin (hCG). The duration of each gonadotropin treatment is shown by the shaded rectangle at the top of each panel. The left panels illustrate serum progesterone in animals that received intravenous infusions of LH and hCG at a constant rate. The right panels illustrate serum progesterone in animals that received intravenous infusions of LH and hCG at an exponentially increasing rate. The dark shaded area encompasses the means +/− 1 standard error of the mean (SEM) of serum progesterone concentrations during luteal phases of three control monkeys, and the light shaded area encompasses the means +/− 1 SEM of serum progesterone concentrations during luteal phases of three pregnant monkeys. *Source: Redrawn with permission from Ref. 494, Copyright 1999, National Academy of Sciences USA.*

In baboons and macaques, CG concentrations decline to near undetectable levels during mid-pregnancy. Whether there are functional requirements that underlie the different patterns of CG secretion, such as direct actions on the conceptus or uterus,[496,497] are not known.

The Luteal–Placental Shift

The sole function of the corpus luteum in the maintenance of pregnancy is the production of steroid hormones, because women with ovarian failure and ovariectomized monkeys can achieve successful term pregnancies after embryo transfer provided they receive exogenous estradiol and progesterone.[498,499] In both humans and nonhuman primates, the corpus luteum is essential until the placenta assumes the major role of steroid secretion. Removal of the human corpus luteum before the fifth week after implantation resulted in a decline in serum progesterone concentrations and abortion.[296] In rhesus monkeys it has been shown that successful pregnancies can be observed after the removal of the corpus luteum as early as 1 week after implantation despite a dramatic fall in serum progesterone and estradiol concentrations.[500] That abortions can be prevented by replacement with progesterone alone in humans and nonhuman primates after luteectomy indicates that this steroid, so aptly named by Corner and Allen for its progestational effects, is the sole luteal substance required for the maintenance of early pregnancy.[501]

The fate of the corpus luteum during pregnancy has been followed in humans by the measurement of 17α-hydroxyprogesterone in blood. Because the 17α-hydroxylase enzyme is present in the corpus luteum but not in the placenta, presumably all 17α-hydroxyprogesterone in blood is derived from the corpus luteum. Plasma concentrations of 17α-hydroxyprogesterone peak during the fourth and fifth week of gestation and decline thereafter, whereas

serum progesterone concentrations continue to rise after the fifth week of gestation, indicating that from week 5 onward, the major source of circulating progesterone is the placenta.[477] Ovariectomy of rhesus monkeys on day 25 of pregnancy does not result in a dramatic fall in serum progesterone concentrations, indicating that by this time the placenta is the primary source of progesterone in this species.[391]

Although steroid secretion by the corpus luteum wanes during early pregnancy, it does not appear that the corpus luteum becomes totally nonfunctional. It has been shown in humans at term pregnancy that venous blood draining the ovary bearing the corpus luteum contains greater concentrations of both progesterone and relaxin than that found in blood from the contralateral ovary and the peripheral circulation.[318] In postpartum monkeys, progesterone concentrations in ovarian venous blood from the ovary that contains the corpus luteum are greater than those found in blood from either the contralateral ovary or the peripheral circulation.[362] The fact that lactating animals have higher concentrations of progesterone in the peripheral circulation as well as in the blood draining the corpus luteum–bearing ovary suggests that prolactin may contribute to the maintenance of the low activity of luteal function observed during pregnancy and immediately after parturition. The physiological significance of the persistence of luteal activity throughout pregnancy and after parturition is not known in view of the observations that successful pregnancies occur when the corpus luteum is removed after the luteal–placental shift.

CONCLUSION

As noted in our introductory comments, the menstrual cycle, and hence the preservation of our species, is dependent upon the physiological signaling processes that occur between the ovaries, pituitary, and brain. The result is a remarkable orchestration of perfectly timed events that culminate in the production and ovulation of a mature oocyte, the formation of the corpus luteum with the concomitant preparation of the uterine endometrium for the implantation of a fertilized oocyte, and the establishment and maintenance of pregnancy. As we have discussed in this chapter, classical negative and positive feedback loops between ovarian hormones, primarily estradiol, and the hypothalamic-pituitary unit coupled with development-dependent changes in gonadotropin responsiveness of the ovary to FSH and LH are sufficient to account for the initiation of preovulatory follicular development, the selection of a preovulatory follicle, ovulation, and the formation and regression of the corpus luteum. The extension of the corpus luteum's functional lifespan during early pregnancy is mediated by the secretion of hCG by the placenta, which overcomes the diminishing responsiveness of the aging corpus luteum to LH. This knowledge has directly led to the development of novel ovulation induction regimens for women that minimize the production of multiple oocytes and the morbidities associated with multiple births. As our knowledge continues to increase in the areas of preantral folliculogenesis and autocrine and paracrine regulation of follicular development (see below), additional therapies for ovarian dysfunction (primary ovarian insufficiency, polycystic ovary syndrome, etc.) are likely to emerge in the future.

With respect to important unanswered questions, at the ovarian level we are just beginning to understand the mechanisms responsible for activation of primordial follicles and the control of preantral folliculogenesis and atresia. The recent findings that the PI3-K signaling pathway plays a major role in primordial follicle activation now provides a target to explore this essential component of follicular growth and reproductive lifespan. What remains to be answered is the identification of the ligand(s) that regulate the PI3-K pathway in primordial follicles and how their production is regulated to control the timing of primordial follicle activation (Chapter 21).

Likewise, the identification of local autocrine and/or paracrine factors that control the growth of both gonadotropin-independent preantral folliculogenesis as well as gonadotropin-dependent preovulatory folliculogenesis could lead to novel strategies in controlling anovulatory folliculogenesis. In this regard, in vitro tissue culture studies with isolated ovarian granulosa and theca cells have led to the identification of a number of autocrine and paracrine agents (IGFs, activins, inhibins, steroids, etc.) that modulate proliferation, differentiation, and apoptosis. However, these tissue culture studies are typically conducted in serum-free culture medium because the presence of serum can adversely affect cellular responses.[502,503] Given that the ovary is likely exposed to serum proteins in vivo, it will be essential to develop novel in vivo approaches to document the physiological actions of these locally acting factors. Although gene targeting approaches have provided in vivo models to explore the effects of autocrine and paracrine factors (see Chapter 21), it will ultimately be necessary to translate information gained from murine models to higher primates.

Another major unanswered question in primate ovarian physiology is the elucidation of mechanism(s) that are responsible for the regulation of luteal regression at the termination of nonfertile menstrual cycles. Is this due simply to an age-related diminution of LH responsiveness (as we believe), or is it the result of the actions of luteolytic agents (prostaglandins, steroids) that impair LH signaling?

Folliculogenesis, ovulation, and luteal function are absolutely dependent upon the pituitary receiving an intermittent stimulatory GnRH signal from the brain that is produced by the hypothalamic GnRH pulse

generator. In fact, an unchanging pulsatile GnRH input to the primate pituitary is sufficient to allow ovarian cyclicity and ovulation to unfold: an observation that led Knobil in 1980 to propose that the role of this releasing factor in the control of the menstrual cycle was permissive. In the absence of a pulsatile GnRH drive to the pituitary, menstrual cyclicity ceases and a state of anovulation, hypoestrogenemia, and amenorrhea ensues. Although the importance of hypothalamic GnRH pulse generation has been appreciated for decades, a promising model to account for the neurobiology underlying this mode of GnRH release has only recently begun to emerge. This model, developed primarily from studies of nonprimates, posits that the KNDy neurons in the arcuate nucleus of the MBH are the cornerstone of the GnRH pulse generator, and that the output of this signal generator is imposed upon a network of GnRH neurons by kisspeptin. Because of the fundamental role of pulsatile GnRH release to all phases of the menstrual cycle, the major question in the context of the neural control of the adult ovary relates first to the validity of this model and the extent to which it can be translated to the human female. If the answer to this question is that the model is compelling and translatable to primates, then it will be important to elucidate the specific neurobiological mechanisms whereby neurokinin B and dynorphin (and perhaps other neuropeptides expressed by KNDy neurons) generate coordinated pulsatility within the network of arcuate KNDy neurons, and how the selective kisspeptin output of this network to the GnRH network is achieved. It will also be important to determine the role, if any, of non-KNDy neurons and other hypothalamic elements such as glia in the context of pulse generation. In our view, the importance of understanding the machinery of the hypothalamic GnRH pulse generator dwarfs all other questions relating to the neural control of the menstrual cycle. This is because (1) GnRH pulse generation is the only hypothalamic input to the pituitary that is obligatory for menstrual cyclicity, (2) the capacity of the human hypothalamus to generate a preovulatory GnRH surge is unclear, and (3) while the relative importance of hypothalamic versus pituitary sites of estradiol feedback on gonadotropin secretion are intellectually interesting, they are unlikely to be answered in an in vivo setting with contemporary technology. Understanding the neurobiology of GnRH pulse generation and the hypothalamic signals that regulate pulse amplitude and pulse frequency may offer new therapeutic approaches to disorders of the menstrual cycle that are occasioned by inappropriate GnRH pulse generation such as PCOS.

CHAPTER

29

Pathophysiology of Ovarian Function in the Human Female

Stephen Franks, Kate Hardy

Institute of Reproductive and Developmental Biology, Imperial College London, Hammersmith Hospital, London, UK

Gerard S. Conway

Department of Endocrinology, University College Hospitals, London, UK

INTRODUCTION

Female infertility has been described and its causes speculated upon for centuries. Indeed, there are several references to infertility in the bible, the earliest being in Genesis 16: "Now Sarai Abram's wife bare him no children". Hippocrates (c. 460–c. 375 BC) refers to infertility in a series of essays entitled "The influence of climate, water supply and situation on health". This is almost certainly one of the first recorded references to the effect of environment (nutrition) on reproduction. Commenting on the influence of obesity on fertility amongst the Scythians, he notes, "The girls get amazingly flabby and podgy… people of such constitution cannot be prolific… fatness and flabbiness are to blame. The womb is unable to receive the semen and they menstruate infrequently and little".[1]

A concise and lucid history of the discovery of the mammalian ovary is provided by Roger Short,[2,3] and further insight into the key landmarks in understanding the physiology of the ovary can be found in Chapter 28. Short includes a reference to the notion that it was Aristotle who was the first to describe the ovaries in an article describing the spaying of sows.[4] However, it was not until the seventeenth century that the seminal work of Regnier de Graaf provided the basis for our current understanding of the functional anatomy of the ovary.[5] The term "Graafian follicle" is still used to describe the preovulatory follicle even though de Graaf, at the time, considered that the structure of what we now know as the mature follicle (comprising the somatic cells and oocyte) was the egg itself. The distinguished anatomist Malpighi, later in that century, observed that the follicular structure that de Graaf had referred to as the egg retained the ovary despite evidence of ovulation. It was Prévost and Dumas in 1824 who concluded that the follicle contained the oocyte but was not the egg itself.[3]

Recognition of the hormonal regulation of ovarian function had to wait until the twentieth century. Crowe and colleagues (1910), followed by P.E. Smith (1927),[6] demonstrated that hypophysectomy in the rat resulted in regression of the gonads (reviewed by Greep[7]). Smith (1930) also showed that pituitary transplant in hypophysectomized animals restored gonadal function. Zondek and Ascheim (1927)[8] provided evidence for gonadotropic substances in the pituitary and suggested that there were two distinct gonadotropins,[9,10] a notion that was later confirmed in the classic studies of Fevold and colleagues.[11] Purification of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary extracts and from urine followed much later.[12–14]

Regarding the assay of reproductive hormones, Levin and Tyndale (1936) described a method for measuring gonadotropins in urine.[15] Applying this methodology, Werner (1941)[15] reported cyclical variation in gonadotropin excretion (as well as cyclical changes in sex hormone excretion) in five women with regular menses, who were studied over a 3- to 4-month period. This method was extremely laborious, involving collection of urine over 48 h periods, an acidification step, followed by extraction of protein, partial purification, and then an in vivo mouse bioassay to examine gonadotropic action.[15] Further assays for gonadotropins in urine were developed by Steelman and Pohley (1953)[16] and Brown (1955).[17]

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00029-6

Gonadotropin measurements in urine later revealed abnormalities in women with disorders of ovulation. It was Ingersoll and McArthur (1959)[18] who first noted excessive excretion of LH in the urine of women with polycystic ovary syndrome (PCOS). In this study and over much of the following decade, the measurement of gonadotropin activity in the extracted protein fraction of urine still relied on the use of a subsequent in vivo bioassay.[19]

The advent of the radioimmunoassay for gonadotropins and sex steroids in the 1960s and its subsequent widespread application in the early 1970s were key factors in advancing our understanding of disorders of ovulation in women as well as shedding new light on the physiology of the hypothalamic–pituitary–ovarian (HPO) axis. The ability to measure hormones in small volumes of blood allowed researchers to distinguish easily between a primary ovarian cause (low estradiol and high FSH) and hypothalamic–pituitary causes of anovulation (low estradiol and low or normal gonadotropins). The demonstration of the pulsatile nature of gonadotropin secretion and the ability to show, convincingly, that disorders of ovulation associated with gonadotropin deficiency were often hypothalamic in origin (i.e., an aberrant pulsatile pattern, indicating disordered gonadotropin-releasing hormone (GnRH) secretion) represent a further, significant advance in understanding the pathophysiology of the HPO axis. Knobil and colleagues, in a study of LH secretion in the ovariectomized rhesus monkey,[20] proposed that LH pulsatility was dependent on an LH-releasing factor produced by the brain. In the same year, Dolais and coworkers reported LH pulses in women.[21] These studies were followed by those of Midgley and Jaffe[22,23] and Wide,[24] who were amongst the pioneers who produced meticulous studies to define the episodic nature of LH and FSH secretion by using highly sensitive immunoassays, and it was then possible to link these findings to the discovery of the identity of GnRH in 1971 (further discussed in this chapter).

At about the same time as the elucidation of the structure of GnRH, the identity of prolactin as a hormone that had a distinctly different structure from growth hormone was reported.[25] A bioassay for prolactin using the pigeon crop sac had been developed as early as 1933 by Riddle and colleagues,[26] and a bioassay for lactogenic hormones (in which there was inevitably cross-reactivity with growth hormone and human placental lactogen) was used for many years.[27] Subsequent development and application of a specific radioimmunoassay for prolactin[28] led to the realization that hyperprolactinemia was a very common cause of amenorrhea in women.[29] MacLeod (1970)[30] had shown that the likely hypothalamic factor that kept prolactin under tonic inhibitory control was dopamine. Coincidentally, the long-acting dopamine agonist bromocriptine became available for the management of Parkinson syndrome, and it was shown that, in small doses, bromocriptine effectively reduced prolactin levels and restored ovulation in women with hyperprolactinemic amenorrhea.[31,32]

Following the identification of the structure of GnRH by Schally and Guillemin,[33,34] it was the seminal work of Knobil and colleagues[35,36] in the 1970s that showed the importance of pulsatile administration of GnRH in restoring ovulatory menstrual cycles in primates. This led to the application of GnRH treatment to restoring ovulation and fertility to women with clinical disorders of gonadotropin secretion.[37–40] The discovery and subsequent synthesis of GnRH were important not only because of its implications for the treatment of infertility but also because it provided unique insight into the physiology of the HPO axis. For example, examination of the endocrinology of GnRH-induced ovulatory cycles in the nonhuman primate and in women with GnRH deficiency revealed not only normal cyclical patterns of estradiol and progesterone secretion but also modulations in the levels of LH and FSH despite using a fixed dose of GnRH. This demonstrated that both negative and positive steroid feedback was operating at the pituitary level and that this was sufficient to produce a normal ovulatory cycle.

Even before the advent of GnRH for therapeutic use, treatment of ovulatory disorders in women had been revolutionized in the 1960s by the use of the antiestrogen clomiphene[41–43] and, in women with gonadotropin deficiency, of exogenous gonadotropins.[44–46] These gonadotropins either were of pituitary origin or were extracted and purified from urine of pregnant (human chorionic gonadotropin–LH activity) or postmenopausal women (predominantly FSH activity).

The enormous progress, in the modern era, in our understanding of the pathophysiology of ovulatory disorders in women and their management is the subject of this chapter.

PHYSIOLOGY OF HUMAN OVARIAN FUNCTION

The normal reproductive lifespan of a woman ranges from her early teens until her early 40s, although fertility is progressively reduced in her 30s. Fertility depends on a number of key factors, of which, of course, regular ovulation is a fundamental requirement but oocyte "quality" is also a major consideration. In this chapter, the main focus will be on disorders of ovulation, which are a highly prevalent cause of infertility and may also impact other aspects of women's health. To set the scene, however, we will discuss some of the more important aspects of the physiology of the human ovary, which is intended to complement the detailed exposition of the menstrual

cycle in higher primates in Chapter 28. The principal causes of disordered ovulation will be described, and their clinical manifestations and management discussed. In an era of fertility treatment that is dominated by the use of assisted conception techniques, it is important to highlight the fact that correct identification of the cause of ovulatory disorders will, in most cases, lead to the successful use of specific treatments that target restoration of normal, mono-ovulatory menstrual cycles. This is an exciting era in reproductive physiology and endocrinology in which the uncovering of important genetic influences upon—and, in some cases, determinants of—many common reproductive endocrine disorders such as hypothalamic amenorrhea, primary ovarian insufficiency (POI), and PCOS have provided real hope of more precise methods of diagnosis and treatment.

Follicle Development in the Human Ovary

The formation of primordial (resting) follicles in the human female takes place during the last trimester of pregnancy and is essentially complete by the time of birth. Follicle formation in the primate ovary is discussed in detail in Chapters 21 and 28. In the human fetal ovary, about two million primordial follicles, from an initial pool of around five million oocytes, are present at birth and, by the time of puberty, that number has declined to an estimated 100,000–200,000.[47] Thereafter, there is a steady decline in the population of follicles throughout childhood and reproductive life as a result either of progression of follicles through the various stages of development or of loss by atresia (follicle death) (Figure 29.1).[48–51] It is evident that growing follicles also undergo atresia because the vast majority of follicles that start to grow never reach the mature preovulatory stages. The most obvious loss of follicles is seen at the antral stages, but there is also evidence that atresia may occur at any stage during development in the primate ovary. The progression of the follicle and its enclosed oocyte from the primordial stage to a mature preovulatory follicle takes several months in the human ovary[52,53] (Figure 29.2).

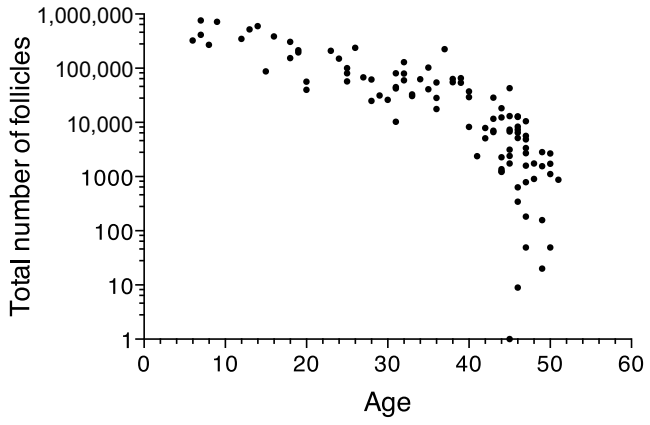

FIGURE 29.1 The decline in follicle number in the human ovary with age. *Source: Data compiled from various sources.*[48–51]

Although there are recent data to suggest that mitotically active oogonial germ cells are present in the human ovary that have the potential to generate new oocytes,[54] it is unlikely that such cells can significantly affect reproductive lifespan because the net loss of follicles clearly exceeds renewal from any stem cell pool. Nevertheless, this is an important observation and, if validated, does open the prospect of being able to "harvest" such cells for therapeutic use in restoring ovarian function in those with, or at high risk of, POI. Essentially the steady decline in follicles with age continues unabated and the rate of loss determines the age of menopause. There is an accompanying reduction, with age, in the competence of oocytes to develop into healthy embryos, as is attested by the steep rise in the rate of aneuploidy and miscarriage observed as women reach their late 30s and beyond (see Ref. 55 and Chapter 1). Nevertheless, there is enormous variation between women in the decline of the oocyte population, which is reflected in the wide range in age for the onset of menopause (40–55 years). Measurement of serum concentrations of anti-Müllerian hormone (AMH), a secretory product of granulosa cells, predominantly from large preantral and antral follicles, has gained favor in the assessment of ovarian follicle reserve, particularly in the context of predicting responses to exogenous gonadotropin stimulation in assisted reproductive technologies. However, whilst serum AMH levels broadly correlate with fertility, there is a huge variation within the normal range,[56] which (coupled with ongoing problems with standardization of the immunoassays[57]) renders such assessment unreliable at present.

Preantral Follicle Development

Preantral follicle development can progress in the absence of gonadotropin stimulation as far as the multilayered, preantral stage. Antrum formation and further progression to large antral follicles are, however, dependent on gonadotropins, and FSH in particular. Nevertheless, granulosa cells of preantral follicles do have receptors for FSH, and it can be shown that even in the very earliest stages of follicle development FSH can act as a survival factor in human ovarian tissue[58] and promote activation of primordial follicles,[59] at least in vitro. These findings suggest that FSH may play a physiological (although nonessential) role even in preantral follicle growth. It is therefore appropriate to use the terms "gonadotropin sensitive" for preantral development and "gonadotropin dependent" for the antral stages (Figure 29.2).

The rate at which primordial follicles enter the growing pool must be tightly regulated in order to ensure a steady supply of growing follicles throughout

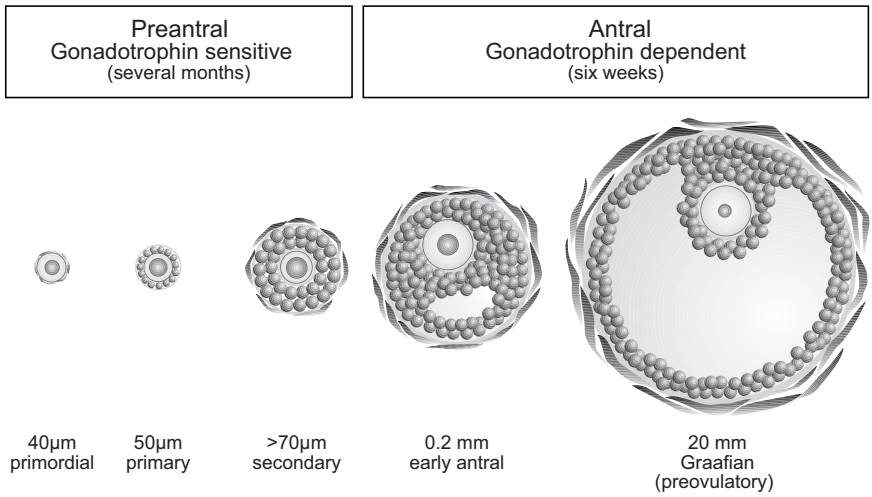

FIGURE 29.2 Stages of human follicle development.

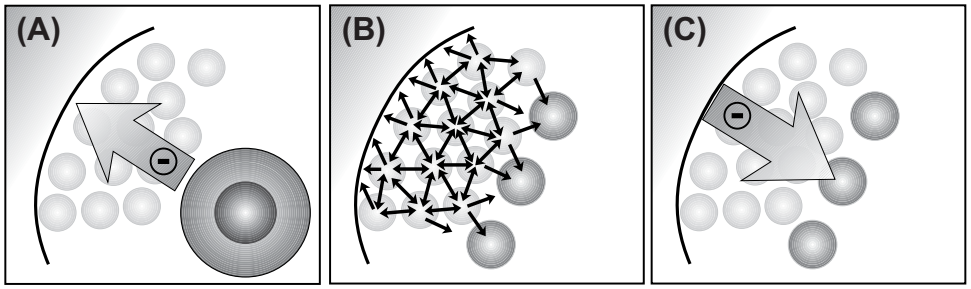

FIGURE 29.3 Possible mechanisms to provide inhibition of activation of primordial follicles in the mammalian ovary. (A) Inhibitory signal from growing follicles; (B) primordial follicles produce a local factor (or factors) that inhibits their neighbors from activating; (C) an inhibitory factor produced by the ovarian surface epithelium.[60]

reproductive life. One approach to understanding initiation of follicle development is to use mathematical modeling to test hypotheses about the mechanisms involved. Observing that primordial follicles tend to exist in clusters near the ovarian surface (whereas growing follicles were less likely to be adjacent to other follicles and more central within the ovary), Da Silva-Buttkus et al.[60] proposed that one of three possible mechanisms determined whether primordial follicles remained in the resting pool or were activated to grow (Figure 29.3). These hypotheses were that (1) primordial follicles produced an inhibitory factor so that adjacent follicles in the cluster inhibit each other, (2) growing follicles produce a factor that inhibits activation of primordial follicles, and (3) an inhibitory factor (or factors) was produced by the ovarian surface epithelium. They mapped positional coordinates of all follicles in sections of juvenile mouse ovary and computed the Euclidian distance between each and every follicle in that section. As illustrated in Figure 29.4, there was clear evidence to support the hypothesis that primordial follicles inhibit each other's growth. The more primordial neighbors in the immediate vicinity of the "target" follicle, the less the chance of it being a growing follicle; conversely, the fewer the primordial follicles in the immediate vicinity, the more likely it was to be

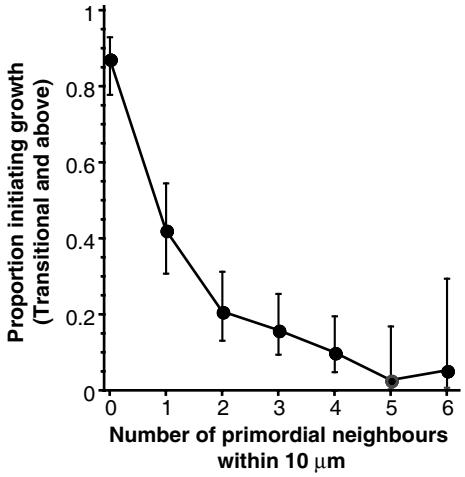

FIGURE 29.4 Neighboring primordial follicles inhibit activation of follicle growth. The proportion of follicles that are growing is inversely related to the number of primordial follicles within a 10 μm radius, suggesting that neighboring primordial follicles inhibit each other from initiating growth (juvenile mouse ovary day P8).[60]

a growing follicle. It is evident that much further work needs to be done before the key factors involved in the putative inhibitory "brake" on follicle activation can be elucidated, but among plausible candidates are growth

factors in the transforming growth factor beta (TGFβ) superfamily and/or their naturally occurring antagonists. Recent data from studies in the mouse have lent support for such a role for these paracrine factors (see the section Polycystic Ovary Syndrome and Chapter 21).

Although most of the studies of initiation of follicle development have taken place in experimental animals, results from the little work that has been done in human ovary suggest that similar phenomena prevail in the activation and growth of human preantral follicles.[52,61–63] What is clear is that the morphological changes that characterize initiation of follicle growth in rodents, domestic animals, and nonhuman primates can also be observed in the human ovary,[52,63] although there is still much to be learned about the growth factors that are implicated in early follicle development in the human ovary.[61] Importantly, it is from such studies in human ovaries that it has been possible to define aberrations in early follicle development in PCOS,[64,65] as discussed at length in the section Polycystic Ovary Syndrome.

Gonadotropin-Dependent Follicle Development

Our understanding of the later, antral stages of follicle development is much greater than that of the factors affecting early follicle growth. The physiology of antral follicle growth and the changes associated with the primate menstrual cycle are described in considerable detail in Chapter 28 and will not be reiterated here except to illustrate, briefly, the particular features of dynamic changes in the HPO axis that characterize the human ovulatory cycle (discussed further in this chapter). What is clear is that development of antral follicles to a size of between 1 and 5 mm in diameter can take place in the absence of cyclical changes in gonadotropins; however, the emergence, maturation, and ovulation of a dominant follicle require the characteristic cadence of gonadotropin secretion that is observed during the menstrual cycle. Such cyclical changes depend, in turn, on a normal pattern of secretion of GnRH, which is itself influenced by afferent inputs in the hypothalamus that, in turn, are sensitive to parameters of the external environment, particularly those related to nutritional status. It is beyond the scope of this chapter to describe the network of neural inputs to the GnRH pulse generator in detail, but suffice it to say that disorders of GnRH secretion are well-recognized causes of anovulation in women and there is increasing evidence that disturbances in afferent neural input to the GnRH neural network play a role in these clinical disorders. These will be discussed in the *Disorders of Ovulation*.

Steroidogenesis in the Human Ovary

Control of steroid hormone production during the follicular and luteal phases of the primate menstrual cycles is described extensively in Chapter 28. That discussion includes the role of insulin-like growth factors (IGFs), as physiological modulators of gonadotropin action, in ovarian steroidogenesis. Later in this chapter, we shall focus on both the possible physiological and the likely pathological implications of the actions of IGFs (and insulin itself) in the context of aberrant steroidogenesis by both theca and granulosa in PCOS.

The Human Menstrual Cycle

The cyclical changes in gonadotropins and ovarian steroids in the human menstrual cycle are summarized in Figure 29.5. Here it can clearly be seen that toward the end of the previous cycle, the steep fall in the serum levels of estradiol and progesterone, which signal the demise of the corpus luteum, is accompanied by a rise in both FSH and LH. The increase in FSH is more marked than that of LH, and it is this intercycle rise in FSH that is critical for the further development of the small cluster of antral follicles (1–5 mm in diameter) that are present at that time. In essence, in the normal early follicular phase of the cycle, FSH concentrations exceed a critical level or "threshold" for further development of that cluster of antral follicles,[67,68] and it is the follicle that is most sensitive to FSH (usually, but not invariably, the largest of the cohort) that becomes dominant and goes on toward ovulation. As estradiol levels rise steadily in the early follicular phase, a negative feedback inhibition of FSH is activated and, whereas the dominant follicle continues to develop in the face of a reduced FSH signal, the subsidiary follicles in the cohort are deprived of sufficient FSH stimulation and become atretic. This is considered to be the major mechanism underlying mono-ovulation in primates. The contribution of inhibins to the physiology of negative feedback regulation of FSH remains a somewhat controversial area. Inhibin B is mainly produced by small antral follicles. Inhibin A is largely secreted by the corpus luteum, but the serum levels rise in the mid- to late follicular phase and it is suggested that both inhibin A and inhibin B contribute to negative feedback inhibition of FSH in the follicular as well as the luteal phases.[69–72] However, inhibin B serum concentrations in the follicular phase of the human ovulation cycle, whilst showing a similar pattern to that of estradiol, lag somewhat behind those of FSH, suggesting that FSH is regulating inhibin rather than vice versa. The rise of inhibin A in the late follicular phase (at a time when inhibin B is declining) ensures that the net effect of inhibin is maintained.[72] Nevertheless, although it can be argued that inhibins play a role in regulation of FSH, mathematical modeling[73] (Figure 29.6) together with other supportive data (Chapter 28) suggest that estradiol feedback is the principal negative feedback regulator of FSH during the follicular phase of the menstrual cycle in both women with regular ovulatory cycles and those with anovulatory PCOS (discussed further here). However, in older

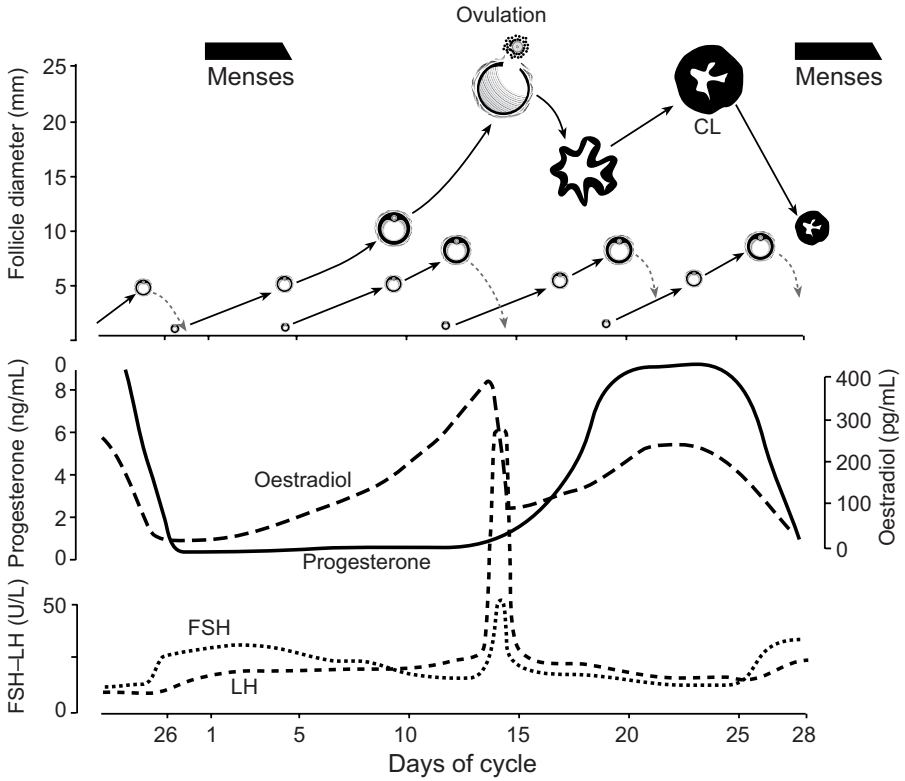

FIGURE 29.5 **The human menstrual cycle.** *Source: From Ref. 66.*

women, elevated FSH levels are associated with normal (or slightly elevated) serum estradiol but lower than normal serum concentrations of inhibin B, and it is feasible that this peptide may play a more important role in regulating FSH secretion in this population.[75]

By the midfollicular phase of the cycle, the dominant follicle has acquired receptors for LH in the granulosa cells, the only time in the life of a follicle that LH receptors are normally present on these cells (this process may be disrupted in PCOS, as shown in the *Polycystic Ovary Syndrome*). In the late follicular phase, the joint action of LH and FSH on the dominant follicle leads to an exponential rise in the levels of estradiol. It is likely that paracrine factors, induced by FSH, also participate in the accelerated growth and increased steroidogenesis in the late follicular phase. For example, the preovulatory follicle shows increased gene expression of type 1 IGF receptors,[76] suggesting that the stimulatory action of endogenous IGFs on estradiol production is amplified at this stage. Indeed, IGF1 has a potent stimulatory action on steroidogenesis in granulosa cells of large antral follicles in the human ovary,[77,78] supporting the notion that local production of IGFs amplifies gonadotropin-induced steroid production in the preovulatory follicle.

The midcycle LH surge is triggered by the rising levels of estradiol and serves three important functions: promoting resumption of meiosis in the oocyte, causing follicular rupture, and stimulating the formation of the corpus luteum. The mechanisms underlying these events are described in great detail elsewhere, as is the function of the corpus luteum (see Chapters 1, 22, and 23). It need only be noted here that among the disorders of the ovulation cycle that are detailed in this chapter, primary dysfunction of the corpus luteum must be considered to be a very rare cause.

DISORDERS OF OVULATION

Disorders of ovulation in women are very common and constitute between 25% and 30% of the causes of infertility. Such disorders also result in menstrual disturbances (amenorrhea, oligomenorrhea (fewer than eight periods per year), or frequent but unpredictably irregular menses) and therefore may cause inconvenience or other morbidities, such as constant vaginal bleeding, in women who are not immediately concerned about their fertility. Disorders of gonadotropin regulation and POI are important causes of anovulation, but PCOS is by far the commonest cause of infrequent or absent ovulation. It is characterized by abnormalities of gonadotropin secretion and also by dysfunctional ovarian follicle development and steroid production. The reproductive and metabolic features of PCOS will therefore be described in considerable detail in this chapter, but due attention will also be paid to other disorders of ovulation in a

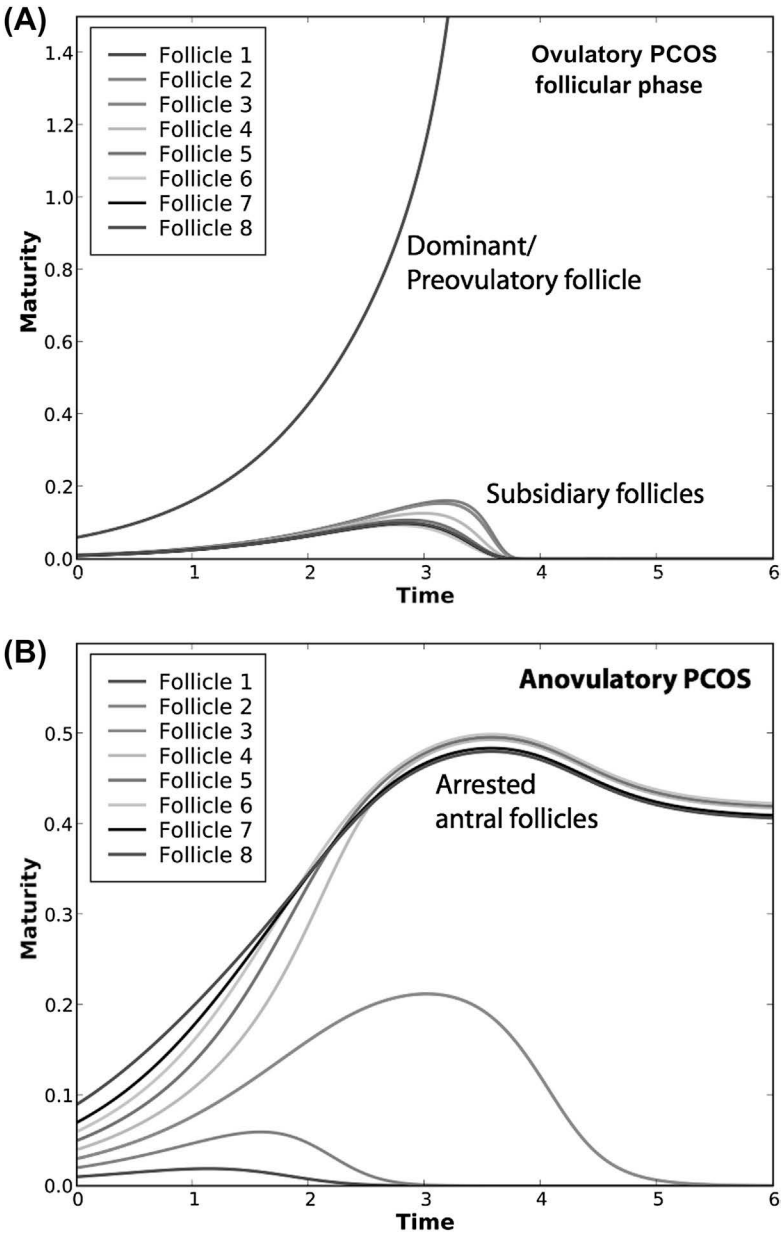

FIGURE 29.6 Mathematical modeling of growth trajectory of follicles in (A) ovulatory and (B) anovulatory polycystic ovary. Time and maturity are in arbitrary units. By applying Lacker's model,[74] it is suggested that in anovulatory PCOS: (1) the primary cause of follicular dysfunction is at the level of the ovary, rather than the pituitary, and is characterized by variable responsiveness of follicles to FSH; (2) arrested follicles have different properties from healthy follicles; (3) the abnormal response to gonadotropins is best characterized by *enhanced* sensitivity to FSH (and LH) in a subpopulation of follicles; and (4) those follicles that are hyperresponsive to gonadotropins produce a high enough concentration of circulating estradiol to suppress FSH to a level that is too low to encourage further development of healthy follicles in the cohort. See also the section Etiology and Pathogenesis of PCOS: Anovulation, Androgen Excess, and Disordered Follicle Development. *Source: Data are from Ref. 73 and Ref. 63.*

systematic fashion. An outline of the causes of anovulation is shown in Table 29.1.

Primary Ovarian Insufficiency

The menopause, defined by the last menstrual period, occurs at an average age of 50.7 years in the Western world.[79] Hypergonadotropic hypogonadism before the age of 40 is most commonly taken to be the definition of POI, which has a prevalence of 1%. It is estimated that for every decade before 40, the prevalence of POI is decreased by a factor of 10. Thus, in the presence of normal karyotype, 1:1000 of women at age 30 has POI, and 1:10,000 at 20, and 1:100,000 of women will present with gonadal failure and primary amenorrhea. POI accounts for 20–50% of females presenting with primary amenorrhea and 10% of those with secondary amenorrhea.[80]

The term POI is preferred to premature ovarian failure as it is an all-encompassing term that accounts for the variable course and occasional remission.[81] The term hypergonadotropic hypogonadism is also used to emphasize ovarian origin whereby the raised concentrations of LH and FSH contrast with the low gonadotropins in hypothalamic or pituitary causes of hypogonadism. Gonadal dysgenesis refers to hypergonadotropic hypogonadism with a known genetic cause such as an abnormal 46XY or 45X karyotype and implies that ovarian development was halted at an early stage of embryonic development. In the case of Turner syndrome, however, it is thought that early ovarian development is usually

Iatrogenic	Ovarian damage following pelvic surgery and radiotherapy of chemotherapy during treatment of cancer
Environmental factors	Viral infections and toxins such as pesticides are presumed

normal but that the chromosomal anomaly leads to rapid germ cell apoptosis.[82]

Diagnosis of POI

The clinical presentation of POI is variable.[83,84] Very early onset in adolescence leads to pubertal delay, with failure to achieve Tanner breast stage 2 by the age of 13 together with primary amenorrhea. After menarche, the presentation is with symptoms of estrogen deficiency and secondary amenorrhea or as part of a workup for infertility or menstrual disturbance. In addition, POI can be part of rare syndromic conditions that can be genetic or autoimmune in origin.

The diagnosis is based on the finding of elevated serum FSH (>40 IU/L) on at least two occasions separated by a few weeks. The requirement for two samples takes into account the natural history of POI (which can fluctuate) and because the diagnosis is so devastating that certainty is required. While it is the expectation that the condition will usually be permanent, some women follow an unpredictable course of relapse and remission, particularly in the first year after diagnosis.[85] There is a commonly quoted pregnancy rate of approximately 1–5% in women with POI, and it is therefore important to inform women with POI of this phenomenon so that they use contraception when appropriate. Because of this background fertility, case reports of effective treatment of POI must be viewed with caution. Fluctuating ovarian function probably accounts for many cases where the older term "resistant ovary syndrome" was applied, and it is now understood that ovarian biopsy is not predictive of remission (the presence or absence of follicles in the biopsy did not correlate with resumption of ovarian function or chance of pregnancy)[85] and should no longer be included as part of the workup of POI. AMH has found a place as a diagnostic marker of ovarian reserve, but once hypergonadotropic amenorrhea is established it offers little extra information.[86]

A careful family history can identify other affected female members in as many as 30% of cases,[87] and in this situation more extensive genetic screening is indicated and genetic counseling for relatives may be appropriate. In routine practice, the only widely available tests currently available for familial POI are karyotype and fragile X (FRAXA) premutation screening.[88] Karyotype assessment should be considered in those with a family history or unusually early onset of POI, and FRAXA should be offered to all women with POI because of its value in detecting a new pedigree at risk of fragile X syndrome.

The etiology of POI is diverse, with multiple mechanisms leading to the same clinical picture.[89] Table 29.2 shows the main categories of pathogenic mechanisms that lead to ovarian insufficiency. Despite diagnostic advances, particularly in the identification of genes causing POI, there remains a large proportion of cases for whom the etiology is unknown.[84]

Pathogenesis of POI

GENETIC CAUSES OF POI

A genetic etiology for POI is suggested not only by a positive family history, which may be present in 30% of cases, but also if there are features of an associated syndrome (Table 29.3). Cytogenetic chromosome anomalies occur in about 2% of cases, with the majority involving the X chromosome.[90–92]

X chromosome defects and Turner syndrome: Defects of the X chromosome associated with POI include complete or partial deletion of one X (Turner syndrome),

TABLE 29.3 Genetic Syndromes Associated with Primary Ovarian Failure

Syndrome	Gene Locus

trisomy X, or X-autosome translocations. In the case of Turner syndrome variants, there is a great deal of variability in severity of the condition, and this corresponds approximately to genotype and the amount of X chromosome disruption. Ovarian histology can vary from streak ovaries to those with well-preserved ovarian structure with numerous follicles. Those with monosomy X (45X) tend to be the most severely affected, while those with partial deletions of the X chromosome or mosaic 45X or 46XX karyotype often lack the typical phenotypic features of the syndrome but may present with only ovarian insufficiency and secondary amenorrhea. Amongst women with Turner syndrome, the prevalence of ovarian failure is between 80% and 90%, with most associated with primary amenorrhea and complete pubertal delay.

X chromosome deletions appear to segregate into two specific regions: POI1 at Xq26-qter and POI2 at Xq13.3–Xq21.1.[93,94] There are various proposed mechanisms by which X chromosome defects cause POI. Genes responsible for ovary development and/or oogenesis located along these critical regions may be interrupted, although breakpoint genes that determine ovarian function have not been convincingly identified. That is, although genes disrupted by breakpoints have been identified in women with POI, these have not subsequently been shown to necessarily be causal mutations by screening affected populations.[90] Many breakpoints on the X chromosome occur in regions where known genes are scarce, leading to the possibility that long-range position effects on the expression of flanking genes account for the adverse effect on ovarian function. It seems most likely, however, that structural rearrangements of the X chromosome do not affect single genes but rather disrupt normal pairing at meiosis, leading to meiotic arrest and subsequent follicle atresia. It must also be noted, however, that some X chromosome breakpoints are not associated with POI.[94]

Single-gene defects causing POI: A growing number of genes have been linked to ovarian failure, although the strength of evidence linking each anomaly with POI is variable.[95] The most clinically useful genetic association is that between carriers of the fragile X premutation and ovarian failure. Premutations in the *FMR1* (fragile X and mental retardation) gene occur in 3% of women with sporadic POI and 15% of those with the familial form, and screening for mutations of this gene is all that is currently advised in the United Kingdom as part of a routine workup of POI.[96] In general, the phenotype of this subgroup of women with POI is indistinguishable from others, although a minority is reported to suffer a progressive neurological deficit in the form of an intention tremor. The pathway by which *FMR1* premutations damage ovarian function is unclear as the described variants of this gene (notably expansion of exon 1) are not thought to affect protein transcription, even though the protein is expressed within the ovary. It is probable that noncoding RNAs are responsible for the molecular pathogenesis.[91]

AUTOIMMUNE CAUSES OF POI

Autoimmune mechanisms may be involved in pathogenesis of up to 30% of cases of POI.[97] POI has been reported to be associated with various endocrine (thyroid, adrenal, hypoparathyroidism, diabetes mellitus, and hypophysitis) and nonendocrine autoimmune disorders (chronic candidiasis, idiopathic thrombocytopenic purpura, vitiligo, alopecia, autoimmune hemolytic anemia, pernicious anemia, systemic lupus erythematosus (SLE), rheumatoid arthritis, Crohn's disease, Sjogren's syndrome, myasthenia gravis, primary biliary cirrhosis, and chronic active hepatitis).[98,99] In many cases, nonovarian autoimmune involvement exists only at subclinical levels.[100,101] POI may be part of the autoimmune polyglandular syndromes (APSs) when accompanied by other autoimmune endocrinopathies. POI is more common with APS types I and III than with APS type II. The single most common autoimmune association is with hypothyroidism, which occurs in 10% of women with POI.

Various pathways of autoimmune ovarian damage have been described, but a reliable ovarian specific autoimmune marker is still lacking. Several putative pathogenic autoantibodies have been explored.[102] Antiovarian antibodies detected by routine *immunofluorescence* have been reported in several studies of women with POI, but their specificity and pathogenic roles are questionable. The incidence of antiovarian antibodies in POI in different studies has been reported to vary from 4% to 69%.[103] Other candidate autoantibodies include those directed against steroidogenic enzymes (such as 3β-hydroxysteroid dehydrogenase), gonadotropins and their receptors, the corpus luteum, the zona pellucida,

and oocytes. None of these, however, have been validated as a prime mover in the process or found to be useful as a diagnostic marker of autoimmune ovarian failure.[104] Therefore, in the clinical workup of POI, screening for an autoimmune etiology is usually only possible by seeking coexisting autoimmune diseases. One report has shown raised serum inhibin to be a distinguishing feature of autoimmune POI compared to other forms, but whether this will be sufficiently robust to be clinically useful is not yet clear.[105]

An animal model of autoimmune oophoritis that develops in mice after neonatal thymectomy has helped in understanding the potential pathogenic mechanisms of autoimmune POI and ovarian antigens.[106] Animal and human disease both show a similar histological distribution of ovarian lymphocytic infiltration, the production of antiovarian autoantibodies, and a reduced natural killer cell activity. In the mouse model, altered T cell regulation has been implicated in the pathogenesis of ovarian failure, and cells with a T helper phenotype can mediate the oophoritis.

Women with idiopathic POI show an increased number of activated T cells in peripheral blood. Similar findings have been described in other autoimmune endocrinopathies, such as recent-onset Graves' disease, type 1 diabetes mellitus, and Addison's disease. However, postmenopausal women also show raised numbers of activated peripheral T cells, and estrogen substitution has been shown to lower the number of activated peripheral T cells in women with POI. Therefore, it is difficult to be certain whether the raised numbers of activated blood T cells are the cause or the result of ovarian failure in this situation.[98]

MISCELLANEOUS CAUSES OF POI

Viral oophoritis is a possible occult etiology that could theoretically account for the many cases of idiopathic POI. There is, however, little direct evidence of viral ovarian damage beyond case reports such as mumps oophoritis.[107] Cigarette smoking is known to be associated with earlier age of natural menopause, but whether environmental effects are sufficiently strong to cause POI is unlikely. The available data regarding the effects of endocrine disruptors, heavy metals, solvents, pesticides, plastics, and industrial chemicals on female reproduction are equivocal.[108]

Management of POI

The major medical issues for health surveillance in women with POI revolve around the quality of life and bone protection offered by hormone replacement therapy (HRT). Options for reproduction include oocyte donation, but adoption should not be overlooked. Women also require personal and emotional support to deal with the impact of diagnosis on their health and relationships. Long-term follow-up is essential to monitor HRT and to consider emerging associated autoimmune pathology.

Deficiency and Disordered Regulation of the Gonadotropins

Abnormalities of gonadotropin secretion account for about 30% of women with either oligo- or anovulation and are found in over 50% of those who present with amenorrhea. Whereas primary pituitary deficiency of gonadotropins is rare, abnormal hypothalamic regulation of gonadotropin secretion is common, whether functional (in which there is no structural pathology—the most frequent form) or organic in origin. In recent years, the discovery of "new" peptides such as kisspeptin, which have an important role in the afferent input into the GnRH neuronal network, has added to our increasing understanding of how the hypothalamic regulation of gonadotropin regulation is subject to influence by environmental factors, particularly those related to energy balance.

Specific Organic Disorders of Gonadotropin Secretion

Organic causes of gonadotropin deficiency (with the exception of hyperprolactinemia) are relatively uncommon but important to recognize. The underlying reasons include specific deletions or modifications of the genes encoding key peptides in the hypothalamic regulation of gonadotropin synthesis and secretion, and destructive lesions of the pituitary or hypothalamus. A comprehensive list of hypothalamic causes of anovulation is shown in Table 29.4. The causes include developmental abnormalities and destructive granulomatous or primary neoplastic lesions, as well as (rarely) secondary deposits of systemic neoplasia.[89] There is often, in such cases, evidence of deficiency of other pituitary hormones, including growth hormone, thyrotropin, and adrenocorticotropic hormone. There may also be involvement of the neurohypophysis, and the consequent, additional presentation with diabetes insipidus is a clear indication of a destructive hypothalamic lesion.

KALLMANN SYNDROME AND ITS VARIANTS

There has been an explosion of knowledge about Kallmann syndrome and its variants, particularly in the last decade when increasing sophistication of genetic analyses uncovered numerous susceptibility loci as a major etiological factor in congenital aberrations in the GnRH neuronal network. Indeed, there is recent evidence that there may be a genetic predisposition to functional disorders of gonadotropin secretion related to weight loss, stress, or exercise, as discussed in this section. Although genetic causes of GnRH deficiency are more common in males than in females, they still represent an important

subgroup in the etiology of delayed puberty in girls and in hypothalamic amenorrhea in adults.

The classic presentation of Kallmann syndrome is the association of hypogonadotropic hypogonadism with anosmia. With the knowledge that Kallmann syndrome was associated with an X chromosome deletion at Xp22.3, Pfaff and colleagues, in a study of fetal tissue carrying that mutation, uncovered the mystery of the link between these features.[109] GnRH neurons were found to originate in the olfactory placode, and later studies in the rodent revealed that these neurons migrate during fetal life, together with the olfactory neurons, toward the medial basal hypothalamus. This process is a complex one and involves several possible mechanisms[110,111] that include a defect in the neural cell adhesion molecule (NCAM) that provides a "scaffold" for migration of both GnRH neurons and the olfactory nerve from the olfactory placode.[112] The Kallmann gene *KAL1* was later found to code for anosmin 1, an extracellular matrix protein implicated in neuronal development and migration.[113]

Since the identification of *KAL1* mutations as a cause of genetic GnRH deficiency, there has been steady progress in understanding the genetic origins of hypogonadotropic hypogonadism, knowledge of which has accelerated impressively in the last decade.[114] This has been an iterative process in which the increasing understanding of the biology of afferent pathways controlling GnRH neuronal secretion has informed genetic studies and in which the finding of novel mutations in patients with GnRH deficiency has led to the discovery of new ligands and their receptors that are functionally important in normal GnRH secretion. Genetic causes of GnRH deficiency can conveniently be categorized according to their developmental origin as (1) disorders of the development and migration of GnRH neurons, or (2) disorders of homeostasis and GnRH deficiency.[114] Of the novel peptides that have been shown to contribute to a functionally important afferent input into the GnRH neural network, it is kisspeptin that has provided one of the most intriguing stories of discovery.[115] The kisspeptin receptor is a G protein-coupled receptor (GPR), and it was the receptor GPR54 that was discovered (by investigators in the cancer field) before the ligand was identified. Targeted deletions of *GPR54* in mice were subsequently shown to cause failure to enter puberty and, around the same time, mutations in *GPR54* were found to be associated with hypogonadotropic hypogonadism in humans.[116,117] Kisspeptin has a key role in the normal function of GnRH secretion, and its therapeutic applications in management of hypogonadotropic hypogonadism are being pursued by several groups.[118] Administration of exogenous kisspeptin increases gonadotropin secretion and may yet prove to be an important means of induction of ovulation in women with hypothalamic amenorrhea (HA). Of particular interest is the observation that a continuous low-dose infusion of kisspeptin10 (a truncated form of the peptide) is capable of producing LH pulses in healthy young males,[119] although it is not yet clear whether, in either males or females, a normal pulsatile pattern can be achieved by such means. Clearly, this observation as well as more recent studies in healthy females raise the possibility of the application of kisspeptin analogs in promoting pulsatile and cyclical gonadotropin secretion in women with hypogonadotropic hypogonadism.[120]

Other key peptides (or their receptors) in the regulatory pathway of GnRH pulse generation include neurokinins and their receptors. Mutations in the neurokinin B gene *TAC3* and its receptor *TACR3* have been found in cases of familial hypogonadotropic hypogonadism.[121] Genetic mutations in genes coding for GnRH itself (*GnRH1*), the GnRH receptor (*GNRHR*), fibroblast growth factor 8 (*FGF8*), and FGF receptor 1 (*FGFR1*), as well as in genes controlling multiple functions during development (e.g., *DAX1*), have also been reported.

Patients with *DAX1* mutations present with adrenal insufficiency together with hypogonadotropic hypogonadism. This rare syndrome is even less common in females but has been reported as a cause of hypogonadism in girls.[122]

PITUITARY TUMORS AND OVARIAN DYSFUNCTION

Generally speaking, hormone-secreting pituitary tumors are amongst the least common causes of disordered ovulation, but the one notable exception is the prolactin-secreting tumor, which is the commonest functional pituitary tumor in both men and women.[123] Indeed, hyperprolactinemia is one of the most common causes of amenorrhea, accounting for upward of 10% of cases.[29] The pathogenesis, presenting features, and diagnostic approach will therefore be described in some detail in the section Hyperprolactinemia, and its management in the discussion of hyperprolactinemia in the section Clinical Management of Ovulatory Disorders. Other pituitary tumors such as somatotrope and corticotrope adenomas are rare causes of anovulation.[124,125]

HYPERPROLACTINEMIA

Hyperprolactinemia has a variety of causes, the most clinically important of which is a prolactin-secreting pituitary tumor (prolactinoma).[123,126] Raised serum prolactin levels are not necessarily pathological; there are physiological variations of prolactin, which include a sleep-related rise that can confound the results of a prolactin measurement taken in an early-morning clinic. Other physiological stimuli are, of course, pregnancy and lactation. Hyperprolactinemia may be a feature of primary hypothyroidism, and so thyroid function tests are important in women with elevated prolactin levels. A variety of pharmaceutical agents can be associated with elevation of serum prolactin, most notably dopamine antagonists including psychotropic drugs such as phenothiazines.[123]

Persistently elevated serum concentrations of prolactin are a common and long-recognized cause of amenorrhea and anovulation (Table 29.1). The syndrome of amenorrhea with galactorrhea (inappropriate lactation) had been reported for many years before the advent of a reliable radioimmunoassay for prolactin in the early 1970s. The development of such assays closely followed the identification of prolactin as a distinct hormone from growth hormone. Until then, these so-called lactogenic hormones were difficult to distinguish from each other biochemically (see the introduction). The application of immunoassays revealed that hyperprolactinemia accounted for upward of 10% of causes of amenorrhea.[29] It was clear that in many cases of hyperprolactinemia, there was radiological evidence of a pituitary tumor. With subsequent improvement in imaging techniques, it is estimated that around 50% of women with hyperprolactinemia have a visible prolactinoma, the majority measuring less than 10 mm in diameter and termed microprolactinomas.

The key endocrine features of hyperprolactinemic amenorrhea are estrogen deficiency associated with low or normal gonadotropin levels.[127] This profile is usually indicative of a hypothalamic disorder of gonadotropin regulation, and indeed this appears to be the major mechanism underlying the failure of ovulation. That hypersecretion of prolactin impacts the GnRH pulse generator (rather, by exerting effects at the level of the pituitary or ovary) is suggested by aberrant pulsatile gonadotropin secretion and borne out by the finding that the administration of exogenous, pulsed GnRH results in ovulatory cycles in the face of persistent hyperprolactinemia.[128]

Functional Disorders of Gonadotropin Regulation

Functional hypothalamic amenorrhea (FHA) is discussed in Chapter 36 but will be briefly considered here. Functional disorders of gonadotropin regulation include women with weight loss-related or exercise-related amenorrhea in which the common feature is energy deficiency associated with low body-fat composition. Conversely, obesity may be associated with reproductive dysfunction, but the adverse effect of obesity on menstrual cyclicity is affected predominantly by an interaction with PCOS (see the section Polycystic Ovary Syndrome). The patterns of pulsatile gonadotropin in weight loss-related amenorrhea may vary according to the severity of the disorder (Figure 29.7). There is also an important group of women with idiopathic hypothalamic hypogonadism in whom changes in body composition are less evident but who often manifest a psychological profile that is suggestive of a stressful lifestyle.[129] Although women with FHA have no organic cause for their hypothalamic dysfunction, it is clear that other elements of the endocrine system may be disturbed, including particularly the hypothalamic–pituitary–adrenal and hypothalamic–pituitary–thyroid axes.[129] Berga has suggested that a common feature in the etiology of FHA is stress, both psychological and metabolic.[129–131] Even in women with FHA, there may be a genetic predisposition to develop disordered gonadotropin secretion.[132]

Anovulation and amenorrhea associated with exercise are yet another example of the complex interaction of environmental influences on the HPO axis.[131,133] Excessive exercise, for example amongst competitive, long-distance athletes,[134] may in itself be responsible for the energy deficiency that results in compromised GnRH secretion. However, psychogenic factors may also have an important role in amplifying the effects of exercise.[129,131]

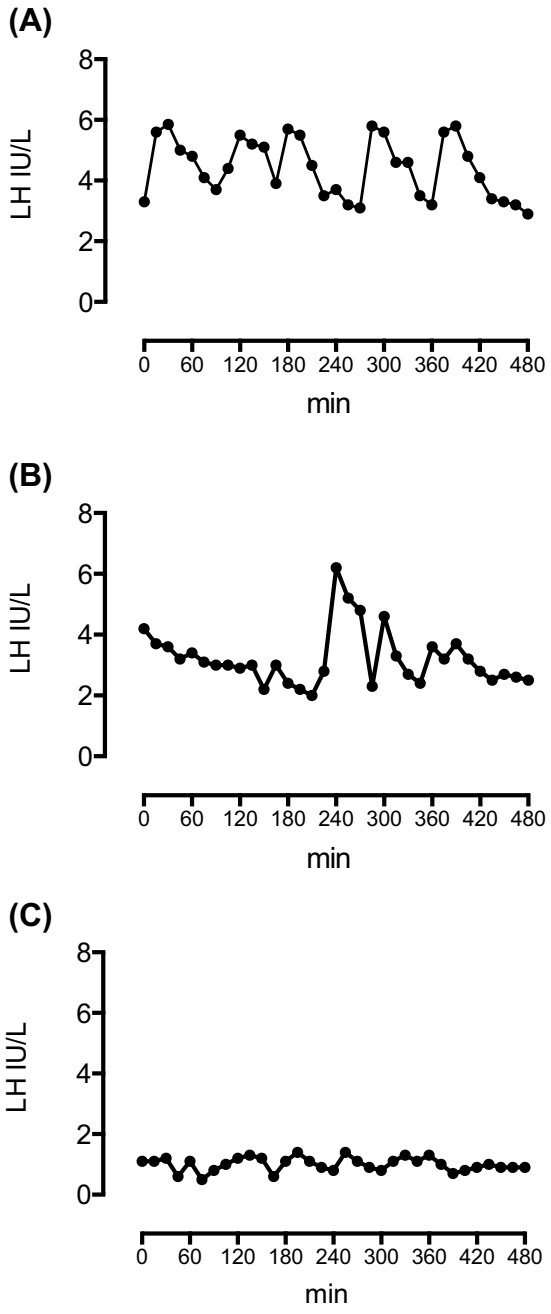

FIGURE 29.7 LH secretory patterns in (A) a normal woman with regular menses, studied in the midfollicular phase; (B) a woman with partially recovered weight loss-related amenorrhea; and (C) a woman with a persistently low BMI.

Polycystic Ovary Syndrome

PCOS is the commonest endocrine disorder in women, and it is now recognized that not only is PCOS the most frequent cause of anovulatory infertility and of hirsutism, but also it is associated with characteristic metabolic abnormalities that may carry an increased risk, in the long term, for the development of type 2 diabetes mellitus (T2DM) and cardiovascular disease. However, the etiology remains uncertain. The heterogeneity of the clinical presentation has inevitably raised the question as to whether PCOS is one disorder or whether its origins are as variable as its manner of presentation. There remain critical questions and controversies not only regarding the etiology of the syndrome but also in diagnostic criteria, investigation, and management of this complex disorder.

Clinical Aspects of PCOS

DEFINITION AND DIAGNOSIS OF PCOS

There has always been debate about the definition of PCOS, and it seems likely to remain so until the specific cause or causes of the syndrome can be elucidated. The classic definition, arising from the National Institute for Child Health and Human Development (NIHCD)- sponsored conference on PCOS in 1990, includes the clinical manifestations of anovulation and hyperandrogenism in women[135]; obesity is a common but not universal accompaniment. Typically, but not exclusively, these features are associated with hypersecretion of LH and androgens but with normal, or slightly low, serum concentrations of FSH. In recent years, the ability to identify PCOS by pelvic ultrasonography (because of multiple antral follicles and increased ovarian stroma) has provided new insight into the spectrum of clinical and biochemical presentation of women with a polycystic morphology of the ovaries.[136,137] It is now evident that this spectrum includes both anovulatory women who are without hirsutism (but are usually hyperandrogenemic) and, conversely, those who are hirsute and have regular ovulatory cycles (but may also have elevated serum LH concentrations). Thus, irrespective of clinical presentation, there is a typical pattern of biochemical abnormalities that seems to unite these subgroups of women with ultrasound evidence of polycystic ovaries.

The recognition that the spectrum of presentation of women with PCOS is broader than was first thought has led to a revision of the diagnostic criteria for PCOS. The joint European Society for Human Reproduction and Embryology–American Society for Reproductive Medicine (ESHRE–ASRM) consensus meeting on PCOS, held in Rotterdam in May 2003, resulted in the recommendation that the definition of PCOS be revised to encompass women with hyperandrogenism and polycystic ovaries but who had regular cycles (see Table 29.5). This definition, like the classic definition, excludes patients who have polycystic ovaries on ultrasound but in whom the primary diagnosis is of pituitary or adrenal diseases (e.g., hyperprolactinemia, acromegaly, and classical or nonclassical congenital adrenal hyperplasia). To add to this definition, the Androgen Excess and PCOS Society (AE-PCOS) suggested a set of diagnostic criteria that was essentially a compromise between the "NICHD" and "Rotterdam" criteria, in that it includes women

TABLE 29.5 Diagnostic Criteria for PCOS

NIH 1990	Rotterdam 2003	AE-PCOS Society 2006
1. Chronic anovulation 2. Clinical and/or biochemical signs of hyperandrogenism (with exclusion of other etiologies, e.g., congenital adrenal hyperplasia) *(Both criteria needed)*	1. Oligo- and/or an-ovulation 2. Clinical and/or biochemical signs of hyperandro genism 3. Polycystic ovaries *(Two of three criteria needed)*	1. Clinical and/or biochemical signs of hyperandrogenism 2. Ovarian dysfunction (oligo-an-ovulation and/or polycystic ovarian morphology) *(Both criteria needed)*

with hyperandrogenism and regular cycles but excludes women with oligomenorrhea without clear evidence of androgen excess.[138] Despite some inconsistencies in results between groups (that may be attributed to different methods of diagnosis), comparative studies have demonstrated that there is a high degree of concordance of ultrasound with histological features of polycystic ovaries and with clinical and endocrine evidence of the syndrome.

The report of the recent NIH Office of Disease Prevention Evidence-based Methodology Workshop on Polycystic Ovary Syndrome recommended that the broader diagnostic criteria were the more generally applicable and practical (http://prevention.nih.gov/workshops/2012/pcos/resources.aspx).

PREVALENCE AND PRESENTATION OF PCOS

PCOS is a highly prevalent disorder. The "classic" syndrome (i.e., the combination of oligo-amenorrhea and androgen excess) may be found in more than 5% of women of reproductive age. Using ultrasonographic, clinical, and endocrine criteria, it has been estimated that PCOS accounts for about 30% of women presenting with secondary amenorrhea, more than 80% of women with oligomenorrhea, and, perhaps most surprisingly, between 60% and 90% of women with hirsutism but who have regular menses. PCOS accounts for 75–85% of cases of anovulatory infertility. The prevalence of obesity in women with PCOS varies from 35–40% to over 70%. Its presence influences the clinical presentation of women with polycystic ovaries; hirsutism and menstrual disturbances are significantly more common in obese compared with lean subjects.

The characteristic endocrinopathy of raised mean levels of serum androgens and LH has been reported in all published series of women with PCOS, but the variation in LH levels between individuals (which depends on not only the criteria for diagnosis but also the method of measurement) means that the diagnostic value of a single hormone measurement is limited. The heterogeneity of LH is evident even when evaluating episodic release of LH (Figure 29.8). Similarly, although serum concentrations of testosterone and androstenedione are elevated in women with PCOS, there is a good deal of variation from patient to patient. This is illustrated by the observation that anovulatory but nonhirsute women with polycystic ovaries may have hyperandrogenemia whilst hirsute women with polycystic ovaries may have normal serum androgen levels. This phenomenon may be explained by the fact that both production and clearance of androgens are increased in women with hirsutism.[139] Low serum concentrations of sex hormone-binding globulin (SHBG)—the principal transport protein for testosterone in the blood—may contribute to increased clearance of testosterone. Blood levels of SHBG are inversely correlated with body mass index (BMI),[140] which may help to explain why obese subjects with PCOS are more likely to be hirsute than their lean counterparts, despite similar serum levels of testosterone. The effects of obesity on SHBG are likely to be mediated by insulin.[141,142] The relevance of hyperinsulinemia and insulin resistance to PCOS is discussed in this chapter.

Other hormonal abnormalities, including hyperprolactinemia and impaired secretion of growth hormone, have been described in women with PCOS. Moderate hyperprolactinemia occurs in 5–10% of women with typical clinical and biochemical features of PCOS.[143,144] The significance of hyperprolactinemia in PCOS remains unclear. Impaired growth hormone secretion in women with polycystic ovaries may simply be a function of accompanying obesity rather than a specific feature of the syndrome.

METABOLIC ABNORMALITIES AND THEIR CLINICAL CONSEQUENCES IN WOMEN WITH POLYCYSTIC OVARIES

The reproductive consequences of PCOS have been recognized for several decades, but over the last 25 years there has been an increasing number of studies illustrating that the syndrome is also associated with a characteristic metabolic disorder.[143,145,146] This, in turn, has led to concern about the impact of PCOS on long-term health, particularly with regard to the advent of diabetes and coronary heart disease.[147] The central features of the metabolic disturbance are peripheral insulin resistance and hyperinsulinemia.[148] The mechanism of these disturbances is not certain, but there is evidence for intrinsic abnormalities of both insulin action and pancreatic beta cell function.[146] There is an important interaction of polycystic ovaries with body weight so that whilst lean women with PCOS often have normal insulin levels and sensitivity, the majority of those whose BMI is greater than 30 kg/m^2 have reduced insulin sensitivity compared with weight-matched controls.[149,150] It is not surprising, therefore, that obese young women with

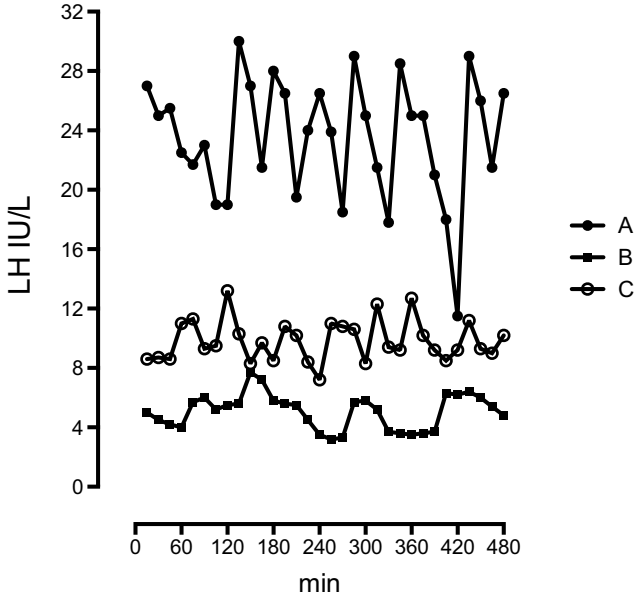

FIGURE 29.8 Heterogeneity of pulsatile LH secretion in women with PCOS showing (A) elevated mean LH and high-amplitude pulses; (B) levels of LH that fall into the normal range (2–12 U/L) (although still above the mean level in normal subjects), with occasional high-amplitude pulses; and (C) normal mean LH and normal pulse amplitude.

PCOS have a high prevalence of impaired glucose tolerance (and indeed, some may have frank diabetes), and there seems little doubt that women with PCOS have a significantly increased risk of developing T2DM in later life.[151] As yet, long-term follow-up studies have been few and far between, but in one epidemiological analysis of a large cohort of women with a history of PCOS (mean age: 57 years), the relative risk of T2DM was found to be three times that of the reference population.[152] Abnormalities of lipids and lipoproteins have also been widely reported in women with PCOS, but it remains uncertain whether these are independent of the effects of obesity.[153]

These metabolic features, together with centripetal fat distribution, constitute a cluster of risk factors for cardiovascular disease, and this has been a major concern in considering the long-term management of patients with PCOS.[147] However, interpretation of the significance of the metabolic abnormalities in terms of cardiovascular risk is by no means easy. First, there are inconsistencies between studies in the features of the dyslipidemia; and, second, it is not yet clear how the combined risk factors translate into a real risk of developing cardiovascular disease.

The remaining uncertainties surrounding the reports of the dyslipidemia of PCOS emphasize the importance of counseling caution about pronouncing on the implications for cardiovascular health of a diagnosis of PCOS in young women. Whilst there seems little doubt that PCOS, independently of obesity, constitutes a significant risk factor for T2DM, there is, at present, no direct evidence for increased morbidity or mortality from coronary heart disease. Endothelial dysfunction and ultrasound evidence of carotid intima-medial abnormalities have been reported in young and middle-aged women with PCOS,[154,155] but these must still be regarded as surrogate indices of cardiovascular disease. Epidemiological data available to date provide no conclusive evidence of an increase in morbidity or mortality from coronary heart disease in a population of middle-aged or elderly women with a history of PCOS.[156,157] However, it is quite conceivable that the incidence of coronary heart disease will diverge from normal as this cohort of middle-aged women grows older. Further long-term follow-up studies are required before a definitive link can be established. It has already been demonstrated that lifestyle changes (especially in diet) can markedly improve the metabolic profile of obese women with PCOS[158–160] and, at the very least, can be expected to reduce the chance of developing T2DM. Metformin and other insulin-sensitizing agents also have a part to play in limiting the impact of the metabolic complications of PCOS.[147,161]

Etiology and Pathogenesis of PCOS: Developmental, Genetic, and Environmental Factors

The precise etiology of PCOS remains uncertain, but there is now a wealth of data from both human studies and animal models that has brought a new understanding of genetic and environmental factors that have a major impact on the genesis of PCOS. This knowledge has progressed hand in hand with new insights into the mechanisms of anovulation and the nature of the metabolic disturbances that are characteristic of the syndrome.

EVIDENCE FOR DEVELOPMENTAL ORIGINS OF PCOS

It has been proposed that PCOS has its origins in early life and that the polycystic ovary is genetically predisposed to hypersecrete androgens, certainly at puberty but also in the early postnatal period or even during fetal development[162] (Figure 29.9). It is very unlikely that maternal androgen excess affects fetal exposure to androgen because high circulating concentrations of SHBG and placental aromatase activity provide an effective barrier between mother and fetus.[162,163] The dogma has been that the fetal ovary is not steroidogenically active, but recent data indicate that somatic cells in the human fetal ovary clearly express CYP17A1 (17-α-hydroxylase/17–20 lyase), the key enzyme in androgen biosynthesis.[164]

Extrapolating from studies in the prenatally androgenized (PA) rhesus monkey or sheep, the hypothesis is that increased exposure to androgens during development leads to the abnormalities of endocrine and metabolic

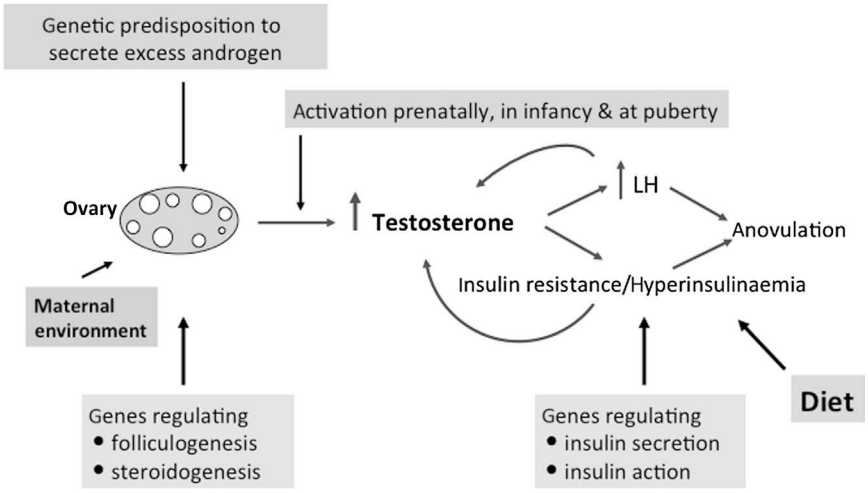

FIGURE 29.9 Proposed developmental etiology of polycystic ovary syndrome (PCOS).[162,163] It is suggested that the ovary is genetically predisposed to hypersecrete androgens, perhaps as early as intrauterine life but certainly during the activation of the hypothalamic–pituitary–ovarian axis that occurs transiently in infancy and in a sustained manner at puberty. Higher than normal circulating levels of testosterone "program" the hypothalamic–pituitary unit to produce high tonic levels of luteinizing hormone (LH), and also amplify the physiological insulin resistance of puberty. Higher than normal concentrations of LH and insulin further enhance ovarian androgen production and may contribute to the mechanism of anovulation.

function that are characteristic of PCOS. Indeed, both the PA rhesus monkey and the PA sheep have proved to be instructive models in understanding the development of PCOS in humans, and have pointed to a key role for androgens in the etiology of both reproductive and metabolic manifestations of this disorder. The PA rhesus monkey, during adulthood, displays abnormal ovarian morphology, ovarian hyperandrogenism (and adrenal androgen excess), hypersecretion of LH, insulin resistance, and anovulation in relation to increased body weight.[165–168] Studies to date in the PA sheep have yielded similar findings with respect to reproductive and metabolic sequelae.[169]

If it is reasonable to hypothesize that genetically regulated androgen excess has a key role in the etiology of PCOS, it is nevertheless important to consider the effects of environmental factors, particularly nutritional influences (Figure 29.9). Prenatally, whereas maternal androgens are unlikely to affect the fetus for the reasons stated here, it remains entirely possible that the metabolic status of the mother does have an impact, for example in the case of maternal diabetes or simple obesity. Certainly, in the postnatal life of the adolescent girl or adult with symptoms of PCOS, diet can have a profound influence on phenotype (as discussed in this chapter).

EVIDENCE FOR A GENETIC BASIS OF PCOS

PCOS is more common within families than in the general population, it has a greater concordance between identical twins than dizygotic twins, and there is evidence for heritability of biochemical traits. These features provide strong evidence for major genetic influence in the etiology of PCOS.[158,166] Given the heterogeneity of PCOS, it has always seemed likely that the genetic basis of PCOS, as in other complex endocrine traits (such as T2DM), involves the interaction of small effects contributed by polymorphisms at several susceptibility loci. The very diversity of presenting features of PCOS raises the prospect of several candidate biochemical pathways to explore in searching for genes involved in the etiology of PCOS. Thus, genes implicated in ovarian follicle development (e.g., those in the TGFβ family), genes involved in the androgen biosynthetic pathway (e.g., *CYP11A*, *CYP17A1*, and *CYP19*), and those affecting insulin secretion or action (e.g., transcription factor 7-like 2 (*TCF7L2*); potassium inwardly rectifying channel, subfamily J, member 11 (*KCNJ11*); insulin receptor; and peroxisome proliferator-activated receptor gamma (*PPARγ*)) have all been cited as plausible candidates. But despite the exploration of more than 150 candidate genes, this approach has, so far, yielded disappointing results. Findings have often been ambiguous because of relatively small sample sizes (i.e., seriously underpowered) and because of genetic and phenotypic heterogeneity within a study population. Importantly, very few of the candidate loci that have been implicated have been confirmed by replication in a subsequent and separate population.[170,171]

There is, however, good evidence for a role in PCOS for the genes coding for fibrillin 3 (FBN3) and the fat mass- and obesity-associated (*FTO*) genes. Evidence for linkage disequilibrium was observed at D19S884, a dinucleotide repeat marker on chromosome 19p13.2.[172–174] Genotyping of the region around D19S884 subsequently identified the *FBN3* gene as a likely candidate for the PCOS susceptibility gene. The association of the *FTO* locus (on chromosome 16) and T2DM and obesity led researchers to explore a role for this gene in the etiology of PCOS. In a case-control study, an association was found between PCOS status and *FTO* genotype.[175] *FTO* variants that were known to predispose to obesity were also implicated in altered susceptibility to PCOS, confirming the mechanistic link between these conditions. Confirmation of the association between *FTO* and PCOS has been provided in studies of other populations[176] and results of a recent meta-analysis support the view

that variation at the *FTO* locus contributes to the etiology of PCOS. Although its role in the genetic makeup of PCOS is predominantly by increasing the susceptibility to obesity (and therefore "amplifying" the phenotype of PCOS), there is limited evidence that polymorphisms in *FTO* contribute to the etiology of PCOS by a mechanism that is independent of body fat mass.[175]

In summary, the candidate gene approach to PCOS has been largely unproductive and, researchers have, not surprisingly, turned their attention to genome-wide association studies (GWAS) of the kind that has paid dividends in the search for genes in T2DM. Although this requires considerable resources in the study of very large case-control populations, early studies have already proved informative. The first reported GWAS identified susceptibility loci for PCOS on chromosome 2p16.3, 2p21, and 9q33.3 in a population of 744 Han Chinese women, and although this was a relatively small sample for a GWAS (compared, e.g., with those employed in studies of T2DM genes), results were replicated in two further populations of Han Chinese[177] and subsequently in other large Chinese cohorts.[178,179] Further evidence implicating the chromosome 2p16.3 locus in the etiology of PCOS comes from a replication series of women of European ancestry.[180] The significance of this locus is that this is the region of DNA in which genes coding for gonadotropin receptors *FSHR* and *LHCGR* are found. Other reproducible variants that were identified initially in the Chinese studies were at the loci for DENND1A (Differentially expressed in normal and neoplastic cells (DENN) domain-containing protein 1A; associated with Rab function in membrane trafficking) and THADA (thyroid-associated protein). Significantly, these findings have been reproduced in recent studies of populations of European origin, suggesting that these pathways may play a part in the genetic origin of PCOS.

Etiology and Pathogenesis of PCOS: Anovulation, Androgen Excess, and Disordered Follicle Development

Oligo- or anovulation is a key clinical feature of PCOS, but there still remains doubt about the mechanism of ovulatory disorders in women with PCOS. The endocrine features of women with anovulatory PCOS include disordered gonadotropin secretion, metabolic abnormalities, and discordant ovarian follicular function. There is much debate about which of these disorders is the primary drive to anovulation, but a strong case can be made for suggesting that there are intrinsic ovarian abnormalities in PCOS that underpin the etiology of anovulation. Anovulation in PCOS is characterized by arrest of antral follicles during the final stages of maturation, that is, typically between 5 and 8 mm in diameter, which is just below that expected of the emerging dominant follicle during a normal cycle.[63] This failure to select, or to complete normal development of, a dominant follicle is almost certainly related to the abnormal endocrine environment. However, there is now evidence that the earliest stages of follicle development, including activation of primordial follicles, are disrupted in anovulatory women with PCOS.

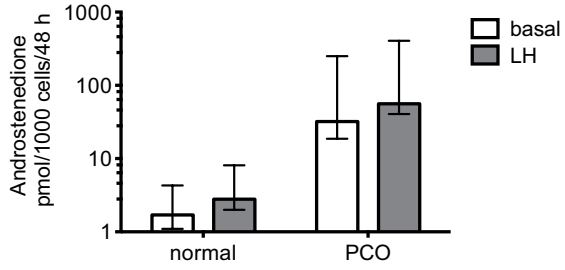

FIGURE 29.10 Production of androstenedione (median, range) by human theca cells in primary culture. Greatly increased androgen production by cells from women with polycystic ovaries is shown. Note the logarithmic scale of the Y-axis. LH stimulated androstenedione production by both normal (1.7-fold) and PCO theca (1.8-fold, $p < 0.005$). *Source: Adapted from Ref. 182.*

Although anovulation is very common in PCOS (and indeed considered to be invariable by the NICHD diagnostic criteria), the biochemical hallmark of PCOS is hypersecretion of ovarian androgen. As described in this chapter in discussing the possible developmental origins of PCOS, ovarian production of excess androgen not only is an important contributory factor in the clinical abnormalities in PCOS, but also may play a central part in the etiology of the syndrome itself. In the remainder of this subsection, abnormalities of antral follicle function (of both theca and granulosa compartments), of related features of gonadotropin secretion, and of preantral follicle development will be described in some detail.

ABNORMAL ANTRAL FOLLICLE DEVELOPMENT: THECA

Hypersecretion of androgens is the most consistent biochemical abnormality in women with PCOS,[181] and the hyperandrogenism is associated with what must be considered to be an intrinsic abnormality of theca cell function. Human theca cells that are derived from women with PCOS have been shown to produce androgens in great excess of the amounts secreted by theca from the ovarian follicles of normal women[182] (Figure 29.10). Production of intermediate steroids in the androgen biosynthetic pathway was also increased, suggesting a global upregulation of steroidogenic enzymes. Such abnormalities of cells in primary culture might be attributed to the abnormal endocrine environment from which the cells were derived (e.g., higher than normal levels of LH and/or insulin), but it is significant that a similar overall increase in steroidogenesis has been noted in theca cells that have undergone several passages in culture.[183,184] Theca cells from polycystic ovaries are

therefore characterized by constitutively increased activity of steroidogenic enzymes. The origin of theca cells in the ovary, and the paracrine signals that guide the recruitment of theca cells to the follicle, remains rather mysterious, and it is legitimate to question whether the primary etiological abnormality in PCOS has its origins in the very earliest stages of follicular development (see the section Abnormal Preantral Follicle Development in PCOS).

ABNORMAL ANTRAL FOLLICLE DEVELOPMENT: GRANULOSA

Perhaps the most important feature in understanding the mechanism of anovulation in women with PCOS is that antral follicles derived from polycystic ovaries show considerable heterogeneity in terms of steroid production and responsiveness to gonadotropins.[185–188] In studies of follicles obtained from unstimulated human ovaries, granulosa cells from small to medium-sized antral follicles (1–9 mm in diameter) taken from women with ovulatory cycles and normal ovaries showed, as expected, a variable response to FSH and no response to LH in terms of production of estradiol and progesterone.[187] There was much more heterogeneity of responsiveness amongst follicles from anovulatory women with PCOS than in follicles obtained from women with a history of ovulatory cycles. Importantly, among small antral follicles (2–9 mm), some were inappropriately responsive to LH.[187] Such premature responsiveness of granulosa cells is likely to result in terminal differentiation of granulosa cells[189] in that subpopulation of follicles and therefore premature arrest of follicle growth. These prematurely advanced follicles are very likely to contribute to circulating estradiol levels in anovulatory women with PCOS that typically are slightly higher than those seen in the early follicular phase of a normal ovulatory cycle. The consequence of this would be suppression of FSH serum concentrations that, whilst in the normal midfollicular phase range, are at a level that is below that seen during the intercycle rise in FSH and consequently below the "threshold" required for the recruitment and progression of antral follicles during the follicular phase. In this way, the further development of normal healthy follicles within this heterogeneous cohort will also be arrested[63,73] (see Figure 29.7). This phenomenon would explain why modest elevation of serum FSH, by the use of antiestrogens or by giving exogenous FSH, usually restores ovulatory cycles; the prematurely advanced follicles remain arrested, but the healthy follicles are able to progress.

As mentioned here, it is the abnormal endocrine environment that seems most likely to be implicated in arrest of antral follicle development. It has been suggested that both hyperinsulinemia and hypersecretion of LH contribute to arrested follicle growth.[77,190,191] Insulin augments the steroidogenic response to LH in cultured granulosa cells from human ovarian follicles.[77] There is evidence that even in a state of peripheral insulin resistance, granulosa cell steroidogenesis remains sensitive to insulin.[77,192]

ABERRANT GONADOTROPIN SECRETION IN PCOS

Abnormalities of gonadotropin secretion are common but not invariable in women with anovulatory or oligo-ovulatory PCOS, and it remains a matter of debate whether such abnormalities are key to the etiology of anovulation or whether they occur secondary to disordered ovarian function. In any case, it is clear that, once established, the pattern of abnormal ovarian function can be sustained by an interaction of hypothalamic–pituitary and ovarian effects. The characteristic pattern is of hypersecretion of LH but with serum FSH concentrations that are typically within the normal midfollicular phase range but are inappropriately low (as discussed in this chapter).[193,194] The pulsatile pattern of LH is often abnormal in that both the amplitude and frequency of LH pulses are increased compared with the profile in the normal follicular phase. However, during a spontaneous or induced ovulatory cycle, the pattern of LH secretion normalizes, indicating that aberrant gonadotropin patterns are due, at least in part, to inappropriate negative feedback (i.e., low estradiol, particularly lack of cyclical progesterone).[194] Nevertheless, abnormal LH secretion, if less obvious, may still be observed even in women with polycystic ovaries who have ovulatory cycles,[195] together with evidence of impaired progesterone-mediated suppression of LH. Women with polycystic ovaries had serum LH levels that were significantly less suppressed during treatment with a combined oral contraceptive than in control subjects with normal ovaries[196] (Figure 29.11). This phenomenon may be attributable to programming of the hypothalamic–pituitary axis by exposure to excess ovarian androgen during development rather than a primary hypothalamic–pituitary

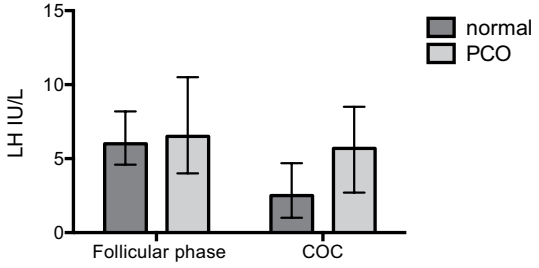

FIGURE 29.11 Serum LH concentrations in women with polycystic ovaries on ultrasound who were studied in the follicular phase of spontaneous cycles or whilst taking the combined oral contraceptive (COC). Note the reduced suppression of LH ($p < 0.05$) in women with PCOS during COC treatment. *Source: Data adapted from a study of the prevalence of PCOS in women in the general population by Ref. 196.*

defect. There is strong evidence to support this from studies of prenatally androgenized monkeys or sheep and also from clinical studies. Girls with adrenal hyperandrogenism associated with congenital adrenal hyperplasia may have elevated LH serum levels,[197] and, in an elegant series of studies, Marshall and colleagues demonstrated that impaired progesterone-mediated negative feedback suppression of LH in women with PCOS could be reversed by treatment with an androgen receptor antagonist.[198,199] These findings support the notions that the primary defect in PCOS resides within the ovary and that changes in the regulation of gonadotropin secretion are consequent upon abnormal ovarian steroidogenesis. Further and direct evidence for an intrinsic and primary ovarian abnormality comes from the studies of the early stages of follicle development (i.e., at a stage when local ovarian factors appear to be more important than gonadotropins in directing the activation and early growth of preantral follicles).[63]

ABNORMAL PREANTRAL FOLLICLE DEVELOPMENT IN PCOS

As summarized in the section Preantral Follicle Development, the time taken from the activation of primordial follicles through their growth to the late preantral stage in the human ovary is estimated to be 3–6 months.[52,53] However, we know little about the factors involved in regulation of normal preantral follicle development and even less about what dictates the aberrations seen in PCOS. Nevertheless, there are characteristic morphological and functional differences between normal and polycystic ovaries in these earliest stages of follicle development. There is a greater density of preantral follicles in the polycystic ovary.[64] The increased density of preantral follicles appears to be largely due to an increase in the primary follicle "pool",[200,201] a phenomenon referred to as "stockpiling" of follicles by Maciel and colleagues.[201] Furthermore, studies of cultured cortical tissue biopsies revealed that the proportion of follicles that initiated growth was significantly higher, and the proportion of primordial follicles reciprocally lower, in tissue from women with polycystic ovaries than in biopsies from normal ovaries. In other words, the dynamics of early follicle development are altered in women with PCOS. Despite the evidence for accelerated activation of primordial follicles, there is nothing to suggest that this leads to premature depletion of the follicle pool. The age of the menopause appears to be no different in women with proven PCOS from those in a reference population.[152] Preservation of the follicle pool in PCOS may be attributable to a higher starting population of preantral follicles,[200] reduced atresia of preantral follicles,[202,203] and/or the accumulation (stockpiling) of follicles at the primary stage.[201]The underlying reasons for the increase in preantral density in polycystic ovaries remain obscure, but these include, plausibly, increased endowment of primordial follicles and reduced loss of follicles by atresia during the early stages of growth (Figure 29.12). Clearly, it is difficult to find direct evidence for the former, but data from tissue culture studies support the notion that there is reduced atresia of preantral follicles.[202]

Accelerated initiation of growth in polycystic ovaries is associated with a higher than normal proportion of granulosa cells and evidence of a higher rate of cell division within the granulosa layer of primordial and early growing follicles. Expression of mini-chromosome maintenance protein2 (MCM2, a marker of DNA replication)[204–206] was increased in follicles from PCOS patients.[207] The observation that MCM2-positive granulosa cells were present even in primordial follicles

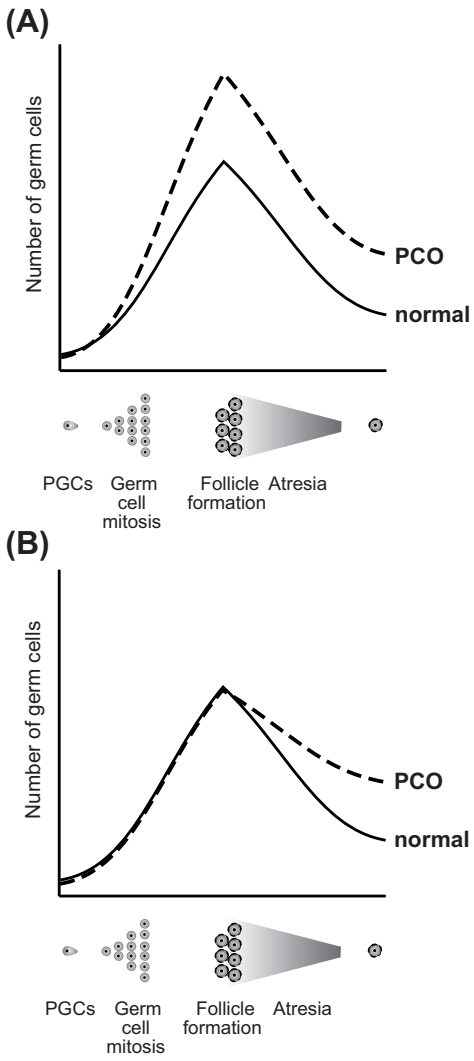

FIGURE 29.12 Proposed mechanisms for increased density of preantral follicles in women with PCOS. (A) Possible mechanisms for increased initial density are (i) more cell division in PGCs leading to (ii) increased endowment of primordial; and/or (B) increased survival of preantral follicles. *Source: Adapted from Ref. 200.*

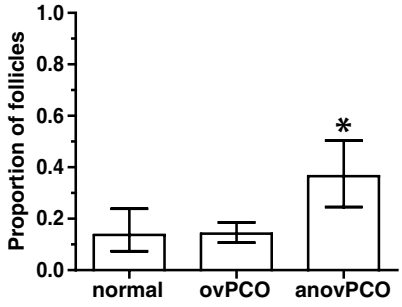

FIGURE 29.13 Granulosa cell proliferation is increased in preantral follicles of women with PCOS. Proportion of preantral ovarian follicles expressing the proliferation marker mini-chromosome maintenance protein2 (MCM2) in women with normal ovaries, and two groups of women with PCOS—those with regular ovulatory cycles (ovPCO) and those with anovulation (anovPCO) (*$p = 0.03$). *Source: Data from Ref. 207.*

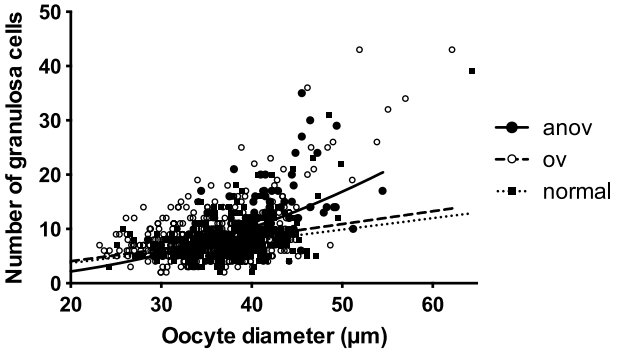

FIGURE 29.14 Relationship between granulosa cell number and oocyte diameter in preantral follicles from normal and polycystic ovaries. Note the discordant pattern in follicles from women with anovulation and PCOS.[207]

suggests that, contrary to current dogma, these follicles are not completely quiescent and there may be a low level of cell division even in this "resting" reserve of follicles. Preantral follicle development, from primordial up to and including the primary stage, was marked by a higher proportion of MCM2-positive follicles in tissue from anovulatory women with polycystic ovaries than in tissue from either of the two ovulatory groups (Figure 29.13). In addition, it was observed that oocytes were larger and there were more granulosa cells per follicle in transitional and primary follicles in polycystic ovaries from an anovulatory PCOS group. However, the increase in the number of granulosa cells was disproportionately greater than the increase in oocyte diameter in the follicles, emphasizing the altered dynamics of early follicle development in polycystic ovaries and implying an alteration in the normal "dialog" between oocyte and somatic cells (Figure 29.14).

It is not clear, as yet, which (presumably intraovarian) factors are involved in abnormal regulation of early folliculogenesis, but both IGFs[76,208–210] and androgens have been implicated, mainly on the basis of studies in nonhuman animal models. In the rhesus monkey, ovarian androgens have been shown to stimulate initiation of follicle development, and this effect may be mediated by increased expression of the type 1 IGF receptor.[209,210] Aberrant follicle development has been observed in the ovaries of prenatally androgenized rhesus monkey and sheep.[166,211–214] If these data are to be extrapolated to the human, they beg the question as to the source of excess androgen. It is most likely to be produced by theca cells of the ovary, but since theca formation is a key element of normal follicle development, it is unclear whether excess production of androgen by theca (an intrinsic abnormality in the polycystic ovary, as discussed in this chapter) is the primary abnormality or whether it is, itself, a consequence of abnormal preantral follicle development. Nevertheless, it seems plausible that, once established, excess androgen production by theca cells contributes to the perpetuation of abnormal dynamics of early follicle development.

Another key question is whether these abnormalities in preantral follicle development are related to the disordered antral follicle function described in this chapter (and, if so, by what mechanism is this brought about?). The argument has been made for arrest of antral follicles being a reflection of the abnormal endocrine environment in anovulatory women with PCOS, but might the disorder of early follicle growth predispose the follicle to an inappropriate responsiveness to endocrine signals? For example, is the premature response to LH of granulosa cells in small antral follicles simply a function of the endocrine environment, or do these cells also respond differently to LH because of their early programming?

INSULIN RESISTANCE IN PCOS

The idea that insulin resistance was a feature of women with PCOS was mooted in the 1970s, but the first clear evidence was in 1983 when Chang and colleagues noted an exaggerated insulin response to an oral glucose load in a group of women with PCOS when compared with weight-matched controls.[215] This was followed by the seminal work of Dunaif and coworkers who used hyperinsulinemic–euglycemic clamp studies to assess directly insulin sensitivity in groups of hyperandrogenemic women.[148,216,217] Insulin resistance is most obvious in overweight and obese women with PCOS but can also be observed in lean women with the syndrome, particularly in carefully weight-matched groups[217,218] (Figure 29.15). More recently, and following the debate about diagnostic criteria for PCOS, it has become clear that insulin resistance is a feature of women with PCOS who have both hyperandrogenism and anovulation, whereas those with polycystic ovaries who have either hyperandrogenism or anovulation alone tend to have normal insulin sensitivity.[219–221] However, it should be noted that recent data from hyperinsulinemic–euglycemic "clamp" studies

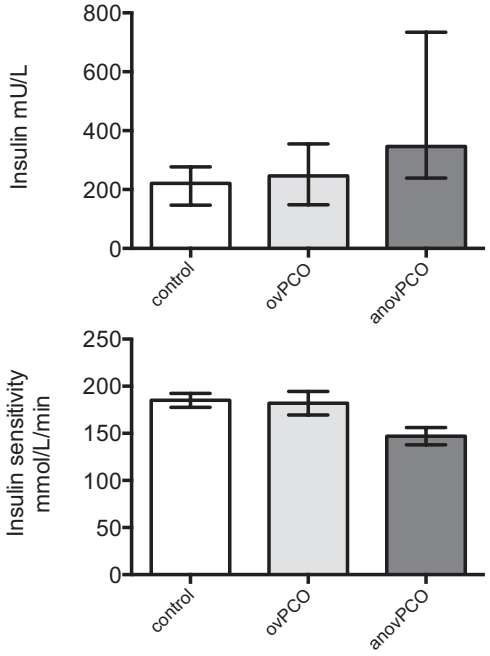

FIGURE 29.15 Sum of serum insulin concentrations during a standard 75 gm oral glucose tolerance test (median and interquartile range), and insulin sensitivity (mean ± SEM) in three groups of weight-matched subjects: women with normal ovaries and regular cycles; women with polycystic ovaries, androgen excess, and regular cycles (ovPCO); and women androgen excess and anovulation (anovPCO). Hyperinsulinemia and insulin resistance are features of anovPCO but not ovPCO. *Source: Data from Ref. 190.*

suggest that these intermediate groups may be mildly insulin resistant relative to controls.[222] But even within the group with both features of PCOS, there is a wide range of insulin sensitivity, with considerable overlap of values with the normal range. In other words, insulin resistance is a common but not invariable feature of women with PCOS, even in overweight or obese subjects.

Insulin resistance in PCOS has been linked to a disorder of energy balance characterized by reduced postprandial thermogenesis (PPT).[218] PPT accounts for about 15% of daily energy expenditure, and reduced PPT may represent a mechanism by which women with PCOS have an increased capacity to gain weight. This brings to mind the concept of the thrifty genotype hypothesis wherein such a "defect" in energy expenditure can represent a biological advantage in terms of survival and, particularly, preservation of reproductive performance (the thrifty reproductive genotype[223]) at times of food shortage. However, it remains debatable whether this quite subtle disorder of energy balance is enough to account for a tendency to gain weight readily in women with PCOS. In fact, obesity is only slightly more common amongst women with symptoms of PCOS in the general population than in those without PCOS.[224] But, of course, weight gain is associated with more symptoms of PCOS and therefore a greater likelihood of presenting to a clinic.

TABLE 29.6 Summary of the Key Investigations in Women with Anovulation

- Serum FSH and LH
- Serum prolactin
- Assessment of estrogen production (serum estradiol and endometrial thickness)
- Serum TSH

The cellular and molecular mechanisms of insulin resistance in PCOS seem to have characteristics that are peculiar to the syndrome. As in many types of insulin resistance, there is evidence for a postreceptor defect and pathway-specific defects in insulin signaling. Dunaif has proposed that there is an increase in serine phosphorylation of both the insulin receptor and insulin receptor substrate 1 that affects metabolic but not mitogenic pathways, not only in classic insulin target tissues but also in the ovary. Abnormalities of serine phosphorylation within the mitogen-activated protein kinase (MAPK)–ERK signaling pathway have also been noted.[146] Selective insulin resistance in the ovary—affecting metabolic but not steroidogenic function—has been alluded to previously. More specifically, insulin-mediated glucose uptake and lactate accumulation have been shown to be impaired in granulosa–lutein cells of women with PCOS.[192,225,226] It is possible that this defect contributes to the subfertility of PCOS by affecting the energy supply of the oocyte, but there is no direct evidence for this. Indeed, oocyte quality appears to be little different from normal in women with PCOS.[227] Insulin-sensitizing drugs can improve the chance of ovulation in women with PCOS,[161] but this is probably effected by lowering the hyperinsulinemic drive to excess steroidogenesis.

Clinical Management of Ovulatory Disorders

Investigation of Ovulatory Disorders

In clinical practice, investigation of patients with ovulatory disorders requires only a small number of well-directed tests[228] (Table 29.6). In patients presenting with amenorrhea, measurement of gonadotropins and prolactin and assessment of estrogen production will provide the essential information, and usually a single blood sample is all that is required. Measurement of FSH will immediately allow distinction between POI and other causes of oligo-amenorrhea, and, in women with normal (or frankly low) FSH, assessment of estrogen status will discriminate between hypothalamic–pituitary causes (low estrogens) and PCOS (normal estrogen status). Although estradiol measurements are routine in most reproductive endocrine clinics, there is considerable overlap between physiological levels of estradiol in the early follicular phase of normally cycling women and

values seen in women with estrogen-deficient amenorrhea. It may be advantageous, therefore, to evaluate estrogen production, using an "in vivo bioassay" of estrogen action by measuring endometrial thickness of ultrasound in patients presenting with amenorrhea. Additionally, in women with low or normal FSH, measurement of prolactin will identify those women who have hyperprolactinemia as the cause of the hypothalamic amenorrhea.

The requirement for additional investigations depends primarily on the clinical presentation but also on the results of the initial tests described here. So, for example, it is important to perform pituitary imaging in women with hyperprolactinemia or serum testosterone in hirsute women with symptoms of PCOS. The approach to any further investigation and treatment of the individual disorders is described throughout the remainder of this section.

Treatment of Ovulatory Disorders

The main focus of the treatment of women with ovulatory disorders will be on restoration of normal ovulatory function (i.e., predominantly in the treatment of infertility). However, management of patients with amenorrhea or oligomenorrhea also includes, in women not wishing to conceive, treatment of associated symptoms and long-term consequences of hormone deficiency, as well as treatment of the effects of hormone excess (e.g., unwanted body hair due to hyperandrogenism).

The results of the few simple tests outlined here inform the optimal choice of treatment for induction of ovulation. With the exception of women with POI (in whom fertility can realistically be restored only by egg donation, with the help of in vitro fertilization (IVF)), disorders of ovulation are eminently treatable. A very important objective in induction of ovulation is to restore normal ovulatory cycles (i.e., to aim for single-follicle ovulation). This is in marked contrast to superovulation (often euphemistically called "controlled ovarian stimulation") in the context of an IVF program where the objective is to override physiology and recover several eggs for IVF.

PRIMARY OVARIAN INSUFFICIENCY

Different fertility options will be appropriate for each individual with POI. It is important that discussions on this topic, from a professional with experience in the field, are made available not only soon after diagnosis but also at intervals throughout follow-up as the technology and opportunities in this field are continually developing. Women with POI have a 5–10% chance of spontaneous conception at some time after diagnosis, as in some cases hormone levels and disease activity fluctuate and return to biochemical normality; this is often transient, and the likelihood of recovery of ovulation is not possible to predict. Pregnancy loss in those who conceive is reported at 20%, which is similar to that of the normal population. Several medical therapies have been tried to induce ovulation in women with POI; however, in a systematic review all were reported to be equally ineffective.[87] In particular, glucocorticoids have been considered for those with autoimmune markers, and although they were promising in early case reports, a controlled trial failed to show benefit.[87] With fluctuating ovarian function being more common in POI than is often realized, it may be tempting to offer close ovarian monitoring to detect times of remission.[229] This technique has yet to be shown to be a significant advance and runs the risk of raising false hope in many to achieve pregnancy in a few.

OVUM DONATION

Assisted conception with donated oocytes has been used to achieve pregnancy in women with POI for over 20 years and remains the only realistic fertility treatment for the majority of women with established POI.[230,231] The availability of donated oocytes varies from country to country, and this option is not acceptable from some ethnic groups. Donated oocytes are fertilized with partner's sperm and the best embryo is chosen for implantation with the recipient, having been prepared with increasing doses of oral estradiol. Because of the lack of a corpus luteum, progesterone support is required that can be administered orally, vaginally, or by injection. Endometrial preparation is established in earlier "dummy" cycles in which endometrial thickness can be tracked by ultrasonography without embryo transfer.[232]

EMBRYO CRYOPRESERVATION

Cryopreservation of embryos is a long-established technique as part of IVF, but it will apply to only a small number of women with normal ovarian function who can anticipate imminent ovarian failure but have sufficient time to allow for ovarian hyperstimulation.[233] This circumstance might arise in some cases of malignancy or in someone who is known to be at risk of ovarian failure, such as those with X chromosome anomalies or FMR1 premutation who may wish to delay starting a family for some years. Donor sperm could be used for those without a partner.

OOCYTE CRYOPRESERVATION

Cryopreservation of oocytes has only been a practical option since the advent of vitrification, which has improved the freezing process for such a large cell.[234] Vitrification involves rapid cooling in high concentrations of penetrating cryoprotectants, which avoids formation of intracellular ice and resulting damage during cooling and warming. In vitro maturation of oocytes, where immature oocytes are retrieved from unstimulated

ovaries, has also emerged as a safe and effective treatment for women with cancer who are undergoing gonadotoxic therapy. Successful pregnancy is possible following in vitro maturation of oocytes from antral follicles, but this is not yet established in clinical practice.[235]

Oocyte cryopreservation also requires controlled ovarian stimulation, but in contrast to preservation of embryos, no sperm is required. In practice, this option is only applicable to women with normal ovarian function and beyond early adolescence. The success rate for achieving pregnancy is likely to be lower than for embryo cryopreservation because oocyte survival and subsequent fertilization are impaired. This option has been used for those women with Turner syndrome who retain some ovarian function,[236] but so far the overall success rate is not known for this subgroup compared to the more common application in women diagnosed with cancer.

OVARIAN TISSUE CRYOPRESERVATION

The use of ovarian tissue cryopreservation for later use has been explored in young women undergoing anticancer treatment. Cryopreservation of one ovary or strips of ovarian cortical tissue has resulted in the birth of over 12 children according to a review in 2012.[237] This procedure has the advantage of not requiring sperm and being appropriate for prepubescent girls accepting that a laparoscopy is required. The cryopreserved tissue can be reimplanted into the pelvis, with ovulation and pregnancy occurring spontaneously or after IVF. Once again, it is too early to be certain of the overall success rate of this procedure, which is only undertaken in specialist oncology centers. In rare instances, successful pregnancy following ovarian transplantation between monozygotic twins discordant for ovarian failure is possible, with 28 births reported.[238]

Disordered Regulation or Deficiency of Gonadotropins

Gonadotropin deficiency caused by destructive lesions of the pituitary or hypothalamus, although rare, will usually be obvious in the context of the clinical presentation, and the need for additional tests (particularly assessment of other anterior or posterior pituitary hormones and detailed imaging) can be considered. With increasing knowledge about *genetic causes of isolated GnRH deficiency*, it is appropriate to screen for known genetic mutations implicated in hypothalamic amenorrhea, particularly when there is a relevant family history.

In women with FHA, treatment of the underlying cause is the priority. It is usually obvious when an eating disorder is the predominant cause of FHA, but in those who do have weight loss-related or exercise-related amenorrhea, it is not simply a matter of advising that they eat more healthily or exercise less vigorously; psychological support is very important in management.[129] Even in those with idiopathic FHA, psychotherapy in the form of cognitive-behavioral therapy may be indicated and has been shown to be effective.[239]

PULSATILE GNRH TREATMENT

The most physiological approach to induction of ovulation is pulsatile GnRH. This is the treatment of first choice in women with organic causes of GnRH deficiency and in those women with FHA who have regained weight, reduced exercise, and/or benefited from psychological therapies but do not resume menses. The advantage of GnRH therapy over exogenous gonadotropins is that the pituitary–ovarian feedback is maintained, restricting the pituitary secretion of FSH in the follicular phase, encouraging the development of a single dominant follicle, and reducing the risk of multiple-follicle development. By contrast, it is not easy to find the appropriate threshold dose of exogenous FSH at which a single dominant follicle is selected, and consequently there is a significant risk of exceeding this threshold and inducing multiple-follicle development. Since the initial "proof-of-principle" studies of the efficacy of pulsed GnRH cited in this chapter, there have been significant refinements with regard to dose and route of administration that have led to effective and convenient management of women with hypogonadotropic hypogonadism.

The initial clinical studies with the use of pulsatile GnRH were performed in the late 1970s and early 1980s, with groups based in Bonn, Boston, Uppsala, and London being the most prominent in the field.[38–40,240,241] Homburg and colleagues reported a cumulative conception rate of 93% in a series of 118 women, 61 of whom had disordered regulation or deficiency of gonadotropins. The prevalence of multiple pregnancy (twins) was, as predicted, lower than that expected after gonadotropin therapy, at 7%. The results from the Boston series were equally impressive across a wide range of causes of GnRH deficiency. Interestingly, subsequent studies have suggested that even patients with mutations in the GnRH receptor may be amenable to treatment with pulsed GnRH, albeit at larger doses.[242] The same group has recently reported a relationship between response to GnRH and genotype in women with isolated GnRH deficiency.[57] Mutations in *CHD7*, *FGFR1*, *KAL1*, *TAC3*, and *TACR3* were associated with a favorable response to GnRH, whereas those women with mutations in *GNRHR* and the prokineticin receptor 2 gene (*PROKR2*) demonstrated pituitary resistance to GnRH therapy. The poor response to GnRH was predictable in patients carrying mutations in the GnRH receptor gene but is less easy to explain in those with a mutation in *PROKR2* (although the latter has been implicated in normal pituitary development). This emphasizes the emerging importance of genetic screening of such patients in the selection of appropriate treatment.

GONADOTROPIN THERAPY

Modern delivery systems (automatic pulsatile infusion pumps) for administration of GnRH are small and unobtrusive but nevertheless need to be worn daily until pregnancy is achieved. This may be a problem for some women, and an alternative is to give exogenous gonadotropins by daily injection. In contrast to the gonadotropin requirements for induction of ovulation in PCOS (or for superovulation for IVF), administration of FSH alone is not sufficient to ensure normal follicular maturation. Women with hypothalamic amenorrhea lack LH and therefore cannot generate enough androgen substrate for production of estradiol. Thus, a combination of LH with FSH is needed, most conveniently in the form of human menopausal gonadotropin (hMG). But because gonadotropin therapy carries a much greater risk of hyperstimulation of the ovaries than does GnRH, it demands more intensive monitoring. For this reason, pulsatile GnRH remains the treatment of first choice for women with hypothalamic amenorrhea. In view of the results of GnRH treatment in women with primary pituitary disease, mentioned in this chapter, a trial of pulsed GnRH may be appropriate even in those women with GnRH receptor mutations or destructive pituitary lesions. Nevertheless, this is a group in whom exogenous gonadotropin therapy is more likely to be effective. Of course, this introduces the possibility of overstimulating the ovaries, but there is limited evidence to suggest that the risk of multiple-follicle development in response to gonadotropins can be reduced by the addition of, or replacement of FSH by, LH in the final stages of follicle maturation.[243,244]

PROSPECTS FOR FUTURE MANAGEMENT

The rapidly emerging knowledge of the GnRH pulse generator and of the endocrine factors that impact it raise the prospect of new methods of restoring pulsatile secretion of GnRH for fertility treatment. A good example of this is the recent work on administration of kisspeptin to women (and men) with GnRH deficiency. In preliminary studies in males, constant infusion of kisspeptin has been shown to induce episodic LH secretion,[245] although it is not clear that the pulse pattern is normal, nor is it yet certain that this will restore normal cyclical ovarian function in women. Much more needs to be learned regarding many issues, including dose-response effects, selection of patients for clinical trials, and how to create effective long-acting analogs for routine clinical use. Another exciting area in the field of endocrine therapies for anovulatory infertility is the development of small molecule mimetics of gonadotropins for oral use. These allosteric modulators of gonadotropin receptors have potential for both pro-fertility and contraceptive application.[246]

Hyperprolactinemia

After excluding pharmacological causes of hyperprolactinemia and primary hypothyroidism, the focus of treatment is direct inhibition of prolactin secretion using long-acting dopamine agonists.[32,247,248] Although hyperprolactinemic amenorrhea is characterized by hypothalamic dysfunction and abnormal GnRH pulsatility, it is much more appropriate to use dopamine agonists (the most commonly used are bromocriptine and the longer acting cabergoline[249]) to inhibit prolactin secretion than to give pulsatile GnRH. Suppression of prolactin to within or near the normal range results in resumption of normal pulsatile secretion of gonadotropins and return of ovulatory menses.[32] Importantly, dopamine agonists also reduce the mass of prolactin-secreting pituitary adenomas, not only in the case of microadenomas but also in many patients with large prolactinomas. It is therefore only rarely necessary, at least in the short term, to perform pituitary surgery, even in women who have large enough tumors to cause local symptoms such as visual field loss. In the long term, microadenomas may apparently be cured by dopamine agonist therapy, but the rate of recurrence for microadenomas is much higher and, although long-term dopamine agonist treatment carries very few risks, surgical treatment may eventually be required.[250] In a small proportion of patients, dopamine agonist treatment is not well tolerated and has to be discontinued because of side effects. Postural hypotension, nausea, and nasal stuffiness are common but usually resolve if the starting dose of bromocriptine or cabergoline is low and then gradually increased to a level that provides effective suppression of prolactin. Resistance to dopamine agonist therapy is uncommon but well recognized.[251]

Polycystic Ovary Syndrome

DIET AND LIFESTYLE MODIFICATION

Overweight and obesity in women with PCOS are associated with both a reduced frequency of ovulation and a poorer response to ovulation induction. Lifestyle modification, specifically calorie restriction and structured exercise programs leading to modest weight reduction of between 5% and 10%, has been shown not only to improve metabolic indices in women with PCOS but also to increase the chances of ovulation and pregnancy.[158–160] For the most part, these studies, although consistent in their findings, have been on a relatively small scale, and we lack systematic data both on longer term outcome and on whether overweight or obese women who respond poorly to induction of

ovulation will show an improved response following weight loss.

ANTIESTROGENS

The treatment of first choice for induction of ovulation in anovulatory women with PCOS is the antiestrogen clomiphene citrate, which results in ovulation in 75–80% of patients.[252,253] The antiestrogenic effect of clomiphene at the level of the pituitary and hypothalamus results in the removal of estrogen-mediated negative feedback and a significant increase in serum FSH, sufficient in most cases to exceed the threshold for further development of medium-sized antral follicles. The usual starting dose is 50 mg per day for 5 days (from day 2 onward) following a spontaneous period or progestin-induced withdrawal bleed. It is prudent to monitor the first cycle of treatment by ultrasound tracking and endocrine tests in order to determine whether ovulation has occurred or whether there has been either a poor response (no dominant follicle emerging) or an excessive response (too many follicles). The dose can then be adjusted accordingly, but there is no clear evidence that increasing the dose above 150 mg per day can improve the ovulation and pregnancy rate.[253] There are promising data to suggest that a useful alternative to antiestrogens is the use of aromatase inhibitors. These have been shown effectively to induce ovulation in women with PCOS. These agents also induce a rise in serum FSH by removal of estrogen-negative feedback, but, in this case, this is due to a transient fall in circulating estradiol concentrations rather than estrogen receptor blockade. They appear to have fewer side effects than clomiphene, but progress in bringing aromatase inhibitors into fertility treatment has been slowed following concerns about possible teratogenicity, albeit in data arising from small, preliminary studies. At the time of writing, a large, multicenter, randomized controlled trial is in progress with the focus on safety for the offspring as well as on efficacy.[254]

GONADOTROPIN THERAPY AND LAPAROSCOPIC OVARIAN DIATHERMY

In women who fail to ovulate on clomiphene (or in those who ovulate but have not conceived after successive ovulatory cycles), the choice of treatment lies between laparoscopic ovarian diathermy (although just how this works remains obscure)[255] or low-dose FSH[253] with careful ultrasonographic monitoring of the ovarian response.[256] Both treatments have proven effective in treatment of clomiphene nonresponders, and the choice is usually determined by a combination of patient preference and availability of specialist resources. The advantage of laparoscopic diathermy (the modern replacement for the time-honored treatment of ovarian wedge resection) is that it is a single-step procedure and it may be particularly appropriate in women with PCOS who are due to undergo routine laparoscopy as a diagnostic procedure during infertility investigations. The disadvantages are that it is an invasive procedure, that adjuvant treatment with clomiphene or gonadotropins is required in about half of the cases, and that it is less effective in obese than in lean women with PCOS. Gonadotropin treatment is equally, if not more, effective, but women with PCOS are more prone to multiple-follicle development and the attendant risks of multiple pregnancy and ovarian hyperstimulation syndrome (OHSS). These undesirable, and dangerous, complications of gonadotropin treatment have led to the development of low-dose, "step-up" gonadotropin treatment regimens.[147,249,256,257] These protocols are based on the pioneering work of Brown and colleagues[67] who argued that by carefully increasing the dose of gonadotropin by small amounts (in order to find the appropriate "threshold" level of FSH for a single dominant follicle to emerge), there was a much greater likelihood of allowing single-follicle ovulation. In our own series of nearly 200 women treated with low-dose FSH, the rate of single-follicle ovulation was over 80% and the incidence of both multiple birth and OHSS was very low (Table 29.7).[258] The key feature of this treatment regimen is that the dose of FSH is sufficiently low to simply "top up" endogenous levels of FSH to the range normally seen in the early follicular phase of the cycle. A glance at the endocrinology of a treated follicular phase reveals that even if the threshold dose is "clamped", the endogenous concentrations of FSH fall in the late-follicular phase, as in the normal cycle. In other words, the normal physiological negative feedback (by increasing levels of estradiol) is maintained with this regimen. It will also be noted that LH levels, which are elevated at the beginning of the treatment cycle, are suppressed into the normal range in the mid- to late follicular phase of the cycle (Figure 29.16). This low-dose, step-up regimen is now widely accepted as the treatment of choice for gonadotropin-induced ovulation in women with PCOS.[147]

TABLE 29.7 Outcome of Treatment with Low-Dose FSH in 199 Women

Cycles	916	
Ovulatory cycles	657	72%
Uniovulatory cycles	562	86%
Pregnancies	91	46%
Miscarriages	21	23%
Multiples (all twin)	3	3%

Mild "OHSS" in 4% of cycles.
From Ref. 258.

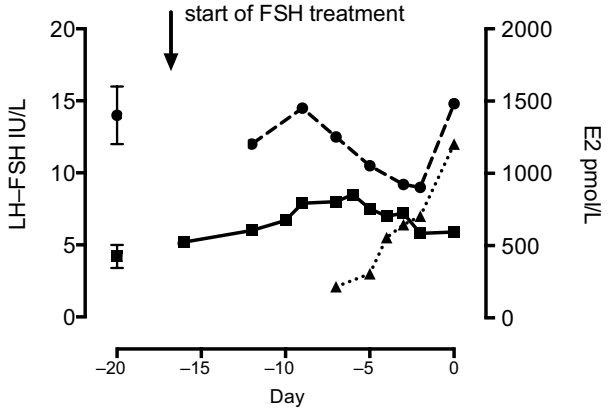

FIGURE 29.16 Mean serum LH (filled circles, day −20) and FSH (filled squares, day −20) concentrations before treatment; and LH (filled circles with dashed lines), FSH (filled squares with solid line), and estradiol (filled triangles with dotted line) during induced mono-ovulatory cycles in women with anovulatory PCOS treated with low-dose FSH. Serum FSH levels are raised to the normal early follicular phase range but show a fall toward day 0 (days normalized to start of the LH surge or injection with human chorionic gonadotropin), indicating preservation of the normal negative feedback control of FSH in the late follicular phase despite a fixed dose of exogenous FSH from day 10 onward. Note also the suppression of high LH levels during the late follicular phase.

CONCLUSION

Our understanding of the physiology of human ovarian function and its control has increased enormously in the last 50 years, aided in no small part by the widespread application of radioimmunoassay to elucidate not only normal cyclical changes in gonadotropins and sex steroids but also the etiology of disorders of ovulation. In the last decade, this knowledge has been greatly enhanced by huge advances in the fields of genetics and cell signaling, but our understanding of the physiology of the ovarian cycle remains the bedrock for investigation and successful management of ovulatory dysfunction in women.

Disorders of ovulation are a very common cause of female infertility, and although the etiology of, and the principles of management of, the various causes of anovulation are now well understood, there remain many areas of uncertainty. These uncertainties are the basis for further research into the physiology and pathophysiology of female reproduction.

In the field of POI, the issue of whether there are stem cells (oogonial stem cells) in the germ cell line within the adult human ovary is an intriguing but highly controversial area that merits further research. If it is indeed possible to generate new oocytes from such stem cells, this has the potential to offer prolongation of the reproductive lifespan in women whose ovarian reserve is low. Of more immediate therapeutic application, however, is the ongoing research using cryopreserved fragments of ovarian tissue for restoration of fertility in young women who are about to receive chemotherapy or pelvic irradiation for cancer.

In women with hypogonadotropic hypogonadism, the role of genetic factors in the etiology of abnormalities of GnRH secretion is assuming increasing importance. Even in those with FHA in whom environmental influences are paramount, there is evidence that there may be a genetic predisposition to disordered regulation of gonadotropins. Continuing research into afferent neural pathways involved in regulation of GnRH networks has important implications for management of hypogonadotropic hypogonadism. For example, the therapeutic potential of kisspeptin and its analogs in restoring normal ovulatory cycles in women with hypogonadotropic hypogonadism is beginning to be explored.

PCOS is perhaps the most complex disorder of reproductive function in women, and it seems that several factors, genetic and dietary in particular, play a role in its etiology. Unlike hypogonadotropic hypogonadism (in which single gene defects are more common), PCOS is a complex endocrine trait in which several susceptibility loci are likely to be implicated, but to date we have insufficient data to be confident about which are key genetic variants. A role for prenatal exposure to androgens in developmental programming of PCOS is an attractive hypothesis with support from studies of both animal models and women with PCOS. However, there is much more that needs to be learned about the mechanisms involved, in particular the putative interaction of genetic, epigenetic, and environmental factors.

CHAPTER

30

Puberty in Mice and Rats

Vincent Prevot

Laboratory of Development and Plasticity of the Neuroendocrine Brain, Jean-Pierre Aubert Research Center, School of Medicine, University of Lille, Lille, France

INTRODUCTION

In its 125th-year celebration issue published in 2005, *Science* magazine listed the problem of what triggers puberty, the period of postnatal development during which the capacity for sexual reproduction is achieved, as one of the "125 great unanswered scientific questions" of our times.[1,2] In accordance with its continuing fascination as a subject, there has been no dearth of reviews recapitulating the history of research into puberty, from the sweepingly broad[3–5] to those whose viewpoint is more focused on certain species, mechanisms, or even molecules.[6–15] In the latter category, homage must be paid to the previous version of this chapter, written by Ojeda and Skinner, which still serves as a model and an inspiration for all subsequent efforts to tackle the topic of puberty in rodents.[16] Indeed, any undertaking of this sort runs the risk of not being completely original, unless history can be rewritten or previously undiscovered reports brought to light (as does occur sometimes; see the reference to a little-noticed French paper from 1970 by Dolais et al.[17] on pulsatile luteinizing hormone (LH) release in men and women, mentioned in Knobil, 2005).[18]

With that in mind, the history of the study of puberty in rodents, like the study of most other scientific subjects, is a glittering patchwork of hard-to-believe hypotheses; indeed, one could almost say leaps of faith, formulated by intellectual giants who often had nothing more to go on than fairly crude experimental techniques and their own faculties of meticulous observation. The eventual proof of the accuracy of these hypotheses was brought years, sometimes decades, later, by other giants with better technology and perhaps more time or manpower or funding at their disposal. And one should not discount the role of serendipity in all this—chance encounters with the right people at the right time seem to underlie many of the most important scientific and technical insights leading to the demystification of the process of puberty and, indeed, of sexual differentiation and function, from which it is inseparable.

Although the earliest conjectures concerning the process of sexual maturation and its functional components were based, as could be expected, on observations of human patients and domesticated animals, by the beginning of the twentieth century, experiments in rodents were already yielding significant insights. At the gonadal level, for example, Marshall and Jolly described the effects of spaying pregnant rats as early as 1905,[19] and used these results as well as others to postulate that the ovary released two distinct hormones, later called oestrin/estrin (or estrogen) and progestin (or progesterone), which had different functions (recapitulated in Marshall's Croonian Lecture, 1936[20]). Perhaps with even greater foresight, Steinach in 1910 suggested that sexual development and behavior in rats was controlled by the actions of the gonads on the brain, and that ovarian hormones were related to testicular ones (Ref. 21; retold in Ref. 22). Among the first studies to directly address the question of puberty in rodents was that of Hermann and Stein, who found in 1916 that injecting ovarian and placental "lipoids" delayed puberty in immature male rats.[23] The classic example, of course, is the work of Long and Evans in 1922, whose experiments revealed that the ovaries of immature female rats (of their now famous Long–Evans strain obtained by crossing wild Norwegian grays with Wistar albinos) could be induced to undergo maturation when transplanted into adult females.[24] This was followed in 1924 by the work of Allen and Doisy[25] showing that an ovarian follicular extract was capable of inducing vaginal opening in immature female rats, the first direct experimental evidence for the existence of estrogen, which Marshall had postulated two decades earlier. This discovery became the subsequent basis of the Allen–Doisy test, in which a substance suspected of containing estrogens is injected into an ovariectomized mouse, and vaginal smears examined for the presence

Knobil and Neill's Physiology of Reproduction, Fourth Edition

of cornified epithelial cells (changes in vaginal cytology during the estrous cycle having already been described by Stockard and Papanicolaou[26] in guinea pigs in 1917). Using the same assay, in 1925, Frank and Gustavson, and later in the year, Frank, Kingery, and Gustavson,[27,28] while investigating whether the normal waiting period to puberty in Long and Evans' rats was due to "restraining influences…at work" or due to the "absence of the female sex hormone", postulated that lipoid extracts of ovarian follicles, corpora lutea, and the placenta, which presumably all contained the same hormone, were capable of inducing vaginal opening and hastening the first ovulation in immature rats. In other words, the time to puberty, in females at least, was not determined by the presence of an inhibitory factor in immature animals, but by the time it took for their ovaries to produce estrogen. In immature males, however, the injection of relatively pure estrin delayed the appearance of primary and secondary sexual characteristics and reduced testicular development in rats and guinea pigs.[29]

While these important discoveries regarding the secretion of ovarian hormones and their influence on puberty, both in males and females, were taking place, other studies were already confirming that the anterior pituitary (also called the pars distalis for its location, and the adenohypophysis or pars glandularis for its hormone-secreting abilities) and not the ovary determined the unfolding of the process. For example, Parkes in 1929 showed that the ablation of the ovarian follicles before puberty, or even in utero in fetal mice, prevented ovarian cycling, but did not affect other changes linked to sexual maturation (Ref. 30; see Ref. 31 for a more detailed account of early experiments on the hypophysial–ovarian relationship). Among their other findings, Long and Evans in 1922 had also shown that the injection of pituitary extracts into female rats would induce ovarian follicles to be converted into luteal tissue—the first experimental demonstration of the involvement of the anterior pituitary in ovarian function.[24] Their conclusion gained support from other studies carried out in 1927 by Zondek and Aschheim in mice,[32] and by Smith and Engle in rats,[33] showing that the transplantation of even a sufficient number of pieces of infantile pituitary, which have some gonadotropic activity, into juvenile animals would lead to vaginal opening, findings confirmed by the experiments of Lipshütz, Kallas, and Paez.[34] Indirect evidence also demonstrated that when an immature female rat was placed in parabiosis with another immature ovariectomized female,[35] or a gonadectomized adult male or female rat,[36] the non-ovariectomized female underwent precocious puberty, suggesting that whatever factor did trigger sexual maturation did not originate in the gonads, but that the ovaries of immature animals, in spite of their immaturity, were capable of responding to it. At around the same time, Moore and Price,[37,38] while using young, castrated male rats to disprove the idea that ovarian and testicular hormones were mutually antagonistic, proposed that gonadal hormones and secretions of the anterior pituitary operated as a close negative feedback circuit or loop, with gonadal hormones inhibiting the secretion of pituitary factors (related in Dorothy Price's biographical memoir of Carl Moore, 1974[39]). Pfeiffer, using transplants of ovaries and testes in neonatally gonadectomized rats, also came to the conclusion that testicular secretions inhibited the default capacity of gonadectomized rats to display ovarian cycles,[40] results that were interpreted as indicating the sexual differentiation of the anterior pituitary in response to gonadal hormones. Around 1930, McCullagh[41,42] also became interested in testicular physiology, and showed that a urinary extract from male animals, which he called "androtin" (both "testosterone" and "androsterone" already being in use for specific male hormonal extracts by this time), could replace all the functions of the castrated testis, except for pituitary hypertrophy. Like Moore, he concluded that the testis produced two hormones, one corresponding to his "androtin", in reality, testosterone and related substances, and another that he called "inhibin", which inhibited pituitary hypertrophy.

What Moore, Price, and Pfeiffer didn't take into account, unfortunately, influenced as they were by the hypophysiocentric views of Fröhlich, Cushing, and the like, was that the pituitary itself was controlled by another entity—the brain. It was left to Hohlweg and Junkmann[43] to suggest that the hypothalamus was at the apex of what we now know as the "hypothalamic–pituitary–gonadal" (HPG) axis, a suggestion that did not meet with a very warm reception for quite some time. However, Hohlweg himself was merely borrowing an idea put forward in 1909, more than 20 years earlier, by Aschner,[44] and one that had profoundly annoyed Cushing, who believed that the pituitary alone controlled peripheral organs such as the adrenals, thyroid, and gonads. In 1912, in his address to the Royal and Imperial Society of Physicians at Vienna, Aschner concluded by saying "Not only hypophysectomy, but even a mere wound in the base of the thalamencephalon leads to atrophy of the gonads in male and female dogs. The extent to which the hypothalamus can be regarded as a regulatory center for endocrine glands must therefore be decided after further research has been carried out" (quoted by Hohlweg[45]). Cushing, in his "The Pituitary Body and Its Disorders", also in 1912,[46] added as a footnote, "Aschner, it must be confessed, has opposed the view of essentiality of the gland to life. He is inclined to attribute the fatalities to some injury of hypothetical nerve centers of the infundibular region. As Biedl points out, the operative method Aschner employed is open to criticism…". But Aschner's "operative method" in dogs consisted of

passing through the roof of the mouth in order to perform a hypophysectomy without injuring the hypothalamus (reviewed by Anderson and Haymaker, 1974)! In 1927, Smith perfected a similar "parapharyngeal" method to hypophysectomize rats, greatly facilitating future studies aimed at dissociating the effects of the removal of the pituitary alone from the effects of damage to the hypothalamus.[47] Indeed, by 1936, van Dyke, in his Physiology and Pharmacology of the Pituitary Body, was able to list nine animal species and eight methods for hypophysectomizing them, and felt that Smith's method was the best.[48]

The 1930s also saw the first fruits of the contact between Harris and Marshall, already an eminent reproductive physiologist, at Cambridge (for a fuller account of Harris' work, see Ref. 49). Indeed, Marshall, who in his Croonian lecture of 1936 gave an account of Hammond's experiments in domestic animals suggesting that the anterior pituitary controlled sexual maturation,[20] had applied electrical stimuli to the heads of rabbits and found that they activated the reproductive organs by activating the anterior pituitary. Harris carried out similar experiments, in rats and with improved electrical equipment, and showed that electrical stimuli delayed ovulation but induced pseudopregnancy, suggesting that the excitation of "some neural structure" had stimulated the anterior pituitary to act on the ovaries.[50] After the second world war, Harris, using Smith's method for hypophysectomy, went on to show, first with Green[51,52] and then with Jacobsohn,[53,54] that the pituitary portal vessels acted as a "humoral relay" between the central nervous system and the anterior pituitary, that the direction of the portal circulation was brain-to-pituitary (confirming Wislocki's assumptions,[55] and refuting Popa and Fielding's)[56] and that the pituitaries, which were not themselves sexually differentiated, exerted their effects on the gonads only if the hypothalamo-hypophysial vascular connection was intact or had been reestablished. Everett, Sawyer, and Markee[57] and Everett and Sawyer[58] also confirmed that the brain and not the pituitary was the seat of sexual differentiation, and that there was a critical period during which a neurogenic signal could act on the pituitary to induce the release of gonadotropic hormones, and thus trigger ovulation. Based on these and other findings, in his 1955 monograph, "The Neural Control of the Pituitary Gland" (Ref. 59; see also Harris' Henry Dale lecture, published posthumously in 1972[60]), Harris concluded that hypothalamic nerve endings in the median eminence released pituitary-stimulating substances into the portal circulation, and that the time needed to achieve puberty was due not to the immaturity of the pituitary, but to the immaturity of the hypothalamus.

Harris' numerous predictions were confirmed by various groups in the following years, mostly in rats. In 1957, Nikitovitch–Winer and Everett[61] also demonstrated that the gonad-stimulating effects of the pituitary depended on its physical proximity to the hypothalamic median eminence, permitting functional portal circulation. Further, McCann, Taleisnik, and Friedman,[62] Courrier et al.[63] and Nikitovitch–Winer,[64] showed that median eminence peptide extracts could stimulate the release of luteinizing hormone by the pituitary. Conversely, Donovan and van der Werff ten Bosch[65] and Elwers and Critchlow[66] showed, respectively, that rats with a lesioned hypothalamus underwent precocious puberty, indicating the existence of an inhibitory influence of the hypothalamus on the pituitary, and that the hypothalamic stimulation of the pituitary–gonadal axis was itself inhibited by the amygdala—the first evidence of the involvement of an extrahypothalamic region in the process. In the early 1970s, Raisman and Field showed that the hypothalamic preoptic area was indeed sexually dimorphic, with a greater number of dendritic spines in females than in males, an effect dependent on gonadal steroid action in the early postnatal period.[67,68] Although Harris himself died in 1971, the groups of Guillemin and Schally, with the tools and resources to identify Harris' hypothalamic "releasing factors", which had now attained the status of "releasing hormones", used literally millions of sheep and pig hypothalami, respectively, to purify, sequence, and characterize luteinizing hormone releasing factor (LRF) (as it was called then), now usually termed gonadotropin releasing hormone (GnRH). For this monumental work, they shared the Nobel Prize for Physiology and Medicine in 1977, and Schally, in his Nobel lecture, acknowledged the founding contributions of Harris.[69,70]

One aspect of this neuroendocrine axis, however, continued to elude scientists over the years—the influence of gonadal secretions themselves on the hypothalamus and the pituitary. After all, if the chain of command was exclusively "top-down", why was sexual maturation altered in parabiotic rats where one partner was gonadectomized,[35,36] and why did the pituitary become hypertrophied following gonadectomy (an effect noted in 1905 in several species, including the guinea pig, by Fichera[71]) and develop "castration cells" (again, noted as far back as 1914 in humans by Schleidt,[72] in Steinach's laboratory, and in 1917 in rats by Addison[73])? Even more importantly, how was it that minute amounts of ovarian or testicular hormones could prevent the formation of these cells[74,75] or the accompanying effect on puberty in immature animals?[76,77] These knotty questions and the growing realization that the HPG axis was in reality an HPG loop led to the formulation of the "gonadostat" hypothesis by Ramirez and McCann in the mid-1960s[78,79] by analogy to the thermostat. According to this hypothesis, in immature animals, the hypothalamo-pituitary segment of the HPG axis would be sensitive to inhibition by gonadal steroids, but this sensitivity would undergo a

downward shift as the animal approached puberty, with a consequent increase in gonadotropin secretion and the stimulation of further gonadal hormone production, until their levels reached those required for fertility.[80] For the next decade and a half, this hypothesis dominated scientific thought as to the mechanism by which gonadal steroids contributed to the onset of puberty, with much experimental proof provided to support it (reviewed in Ref. 16) and but one dissenting view—that of Morrison and Johnson, suggesting that the restraining influence on gonadotropin secretion originated not from gonadal steroids, but from inhibitory factors present in the hypothalamus in immature animals.[81] It was not until 1981, when Ojeda's group demonstrated that in fact the switch in the sensitivity of the hypothalamo-pituitary unit to negative feedback by estrogen occurred not *before* but *after* the onset of puberty,[82] that the "gonadostat" hypothesis was definitively replaced by our current view of the maturation of the HPG axis.

During these fruitful decades, many of the important strides made in deciphering the mechanisms underlying the hypothalamic–pituitary connection were also due to technical advances: the invention of the radioimmunoassay in the late 1950s by Yalow,[83] which allowed hormone levels in the blood to be accurately measured (and for which she shared the Nobel with Guillemin and Schally), and its adaptation to pituitary gonadotropins by Odell and colleagues[84,85] as well as other groups, and to hypothalamic releasing factors by Naftolin under Harris' mentorship;[86] the invention of the ovarian ascorbic acid depletion method to assay LH levels, used by McCann et al.;[62] a method for collecting portal blood devised by Worthington, and used by Fink in Harris' laboratory to measure GnRH in the portal circulation of rats;[87,88] the invention of Halász' famous knife, which allowed afferents and efferents to the mediobasal hypothalamus to be transected without interrupting the portal circulation,[89] thus permitting a generalized map of hypothalamic regions and their connections to be established;[90] the extraction and isolation of molecules by chromatographic separation using Sephadex columns;[91] and others tools and techniques too numerous to list here. By the end of the 1970s, however, once the presence of GnRH neurons and projections in the hypothalamus, and especially in the preoptic area, had been demonstrated by Barry, with other groups hot on his heels,[92–94] the history of puberty entered a new phase—that of genetic and molecular characterization.

The first step in this direction was an entirely serendipitous one—the discovery by Fink's laboratory in 1977 of a naturally occurring mouse mutant that did not produce functional GnRH: the hypogonadal or *hpg* mouse.[95] By 1986, the genetic abnormality of this very useful animal model in which to study the effects of GnRH was elucidated by the Seeburg group—a deletion mutation in the GnRH gene leading to a lack of GnRH peptide.[96] Although this mouse model, "Nature's Knockout" as it has been called by Gibson et al.,[97] has taught us a lot about the role of GnRH in the establishment of sexual maturation, new tools that allow the expression of genes to be manipulated at the level of specific cells or specific periods of development, the establishment of immortalized GnRH neuronal cell lines, the possibility to trace functional neuronal pathways even beyond the synapse, etc., are leading to ever greater insights into these processes, and model systems in which to study them.[98–101] Among relatively recent developments, it is now known, for example, that GnRH neurons themselves express some nonclassical types of estrogen receptors,[8,102] providing one of the missing pieces of the puzzle posed by the HPG loop. In addition, the identification in 2003 of another master molecule in the regulation of puberty, kisspeptin, by de Roux and colleagues and Seminara and colleagues,[103,104] has led to a veritable spate of papers characterizing its role. And Marshall's recapitulation of the influence of the abundance of food on reproductive activity in humans and animals in his Croonian lecture of 1936 appears particularly prophetic in light of new findings regarding the overlap between hypothalamic cells, molecules, and pathways involved in regulating sexual maturation on the one hand, and those controlling the response to metabolic cues on the other.[105] Moreover, elements discovered in one field, such as the occurrence of adult neurogenesis in the hypothalamus in connection with energy homeostasis[106,107] or the role of those mysterious and plastic glial cells, the tanycytes,[108–110] may well have as yet unsuspected repercussions on the other.[111,112] After all, four decades after Julien Barry first demonstrated the presence of GnRH neurons in the hypothalamus in the very laboratory at Lille from which I am writing, this system still has the power to surprise us!

In this chapter, I will present an overview of the neuroendocrine control of puberty, with a particular focus on rodent models. Briefly, I will discuss the advantages and shortcomings (including species differences) of the use of rats and mice as models, the various components of the GnRH system (the GnRH neurons and their associated cellular network, including both other neurons and various types of glia), its structural and functional maturation in males and females during embryogenesis and in postnatal life leading up to puberty, and mechanisms and factors regulating the expression of the GnRH peptide. It should be noted that in this chapter I will use the terms "gonad-dependent" and "gonad-independent" process to indicate changes that are correlated with gonadal steroid secretion or not correlated with the same, respectively. This terminology will not be restricted to the historical use of these terms to differentiate between the suppression of gonadotropin secretion, is only evident in the presence of steroid (gonad-dependent), from that evident in gonadectomized individuals (gonad-independent). For an excellent discussion of other topics related to puberty in rodents and not dealt

with here for a lack of space, such as a detailed description of the maturation of the gonads, the effect of endocrine disruptors on the onset of puberty, upstream gene networks etc., the reader is referred to the previous version of this chapter by Ojeda and Skinner.[16]

RATS AND MICE AS MODELS

Although the subject of puberty has intrigued clinicians and scientists alike for decades, as we have seen above, the mechanisms that trigger its onset and modulate its progress and completion, and in particular the timely activation of GnRH neurons—the key event that sets in motion the rest of the process—remain an important unsolved mystery. Rodents, especially rats and mice, have been very useful animal models in which to study this developmental process, vital to the survival of mammalian species, and, as indicated by the occurrence of the GnRH peptide and its hypophysiotropic role in all vertebrates (reviewed in Refs 5,113), evolutionarily conserved. Apart from their short life spans, high fecundity, and relative ease of maintenance in a laboratory setting, most of the hormonal, cellular, and molecular mechanisms of reproductive maturation identified in rodents so far are similar to those found in higher mammals. This group includes primates, whose use is restricted by their size, cost, and limited reproductive capacity. Although the rat model has been instrumental in deciphering the physiology of sexual maturation, the mouse model, with the advent of modern genetic tools and techniques, has played a key part in helping us understand the underlying cellular and molecular mechanisms, notably by helping to decode the effects of specific mutations seen in human patients, whose phenotype may not always be due purely to a single genetic change. In addition, in cases where human mutations have not yet been identified, animal phenotypes generated by genetic engineering help in predicting the effects of such mutations in humans, and thus constitute invaluable models for translational research. However, a major caveat to keep in mind when using mice and rats to study puberty and extrapolate the results obtained to humans is that, in contrast to our own species, laboratory rodents have a very short prepubertal period (around 6 weeks versus 10 years in humans) because of their limited lifespan and do not exhibit the so-called "juvenile pause" in gonadotropin secretion and gonadal activity that is characteristic of primates[114,115] (however, see the section on puberty in males). Mice and rats thus have not been considered appropriate animal models in which to investigate the mechanisms underlying this quiescent period of relative hypogonadotropism, which is clearly evident in agonadal primates, including man[116–118] (see also Chapter 32). Although primate species are more amenable to the investigation of this particularly intriguing phenomenon, the daily awakening of the gonadotropic axis seen in rodents at the end of their juvenile development[119] may be a useful model for the study of the transition between the juvenile period and the reactivation of the HPG axis in primates.[115,119]

Species Differences between Mice and Rats

From a developmental perspective, it is important to note that some of the events that occur postnatally in rodents are known to take place during embryogenesis in primates.[120–122] However, even among rodents, the rat and the mouse are two distinct species in spite of their comparable life spans, and their physiology is not strictly identical, at least as concerns the external morphological parameters commonly used to assess the progression of sexual maturation during postnatal development.

Females

In the rat, vaginal opening is used as an external sign of the onset of puberty since it is associated with the first ovulation[123,124] and occurs in most cases at the end of the first proestrus,[123] when animals exhibit a uterus weighing >200 mg and ballooned with fluid, and ovaries with large follicles. Within 24 h of vaginal opening, rats typically present their first vaginal estrus.[123,125] Postmortem, rodents can readily be classified according to the phase of puberty depending upon uterine weight, the presence of intraluminal fluid in the uterus, vaginal opening, and the presence of corpora lutea: criteria originally defined by Ojeda and collaborators.[123] In contrast to vaginal opening in rats, the appearance of the vaginal introitus in mice does not coincide with the first ovulation, i.e., puberty, which can occur more than 20 days later,[126,127] but is rather an indicator of the increase in circulating estradiol levels, which prompts this apoptosis-mediated event.[128] The first estrus in mice, as identified by the daily collection and analysis of vaginal secretions from the day of vaginal opening,[129] is strictly correlated with the ability of the female mouse to become pregnant when housed with a sexually mature male.[130]

Males

The production of motile sperm in males occurs between 40 and 55 days of age both in rats and mice.[131–134] Testicular descent occurs after 15 days of age in both species,[135,136] and sexual maturation can be followed by monitoring the growth of the testis[131,137] and preputial separation.[138] However, although the separation of the prepuce from the glans penis (or balanus) as a result of the cornification of the balanopreputial epithelium occurs between 2 and 8 days before the appearance of motile sperm in the epididymis in rats (i.e., around 45 days of age),[138,139] it happens around weaning in mice (around 21 days of age),[140] and thus only marks an early phase of sexual maturation in the latter species. More recently, the

detection of mouse urinary proteins (MUPs≈20 kDa), whose excretion in the urine is stimulated by testosterone, has also been used as a noninvasive marker of early or delayed sexual maturation in mice.[140,141] Postmortem examination of the reproductive tract, e.g., the weight of the seminal vesicles and prostate, can also provide an indication of circulating androgen levels in animals, which can be correlated to the degree of sexual maturation of the individual under scrutiny.[138,140,141]

PUBERTY AND DEVELOPMENT

The onset of puberty and the regulation of fertility are governed by a complex neural network, primarily in the hypothalamus, that converges onto GnRH-producing neurons, the master regulators of gonadotropin secretion and postnatal gonadal growth and function. The proper development of GnRH neurons, GnRH expression, and GnRH signaling is essential for sexual maturation and the normal functioning of the HPG axis in mammals.[95,96,142,143]

The GnRH Neuron

Embryonic Development

Origin and migration of GnRH neurons. GnRH neurons are peculiar neuroendocrine neurons because, unlike other paraventricular neurosecretory neurons that arise from the neuroepithelium of the third ventricle,[144] they originate from both the neural crest and ectodermal progenitors in the olfactory placode,[145] and subsequently migrate from the nose to the brain during embryogenesis.[146,147] In mice and rats, GnRH cells begin to leave the epithelium of the medial olfactory pit around embryonic day 11.5 (E11.5). They migrate through the frontonasal region in close association with growing fibers of the vomeronasal nerve (in an axonophilic mode of migration[148]), penetrate the rostral forebrain at about E12.5 together with the central process of this nerve, and continue their migration towards the hypothalamic region along a ventral branch of the vomeronasal nerve that projects to the basal forebrain[149–152] (Figure 30.1(A and B)). Finally, the neurons detach from their axonal guides throughout their migratory path, disperse further into

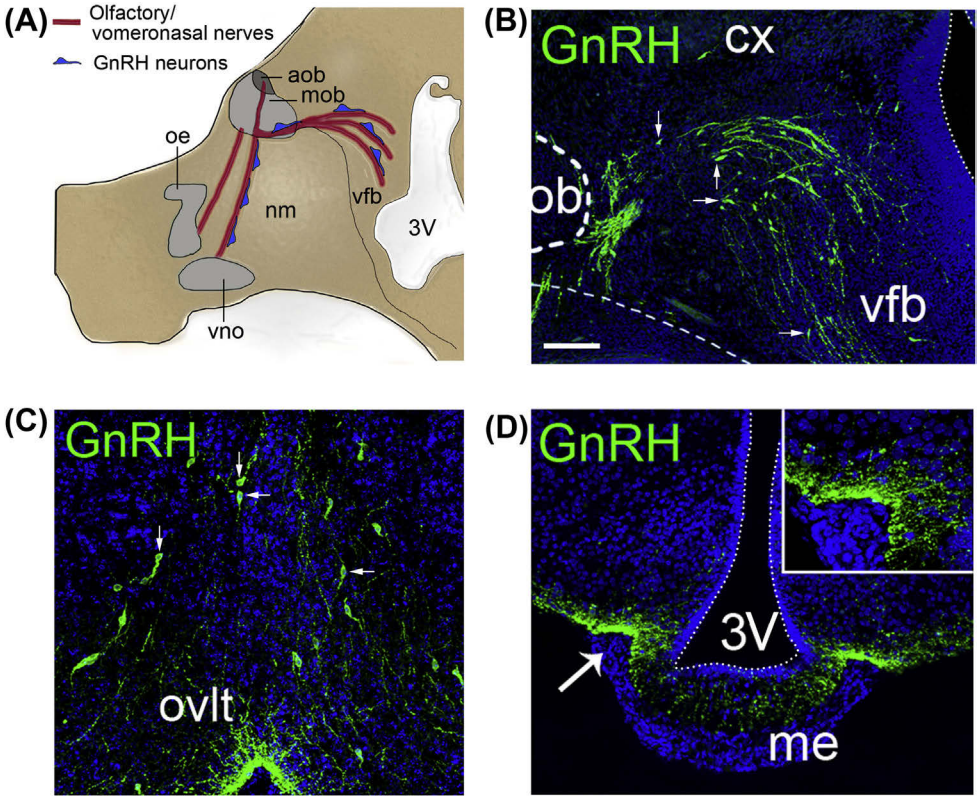

FIGURE 30.1 This figure is reproduced in color in the color plate section. (A) Schematic representation of the head of a mouse embryo at E14.5, showing the scaffold of vomeronasal/terminal nerve fibers (thick lines) along which GnRH cells (neuron-like shapes) migrate from the nose to the brain. (B) Sagittal section of the rostral and ventral forebrain regions at E14.5, immunolabeled for GnRH. Arrows show GnRH neuronal cell bodies. (C, D) Coronal section of the preoptic region showing GnRH neuroendocrine cells (arrows, C) and their nerve terminals in the median eminence (me, D) in newborn (P0) mice. In D, the inset shows a higher magnification of the area identified by the arrow in the main panel. Abbreviations: oe, olfactory epithelium; vno, vomeronasal organ; nm, frontonasal mesenchyme; mob, main olfactory bulb; aob, accessory olfactory bulb; vfb, ventral forebrain; cx, cerebral cortex; ovlt, organum vasculosum of the lamina terminalis; 3V, third ventricle. Scale bar: 100 μm (50 μm in inset).

the brain parenchyma (in particular to the medial preoptic area of the hypothalamus) (Figure 30.1(C)), and stop migrating. At birth, GnRH neurons have reached their final destination, mainly in the hypothalamus, and their projections towards the median eminence and the pituitary portal system are already established (Figure 30.1(D)). Alterations to the birth, migration, or growth and guidance of neurites of GnRH neurons during embryogenesis cause a wide range of malfunctions of the reproductive system, including delayed puberty, subfertility, and even infertility.

Molecular determinants of GnRH neuronal migration. The mouse has been a particularly useful animal model for the study of GnRH neuronal migration and for the identification of some of the genes involved in this process (Table 30.1).

Mutations in many of the genes listed in Table 30.1 are known to be embryonic lethal. However, they provide invaluable information about the natural history of sexual maturation and fertility in mammals. For example, GnRH neurons are completely absent from the noses and brains of mouse embryos with a partial loss of function of the *Fgf8* gene[171] or an invalidation of *Lhx2*,[198] strongly suggesting that these neurons arise exclusively from the nasal region. Indeed, FGF8 is thought to play a role in the fate specification of neurons emerging from the olfactory placode, and its deficiency results in the agenesis of the vomeronasal organs, from which GnRH neurons are first seen to arise during embryogenesis, as well as from the olfactory bulb (see for review Ref. 200). LHX2 is also involved in the formation of the primary olfactory pathways required for vomeronasal nerve development.[198] As expected, the absence of GnRH neuronal migration from the nose to the brain in LHX2-deficient mice, which, in contrast to homozygous FGF8-deficient mice, do not die during development, leads to the nonoccurrence of puberty and to hypogonadotropic hypogonadism.[198] A less severe phenotype (with some GnRH neurons reaching the hypothalamus) is seen in mouse mutants in which vomeronasal projections are only partially disrupted. For example, SOX10-deficient embryos display altered survival of the glia-like olfactory ensheathing cells,[199] which secrete guidance cues key to olfactory/vomeronasal axon development and GnRH neuron chemotaxis.[201] The same is true of mice lacking receptors for NETRIN-1 or SEMA3A (DCC and neuropilin 1, respectively), required for the development of the ventral branch of the vomeronasal nerve, which extends from the olfactory bulb to the presumptive hypothalamic territories and guides GnRH neuronal migration within the brain.[155,164] Interestingly, the few mutant mice with deficient SEMA3A receptor signaling that survive into adulthood (SOX10 and DCC mutants all die around birth[155,199]) exhibit delayed puberty,[164] suggesting that the timing of sexual maturation during postnatal development could be modulated by the number of GnRH neurons that reach the hypothalamus during embryogenesis. However, this idea is brought into question by several studies. For example, Herbison and colleagues have examined in greater detail the relationship between embryonic GnRH neuronal migration and sexual maturation during postnatal development by using the GN23 mouse, in which ephrin signaling is altered by an upregulation of the expression of the receptor EPHA5 in the nasal compartment, migrating GnRH neurons and certain brain regions.[157,202] Excessive EPHA5 signaling appears to inhibit axonophilic GnRH neuronal migration in a dose-dependent manner, as only 12% and 34% of the total GnRH neuronal population usually seen in the hypothalamus of wild-type mice are found in their homozygous and hemizygous GN23 littermates, respectively. Surprisingly, although homozygous GN23 mice

are either infertile or markedly subfertile, the onset of puberty is not substantially altered in these mice, despite clear hypogonadism.[157,202] These findings are also strongly supported by the observation that the genetic ablation of more than 90% of GnRH neurons at birth does not delay the onset of puberty.[203] Taken together, these studies suggest that, because of the robustness of the system, any alteration that affects only the number of GnRH neurons reaching the hypothalamus during embryonic development may result in subtle rather than absolute alterations in sexual maturation during postnatal development.

These deductions presuppose a simple genetic background in which the effects of the lack or overexpression of a given gene can be clearly teased apart. In humans, with their heterogeneous genetic background, however, a reduction in the number of hypothalamic GnRH neurons in association with sequence variations in certain genes is thought to be responsible for absent, partial, or delayed puberty.[204,205] The penetrance of these mutations appears to be modulated by an interaction between genetic (presence or not of disease-modifying genes) and environmental factors, and stochastic events (e.g., environmental cues), and modifier genes are often proposed to explain, at least in part, the phenotypic variability observed, as they might influence the expression of a given disorder.[204,205]

Establishment of GnRH neuroendocrine projections. The cell bodies of GnRH neurons are located in a continuum along their migratory pathway, with an especially high concentration in the medial preoptic area of the hypothalamus. In order to stimulate gonadotropin release from the anterior pituitary, the neurohormone needs to be released into capillaries of the pituitary portal system in the median eminence. GnRH neuroendocrine axons are first seen to reach the median eminence by around E15–E16 in rodents.[206–208] An interesting phenomenon in the GnRH system, as in other neural circuits,[209] is that many of the molecular signals controlling the migration of these neurons to their destinations reemerge periodically to play other roles throughout the development of the system. For instance, a gene known to regulate GnRH neuronal migration, such as the semaphorin SEMA7A, may be reused at a later development stage for neurite extension. SEMA7A and its receptor, β1-integrin, regulate GnRH neuronal motility during their journey from the nose to the brain, and their genetic invalidation in mice results in a 30% reduction in the number of GnRH cell bodies in the hypothalamus of adult animals;[168,169] surprisingly, β1-integrin expression in GnRH neurons is also required for neuroendocrine axon extension towards the median eminence.[169] Mice lacking β1-integrin expression selectively in GnRH neurons, in which both GnRH cell migration and axonal extension are disrupted (more than 70% of GnRH-immunoreactive fibers are lost in the median eminence of mutant mice when compared to control littermates), exhibit striking pubertal deficits, such as retarded vaginal opening, a marked delay in first ovulation, and GnRH deficiency in adulthood (disrupted estrous cycles and the inability to generate a normal LH surge).[169] A milder phenotype is observed in mice harboring GnRH neurons with impaired FGFR1 signaling,[210] which has been shown to promote GnRH neurite outgrowth in primary neuronal cultures in both rats[211] and mice.[212] As these processes are studied in greater detail, no doubt more instances of such polyvalent molecules will be uncovered.

GnRH release and signaling. By the time the first neuroendocrine projections arrive at the median eminence, around E15–E16,[206–208] the vasculature of the median eminence already displays the essential characteristics of primary portal capillaries, including an attenuated, fenestrated endothelium, designed to facilitate the free exchange of molecules between the portal circulation and the brain by bypassing the blood–brain barrier (BBB).[206,213] However, it is only by E17–E18 that the first dense-core vesicles carrying the neurohormone reach these neuroendocrine axon terminals[207,208,214] and that the first neurohemal contacts can be visualized.[206] Together, these ultrastructural findings suggest that neurohormone release into pituitary-portal blood vessels occurs during the last 2 or 3 days of fetal life, when hypothalamic GnRH content, pituitary LH content, and GnRH binding sites (the GnRH receptor, GnRHR) are seen to increase dramatically,[215,216] and pituitary cells respond to exogenous GnRH by releasing LH.[217] This early GnRH-mediated activation of pituitary gonadotropes likely plays a key role in the priming of the HPG axis by favoring the formation of functional anterior pituitary endocrine cell networks.[218–220] Indeed, the genetic engineering of mice, in which GnRHR-expressing cells can be ablated under the effect of diphtheria toxin, has demonstrated that the embryonic increase in LH secretion is needed to promote the proper development of FSH-expressing gonadotropes.[221] GnRH stimulation of pituitary gonadotropes activates GnRHR, a G protein-coupled receptor, and induces the secretion of the gonadotropins LH and FSH, in large part through $G_{q\alpha}$ and $G_{11\alpha}$ activation and the subsequent induction of calcium mobilization.[222–224] Although the constitutive activation of GnRHR has been reported to lead to precocious puberty,[225] deleterious mutations in the GnRHR gene have been shown to cause hypogonadotropic hypogonadism with a delay or absence of puberty in both humans[143] and mice,[226–228] without affecting embryonic GnRH neuronal migration.[229]

Postnatal Maturation

Stages of postnatal maturation. As mentioned above, at birth, GnRH neurons have reached their final destination within the hypothalamus, where they are diffusely

distributed and are particularly abundant in the preoptic region in both mice and rats. Their axons target the pericapillary space of the median eminence, where they release their neurohormone into the fenestrated vessels of the pituitary portal blood system for delivery to the anterior pituitary. During postnatal development, GnRH neurons are subjected to a sequence of complex maturational events affecting their biosynthetic capacity, neurosecretory pattern, and morphology, which ultimately lead to sexual maturation and the initiation of puberty. This array of events, which may be linked, at least in part, to the integration of postmigratory GnRH neurons into the neural network responsible for relaying bodily information to these core neurons, has been divided into several phases in both males and females based on morphological and physiological parameters, as delineated earlier by Ojeda and colleagues.[121] In males, postnatal sexual development can be divided into four stages: a neonatal period that comprises the first week of extrauterine life (where the day of birth is designated postnatal day 0 or P0), an infantile period that extends from P8 to P21 (age at weaning), a juvenile period that ends around P35 (in rats), and a peripubertal period that ends at 55–60 days of age with the appearance of mature sperm in the vas deferens. Female postnatal development of the reproductive axis can also be divided into four stages: a neonatal period from birth to P7; an infantile period from P8 to P21; a juvenile period that ends around day 30 in rats and between days 25 and 40 in mice, depending on the strain; and a peripubertal period that is variable in duration but culminates with the occurrence of the first ovulation.

Hypothalamic expression of the GnRH gene. The expression of the GnRH gene appears to be required neither for GnRH neuronal migration nor for GnRH neuronal maturation, since the distribution of GnRH neurons in *hpg* mice harboring a naturally occurring deletion of about 33.5 kb encompassing the distal half of the gene encoding the GnRH precursor is similar to that in wild-type mice,[96,229] and the lack of the GnRH peptide does not preclude the spontaneous generation of bursts of action potentials in GnRH neurons.[229] However, decreased brain GnRH expression caused by the deletion of an enhancer region in the GnRH promoter that is critical for its expression in the hypothalamus,[230] or by the selective deletion of some kinases, such as JAK2 (Janus-activated kinase 2) in GnRH neurons,[231] has been shown to be associated with a significant delay in the onset of puberty and abnormal estrous cyclicity in adults.[231,232] Even though the overall impairment of fertility in these mice varies widely, from mild[232] to severe,[231] these two studies suggest that the proper regulation of enhancer/repressor elements in the GnRH promoter is required for the timely completion of female sexual maturation. Insights into the molecular mechanisms that regulate the expression of the GnRH gene by acting directly on its promoter have mostly been gained by studies performed in the immortalized murine GnRH-secreting cell lines GT1-7[99] and GN11[233] in vitro (Table 30.2). In contrast, few, if any, studies have been undertaken to determine whether these regulators play an actual role in the control of the GnRH promoter in vivo, and whether they are important for the normal physiological events associated with reproduction, including puberty, estrous cyclicity, and fertility. One study has shown that mice in which GnRH neurons are selectively lacking in the expression of CREB (cAMP response element-binding protein), a repressor of the GnRH promoter in vitro,[252,253] undergo normal puberty,[254] suggesting that this transcription factor does not play a major role in the postnatal maturation or function of GnRH neurons in vivo. In contrast, another study has shown that the selective invalidation in vivo of the expression of OTX2 (orthodenticle homeobox 2), a well-known activator of GnRH gene expression,[243–245] in GnRH neurons, results in a marked decrease in GnRH mRNA expression in the hypothalamus of adult mice as well as the delayed onset of puberty. Unexpectedly, however, this decrease appears to be due to the premature death of GnRH neurons during embryonic migration in these mice.[197] However, the use of these mice has enabled the demonstration that OTX2 expression is required to mediate the in vivo increase in GnRH gene

TABLE 30.2 Factors Thought to Influence the Transcriptional Activity of the GnRH Gene in Rodents

Activation	Repression	Inhibition of repression
POU2F1[234–238]	MSX1[239,250]	AES[245,250]

expression induced by kisspeptin,[246] another primarily hypothalamic peptide that potently stimulates GnRH neurons and whose action is essential for puberty and subsequent fertility.[255]

Postnatal changes in hypothalamic GnRH content. In both male and female rats and mice, hypothalamic GnRH content increases steadily during the neonatal period.[215,256–259] Although it remains constant in the first part of the infantile period, between 8 and 12 days of age, it subsequently increases sharply between P12 and P16, and continues to increase during the juvenile period to reach a maximum during the peripubertal period in females.[95,258,259] In males, however, GnRH content does not peak but continues to increase throughout adulthood.[95,256] Interestingly, in vitro experiments using retrochiasmatic hypothalamic explants containing GnRH axons and nerve terminals, but probably few cell bodies [260] from male and female rats, have shown that GnRH is secreted in a pulsatile fashion from postnatal day 5 to puberty.[257,261] Also, changes in pulsatility have been shown to differentially regulate gonadotropin secretion both in vitro[262] and in vivo.[263]

FEMALES: the pattern of postnatal GnRH secretion, changes in circulating gonadotropins, and the recruitment and maturation of the first ovarian follicles (Figure 30.2).

Neonatal period. As mentioned previously, and as indicated by its name, the ultimate function of GnRH is to stimulate the secretion of the gonadotropins FSH and LH, and thus influence gonadal development and function. In females, the ovary at birth consists of cords and oogonia.[122] Primordial follicles are formed by 3 days after birth, whereas well-developed secondary follicles are seen by P7.[264–267] The activity of the hypothalamic–pituitary unit does not appear to be required for ovarian development during this first week of postnatal life, since follicular development is seen to be normal in GnRH-deficient *hpg* mice at 7 days of age.[268] In addition, FSH and LH are unlikely to exert any direct effect on the primordial follicles because they still lack a functional gonadotropin receptor signaling mechanism.[269–272] Instead, primordial follicles may respond to activators of the cAMP pathway that are released by sympathetic nerves, which develop before the initiation of folliculogenesis[273–275] or other paracrine factors produced within the ovary (see Chapter 21)

Infantile period. During the second and third weeks of life, when the first wave of ovarian follicles, which will ovulate at puberty, have reached the secondary stage and become responsive to FSH,[269–272] key neuroendocrine events prompt them to develop into preantral and then antral follicles over the next 3 weeks.[264–267] At the beginning of the infantile period, circulating FSH levels rise dramatically and reach peak values at 12 days of age in both rats[276–279] and mice.[259,280] This infantile surge in FSH enhances the development of preantral follicles and rescues early antral follicles from apoptotic death.[122] Blunting this infantile rise in FSH levels by GnRH antagonist treatment decreases ovarian weight and preantral follicle development in rats at P19, whereas FSH treatment rescues these effects.[266] In addition, FSH-deficient mice are infertile due to the lack of maturation of secondary or preantral follicles into antral follicles.[281] Along the same lines, the absence of circulating FSH in *hpg* mice (which lack GnRH), is associated with a dramatic reduction in the number of follicles reaching the preantral stage and the complete absence of ovarian follicles attaining the antral stage.[268] Similarly, the alteration of the course of the infantile FSH surge in transgenic mice, which exhibit hypothalamic defects in GnRH release, results in delayed puberty and reduced fertility in primiparous females.[259] Even if their fluctuation is less consistent during this period, LH levels are also elevated in both infantile rats and mice,[259,277,282] and sporadic bursts of secretion have been reported to occur.[277,283] However, LH does not appear to play a major role in ovarian development at this early stage of sexual maturation, since LH receptor knockout mice, in contrast to FSH knockout animals,[281] exhibit early antral follicles.[284]

How do these developmental changes in circulating gonadotropin levels relate to GnRH release during the infantile period? Both early and more recent in vitro experiments, which measure GnRH release from hypothalamic explants by using radioimmunoassay, have suggested that the frequency of GnRH pulses increases throughout sexual maturation.[261] Indeed, GnRH pulses occur every 90 min at P5, every 60 min at P15, and every 30 min during the juvenile and peripubertal periods in rats.[257,261] Thus, this provides a tentative explanation as to why the secretion of FSH during the infantile period is so different from that of LH: unlike high-frequency GnRH pulses, which promote LH release, low frequency GnRH secretion in infantile animals has been shown to induce high levels of FSH secretion,[262,263] which are at least five times greater than in peripubertal animals. These high levels of FSH may also be linked to the responsiveness of the pituitary to GnRH, which appears to be much higher in infantile rats than in animals at later developmental stages,[285–287] as well as to the lack of negative feedback onto the brain.[288,289] It is worth noting in this context that between 7 and 21 days of age, there is an overall increase in steroidogenic enzyme activity in the ovary. This leads to, among other results, a marked and continuous increase in the production of estrogens, thought to result from an interaction between FSH and LH signaling within the infantile ovary in a manner similar to that seen in adult animals.[290,291] Indeed, this developmental change requires gonadotropin stimulation, since ovarian metabolism in adult GnRH-deficient *hpg* mice is similar to that in normal mice at 7 days.[292] However, because of the presence of the estradiol-binding α-fetoprotein (AFP) in the circulation,[293,294] whose levels remain high until

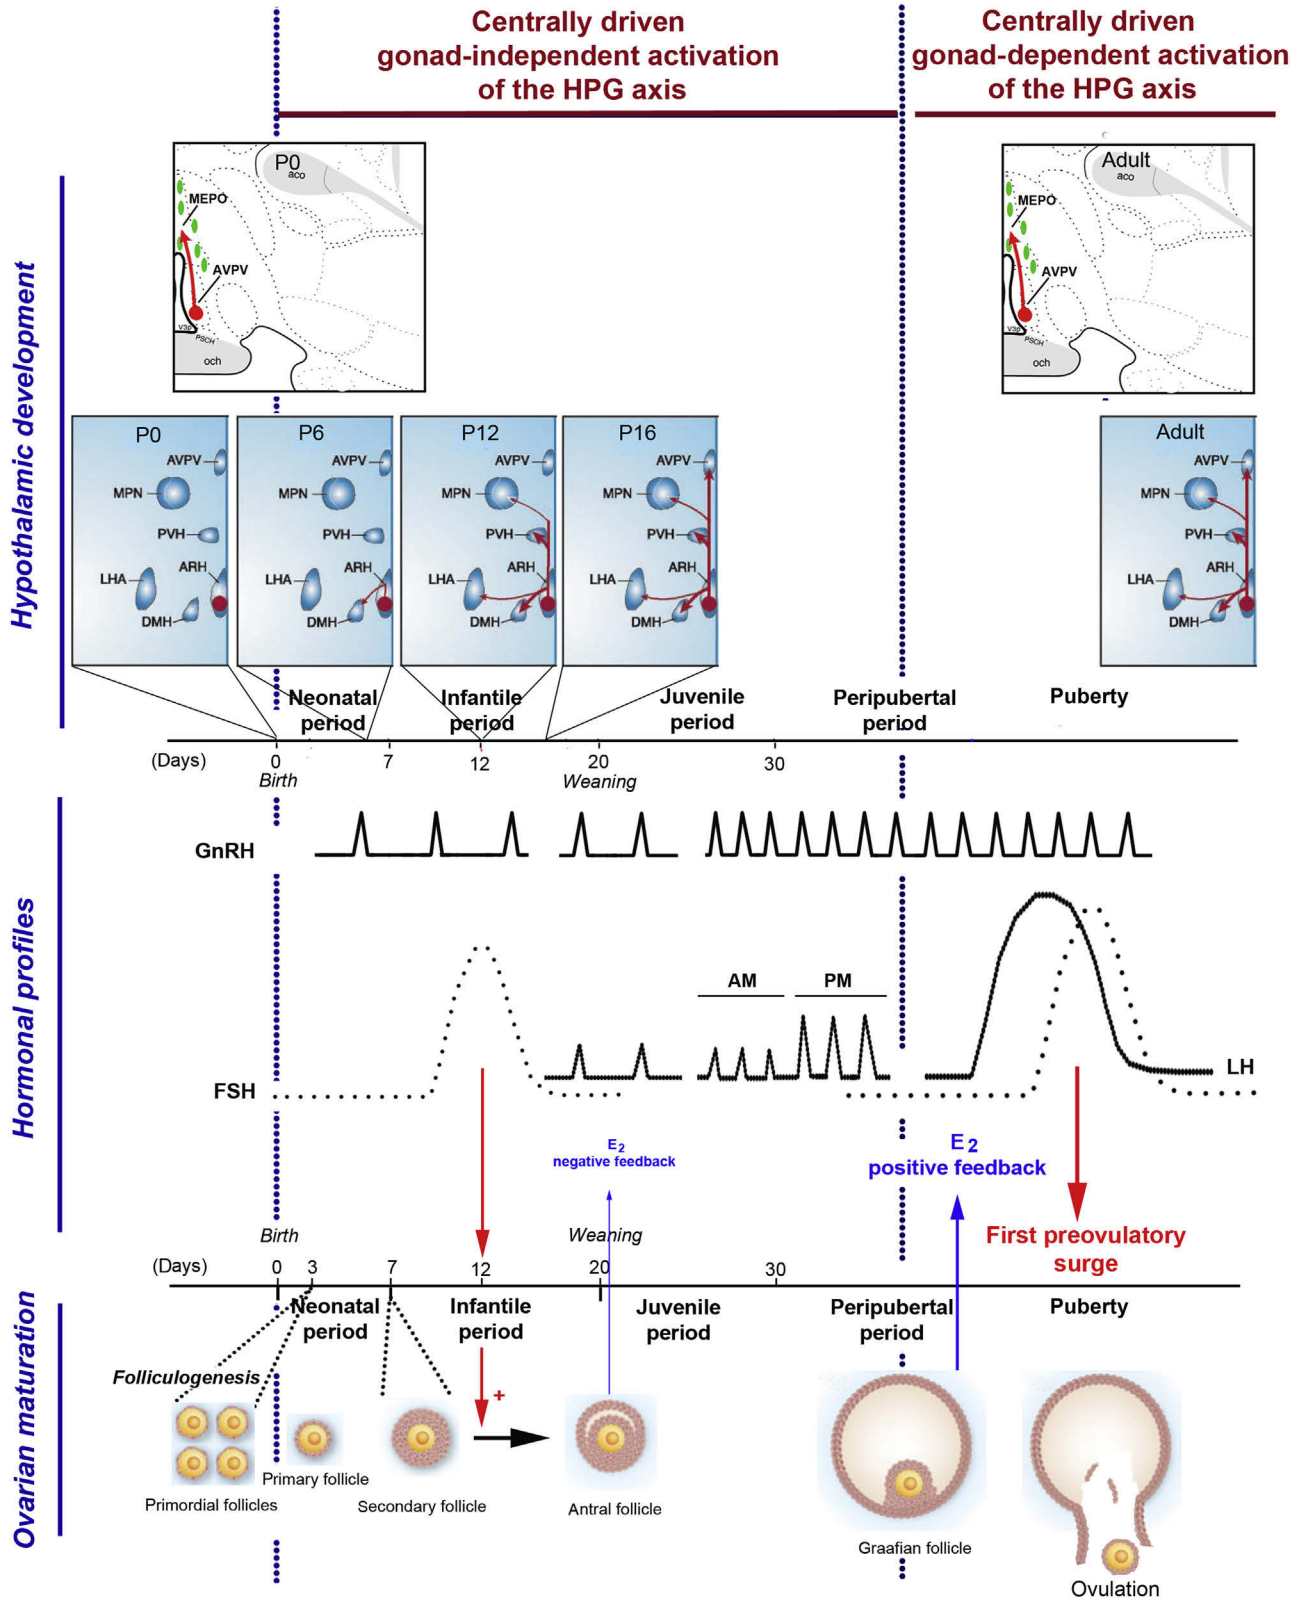

FIGURE 30.2 Centrally driven gonad-independent and gonad-dependent activation of the female HPG axis. (*Hypothalamic development*) Although the morphological development of the hypothalamic site (the AVPV) known to mediate the positive-feedback effect of estradiol (E_2) onto GnRH neurons (ovals) in sexually mature female individuals is complete at birth, axons of the ARH neurons, which are suspected of playing a key role in mediating the estrogen negative feedback, first reach the preoptic region during the infantile period. Mature projections are established by postnatal day 16 (P16). (*Hormonal profiles*) Schematic diagrams illustrating our present understanding of centrally driven gonad-independent and gonad-dependent changes in hormonal profiles during female postnatal development. (*Ovarian maturation*) Schematic diagram illustrating how the aforementioned changes affect folliculogenesis, and conversely, how the advancement of follicular maturation modulates hypothalamic/pituitary function through E_2 secretion during postnatal development. AVPV, anteroventral periventricular nucleus; ARH, arcuate nucleus of the hypothalamus; DMH, dorsomedial nucleus of the hypothalamus; LHA, lateral hypothalamic area; MEPO, median preoptic nucleus; MPN, medial preoptic nucleus; PVH, paraventricular nucleus.

P16[293–295] to protect the female brain from masculinization and defeminization,[296] the negative feedback of ovarian estradiol onto the hypothalamus, which could reduce GnRH secretion and thus limit circulating FSH, is relatively ineffective during the infantile period,[288,289] even if it becomes operational as early as P12-P16 in mice.[297] In summary, the infantile period constitutes a key stage of postnatal development during which the first centrally driven, gonad-independent activation of the HPG axis occurs.

Juvenile period. By the end of the infantile period, at weaning, together with the steady decrease in peripheral AFP concentrations[298] and constant ovarian growth,[282] circulating FSH levels decrease to nadir values, the sporadic bursts of LH release described above disappear, and plasma LH levels remain low.[277,282,283] GnRH pulse frequency in hypothalamic explants is, however, seen to increase significantly to reach adult values, i.e., about one pulse every 30 min,[261] a frequency known to maximally stimulate LH secretion both in vitro[262] and in vivo.[263] In accordance with these data, the pattern of LH secretion, which is distinctly pulsatile and accelerates during the latter part of the juvenile period,[119,299–301] is also seen to exhibit interpulse intervals of about 30 min in vivo.[119] These findings suggest that despite the constant increase in steroid negative feedback on gonadotropin release, which becomes maximally effective during the juvenile period,[298,302–304] GnRH neuroendocrine output matures.

In line with this notion, although proestrous levels of exogenous estradiol fail to promote LH release during the infantile period, they become capable of doing so when animals enter the juvenile period, and sensitivity to preovulatory levels of estradiol increase dramatically with age to reach a maximum at the end of the juvenile period, i.e., around P30.[288] This stimulatory effect of estradiol on LH release no doubt involves the activation of hypothalamic GnRH secretion, as gonadal-steroid-induced LH surges in juvenile rats have been shown to occur concomitantly with an increase in GnRH release into pituitary-portal blood vessels.[305] In summary, during the juvenile period, the hypothalamic–pituitary axis becomes sensitive to the low levels of estradiol produced by the ovaries, thus enabling the development of negative feedback by estradiol. In parallel, the hypothalamic–pituitary axis acquires the ability to respond to high exogenous estrogen levels, although the ovarian follicles at this stage of development do not produce sufficient amounts of estradiol,[306] or for sufficient periods of time, to exert a positive feedback effect and stimulate a surge of LH.

Peripubertal period. The transition between the juvenile and the peripubertal periods is marked by the appearance of morning–afternoon differences in the serum concentration of LH.[119,307] This diurnal pattern of release is established in female rats around P30 and is characterized by an increase in both basal LH levels and LH pulse amplitude in the afternoon, whereas LH pulse frequency remains unchanged between the morning and the afternoon.[119,299] Importantly, this phenomenon does not appear to be driven by the gonads, since higher plasma LH levels in the afternoon are also seen in peripubertal rats ovariectomized shortly before measurements.[308] In parallel to this centrally driven, gonad-independent activation of pituitary gonadotropin secretion, some peripubertal animals also exhibit a midafternoon episode of more sustained LH secretion, defined as an LH minisurge.[119] In contrast to the afternoon increase in LH pulse amplitude, these minisurges of LH secretion appear to be caused by subtle increases in serum estradiol levels.[309] In vitro experiments in which peripubertal ovaries are perfused with an LH regimen designed to mimic either morning–afternoon pulses of LH secretion, or LH minisurges, demonstrate that these peripubertal changes in the pattern of LH release are physiologically relevant for the functional development of the ovaries, and presumably stimulate them to produce more estradiol and progesterone.[310] In turn, minisurges in LH secretion evoked by subtle changes in estradiol levels[309] would then lead to further ovarian activation.[310]

Puberty: the first preovulatory surge of gonadotropins and the first ovulation. The ovary's acquisition of the capacity to secrete high levels of estrogens over a period of about 24 h[311] represents the key event in the determination of the timing of the first preovulatory GnRH/LH/FSH surge, i.e., puberty.[123,305] Early immunoneutralization experiments have demonstrated that rising blood estrogen levels (resulting from the stimulation of the ovaries of sexually immature rats with pregnant mare serum gonadotropin [PMSG]) constitute the trigger that activates the release of proestrous levels of LH.[312] In the hypothalamus, this trigger evokes the discharge of GnRH neurons, releasing the neurohormone;[305] in the pituitary, it sensitizes gonadotropes to the stimulatory effect of GnRH.[313] Besides estrogens, progesterone, whose levels also increase dramatically on the day of the first proestrus,[314,315] appears to have a role in facilitating the stimulatory effects of estrogens on GnRH release.[316] In mice, treatment with estradiol, progesterone, or both, is also known to promote pubertal ovulation in sexually immature individuals.[317] In contrast to the infantile, juvenile, and peripubertal periods of sexual maturation, where changes in gonadotropin secretion appear to be gonad-independent, the onset of the first preovulatory surge of gonadotropins, the landmark of puberty, thus appears to result from a centrally driven gonad-dependent activation of the HPG axis (Figure 30.2), as occurs on proestrus in adults.

MALES: the relationship between the pattern of postnatal GnRH secretion, changes in circulating gonadotropins, and testicular maturation (Figure 30.3).

Neonatal period. As seen in females for ovarian growth, the activity of the hypothalamic pituitary axis does not appear to be required for testicular development during the neonatal period. Intriguingly, testosterone during the fetal and neonatal periods, essential for male sexual differentiation, is produced by fetal Leydig cells, which, in contrast to the Leydig cells that develop postnatally, do not require LH for their proliferation or differentiation. Instead, they are completely dependent on placental chorionic gonadotropin.[318–321] The sexual differentiation of male *hpg* mice is normal, despite the nearly complete lack of gonadotropins.[322] The testes of newborn mice deficient in GnRH or FSH, or harboring mutations in the LH receptor, are similar in size, appearance, and function to those of their wild-type littermates, and their intra-abdominal location adjacent to the urinary bladder is the same as in wild-type males.[95,281,284,323] However, postnatally, germ cells in GnRH- or LH-receptor-deficient mice fail to progress beyond early meiosis (the diplotene stage)[95] or are arrested at the round spermatid stage,[284] and the testes, which remain very small, never descend into the scrotum in these infertile mice.[95,284] In contrast, in FSH-deficient mice, spermatogenesis appears grossly normal and males eventually reach puberty and are fertile.[281] During the neonatal period in rats, circulating FSH levels appear to be high up to postnatal day 5, when they drop dramatically[283,324,325] (Figure 30.3), whereas circulating LH levels remain constantly low or undetectable.[283,324,325]

Infantile, juvenile, and peripubertal periods. Although data about putative changes in LH levels during the infantile period in rats are scarce and inconsistent (see for review Ref. 16), it is clear that circulating FSH levels rise dramatically after the second week of life and reach a maximum between 30 and 40 days of age, then decrease when serum testosterone concentrations attain levels similar to those seen in adults both in rats[277,282,283,324–327] and mice.[140,328] The key role of infantile/juvenile GnRH release in male sexual development has been shown using passive immunization[329–331] and treatment with a GnRH antagonist,[332,333] which result in delayed puberty, the permanent impairment of testicular function and defective adult sexual behavior. Concerning the pattern of GnRH release, in vitro studies in the rat have shown that GnRH pulse frequency gradually increases during the juvenile period (0.1 pulse/h) to reach peripubertal values (0.3 GnRH pulses/h).[257] Whether similar changes occur in the mouse is not known. However, the recent development of fast-scan voltammetry to measure GnRH release in real time from brain slices[334,335] suggests that the picture is more complex than believed previously. For example, in mouse brain slices, the pulse frequency of GnRH release has been reported to be much higher in 7–10-day-old infantile than in 40-day-old peripubertal male mice,[335] and this phenomenon appeared to be paralleled by changes in the frequency of GnRH neuron firing.[335] While as suggested by Moenter and colleagues,[335] the pulse frequency of GnRH release could in fact be high during the early infantile period (3.1 GnRH pulses/h), decrease abruptly during the late infantile period (0.1 pulse/h),[257] and gradually go back up to peripubertal values (0.3 GnRH pulses/h)[257,335] during the juvenile period. This possibility is still in the realm of speculation for the moment in the absence of advanced technology capable of permitting longitudinal studies in vitro. Nor is it known whether such a putative triphasic pattern of frequency regulation is due solely to gonadal steroid negative feedback, or whether it is homologous to the hiatus in GnRH secretion seen in nonrodents/higher mammals during the juvenile period. This is an exciting possibility that requires further investigation.

Genetic mouse models in which the signaling pathways of GnRH, LH, or FSH are mutated or harbor gain-of-function mutations, have also added to our understanding of the role of LH and FSH in the control of testicular growth and spermatogenesis.[140,226–228,281,336–342] From these studies, it is clear that changes in the secretion of gonadotropins precede the maturation of the testes. FSH binds to Sertoli cells within the seminiferous tubules to promote their proliferation, which influences spermatogenesis on a quantitative level, but is not essential for fertility.[281,336,337,339] LH stimulates testosterone secretion by acting directly on the Leydig cells that develop postnatally, around day 7 in mice, and whose proliferation and differentiation are also highly dependent on LH.[319] Testosterone is the most important androgen produced by the gonads in males, as it plays pivotal roles in spermatogenesis, the differentiation and maintenance of accessory sex organs and sexual behavior,[343–345] and potentiates the pituitary response to GnRH.[346] Interestingly, testosterone exerts a negative feedback effect on the hypothalamic–pituitary axis throughout life, even during the neonatal period, as shown by experiments in which orchidectomy leads to an immediate increase in gonadotropin secretion that can be suppressed equally readily by the administration of exogenous testosterone.[79,347–350]

Puberty: presence of motile sperm in the epididymis and capacity for sexual reproduction. Spermatozoa in the cauda epididymis–vas deferens junction are first observed around 40 and 55 days of age in mice[131,132] and rats,[133,134] respectively. In line with the fact that the first spermatozoa to appear are few in number and exhibit poor motility and aberrant morphology, and that these characteristics are normalized with age,[132,351] the incidence of fertile matings in mice, for example, increases steadily from 40 to 55 days of age.[131] All these events occur concomitantly with a steep increase in testosterone levels,[140,325,328] whose pattern of secretion has been shown

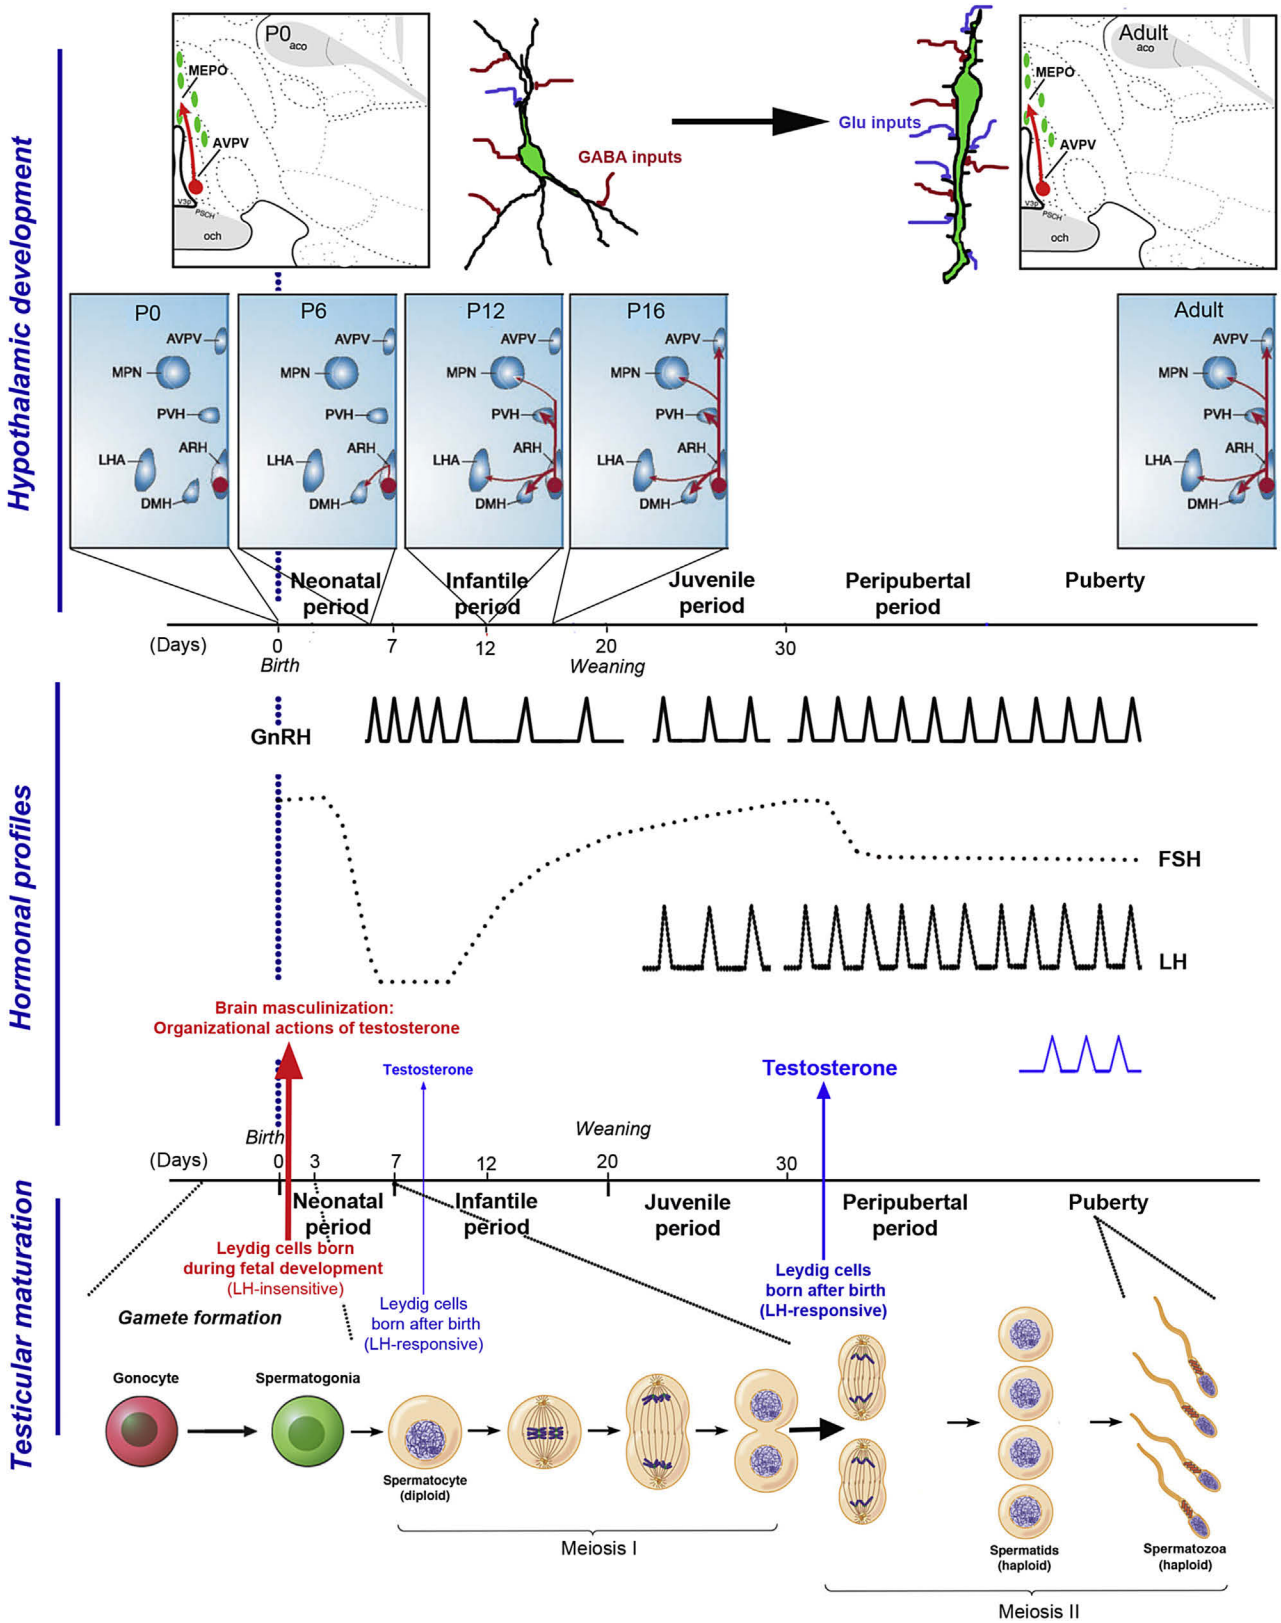

FIGURE 30.3 Postnatal maturation of the male HPG axis. (*Hypothalamic development*) As in females, although development of the sexually dimorphic AVPV is complete at birth and its masculinization via gonad-dependent mechanisms occurs during the neonatal period, ARH projections to the preoptic region develop and mature during the infantile period. In the male, GnRH neurons (ovals) are subjected to extensive pruning of their dendrites and changes in dendritic spine density during postnatal development; although GABAergic inputs to GnRH neurons do not appear to change, glutamatergic afferents are thought to increase dramatically between the infantile period and adulthood. (*Hormonal profiles*) Schematic diagrams illustrating our present understanding of centrally driven (and likely gonad-independent changes in hormonal profiles during male postnatal development). (*Testicular maturation*) Schematic diagram illustrating how the aforementioned changes affect spermatogenesis and Leydig cell function in the testes. Glu, glutamate; AVPV, anteroventral periventricular nucleus; ARH, arcuate nucleus of the hypothalamus; DMH, dorsomedial nucleus of the hypothalamus; LHA, lateral hypothalamic area; MEPO, median preoptic nucleus; MPN, medial preoptic nucleus; PVH, paraventricular nucleus.

to be highly correlated with pulses of LH secretion[352] (Figure 30.3). It is worth noting that in mice and rats, 40–54 days are required to complete the initiation of spermatogenesis, a time period that corresponds exactly to the age at puberty in these species.[353] Spermatogenic development in advance of the normal age of onset of puberty cannot be achieved with precocious gonadotropin stimulation. For example, although mice harboring a common activating mutation of the human LH receptor (D582G), which in boys causes precocious puberty,[318,354] exhibit signs of accelerated sexual maturation such as early preputial separation, spermatogenesis is not advanced, i.e., there is no true precocious puberty.[140] However, premature expression of the androgen receptor in the Sertoli cell of mice accelerates maturation of this critical somatic cell and advances spermatogenesis[328] (see Chapter 16). In humans, approximately 64 days are required for undifferentiated spermatogonia to differentiate to spermatozoa,[355] and this process is not initiated until the onset of puberty is reached after the age of 10 years.

Structural Maturation of the GnRH Neuron

Over the past two decades, several studies have suggested that the structural remodeling of GnRH neurons accompanies developmental changes in their function. Early immunocytochemical studies have shown that the number of GnRH neurons bearing spine-like processes[356,357] increases during postnatal development in both male and female rats.[358,359] Recent studies by Herbison and collaborators, using biocytin filling of green fluorescent protein (GFP)-tagged GnRH neurons in acute brain slice preparations,[360] have extended these findings by showing that the spine density in GnRH neurons increases twofold between the second week of postnatal life and adulthood (when GnRH pulse frequency is thought to increase dramatically,[257,261] see Figure 30.3), both at the level of the somata and of the proximal dendrites in male transgenic mice.[361] Whether similar phenomena occur in females during postnatal development is not known. However, in adult female mice, estrogens have been shown to play an important role in regulating dendritic spine plasticity in GnRH neurons during the ovarian cycle,[362] an effect that may require estrogen receptor β (ERβ) and CREB signaling pathways in GnRH neurons themselves.[254,363] Herbison and colleagues have also shown that in addition to changes in spine density, a specific subset of GnRH neurons is subject to a biphasic pattern of remodeling of the dendritic tree during postnatal development.[361] Indeed, unlike GnRH neurons in the medial septum, GnRH neurons in the preoptic area, which in females are specifically involved in the generation of the GnRH surge at proestrus,[364–366] exhibit an expansive and highly branched dendritic tree during the neonatal period (between P0 and P10). This tree subsequently undergoes dramatic pruning before the peripubertal period (P35) to yield the relatively simple phenotype previously described for mature unipolar or bipolar GnRH neurons.[367] In sexually mature animals, bipolar GnRH neurons extend dendritic processes up to 1 mm in length,[360,368] and sometimes even reach brain sites outside the BBB, such as the organum vasculosum of the lamina terminalis (OVLT)[369–371] and the median eminence.[372–374] In the latter, a recent study has suggested, provocatively, that GnRH neuronal processes could even share both axonal and dendritic functions.[372] For further discussion of the GnRH neuron, the reader is referred to Chapter 11.

The GnRH Neural Network

As the final common target for the central control of reproduction, the activity of GnRH neurons is regulated by a complex array of excitatory and inhibitory transsynaptic and nonsynaptic inputs[14,375–379] (Figure 30.4). This dynamic neural network, which converges onto the GnRH neurons and is likely subject to the direct and indirect influence of a plethora of internal and external signals, matures throughout the developmental period leading to puberty.[16,380,381] Thus, some of these communication pathways are established as soon as the GnRH neurons reach the hypothalamus, whereas others may only appear during postnatal development.[382,383]

The complexity of the neuronal network synaptically connected to GnRH neurons, originally suspected from studies that used classic neuroanatomical techniques to trace neuronal inputs to the medial preoptic nucleus in rats,[384–389] has recently been confirmed using advanced genetic strategies in mice.[98,100,366] Indeed, these latter studies have revealed that neurons from most areas of the hypothalamus, including the anteroventral periventricular nucleus (AVPV) and other preoptic nuclei; the arcuate, ventromedial, and dorsomedial nuclei of the hypothalamus (ARH, VMH, DMH); the lateral hypothalamus (LA); the ventral premammillary nucleus (PMv); and the suprachiasmatic nucleus (SCN); as well as those from the main and accessory olfactory bulbs and the brain stem, synapse directly with GnRH neurons in both males and females. The sequence of establishment of these connections and their maturation are likely to play a major role in the timely unfolding of the developmental program leading to puberty.

Embryonic Development

Most neuronal populations seen to synapse with GnRH neurons in adults[98,100,366] are born during embryogenesis.[144,390–392] For example, hypothalamic neurons,

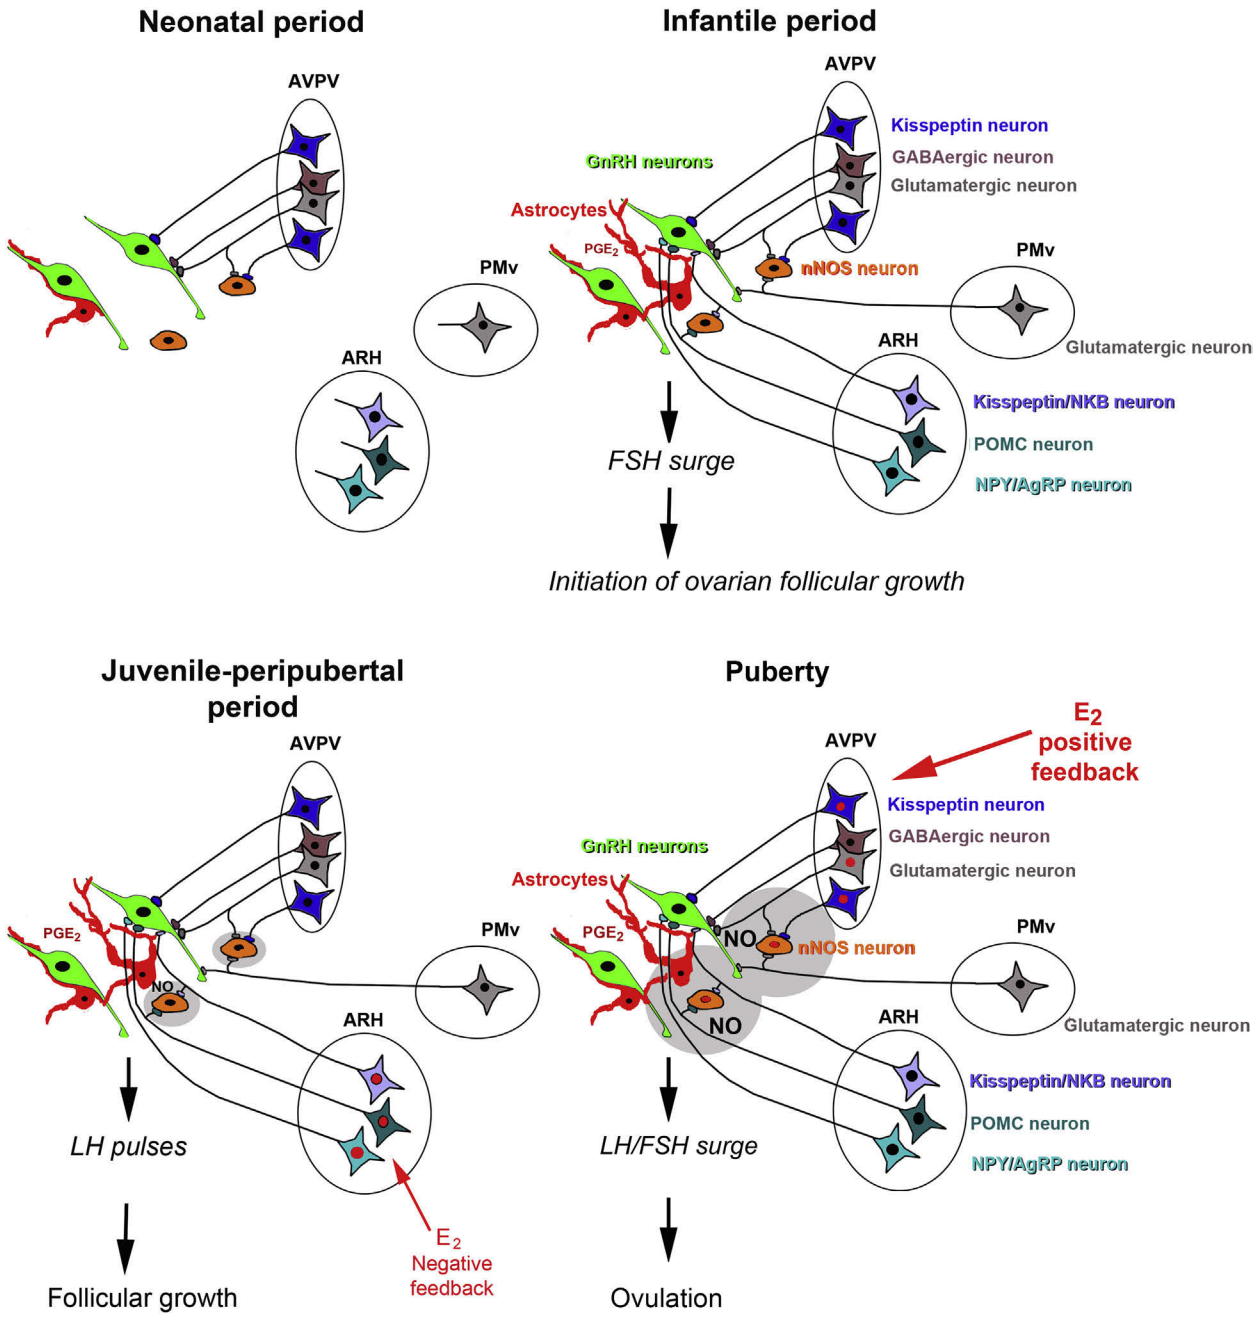

FIGURE 30.4 Schematic diagram illustrating the different maturational steps leading to the onset of puberty in females and their putative neural control during postnatal development. The projection of ARH neurons to the preoptic region during the infantile period and the maturation of the synaptic contacts they establish may constitute the first centrally driven gonad-independent trigger for sexual maturation, by prompting the infantile FSH surge and thereby initiating the growth of the follicles that will ovulate at puberty. Subsequently, with the gradual decrease in circulating levels of alpha-fetoprotein, the low estradiol (E_2) levels produced by growing follicles progressively gain access to the hypothalamus, where they exert a negative-feedback effect on ARH neurons. Besides, neurons and glial cells from the tuberal and preoptic regions of the hypothalamus, and possibly also neurons from other brain areas, contribute to the maturation of the pattern of pulsatile LH secretion throughout the juvenile and peripubertal periods, further promoting follicular growth. When ovarian follicles reach the Graafian stage, the increasing amount of E2 they produce exerts a positive-feedback effect on the neurons of the AVPV, which coordinate the onset of the first preovulatory GnRH and LH/FSH surge, thus triggering the first ovulation and conferring fertility on the individuals. PGE_2, prostaglandin E_2; AVPV, anteroventral periventricular nucleus; ARH, arcuate nucleus of the hypothalamus; PMv, ventral premammillary nucleus.

which are generated predominantly from the epithelium of the third ventricle, are born between E12 and E14 in mice[393–395] and between E12 and E17 in rats.[396–399] Subsequently, these neurons migrate from their site of origin to their final position, a process that is also mostly complete before birth.[400] Two recent thought-provoking studies have demonstrated, using advanced genetic tools to perform toxin-mediated "cell knockouts" in mice, that during embryogenesis and the early neonatal period, the hypothalamus is endowed with a high degree of plasticity, and is capable of coping with the loss of a key neuronal population by developing network-based compensatory mechanisms. Indeed, the ablation of kisspeptin neurons or orexigenic neurons expressing neuropeptide Y/agouti-related protein (NPY/AgRP), two neuronal cell types key to the central control of fertility and food intake, respectively, has no major effect on the physiology of these mice.[203,401] However, the ablation of these neuronal populations later on in life, such as during adulthood, causes infertility and death of the animals due to starvation, respectively.[203,401] Concerning the kisspeptin system, the phenotype seen in the "cell knockout" mice is in striking contrast to that observed in "gene knockout" (or mutant) mice[255] and humans,[402] both of which display an absence of puberty and infertility. One could argue that in the former mouse model, the ablation of kisspeptin neurons is not complete, and that suboptimal numbers of surviving neurons could nevertheless be sufficient to drive the entire system,[403] as is the case with GnRH neurons themselves.[203] However, if this were the case, one could ask why neuronal deletion is complete in adults,[203] leading to infertility, but incomplete in neonates, with the rescue of some residual fertility. An alternative explanation for this remarkable difference is that in the "cell knockout" situation, kisspeptin neurons are appropriately integrated into the GnRH neuronal circuit, as shown by the correct expression of the *LacZ* reporter gene in mutant mice,[255] and likely continue to release the other neuropeptides and neurotransmitters that they express, including neurokinin B, dynorphin,[404–408] and dopamine.[409] In the absence of kisspeptin secretion from these otherwise active neurons, the function of the GnRH neuronal network is thus dramatically disrupted, whereas the total loss of kisspeptin neurons in the "cell knockout" model, and the concomitant absence of all signaling molecules that they made, initiates compensatory adaptations in the neonate.

Postnatal Development

Establishment of afferent projections to GnRH neurons. In both rats and mice, the hypothalamus is still relatively immature at birth, despite the fact that the GnRH neurons themselves and their projections towards the portal circulation in the median eminence are already in place, and continue to develop during the first 2–3 weeks of postnatal life. Indeed, while neurons of the AVPV, the hypothalamic site known to mediate the positive feedback effect of estradiol in mature females,[366,410,411] have completed their projections to the median preoptic nucleus (MEPO) and contact GnRH neurons by birth.[412] The axons of ARH neurons, which are suspected of playing a role in mediating estrogen and testosterone negative feedback[410,413–415] and in the control of pulsatile GnRH secretion,[405,414] first reach the MEPO at P12 and only achieve their final distribution by the end of the infantile period in both males and females,[416,417] when circulating FSH levels dramatically rise[140,276,280,282] (Figures 30.2 and 30.3) and estrogen-negative feedback starts to operate in females.[289,297] The fact that the arrival of the ARH fibers in the preoptic region could contribute to the maturation of estrogen negative feedback is strengthened by a recent study showing that perturbing the establishment of these ARH projections during the infantile period blunts the LH response to ovariectomy in juvenile mice, i.e., that the ability of the GnRH neuronal network to increase its secretory output in response to the loss of inhibitory control by estrogen is disturbed in these animals.[417] Efferents from other nuclei of the tuberal region of the hypothalamus that are functionally connected with GnRH neurons,[98,100] such as the VMH and DMH, also develop postnatally but are seen to reach the preoptic region earlier than ARH fibers.[416] Intriguingly, analogous to the critical period during neonatal life when sex steroids may specify sexually dimorphic patterns of development in the mammalian forebrain,[382,418,419] it has been shown over the past decade that the establishment of at least some of the projections of ARH neurons (e.g., the projections of the POMC and NPY/AgRP neurons) is also determined by metabolic hormones (e.g., leptin, ghrelin, and insulin) during a second critical period of postnatal development.[390] This developmental activity of peripheral metabolic signals is restricted to a neonatal/infantile window of maximum sensitivity characterized by the sequential elevation of the secretion of leptin,[420,421] which promotes ARH axon growth,[422,423] and of ghrelin,[424,425] which arrests this growth,[426] while insulin levels, which reflect the metabolic state of the pup, fine-tune these events.[427]

Synapse formation. The formation of synapses is a dynamic process that follows the development of axonal projections, and appears to continue well past the third week of postnatal life in the hypothalamus. For example, Reier and collaborators have reported that synapses in the preoptic region, which are sparse at birth, are primarily formed during the first 10–15 days of postnatal life and reach adult levels by P25 in rats of

both genders.[428] These ultrastructural changes are paralleled by an increase in the number of dendritic spines, as visualized by light microscopy in Golgi–Kopsch preparations,[428] which are thought to represent the location of predominantly glutamatergic excitatory inputs to these neurons.[429] As mentioned in the former section, GnRH neuronal somata and dendrites are themselves subject to an increase in spine density during postnatal development.[358,359,361] As in the preoptic region, in general, these changes occur between P10 and adulthood[361] and are concomitant with the arrival of neuronal projections from the ARH.[416] Promising preliminary studies from our laboratory show in addition that these events, which occur during the infantile period, are accompanied by a wave of astrogliogenesis.[430] Since astrocytes have been shown to be required for synaptogenesis,[431,432] and since altering astrocyte signaling[259] or preventing local cell proliferation around GnRH neurons during the second postnatal week by the stereotaxic injection of beads that release paclitaxel, an inhibitor of mitosis[430] leads to delayed puberty, the birth of new astrocytes during the infantile period may play an important role in this wiring process and could constitute one of the signals that set in motion the initial gonad-independent central activation of the gonadal axis.

Components

TRANSSYNAPTIC INPUTS

Glutamate. In accordance with the aforementioned neuroanatomical data, hypothalamic glutamate content gradually increases during postnatal development to reach a maximum after the onset of puberty.[433] In vivo push–pull perfusion experiments show that glutamate release from the preoptic region of female rats increases during the juvenile–peripubertal periods,[434] and is markedly elevated during the LH surge induced by gonadal steroids in ovariectomized animals.[435,436] Concomitantly, the ability of glutamate receptor agonists to stimulate GnRH release from hypothalamic explants increases gradually during the infantile–juvenile periods,[437] a phenomenon that is accompanied by an gonad-independent increase in NMDA-type glutamate receptor activity.[438] In vivo, gonadotropin release can be induced in sexually immature rats by treatment with the glutamate receptor agonists kainate and NMDA.[439–442] Remarkably, NMDA treatment in P16 infantile rats causes a significant increase in FSH release,[442] and the administration of NMDA advances the timing of puberty in rats[441,443] whereas treatment with NMDA antagonists delays it.[444–448] Together, these findings strongly suggest that the gradual increase in glutamatergic inputs to the preoptic region is a physiological component of central mechanisms underlying both the infantile activation of the gonadal axis and the first preovulatory surge of gonadotropins.[442,444–448]

The source of the glutamatergic inputs that mediate these changes in glutamate transmission during postnatal development remains to be determined. Several hypothalamic areas projecting to the preoptic region, such as the ARH, VMH, DMH, and PMv, and the preoptic region itself expresses type 2 vesicular transporters, an anatomical marker of glutamatergic cells.[101,449–452]

The investigation of glutamate receptor expression in GnRH neurons shows that up to 50% of them express the NMDA glutamate receptor[453–455] or the GluK5 kainate receptor (KA2).[456] The expression profile of the obligatory NR1 subunit of the NMDA glutamate receptor markedly increases in GnRH neurons during the infantile and peripubertal periods in mice[455] and rats,[454] respectively. In addition, electrophysiological studies have demonstrated that GnRH neurons also express functional AMPA receptors.[457,458] Even though GnRH neurons receive glutamatergic connections from diverse brain regions, including the AVPV, the electrical stimulation of which evokes monosynaptic NMDA and AMPA currents in GnRH neurons,[459] surprisingly, the deletion of neither AMPA nor NMDA glutamate receptors in GnRH neurons alters the onset of puberty or fertility in mice of either sex.[460] This study suggests that the expression of neither of these receptors in GnRH neurons is essential for the onset of puberty, and that, if they are important, their loss can be compensated for by the remaining glutamate receptor or by other afferent inputs of either neuronal or glial origin (see paragraphs below detailing nonclassic inputs).

GABA. γ-Aminobutyric acid (GABA) is a dominant neurotransmitter in the hypothalamus[461] and is synthesized from glutamate via a decarboxylase reaction catalyzed by two forms of the enzyme glutamic acid decarboxylase (GAD), GAD-65, and GAD-67. Expression levels of GAD mRNA increase in the preoptic region initially during the neonatal/infantile period[462] and then again during juvenile development.[463] GABA concentrations in brain tissues follow the same temporal pattern.[433,464,465] However, push–pull perfusion experiments suggest that GABA release from the preoptic region decreases during the juvenile–peripubertal transition period.[434]

Although the global effect of GABA on the onset of puberty and the GnRH network appears to be inhibitory,[466] emerging evidence suggest that its direct effect on GnRH neurons could be excitatory.[467] The infusion of GABA or the $GABA_A$ receptor agonist muscimol into the third ventricle or the preoptic region blocks the preovulatory surge of LH in intact female rats[468,469] and reduces the size of the estrogen-induced LH surge in ovariectomized rats.[470] In contrast, both intraventricular and intravenous infusions of bicuculline, a $GABA_A$ receptor blocker, advance the timing of the LH surge in proestrus and in gonadal-steroid-primed ovariectomized

rats.[471,472] Most GnRH neurons express functional ionotropic $GABA_A$ receptors that are synaptically activated both in brain slice preparations[457,459,473–476] and in vivo.[477] The various methods used to study GABA receptor expression in GnRH neurons clearly show that these neuroendocrine neurons express several different $GABA_A$ receptor subunits,[478–482] as well as the $GABA_B$ receptor.[483] Although GnRH neurons appear to express $GABA_A$ receptors throughout development, the subunit composition of these receptors changes considerably over time,[478,484] with a decrease in the range of subunits expressed before the end of the infantile period.[478] Both naturally occurring and induced $GABA_A$ receptor activation in GnRH neurons appear to be excitatory in nature throughout life;[459,485–487] however, as for the AMPA and NMDA glutamate receptors,[460] the knockdown of $GABA_A$ receptor signaling in GnRH neurons has no major effect on puberty onset or fertility.[488] This last study, in which the GABA response of GnRH neurons was reduced by 70–90%, suggests that either GnRH neurons compensate for their electrical excitability by other unknown inhibitory afferents or that normal levels of $GABA_A$ receptor-mediated transmission in the GnRH neuron are not important in shaping GnRH secretion at the median eminence.

Although changes in gonadotropin output triggered by experimental manipulations of the GABAergic system are contrary to those induced by the manipulation of the glutamatergic system, it is clear that both systems are tightly intertwined. Because glutamate is the natural precursor for GABA synthesis, any changes in glutamate availability directly affect GABA levels.[489] In addition, the two neurotransmitters have been shown to modulate each other's effects at both presynaptic and postsynaptic sites in the developing brain.[490] Unusually, AVPV neurons innervating GnRH neurons have been shown to co-express and co-release GABA and glutamate,[452,459] and the number of dual-transmitter-expressing neurons appears to increase around the onset of the LH surge and to be tightly regulated by estrogens.[452] One could hypothesize that such GABA/glutamate interactions also play an important role in the timely activation of the GnRH system during postnatal development.

Kisspeptin. During the last decade, kisspeptin,[491] a potent neuropeptidergic activator of GnRH neuronal activity, has emerged as a key player in the regulation of the onset of puberty and reproductive function.[492–495] Several comprehensive reviews on kisspeptin signaling and puberty have been published recently;[12,13,496–498] the following paragraph will therefore limit itself to the most salient aspects of the relationship of kisspeptin signaling with the timing of puberty.

Detailed studies in rodents have identified two prominent populations of kisspeptin neurons in the hypothalamus, one located in the ARH and the other in the AVPV, that are differentially regulated by gonadal steroids acting through ERα, and possibly the androgen receptor.[415,499,500] These populations are sexually dimorphic, with kisspeptin neurons being predominantly present in the ARH of both sexes,[492] where they have been proposed to mediate the negative feedback effect of sex steroids upon GnRH release,[499] however, they are present at a greater density in females than in males in the AVPV, where they are poised to elicit the preovulatory GnRH/LH surge through positive feedback mechanisms.[9] In addition, kisspeptin neurons of the ARH, which in contrast to those of the AVPV also express neurokinin B and dynorphin-A,[404–408] have recently been proposed to play a role in the control of pulsatile GnRH release via autaptic self-activation by neurokinin B and inhibition by dynorphin-A.[405,501,502] In both male and female rodents in adulthood, the expression of mRNA for the neurokinin B gene, *Tac3*, in arcuate neurons is inversely correlated to circulating levels of gonadal steroids, further supporting the putative involvement of these neurons in mediating the negative feedback of the gonads upon GnRH release.[408,503,504] The neurokinin B system in the ARH, which is sexually dimorphic,[404] has been shown to be immature at birth and to acquire adult features during postnatal development.[505] Surprisingly, rodents in which the activity of the neurokinin B receptor NK3R has been pharmacologically or genetically impaired[504,506,507] show normal puberty and only a mildly altered reproductive phenotype, unlike humans, in whom mutations disabling NK3R result in abnormal pubertal development and hypogonadotropic hypogonadism.[508] Whether the lack of effect of NK3R mutations on puberty reflects the ability of other tachykinin receptors to mediate NKB effects, as has been suggested in adults,[509] remains unclear. A recent report that the blockade of the kappa-opioid receptor advanced puberty in rats [502] points to a possible role for dynorphin in these neurons in pubertal development, although the deletion of this receptor decreased LH secretion in ovariectomized adults.[405]

Both mice and humans harboring deleterious mutations in the genes encoding kisspeptin (*Kiss1, KISS1*)[402,510,511] or its receptor (*Kiss1r, KISS1R*),[103,104,512–514] exhibit hypogonadotropic hypogonadism and infertility, whereas individuals carrying an activating mutation for *KISS1R*[515] show central precocious puberty. Even though spermatogenesis and ovulation appear to be severely impaired in most kisspeptin and KISS1R mutant mice, in some mouse lines, subsets of females undergo vaginal opening and show estrous cyclicity, whereas males exhibit varying degrees of spermatogenesis, ranging from arrest at meiosis II to the appearance of mature sperm.[511,516] The use of acyline, a GnRH receptor antagonist, has revealed that this remnant sexual activity, which can lead to estrogen-dependent increases in LH release in ovariectomized mutant mice,[512] and is also observed

in patients,[104,517] is mediated by hypothalamic GnRH signaling.[512,516] Importantly, an analysis of ovarian histology in mutant females exhibiting estrous cyclicity shows that these cycles are in fact anovulatory, since these ovaries contain follicles at all stages of development and a large number of atretic follicles, but no corpora lutea.[516] These findings, together with data showing that the proportion of GnRH neurons that respond directly to kisspeptin increases dramatically between the peripubertal period and adulthood,[493] and that kisspeptin-KISS1R signaling appears to be essential for the GnRH neuronal activation that initiates ovulation,[518,519] suggest that kisspeptin neurons, especially the population residing in the AVPV, might play a particularly important role during sexual maturation at the time of puberty onset. The relevance of peripubertal kisspeptin signaling for the acquisition of sexual maturity is reinforced by the observation that the pharmacological blockade of KISS1R during this period blunts the onset of puberty in female rats.[520] However, studies in which ERα has been selectively invalidated in kisspeptin neurons, leading to precocious puberty,[521] also suggest that kisspeptin neurons play a key role during the late infantile period when kisspeptin fibers from the ARH first reach the preoptic region.[417] These fibers likely mediate the negative feedback of estrogens onto GnRH neurons[521] that has been shown to be initiated around this time,[297] and thus tightly control the timely progression of female sexual maturation during postnatal development.

The direct apposition of kisspeptin fibers to GnRH neurons can first be visualized during the juvenile-peripubertal period; it attains maximal levels in sexually mature animals, with 12% and 40% of GnRH neurons displaying the apposition of kisspeptin fibers to their cell bodies in male and female mice, respectively.[522] The use of the transgenic *Kiss1r-LacZ* knock-in mouse model has shown that 50–70% of GnRH neurons express the *Kiss1r* gene, as visualized by X-gal histochemistry.[494,523,524] By rescuing fertility through the reintroduction of KISS1R into GnRH neurons in systemic *Kiss1r* knockout mice or by causing infertility with the selective deletion of *Kiss1r* expression in GnRH neurons, Herbison and colleagues have recently demonstrated that KISS1R expression in GnRH neurons is essential for the onset of puberty and reproduction in mice.[525]

POMC-derived peptides. The anorexigenic (appetite suppressing) proopiomelanocortin (POMC)-expressing neurons of the ARH[526] constitute one of the estrogen-sensitive afferents to the preoptic region[389] that can be seen synapsing onto GnRH neurons.[527] The loss of ERα in POMC neurons has recently been shown to blunt the ability of estrogens to mediate their negative feedback regulation of gonadotropin secretion and to cause subfertility in mice.[528] Among the POMC-derived neuropeptides, β-endorphin appears to be relatively ineffective in modulating GnRH neuronal firing,[529] which is in good agreement with studies that have found no evidence for μ-opioid receptor expression in GnRH neurons.[530,531] In contrast, α-melanocyte-stimulating hormone (α-MSH) has been shown to promote the firing of the majority of GnRH neurons in the preoptic region via the direct postsynaptic activation of melanocortin receptor 3 (MC3R) and MC4R, both in adult and peripubertal female mice.[529,532] Together, these results suggest that hypothalamic POMC neurons, which lie at the crossroads between the central control of energy homeostasis and reproduction, may play a significant role in postnatal sexual maturation.

NPY/AgRP. The orexigenic (appetite promoting) NPY/AgRP ARH neurons,[526] which, like the POMC neurons, constitute estrogen-responsive afferents to the preoptic region,[389] establish morphological and functional synapses with GnRH neurons.[388,529,533,534] The intracerebroventricular injection of an antiserum to NPY delays the age at puberty in female rats,[535] whereas a single intracerebroventricular injection of NPY advances vaginal opening and the first ovulation in these animals.[535] In rats, NPY hyperpolarizes GnRH neurons through the Y5 NPY receptor.[534] In mice, the activity of the majority of GnRH neurons is found to be modulated by NPY, which acts either through Y4 or Y1 to excite or inhibit GnRH neuronal activity, respectively.[529] Although there is evidence for the stimulatory effects of Y4 receptor activation on the HPG axis in rats,[536,537] the deletion of Y4 signaling restores the onset of puberty in the leptin-deficient *ob/ob* background without having any beneficial effect on body weight.[538] Similarly, deletion of the *npy* gene in ob/ob mice improves fertility but only partially restores metabolic functions.[539]

In rodents, NPY neurons in the ARH co-express AgRP,[401] an endogenous MC3R and MC4R antagonist[540,541] that has been variously shown to inhibit, promote,[529] or have no effect[532] on GnRH neuronal firing when bath-applied to brain slices, and to completely block depolarization promoted by the MC3/4R agonist melanotan.[532] In addition, ablation of the *Agrp* gene and heterozygosity for *Mc4r* have both been shown to restore puberty in female leptin-receptor-deficient *db/db* mice.[532]

Overall, estrogen-sensitive NPY/Agrp neurons are, like POMC neurons, in an ideal position to integrate a wide variety of metabolic signals such as leptin and ghrelin, which access the hypothalamus via the portal blood vessels and the tanycytic barrier,[109,110,542] and to coordinate both feeding and reproduction.

Other factors. Other factors such as the catecholamines, vasoactive intestinal peptide, neurotensin, and the opioids (other than dynorphin A, discussed above) have been suspected of being involved in the timely control of sexual maturation and the onset of puberty (see for review Refs 14,16).

ATYPICAL INPUTS

Nitric oxide. Originally described as the endothelial-derived relaxing factor,[543–545] nitric oxide is a highly

labile, gaseous messenger molecule that is generated as a product of the conversion of L-arginine to L-citrulline. The physicochemical properties of NO are such that it cannot be stored in vesicles following its synthesis, but instead diffuses across biological membranes to exert its effect. However, the ability of NO to act is delimited by its half-life and the proximity of NO-containing cells to their targets. In the brain, NO is typically considered to be a retrograde neurotransmitter (i.e., one that increases the release of other neurotransmitters, such as GABA and glutamate, from presynaptic sites); however, it also acts at postsynaptic sites (see for review Ref. 546).

Since the early 1990s, NO has been known to be a regulator of LH secretion (see for review Ref. 378). Indeed, several pharmacological studies have suggested that NO is a key modulator of GnRH secretion,[547,548] and a contributor to the onset of the preovulatory surge of GnRH/LH both in rats[549–553] and mice.[523] For instance, the intracerebroventricular injection of antisense oligonucleotides to nitric oxide synthase (NOS) has been shown to block the LH surge in steroid-primed ovariectomized rats.[552] In addition, the intracerebral infusion of N(G)-nitro-L-arginine methyl ester (L-NAME, a NOS inhibitor) into either the preoptic region or the median eminence in rats results in a marked disruption of estrous cyclicity,[510,554] and studies administering L-NAME (which crosses the BBB[555]) through the drinking water have shown that even the systemic inhibition of NOS delays the onset of puberty in female rats.[556] Surprisingly, the first targeted disruption of exon 2 of the neuronal (n) NOS gene did not markedly alter fertility in mutant mice;[557] however, these mice retained residual nNOS activity.[557] In contrast, the deletion of exon 6, which harbors the catalytic domain of nNOS, has been shown to cause hypogonadotropic hypogonadism and infertility in mutant mice.[558]

Although the global effect of NO on the onset of puberty and the GnRH network appear to be stimulatory,[549–553,558] electrophysiological data show that the direct effect of NO, whether endogenously produced by neurons or released by exogenous NO donors, is inhibitory on GnRH neuronal activity.[559] The mapping of the nNOS isoform within the hypothalamus demonstrates that GnRH perikarya in the OVLT/MEPO area are surrounded by nNOS-containing neurons, but do not themselves express nNOS.[523,559–562] Interestingly, preoptic nNOS neurons express all the key receptors known to be involved in the control of puberty onset and fertility, such as ERα,[563,564] NMDAR,[510,560] the μ-opioid receptor,[565,566] and the leptin receptor.[567] In addition, a recent study has demonstrated the abundant apposition of kisspeptin fibers to preoptic nNOS-containing neuronal cell bodies and the expression of KISS1R by these neurons, as well as the involvement of the estradiol→kisspeptin/KISS1R→nNOS signaling pathway in the estrogen-mediated negative feedback of GnRH/LH release.[523] The pharmacological activation of NMDAR→nNOS signaling, which is involved in the onset of the preovulatory GnRH/LH surge,[510,568] has also been shown to be able to promote LH release in KISS1R and kisspeptin null mice.[569]

In addition to mediating estrogen-dependent neural inputs, such as kisspeptidergic signals, the population of NO-synthesizing neurons in the OVLT/MEPO has also been shown to sense leptin,[570] thereby transmitting information regarding peripheral energy stores to GnRH neurons that do not express the leptin receptor.[571] Together, these data raise the provocative notion that nNOS-neurons of the OVLT/MEPO could be a vital cell population for the rapid integration and transmission of both gonadal and metabolic signals in the neuroendocrine brain, and thus play a role in the timing of puberty onset.

PGE_2. Prostaglandin E_2 (PGE_2) is one of a number of prostanoids synthesized from arachidonic acid, and is produced from membrane phospholipids by a phospholipase A_2. Arachidonic acid is converted to bioactive prostanoids by the cyclooxygenases (COX-1 and COX-2) and a class of terminal synthases (see for review Ref. 572). Several studies suggest that PGE_2 is mainly derived from the COX-2 pathway.[573–575] PGE_2 signaling is propagated by four G-protein-coupled receptors, EP1–EP4 (see for review Ref. 576).

The first indication that PGE_2 was involved in the process of GnRH secretion was provided by experiments showing that PGE_2 injected into the third ventricle of the rat brain induced the release of LH into the general circulation[577] and of GnRH into the pituitary portal blood vessels.[578,579] To bring about the activation of the GnRH axis, PGE_2 acts at two main hypothalamic sites: the preoptic-anterior hypothalamic region in which GnRH cell bodies reside, and the tuberal region of the hypothalamus, which contains the median eminence and GnRH-releasing neuroendocrine terminals.[580] The use of COX inhibitors, such as indomethacin, has provided further support for a physiological role of the prostaglandins in the control of GnRH release. In rats, the intraventricular or intrahypothalamic administration of indomethacin inhibits both pulsatile LH release and the LH discharge induced by ovarian steroids.[581] Other studies have demonstrated that the microinjection of either aspirin, a nonsteroidal COX inhibitor, or N-0164, an antagonist of prostaglandin and thromboxane, into the tuberal region of the rat hypothalamus results in the suppression of ovulation.[582,583] Finally, experiments conducted using hypothalamic explants in vitro have revealed that PGE_2 is an effective stimulator of GnRH release from median eminence nerve terminals.[584–586]

A sizable body of evidence also implicates PGE_2 as a physiological component of the GnRH system during postnatal development. For instance, PGE_2 can induce the release of GnRH long before puberty in both mice and

rats.[259,587] Biochemical analyses during the last phase of sexual maturation, i.e., at the first proestrus, have demonstrated that the capacity of the reproductive hypothalamus to metabolize arachidonic acid through the COX pathway leads to a specific increase in PGE_2 synthesis.[588] This effect appears to be estrogen-dependent, since it is mimicked by the treatment of juvenile animals (early postweaning period), with estradiol at doses capable of inducing a preovulatory surge of LH.[588] More recent studies have shown that an estradiol-induced increase in hypothalamic PGE_2 levels can be seen even during the neonatal period in male rats.[589] Additionally, experiments showing that estradiol treatment upregulates both COX-2 mRNA and protein synthesis in the hypothalamus of female rats during postnatal development[590] raise the possibility that estrogens may act on COX-2 expression to promote PGE_2 synthesis at puberty.

Glia: the main source of PGE_2 within the GnRH neurosecretory system. Although PGE_2 was initially postulated to be an intracellular messenger produced by the binding of neurotransmitters to receptors located on GnRH neurons and acting within these neurons,[591–593] this concept has been revisited following studies showing that the actions of PGE_2 on GnRH release are initiated by its binding directly to specific membrane receptors[576] expressed by GnRH neurons,[594] and the recognition that astrocytes represent a major source of PGE_2 in the brain[595–597] (Figure 30.5). Two decades ago, seminal studies by Ojeda and colleagues revealed that the PGE_2-mediated activation of GnRH neuronal secretory activity, which is triggered by estrogen at the time of puberty, required the activation of growth-factor-dependent glial signaling pathways involving receptor tyrosine kinases of the ERBB family.[608–610]

Of the four known members of the ERBB family, three (ERBB1, ERBB3, and ERBB4) bind and are activated by cognate ligands. In contrast, erbB2 has no known ligand, and functions primarily as a modulator of the other members of the family.[611] Although erbB receptors do not appear to be expressed in GnRH neurons,[211,259,606,612] ERBB1, ERBB2, and ERBB4, but not ERBB3, are expressed in hypothalamic astrocytes, known to morphologically and physically interact with GnRH cell bodies[613–616] both in rodents and humans.[259,605,606] In addition, hypothalamic astrocytes express the erbB1 ligand, transforming growth factor alpha (TGFα), and several forms of the erbB4 ligand, neuregulin.[605,606,609,612] Importantly, gonadal steroids have been found to induce dramatic increases in the expression levels of the ERBB receptors and their ligands within the hypothalamus at puberty; no such changes are seen in the cortex or other brain regions unrelated to reproductive control.[606,609,612]

The pharmacological or genetic inhibition of ERBB1, ERBB2, and/or ERBB4 receptor signaling pathways delays the onset of puberty[259,609,617,618] and alters adult reproductive function in rodents.[618] In vitro studies using either hypothalamic explants or the coculture of primary hypothalamic astrocytes with a GnRH-producing neuronal cell line have shown that although erbB receptor ligands can stimulate GnRH release from the explants or neuronal cells, they do so indirectly, by inducing astrocytes to secrete PGE_2.[259,595,606,610,618] In addition, ligand-mediated activation of erbB receptors has been shown to promote morphological rearrangements in hypothalamic astrocytes[605] (Figure 30.5), raising the possibility that ERBB signaling may also influence the astrocytic coverage of GnRH neurons in vivo (see for review Ref. 376).

In vitro experiments suggest that ERBB signaling in hypothalamic astrocytes is functionally connected to the neuronal glutamatergic system, the primary mode of excitatory transsynaptic communication used by hypothalamic neurons,[619] and as discussed above, one that is known to increase GnRH secretion[620,621] and accelerate the initiation of puberty in both rodents and primates.[441,446,622] In hypothalamic and nonhypothalamic astrocytes alike,[596,623,624] transmitter spillover from nearby synaptic activity (i.e., synaptically released transmitters from synaptic terminals are believed to bind to cognate receptors located at the surface of glial processes enwrapping the synaptic bouton) results in an elevation of PGE_2 release (Figure 30.4).[607,625] For example, excess glutamate released by neurons can reach and engage biochemical signaling in astrocytes through the co-activation of AMPA and metabotropic glutamate receptors, leading to a ligand-dependent increase in astrocytic ERBB signaling and PGE_2 release[604] (Figure 30.5). This in turn signals back to GnRH neurons, facilitating neuroendocrine development and adult reproductive function,[259,618] and possibly explaining the lack of an effect of the deletion of specific glutamate receptors in GnRH neurons themselves on sexual maturation.[460]

PGE_2, a newly uncovered gliotransmitter within the GnRH neurosecretory system. Even though PGE_2 has been known to trigger GnRH release from hypothalamic neurons controlling reproduction for almost 40 years, it has only recently been identified as a potent excitatory regulator of GnRH neuronal activity, both in male and female mice.[603] Patch-clamp recordings in brain slices have shown that PGE_2 induces a reversible membrane depolarization of GnRH neurons, leading to the initiation of spike firing via a postsynaptic effect involving the activation of a nonselective cation current[603] reminiscent of the ones recently described in GnRH neurons by other groups.[626,627] Although GnRH neurons are known to express both the EP1 and EP2 subtypes of prostaglandin receptors in vivo,[594,628] the excitatory effect of PGE_2 on GnRH neuronal activity is selectively mimicked by the EP2 receptor agonist butaprost,[603] previously shown to promote GnRH release in the GnRH-producing neuronal

cell line GT1-7.[594] The PGE_2-mediated membrane depolarization of GnRH neurons has also been shown to require the cAMP/protein kinase A (PKA) pathway,[603] which is known to be coupled to the EP2 receptor[574,576] and to underlie the stimulatory effect of PGE_2 on GnRH secretion.[629]

As alluded to above, the selective disruption of erbB4 signaling in astrocytes by the overexpression of a dominant-negative erbB4 receptor, under the control of the human GFAP promoter, leads to diminished PGE_2 release in response to ligand-dependent ERBB4 activation, leading in turn to reduced GnRH release, delayed puberty, and disrupted adult reproductive function.[259,618] What is more, electrophysiological analyses have shown that the spontaneous activity of GnRH neurons in these animals is also decreased, and that this deficiency can be mimicked by the bath application of either fluoroacetate, an inhibitor of astrocyte metabolism,[630,631] or the COX blocker indomethacin, to slices of the preoptic region of wild-type animals.[603] The fact that GnRH neuronal

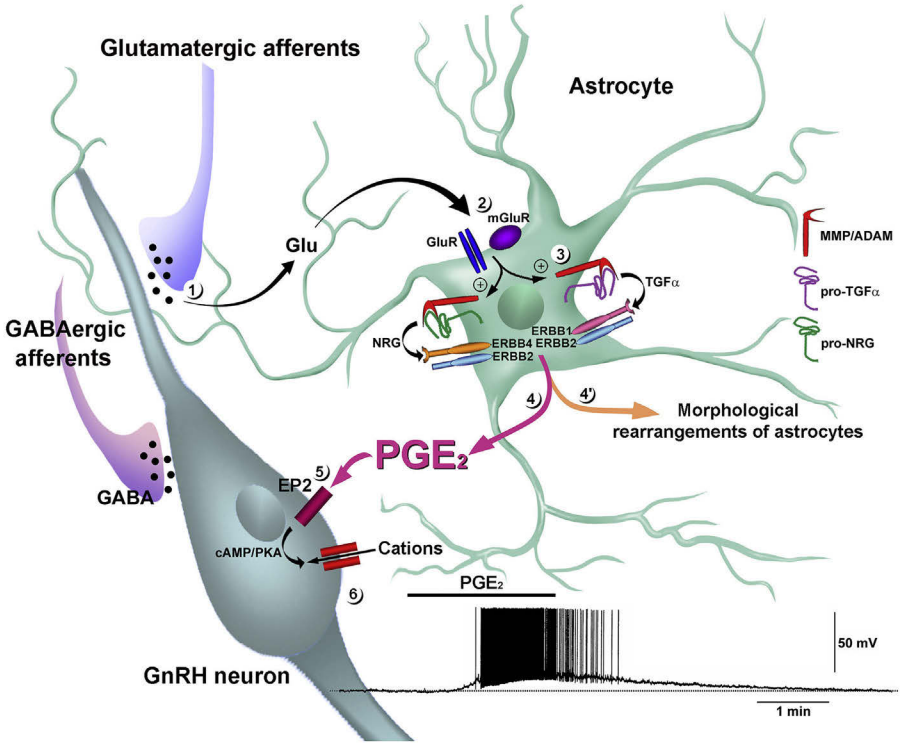

FIGURE 30.5 There is now a growing body of evidence to indicate that, concurrently with the transsynaptic regulatory mechanisms illustrated in Figure 30.4, cell–cell interactions involving nonneuronal cells such as astrocytes are also of critical importance for the regulation of GnRH secretion. Indeed, in the hypothalamus, as in most areas of the central nervous system, the classic one-way dialogue at the chemical synapse that forms the functional unit for the transmission of information between a nerve terminal and its target is being reevaluated on the strength of recent demonstrations that glial cells, the presumed electrically silent cohabitants of the nervous system, might be a critical third element of the synapse.[431,432,598–602] The present schematic diagram depicts one example of a mechanism by which hypothalamic astrocytes may contribute to the maturation of the GnRH neural network during postnatal development via the release of a gliotransmitter, prostaglandin E_2 (PGE_2), that not only potently stimulates the electrical activity of GnRH neurons,[603] but also modulates spine density in hypothalamic neurons.[590] Experimental studies have suggested that neuronally released glutamate (Glu) (1) coactivates metabotropic glutamatergic (mGluR) and AMPA glutamatergic receptors (GluR) in astrocytes, (2) stimulating the activity of zinc-dependent matrix metalloproteinases (MMPs) of the ADAM (a disintegrin and metalloproteinase) family, and (3) the MMPs catalyze ectodomain shedding by the pro-EGF ligands pro-TGFα and pro-NRG (proneuregulin). In particular, the processing of pro-TGFα has been shown to involve the metalloproteinase ADAM17, also known as tumor necrosis factor α converting enzyme (TACE). The subsequently released mature TGFα and NRG activate ERBB1/ERBB2 and ERBB4/ERBB2 heterodimers, respectively.[604] The co-activation of glutamatergic receptors induces the recruitment of ERBB1, ERBB4, and their pro-ligands to the cell membrane, where multiprotein complexes form, as demonstrated by the direct physical association of glutamatergic and erbB receptors (not shown). The activation of ERBB receptors in hypothalamic astrocytes promotes profound morphological changes, including cytoplasmic retraction and the elongation and stellation of processes[605] (4′). The activation of ERBB receptors also promotes the release of PGE_2[595,604,606] (4), which stimulates a cAMP/protein kinase A (PKA) pathway in GnRH neurons through the mobilization of EP2 receptors (EP2-R)[603] (5). The activation of this signaling pathway induces a reversible membrane depolarization of GnRH neurons leading to the initiation of spike firing via a postsynaptic effect involving the activation of a nonselective cation current[603] (6). The perception of synaptically released glutamate, GABA, or both, [607] by astrocytes, may contribute to the increase in hypothalamic GnRH feed-forward signaling in developing mice and rats. Indeed, the selective alteration of only one of these signaling components in astrocytes, such as ERBB4, hampers spontaneous GnRH neuronal activity[603] and delays puberty onset.[259]

activity under all these conditions can be rescued by exogenous PGE_2[603] strongly indicates that glial PGE_2 is an important component of the homeostatic mechanism controlling GnRH neuronal excitability. The role of glia in the control of GnRH neuronal activity is further supported by a recent study demonstrating that glial prostaglandins may decrease the efficacy of GABAergic inputs to GnRH neurons in ovariectomized mice.[607] Repeated action-potential-like depolarizations of a GnRH neuron have been shown to cause a short-term reduction in the frequency of spontaneous GABAergic postsynaptic currents in the neuron, suggesting the presence of local circuit interactions between GnRH neurons and their GABAergic afferents.[607,632] It is important to note that in this local circuit, the activation of $GABA_A$ receptors exerts a depolarizing effect that can trigger action potential firing due to the elevated chloride levels maintained in adult GnRH neurons.[467,485,633] Consequently, this represents a negative feedback loop in which depolarized GnRH neurons reduce the activity of their own excitatory GABAergic afferents. In addition to being steroid-dependent and under the influence of both glutamatergic and endocannabinoid signaling mechanisms via the activation of presynaptic metabotropic glutamate receptors and cannabinoid CB1 receptors, respectively,[607,632] this local negative feedback loop also requires the action of glial-derived prostaglandins.[607] Indeed, the incubation of brain slices with indomethacin, the broad-spectrum prostaglandin receptor antagonist AH 6809, or fluorocitrate, which like fluoroacetate, is a specific blocker of astrocyte metabolism, prevents the depolarization-induced suppression of GABAergic transmission in GnRH neurons.[607] Since GABA exerts a depolarizing action in this local circuit, we could envisage that glial prostaglandins, by suppressing excitatory drive, would reduce GnRH neuronal activity. Estradiol could also differentially influence this local inhibitory feedback to exert its positive or negative feedback effects.[607] Thus, in addition to exerting a direct postsynaptic excitatory action on the cell body of GnRH neurons, prostaglandins released from astrocytes could also participate in mechanisms that regulate the activity of their GABAergic presynaptic inputs. In the GnRH system, thus, PGE_2 fulfils all the criteria that qualify a compound as a "gliotransmitter"[634]: (1) it is synthesized by astrocytes; (2) its regulated release is triggered by physiological stimuli; (3) it acutely activates the firing of GnRH neurons and modulates the activity of their GABAergic afferents; and (4) it plays a role in an important physiological function, i.e., the neuroendocrine control of the onset of puberty and fertility.

Semaphorins. Recent evidence suggests that the semaphorins, members of a family of secreted guidance molecules, continue to be expressed in the postnatal brain and to have important implications for neuronal plasticity and nervous system physiology.[635,636] Strikingly, as can be seen below, several semaphorins also appear to play key roles in the GnRH system, controlling both the migration of GnRH neurons during embryogenesis, the timely onset of puberty,[164,167–169] and the amplitude of GnRH/LH release in adulthood by regulating the direct access of GnRH neuronal terminals to pituitary-portal blood vessels.[169,637,638]

SEMA3A: An endothelial-cell-derived GnRH axon-outgrowth-promoting factor that regulates the onset of the preovulatory surge. Of the semaphorins, Sema3A, a gene newly discovered to be involved in Kallmann syndrome, that acts as a guidance factor during the migration of GnRH neurons during embryogenesis,[163,164] as well as exerts both repulsive and attractive effects on growing axons,[639–641] is also expressed in the terminal field of GnRH neurons in the postnatal brain.[637] In the postnatal brain, however, the expression of SEMA3A is restricted to the fenestrated endothelium of pituitary-portal capillaries in the median eminence, and is tightly regulated by estrogens.[637] GnRH neurons are known to undergo extensive axonal growth towards the vascular wall during critical time windows, such as at the onset of the preovulatory surge, when a peak in the release of GnRH has to occur to trigger ovulation.[376] A recent study has highlighted a new mechanism by which endothelial cells of the median eminence release the 65 kDa isoform of SEMA3A (p65-SEMA3A) with precise timing during the ovarian cycle, promoting the extension of GnRH axon terminals towards the vascular plexus during the preovulatory surge, an effect that requires the expression of functional neuropilin-1, the SEMA3A receptor, in GnRH neurons.[637] The immunoneutralization of SEMA3A or the genetic impairment of SEMA3A release by endothelial cells impedes the onset of the preovulatory GnRH/LH surge.[637] Because ovarian-cycle-regulated GnRH axonal elongation in the postnatal brain is likely to depend on the coordinated activity of many extracellular factors, endothelial p65-SEMA3A may function in concert with other secreted molecules, including NO, TGF-β1, BDNF, and VEGF, which are particularly enriched in the capillary zone of the median eminence,[109,554,642,643] and may influence axonal plasticity through the modulation of the endothelial expression of or responsiveness to semaphorins.[640,644–646]

SEMA7A: A tanycyte-derived factor regulating neuroglial plasticity at the GnRH neurovascular junction. SEMA7A is another gene that has recently been found to be mutated in both patients with anosmic and normosmic hypogonadotropic hypogonadism.[170] It acts as a guidance factor for the migration of GnRH neurons during embryogenesis[168,169] and is also expressed in the terminal field of GnRH neurons in the postnatal brain.[647] The postnatal expression of SEMA7A is restricted to tanycytes of the median eminence, and is tightly regulated

by progesterone.[638] SEMA7A has been shown to play a dual role, inducing the retraction of GnRH terminals via one of its receptors, Plexin C1, although promoting the ensheathment and occlusion of GnRH nerve terminals by tanycytic end-feet through its other receptor, β1-integrin.[638] The genetic invalidation of Plexin C1 in GnRH neurons or of β1-integrin in the tanycytes of mice induces dramatic neuronal and glial rearrangements in the median eminence, which are correlated with impaired fertility.[638]

Together, these studies demonstrate that several molecules that play a key role during GnRH system ontogenesis are brought back into play during postnatal development to control neurosecretion, and any postnatal defect in the underlying mechanisms is likely to alter sexual maturation in the affected individuals.

Transcriptional Repression Mechanisms in the Control of GnRH Release

As shown in Table 30.2, the expression of the GnRH gene is regulated by a number of different molecules and transcriptional pathways, many of which are fairly widespread. In addition, although some of these molecules play a clearly activatory or inhibitory role, others, such as ERβ, can do both, depending on the context. A number of genes involved in regulating either the development of the GnRH system or the initiation of puberty are organized into functional networks that work more or less as discrete, although interconnected, units (see for review Ref. 648) Many of these do not directly regulate the transcription of GnRH, but act indirectly, for instance, by inhibiting the preexisting repression exerted by another molecule. The latter category has grown considerably over the last few years, as the involvement of several new molecules in the transcriptional activation or derepression of GnRH or its upstream activators, such as kisspeptin, has been revealed (reviewed in Ref. 649), transferring to the genetic level the notion that GnRH secretion occurs in the absence of inhibitory inputs to these neurons (reviewed in Ref. 650). How does this derepression work? In the case of kisspeptin neurons in the ARH, which are not sexually dimorphic but whose activity is necessary for pulsatile GnRH release, Lomniczi et al.[651] have shown that *Kiss1* expression is normally repressed by a polycomb complex, itself consisting of several gene products including those of *Eed* and *Cbx7*. At puberty, the promoters of these two genes are methylated, decreasing their expression and their participation in the polycomb complex binding to the *Kiss1* promoter and inhibiting transcription through other epigenetic modifications at the level of histone H3. The resulting derepression of *Kiss1* expression leads to the GnRH surge responsible for the pubertal activation of the pituitary–gonadal axis. On the other hand, steps aimed at stabilizing the polycomb complex and its binding and repression of the *Kiss1* promoter lead to the delay or nonoccurrence of puberty. Another gene involved in regulating GnRH release indirectly by transcriptional repression mechanisms is FGF21,[652] which acts by repressing vasopressin expression in suprachiasmatic nuclear afferents to kisspeptin neurons in the AVPV, thus inhibiting the kisspeptin-induced stimulation of GnRH neurons.[652] In addition, the fact that FGF21 is a metabolic signal secreted in response to temporary starvation provides another link between reproductive and metabolic states. The clinical relevance of such transcriptional repressive mechanisms to the control of reproductive maturation and function has been suggested recently by the finding that in a third of families in a cohort with central precocious puberty, there appears to be a loss-of-function mutation in the gene for the maternally imprinted makorin RING-finger protein 3 (*MKRN3*).[653] Although the precise function of this protein is not known, it belongs to the relatively conserved makorin protein family, and its expression in the ARH of mice is dramatically downregulated immediately before puberty.[653] Interestingly, MKRN3 is similar in structure to another RING finger protein, enhanced at puberty 1 (EAP1, also known as IRF2BPL), identified as being involved in controlling puberty onset both in rodents and primates.[654]

MODULATORY INFLUENCES REGULATING THE TIMING OF PUBERTY

The timing of the onset of puberty is also influenced by other factors, both intrinsic (e.g., hormones or signaling molecules secreted by other glands or produced during physiological processes) and extrinsic (environmental factors, both toxic and beneficial). An excellent and detailed account of several of these factors is provided in the previous version of this chapter by Ojeda and Skinner.[16] Here, I will limit myself to discussing one intrinsic factor (leptin) and one category of extrinsic factor (pheromones) respectively, for two different reasons. With respect to leptin, our knowledge of the involvement of this molecule in both metabolic and reproductive signaling has greatly increased over the last few years. Indeed, leptin appears to be a crucial link between the physiological systems regulating reproduction and metabolism, and the nature of the neuronal circuits mediating this cross talk are only just beginning to be unraveled. With respect to the pheromones, the fact that the principal rodent model for neuroendocrine studies until now has been the rat, in which pheromonal signaling plays only a cursory role, has led to an underestimation of their involvement in sexual maturation and function. However, pheromonal involvement in mice is

another matter entirely, and the advent of genetic mouse models for the study of reproduction makes it necessary to take into account their influence on, and interference with, the mechanisms being studied.

Leptin

As discussed in detail in Chapter 35, leptin, a peptide hormone mainly produced by adipocytes, plays a key role in the regulation of energy homeostasis and reproduction.[655–658] Although during the neonatal and infantile periods, leptin has no apparent effect on energy homeostasis,[659] after weaning, when pups have to seek their own food, leptin serves as an indicator of stored energy in the form of white adipose tissue,[660] and circulating concentrations of leptin are positively correlated with adiposity.[661] With respect to the onset of puberty, leptin appears to have two different but mutually overlapping functions, as a permissive signal that interacts with defined regions of the brain to allow or prevent the maturation of the HPG axis, and as an organizational cue that mediates the connectivity of key neuronal projections.

With regard to its permissive role in the onset of puberty, leptin deficiency, caused by a loss-of-function mutation of leptin or of its receptor, results in obesity and a failure to complete puberty, and consequently, to infertility, and these phenotypes can be rescued by treating individuals with leptin[662] or by reintroducing leptin receptor expression in neurons,[663] respectively. Conversely, the transgenic overexpression of leptin in mice causes precocious puberty.[664] Leptin does not appear to exert its effects on GnRH neurons directly, since the selective deletion of the leptin receptor in this neuronal population does not alter puberty onset or fertility,[571] but rather acts through cells afferent to these neurons,[101,665] through those that interact morphologically with them, or both.[666] Surprisingly, POMC and NPY/AgRP neurons of the ARH, which are critically involved in mediating leptin's anorexigenic effects,[667] do not seem to play major roles in the central action of leptin on the HPG axis, since the deletion of the leptin receptor in these neurons does not appear to induce any reproductive deficits.[668,669] Neither does the effect of leptin on puberty onset appear to involve kisspeptinergic ARH neurons,[449] of which only a very limited proportion express the leptin receptor.[666,670] The permissive action of leptin on sexual maturation could thus be mediated via neuronal populations that reside outside the ARH. An intriguing study by Elias and collaborators suggests that leptin-sensitive neurons that lie in the PMv could constitute one of these populations. Indeed, the selective bilateral lesion of the PMv prevents leptin-mediated rescue of fertility in ob/ob leptin-deficient mice without affecting the ability of leptin to restore body weight,[449] whereas the selective rescue of the leptin receptor in the PMv restores puberty onset and fertility in leptin-receptor-deficient mice without causing any change in body weight and food intake.[449]

Concerning its second function, leptin also appears to play a major role in the establishment of ARH projections to the preoptic region during the infantile period.[383] Indeed, in both rats and mice, there is a transient increase in circulating leptin concentrations during the first two postnatal weeks.[420,421,671,672] Bouret and collaborators have demonstrated that this rise in leptin promotes the outgrowth of ARH fibers by acting directly on ARH neurons expressing functional leptin receptors.[422,423] Although this surge in infantile leptin is independent of body fat mass, and the mechanisms of its regulation are still unknown, growing evidence indicates that the manipulation of neonatal feeding (i.e., either undernutrition or overnutrition) significantly alters circulating leptin concentrations during neonatal/infantile development.[672–674] This change in feeding has deleterious long-term effects on the animal's physiology, including alterations in the timing of puberty onset.[139,417,675] The importance of the organizational effects of leptin on reproductive circuits with respect to sexual maturation is highlighted by the fact that disrupting leptin-receptor-triggered STAT3 signaling causes a slight delay in puberty onset and altered fertility in mice.[676] This is particularly interesting when one considers that STAT3 signaling downstream of leptin has recently been shown to be required for the establishment of projections from the POMC neurons of the ARH,[423] which are not involved in mediating the direct effects of leptin on the activation of the HPG axis. However, further studies are required to determine whether infantile leptin promotes fiber outgrowth only in leptin-responsive ARH neurons or also in other ARH cell populations that send projections towards the preoptic region, such as the kisspeptin/neurokinin B neurons,[417] and whether these effects are mediated by direct or indirect trophic effects on the growing neurons themselves or by the triggering of chemorepulsive cues secreted by other leptin-sensitive neuronal populations that results in these projections leaving the ARH.

Pheromones

Pheromones are specific biologically active substances "which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavior or a developmental process" as defined by Karlson and Lüscher in 1959.[677] In most mammals, including mice and rats, the nasal cavity contains at least two major sensory systems that may be involved in the detection of these chemical messenger molecules: the vomeronasal and the main olfactory

systems (see for review Refs 678,679). In rats, even though pheromones drive important behaviors such as the licking and cleaning of a pup's anogenital area, an act prompted by compounds that are produced by the pup's preputial glands and urine and required for the pups to defecate,[680] their effects on sexual maturation are relatively marginal.[681,682] However, this system plays a key role in sexual maturation and function in mice (see for review Ref. 683), whose interactions with their environment are largely triggered by pheromonal signals. Indeed, early studies have demonstrated a number of incontrovertible effects of primer pheromones in the latter species. For example, female mice living in groups modify or suppress their estrous cycle (the Lee–Boot effect),[684] whereas male urine can restore and synchronize the estrus cycle of noncycling females (the Whitten effect)[685] or accelerate puberty onset in immature females (the Vandenbergh effect).[686] Conversely, a very recent study has shown that the lachrymal glands of juvenile female mice secrete peptides in their tears that exert a powerful inhibitory effect on adult male mating behavior.[687] Besides, it has been known since the late 1950s that the exposure of a recently mated female mouse to a strange male prevents the implantation of the fertilized ova (the Bruce effect),[688] implying that the stud or its individual odor is memorized at the moment of mating and can be recognized later. These pheromonal effects, most of which are likely conveyed by stimuli present in the urine and acting via the vomeronasal organs, are powerful tools with which to probe the natural degree of maturation reached by the GnRH system during postnatal development (the Vandenbergh effect) and its function in adolescent mice (the Whitten effect), respectively. Indeed, studies by Bronson and colleagues have shown that exposing juvenile female mice between 26 and 30 days of age and weighing more than 17 g to a sexually mature male causes LH and FSH levels to peak, attaining preovulatory values, after 62 and 72 h, respectively.[689] Females that attain puberty at such a remarkably early age are capable of conceiving and carrying litters to term.[130] Interestingly, the immediate responses of the young females to male cues include a rapid release of LH, reminiscent of the LH minisurges in peripubertal female rats,[119] followed shortly afterward by a dramatic increase in serum estradiol.[689] Although the cohabitation of a single juvenile female with an adult male rapidly leads to pubertal ovulation,[126,690] young females housed in the absence of these cues show, after vaginal opening, greatly prolonged vaginal and uterine cycles that are anovulatory until quite an advanced age,[280] as elaborated in the section Rats and Mice as Model. In adolescent mice showing ovulatory cycles, the natural peak of LH release necessary for ovulation can be induced only by placing these mice on the day of diestrus I for 62 h in a cage that had previously held a sexually experienced male, i.e., by exposing them to male pheromones.[637,690] In striking contrast, rearing juvenile males in the presence of adult males depresses spermiogenesis and reduces plasma androgen concentrations,[691] an effect that could be linked to the significant decrease in LH and FSH concentrations in subordinate animals,[692] i.e., the inhibition of the hypothalamo-pituitary neuroendocrine system.

CONCLUSION

The study of the central control of puberty, or the attainment of sexual maturity, has advanced by leaps and bounds over the last few years. In contrast to our historical comprehension of this developmental phase as a fairly linear process, puberty now appears to be the culmination of an extraordinarily complex series of events occurring during embryonic and postnatal development, and ensuing from an intermingling of genetic, epigenetic, structural, neuroanatomical, and functional processes. The proper unfolding of this sequence of events requires a constant dialogue, initiated prenatally, between the hypothalamus and the periphery, mainly the pituitary and the gonads, but also other organs that transmit organizational and homeostatic signals to the brain and thus dictate the proper integration and function of GnRH neurons, the master regulators of the HPG axis. The elucidation of some of the cellular, molecular, and gene networks controlling every aspect of GnRH secretion has resulted in a multidimensional and ever-plastic picture, as befits a neuronal system controlling the most fundamental aspect of life—the propagation of the species.

In both males and females, GnRH neurons migrate from the nose to the brain during embryonic life under the control of a number of signals. At birth, the neuroendocrine terminals of these neurons target the pericapillary space of pituitary-portal blood vessels in the median eminence. GnRH neurons and the neural network to which they belong are then subjected to different periods of activation during postnatal development, leading to gonadotropin secretion. In females, the first activational period of the HPG axis coincides with the arrival of ARH fibers in the preoptic region (Figure 30.4), which results in an infantile surge of FSH that triggers the growth of the first pool of ovarian follicles, destined to ovulate at puberty, as well as the sporadic elevation of LH levels that contribute to their maturation (Figure 30.2). Low circulating estradiol levels produced by the growing follicles then gain progressive access to the hypothalamus, where they are posited to exert a negative-feedback effect on ARH neurons (Figure 30.4). Neurons and glial cells from the tuberal and preoptic regions of the hypothalamus, and possibly also neurons from other brain areas,

contribute to the maturation of the pattern of pulsatile GnRH secretion throughout the juvenile period, further promoting gonadotropin release and follicular growth. The second activational period occurs during the peripubertal period, when a diurnal rhythm of LH release that accentuates the functional development of the ovaries is established. A third and final activational period coincides with the moment when ovarian follicles reach full maturity, i.e., the Graafian stage, and release increasing amounts of ovarian steroids, specifically estradiol (Figure 30.2), which exerts a positive-feedback effect on the neurons of the AVPV (Figure 30.4), coordinating the onset of the first preovulatory GnRH and LH/FSH surge and thus triggering the first ovulation and conferring fertility on the individuals. In males, as in females, the primary events that initiate the onset of puberty originate within the hypothalamus. Following the neonatal masculinization of the brain via mechanisms involving the release of testosterone by Leydig cells that were born during embryogenesis, increases in FSH release (Figure 30.3) occur concomitantly with the arrival of ARH neuronal fibers into the preoptic region during the infantile period (Figure 30.4). This FSH then acts on the seminiferous tubules to promote the proliferation and differentiation of Sertoli cells, which facilitate spermatogenesis and enhance the function of Leydig cells born after birth. The latter, unlike embryonic Leydig cells, respond to LH by releasing testosterone, which plays a pivotal role in spermatogenesis. Between the juvenile and the peripubertal period, the frequency of secretion of both GnRH and LH increases gradually to attain an adult pattern. This maturation of the pattern of GnRH/LH release is paralleled by an extensive pruning of GnRH dendrites and changes in dendritic spine density, suggestive of an increase in glutamatergic afferents, and the appearance of the first motile sperm in the epididymis (Figure 30.3).

With so much that is known then, we come full circle to the question posed by the 125th anniversary edition of *Scienc*e, cited at the beginning of this chapter—What don't we know? The answer is, quite a lot. Even though in the process of deciphering these intricate pathways, several other aspects of the GnRH system have come to light in the last decade or so; for instance, the discovery that kisspeptin neurons are regulators of GnRH secretion, itself considered "the" master molecule for so long, many of the mechanisms underlying the cellular, genetic, and hormonal juggernaut leading to puberty are still obscure. For instance, even the very first step in the postnatal activation of the HPG axis, the arrival of afferents from the ARH, is steeped in mystery. How is the projection of these neurons to the preoptic area, where the majority of GnRH neurons reside, established, and what growth factors or guidance cues control this process? And more generally, what other neuronal populations influence GnRH neuronal activation, and how does this signaling take place? This is a particularly important question when one considers that, in our current state of knowledge, ARH neurons are poised at the interface between two primordial functions—reproduction and metabolic homeostasis. And perhaps the most fundamental question of all: how exactly is the expression of the GnRH gene itself controlled, and does this control play a role in the function of individual GnRH neurons and the activation of the HPG axis? The next decade should answer many of these questions, and raise new and even more interesting ones.

However, if the ultimate aim of these studies is to understand human reproduction, then it appears as if our understanding is fast approaching a plateau. All the mutations affecting the onset of puberty and fertility uncovered so far in human patients—whether with Kallman syndrome or various forms of hypogonadotropic hypogonadism or other manifestations of perturbations of the HPG axis—only serve to explain a third of the phenotypes seen in these patients. Although the exponential growth of screening methods at every possible molecular level will no doubt bring to light a few new molecular components and pathways, it seems equally possible that the actions of already identified genes and pathways could be altered in novel ways to result in the phenotypic permutations seen in humans. Several of these human disorders could actually be polygenic in nature, with "modifier genes" controlling the phenotype produced by a basic set of genes. Another candidate mechanism is the modification or suppression of naturally occurring transcriptional repression, whether by epigenetic modifications, as recently shown for *Kiss1*, the expression of miRNAs,[693] or other processes, remains to be determined. No doubt other mechanisms will be elucidated in the years to come. In this new and exciting "postgenetic" era of the study of the onset of puberty and the maintenance of reproductive competence, the use of rodent models, which can be easily manipulated and analyzed at every level from the addition of a simple methyl group to the production of young, will still have a place.

Acknowledgments

I am indebted to Dr S. Rasika for the editing of the manuscript. This research was supported by the Fondation pour la Recherche Médicale (Equipe FRM 2005 & DEQ20130326524, France), the European INTERREG program TC2N, and the European Research Council COST action BM1105.

INTRODUCTION

Historical Overview

Historically, the sheep is preceded only by the dog in the temporal sequence of domestication. People of an agricultural, Mesolithic culture began the gradual domestication process of the wild Urial sheep (*Ovis orientalis*), probably in southwest Asia about 9000 BC; the Argali (*Ovis ammon*) and Mouflon (*Ovis musimon*) are now considered to have also contributed toward the Asiatic and European breeds of domestic sheep (*Ovis aries*) (see Ref. 1 for a review). The sheep, prized for its production of wool, meat, and milk, has been a successful species, adapting to divergent climatological conditions ranging from desert to Arctic areas and often living in marginal areas unsuitable for cultivation. Over 60 years ago, Hammond[2] published his classic study examining the effects of environment on puberty in lambs, pointing out that this "universal provider" was the most widely used domestic animal species for studies of female reproductive physiology. Subsequent studies over the next 25 years in sheep had little impact on the conceptual development of the field, but they were important from an agricultural standpoint. Understanding how puberty is timed is critical for developing practical strategies to synchronize lambing with market demand and for potentially decreasing the generation interval in farm animals, thereby increasing the overall production of food and fiber.

With the advent of radioimmunoassays that allowed detailed physiological studies on the control of gonadotropin secretion throughout puberty, the lamb developed into an important model in which to test theories based on work in other species because it has a large blood volume and a pubertal hiatus of 6–7 months that allowed for experimental manipulations at various ages prior to puberty. The first of these to be directly tested in the lamb was the "gonadostat" hypothesis which proposed that puberty resulted from a change in the hypothalamic set-point for estradiol negative feedback so that the low concentrations of this steroid in prepubertal animals could no longer hold gonadotropin-releasing hormone (GnRH) and luteinizing hormone (LH) in check. This hypothesis—the origins of which may be traced back nearly half a century (see Refs 3 and 4 for a brief history)—was initially developed based on data from rats and was soon thereafter applied to humans. Ironically, at the same time that strong evidence supporting this hypothesis in female lambs was being developed in the late 1970s and early 1980s (described later in this chapter), work in female rats raised questions about its validity and data, first from rhesus monkeys and then humans, indicating that it was not applicable to much of the prepubertal period in these species. The current consensus appears to be that this hypothesis can account for the onset of puberty in sheep, ferrets, heifers, and male rats and for the final stages of reproductive development between menarche and first ovulation in primates.

With the fundamental neuroendocrine basis for puberty onset in sheep identified, workers turned to examining the control of puberty by photoperiod (in the 1980s) and nutrition. The former studies were relevant to many seasonally breeding species and the latter tested another long-standing hypothesis for the timing of puberty. Kennedy and Mitra[5] had hypothesized in 1963

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00031-4

that changes in energy availability serve as important cues timing puberty. They argued that sexual maturation is completed when sufficient somatic development has occurred so that excess energy reserves are available to support reproductive function. This hypothesis was soon applied to humans and has since been refined and championed by Rose Frisch and her colleagues. Work in prepubertal sheep (primarily in the 1990s) described in this chapter provided compelling evidence that suppression of somatic growth would dramatically delay puberty onset. Thus, the lamb provided a useful model to investigate how internal and external cues are channeled into the brain mechanisms that time the onset of fertility. During this same period, the technique for monitoring GnRH secretion in hypophyseal portal blood was applied to the lamb so that the relevant output of the brain could be directly monitored. This technique had been developed in adult sheep by Clarke and Cummins in Australia, refined by Caraty and Locatelli in France, and modified by Karsch in the United States to allow remote sampling (see review by Caraty et al.[6]).

Work in the late 1990s and early part of the twenty-first century focused on neural systems controlling GnRH secretion during puberty and the peripheral signals providing information about metabolic status. Because the pubertal increase in LH secretion (or the escape from estradiol negative feedback mentioned above) occurs much earlier in male than female lambs, interest also developed in sex differences for mechanisms timing puberty and how such differences develop prenatally. The long gestation of the sheep, which is approximately 5 months, coupled with the large size of the offspring permitted detailed studies of when and how fetal hormones exert their organizing action on the brain before birth to cause sex differences in the expression of pulsatile hormone secretion timing puberty. Despite the wealth of information available on pubertal mechanisms in lambs, progress in understanding these mechanisms in recent years has been limited. This lack of substantial progress is likely due to the loss of some more established investigators to retirement and a reduced entry of young investigators into the area, as well as the difficult funding environment of the day. In addition, while the sheep has many advantages regarding its use as an animal model, it is also a more costly animal to keep and maintain in comparison to smaller rodent models.

Because of the limited progress made in understanding the mechanisms underlying puberty onset in the sheep since 2006, much of the current text has not been changed from the previous version of this chapter. Specifically, it is organized into the same four major themes: (1) neuroendocrine sequence during the transition into adulthood; (2) internal determinants timing puberty; (3) external determinants timing puberty; and (4) sex differences in the timing of puberty. Nonetheless, updates in two areas are of particular note. First, consideration of the important role of a set of neurons in the hypothalamus called KNDy neurons—so named because of their coexpression of kisspeptin, neurokinin B, and dynorphin—to puberty onset is now included in the first theme. Second, we have expanded the consideration of the effect of factors such as androgens or environmental disruptors on development in utero and the subsequent effect on puberty in the fourth theme.

Comparative Considerations

From a broad vantage point, mechanisms underlying initiation of fertility in the sheep can be compared with those of other well-studied species to better understand the conservation and evolution of developmental strategies in differing ecologies. In this regard, the sheep is precocious in its development compared to the laboratory rat and rhesus monkey, both of which are altricial species. The lamb is well developed at birth, and many stages of maturation that are attained postnatally in species such as the rat (see Chapter 30) and primate (see Chapter 32) are achieved prenatally in the sheep. This rapid maturation is illustrated in Figure 31.1, which shows the relative growth curves for the sheep and for the human, another altricial species. Both are born at approximately the same body weight, but the lamb grows much more rapidly. Whereas by 30 weeks of age the weight of the human infant has only doubled, that of the lamb has increased tenfold and reproductive cycles have begun. Therefore, the degree of sexual development attained by the lamb in slightly greater than 6 months requires 13–15 years in the human child. Thus, the compressed developmental

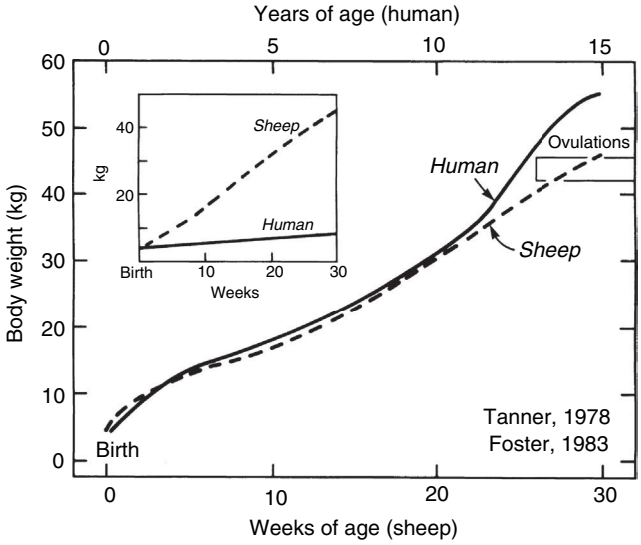

FIGURE 31.1 Growth based upon body weight from birth through the initiation of ovulation for sheep (mean) and human beings (50th percentile). Note the different *x*-axes. Growth during the first 30 weeks is shown (*inset*). *From Ref. 7, with permission.*

period of the lamb facilitates studies of sexual maturation of large, long-lived mammalian females.

Because its manifestation of puberty is subject to modification by external factors, the sheep is representative of many mammalian species living in natural conditions. Most mammals reproduce seasonally; as a consequence, their sexual development is influenced by environmental changes (food availability, photoperiod, temperature, rainfall, etc.). Which of these cues predominates depends on several factors, including the physical size of the species (larger animals have lower metabolic rates and more capacity for energy storage), longevity, and seasonal variation in local environment (see Chapter 34). The modern human deviates from the generalization that breeding in mammals is seasonal. Because of this, it could be argued that the expression of sexual maturity in most mammals is more complex than that of the human. As for all species, the young of seasonal breeders must grow to become sexually mature. However, they must also coordinate the timing of puberty with environmental changes such that their first matings occur at the same time as sexual activity is in progress in adults during the annual breeding season.

Definitions of Puberty in Female and Male Sheep

Puberty can be considered to be the process whereby an individual gains the capacity to reproduce. From a clinical or research standpoint, however, it is usually desired to provide a time point at which puberty occurs in order to classify its onset as precocious or delayed or provide a means to compare experimental groups. In the female lamb, the first mating can result in a pregnancy; therefore, many investigators use first estrus as the definition of puberty in the sheep. Others equate the initiation of ovulation with puberty. Because estrous behavior in sheep requires progesterone priming of neural substrates so that they can produce a behavioral response to estrogens (see Chapter 27), the first ovulation in lambs is not accompanied by estrous behavior. Indeed, two such "silent ovulations" may occur during puberty in lambs that have a short luteal phase after their first ovulation. Nevertheless, because first ovulation and first estrus typically occur within 2–3 weeks of each other in the sheep, a distinction between the two to define the onset of reproductive cycles normally has little practical usefulness, considering that the interval between birth and either of these events is 6 months or more. Puberty in males is a bit more difficult to determine as production of sperm, often used as an endpoint for designating achievement of puberty, is the summation of a process that begins approximately 60 days earlier. In addition, estrous behavior associated with puberty in the female can be detected through the use of vasectomized rams or by assessing the changes in progesterone secretion associated with luteal activity that can be measured by radioiummonoassay. In males, determination of production of mature sperm requires the collection and assessment of semen, a more complicated and laborious process. As will be noted later in this chapter, other definitions of puberty are applicable to reproductive development. For example, "neuroendocrine puberty" refers to maturation of the brain drive that produces hormonal signals to the gonads. This definition will be used in studies of steroid negative feedback control, as increased GnRH/LH secretion in response to reduced inhibition by estradiol during pubertal development is a common and critical event in puberty onset for both sexes. As such, this measure makes it easier to directly compare timing of puberty in the two sexes. In addition, because the discussion encompasses the broad aspects of seasonal influences on the timing of first ovulation and estrus, differences between "onset of breeding season" and puberty are considered. The reader is encouraged to deliberate the nuances of these related terms and concepts that apply to the transition to adulthood in the seasonally breeding sheep.

NEUROENDOCRINE SEQUENCE DURING THE TRANSITION INTO ADULTHOOD

Onset of High-Frequency GnRH Secretion Initiates the Transition into Adulthood

Because ovulation requires a surge of LH and follicle-stimulating hormone (FSH), any hypothesis for puberty in the female requires an explanation for how the preovulatory surge mechanism becomes operational. The hormonal events that lead to the preovulatory gonadotropin surge during the follicular phase of the adult estrous cycle have been particularly well characterized for the sheep (see Chapter 27). Briefly, during the 48- to 72-h follicular phase, GnRH pulse frequency becomes more rapid, and a sustained rise in basal LH secretion occurs as the frequency of LH pulses increases to greater than one per hour. The increased LH stimulus together with continued secretion of FSH drives one or more ovarian follicles to the preovulatory stage; estradiol production increases to high levels that are sufficient to activate the gonadotropin surge mechanism. Ovulation occurs, and one or more corpora lutea that secrete progesterone are formed.

In the immature female sheep, preovulatory gonadotropin surges do not occur spontaneously. Although the surge system is capable of function from a very early age, it remains dormant until puberty because of inadequate tonic (pulsatile) LH secretion. Pulses of LH, along with FSH, are ultimately responsible for the production of estradiol by the ovarian follicle. The pattern

of LH reflects that of its neurosecretotrophic stimulus, GnRH. In the prepubertal female, these LH pulses do occur; moreover, their amplitudes are as great or greater than those of the adult. The frequency, however, is much lower than that required to produce the large increases in follicle size and estrogen production required for triggering the GnRH/LH surge. The LH discharge rate in the immature female is no faster than once every 90–120 min for any prolonged period. During such slow frequencies, concentrations of circulating LH between each pulse return to low levels, and only transient rises in circulating estradiol are produced by small ovarian follicles. The young lamb is readily capable of generating requisite high-frequency GnRH/LH pulses, but this pattern is not produced because sensitivity to estradiol feedback inhibition is high. During puberty, a pronounced reduction in sensitivity to estradiol inhibition of GnRH secretion occurs, and the high-frequency rhythm of GnRH secretion is first expressed. As a result, the follicular phase begins and culminates in the first GnRH surge and ovulation. Subsequent events that occur during the pubertal transition, which include a short luteal phase in some lambs and first expression of sexual receptivity, will be considered at the end of this section, as will the switch from estradiol to progesterone as the primary regulator of LH pulse frequency with the emergence of corpora lutea.

The foregoing working hypothesis focuses on the mechanism governing the frequency of GnRH secretion, because this is the rate-limiting system in the onset of reproductive function. The rationale for this is based upon several considerations, namely: (1) the *potential* for the gonadotropin surge mechanism to respond to the stimulatory feedback action of estradiol exists long before puberty; (2) the *potential* for the ovary to produce follicular-phase levels of estradiol in response to hourly pulses of LH exists long before puberty; (3) the *potential* to produce high-frequency GnRH pulses exists long before puberty; (4) the response to estradiol inhibition of GnRH secretion decreases during the pubertal period. Evidence to support each of these contentions is presented in the following sections.

Competency of the Preovulatory Gonadotropin Surge Mechanism before Puberty

Numerous studies have demonstrated unambiguously that exogenous estradiol can induce an LH surge in the sexually immature female sheep.[8–15] As illustrated in Figure 31.2, the potential to respond to the stimulatory feedback action of estradiol is attained within a few weeks after birth. In the study shown, the amplitude of the LH surge increased progressively with age. By 12–20 weeks, the magnitudes of the induced LH surges were well within the range of those capable of producing ovulation. The sensitivity of the preovulatory

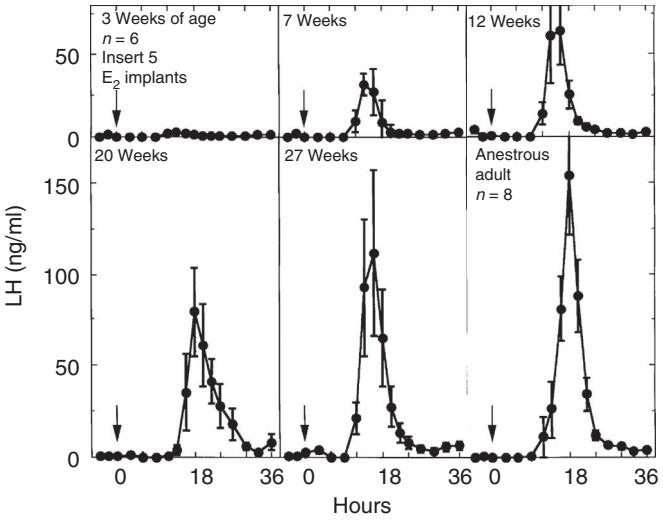

FIGURE 31.2 Development of the response to the stimulatory feedback action of estradiol on LH secretion in the female sheep. Estradiol was administered (*arrows*) subcutaneously by Silastic capsules for 96 h at each age in the same lambs. *From Ref. 10, with permission.*

gonadotropin surge system to stimulation has been tested in the prepubertal female several weeks before the first spontaneous ovulation.[12] Various lengths of Silastic capsules containing crystalline estradiol were used to produce physiologic rises of estradiol over a range of 2–10 pg/ml after endogenous estradiol had been removed by ovariectomy. The sensitivity in the immature female was found to be equal to that of the adult, and, remarkably, an estradiol increment as small as 2 pg/ml induced an LH surge. Moreover, administration of progesterone before estradiol in the immature female effectively prevented the estradiol-induced surge,[10] indicating that the potential for this blocking action becomes established well before its source of secretion, the corpus luteum. Taken together, these findings demonstrate that the mechanism governing the preovulatory surge system is exquisitely sensitive to the stimulatory feedback action of estradiol long before puberty, but that surges do not occur in the sexually immature lamb because they do not generate a sustained rise in endogenous estradiol. Although the ability to produce a GnRH/LH surge is obviously critical for puberty onset, very little if any attention has been devoted to understanding the neurobiology of surge development in the female aside from the role of androgens in masculinizing the surge system. This is likely due to the fact that, as discussed above, this aspect of the reproductive cycle is not "rate-limiting" to puberty onset.

Competency of the Ovary before Puberty

The ovary matures rapidly in the sheep. Antral follicles are evident before birth, but they do not respond to exogenous gonadotropins until after 2–4 weeks of

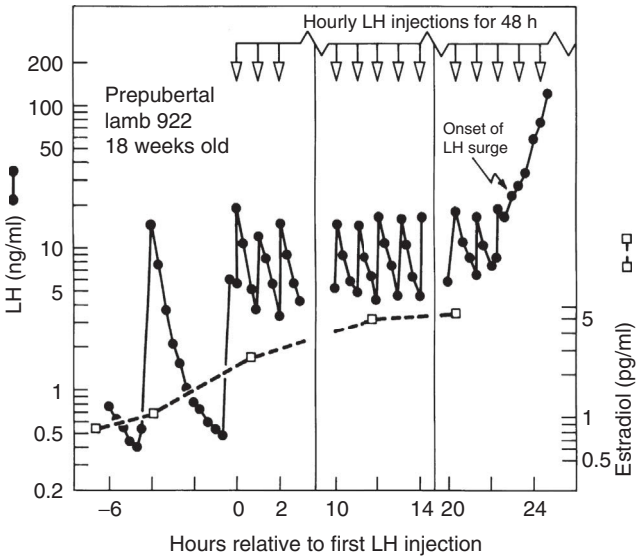

FIGURE 31.3 Rapid administration of LH induces ovulation in the immature sheep. Circulating LH and estradiol concentrations are shown at various times before and during hourly injections (*arrows*) of purified ovine LH in an individual female. High LH values between hours 22 and 24 reflect the initial portion of a preovulatory LH surge that was followed by an 11-day luteal phase with three corpora lutea. *From Ref. 25, with permission.*

age,[16,17] when granulosa and thecal layers become well developed.[18] At a slightly older age (5–6 weeks), exogenous gonadotropins (pregnant mare serum gonadotropin, human chorionic gonadotropin) can induce ovulation and formation of corpora lutea.[19] These exogenous gonadotropins can act by stimulating follicular growth and increasing estradiol production to activate the preovulatory gonadotropin surge mechanism,[20] much the same as occurs during the normal follicular phase (see Chapter 27). Moreover, the capacity of gonadotropin-primed follicles from 10- to 16-week-old lambs to secrete sex steroids in vitro was found to be similar to that of follicles from adults.[21] The precocious development of the lamb ovary has been used to practical advantage. Induction of ovulation by exogenous gonadotropins before the normal time of puberty[22,23] permits early mating to reduce the generation interval. Although, in principle, this could increase the overall lifetime agricultural production of ewes, fertility is low in such females as for young females of any species.

The competency of the lamb ovary to behave in an adult-like manner before puberty has been demonstrated in a more physiologic framework.[15,24] In the study shown in Figure 31.3, purified ovine LH was injected (intravenously) hourly for 48 h into prepubertal lambs to simulate a key aspect of the follicular phase of the estrous cycle—high-frequency LH pulses. The dose of LH used was chosen to replicate the amplitude of the pulses that are characteristic of the immature lamb (Figure 31.3, 6-h period before treatment). In response to hourly LH pulses, circulating estradiol rose to follicular phase concentrations and a preovulatory surge occurred, which resulted in ovulation and the formation of progesterone-secreting corpora lutea. Remarkably, for some prepubertal females in the study, as few as 22 hourly injections were required to initiate the sequence of ovulatory events. By contrast, high-amplitude, low-frequency pulses of exogenous LH are ineffectual in this regard.[15,24] Therefore, the absence of large, sustained estradiol rises in the prepubertal lamb is not due to immaturity of the ovary, but rather to the lack of a sustained, high-frequency gonadotropic stimulus.

Parenthetically, it should be mentioned that the time of spontaneous puberty and subsequent ovarian cyclicity is not advanced after the induction of ovulation in the immature female sheep by administration of gonadotropins. For example, prepubertal females in which an ovulatory cycle is induced by hourly LH injections fail to exhibit multiple, consecutive reproductive cycles after the corpora lutea of the induced ovulation regress.[15,24] Such lambs spontaneously initiate their first estrous cycles at the normal age (~30 weeks).[24] According to the working hypothesis, these immature females return to the anovulatory condition after luteal regression because the frequency of endogenous LH pulses remains low, and hence is insufficient to develop a preovulatory follicle.

Competency of the Pituitary to Secrete Gonadotropins before Puberty

The foregoing considerations about the ovary and surge mechanism lead to the conclusion that simple hypogonadotropism underlies the anovulatory condition of the immature sheep. More specifically, the deficiency appears to be in LH, rather than FSH secretion, because administration of LH *alone* induces the follicular-phase sequence (23, see Figure 31.3). A threefold to fourfold increase in LH pulse frequency has been reported by Huffman et al.[26] to occur gradually over the last week before first ovulation in the lamb (Figure 31.4). Before that period, the frequency is variable, although it is typically low, with the interval between pulses being 2–3 h or more.[26–30]

In contrast to LH, whether there is a role for FSH in the transition into adulthood in the sheep cannot easily be resolved. Circulating FSH in the lamb is well within the adult range by 10–12 weeks of age.[27,31] In one study, a subtle rise in peripheral FSH concentrations was detected 7–10 days prior to the first preovulatory surge in gonadotropins in samples of blood collected every 4 h.[32] However, in another study, this increase was not detected when circulating FSH was monitored more frequently (12-min intervals for 6 h) at various times before puberty[26] or at 2-week intervals during the first year of life.[33] Perhaps qualitative changes, rather than quantitative changes, in FSH may be important to the

transition into adulthood. An increase in the bioactive, or the more acidic, isoform of FSH was noted when puberty was induced by hourly GnRH administration.[34] No change in immunoreactive FSH was seen. However, a subsequent study[35] showed that the less acidic form of FSH was better at stimulating follicular development than the more acidic form. In addition, McNatty et al.[33] reported no change in either the bioactive or immunoactive forms of FSH with pubertal development; the more bioactive form was actually higher in lambs that did not reach puberty. Therefore, although FSH is required for follicular development and, thus, puberty onset, whether peripubertal changes in the secretion or bioactivity of FSH is involved is doubtful.

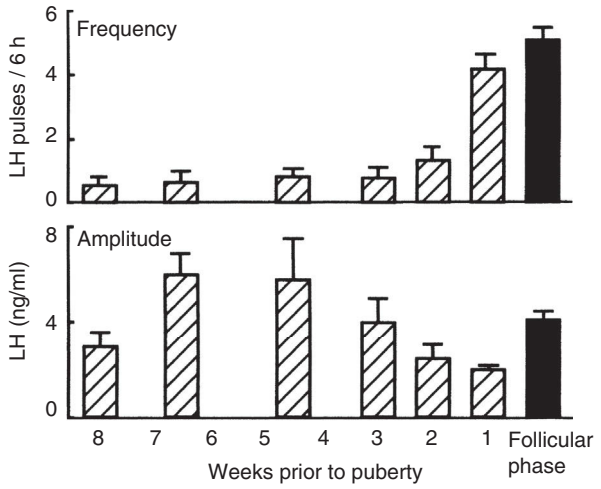

FIGURE 31.4 Mean (± SEM) LH pulse frequency (*top panel*) and amplitude (*bottom panel*) during the prepubertal period (*striped bars*) and the first postpubertal follicular phase (*solid bars*). Values for weeks 4–5 and 6–7 were combined to increase the number of observations contributing to the means. Each mean frequency was based on values from 7 or 8 lambs. Because of the absence of LH pulses during some collection periods, mean pulse amplitudes were based on values from 4 (weeks 3, 6–7, 8); 5 (weeks 2, 4–5); or 7 (week 1, follicular phase) lambs. *Redrawn from Ref. 26, with permission.*

At the outset, the simplest explanation for the low-frequency LH pulses before puberty is that the neuroendocrine system is not sufficiently developed to produce high-frequency GnRH pulses. This is not the case. Even during the early postnatal period, spontaneous hourly LH pulses can be readily produced under special conditions (removal of the ovaries, no negative feedback; Figure 31.5, bottom). Therefore, the potential to produce high-frequency LH (and GnRH) pulses, like those that initiate the follicular phase (Figure 31.3), exists from within a few weeks after birth in the sheep. Finally, the finding that high-frequency LH pulses can be produced before puberty (in the absence of steroid feedback) provides additional evidence that the pituitary is highly responsive to GnRH. Moreover, administration of GnRH readily produces LH pulses; if this is prolonged for 72 h[37] or more,[38] it can produce sufficient stimulation of the pituitary–ovarian axis to induce ovulation.

Competency of the Hypothalamus to Produce GnRH before Puberty

Determination of the pattern of GnRH to which the pituitary is exposed has been difficult for any species, largely because of the inaccessibility of the circulation between the hypothalamus and pituitary (portal vasculature) and because of the minute amounts of the neuropeptide actually secreted into the pituitary circulation. However, as described earlier, a technique to collect hypophyseal blood from unanesthetized adult sheep was developed in the 1980s. When this technique was adapted to younger animals and GnRH secretion was examined in the prepubertal lamb (19 weeks of age) without ovaries, the pattern of LH faithfully reflected

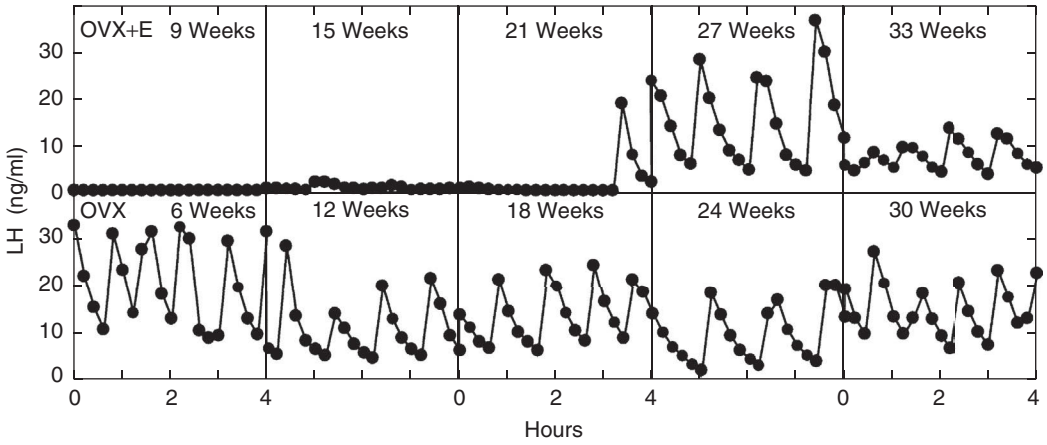

FIGURE 31.5 Patterns of circulating LH in the same ovariectomized (OVX) lamb in the presence (weeks 9, 15, 21, 27, 33) and absence (weeks 6, 12, 18, 24, 30) of exogenous estradiol (E, 2 pg/ml by implant). Samples were collected 3 weeks after insertion (*top*) or removal (*bottom*) of implant. Ovariectomy was at 3 weeks of age. *From Ref. 36, with permission.*

the pattern of GnRH secretion.[39] Each LH pulse was preceded by a GnRH pulse; moreover, each obvious GnRH pulse resulted in an LH pulse. Such findings provide the necessary direct evidence that the developing female sheep has the potential to produce high-frequency GnRH pulses long before puberty.

Decrease in Sensitivity to Estradiol Feedback Inhibition of GnRH Secretion during Puberty

The "gonadostat" hypothesis, which was originally developed based on data from rats, offers a conceptual explanation for why high-frequency GnRH pulses are not expressed in the immature female lamb. The prepubertal sheep seems to be very sensitive to estrogen-induced inhibition of GnRH/LH secretion; very low doses of estradiol (<1 pg/ml) delivered by subcutaneous (sc) implant will reduce the frequency of LH pulses to 50% within 24 h and a slightly greater dose (1–2 pg/ml) will completely suppress LH pulses.[40] Because of this highly suppressive effect of extremely low doses of estradiol in the ovariectomized prepubertal sheep model, it is of interest that the response of LH secretion to inhibition by a fixed, chronic low dose of estradiol decreases markedly during the pubertal period.[41] Although low physiologic concentrations of exogenous circulating estradiol were able to prevent high-level LH secretion in ovariectomized lambs before the typical age of puberty, the same estradiol levels were ineffective in this regard afterward (Figure 31.6). Circulating LH increased in these chronically estradiol-treated agonadal lambs when ovulations were beginning in ovarian-intact females. This leads to the conclusion that the decrease in feedback sensitivity to estradiol inhibition allows the follicular phase pattern of persistent high-frequency LH pulses to become expressed for the first time in the presence of the ovaries. This would rectify the typically hypogonadotropic condition of the developing lamb, and the ovarian follicle would be driven through the follicular phase of the first successful reproductive cycle—one that results in ovulation.

Detailed studies of the model used to examine changes in set-point to steroid negative feedback have revealed that estradiol administration (via Silastic implant) reduces LH pulse frequency, but not amplitude, in the immature ovariectomized lamb.[40,43] Accordingly, the subsequent increase in basal LH in such estradiol-treated females during the pubertal period reflects an increase in LH pulse frequency.[44] This phenomenon whereby high-frequency LH pulses become expressed during the pubertal period because of a reduction in sensitivity to estradiol inhibition can readily be demonstrated by periodically opening and closing the inhibitory feedback loop between estradiol and LH secretion within the same individual. For example, as shown in Figure 31.5, removal of the ovaries at 3 weeks of age results in high-frequency LH secretion by 6 weeks of age; insertion of an estradiol implant then suppresses LH secretion, as evidenced by the pattern at 9 weeks of age. Subsequent removal of the estradiol again reveals the potential for high-frequency LH secretion. This relationship was maintained upon insertion and removal of the estradiol implant with the same lamb until approximately 27 weeks of age, when insertion of the same estradiol implant had no apparent effect. This is about the age at first ovulation in intact lambs. Thus, before the age of puberty, estradiol is extremely effective in suppressing

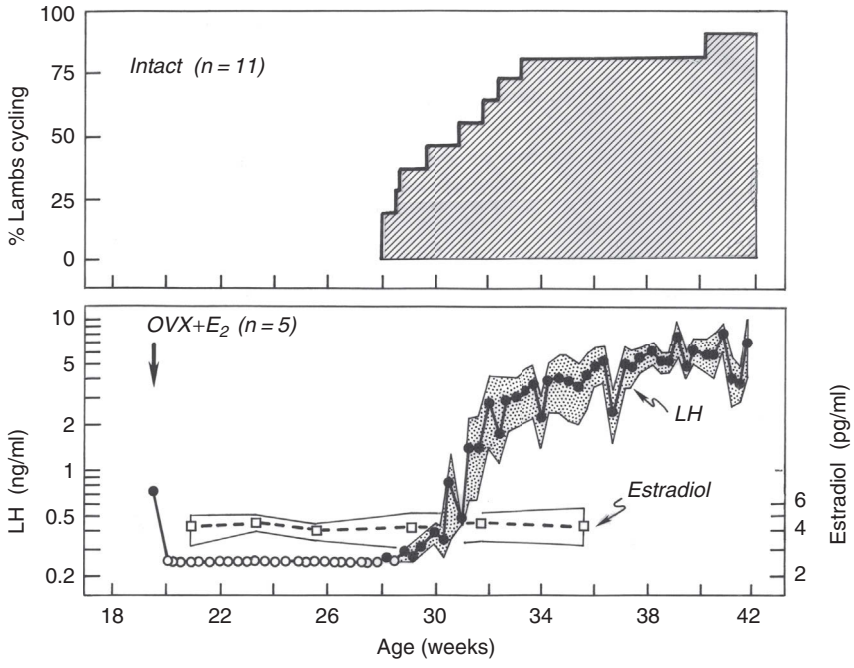

FIGURE 31.6 Response to estradiol inhibition of tonic LH secretion decreases during puberty. *Top*: Onset of reproductive cycles in untreated lambs based upon the appearance of luteal-phase concentrations of circulating progesterone. *Bottom*: Mean (± SEM) concentrations of circulating LH and estradiol (E_2) in ovariectomized lambs treated chronically with Silastic implants of estradiol from the time of ovariectomy (*arrow*); undetectable LH values (*open circles*). *From Ref. 42, with permission.*

pulsatile LH secretion, and it loses its effectiveness as the time of puberty is approached. Progesterone then assumes the role of the major inhibitory feedback control of GnRH secretion. Although the female sheep is responsive to the negative feedback action of progesterone on LH secretion before puberty,[45] this has no physiological relevance until the source of its secretion appears after first ovulation. When viewed in the context of the gonadostat hypothesis and pubertal process, these results offer additional strong evidence that in the female sheep, the mechanism governing GnRH secretion is highly responsive to estradiol inhibitory feedback before puberty, and that a decrease in response of the mechanism to estradiol feedback is responsible for the increase in GnRH pulse frequency that underlies the transition into adulthood.

Ultimately, the changing sensitivity to inhibitory steroid feedback control of GnRH secretion must be explained in electrophysiologic/neurobiochemical terms. In the adult of several species, there is strong inferential evidence for the changing electrophysiological activity of neurons that periodically secrete GnRH into the pituitary portal vasculature. LH pulses have been found to occur closely in time with volleys of electrical activity recorded from multiple neurons in the adult hypothalamus (sheep,[46] rat,[47] monkey,[48] goat[49]). A limited study has been performed in the developing sheep. In anesthetized male lambs, Pelletier and colleagues[50] recorded multiunit activity in an area between the optic chiasm and median eminence that was related to pulsatile release of LH in adult ovariectomized female sheep. Rhythmic changes in firing rates were recorded at 40–60 min intervals; however, because of the anesthesia, LH secretion was reduced such that pulses could not be detected. Hence, no correlation between electrical activity and LH secretion could be determined in this study.

In searching for a biochemical explanation for the observed decrease in sensitivity to estradiol during the pubertal period, Wilkinson and Landymore[51] have suggested that the opioid system may play a role. According to their hypothesis, endogenous opioids mediate inhibitory steroid feedback and a reduction in opioid inhibition provides a neurochemical explanation for resetting the gonadostat. Support for this idea was recently provided by the report that administration of a kappa-opiate receptor antagonist to female rats accelerated puberty onset.[52] This hypothesis has been investigated in the developing sheep by administering an inhibitor of endogenous opioids (naloxone) to female lambs at various ages.[53] Some were reared to undergo normal puberty (Figure 31.7, top panel, for representative females), whereas others were exposed to a photoperiod treatment that delayed puberty (Figure 31.7, bottom panels). In both groups, naloxone had no effect on LH secretion at the earliest age tested (9 weeks, data not shown); however, at all later developmental stages, the opioid antagonist increased LH pulse

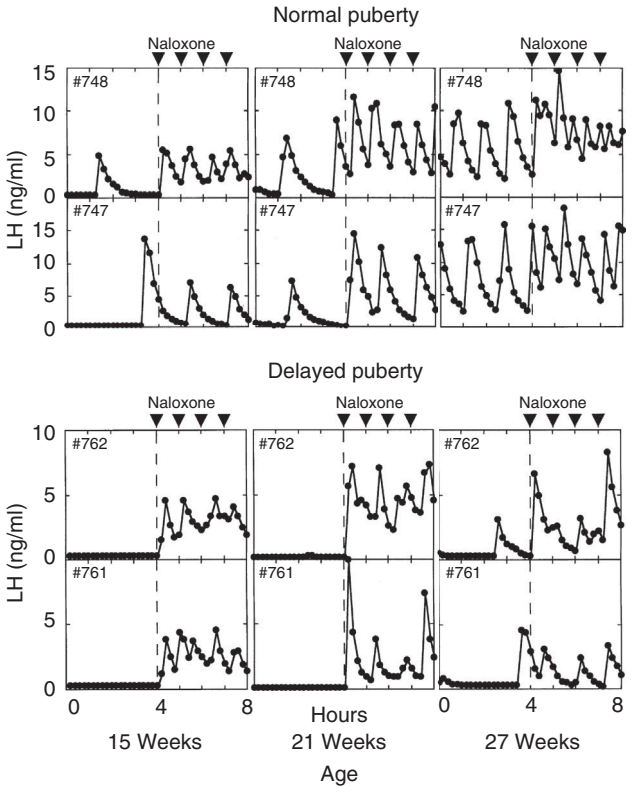

FIGURE 31.7 Effects of naloxone on serum LH concentrations in developing estradiol-treated OVX lambs at 15, 21, and 27 weeks of age. Data from four representative individuals are shown. During each naloxone test, the first 4 h served as a control period; four intravenous injections of naloxone (1 mg/kg body weight) were administered hourly for 4 h (*arrows*). *Top*: Two individuals (748 and 747) were raised on a permissive photoperiod; note the age-related increase in LH pulse frequency during the control periods. *Bottom*: Two individuals (762 and 761) were raised on an inhibitory photoperiod; note that LH secretion remains low in the control periods throughout the experiment. *Redrawn from Ref. 53, with permission.*

frequency. Importantly, the incremental change in LH pulse frequency after naloxone treatment did not differ with age. Even with photoperiodically delayed puberty, robust responses were induced after opioid receptor blockade. This leads to the conclusion that endogenous opioid mechanisms provide important inhibitory control of pulsatile LH secretion in the developing sheep. However, the ubiquity of response to opioid blockade in pre- and postpubertal females does not support the hypothesis that a reduction in opioid inhibition underlies puberty. A similar conclusion was reached in a comparative study of opioid blockade of LH secretion in developing male and female lambs; the response to naloxone administration is not sexually differentiated,[54] although the timing of puberty is.[55,56] This provides additional evidence that the response to naloxone develops very early in life and is not related to time of puberty. Finally, the basic premise that endogenous opioids mediate inhibitory estradiol feedback must be rejected because opioid

receptor blockade further increases LH pulse frequency in the lamb without ovaries.[53]

Studies in humans examining the association between gene mutations and hypogonadotropic hypogonadism have suggested an important role for two hypothalamic neuropeptides, kisspeptin and neurokinin B (NKB), in regulating GnRH release. Loss-of-function mutations in either kisspeptin[57] or its receptor, KISS1R (aka GRP54),[58,59] result in a failure to reach puberty. In addition, a mutation that apparently leads to prolonged intracellular activation by kisspeptin is associated with precocious puberty.[60] Administration of kisspeptin has been shown to stimulate LH release in several species, including mice,[61] rats,[62] nonhuman primates,[63] humans,[64] cattle[65] and sheep,[66] and this influence on LH secretion appears to be primarily due to actions on GnRH neurons.[61,62,66] Two populations of kisspeptin neurons are evident—one in the preoptic area/rostral periventricular area and one in the arcuate nucleus of the hypothalamus. In sheep, kisspeptin neurons in the preoptic area are generally believed to be involved in generation of the GnRH surge,[67] whereas those in the arcuate nucleus may regulate both tonic and surge release of GnRH.[68,69] A more detailed discussion of kisspeptin and NKB and their role in the adult sheep model can be found in Chapter 27. Few studies to date have examined the potential role of kisspeptin in timing puberty in the sheep, but those that have suggest that it could play a role in driving increased GnRH secretion. Hourly administration of kisspeptin in prepubertal female lambs elicits corresponding pulses of LH and eventually an LH surge,[70] and LH pulse frequency in ovariectomized lambs treated with estradiol during pubertal development is positively correlated with *Kiss1* mRNA-containing cell numbers in the middle portion of the arcuate nucleus.[71] Another study[72] found that kisspeptin-immunoreactive cell numbers in the arcuate nucleus are higher in postpubertal female lambs compared to prepubertal female lambs and that this increase is mirrored by an increase in the percentage of GnRH neurons receiving kisspeptin-positive close contacts identified at the level of the light/confocal microscope (Figure 31.8). In addition, that study also found that kisspeptin immunoreactive cell numbers increased following ovariectomy in prepubertal, but not postpubertal, lambs, indicating expression is inhibited by estradiol prepubertally. Kisspeptin or KISS1R deletion in the mouse[59,73–76] is supportive of an important role for kisspeptin regulating the control of GnRH secretion during sexual maturation in this species, but similar studies are not available for the developing sheep.

Similar, albeit more limited, information is available for NKB. Mutations in either the *TAC3* or *TACR3* genes, which encode for NKB and its receptor, respectively, are associated with hypogonadotropic hypogonadotropism in humans.[77] An important role for NKB or its receptor in rodent sexual maturation is somewhat unclear at this point as the effects of NKB on LH release have been reported to be stimulatory, inhibitory, or insignificant.[78–81] In addition, mice with a deletion of NK3R (an NKB receptor) appear to be fertile.[82] Recent work in prepubertal male nonhuman primates[83] and prepubertal female sheep[72] showed that senktide, an agonist for NK3R, stimulates LH release. Furthermore, although Nestor et al.[72] reported that NKB-positive cell numbers in the arcuate nucleus were not different between ovary-intact prepubertal and postpubertal female sheep, NKB fiber density within the arcuate nucleus was increased in postpubertal females compared to prepubertal females, perhaps indicating an increased synthesis and transport of NKB. In that study, NKB cell numbers did increase with removal of ovarian steroids at both stages, suggesting that NKB expression was under the control of estradiol-negative feedback.

Interestingly, kisspeptin and NKB, along with dynorphin, are frequently colocalized in the same neurons within the arcuate nucleus,[84] leading to the moniker of KNDy neurons. Although any role for dynorphin in the ability of sheep to express sexual maturity is largely unexplored, dynorphin has been shown to inhibit LH release and mediate progesterone negative feedback control of LH secretion in adult female sheep.[85–87] It has also been reported in adult female sheep that KNDy neurons express NK3R,[88] but not KISS1R,[89] whereas GnRH neurons express KISS1R, but not NK3R.[88,89] Along with evidence in rodents that kisspeptin neurons in the arcuate nucleus express kappa opiate receptors for dynorphin,[79] it has been postulated that NKB may act in a paracrine or autocrine fashion to stimulate kisspeptin release, which then acts to cause a pulse of GnRH to be released. This pulse is then terminated by local dynorphin actions on KNDy neurons. However, it should be noted that effects of NKB outside of the arcuate nucleus on LH release have also been reported.[90] Thus, although KNDy peptides appear to be necessary to express sexual maturity through the regulation of GnRH secretion, the exact mechanisms whereby they participate in this process remain to be determined. Finally, it must be emphasized that many neuropeptides could play an essential role in the regulation of GnRH secretion in addition to the KNDy peptides.

Workers using sheep, ferrets, and cattle as experimental models have embraced the gonadostat hypothesis as an explanation for the ultimate timing of the pubertal rise in GnRH/LH secretion (see Ref. 91 for a review). However, those working with the rhesus monkey, a subhuman primate, have differing perspectives (see Chapter 32). Studies[92,93] have been conducted testing the gonadostat hypothesis in the rhesus monkey using the same protocol as in the sheep (e.g., see Figure 31.6, bottom panel). The results reveal that low physiologic

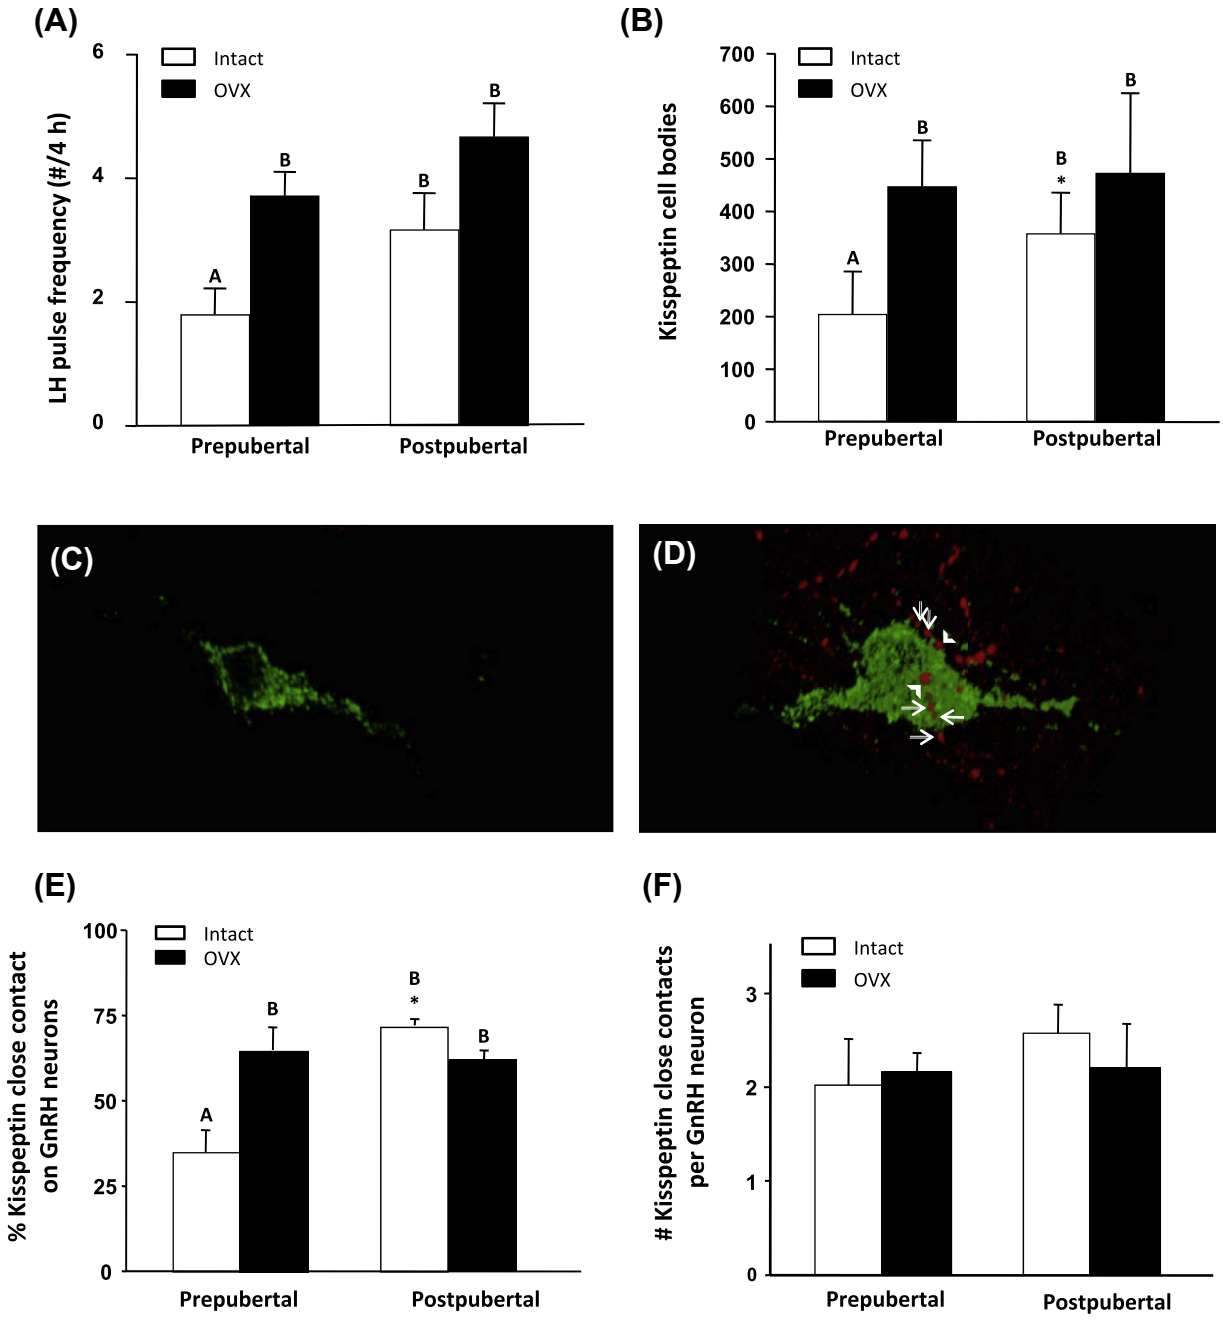

FIGURE 31.8 Changes in LH pulse frequency and kisspeptin during pubertal development. Panels C and D of this figure are reproduced in color in the color plate section. *Panel A*: LH pulse frequency in prepubertal and postpubertal female lambs that were either gonad-intact (Intact) or ovariectomized (OVX). Postpubertal intact lambs were in the early follicular phase. LH pulse frequency was higher in intact postpubertal female lambs than in intact prepubertal female lambs and rose following ovariectomy in the prepubertal, but not postpubertal, lambs. *Panel B*: Kisspeptin-immunopositive cell numbers were greater in postpubertal intact females than prepubertal intact females and increased with ovariectomy in the prepubertal, but not postpubertal, lambs. *Panels C and D*: GnRH neuron from a prepubertal female (panel C) and postpubertal female (panel D). Heavy arrows indicate point of contact between kisspeptin-containing varicosities and the GnRH neuron. Lighter arrows depict kisspeptin-positive nerve fibers. *Panels E and F*: The percentage of GnRH neurons exhibiting at least one kisspeptin close contact (panel E) was greater in intact postpubertal females than intact prepubertal females. This percentage increased with ovariectomy in the prepubertal, but not postpubertal, group. Numbers of contacts per GnRH neuron (panel F) did not differ among groups. *Redrawn from Ref. 72, with permission.*

concentrations of the steroid produce a potent inhibition of LH secretion for a prolonged period in the ovariectomized postmenarchial rhesus monkey; however, a rise in circulating LH eventually occurs; when it does, it is over the same age range as for first ovulation. Similar observations have been made by Wilson for the control of FSH secretion by estradiol in the developing rhesus monkey.[93] Thus, the sensitivity to estradiol negative

inhibition decreases in the postmenarchial monkey and is likely to be important for the first ovulation. Transient returns to periods of hypersensitivity to estradiol negative feedback and hypogonadotropism do occur in the young monkey, and they perhaps explain the long anovulatory menstrual cycles, which are characteristic of early adulthood and its periods of irregular adolescent sterility.[94]

It is important to point out that a prolonged steroid-independent (i.e., evident in ovariectomized monkeys) hiatus in GnRH secretion dominates the prepubertal period before menarche in the primate (see Chapter 32). Explanations for the regulatory mechanisms responsible for the prolonged hypogonadotropism in the premenarchial primate are of great interest, but they should neither overshadow nor be overshadowed by the gonadostat hypothesis because the latter mechanism relates only to the *final* stages of sexual maturation after menarche. During this period, steroid-independent drive to GnRH secretion is highly developed, but GnRH release remains suppressed until the response to the negative feedback actions of the low circulating concentrations of estradiol decreases, allowing for the final pubertal rise in GnRH to occur. Viewed from this perspective, both control systems would be used in the timing of first ovulations, with the steroid-independent system providing coarse control and the steroid-dependent system providing fine control. The steroid-independent control of GnRH secretion would determine the year when first ovulation is possible, while the steroid-dependent control mechanism would determine the week in which first ovulation occurs.

Similar to the altricial rhesus monkey, the precocial sheep has developed many components of the hypothalamo-hypophyseal-ovarian axis necessary for puberty (Stage III) within a few weeks after birth (Figure 31.9, bottom), such as a capacity for elevated secretion of GnRH/LH in the absence of the ovary. This ability to secrete GnRH/LH at a high rate, however, is quelled in the postnatal sheep through the estradiol hyperresponsiveness that dominates the vast majority of the developmental period until first ovulation at seven months of age. In contrast, for the monkey, the analogous period when sensitivity to steroid feedback inhibition is the primary regulator of LH secretion comprises only the final 25–30% of its postnatal development (~10 months between menarche at 30 months of age and first ovulation at 40 months) with the majority of the prepubertal hiatus in LH secretion due to steroid-independent inhibition (See Chapter 32). It is noteworthy that the developing sheep may have an analogous mechanism for nonsteroidal depression of GnRH secretion. However, because the sheep is a precocial species and is born in an advanced stage of reproductive development, this nonsteroidal inhibitory

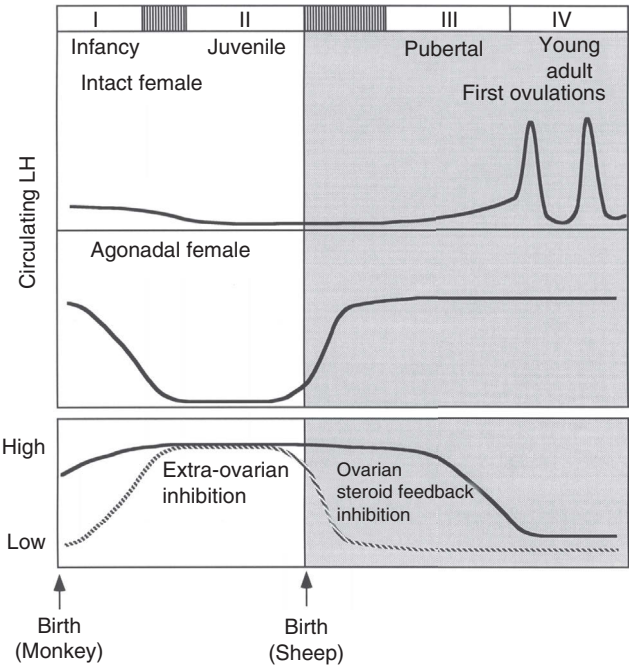

FIGURE 31.9 Analogous phases of sexual maturation based on the control of LH secretion in the monkey and sheep. The times of birth for each within the maturational scheme are indicated. Central to the hypothesis is that the sheep is born at a relatively advanced stage of sexual maturation, one that is comparable to that developed by the monkey shortly before menarche. *From Ref. 91, with permission.*

system is proposed to function before birth (see Refs 91 and 95 for reviews). Although this unifying hypothesis is attractive, it remains untested. Circulating LH in both sexes diminishes during the final stages of gestation in the absence of the gonad,[96] but the source of the "nongonadal" inhibition cannot be determined given that the fetus remains exposed to many exogenous substances, including maternal and placental steroids. The postnatal period of hypogonadotropism can be prolonged in the sheep if growth is retarded (see the section Energetics of Sexual Maturation). In such slowly growing lambs, removal of the gonads does not result in the high-frequency GnRH pulses typical of rapidly growing lambs. The issue of sensitivity to steroid feedback becomes important only after such animals have sufficient energy available to support the production of high-frequency GnRH secretion in the absence of any steroid feedback inhibition.

Events after the First LH Surge

An understanding of the first gonadotropin surge and the changes that precede this event is clearly important to unraveling the initiation of the pubertal process. Nevertheless, later changes occur in the sheep that are worthy of mention to provide the broad picture of the transition into adulthood. Sexual maturation continues well after the first ovulation; for example, the initial

ovulation is followed by a short luteal phase in some lambs because of premature release of $PGF_{2\alpha}$ from the uterus. There are also changes in the control of pulsatile LH secretion, initiation of normal sexual receptivity, and eventually a seasonal pattern of reproduction becomes manifest, with the young female returning to the anovulatory condition—much the same as before puberty.

Postpubertal Shift in Steroid Control of LH Secretion

During the pubertal period, the hypothalamo-hypophyseal system controlling pulsatile GnRH secretion decreases its ability to be inhibited by estradiol. High-frequency GnRH pulses do not occur indefinitely thereafter because a qualitative shift occurs in their steroid feedback control. The new inhibitory steroid is progesterone, and the new timing mechanism that dictates the intervals between ovulatory cycles is its source of secretion—the corpus luteum. According to the hypothesis developed for neuroendocrine control of the estrous cycle, rising luteal phase progesterone concentrations decrease GnRH pulse frequency (see Chapter 27). The resultant low-frequency LH pulses do not sufficiently stimulate the final stages of preovulatory follicle development. Following regression of the corpus luteum and the decline in circulating progesterone, LH pulse frequency again increases, and another 2- to 3-day follicular phase begins to set in motion the next reproductive cycle. This sequence of progesterone dominance and withdrawal is repeated at 15- to 17-day intervals (length of estrous cycle). The inverse relationship between circulating progesterone and LH pulse frequency during the first estrous cycles of the postpubertal female has been characterized.[27] As with the many other control systems, the potential for this feedback system to function exists well before puberty; experimentally, exogenous progesterone can decrease tonic LH secretion in the immature ovariectomized lamb.[45]

Sexual Receptivity

In the adult female sheep, progesterone plays an important "priming" role for estrogen induction of sexual behavior (see also Chapter 27).[97–100] As determined by treatment of the ovariectomized female sheep with physiologic patterns and levels of steroids, the sequence for induction of estrus is a sustained (at least 6 days) increase in circulating progesterone, withdrawal of progesterone, and an increase in circulating estradiol.[101] The requirement for this hormonal sequence may be used to explain why the first and even second ovulation of the lamb during the pubertal period is not accompanied by estrous behavior.[32,102] Before first ovulation, there is no corpus luteum, and hence there is no major increase in circulating progesterone to prime the neural centers that regulate sexual behavior to respond to the sustained estradiol rise that induces the first LH surge. The resultant short luteal phase generates only small amounts of progesterone, and therefore the increase in circulating estradiol before the second LH surge does not usually result in the expression of sexual behavior. Finally, after exposure of the brain to high concentrations of progesterone for several days during the first normal luteal phase, estrus first occurs in response to the rise in circulating estradiol typically during the third follicular phase. Therefore, as many as two "silent ovulations" (ovulations without estrus) may go unnoticed by the ram. Interestingly, estrus without ovulation has been reported in female lambs,[103] and this raises the question of whether the adult might have a more stringent requirement for progesterone priming. Other age-related differences have been noted in that the behavioral signs of sexual receptivity in the lamb, when they finally occur, are much weaker than in the fully mature female.[104] Moreover, the duration of estrus is shorter in lambs.[104–106] Nevertheless, a fertile mating can occur during the first reproductive cycles, and a pregnancy can be carried to term.[27,107] Compared to mature females, however, fertility of postpubertal lambs is lower (see Refs 22 and 23 for reviews). There is greater fertilization failure and embryo mortality,[104] and this has been attributed to a delay in development within the HPG axis, including the timing of ovulation relative to estrus and a lower viability of the ovum.[23]

Postpubertal Sterility—Seasonal Anestrus

Unequivocally, the greatest contributor to postpubertal infertility in the female sheep is seasonal anestrus.[108] Under natural conditions, the normal season of birth is spring. Puberty in spring-born lambs is attained between 25 and 35 weeks of age, after which estrous cycles occur at 15- to 17-day intervals. However, after only a few reproductive cycles, the young female becomes anovulatory and no longer exhibits estrous behavior. As determined through use of an experimental model, the ovariectomized estradiol-treated lamb, the female once again becomes hypersensitive to estradiol feedback inhibition of LH secretion. Thus, even before 1 year of age, the postpubertal lamb reverses its sensitivity to estradiol negative feedback and reverts to the anovulatory condition. This terminates the first breeding season.

The mechanism underlying seasonal cessation of estrous cycles in the sheep is hypogonadotropism due to insufficient GnRH secretion. The last cycle of the season occurs when the female attempts to drive the follicular phase, under increasing sensitivity to estradiol feedback inhibition that begins in late winter and early spring (also see the section Seasonal Reproduction in Adult Sheep). After luteal regression and the decline in progesterone, GnRH pulses start to increase and begin the next follicular phase, but the GnRH secretory mechanism

again becomes locked in a tight negative-feedback loop with estradiol. Under increasing estradiol hypersensitivity, the follicular phase cannot be completed because the high-frequency LH pulses required for the final developmental stages of the follicle necessary for ovulation cannot be produced. Consequently, not enough estradiol is secreted to activate the preovulatory gonadotropin surge system or induce estrous behavior. There is a marked seasonal change in the inhibitory feedback effect of estradiol on the pulsatile secretion of GnRH in adult ovariectomized female sheep.[109] During the breeding season, low doses of estradiol have no discernible inhibitory effect on GnRH secretion, whereas during the anestrous season, they produce a profound depression of GnRH pulse frequency.

DETERMINANTS TIMING THE TRANSITION INTO ADULTHOOD: THE CORE ISSUE

Clearly, the production of sustained high-frequency GnRH pulses initiates the sequence of events that activate the ovary. Consideration of the details of brain mechanisms involved in the production of these high GnRH pulse frequencies can be found in Chapters 11 and 27. The core question underlying the biology of puberty relates to what controls when this all-important increase in GnRH pulse frequency will occur. Is the timing by growth cues? How important are nongrowth cues? Is there a developmental clock regulated by genes? Why does puberty occur at different times in females and males? To begin to explore these fundamental issues, we can conveniently consider the sources of timing information as internal and external. Whatever explanation is ultimately forthcoming for the sheep, it must include how somatic signals communicate with the hypothalamus to control the developmental changes in sensitivity of GnRH secretion to inhibitory gonadal steroid feedback.

Internal Determinants

In virtually all living organisms, sufficient growth (and hence nutrition) is required to begin reproduction (Figure 31.10). However, we remain fundamentally ignorant of how growth is perceived by the central nervous system in any vertebrate species. The following sections are focused on potential humoral signals and neural mechanisms linking growth/nutrition with reproduction.

Energetics of Sexual Maturation

As noted earlier, Kennedy and Mitra[5] hypothesized 50 years ago that changes in energy availability serve as important cues timing puberty because the energy demands of thermoregulation and growth take

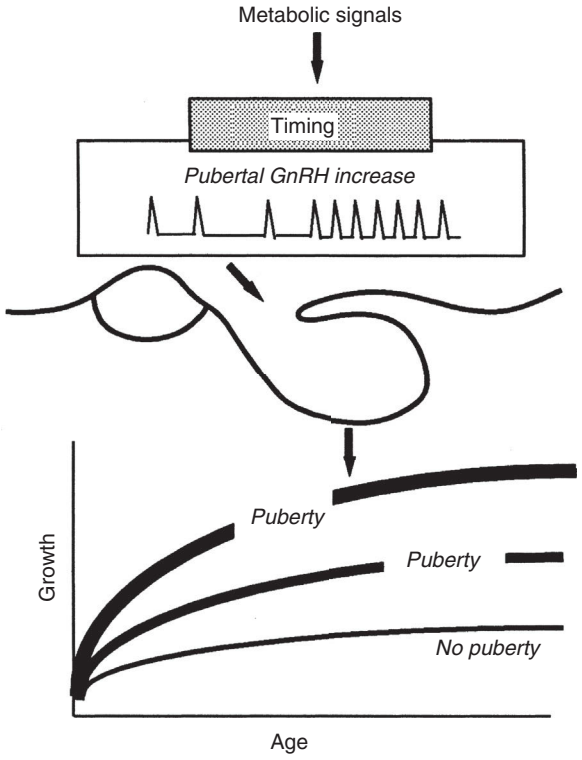

FIGURE 31.10 Growth and the timing of puberty.

precedence over that for reproductive function. As pointed out by Bronson and Manning,[110] the energetic cost of the physiological processes involved in ovulation are minuscule compared to the vastly higher energetic consequences of pregnancy and lactation. A similar argument could be made for the male, in which little energy is required for spermatogenesis compared to the great energy expenditure that occurs during intraspecies competition for females.

In view of the foregoing considerations, the energetics of the developing sheep can be considered. The newborn has almost no body fat[111,112] and therefore relies on milk from the mother for a continuous supply of energy. Compounding the lack of stored energy is its high energy expenditure. During early postnatal development, the ratio of large surface area to relatively small body mass results in rapid heat loss, and the metabolic rate must be correspondingly high to maintain core body temperature.[111,112] The greatest energetic cost is thermoregulation and cellular maintenance (Figure 31.11), and most of the remaining energy intake is allocated to muscular activity and growth. There is no excess energy as evidenced by the virtual absence of fat; consequently, according to the energetic hypothesis being developed, the priority for nonessential processes such as reproduction is low. The developing individual remains reproductively inactive due to hypogonadotropism. As body mass becomes larger with growth and the relative surface area

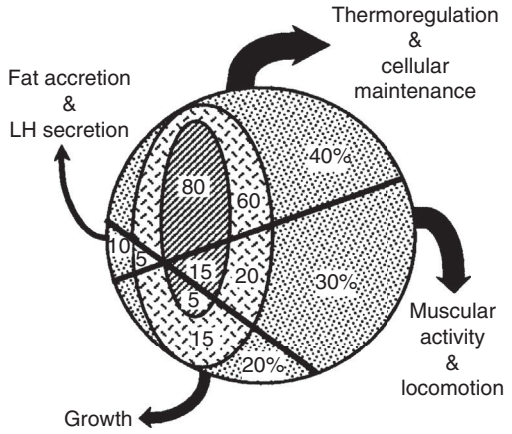

FIGURE 31.11 Partitioning of metabolic fuel during development in the sheep. The circles represent increasing body mass from birth (inner circle) to maturity (outer circle). Each circle is divided into four quadrants to represent the estimated relative proportion of energy allocated at each stage of development. *Modified from Bucholtz DC [Ph.D. Thesis]. University of Michigan.*

decreases, the metabolic rate correspondingly decreases. The eventual decline in metabolic rate allows more internal energy to become available for other physiologic demands, such as fat storage and, importantly, reproductive activities.

One potential approach to unravel how somatic signals influence brain pathways to govern GnRH secretion during sexual maturation is to study the influence of slow or restricted growth produced by restricted diet. With reduced energy intake, the majority of available energy is used for cell maintenance and thermoregulation, and very little remains for growth. Thus, there is a delay in reaching the transition point at which the metabolic rate declines and excess energy becomes available for fat deposition and reproduction—that is, puberty is delayed. Eventually, if growth is sufficient, some energy can be expended for the eventual consequences of reproduction (pregnancy/lactation or male–male competition). One could argue that studying the slowly growing or growth-retarded individual may not reveal mechanisms timing normal puberty; however, it is axiomatic that the rate of growth depends upon the available nutrition. Thus, because of large differences in food supply, a wide range of "normal" growth rates occurs in nature (outside the laboratory) for each species. Unfortunately, we have little definitive evidence on the sensors and pathways that link energy, metabolism, and reproduction via neural substrates. At the outset, we are presently hindered by an incomplete understanding of how the brain monitors energy metabolism both on a moment-to-moment basis and over the long term. Older work in rodents suggested that sensing of energy status may involve neurons in both the hypothalamus and brainstem[113,114] and that metabolic fuel sensing in the area postrema of the brainstem may play a role in energetic control of fertility.[115] However, the pathways that connect sensing of metabolic state to GnRH release are not well understood, and this is particularly true for the sheep. Candidate neuropeptides that may be involved will be discussed later in this section. Clearly, such knowledge is essential to provide an explanation of how the brain normally monitors growth to determine when it is sufficient to increase GnRH secretory activity to initiate puberty.

In the developing sheep, the influence of growth on GnRH secretion is readily apparent when the *ontogeny* of pulsatile LH secretion is examined in a population of lambs. Although the frequency of LH pulses increases in the neonatal period, the correlation is much greater with body weight (growth) than with age. This relationship is demonstrable in the presence[116] or absence (D.C. Bucholtz and D.L. Foster, unpublished observation) of the gonads. Perhaps such results reflect differences in energy supplies available to offspring before weaning, as the rates of lactation vary considerably between mothers. Experimentally, the relationship between LH pulse frequency and energy can be readily demonstrated by carefully controlling energy intake in lambs removed from their mothers and fed an artificial milk substitute.[117] Reducing the daily intake of calories to such suckling lambs profoundly retards the increase in LH pulse frequency. Eventually, they begin high-frequency LH secretion. However, with minimal fat stores (energy reserves), mechanisms controlling GnRH secretion remain energetically sensitive. Compared to rapidly growing peers that have accumulated sufficient energy reserves to withstand short-term (24-h) fasting, the slowly growing lambs are unable to do so. Short-term fasting of such lambs gradually depresses LH secretion. With realimentation, LH pulse frequency increases rapidly (i.e., within 4 h on the artificial milk diet). Remarkably, this increase can occur in some animals as quickly as within 20 min of refeeding. These findings suggest that without large energy reserves (fat) during development, mechanisms governing GnRH secretion are highly sensitive to changes in external sources of metabolic fuel (e.g., milk), even on a moment-to-moment basis. From a broader perspective, growth may influence the time course of sexual maturation via the accumulation of somatic fuel stores capable of sustaining GnRH secretion between meals.

Leptin as a Signal Linking Metabolism and Reproduction

What is the signal to the brain that relays energetic information to effect changes in reproductive activity? A long-held popular hypothesis, largely emanating from clinical literature and reviewed by Frisch,[118] is that a certain level of fatness must be achieved to begin reproductive cycles in the female. However, until the discovery of

the adipocyte-derived hormone leptin,[119] there had been no mechanistic hypothesis about how fatness per se could ultimately affect the activity of GnRH neurons. Leptin is a 16-kDa protein secreted primarily by adipocytes that acts within the hypothalamus to suppress appetite.[120,121] The first link between leptin and reproductive function was made after the observation that administering leptin to obese, hypogonadal, leptin-deficient *ob/ob* mice suppresses appetite, reduces body weight, and establishes fertility.[122] In adult sheep, peripheral concentrations of leptin are associated with measures of body fat,[123–125] and circulating leptin levels typically decrease during periods of reduced energy intake or availability[124–126] that are associated with reduced gonadotropin secretion. For leptin to serve as an important bloodborne metabolic signal timing the pubertal increase in GnRH secretion, two criteria must be satisfied: (1) puberty is associated with an altered pattern of peripheral leptin secretion; (2) exogenous leptin stimulates reproductive neuroendocrine function or advances the onset of puberty in otherwise sexually immature individuals.[127]

A developmental increase in peripheral concentrations of leptin has been reported for rodents and primates in some studies but not in others.[128–141] In addition, the pattern differs between males and females and may not always correspond temporally with indices of sexual maturation. In sheep, the pattern of leptin seems to depend on the sex, gonadal status, and nutritional conditions. In the neonatal lamb, serum concentrations of leptin are low (~2 ng/ml) as would be expected in view of its low amount of body fat.[142] An initial increase in circulating leptin occurs during the first week of life in both females and castrated males, and this is thought to result from the transfer of leptin from the mother to offspring during early lactation. Leptin then gradually declines between 1 and 7 weeks of age in both sexes. Throughout this pre-ruminant period (weaning typically occurs at 8–10 weeks of age), plasma leptin levels are regulated principally by level of nutrition.[143] In males reared from birth on an ad libitum milk substitute diet, plasma concentrations of leptin continuously increased as lambs grew to a body weight of 20 kg at approximately 8 weeks of age, and leptin was positively correlated with body fat as a percent of body weight. However, when lambs were fed milk substitute to provide a low plane of nutrition, plasma leptin did not increase and leptin was not correlated with the amount of body fat, even though the percentage of body weight attributable to fat increased with age. In a study of the patterns of LH secretion in males fed a solid diet of moderate energy, leptin concentrations increased between 6 and 12 weeks of age (L.M. Jackson, R.A. Ehrhardt, Y.R. Boisclair, and D.L. Foster, unpublished data). Leptin levels were positively correlated with body weight at 6 weeks of age (prepubertal), but the correlation was not significant at older ages. Plasma concentrations of leptin also correlated with the frequency of LH pulses in prepubertal males, which suggests that the growth-dependent increase in LH pulse frequency could be associated with an increase in plasma concentrations of leptin. Whether a causal relationship exists between peripheral leptin levels and the onset of high-frequency LH secretion in male sheep will require additional studies. Furthermore, peripheral leptin levels throughout development have not been characterized in female sheep; therefore, whether there are sex differences in the importance of leptin as a pubertal signal in this species is not known.

Regarding the second criterion for leptin as a pubertal signal, there is no consensus on the ability of exogenous leptin to stimulate gonadotropin secretion or advance puberty in sexually immature individuals. This could be due, in part, to the anorexigenic effects of leptin and the importance of adequate nutrition for activation of reproduction. In developing sheep, the effect of exogenous leptin on reproductive neuroendocrine function has been studied in both sexes. In prepubertal females, LH secretion was not stimulated after 8–10 days of recombinant ovine leptin treatment delivered either intracerebroventricularly (ICV)[144] or peripherally by intravenous infusion.[145] With peripheral leptin treatment, feed intake was not suppressed, but the ICV treatment dramatically suppressed feed intake to the extent that one would predict a decrease in LH secretion. One could speculate that because the expected reduction in LH pulses did not occur, the centrally delivered exogenous leptin actually preserved pulsatile LH secretion. Thus, there is no clear evidence that GnRH or LH secretion is stimulated by artificially increasing leptin levels in young female sheep.

In the developing male sheep, the ability of leptin to stimulate LH secretion appears to depend upon the stage of development and energy availability. The treatment paradigm used was previously shown to increase pulsatile LH secretion in a nutritionally hypogonadotropic adult model (gonadectomized, steroid-replaced, short-term fasted).[146] In this fasting model, subcutaneous administration of recombinant human leptin increases LH pulse frequency. Furthermore, leptin treatment is as effective at restoring reproductive neuroendocrine function as is refeeding. When the same dose of leptin that restored LH secretion in fasting adults was administered to prepubertal male lambs, LH pulse frequency increased, but the magnitude of the response depended upon individual pretreatment LH pulse frequencies.[146] These different patterns of gonadotropin secretion reflect the natural variability in levels of maturity at the same age. Leptin treatment did not increase the frequency of LH pulses in most lambs not yet producing LH pulses or in those individuals already producing hourly (or faster) pulses. However, in some lambs that were not producing

pulses before treatment and those lambs producing low-frequency pulses (1–3 pulses in 4 h), LH pulse frequency increased after leptin treatment. The ability of leptin to stimulate LH secretion in the prepubertal male contrasts with its effects in the female, which raises the possibility that there are sex differences in responses to growth cues timing the pubertal increase in GnRH secretion. However, as discussed below, female sheep are highly photoperiodic with respect to the timing of puberty, so it remains to be determined if the sex difference in the response to leptin in prepubertal individuals is due to differences in the responses to growth cues, photoperiod, or both.

The response in prepubertal male sheep to leptin differed from that in fasted adults. In all nutritionally hypogonadotropic adults, leptin increased LH secretion, but this was not the case in developmentally hypogonadotropic lambs. Such a finding suggests that there are additional developmental or metabolic signals that control the hypothalamo-pituitary response to leptin before puberty. Moreover, hypogonadotropism in the prepubertal individual experiencing limited energy availability due to rapid growth may not be functionally equivalent to nutritionally induced infertility in the adult. In the growth-retarded male lamb, responsiveness to leptin treatment does not improve with increasing age (Figure 31.12).[147] In fact, continued growth restriction reduced pulsatile LH secretion without leptin treatment and eliminated a neuroendocrine response to leptin in individuals who had been responsive at an earlier age when growth was normal or less severely restricted. These findings indicate that the mechanism regulating the onset of high-frequency GnRH secretion relies on one or more metabolic cues for information regarding growth and energy balance. Leptin can stimulate gonadotropin secretion in the prepubertal sheep, but the response appears to be regulated by other developmental or metabolic signals. Thus, this fat-derived hormone must be considered as a permissive signal timing puberty.

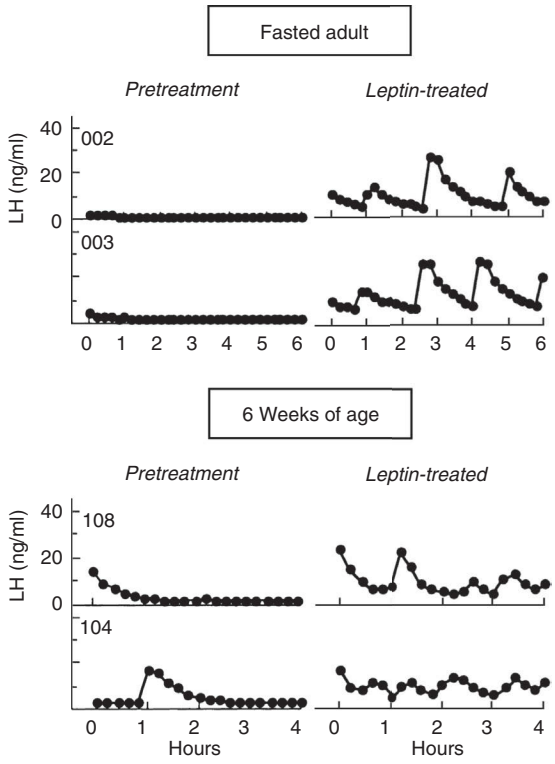

FIGURE 31.12 Patterns of LH secretion in representative gonadectomized, estradiol-treated male sheep before and after treatment with recombinant human leptin (12.5 μg/kg sc every 4 h). *Top*: LH pulse frequency is reduced in adults fasted for 48 h (*left*); 48 h of leptin treatment while continuing the fast increases LH secretion (*right*). *Bottom*: LH pulse frequency is low in nonfasted, growing lambs at 6 weeks of age (*left*); pulsatile LH secretion is increased after 72 h of leptin treatment (*right*) although responses were variable (see text for discussion). *Data from Ref. 146.*

Other Metabolic Signals

Before the discovery of leptin as a potential metabolic cue for puberty, the correlation of fatness with onset of fertility prompted other studies of the role of energy metabolites in timing puberty. Evidence for control of central mechanisms involved in the regulation of LH secretion by metabolic signals stems from studies using competitive inhibitors of glucose (2-deoxyglucose, 2DG) and free fatty acids (methyl-palmoxorate). As reviewed by Wade and Schneider,[148] such blockers were historically used for studies of appetite control, but their usefulness in the study of reproduction was later realized. For example, concurrent treatment with the inhibitors of both fatty acid and glucose oxidation in the hamster disrupts estrous cyclicity.[149] When this approach was applied to the developing sheep, pulsatile secretion of LH was suppressed within a few hours; interestingly, these treatments suppressed frequency in some lambs; in others, they suppressed amplitude.[150] Moreover, because the fatty acid blocker was administered after the glucose blocker, it is uncertain whether the major suppression of LH occurred in response to inhibition of glucose metabolism or fatty acid metabolism. In another study, when 2DG was administered alone, clear pulses of LH in the ovariectomized lamb were abolished.[151] Presumably, 2DG blocked the release of endogenous GnRH because both exogenous GnRH and a GnRH secretagogue (N-methyl-D, L-aspartate (NMDA)) were able to maintain pulsatile LH secretion when they were administered within 1 h of 2DG treatment. Such studies provide evidence for a role of energy balance in the moment-to-moment regulation of LH secretion. Interestingly, leptin may modulate glucose availability to provide information about energy balance because administration of 2DG blocks the ability of leptin to stimulate LH secretion during fasting.[152] Another possibility is that leptin, glucose, and perhaps

other substances serve as independent metabolic signals that are integrated within the brain to provide information about overall energy balance. If this is the case, perhaps a hierarchy of metabolic signals exists and the action of one signal is dependent upon the relative input provided by the remaining constellation of signals.

The metabolic hormone insulin-like growth factor-1 (IGF-1) has been proposed to be an important signal for puberty because circulating levels of the hormone increase during puberty in the rat,[153,154] monkey (see Refs 132 and 155 for reviews), and sheep.[156,157] In rodents, disruption of the growth hormone (GH)–IGF-1 axis by deletion of the gene for the GH receptor[158] or passive immunization against growth hormone-releasing hormone (GHRH)[159] reduces growth and delays sexual maturation. Furthermore, administration of IGF-1 increases peripheral concentrations of LH and advances puberty in the female rat[160]; in female monkeys, IGF-1 accelerates the decline in sensitivity to the negative feedback effects of estradiol[161] and advances the age at first ovulation.[162] In female lambs, the age of puberty is correlated with body weight and concentrations of circulating IGF-1 and the GH response to exogenous GHRH tends to be greater in those individuals reaching puberty at younger ages.[163] Similarly, plasma concentrations of IGF-1 in developing male lambs are positively correlated with testis size, plasma testosterone, and body weight, and IGF-1 levels are reduced in juvenile sheep during feed restriction and delayed puberty.[156] A direct effect of IGF-1 on the timing of puberty in sheep has not been studied, but chronic treatment with GH increases plasma concentrations of IGF-1 in prepubertal females and advances the age at which high-frequency (hourly) pulses of LH are produced.[164] In adult sheep, peripheral IGF-1 acutely increases LH secretion,[156] and the magnitude of the response is amplified in estradiol-treated or undernourished individuals. However, contrary to the rat,[165] the sheep hypothalamus appears to contain few IGF-1 receptors.[166] IGF-1 receptors and binding proteins are abundant in the ovine pituitary gland[167] and IGF-1 stimulates LH secretion in vitro from cultured ovine pituitary cells in a dose-dependent manner.[166] Furthermore, IGF-1 increases in peripheral circulation but not cerebrospinal fluid following an increase in nutrients that stimulates gonadotropin secretion,[168] and ICV administration of IGF-1 does not alter pulsatile LH secretion.[169] Thus, the major impact of IGF-1 on gonadotropin secretion in the sheep appears to be at the level of the pituitary gland.

Insulin is another metabolic hormone that has been proposed to regulate LH (GnRH) secretion (see Ref. 170 for a review). Specifically, low nutrition would result in low insulin concentrations that, in turn, would provide information to the GnRH neurosecretory system to reduce its function. This hypothesis has been tested in the growth-retarded lamb by acute injection of insulin into the lateral ventricles in an attempt to replicate improved energy balance and thereby to provide a positive signal for GnRH secretion.[171] Central administration of insulin minimized possible peripheral effects on glucose, amino acids, free fatty acids, and other metabolites that may affect neuroendocrine function. Acute injections of insulin failed to stimulate LH secretion which indicates that the increased circulating concentrations of insulin associated with increased feed intake after growth restriction may not be causal to the accompanying increase in LH secretion. Such findings do not support the role of peripheral insulin alone as an important signal mediating the effects of metabolism on GnRH secretion in the lamb. However, in another study, mean LH concentrations increased after two and four days of ICV infusion of insulin to diet-restricted, pubertal female sheep,[172] despite the hypophagia induced by the insulin treatment. The difference between the responses to acute and chronic insulin treatment raises the possibility that central levels of insulin must be integrated over time or with other metabolic factors to provide information about nutrient status to the GnRH neuronal system.

Pathways of Energy Metabolism in Modulating GnRH Secretion

While the energetic state of an individual clearly plays a role in timing puberty onset, the neural pathways whereby nutritional status is transduced into a signal influencing LH secretion are not completely known. One commonly used approach to uncover neural pathways involved in mediating the effects of nutrition on GnRH/LH secretion is acute or chronic feed restriction. Various lines of evidence indicate that the reduced gonadotropin secretion in the growth-retarded lamb is specifically due to reduced GnRH secretion (Figure 31.13). First, the frequency of GnRH pulses, as measured in the pituitary portal vasculature, is markedly reduced in growth-retarded lambs compared to rapidly growing lambs.[174] Second, GnRH content in the median eminence (terminals) and preoptic area (cell bodies) is not diminished in growth-retarded lambs.[175] Third, hourly, intravenous administration of the glutamate analog, NMDA, to nutritionally growth-retarded lambs produces corresponding LH pulses that are similar in size to those induced by a physiologic dose of GnRH.[175] Fourth, the anterior pituitary gland contains adequate concentrations of LH and FSH,[176] and physiologic doses of GnRH readily induce LH and FSH secretion.[175] These findings, considered together, lead to the inference that the central mechanisms controlling GnRH release, rather than synthesis of GnRH or LH, are limiting LH secretion when sexual maturation is delayed by growth retardation. The following paragraphs will discuss a few of the more likely central neuropeptide candidates that may be involved and for which there is data available in the sheep.

There are several neurotransmitter/neuropeptide systems that regulate GnRH secretion and that are also altered during nutrition-induced growth retardation and its resultant hypogonadotropism. Increased inhibition by endogenous opioids was one of the first mechanisms postulated whereby metabolic changes influence the pulsatile secretion of GnRH. In the rat, there is limited evidence that fasting impairs LH secretion by activating an endogenous opioid pathway.[177,178] In the growth-restricted lamb, however, such evidence has not been obtained. Although endogenous opioids appear to be involved tonically in the steroid-independent inhibition of LH secretion in the lamb as discussed previously (in the section Decrease in sensitivity to estradiol feedback inhibition of GnRH secretion during puberty), whether this inhibition is heightened during growth retardation is uncertain. Blockade of endogenous opioid receptors with naloxone in the hypogonadotropic gonadectomized lamb does not increase LH pulse frequency at doses that are effective in this regard in the rapidly growing agonadal female. Even greater doses of naloxone[175] or the long-acting antagonist, naltrexone (H. I. Anson and D.L. Foster, unpublished observation), have not been able to disinhibit LH secretion. One explanation is that other inhibitory neuronal pathways are also activated during periods of reduced energy metabolism. Thus, opioidergic inhibition of GnRH secretion may occur, but it would be masked by one or more other inhibitory neurotransmitter pathways, and blockade of only opioid receptors by an antagonist would be without an effect on GnRH secretion. The use of multiple pharmacologic agents, along with the opioid antagonist, would be required to test this possibility. Nevertheless, based on the existing evidence, we conclude that a massive increase in opioid tone cannot be the primary cause of hypogonadotropism in the growth-retarded lamb.

Neuropeptide-Y (NPY) is another candidate neurotransmitter for modulation of GnRH secretion during low nutrition. Hypothalamic NPY neurons are responsive to metabolic signals as evidenced by co-localization of leptin receptors on NPY neurons in rodents[179] and nonhuman primates,[180] and a reduction in hypothalamic NPY mRNA expression[181,182] and NPY secretion[182] in response to leptin treatment. Expression of leptin receptor mRNA has been reported in the arcuate nucleus in the sheep, an area that also contains many NPY neurons.[183] Concentrations of NPY in the cerebrospinal fluid are higher in food-restricted, ovariectomized, estradiol-replaced lambs than in well-nourished lambs[184] and, in ovariectomized sheep, ICV infusion of NPY decreases LH secretion.[184–186] Because ICV injections of NPY also stimulate feeding in sheep,[187,188] as in other species (see Ref. 189 for a review), the neuropeptide may serve a dual role in the pathway of signal transduction that conveys information about metabolic cues to the neuronal systems controlling GnRH secretion and ingestive behavior. In a prepubertal individual, elevated NPY levels would suppress GnRH secretion until circulating metabolic signals (e.g., leptin) reflect somatic maturation, at which point the inhibitory NPY input would diminish and GnRH secretion would increase. NPY neurons also coexpress agouti-related peptide (AgRP) and AgRP also increases with feed restriction.[190–192] Reports regarding the effect of AgRP on reproduction generally report an inhibitory function,[193–195] although a stimulatory effect in male mice was noted in an early study.[196] Data regarding the role of AgRP in regulating LH secretion in the sheep is sparse, but an inhibitory function fits with one report wherein AgRP mRNA expression was negatively correlated with LH release in sheep on a decreasing plane of nutrition.[197] As AgRP is an endogenous antagonist to α-melanocyte stimulating hormone (αMSH) and αMSH appears to be stimulatory to LH release (see below), AgRP may act to inhibit αMSH input and thereby reduce GnRH/LH secretion.

αMSH is produced as one of several products of the proopiomelanocortin (POMC) gene. Proopiomelanocortin gene expression decreases with food restriction and is a direct target of leptin, which stimulates its expression.

αMSH acts through various isoforms of the melanocortin receptor (MCR), of which MCR-4 is considered the most important for body weight regulation.[198] As mentioned above, both αMSH and AgRP bind to MCR-4 in antagonistic fashion, and the fact that deletion of these receptors leads to obesity and hyperphagia[199] strongly suggests that αMSH predominates in that relationship. Activation of MCR-4 is generally considered stimulatory to reproduction[200–203]; in sheep, administration of MTII, an agonist of MCR-4, increases LH in the luteal phase.[204] Whether these effects are directly exerted at the GnRH neuron,[195,205] exerted indirectly,[204] or both remains to be determined.

Kisspeptin-containing neurons of the arcuate nucleus may also play a role. Kisspeptin expression in rodents is reduced by food restriction[206–210] and is reduced in male mice with a deficiency of leptin.[211] Arcuate kisspeptin neurons, but not those in the preoptic area, coexpress the receptor for leptin (although to what extent is a matter of contention[211–214]), as well as receptors for insulin.[215] Given these findings and the importance of the kisspeptin system to puberty onset, it is not suprising that they are a topic of great interest where metabolic regulation of reproduction is concerned. In mice, deletion of leptin receptors from kisspeptin neurons had no affect on puberty onset[216] and reintroducing leptin receptors to kisspeptin neurons in mice globally lacking leptin receptors (*db/db* mice) did not restore fertility.[217] Interestingly, deleting insulin receptors from kisspeptin neurons delayed onset of puberty.[215] In sheep, *KISS1* mRNA expression is lower in female sheep fed to be lean as compared to females of a normal body weight and is partially restored by leptin treatment.[218] These authors also reported that all kisspeptin neurons examined in that study coexpressed leptin receptor. They further reported reciprocal connections between kisspeptin neurons and both NPY and POMC neurons and that kisspeptin treatment increased NPY mRNA, but reduced POMC mRNA levels. Given the respective effects of NPY and αMSH on LH secretion, this would seem counterintuitive. Thus, the exact nature of such interactions in the sheep awaits further clarification.

External Determinants Timing Puberty

Because the sheep is a seasonally breeding species, it is logical to consider that external cues would be integrated with internal, growth-related cues to modulate the activity of the GnRH pulse generator (Figure 31.14). These cues might provide conflicting information. For example, if environmental information indicates that the season for puberty is not optimal, the expression of high-frequency GnRH pulses will not be permitted, despite the fact that growth-related information indicates that an adequate size or sufficient energy balance for puberty has been attained. Similarly, sexual maturity will not occur if seasonal cues indicate that the appropriate time of the year for puberty has arrived, but metabolic cues indicate that the lamb cannot bear the energetic consequences of increasing GnRH pulse frequency and initiating reproductive function. The sustained increase in GnRH pulse frequency will occur only when internal and external cues indicate that both size (positive energy balance) and season are favorable for initiating a pregnancy. To appreciate mechanisms of how seasonal cues impact neuroendocrine mechanisms regulating the onset of fertility in the female lamb, the seasonal nature of reproduction in the adult female sheep is considered below (also see Chapter 34; Refs 219 and 220 for reviews).

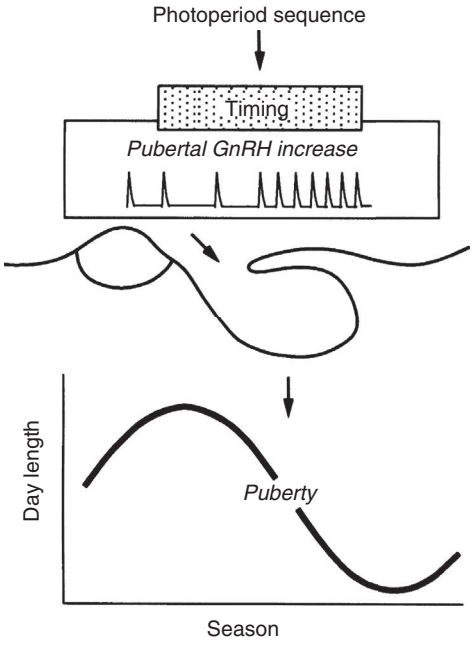

FIGURE 31.14 Photoperiod and the timing of puberty.

Seasonal Reproduction in Adult Sheep

Although the sheep has long been associated with humans, it retains a seasonal pattern of reproduction. Conception is restricted to a certain period of the year—the *breeding season*. During the remaining *anestrous season*, the female is anovulatory and will not exhibit estrous behavior. As with other seasonal breeders, the ability of the sheep to turn the reproductive system off and on, a process of reversible fertility, may be viewed as "nature's own contraceptive."[221] Because the length of pregnancy in female sheep is about 5 months, the breeding season occurs in autumn and winter so that the births of lambs are clustered in spring, the "season of plenty." This reproductive strategy allows access to high-quality forage, both to meet the demands of lactation for the adult and to meet the subsequent growth requirements of the postweaning lamb. As will be pointed out later, birth

in spring is advantageous in another regard. It allows the majority of postnatal development to occur during spring and summer so that puberty can occur during the same year, in the first autumn after birth. Artificial selection and better nutrition have extended the breeding season, and now a gradation exists from the monoestrous state of some wild species to the polyestrous condition of domestic breeds.[106] Various breeds are capable of mating for as many as 8–10 months of the year,[222,223] and some individuals have even been reported to exhibit estrous cycles at 15- to 17-day intervals throughout the year.[107,224] This suggests that the potential for continuous reproduction exists in the sheep, and artificial selection could make this possible. Presently, assisted reproductive technologies, including hormonal manipulations, facilitate conception and birth of lambs at any time of the year if so desired.

Numerous types of experiments have demonstrated that day length is the primary environmental factor timing the annual reproductive cycle of the sheep. Originally, Marshall[225] determined that transferring female sheep across the equator to a locale where environmental variables were 6 months out of phase eventually shifted the breeding season 6 months. More definitively, reversal of the annual changes in only day length by artificial photoperiod from that which occurs under natural conditions reverses the breeding and anestrous seasons.[226–228] Acceleration of the changes in the annual photoperiod, by alternating 90-day cycles of long days and short days, also accelerates the annual reproductive cycle to produce two breeding seasons and two anestrous seasons per year.[229] Finally, manipulation of the circadian pattern of melatonin, the pineal hormone involved in transducing photoperiodic information into a neuroendocrine signal, results in changes in timing of when reproductive cycles occur (see Ref. 220 for a review). These types of investigations in which photoperiod or its pathway of transmission into neuroendocrine signals is changed offer compelling evidence for a deterministic role for day length in synchronizing breeding activity among mature female sheep. As discussed below, this pathway is also used by the developing female to synchronize its first reproductive cycles to the autumnal breeding season of the adult.

Photoperiod and Puberty

The month of birth will influence the age of puberty, and this is most evident in those breeds that exhibit the most pronounced seasonal reproduction. The classic study by Hammond[2] in 1944 led to the general conclusion that regardless of season of birth, lambs would reach puberty only during the breeding season. Moreover, it has been noted in several breeds of sheep that winter-born and spring-born lambs reach puberty at about the same time of the year; however, because the latter are born several months later, they are much younger at the first mating.[2,106,107,223,230] Births later in the year (summer) may even further reduce the age at puberty.[31,223,231] However, if births occur extremely late in the year (autumn), lambs delay initiation of reproductive cycles until the following year to coincide with the subsequent breeding season.[2,107,223,230,232]

Long-standing evidence that photoperiod is the major environmental factor phasing the annual rhythm of reproduction in the adult female led to the consideration that seasonal changes in day length might also serve as the outdoor cue to synchronize the time of puberty to the appropriate season for first conception. This is summarized in Figure 31.15. According to this scheme, the

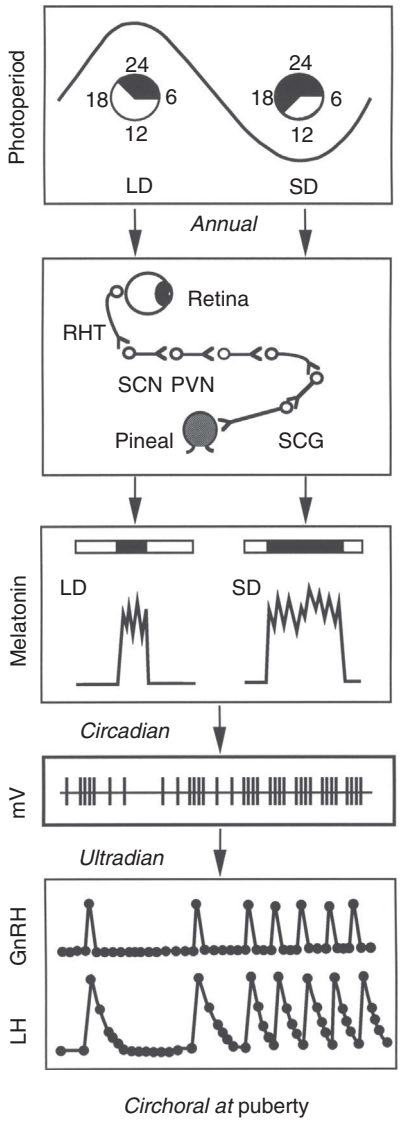

FIGURE 31.15 Interplay among rhythms timing puberty involving day length, the pineal gland, electrical activity of GnRH neurons, and GnRH/LH secretion. LD, long day; SD, short day; RHT, retinohypothalamic tract; SCN, suprachiasmatic nucleus; PVN, paraventricular nucleus; SCG, superior cervical ganglion. *Redrawn from Ref. 233.*

developing sheep maintains a photoperiod history from a very early age using the same photoneuroendocrine pathway as the adult to transduce seasonal changes in day length into humoral signals that eventually modulate neuroendocrine function. The long days of spring and summer, followed by the decreasing day length of autumn, provide the stimulatory (permissive) photoperiod sequence to initiate puberty. As reviewed elsewhere for the adult,[219] information about length of day (hours of light vs hours of darkness) is relayed from the retina through a retinohypothalamic tract via the suprachiasmatic nuclei, which provide circadian input; the information proceeds through the paraventricular nuclei, and then via a multi-synaptic pathway involving the superior cervical ganglia to the pineal gland. Thus, the environmental light/dark cycle entrains the circadian-based melatonin rhythm such that melatonin is only secreted for the duration of the dark phase of the photoperiod. Long days produce a short duration of high melatonin secretion, whereas short days induce a long duration. These patterns of melatonin form the basis of a neuroendocrine record of photoperiod experience that modulates the frequency of GnRH secretion.

Evidence for key elements of the foregoing integrated mechanism that will be discussed in detail next includes: (1) a seasonally reversed artificial photoperiod sequence can reverse seasonally delayed puberty; (2) normal puberty requires the experience of long days before short days; (3) photoperiodically delayed puberty is associated with slow LH pulse frequency due to prolonged hypersensitivity to estradiol negative feedback; and (4) removal of pineal gland function delays puberty, and timed infusions of its product, melatonin, restore the time of puberty to normal.

SPRING-BORN VS AUTUMN-BORN LAMB—A CASE OF DELAYED PUBERTY

A study of the age of puberty in lambs (Suffolk breed) born in spring or in autumn was one of the first to implicate photoperiod as an important environmental timer of puberty.[232] In that study shown in Figure 31.16, onset of cycles was determined by estrous behavior using mature vasectomized males housed continuously with the lambs; the increase in circulating progesterone to luteal phase concentrations confirmed that reproductive cycles had begun. In natural photoperiod, spring-born lambs attained puberty at about 30 weeks of age during the breeding season (Figure 31.16, second panel). By contrast, autumn-born lambs raised in natural photoperiod reach the pubertal age of 30 weeks during the anestrous season; reproductive cycles did not occur in such females (Figure 31.16, third panel) despite their having sufficient somatic development for initiation of ovulations. Rather, puberty was delayed until the following breeding season, when the lambs were nearly 1 year old. This seasonally induced delay in onset of reproductive cycles can be attributed to day length. Evidence supporting this inference is that the age at puberty was restored to normal in autumn-born females when they were raised in an artificial, annually reversed photoperiod simulating that had they been born in spring (Figure 31.16, bottom panels).

Although the foregoing study provides evidence that lambs of the Suffolk breed are highly photoperiodic with respect to the timing of puberty, this may not be the case in all breeds. This is shown in Figure 31.17 in a study of the effect of season on timing of puberty in the D'man breed.[234] The D'man is a subtropical sheep that has evolved under a highly intensified production system in the oases of pre-Saharan regions, and it has a pattern of relatively continuous reproduction (90% conception rate in both spring and autumn).[1,235] Thus, it provides

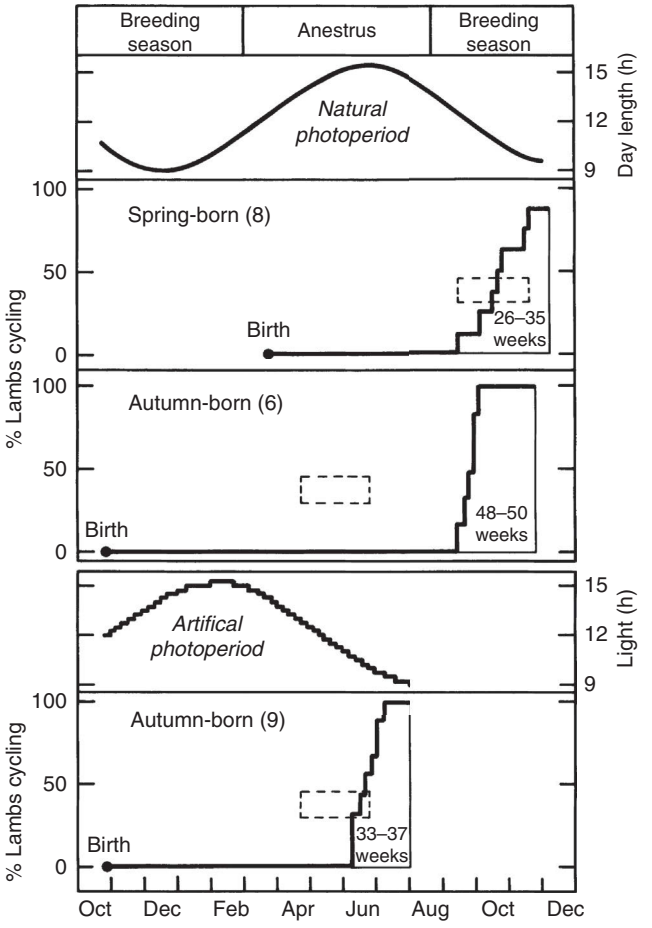

FIGURE 31.16 Delay in puberty in autumn-born lambs due to inappropriate photoperiod during development. Shown are the ages and months at first ovulation in spring-born and autumn-born females raised in natural photoperiod (*first three panels*) and in autumn-born females reared in an artificial, seasonally reversed photoperiod (*last two panels*). Ovulations were initiated in spring-born females during the age range of 26–35 weeks (*dashed rectangle*). *From Ref. 20, with permission.*

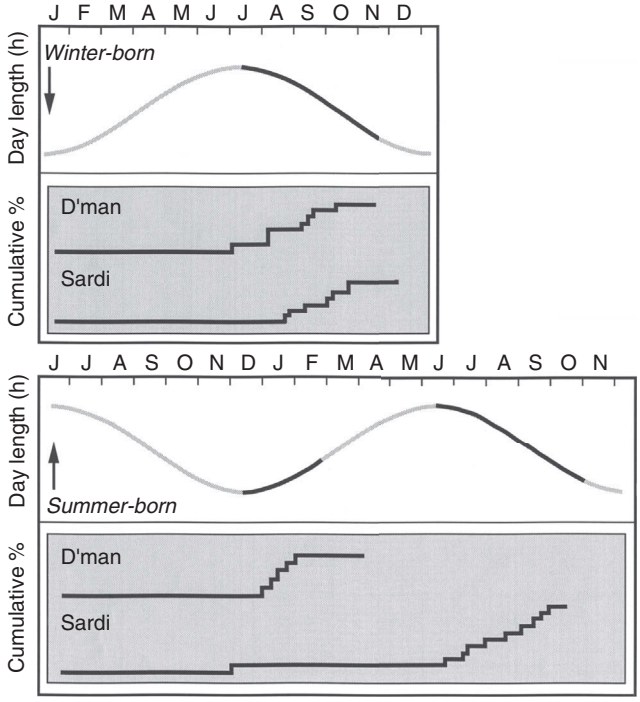

FIGURE 31.17 Timing of puberty, as evidenced by the first rise in circulating progesterone to luteal phase concentrations in lambs of the D'man breed and of the Sardi breed. Lambs were born either in winter (*top*) or summer (*bottom*) and raised in natural environmental conditions in Morocco. *Data from Ref. 234, with permission.*

an exception to the rule that reproduction in the sheep is highly seasonal. As a comparison to the D'man breed in the same area (Morocco), the Sardi breed is raised under much more open conditions and is seasonal in its pattern of reproduction. In this Moroccan study[234] conducted under natural photoperiods, conception was regulated so that lambs of both breeds were born in two different periods of the year, January and June. As expected, winter-born lambs of both breeds attained puberty as evidenced by initiation of luteal function in the autumn, much the same as the Suffolk lamb as shown in Figure 31.16. However, in the strongly seasonal Sardi breed, lambs born in the summer delayed puberty, again much like the autumn-born Suffolk female. By contrast, summer-born lambs of the D'man breed initiated reproductive cycles at the same age as those born in the winter. Taken together with information about seasonality of reproduction in the adults of these breeds, one is led to the conclusion that seasonal cues only play a role in timing of puberty if reproduction in the adult is seasonal.

The photoperiod is used to time puberty through the timing of the decrease in sensitivity to estradiol inhibition of LH secretion. This is shown in Figure 31.18 for the ovariectomized model in which the potential to produce high-frequency LH pulses typical of the follicular phase is revealed at an early age (e.g., by 12 weeks of age). In the presence of physiologic levels of circulating estradiol (by sc implant), only a low frequency is maintained; the time when high-frequency pulses are expressed depends upon photoperiod history. The lamb raised in a stimulatory (i.e., permissive) photoperiod does not express the high-frequency LH pulses until 25–30 weeks of age in the presence of estradiol (top panels, ovariectomized (OVX) + estradiol (E)), despite its having achieved this potential at a much earlier age (top panels, OVX). However, the lamb raised in an inhibitory photoperiod does not reduce its sensitivity to estrogen feedback inhibition at the same time as the lamb raised under the stimulatory photoperiod, and LH pulse frequency remains suppressed for much longer (bottom panels, OVX+E).

In the context of season of birth and the timing of puberty (Figure 31.16), the delay in initiation of reproductive cycles in the autumn-born lamb reared outdoors arises from prolonged hypersensitivity to estradiol negative feedback.[232] Whereas the response to estradiol feedback inhibition of LH secretion diminishes in the spring-born lamb at 30 weeks of age during decreasing day length, the autumn-born female remains hypersensitive to estradiol at this age because of increasing day length. This maintains tonic LH secretion at low levels, thereby preventing the initiation of preovulatory follicular development (and subsequent pregnancy) during the long days of summer in such females born in the "wrong" season. The reduction in feedback sensitivity then occurs during the decreasing day length of autumn to synchronize puberty to the breeding season. Finally, this delay in reduction of sensitivity to estradiol negative feedback can be prevented experimentally. When the autumn-born female is raised indoors in an artificial, annually reversed photocycle, the decrease in feedback sensitivity is restored to the normal age (~30 weeks).[232] Therefore, photoperiod cues, as well as growth-related cues, are used to time the initiation of ovulations in the developing sheep.

Studies of neuroendocrine timing of puberty in nonseasonal breeds of sheep have only begun. In this regard, the pattern of LH secretion during puberty in Sardi (strong seasonal breeder) and in D'man (aseasonal) accords with the timing of puberty shown in Figure 31.17. In the D'man, the increase in LH secretion was the same regardless of whether the lambs were born in winter or summer. By contrast, in the summer-born Sardi female, much like the Suffolk female, the increase in LH pulse frequency did not occur at the usual age, and was delayed until the next breeding season. Thus, in some breeds of sheep, only growth cues may be used to time puberty, whereas in others, both growth cues and photoperiod cues are important (L. Derqaoui, unpublished observation[234]). Studies of female Soay sheep using photoperiodic and growth manipulations suggest that, within the body weight range examined, photoperiod is the dominant cue timing puberty in this less

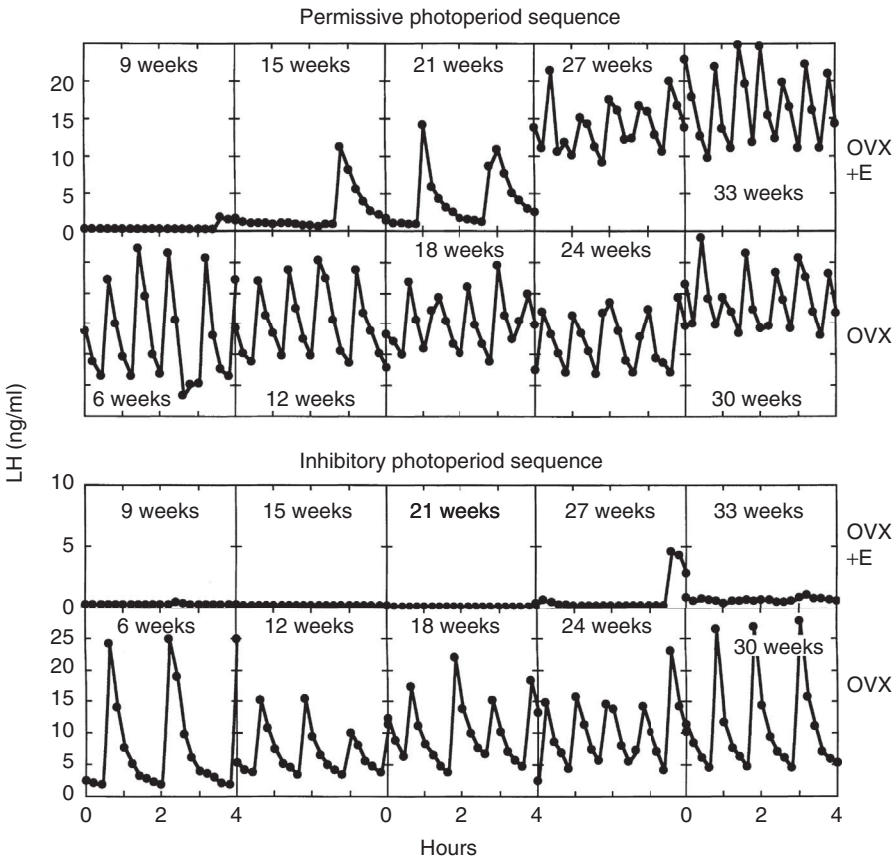

FIGURE 31.18 LH patterns at different ages in a lamb maintained in a permissive photoperiod sequence for puberty (*top two panels*) and in a lamb maintained in an inhibitory photoperiod sequence for puberty (*bottom two panels*). For each lamb, upper panels depict LH patterns 3 weeks after replacement of a constant release estradiol capsule; lower panels depict LH patterns 3 weeks after removal of estradiol. *From Ref. 44, with permission.*

domesticated breed.[236] This finding that photoperiod can induce puberty in Soay females with very limited growth while the same degree of growth restriction delays puberty in Suffolk females, could simply reflect an extremely low threshold for the energy balance required to initiate high-frequency GnRH secretion in the more feral breed. However, it could also represent an adaptation to harsh environmental conditions in which adequate forage during lactation and weaning are critical for offspring survival. Strict adherence to photoperiodic cues for timing puberty would optimize reproductive success by minimizing the number of births that would occur during late winter or early spring when food availability is unpredictable.

PHOTOPERIOD SEQUENCE FOR PUBERTY

The simplest hypothesis for photoperiodic timing of puberty in the female sheep is that the lamb can begin reproductive cycles during short days, but not during long days. Thus, the spring-born lamb could monitor photoperiod, and when day length becomes sufficiently short in the autumn, puberty occurs. Indeed, females raised from birth under long daily artificial photoperiods do not begin reproductive cycles during the normal age (25–35 weeks).[237] Eventually, ovulations began during the second year, although in many long-day-reared lambs they occur at irregular intervals, and many result in short luteal phases. Although the latter finding importantly indicates that long days can block the normal timing of puberty, its eventual onset implies that the lamb is able to reject photoperiod information (become photorefractory) so that puberty cannot be forestalled indefinitely in an unfavorable light environment. Apparently, after growth requirements have been satisfied, the window of opportunity to achieve fertility can be shifted, but not closed entirely. This underscores the timing role, rather than driving role, played by photoperiod in puberty in the female sheep.

An unexpected finding in a series of photoperiod studies was that exposure of the female sheep to short days alone delays puberty, much the same as long days. When lambs are raised from birth under continuous short days, repetitive ovulations do not even begin during the first year after birth (Figure 31.19, top). It appears that lambs must experience alternate photoperiods to begin reproductive cycles at the appropriate age. Specifically, long days must precede the short days during which puberty is attained. Systematically reducing the duration of long-day exposure in the study shown in Figure 31.19 revealed that as little as 1 week would induce reproductive cycles in lambs otherwise raised in short days. Clearly, the photoperiodic timing of puberty in the female lamb is much more complex than the simple notion that the mere experience of short days alone

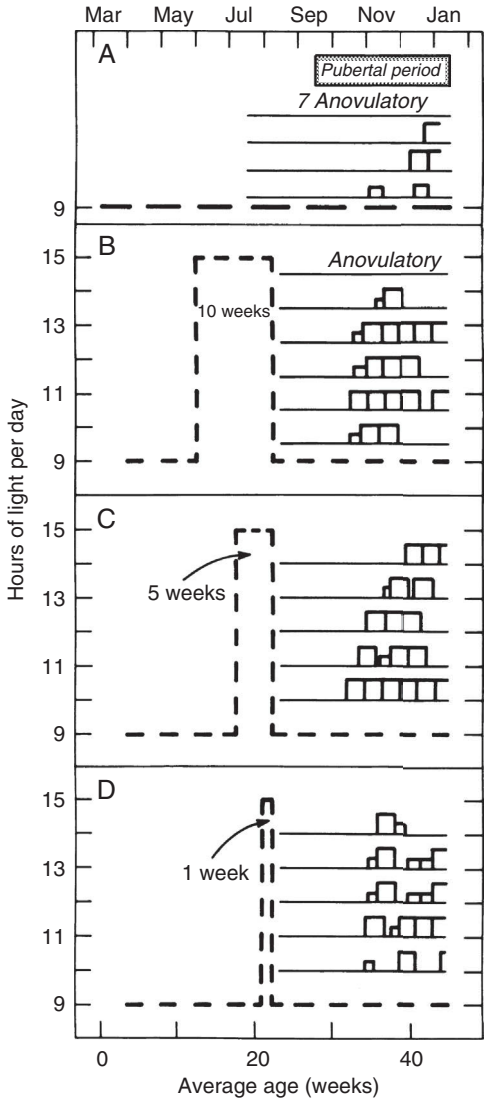

FIGURE 31.19 Alternate photoperiods initiate reproductive cycles. Spring-born lambs were raised entirely in artificial short days of 9 h light: 15 h dark (9L:15D) or with 10 weeks, 5 weeks, or 1 week of long days of 15 h light: 9 h dark (15L:9D). Reproductive cycles with normal luteal phases (*large blocks*); cycles with short luteal phases (*small blocks*); photoperiod (*broken lines*). Each horizontal line shows data for an individual lamb, except in the top panel, which indicates that seven of 10 lambs remained anovulatory. *From Ref. 42, with permission.*

initiates reproductive cycles. The finding of a long-day requirement to begin ovulations in this young short-day breeder raises the possibility that the lamb maintains a *photoperiod history* and that it uses the long days of spring and summer as a contrast reference to time puberty to the relatively shorter days of autumn.

PINEAL GLAND AND MELATONIN

In the adult sheep, melatonin plays an important role in the timing of seasonal reproduction. It is likely that it has a similar role in the lamb to regulate the photoperiodic timing of puberty. Important sites for melatonin action appear to be in the hypothalamus, but uncertainty exists about the mechanisms that translate information about the pattern of melatonin to alter the pattern of GnRH secretion (see Chapter 34). Using microimplants of melatonin into various areas of the ovine brain, early studies identified targets for melatonin action that affected LH secretion in the mediobasal hypothalamus[238] and premammillary region.[239] Interestingly, several studies[240–243] have reported binding sites of melatonin in the pars tuberalis of the pituitary, and more recent work indicates that melatonin action in this region may well be critical for seasonal breeding (see Chapter 34 for detailed discussions of this mechanism). The issue of a timekeeping relay is essential to our understanding of melatonin action because of the long lag time (several weeks) between changes in the pattern of melatonin secretion and the appropriate LH response.[219,233] Moreover, studies in adult female sheep have found that melatonin does not have an acute action (within minutes) in the modulation of LH secretion.[244] In view of the foregoing considerations about the long time constant, it is possible that melatonin modulates GnRH secretion through inducing changes in morphology by remodeling yet unknown elements within the brain. The lack of exact understanding about how melatonin interacts with mechanisms controlling GnRH secretion, however, should not detract from the important concept that the pattern of circulating melatonin encodes day length. This information is then used to increase or decrease the sensitivity of the GnRH neurosecretory system to estradiol negative feedback to alter the frequency of LH secretion.

The sheep is exposed to the photoperiod-linked melatonin rhythm very early in life. Melatonin has been detected in the circulation of the fetus, and the pattern exhibits a well-defined rhythm, with the highest levels occurring during the hours of darkness.[245,246] The pattern in the fetus mimics that of the mother, although its amplitude is reduced. This is for good reason because the mother generates the rhythm as evidenced by the observation that removal of the maternal pineal abolishes the nocturnal increases in melatonin in both the maternal and fetal circulation.[247,248] This leads to the conclusion that the fetal pineal gland may not produce melatonin and that the melatonin in the fetal circulation is derived from the maternal pineal gland. Such a conclusion is reinforced by the finding that exogenous melatonin can cross the placenta from the maternal to the fetal side.[247–249] However, melatonin has been detected in the fetal pineal gland[245] raising the possibility that melatonin could be secreted in very small quantities before birth because the pineal gland does not store melatonin appreciably.[250] In view of the depressed melatonin in fetuses of pinealectomized mothers, however, the secretion of

melatonin by the fetal pineal may be insignificant. Moreover, if the fetal pineal were to secrete melatonin, then the circadian pattern of secretion would not accurately reflect day length because it is not obvious how the fetus would be able to detect changes in ambient photoperiod to phase its secretion with the daily light/dark cycle.

Perhaps distinct nocturnal melatonin secretion begins only after birth when the newborn is first exposed to retinal light changes. Indeed, some (but not all) lambs exhibit a clear nocturnal melatonin rise by 1 week of age. For example, in studies of four sets of newborn twins (male/female) of the same age and weight, a circadian rhythm of melatonin was evident in both individuals of two pairs; however, in the other two pairs, only ambiguous patterns were found.[251] Because the differences in ontogeny of melatonin were greater between twin pairs than between siblings within a pair, there may be some genetic basis for the differential rate of development of circadian melatonin rhythmicity. By at least 6 weeks of age, nocturnal rises in melatonin are well established.[252] Moreover, the young lamb can shift its melatonin rhythm to accord with a new photoperiod based on the patterns of circulating melatonin in lambs and their mothers shifted from long days (short durations of daily melatonin secretion) to short days (long durations of daily melatonin secretion). As shown in Figure 31.20 (left), the daily period of increased melatonin, which is of short duration during long days, begins to expand during the first long night. By 2 weeks of age, the melatonin rhythm was entrained completely in all lambs; of importance, the rate of entrainment for the lambs was the same as for the mothers (Figure 31.20, right). Arguments that either melatonin may be transferred from the lactating mother through the milk or that the melatonin rhythm of the lamb is entrained through some other maternal mechanism are not likely to be tenable based upon considerations reviewed elsewhere.[252] Thus, in view of the foregoing data from the fetus and early postnatal lamb, the developing sheep receives information about ambient day length via the mother before birth and then via its own secretory profile of melatonin during the early postnatal period.

Surgical removal of the adult pineal gland abolishes the inductive reproductive response of the female to short days and the inhibitory response to long days.[219] However, an initial study of the role of the pineal gland in the onset of puberty in the female sheep was unable to detect any abnormal timing of first matings in pinealectomized lambs outdoors.[253] This surprising finding was attributed to the possible photoperiod insensitivity of the Merino, a breed of sheep with a relatively long annual breeding season and an indistinct anestrous period. A subsequent study from the same laboratory found that pinealectomy delayed puberty in crossbred

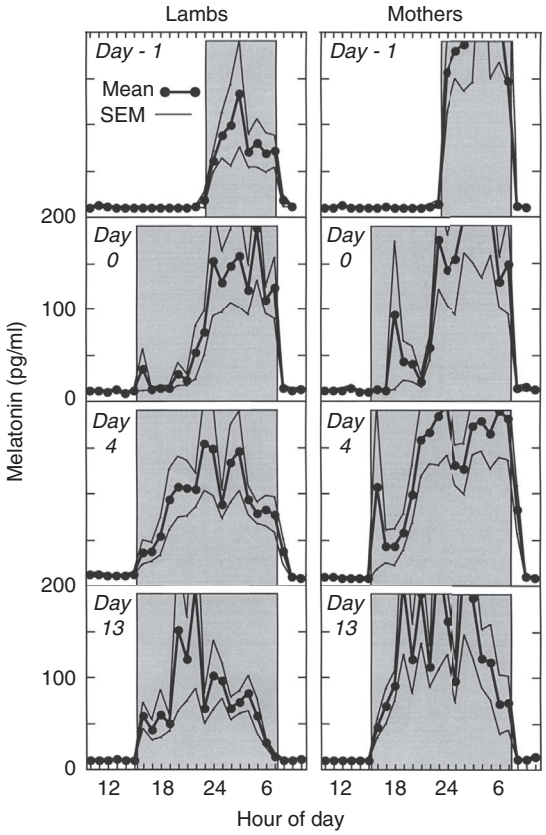

FIGURE 31.20 Change in melatonin pattern after shift from long days to short days. Circulating melatonin (mean ± SEM, $n = 8$) is shown during a 24-h period for 7-week-old lambs (*left*) and their mothers (*right*) on long days (Day −1), on the day of the shift to short days (Day 0), and on Days 4 and 13; periods of darkness (*shaded areas*). *From Ref. 252, with permission.*

Merino lambs (×Border Leicester × Dorset breeds)[254]; clearly, breed differences in the photoperiod modulation of puberty remain to be clarified for the sheep. Another approach to disruption of the pathway for transmission of photoperiod information is ablation of the sympathetic innervation of the pineal gland by bilateral removal of the superior cervical ganglia (see Figure 31.15 for pathway). After this procedure, melatonin secretion may continue, albeit at very low levels, and any modest rises are not consistently related to any particular time of the photocycle (Figure 31.21, bottom inset). Superior cervical ganglionectomy of lambs of the Suffolk breed at an early age (6 weeks) delays initiation of reproductive cycles, suggesting that normal pineal function is necessary for timing puberty to the appropriate season (Figure 31.21).[255] Cycles do begin in lambs in which pineal function is absent (pinealectomized[254]) or impaired (ganglionectomized[255]), but they are unusually late; such females may even attain puberty at the time when untreated lambs end their first breeding season and enter seasonal anestrus. From these studies and those using continuous long days or short days, the

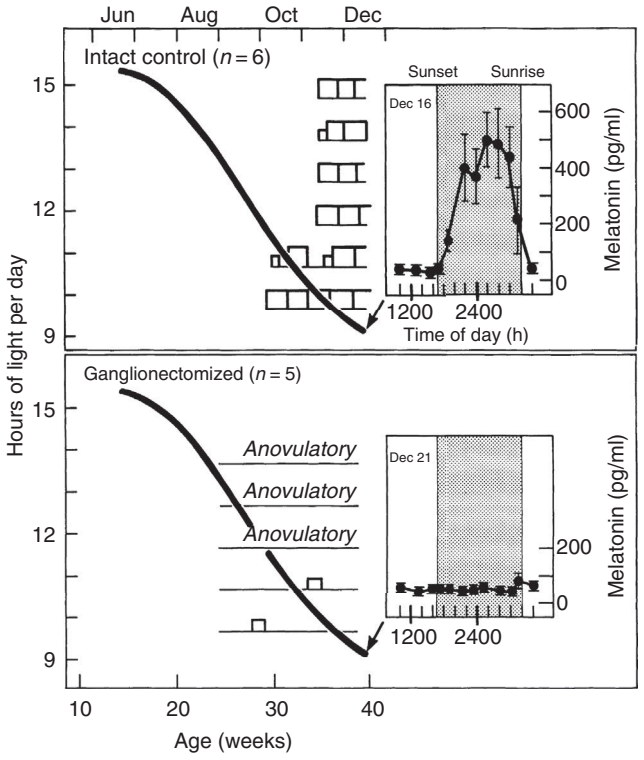

FIGURE 31.21 Denervation of the pineal gland of the lamb prevents onset of repetitive reproductive cycles at the normal age in natural environment (*bottom*). The 24-h pattern of circulating melatonin (mean ± SEM (insets)) is shown at 40 weeks in lambs in which the superior cervical ganglia were removed bilaterally at 6 weeks of age (*bottom*); also shown is the melatonin pattern in unoperated postpubertal lambs that were exhibiting normal reproductive cycles (*top*) (see Figure 31.19 for details of coding of luteal phases). *From Ref. 25, with permission.*

concept is reinforced that photoperiod cues can readily modify the timing of puberty, but they cannot forestall or advance puberty outside of certain limits. Finally, melatonin is involved in regulating the timing of puberty by photoperiod in the female sheep[254–257] because the pattern of melatonin encodes information about day length, as in the adult.

Interestingly, chronic administration of melatonin by implants, which is a relatively easy method to deliver the indolamine, has been used in an attempt to alter the onset of ovarian cycles in the lamb. Constant-release devices do not produce a circadian pattern of hormone, but as in the adult,[258,259] chronic melatonin treatment may be interpreted as a series of short days. In this regard, melatonin implants have been reported to have no effect, to advance puberty, or to delay puberty in pineal-intact lambs raised outdoors.[255–257] The varied effect appears to be related to the age when chronic treatment began; delayed puberty was associated with early initiation of melatonin administration, and precocious puberty was associated with a later insertion of implants. Similar results have been obtained for the timing of puberty and age of exposure to short days.[237] A great deal remains to be learned from such studies that attempt to use principles about photoperiod to time onset of reproductive cycles through practical approaches that do not require circadian delivery of melatonin (see Ref. 233 for discussion).

ONTOGENY OF PHOTOPERIODIC RESPONSES

It is clear that the young lamb can receive photoperiod information even before birth via the maternal melatonin rhythm. Can such information be used to influence the neuroendocrine control of hormone secretion? Thus far, studies have largely examined the regulation of prolactin in this context; even though this hormone has little to do with puberty in the sheep, prolactin is consistently increased by long days and decreased by short days in a steroid-independent manner. It is tempting to conclude that photoperiod can influence fetal neuroendocrine function from the observation that the level of fetal prolactin in late gestation differs according to time of year.[260] More direct evidence that photoperiod is the key seasonal factor regulating early prolactin secretion has been derived from a study using artificial photoperiod.[261] In that study, the results of which are shown in Figure 31.22, pregnant sheep were maintained in either short days (8L:16D) or long days (16L:8D) for the final third of gestation. Then, on the day of birth, all lambs and their mothers were transferred to an intermediate photoperiod (12L:12D), and prolactin was monitored daily. In lambs gestated in long days, circulating prolactin at birth was high, which most likely reflects a carryover of this pattern of secretion from before birth. By contrast, lambs gestated in short days had low concentrations of circulating prolactin at birth. During the neonatal period, the high levels of prolactin in long-day gestated lambs declined in the equatorial photoperiod, whereas in short-day gestated lambs, circulating prolactin increased in response to the 12L:12D photoperiod. It is noteworthy that there was no sex difference in patterns of circulating prolactin—a finding that is of general interest for the later discussion of differences in the timing of puberty in male and female lambs. The results of this study demonstrate two aspects of the fetal response to photoperiod cues received by the mother. First, photoperiod can modulate neuroendocrine functions before birth, thus accounting for the differential prolactin secretion at birth. Second, the lamb begins to construct a photoperiod history before birth, with which it can interpret photoperiod signals postnatally. Therefore, in the study illustrated, long-day gestated lambs respond to the 12L:12D photoperiod as a short day because it is a decrease relative to the photoperiodic signals received in utero; the short-day gestated lambs react as if this postnatal photoperiod were a long day.

GROWTH DURING DIFFERENT SEASONS AND TIMING OF PUBERTY

The photoneuroendocrine system of the developing female sheep transmits the main seasonal cue used to time the decrease in sensitivity to steroid feedback and permits the expression of the high-frequency GnRH pulses driving the pubertal follicular phase. However, this can only occur if growth cues related to energy metabolism indicate that physiologic size is appropriate to support the consequences of pregnancy and lactation.

This interaction between growth (and by inference, nutrition or energetic state) and environment is illustrated in Figure 31.23, which presents the time of initiation of reproductive cycles in groups of lambs that are born at the same time of year (spring), but for which the growth rates differ. The study[231] was conducted in natural photoperiod, with the rate of growth altered by changing the availability of food. Some females, well fed from birth, grew rapidly and puberty occurred at the usual age (Group A, ~30 weeks). Other lambs (Groups B, C, and D) were placed on a restricted diet for varying periods after weaning and before they were fed ad libitum. The onset of reproductive cycles was delayed by various amounts in such females. Despite their having experienced an appropriate photoperiod for initiation of ovulations, puberty did not occur when they were growth retarded, presumably because sufficient energy was not available to support the consequences of activation of the reproductive system. This underscores the importance of reaching a metabolic balance where somatic growth is sufficient, but where energy is also available for other processes such as reproduction. Photoperiod time measurement is maintained in growth-retarded lambs[263]; when they were then induced to grow during the autumn and winter breeding season (Groups B and C), cycles began at a smaller size (i.e., 35 kg) than for controls (i.e., 45 kg). This raises the possibility that the normally growing females (Group A) had grown sufficiently to have the potential to attain puberty earlier in the year (August), but day lengths were too long at the younger age (i.e., 25 weeks) to reduce hypersensitivity to estradiol feedback inhibition. Later in the year (October), when day length became much shorter, sensitivity to estradiol negative feedback could be reduced to initiate reproductive cycles (i.e., 30 weeks of age). Finally, when the phase of rapid growth was induced during the anestrous season (Group D), the lambs grew well beyond the normal size required to initiate reproductive cycles, but they remained anovulatory. These females maintained hypersensitivity to estradiol negative feedback because of the long days of summer, and it was not until the decreasing day lengths of autumn that the cycles could begin. Thus, both season and size serve as determinants timing the initiation of reproductive cycles in the lamb through photoperiod and growth-related cues. This same conclusion was reached earlier when season of birth, rather than growth, was experimentally altered (Figure 31.16).

It is of interest that photoperiod itself can modify growth rate (see Ref. 264 for a review). In lambs, increasing daily exposure to light increases both food intake and efficiency of amount of feed consumed to amount of weight gained. The hormonal mechanisms for the photoperiod-induced increases in growth remain to be established. The anabolic effect of long days does not appear to be associated with alterations in growth hormone, insulin, or thyroxine because these hormones are unaffected by photoperiod. Although pinealectomy prevents photoperiod-induced changes in prolactin and photoperiod-induced increases in growth rate in sheep,[265] there is no definite proof that prolactin is the hormonal mediator of increased growth under long days.

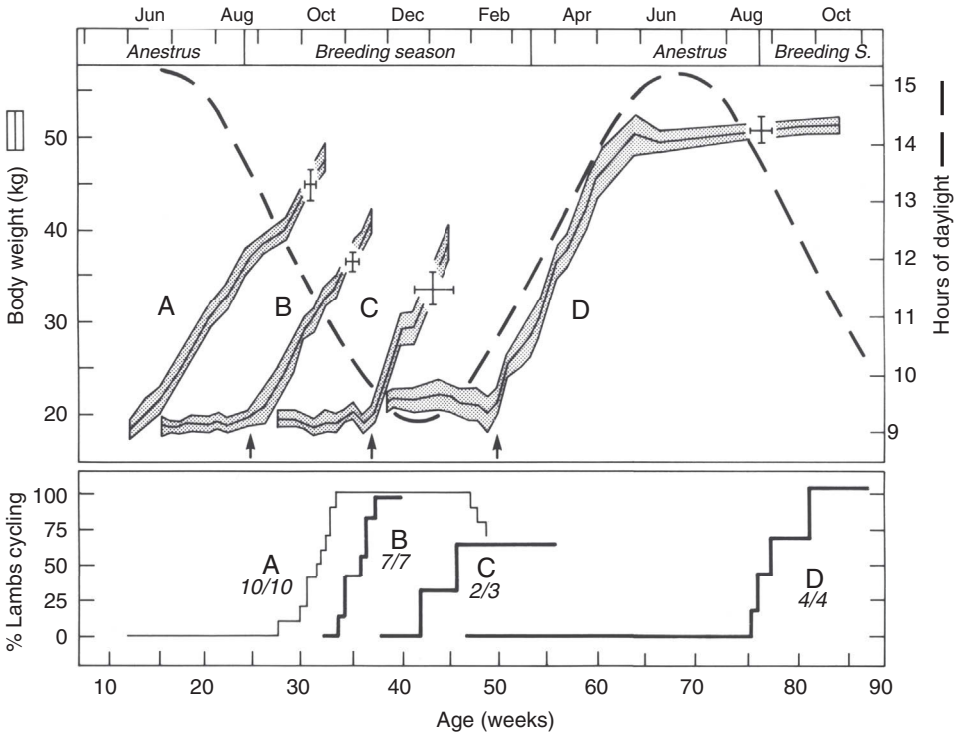

FIGURE 31.23 Season and growth influence timing of onset of reproductive cycles in female lambs (top, mean (±SEM) BW and age at first luteal phase; bottom, cumulative % ovulating for each group). Lambs were born in spring (March) and were raised outdoors (*broken line*, photoperiod). They were either fed ad libitum after weaning at 10 weeks of age (Group A), or were placed on a restricted diet of similar composition (Groups B, C, D); at various ages (*arrows*), feeding ad libitum was begun in food-restricted lambs. *From Ref. 231, with permission.*

Sexual Maturity vs Puberty vs Onset of Breeding Season

In a developing seasonal breeder, it is difficult to distinguish among the terms "sexual maturity," "puberty," and "onset of breeding season." Puberty in the young female and onset of breeding activity in the adult after seasonal anestrus are both transitions from anovulatory conditions to those of cyclic ovarian function. An increase in GnRH pulse frequency is considered to underlie each transition.[39,109] Because of this, the hypothalamus can be viewed as the ultimate common final pathway governing the two states of reproductive activity (see Refs 266 and 267 for reviews). The rhythm of the GnRH neurosecretory system is modified by estradiol such that during periods of high feedback sensitivity, its activity is slowed. The female lamb is born exquisitely sensitive to estradiol negative feedback. The reduction in sensitivity first occurs at puberty (Figure 31.6) and then occurs at each transition from the anestrous to the breeding season. Thus, the ability to alter feedback sensitivity, first used by the lamb as a mechanism to regulate the tempo of sexual maturation, is retained during adulthood to regulate seasonal reproduction.

Because the developing sheep uses environmental cues to time the first cycles (puberty) to the appropriate season for conception (breeding season), a key question becomes, "When does *sexual maturity* occur?" To provide an appropriate setting to begin to answer this question, it is instructive to return to the case of the autumn-born lamb and the timing of its first reproductive activity (Figure 31.16). Recall that such lambs remain anovulatory during the summer anestrous season despite having attained the appropriate age and size for initiation of reproductive activity. Then, several months later at the onset of the adult breeding season, they initiate ovulations without further growth. There are two conceptually different explanations to account for this delay in the autumn-born lamb: (1) development is retarded by inhibitory photoperiod (long days), and the delayed onset of cyclicity reflects delayed sexual maturity; (2) development is not retarded but long-day photoperiod induces seasonal anestrus at sexual maturity, and in this case, the onset of cyclicity simply reflects the onset of a breeding season when day length decreases sufficiently. According to the latter explanation, the transition to adulthood is "masked." If this argument were valid, then even in the normal spring-born lamb sexual maturity is masked. Interestingly, puberty in spring-born lambs occurs at a later time than onset of the breeding season in adults.[41,106] Although the underlying reason for this is unclear, it may involve a differing requirement in the shortness of days to induce the change in estradiol negative feedback in adult females versus lambs. Such an argument for masking by photoperiod has been inferred from the results found in Figure 31.23 where rapidly growing lambs (Group A) initiated reproductive cycles at a size (~45 kg) much larger than that required for this phenomenon (~30–35 kg). According to this explanation, they continued to grow and remained anovulatory until day length became shorter. Support

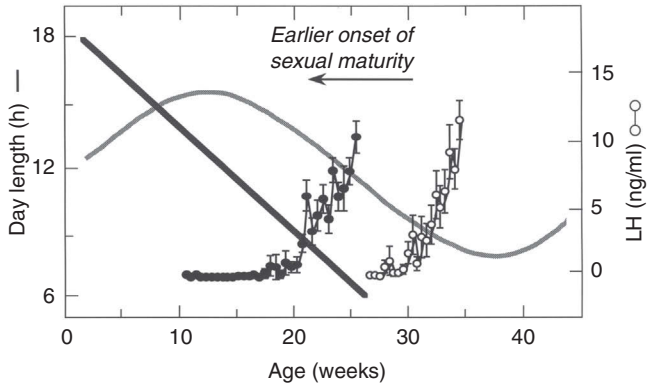

FIGURE 31.24 Increase in mean (± SEM) circulating LH in rapidly-growing estradiol-treated, ovariectomized lambs exposed to either natural photoperiod (*open circles*, $n=7$) or to decreasing artificial photoperiod (*solid circles*, $n=8$) from birth. *Artificial photoperiod data from Ref. 268.*

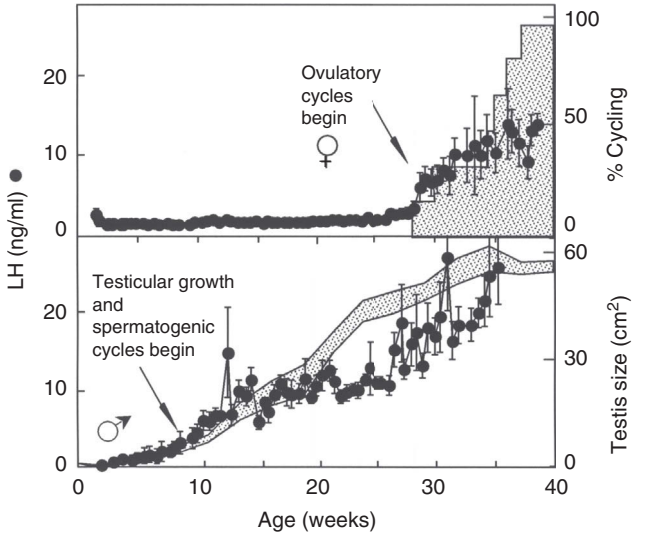

FIGURE 31.25 Sex differences in the timing of the pubertal increase in GnRH secretion and gonadal activation. Mean (± SEM) LH concentrations (*solid circles*) in gonadectomized female (*top*) and male (*bottom*) sheep treated chronically with a constant level of estradiol by subcutaneous Silastic implant. The time of the increase in LH secretion is associated with the onset of ovulatory cycles (shaded histogram) in intact females, and testicular growth and spermatogenesis (shaded line) in intact males. *Redrawn from Ref. 270.*

for this has been obtained by simply exposing lambs earlier in life to a permissive (stimulatory) photoperiod that markedly advances initiation of reproductive activity to a younger age and smaller size[268] (Figure 31.24). In the example shown, exposure of females to a gradually decreasing artificial day length beginning at birth allowed reproductive activity to be initiated at 20 weeks of age. Typically, puberty occurs at 30 weeks of age outdoors when day length begins to decrease at approximately 15 weeks of age. Thus, advancing the decrease in day length by 15 weeks, advanced puberty by 10 weeks. By using such approaches, the minimal age for the onset of reproductive activity as timed by growth cues should eventually be revealed. This knowledge is essential to establish when growth cues serve as important internal determinants of somatic size timing onset of reproductive activity and when photoperiod cues serve as an important external determinant synchronizing the expression of sexual maturity with the appropriate season. Only then will we be able to rid ourselves of the confusing terminologies presently used and be able to explain how reproductive activity is timed in more conceptual terms. Until then, it would appear that "sexual maturity" of the female (potential to ovulate) is attained well before "puberty" (onset of ovulations).

SEX DIFFERENCES IN TIMING THE TRANSITION INTO ADULTHOOD

There is a profound sex difference in the timing of puberty in many species. In the sheep, spring-born male lambs begin reproductive development at about 10 weeks of age in midsummer, as evidenced by the onset of spermatogenesis,[56,269] whereas females remain prepubertal until 25–35 weeks in the autumn when they first ovulate (Figure 31.25). This strategy maximizes the reproductive opportunity for each sex. It is reasonable that the young male initiates the pubertal process earlier. A longer time is required for spermatogenesis (5–10 weeks) than for the development of an early antral follicle to the preovulatory stage (few days). More importantly, the prolonged exposure to progressively increasing levels of testosterone is necessary to continue to program and reinforce behaviors necessary for competition with older males and mating with females. Such a reproductive strategy would be particularly relevant in species where the initial matings and conception occur in the first autumn after birth. By contrast, very fast maturing, short-lived species (i.e., rodents) that first mate within weeks after birth in spring and summer may not be expected to exhibit such pronounced differences in the age at puberty. Similarly, in long-lived species that mature over an extended time (years), early puberty in the male would have no obvious advantage. In fact, males of higher primate species, such as the rhesus monkey and the human being, mature at an even slower rate than females.

Sex Differences in the Pubertal Increase in GnRH Pulse Frequency

Studies of the underlying cause of the sex difference in initiation of puberty face the obvious problem of how to compare reproductive development between the two sexes. In most species, the outward signs of puberty in males and females are different and are therefore difficult to equate. These physical and behavioral changes

during puberty are produced by sex steroid hormones, but differences in quality, quantity, and pattern of steroids arise from differences in the production of the male and female gametes (continuous liberation of spermatozoa vs the cyclic release of ova). Common to both sexes, however, is the antecedent rise in LH (GnRH) secretion during puberty when the sensitivity to gonadal steroid feedback inhibition decreases. This phenomenon has been demonstrated in both sexes (Figure 31.25). Therefore, studies on sexual differentiation of the timing of puberty have used the pubertal increase in LH (GnRH) secretion as an index of "neuroendocrine sexual maturity" because it allows comparison of sex differences in the development of control systems within the brain unencumbered by differences in the gonad (ovary vs testis). In this "neuroendocrine" model (neonatally gonadectomized lamb replaced with a constant feedback of exogenous steroids), the pubertal increase in LH is robust in both sexes. It positively correlates with indices of sexual maturation (initiation of testicular maturation and ovarian cycles) in gonad-intact males and females. The sustained increase in LH secretion beginning shortly after birth in the male indicates that a decrease in sensitivity to steroid inhibitory feedback occurs much earlier than it does in the female. The model uses estradiol as the steroid inhibitory feedback hormone in both females (to replace estradiol secreted by the ovary) and males (to replace estradiol produced by aromatization of testosterone in the brain).[271–273] Although testosterone is the major sex steroid produced by the testes, previous work showed that puberty-related changes in LH secretion in intact male lambs could be equally recapitulated in castrated male lambs implanted with either testosterone or estradiol,[271] suggesting that, similar to females, estradiol may be the major inhibitor of GnRH/LH release in prepubertal males. Nonetheless, a role for the actions of testosterone per se or its metabolite, dihydrotestosterone, cannot be ruled out and has not been examined to date in prepubertal male sheep. In yearling male sheep, blockade of 5α-reductase, the enzyme that synthesizes dihydrotestosterone from testosterone, increased pulsatile LH secretion in testosterone-treated castrates,[274] suggesting that dihydrotestosterone may mediate, at least in part, inhibition of GnRH release by testosterone in young adult males.

Programming of Sex Differences in the Timing of the Pubertal GnRH Rise by Prenatal Steroids

The pubertal increase in LH secretion in the male is programmed before birth through the organizing action of testicular steroids on the brain mechanisms controlling sensitivity to the feedback action of estrogen. This inference was made because prenatal exposure of the female fetus to exogenous testosterone advances the age when high-frequency LH pulses are expressed (neuroendocrine sexual maturity) using the neuroendocrine model (estradiol implant, no ovaries). In the study illustrated in Figure 31.26(A)–(C) using the neuroendocrine model, testosterone was administered to pregnant sheep and as expected, this treatment masculinized the external genitalia of female lambs.[56] Importantly, the pubertal increase in circulating LH in these developing females occurred at the same time as that in males which was several months earlier than normal females. In this study, more frequent measurements provide evidence that this precocious increase in LH is due to an increase in LH pulse frequency, not amplitude. Reduced sensitivity to estradiol negative feedback before onset of puberty was confirmed in a later study.[275] The *time of testosterone exposure* during development is important, with the critical period in early pregnancy. Exposure of the unborn female between Days 30 and 90 of gestation (~150 days term) produces the profound advance in the timing of the pubertal GnRH rise, whereas the same treatment from Days 89–135 of pregnancy is without effect (data not shown, see Ref. 56). The *duration of*

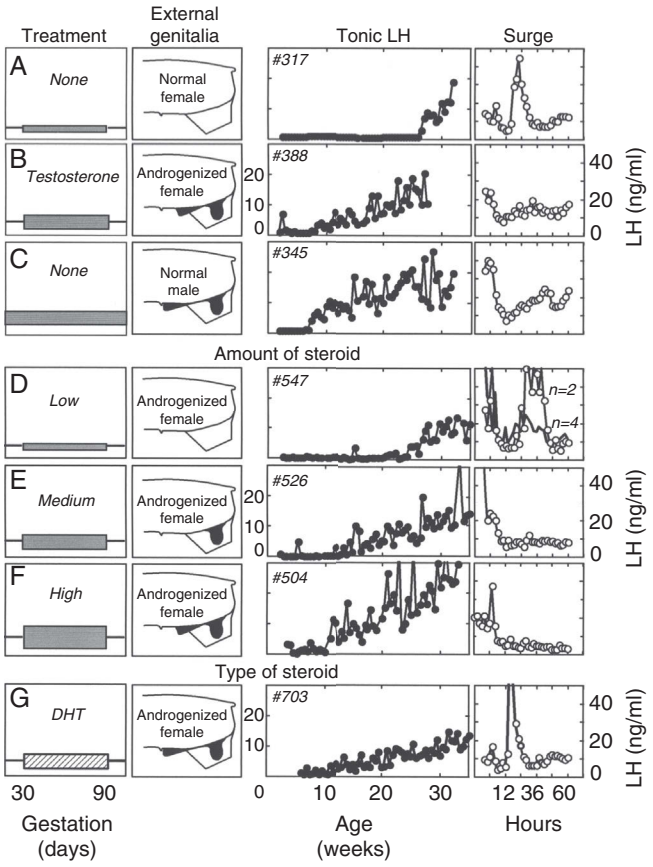

FIGURE 31.26 Prenatal exposure to testosterone (*panels a-f*) or DHT (*panel g*) and its effect on external genitalia (*left*), the developmental pattern of tonic LH secretion (*middle*), and the LH surge (*right*). The lambs were gonadectomized within 3 weeks after birth and implanted with a Silastic capsule containing estradiol. *Redrawn from Ref. 270.*

testosterone exposure is important. Treatments for a short duration (e.g., Days 30–60 or Days 60–90) are effective, but the timing of the pubertal LH rise is less advanced (data not shown, see Refs 276 and 277). The *amount of testosterone exposure* is important as determined in a dose–response study (Figure 31.26(D)–(F)).[278] The patterns of LH secretion were related to the amount of testosterone experienced as assessed by the external genitalia. Those treatments producing the greatest external masculinization also produced the earliest decreases in response to steroid feedback and, hence, the earliest increase in LH secretion. The *type of steroid* is important. Because testosterone can be converted to a more potent androgen or an estrogen by the brain, the type of steroid action could not be determined in studies in which testosterone alone was administered. Administration of dihydrotestosterone, the androgenic metabolite that cannot be converted to an estrogen, also advanced the time of the pubertal rise in LH (Figure 31.26(G)) suggesting that androgenic action is involved in this programming.[279] Although this pure androgen produced similar results as testosterone, they were not identical, leaving some possibility for a role of estrogens in organizing the timing of the pubertal increase in GnRH secretion.

Masculinization of the timing of puberty most likely occurs in the neural control of GnRH secretion because the effect of prenatal androgens was to increase the frequency, rather than the amplitude of LH pulses. Androgen effects on pituitary function are less likely as the pituitary response to GnRH challenge is neither affected by androgenization nor is it sexually differentiated in the sheep.[280,281] However, Robinson et al.[282] recently reported that prenatal androgenization with testosterone increased pituitary weights in both male and female offspring by 40%. This effect was not seen in lambs treated in utero with dihydrotestosterone, suggesting that the effect was due to aromatization of testosterone to estrogen. In addition, testosterone decreased the amount of colocalization observed for LHβ and ERα, perhaps indicative of a decreased ability to respond to estradiol-negative feedback that may explain, in part, the hypersecretion of LH observed in this animal model.

Programming of Sex Differences in Other GnRH Controls by Prenatal Steroids

Besides organizing the timing of the pubertal increase in GnRH secretion by modifying the sensitivity to estradiol negative feedback, prenatal steroids also program brain sex differences in the function of other steroid feedback controls. This would be expected because neuroendocrine mechanisms timing the discontinuous liberation of ova are more complex than those for the continuous production of spermatozoa. Such differences in regulation are manifest during puberty when gametes are first produced and liberated. Indeed, in the sheep the neuroendocrine regulation of ovulatory cycles requires four well-known steroid feedback mechanisms to control GnRH secretion. Two feedbacks regulate the surge mode of GnRH secretion—the stimulatory feedback action of estrogens to induce a GnRH surge and the ability of progesterone to block this stimulatory feedback action; two feedbacks control the pulsatile mode—the inhibitory feedback of estrogens and the inhibitory feedback of progesterone. In the male, three of these mechanisms are not necessary; for central regulation of the control of spermatogenesis, only the simple, estrogen negative feedback system is required. To explain how these differences arise, one must consider whether the female sheep adds the extra feedback control systems or the male sheep removes them. The latter is the most salient explanation. According to this hypothesis, multiple feedbacks are inherent in both genetic sexes, and they require no further developmental input for normal function during adulthood. However, if the ovine fetus is male, the three irrelevant steroid feedback controls of GnRH secretion are either abolished or become functionally inoperative through programmed reductions in sensitivity. This central programming in the ovine male occurs through exposure of the developing brain to his own testicular steroids that act as androgens and estrogens to organize the brain during a critical period of development. In the sheep, neuroendocrine programming begins before birth and continues well into postnatal life. Evidence for this scheme is accumulating as shown by exposure of developing lambs to combinations of exogenous testosterone and estradiol (Refs 283 and 284; for reviews, see Refs 285–288).

GnRH Surge System

The GnRH surge system is not functional in the male. Prenatal treatment with testosterone perturbs the ability to respond to the stimulatory feedback action of estrogen in young adults (high doses abolish the response; low doses prolong the latent period). Whether the failure of the LH surge to occur in the normal male or in females prenatally treated with testosterone is due to deficits in GnRH release has been tested. GnRH was measured in the pituitary portal system during standardized estradiol treatment that induces preovulatory surges of the neurohormone in normal females.[289] A prolonged discharge of GnRH was not detected in individuals prenatally exposed to endogenous or exogenous testosterone, indicating that indeed the early programming of the GnRH surge mechanism is at the level of the brain. Whereas exposure to high doses of testosterone abolishes the surge mechanism (Figure 31.26(E) and (F), right), low doses do not (Figure 31.26(D), right).[278] In low-dose females, the surge system is retained during adulthood, but the latent period from the administration

of estradiol to the LH surge is prolonged. There may also be some effect of breed as ovary-intact Suffolk sheep treated from days 30–90 twice weekly before birth with either 200 mg[290] or 100 mg[291] testosterone propionate displayed delayed surges that were reduced in amplitude, but ovary-intact Polled Dorset sheep similarly treated prenatally with testosterone propionate[292] exhibited a total absence of LH surges in response to estradiol. Prenatal administration of dihydrotestosterone—the potent, nonaromatizable androgen—has no effect on the GnRH surge system (Figure 31.26(G), right)[279] suggesting that the programming of the GnRH surge mechanism is due to the estrogenic action of testosterone. This is of interest because prenatal treatment of the female with dihydrotestosterone reduces the sensitivity to the negative feedback action of estrogen early in life and results in a precocious pubertal rise in LH secretion (Figure 31.26(G)). The androgenic action of testosterone on timing the pubertal increase in GnRH has been further confirmed by blocking the androgen receptor with the antagonist flutamide.[293] Thus, the tonic and surge modes of GnRH secretion may be organized by the two different metabolites of testosterone. Perhaps prenatal androgens organize the level of sensitivity to the inhibitory feedback action of steroids and the timing of the pubertal GnRH rise, whereas prenatal estrogens organize the mechanisms involved with the stimulatory feedback action of estrogen and production of the GnRH surge.

Progesterone Feedback Systems

Two progesterone feedback controls of GnRH exist in the female sheep. One regulates the surge mode of secretion as, during the ovulatory cycle, progesterone can block the stimulatory feedback action of estrogen to prevent the GnRH surge. Whether this regulatory system is sexually differentiated is not known because the blocking actions of progesterone cannot be examined in males or females in which the surge system has been masculinized (i.e., by exogenous testosterone or estrogen). An androgenic action might masculinize this action of progesterone, but this possibility has not been tested; if this occurred, it would suggest that the sexual differentiation of GnRH feedback controls is more complex than presently envisaged. The second feedback action of progesterone is clearly sexually differentiated, namely the inhibition of tonic GnRH secretion to prevent high-frequency GnRH secretion from occurring during the luteal phase. In females treated with testosterone before birth, LH pulse frequency is greater than in normal females even though circulating progesterone concentrations are similar.[291] This was predictable because when this inhibitory feedback action of progesterone was tested earlier in both sexes in the absence of endogenous gonadal steroids, the male sheep was much less responsive than the female; prenatal treatment of females with testosterone reduced the response.[294,295] Cheng et al.[296] reported that prenatal treatment of sheep with testosterone reduced the number of dynorphin-immunopositive cells in the arcuate nucleus while having no significant effect on the number of kisspeptin-positive cells. As dynorphin in this area has been implicated to mediate progesterone feedback inhibition[85–87] and kisspeptin stimulates GnRH/LH release, perhaps prenatal exposure to testosterone programs a change in the balance between stimulatory and inhibitory input to reduce the postnatal response to progesterone feedback inhibition of GnRH secretion.

It will be of interest to understand how independent the mechanisms responsible for development of the tonic mode of GnRH secretion are from the surge mode. In addition to differences in the type of steroid involved in each, there may also be differences in critical periods. As originally conceived from studies of the differentiation of the surge mode, the "critical period for sexual differentiation" denotes the broad period of sensitivity to organization by gonadal steroids (see Ref. 297 for a review). An emerging concept is that the "critical period" is not one single entity. So far in the sheep, discrete critical periods for the control of anatomy, behavior, and neuroendocrine function have already been noted.[298–300] There is additional evidence that postnatal exposure to estradiol may be important for complete defeminization (or masculinization) of the surge mechanism. Ovary-intact lambs treated prenatally with testosterone did not exhibit LH surges in response to estrogen.[284] However, lambs in that study that were treated prenatally with testosterone, but ovariectomized soon after birth, did exhibit LH surges, albeit they were longer in duration and appeared to be of a decreased magnitude. Thus, each sexually dimorphic trait may have unique requirements for its sexual expression regarding the duration or type (androgen vs estrogen) of steroid exposure. We already have evidence to support this possibility based on the different organizational actions of androgens and estrogens on the feedback mechanisms controlling the tonic and surge modes of GnRH secretion.

Endocrine Disruptors: A Case for Fetal Origin of Reproductive Dysfunctions

Given the sensitivity of the reproductive axis to both the organizational and activational effects of steroids, it is not surprising that the effects of endocrine disrupting compounds on reproduction has been the focus of much research in recent years. Data examining the effects of such compounds on reproduction in ruminants are limited largely to examining the effects of bisphenol A and octylphenol (both estrogenic in nature), polychlorinated biphenyls (PCBs; estrogenic, androgenic, antiestrogenic and antiandrogenic activities), and methoxychlor (estrogenic, androgenic, and antiandrogenic activities)

(for a review, see Ref. 301). The Environmental Protection Agency has identified hundreds of compounds that are exogenous in nature, but which can have significant effects on the structure or function of the endocrine system. Such compounds can be found in manufactured consumer goods, but also exist as plant-derived materials, such as the phytoestrogens. Many of these chemicals can bind to steroid receptors. The sheer number of compounds and a potential for their effects to be compound-specific and dependent upon factors such as dose, time of exposure, route of exposure, and differing periods of sensitivity during development have made their study difficult. Further, studies addressing the influence of endocrine disrupting chemicals usually involve acute exposure to relatively high doses, whereas exposure under normal circumstances usually involves chronic exposure to low doses or exposure to low doses of several chemicals at one time which may be synergistic or additive. Nonetheless, data is developing in ruminants to suggest that endocrine disrupting compounds could significantly affect reproduction at all levels of the hypothalamic-pituitary-gonadal axis.[302] Administration of bisphenol A from day 30 to day 90 of gestation in sheep increased LH secretion during the first postnatal month of life and decreased the amplitude of the postpubertal LH surge[303] while treatment with methoxychlor for the same period did not influence LH but delayed the LH surge. A subsequent study by this group examined both stimulatory and inhibitory actions of exogenous steroids and concluded that the defects seen in the earlier work was due to ovarian deficits as estradiol stimulatory feedback and inhibitory feedback by either progesterone or estradiol appeared normal.[304] A study by Evans et al.[305] reported that bisphenol A administration for 5 weeks beginning at 4 weeks of age in female lambs reduced the increase in LH pulse frequency normally seen in response to ovariectomy. In goats, administration of valproate, an antiepileptic drug thought to have effects both centrally on LH secretion and on gonadal conversion of testosterone to estrogen, from two to 10 months of age reduced LH secretion,[306] as did administration of PCB153, but not PB126, during gestation.[307,308]

Only a very limited number of studies have examined the timing of puberty in ruminants following exposure to endocrine disrupting chemicals. Puberty onset was accelerated in female lambs exposed to octylphenol from day 70 of gestation to weaning, day 70 of gestation to birth, or from birth to weaning.[309] Interestingly, administration of octylphenol after weaning did not appear to influence LH secretion,[305] raising the possibility that windows of sensitivity to this disruptor exist. Savabieasfahanbi et al.[303] reported that puberty was unaffected by bisphenol A or methoxychlor administration during gestation, even though both influenced amplitude or timing of the LH surge and bisphenol A caused an early cessation of the breeding season. In goats, puberty onset was delayed following exposure of females to valproate from 2 months to 10 months of age,[306] and in both male[307] and female[308] goats following PCB153 exposure. The delay in puberty observed in male goats was associated with increased DNA damage in sperm.

The mechanisms whereby puberty may be affected by endocrine disruption are unclear, but may involve alterations in hypothalamic neuropeptide expression. Bellingham and coworkers[310] reported that maternal exposure to sewage sludge, a not totally characterized mixture of many anthropogenic endocrine disrupting compounds, decreased *KISS1* mRNA expression in 110 day old fetal hypothalamic tissue. A subsequent study by this same group using a similar approach reported a reduction in GnRH mRNA, GnRH receptor mRNA, and galanin receptor mRNA expression in fetal hypothalami.[311] The study by Bellingham et al.[310] also observed a decrease in kisspeptin, LH-β subunit, and estrogen receptor-α protein expression (as measured by immunocytochemistry) in fetal pituitary tissue, suggesting that the effects of sewage sludge may not just be localized to the brain. Thus, exposure in utero to either naturally occurring or man-made compounds that mimic endogenous endocrine activity have the distinct potential to influence subsequent reproductive events in both males and females.

Sex Differences in Response to Internal and External Factors Timing Puberty

Two major physiologic determinants timing the pubertal LH (GnRH) rise in the female sheep are growth and photoperiod. The response to one or both of these must be sexually differentiated because male lambs attain puberty at a smaller body size and under longer photoperiods (spring/summer) compared to female lambs (autumn). Moreover, the prenatally androgenized female lamb also exhibits puberty at a smaller size and longer day length. As indicated in the next two sections, the current evidence implicates a sexual differentiation of the photoperiod response mechanism, rather than those systems responding to growth-related cues. This leads to the hypothesis that testosterone emanating from the fetal testes acts within the brain during the critical period of development before birth to alter the reproductive response to photoperiod history.

Sex Differences in Response to Photoperiod

As discussed earlier, in the female sheep the initiation of reproductive cycles is not normally timed by growth cues, but instead, reproductive maturation is expressed in response to photoperiod cues. Much less is known about the role of photoperiod and maturation in the

male. Studies conducted in several breeds (Ile de France, Merino-Border Leicester, Suffolk) lead to the conclusion that the developing male sheep may be relatively insensitive to photoperiod.[256,312,313] This is illustrated by raising males and females in an artificial photoperiod simulating that which occurs naturally after birth in the spring (Figure 31.27, top) or in an artificially reversed photoperiod simulating birth in the autumn (Figure 31.27, bottom).[314,315] As expected in the natural simulate photoperiod, the pubertal LH rise in females began between the usual ages of 25 and 30 weeks, but in the reversed photoperiod, this was delayed beyond the end of the study. In males, the pubertal LH rise began at the same time in either photoperiod. In androgenized females, prenatal exposure to testosterone not only prevented the delay in the pubertal LH rise that occurred in the female in an inappropriate photoperiod, but advanced it to a much earlier age, one similar to that of the male. In the context of the hypothesis for sexual differentiation of the timing of puberty by photoperiod, these findings indicate that the default mechanism is to delay expression of sexual maturation during increasing or long photoperiods of spring and summer. Without prenatal programming by testosterone, as in the case of the normally developing female, breeding in these seasons will delay the initiation of pregnancy until the decreasing day lengths of autumn. As noted earlier, this strategy results in spring-born young. However, as in the normal male, exposure to fetal testosterone during a critical period of sexual differentiation alters the photoperiodic timing mechanism such that reproductive activity will begin regardless of day length when growth cues are appropriate. Interestingly, the male does not remain unresponsive to photoperiod. By the second year or earlier, the control of GnRH begins to respond to this seasonal cue as an adult, and reproductive activity waxes and wanes becoming locked into seasons of increasing and decreasing fertility. Although fertility is reduced but not lost in males during the nonbreeding season in most breeds, in some primitive breeds, such as the Soay sheep, the testes regress markedly during the non-breeding season and become aspermic. Thus, the male is programmed for a temporary hiatus in photoperiod control of its reproductive system during its formative stages in the transition into adulthood.

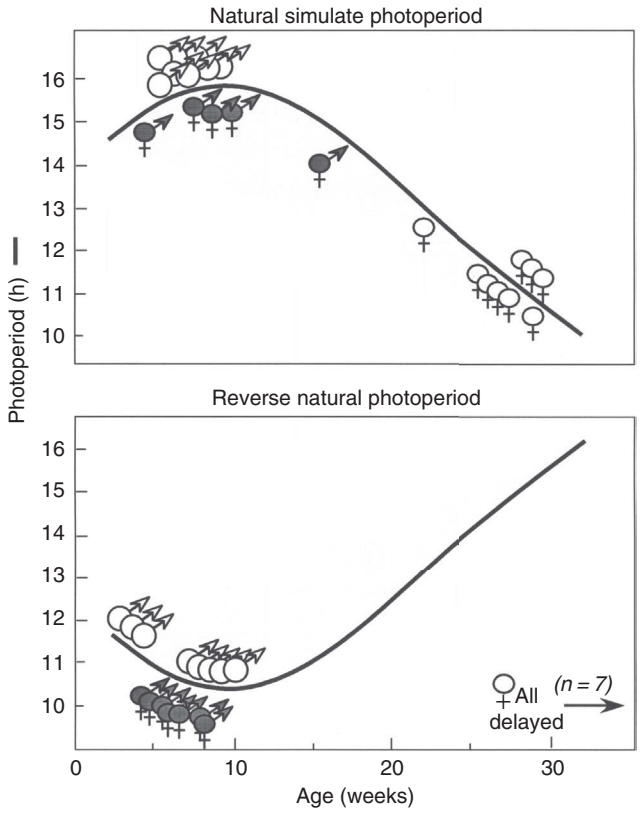

FIGURE 31.27 Photoperiodic regulation of the timing of puberty in male, female, and prenatally testosterone-treated female (shaded symbols) sheep. Symbols indicate timing of pubertal LH rise. *Top*: Animals raised indoors in a simulated natural photoperiod. *Bottom*: Animals raised indoors in a reverse natural photoperiod. Puberty was delayed in females in the reverse natural photoperiod beyond the end of the study. *Redrawn from Ref. 270.*

The sex difference in response to photoperiod is not due to a difference in the pattern of melatonin secretion. The pattern of melatonin is similar among males and females during development[251] indicating that the marked difference in timing of puberty in males and females does not originate from the pineal gland. Rather, it arises from a post-pineal difference in the mechanism by which the melatonin signal is subsequently used to govern the expression of sexual maturation. This type of reproductive development where the timing of puberty in the male is not influenced by photoperiod differs from the general developmental strategy for long-day breeding species. For example, in the short-lived grasshopper mouse[316] and field vole,[317] both sexes are responsive to photoperiod before puberty such that reproductive development is advanced by long days and retarded by short days.

Sex Differences in Response to Growth Cues

Bronson[318] has proposed that the growth requirements for activation of the reproductive neuroendocrine axis of the female should be more critical than those for the male because of her greater metabolic demands for reproduction (i.e., pregnancy and lactation). In view of this hypothesis, one could argue that the developing female would be more sensitive than the male to perturbations in metabolic signals and that such a difference might be revealed during growth restriction. A study comparing male and female developing sheep has determined if LH(GnRH) secretion is altered differentially by chronic growth retardation and acute increases and decreases in nutrition.[319] The gonads were removed to avoid the

confounding influence of gonadal steroids in developing males and females. No sex difference in gonadotropin secretion under chronic growth restriction was apparent, and LH pulse frequency became depressed equally in males and females during long-term malnutrition. For the acute responses, a small sex difference occurred—one in which males were somewhat more responsive than females to increases and decreases in level of nutrition on gonadotropin secretion. The results of these studies modulating energy intake indicate that the reproductive neuroendocrine system in the developing male is at least as sensitive, and perhaps even more so, than that of the female to changes in level of nutrition. Such findings do not support the notion that the growth requirements for the neuroendocrine control of puberty are markedly sexually differentiated.

CONCLUSION

Figure 31.28 summarizes and synthesizes an integrated model for puberty in the sheep by focusing on the GnRH neurosecretory system and the type of information that is integrated to increase the frequency of GnRH pulses. This model, although far from complete, accounts for both the sex difference in when this transition occurs and the different signals that time it in males and females. The core pattern of GnRH secretion in the developing sheep, like other long-lived species, is an increase in activity, and then a decline of varying durations followed by the pubertal rise. The response to the early increase in GnRH secretion that occurs before birth in the sheep, a precocial species, programs the type of information that is used to produce the sex-specific pattern of GnRH secretion after birth. If no testes are present in utero, multiple reproductive neuroendocrine feedback controls remain operative, and the (female) lamb becomes photoperiodic with respect to the timing of puberty using heightened sensitivity to steroid negative feedback. Although metabolic cues provide information that sufficient growth has occurred to begin reproduction, the young female cannot express her sexual maturity because the photoperiod is not appropriate. Sexual maturity is masked, the ovary remains quiescent, and she immediately enters seasonal anestrus. Once she has experienced the requisite photoperiod sequence, the long days of summer followed by the short days of autumn, the neuroendocrine sensitivity to steroid negative feedback decreases, and high-frequency GnRH pulses are expressed. The other feedback controls remain operative, and repeated ovulatory cycles are initiated to begin the breeding season. This strategy allows young females to synchronize the beginning of reproductive activity with those of mature, seasonally breeding females.

By contrast, the male lamb tracks photoperiod in utero much like the female lamb, but he does not use photoperiod to time the expression of high-frequency GnRH pulses. In response to the first increases in GnRH

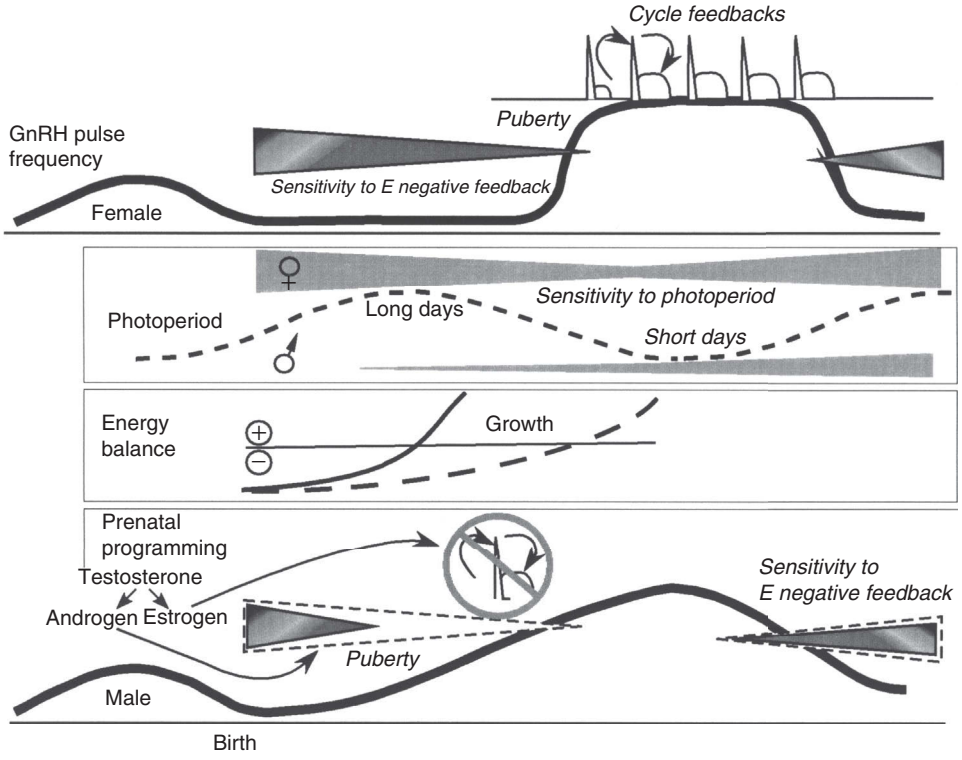

FIGURE 31.28 Integrated model for internal and external determinants timing the onset of puberty in the sheep.

secretion and the resultant gonadotropin drive to the testes before birth, testosterone is secreted to masculinize the photoneuroendocrine system; this effectively reduces the reproductive response to day length. Rather than considered to be masculinization, this programming could be thought of as defeminization because the testicular steroid action modifies an innate function. This is much like the defeminization of the unnecessary feedback controls in the male that underlie ovulatory cycles. By removing the photoperiod requirement for the expression of high-frequency GnRH pulses, puberty in the male begins once metabolic signals provide information that positive energy balance is sufficient for reproductive activity. Most interestingly, after further maturation, in the second year the reproductive neuroendocrine system of the young male does become regulated by photoperiodic cues, much like that of the female, to result in seasonal changes in sensitivity to negative feedback regulation of GnRH secretion. Thus, while metabolic cues time hypothalamic sexual maturity in both sexes, the presence or absence of prenatal programming by testosterone and its metabolites determines whether photoperiod serves as a permissive cue to begin reproductive activity. Viewed in a broad sense, different signals time "puberty" in the two sexes. Metabolic signals time puberty in the male, but photoperiod cues time puberty in the female. Perhaps the hiatus in photoperiodic control in the male during the first year is necessary to increase the GnRH/LH drive to the testes early to develop the behavior necessary to begin competition with older males for females. This strategy for sex differences in timing of puberty is a prime example of how fundamental mechanisms have been conserved while speciation has led to adaptive modification of the control of these mechanisms to allow for optimal timing of the onset of fertility.

The model described is far from complete. The terms puberty, sexual maturity, and initiation of reproductive activity are imprecise; fundamental questions remain to be asked and answered. So far we have focused on the simpler ones. This leads to consideration of ultimate and proximate signals, sensors, and pathways. There is little argument that an increase in GnRH secretion is the ultimate neuroendocrine signal that initiates puberty. This is not a unique signal, however, because such an increase also occurs at other transitions from infertility to fertility later in life. Similarly, understanding details of the *proximal* regulators (neurotransmitters) of GnRH is important, but it will not contribute to our knowledge of how puberty is timed. In addition, a deeper understanding of other proximal signals that are permissive such as photoperiod, social cues, and energy balance will also not help our understanding of what and where is the deep, unique proximal signal(s) that starts the cascade. The signaling mechanisms by which photoperiod influences puberty onset in females are now well understood, but their specific actions in the hypothalamus need to be identified. Our understanding of the metabolic signals that potentially provide information to the brain about energy availability is expanding. However, a number of questions remain unanswered about the signals, sensors, and pathways by which growth cues time puberty. For example, what specific aspect of metabolism or growth provides information to the brain that sufficient energy is available to begin reproductive activities that are induced by GnRH secretion? Is there one ultimate signal or is some combination of metabolic cues required? What specific brain regions/neural mechanisms are involved in transforming signals of energy availability to signals modulating GnRH secretion? Many of the potential candidate neurons express steroid receptors. Do growth-related signals about energy metabolism that regulate steroid-independent GnRH secretion also modulate sensitivity to steroid feedback inhibition of GnRH secretion? How are these internal cues integrated with external cues that provide information about the environment to the developing individual?

An important unanswered question that relates to the timing of puberty in sheep and other species is whether there exists a neural component that functions as a developmental clock (Figure 31.29)[320] i.e., is there a minimum age where puberty is genetically programmed to begin, which is then modified by internal and external cues? If so, is the innate developmental "clock" a single timer or a series of timers under species-specific genetic control, and what and where is the clock? Ojeda and his colleagues have considered how a hierarchy of gene networks might control puberty.[321] They propose a system of at least three layers of networked inputs, one tier of genes required for cell-to-cell communication, a second for genes that regulate the intercellular interactions and a third tier of higher echelon genes that transcriptionally regulate subordinate genes in the first two tiers. Further, the organization of such a hierarchy might involve the time-dependent expression of genes that would interact with pathways of extrinsic information to modify the activity of GnRH neurons to time puberty. Once these components are identified one could determine how and where this intrinsic clock-type information is integrated with extrinsic/permissive information about energy and physical environments. Does such a putative pubertal clock in sheep strike early in development, thereby signaling for reduced sensitivity to steroid feedback, only to await the integration of permissive extrinsic and intrinsic signals which allow for increased GnRH and LH secretion, or is timing of the pubertal clock altered in some way by extrinsic or intrinsic signals? If an integrator is involved, is it the same as that for the adult, which also uses information about

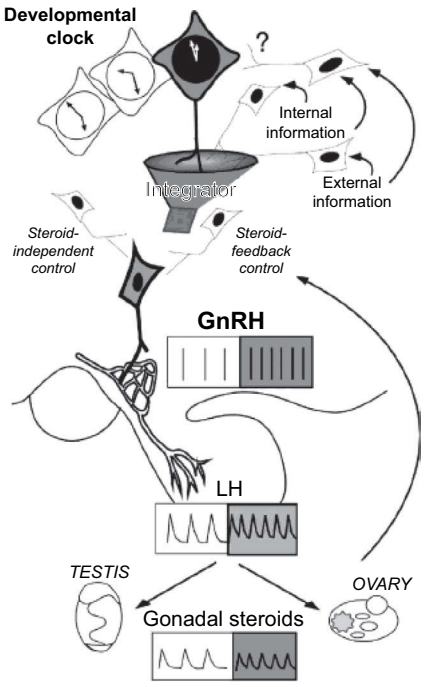

FIGURE 31.29 Model for integration of signals and control mechanisms timing puberty through the regulation of GnRH secretion. A genetically linked developmental clock is proposed to signal when it is first possible to produce the pubertal increase in GnRH secretion but the actual time when it occurs is fine-tuned by multiple permissive signals that provide information about internal and external environments. These signals regulate steroid-dependent and steroid-independent feedback control of GnRH pulse frequency. *From Ref. 287, with permission.*

energetic, social, geophysical, and other cues to time the periodic seasonal resumption of high level GnRH secretion? Armed with such concepts, and other models for a developmental clock, we can then focus on identification of its neuroanatomical location(s) and output pathways to the GnRH neural regulatory system. In going forth conceptually, the challenge will be to differentiate unique signals, sensors, and pathways from permissive ones, and from those that are used after puberty as well. Only then will we have a more complete neurobiological explanation of how reproductive activity begins for the first time.

Acknowledgments

The authors are grateful to the undergraduate and graduate students, postdoctoral fellows, and visiting scientists in our laboratories and to the numerous other investigators who have generated the data described in this chapter; to the technical staff for work in animal experimentation, especially Mr. Douglas D. Doop and Dr. Miro Valent; to the many colleagues of the Reproductive Sciences Program at the University of Michigan, especially Drs. Vasantha Padmanabhan and Fred J. Karsch and their laboratories, and to colleagues of the Reproductive Sciences Program at West Virginia University, especially Dr. Keith Inskeep and Dr Robert Goodman and members of their laboratories; to the National Institutes of Health, the National Science Foundation, and the United States Department of Agriculture for research support.

INTRODUCTION

Puberty as defined by Webster "the period of becoming first capable of reproducing sexually, marked by maturation of the genital organs, development of secondary sex characteristics, and, in the human and in higher primates, by the first occurrence of menstruation in the female",[1] requires little clarification. Of keynote importance in Webster's definition is the phrase "the period of becoming", since it correctly implies that puberty is a temporal process involving transition and development. Development may be viewed as the summation of differentiation and growth, and in highly evolved primates (Old World monkeys, apes, and humans),[a] normal puberty is observed during the terminal phase of growth. The transition into primate puberty is driven to a variable, species-dependent extent by two physiologic processes: gonadarche and adrenarche.[3] Gonadarche comprises growth and maturation of the gonads, and is associated with increased secretion of sex steroids and with the initiation of folliculogenesis and ovulation in the female and spermatogenesis in the male. Adrenarche comprises maturation of the adrenal cortex and is associated with increased secretion of adrenal androgens. While gonadarche is obviously critical for puberty in all species, adrenarche late in prepubertal development appears to be peculiar to man and the great apes.[3–7] In man, the physical manifestations of adrenarche are known as pubarche, and include the appearance of pubic and axillary hair, acne, and adult apocrine odor. The absence of adrenarche in humans does not prevent fertility, nor does it dramatically influence the timing and tempo of gonadarche,[3,8,9] and thus from a biological perspective adrenarche can be viewed as a temporal corollary of the pubertal process rather than as an integral and fundamental component of this important developmental event.

[a] The order primates comprises five major groups; Lemuriforms (lemurs), Lorisoforms (lorises and bushbabies), Tarsiiformes (tarsiers), Platyrrhini (New World monkeys and marmosets), and Catarrhini (Old World monkeys, apes, and humans)[2]. The latter infraorder is divided into two super families: Cercopithecidae (Old World monkeys) and Hominoidea (apes and humans).

[b] The following trivial names have been employed: African green monkey, *Cercopithecus aethiops*; baboon, *Papio*; bonnet monkey, *Macaca radiata*; bonobo, *Pan paniscus*; capuchin monkey, *Cebus apelle*; chimpanzee, *Pan troglodytes*; common marmoset, *Callithrix jacchus*; cotton-top tamarin, *Sanguinous oedipus oedipus*; crab-eating or cynomolgus monkey, *Macaca fascicularis*; gorilla, *Gorilla*; hanuman langur, *Presbytis entellus*; mandrill, *Mandrillus sphinx*; owl monkey, *Aotus trivirgatus griseimembra*; pigtail monkey, *Macaca nemestrina*; rhesus monkey, *Macaca mulatta*; saddle-back tamarin, *Saquinus fuscicollis*; sooty mangabey, *Cercocebus atys*; squirrel monkey, *Saimiri sciureus*; and talapoin monkey, *Miopithecus talapoin*.

Knobil and Neill's Physiology of Reproduction, Fourth Edition

Perhaps the most striking feature of sexual development in primates is the pronounced interval that exists from birth until the initiation of the pubertal process. For example, although the sexually mature common marmoset[b] has a body weight similar to that of an adult rat (300 g), puberty in this small New World monkey is not observed until at least 6–12 months later than that in the laboratory rodent.[10] The delay in the onset of puberty is most conspicuous in our own species, where initiation of spermatogenesis and ovarian cyclicity does not normally occur until the second decade of life. Thus, puberty in primates is separated in a most definite fashion from perinatal development. In these species, therefore, identification of the initiation of the pubertal process and its physiological and behavioral concomitants is a relatively simple task. At the other end of the spectrum of mammalian development are the rapidly maturing species, such as laboratory rodents, in which the processes of neonatal differentiation and puberty are much more difficult to separate.

In man, the prolonged period of development from birth to adulthood may be divided into five life history stages, namely infancy, childhood, juvenile, adolescence (pubertal), and adulthood.[11] Infancy is defined as the period when nourishment of the offspring is obtained via suckling or from formula and ends at the time of weaning. Childhood is the period during which the offspring remain dependent on their parents (or surrogate elders) for food and protection. In contrast to children, juveniles are no longer dependent on parents (elders) for survival. The juvenile phase of development is terminated by the onset of puberty, and at this time the individual enters adolescence. Since childhood is observed only in hominids,[11] for the purpose of the present chapter the term juvenile will be used to describe the phase of development between infancy and puberty in both human and non-human primates.

In primates, as in other mammalian species, the state of having entered the development stage defined as puberty is recognized by the cascade of morphological, physiological, and behavioral sequelae of increased gonadal and, in some cases, adrenal activity at this time. In Old World monkeys, apes, and man this stage of development may span a time frame of several years. Some of the biological changes associated with puberty are relatively discrete and, therefore, provide quantitative markers of this transitional phase in development. Many others, however, are less obvious and more difficult to monitor. It has thus not been possible to pinpoint the beginning or the ending of puberty in primates with any degree of precision, nor has it been possible to provide for any of these species a complete chronicle of events that unfold as an individual progresses through puberty. It is important to appreciate at the outset that the foregoing paucity of descriptive information has minimal impact on our ability to construct and to test physiological models that have been, or may in the future be, proposed to account for the timing of puberty in primates. The purpose of this chapter is to examine the control systems that underlie the transition into puberty, rather than providing a comprehensive review of the morphological, physiological, and behavioral concomitants associated with puberty (see Ref. 3 for man). Emphasis will be placed on the highly evolved primates, which include the Old World monkeys and apes, including our own species.

The conceptual framework, which serves as the basis for our classical understanding of puberty, has been elegantly reviewed by Donovan and Van der Werff ten Bosch.[12] Only the major steps in the progression of thinking on this subject need to be reiterated here. That a major component of puberty involves a change in gonadal activity became apparent before the time of Christ, as knowledge of the effects of castration during prepubertal development in our own species first began to accumulate.[13] Similarly, the idea that the pubertal change in gonadal activity is of a humoral nature is not of modern origin and, as pointed out by Donovan,[14] dates back to at least the seventeenth century. The signal finding of Foa at the turn of the present century, that transplantation of ovaries from an immature animal into an adult host led to a premature onset of pubertal activity in the transplanted gonad,[15] provided the foundation for the view that although maturational processes may occur within the gonad of the immature animal, these are terminated long before the onset of puberty. Confirmation of Foa's original finding by several other groups led Lipschutz and his colleagues[16] to formulate in 1929 the "law of puberty", which stated that the onset of pubertal changes in the gonad is determined by maturation of a somatic component rather than by that of the gonad itself.

That the somatic component of the control system governing puberty might be the pituitary gland was suggested by the early finding of Crowe et al.[17] that partial ablation of the adenohypophysis in the prepubertal canine prevented the onset of sexual maturation. Definitive proof for the pituitary's role in puberty was provided 17 years later by Smith and Engel,[18] who convincingly demonstrated that implantation of pituitary fragments in immature rats and mice led to premature sexual maturation in these species. However, with the subsequent forging of contemporary understanding of the neural regulation of anterior pituitary function by Geoffrey Harris and others,[19] the role of the pituitary gland in puberty was relegated to that of a slave to the brain. In a fashion analogous with Foa's earlier ovarian transplantation experiments, Harris and Jacobsohn[20] found that when pituitary glands taken from immature rats were transplanted to a site beneath the median eminence of their hypophysectomized mothers, estrous cyclicity was reinitiated in the recipient animals well before puberty would have been

expected to occur in the donors if the latter had remained intact. This result provides compelling evidence in support of our current concept that an intrinsic immaturity of the pituitary is not the cause of the relative ovarian and testicular quiescence during prepubertal development in many mammalian species, including primates.[21]

The finding from one of the authors' laboratories that chronic intermittent neurochemical stimulation of the hypothalamus of the prepubertal monkey imposes a precocious adult pattern of activity in the hypothalamus–pituitary–testicular axis indicates that the network of gonadotropin-releasing hormone (GnRH)[c] neurons, which provide the major drive to this axis, must also be viewed as a nonlimiting component of the control system that governs the timing of puberty.[22] Instead, the onset of puberty appears to depend on the ontogeny of central neural mechanisms that are upstream of the GnRH neuron and are able to dictate the postnatal activity of these cells. The critical importance of the central nervous system (CNS) in the pubertal process in primates is graphically reinforced by an extensive clinical literature documenting an association between lesions of the human brain, particularly those of the hypothalamus and adjacent areas, and disorders of puberty, such as GnRH-dependent precocious and delayed gonadarche.[3] With the discovery in 2003 that loss of function mutations in G-protein coupled receptor 54 (GPR-54; also known as kisspeptin receptor, KISS1R) is associated with hypogonadotropic hypogonadism and delayed or absent puberty in man,[23,24] the idea that hypothalamic kisspeptin signaling is the single most important upstream regulator of the GnRH neuronal network has emerged.

GONADAL AND ADRENAL FUNCTION DURING PUBERTY

The Testis

The growth of the human testis during the first decade of postnatal life is unremarkable. A dramatic increase in testicular volume between 9 and 13 years from 2 ml to the adult volume ranging from 20 to 25 ml[3] marks male gonadarche. The chimpanzee exhibits a pattern of testicular growth similar to that of humans, although the phase of pubertal enlargement is initiated at approximately 6 years of age.[25–28] In rhesus, crab-eating, and bonnet monkeys and in baboons, there is also little growth of the testis during prepubertal development.[29–33] At around 3 years of age in these species of Old World monkey, testicular size increases markedly within a period of 1.5 years, from a volume of approximately 2.5 ml to an adult capacity of 25 ml. In the mandrill, pubertal testicular enlargement is observed between 4 and 8 years of age.[34] A similar developmental pattern of testicular growth has been reported for the common marmoset, although, in the case of this New World primate, initiation and completion of the pubertal phase of rapid growth take place at a much earlier age than in highly evolved primates.[10] In two other species of platyrrhine, the owl monkey and the capuchin monkey, a marked pubertal acceleration in testicular growth was only noted in the latter species.[35,36]

The testes of postinfantile, prepubertal macaques and humans contain few, if any, recognizable Leydig cells,[37–40] and testicular testosterone secretion during this phase of development, in these and other species of primate, is minimal.[40–52] The precise temporal relationship among the acceleration in testicular growth, the development of Leydig cells, and the increase in testosterone secretion during early puberty has not been systematically studied in any species. The development of Leydig cells and a rise in intratesticular androgen concentration, however, likely precede both the acceleration in testicular growth and the rise in circulating androgen levels. In humans, daytime levels of plasma testosterone begin to rise above prepubertal concentrations of 0.2 ng/ml during the tenth year of life and continue to increase progressively before reaching, at 14–15 years of age, a value (6 ng/ml) typical of that observed in adult men.[41,42,53] The initiation of the pubertal rise in circulating daytime testosterone levels has been observed to occur between the ages of 6 and 8 years in the chimpanzee[28,43]; 4 and 8 years in the mandrill[34]; 2.5 and 4 years in the rhesus, crab-eating, and African green monkeys, the sooty mangabey, and the baboon[45,47–52]; 2.5 and 3 years in the squirrel monkey[46]; and approximately 1 year in the common marmoset and the owl monkey.[10,35] Studies of humans and the rhesus monkey show that initial activation of testicular testosterone secretion during early puberty occurs nocturnally.[49,54–56] In the rhesus macaque, a nighttime increment in circulating testosterone concentrations may be observed as early as 2–3 years of age, several months before the onset of the pubertal rise in daytime concentrations of this steroid.[49] Although longitudinal studies of the peripubertal time course in testosterone secretion are scant, the available data for humans[57,58] and the rhesus monkey[33] suggest that the transition from a prepubertal to an adult pattern of secretion may occur relatively briskly. Longitudinal studies of sexual development in humans also reveal a striking increase in testicular growth during puberty.[12]

The age at which spermatogenesis is initiated has been less precisely defined than that for the pubertal onset of steroidogenic activity by the Leydig cell because of the difficulty in obtaining serial ejaculates

[c] Throughout the chapter we will use GnRH to describe GnRH-1 (mammalian GnRH).

and testicular biopsies. Limited data are available for macaques and humans only, and no attempt has been made to systematically relate the maturation of seminiferous tubule morphology to the pubertal initiation of Leydig cell function. In contrast to the steroidogenic component of the primate testis, which appears to be quiescent during the postinfantile, prepubertal stage of development, the seminiferous cords lengthen during this phase of development due to proliferation of Sertoli cells and undifferentiated type A spermatogonia.[33,37,38,59–62] The acceleration in testicular growth during early puberty results largely from an increase in diameter and tortuosity of the seminiferous tubules associated with the appearance of mature Sertoli cells and proliferation of germ cells. Although spermatogenesis has been generally recognized to become established between the 12th and 16th year of life in humans,[37,59] studies of the incidence of spermaturia in boys suggest that the onset of sperm production may occur in association with the initiation of accelerated testicular growth.[63,64] In a qualitative sense, the postnatal ontogeny of the germinal epithelium in macaques appears comparable to that described for humans. In these Old World monkeys, sperm are first observed in the seminiferous tubules between 3 and 4 years of age.[32,33,38,60] In New World monkeys, spermatogenesis is probably initiated during the first year of life; spermatocytes have been reported in the marmoset testis at 35 weeks of age,[10] and cotton-top tamarin males as young as 22 months of age may impregnate female.[65]

The Ovary

Knowledge of the ontogeny of the primate ovary has been derived primarily from studies of the human and rhesus monkey.[66–70] In contrast to the postnatal pattern of testicular growth, the size of the ovary increases in a rectilinear fashion from infancy to adulthood. Moreover, growth and atresia of ovarian follicles begin in utero and continue during the prepubertal years. From a peak of approximately six to seven million oocytes in the human female fetus at midgestation, some 350,000 remain at birth due to losses secondary to apoptosis.[71,72] Enlargement of the ovary prior to puberty is the result of age-related increases in the number and size of antral follicles and in the quantity of medullary stroma independent of gonadotropin stimulation. Sonography shows small follicles in the ovaries from the majority of prepubertal girls with increasing variation in follicular size postmenarche.[3] Although the size attained by a growing antral follicle before atresia intercedes is variable, Graafian (preovulatory) follicles are not observed during prepubertal development. Whereas primordial and pre-antral follicles predominate during the prepubertal years, small antral follicles can develop prior to puberty. With gonadotropin stimulation at the initiation of puberty, the adolescent ovary may appear on ultrasound images to be multi-cystic.[73]

The availability of sensitive and specific methodology to measure the low serum estradiol concentrations in prepubertal girls and non-human primate females is limited. Two observations in prepubertal female monkeys, however, demonstrate that the prepubertal ovary actively secretes estradiol. First, ovarian vein concentrations of estradiol are three- to fourfold greater than peripheral levels,[74] and second, circulating estradiol concentrations decline following ovariectomy.[75] That the prepubertal human ovary also secretes estradiol is supported by the finding, obtained with an ultrasensitive estradiol bioassay, that circulating levels of this steroid are significantly greater in prepubertal girls than in boys.[76,77] Cross-sectional studies of girls have demonstrated that between 8 and 10 years of age, estradiol concentrations in serum samples collected during the morning begin to increase to values typically seen in adult women during the early follicular phase of the menstrual cycle.[78–80] Concomitant with the rising estradiol concentrations, the early clinical feature of gonadarche, namely the initiation of breast development, occurs. Uterine volume increases throughout puberty, with the greatest increase occurring during midpuberty.[81] In the female rhesus monkey, circulating estradiol concentrations rise between 2.5 and 3 years of age in association with nipple growth and an increase in perineal swelling and coloration.[82,83]

In the human female, further development of secondary sexual characteristics occurs as puberty progresses and culminates in menarche, which generally occurs 2–3 years following the onset of breast development.[3] The Third National Health and Nutrition Examination Survey (NHANES III), conducted between 1988 and 1994, reported the average age at menarche to be 12.54 years in North American girls, with an average age estimated to be 12.6 years for whites and 12.14 years for blacks.[84] Menarche presumably represents acute withdrawal of hormonal support of estrogen-induced endometrial proliferation. Typically, menstrual cycles during the first year after menarche are often irregular and anovulatory,[85–90] with most ranging in duration from 21 to 45 days. Within 5 years of menarche, the majority of cycles are regular and range from 21 to 35 days. Fertility during the peripubertal years appears to be compromised by a relatively high incidence of menstrual cycles with short luteal phases.[87,89,90]

Although menarche occurs in the great apes and Old World monkeys at a younger age than that in the human female (Table 32.1), the postmenarcheal phase of development in these species is also characterized by a variable phase of adolescent infertility[85,91,94,97] that, in the case of the rhesus monkey, is the result of a high incidence of anovulatory and short-luteal-phase cycles.[103,104]

TABLE 32.1 Age at Menarche in Old World Monkeys and Great Apes

Species	Age (year)	Reference
Chimpanzee	7–11	91–93
Gorilla	6–8	94
Baboon	3–4	95,96
Talapoin monkey	3–4	97
Pigtail monkey	2–4	98
Rhesus monkey	2–3	99,100
Crab-eating monkey	2–3	101
Hanuman langur	2–3	102

In the common marmoset and squirrel monkey, species of New World primate in which menstruation is not observed, ovulation as indicated by elevated plasma progesterone levels and conception may occur as early as 2.5–3 years of age.[10,46] In other species of platyrrhine monkey—for example, the saddle-back tamarin, in which conception has been reported as young as 210–230 days of age[105]—the transition into puberty occurs within the first year of life under appropriate environmental and social conditions (see below).

The Adrenal

The adrenal cortex consists of three histologically and functionally distinct zones; the zona glomerulosa produces mineralocorticoids (aldosterone), the zona fasciculata produces glucocorticoids (cortisol), and the reticularis produces the C-19 adrenal androgens, dehydroepiandrosterone (DHEA), DHEA-sulfate (DHEAS), and androstenedione. The pituitary regulates circulating cortisol concentrations through secretion of adrenocorticotropin (ACTH), a peptide derived following proteolytic cleavages of proopiomelanocortin (POMC). In the adrenal cortex, ACTH binds to its cognate receptor, a G-protein coupled 7-transmembrane domain receptor that signals via cyclic AMP and protein kinase A. ACTH has both acute and chronic effects on the adrenal cortex. Acutely, ACTH promotes uptake of low density lipoprotein, stimulates cholesterol esterase activity, enhances synthesis and phosphorylation of steroid acute regulatory protein, and promotes cortisol secretion. The chronic effects of ACTH involve stimulation of transcription and translation of steroidogenic enzyme genes. ACTH secretion is controlled by hypothalamic releasing factors, such as corticotropin-releasing hormone (CRH) and vasopressin.

Adrenarche refers to the increased secretion of C-19 steroids (DHEA, DHEAS, and androstenedione) by the zona reticularis that begins at 6–7 years of age in humans.[3] Circulating DHEAS concentrations peak during the second decade of human life and, then, progressively decline.[106] While designated as adrenal androgens, these steroid hormones do not activate the androgen receptor. Rather, they serve as precursors for testosterone and dihydrotestosterone in target tissues.

In contrast to the role of hypothalamic GnRH in the initiation of gonadarche (see below), CRH and vasopressin do not appear to trigger the onset of adrenarche. Adrenarche occurs independently of developmental changes in the hypothalamic–pituitary–gonadal axis. For example, children with gonadal dysgenesis experience normal adrenarche and pubarche (growth of pubic hair), whereas children with primary adrenal insufficiency may have normal gonadarche.[3,8,107] No significant changes in ACTH concentrations have been noted during adrenarche, and no specific adrenal androgen-stimulating factors have been isolated from the pituitary. Nevertheless, decreased DHEAS concentrations in patients with ACTH resistance associated with mutations in the ACTH receptor gene (*MC2R*), and patients with ACTH deficiency, indicate that ACTH plays a permissive role in adrenarche.[108] Patients with ACTH resistance fail to experience adrenarche and females have poor pubic hair development.[108] Available data suggest that undefined gradual developmental changes in the enzymatic machinery responsible for steroidogenesis within the adrenal cortex underlie adrenarche.[3]

PUBERTAL STAGING

The physical changes associated with the onset and progression of puberty in highly evolved primates have been systematically defined only in man. Specifically, the genital and pubic hair changes that emerge in association with the onset of puberty in boys and girls are classified into five stages: Tanner stage 1 is prepubertal and Tanner stage 5 is adult.[3] These physical changes may be the result of either gonadarche, as in the case of breast or testicular enlargement, or adrenarche, as in the case of pubic hair development, particularly in girls. Although the physical sequelae of gonadarche and adrenarche generally occur concomitantly, a discordance of the two processes may also be observed in normal development.

Increased estrogen secretion promotes breast development in girls. The development of breast buds with increased areolar diameter is considered to be stage 2, and greater enlargement of the breasts occurs in stage 3 accompanied by increased pigmentation of the areolae and nipples. During stage 4, the areolae are mounded above the breast tissue. Recession of the areola to the general breast contour represents breast stage 5. Additional effects of estrogen at this stage of development include cornification of the vaginal mucosa, uterine growth, and morphogenesis of an adult female body habitus.

In girls, increased adrenal androgen secretion is considered to be responsible for the development of darker hairs usually along the labia, which is classified as pubic hair stage 2. During pubic hair stage 3, the hair is darker and coarser, spreading over the pubic symphysis with gradual progression to a full female escutcheon. Apocrine odor may precede or accompany the development of pubic hair. Associated findings include acne and oiliness of skin and hair.

For boys, an increase in testicular volume is considered genital stage 2. At stage 2, the testes are approximately 4–8 ml in volume with the longest axis being approximately 2.5 cm. With increasing testicular volume, the scrotum enlarges and is accompanied by decreased rugation of the skin. The volume of the mature human testis is approximately 20–25 ml and represents increased growth of the seminiferous tubule due to Sertoli cell proliferation and differentiation, and initiation of spermatogenesis. At genital stage 3, further growth of the testes has occurred, and the length and diameter of the penis has increased. At genital stage 4, penile size has increased with darkening of the scrotal skin.

Male pubic hair stage 2 consists of downy hair at the base of the penis. For pubic hair stage 3, the hair is longer and darker, and extends over the junction of the pubic bones. For pubic hair stage 4, the extent of hair has increased, but has not yet achieved the adult male escutcheon. Other secondary sexual characteristics in boys include increased size of the larynx, deepening of the voice, increased bone mass, and increased muscle strength. Approximately 3 years after the appearance of pubic hair, terminal hair appears in androgen-dependent regions on the face and trunk, where it may develop for years thereafter. The distribution and density of beard, chest, abdominal, and back hair vary considerably, presumably reflecting genetic differences. The appearance of spermatozoa in early morning urine specimens (spermaturia) occurs during genital stage 3. Transient gynecomastia (breast development) is observed in approximately 50% of boys.[109] Typically, this is most prominent in midpuberty when the ratio of circulating concentrations of estradiol to testosterone is relatively high.

The pubertal growth spurt in girls occurs concurrently with the onset of breast development. Usually only 4–6 cm of growth occur after menarche. In boys, the pubertal growth spurt, with an average height velocity of 9.5 cm/year, occurs around genital stages 3–4. In general, the age at peak height velocity shows an inverse relationship with the magnitude of the growth spurt.

A timeline of pubertal staging in female rhesus monkeys based on measurements of physical parameters and reproductive hormones has been established.[82] The first sign of female puberty in this species is a slight increase in the nipple volume, which is followed by an increase in perineal sex-skin swelling. During this period acceleration of body weight also occurs. These somatic changes are due to a small increase in circulating estradiol levels. Menarche occurs at around 30 months of age. Increases in nipple volume, sex-skin swelling, estradiol levels and body weight are further accelerated until the time of first ovulation around 42 months of age, after which all of these parameters reach a plateau. Thus, the pubertal stages in female rhesus monkeys are defined as follows: "prepubertal": no sign of puberty; "early pubertal": the period between the first sign of puberty and menarche; and "midpubertal": the period between menarche and first ovulation. These stages correspond to Tanner stages 1, 2, and 3, respectively, in girls.

SECULAR TRENDS

Over the last century and a half, the age of menarche in North America, Europe, and other industrialized areas of the world appears to have decreased dramatically from 16 to 17 years of age in the middle of the nineteenth century to 12–13 years of age in the late twentieth century.[3,9,110–113] This well-established trend toward an earlier age at menarche, which in the early twenty-first century may be coming to a halt,[3,114–119] is generally attributed to a corresponding secular improvement in the standard of living, including better nutrition and health care. Additionally, environmental contamination, with agents such as bisphenol A, is also considered to be a possible cause of early puberty.[120,121] Although analogous data for puberty in the human male are scant, in a recent study of American boys who were taller and heavier than those in previous cohorts, pubic hair and testicular development were reported to occur earlier than previously recognized.[122] Interestingly, a secular trend toward an earlier age of menarche has also been reported for the rhesus monkey in laboratory settings, and this is attributed to an increased calorie intake.[99,123]

PITUITARY GONADOTROPE FUNCTION DURING PUBERTY

Conceptually, it is useful to define two modes of gonadotropin secretion, namely basal (or tonic) and surge. The tonic mode accounts for the secretion of these hormones in the male, and for the relatively low circulating luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels observed in females during the greater part of the menstrual cycle (see Chapter 28 for details). In the male, this mode of secretion is responsible for maintaining spermatogenesis and stimulating testosterone secretion. In the female, tonic gonadotropin secretion drives folliculogenesis and estradiol production in the follicular phase and maintains the corpus

luteum in the second half of the cycle. The surge mode of gonadotropin secretion, which results in the massive mid-cycle discharge of LH and FSH, triggers ovulation, and is termed the preovulatory gonadotropin surge.

Our understanding of tonic gonadotropin secretion during puberty in primates has been obtained primarily from studies of humans, and these were reviewed in detail in the last edition of this book.[124] With the advent, in the late 1960s, of radioimmunoassay (RIA) for the determination of LH and FSH in small volumes of serum, a large number of research groups examined, in comprehensive cross-sectional studies, the time courses of circulating LH and FSH concentrations in normal boys and girls during pubertal development. The general statement may be made that the transition into puberty in both boys and girls is tightly coupled with an initiation of a progressive increase in the overall secretory activity of the pituitary gonadotropes, as reflected by the time courses in circulating LH and FSH concentrations during this phase of human development. With the advent of the more sensitive immunoradiometric or immunofluorometric assays for the measurement of blood gonadotropin concentrations, it is now clear that FSH and LH levels rise concomitantly at puberty in both boys and girls, and that the increase in LH at this stage of development is particularly robust. In the case of LH, where bioassay has also been applied, the pubertal rise in this gonadotropin is revealed to be an immediate, rapid, and striking event.

Although studies of the time courses of basal gonadotropin secretion during juvenile and pubertal development in non-human primates, specifically, the chimpanzee,[28,125] the macaques,[30,31,49,52,83,126] and the sooty mangabey,[48] have been collectively less comprehensive than those of humans, the coupling between a rise in circulating LH and FSH concentrations and the transition into puberty is a general characteristic of sexual maturation in highly evolved primates. Indeed, the switch to an LH-dominated pattern of gonadotropin secretion at puberty is reflected in the male rhesus monkey by a greater proportion of LH immunoactive gonadotrophs in the pituitary of the adult compared with that of the juvenile.[127]

In boys and the male rhesus monkey, the pubertal increase in gonadotropin secretion is characterized by nocturnal elevations of LH concentrations that drive nighttime testosterone secretion characteristic of this stage of development.[49,54,55,128–133] Increased nocturnal activity in the pituitary–Leydig cell axis is sleep related in boys.[134] The pubertal activation of the pituitary gonadotrope in the female is also characterized by nocturnal elevations in LH secretion,[124,135–138] which, in the case of the human female, are also sleep related.[135,136]

It is also during the pubertal phase of development that spontaneous preovulatory gonadotropin surges are first observed in the female[d]. In the rhesus monkey, and probably in humans, this takes place after menarche.[82,139–141]

The fundamental role of increased gonadotropin secretion to initiate gonadal development at puberty is well established. In humans, spermatogenesis and ovulation may occur at very young ages as a result of premature gonadotropic stimulation of the gonad.[3,142–144] Similarly, stimulation of the gonad in the prepubertal rhesus monkey with either exogenous or endogenous gonadotropin leads to the premature onset of ovulation and spermatogenesis.[21,22,145–148] Also, chronic stimulation of gonadotropin secretion in subjects with delayed puberty secondary to hypogonadotropic hypogonadism results in the pubertal-like activation of the testis and ovary and fertility.[149–152] Conversely, a delay in the onset of puberty in humans is associated with low circulating gonadotropin concentrations and hypogonadism,[3,9,153] and inhibition of gonadotropin secretion in individuals with precocious gonadarche results in a return to testicular and ovarian quiescence.[3,143,144,154]

Taking the foregoing findings together it is clear that an understanding of the physiological mechanisms that regulate the timing of puberty requires an appreciation of the control system that governs gonadotropin secretion and its development.

NEUROENDOCRINE CONTROL OF GONADOTROPIN SECRETION IN THE ADULT

Before embarking on a discussion of the development of the neuroendocrine control system that governs gonadotropin secretion, we provide perspective by presenting a brief overview of the essential features of the regulation of gonadotropin release in the adult. For detailed examinations of this subject in the female, the reader is referred to Chapter 28. The primary stimulus to pituitary gonadotropin secretion is generated within the CNS and is transmitted to the gonadotropes of the adenohypophysis via the hypophysial portal circulation by an intermittent hormonal signal in the form of the hypothalamic releasing factor, GnRH. Parenthetically, it should be noted that a second GnRH (GnRH-II) is also found in the primate hypothalamus,[155,156] and the gene encoding the GnRH-II receptor is expressed in the anterior pituitary,[157,158] although the human gene encoding for this receptor does not generate a functional protein.[159,160] Although intravenous administration of GnRH-II to the rhesus monkey is able to elicit LH release,[161] and in this species GnRH-II is developmentally regulated[156] and estrogen responsive,[162] the role of

[d] It is to be noted that the ability of estradiol to elicit gonadotropin surges during infantile development has not been tested.

this peptide in regulating the primate pituitary–gonadal axis is unclear. Similarly, an RF amide-related peptide, RFRP3, that is considered to be a homolog of gonadotropin-inhibitory hormone has been identified in the mammalian hypothalamus,[163] but its neuroendocrine role in primates has yet to be established.

The distribution of GnRH perikarya and their projections within the primate hypothalamus has received considerable attention (see Chapter 11), and insight into the neurobiology of the hypothalamic GnRH pulse generator is beginning to emerge. In the primate hypothalamus there are some 1000 to 2000 diffusely distributed GnRH neurons, many of which send their projections to the median eminence where they synchronously and intermittently discharge their peptide into the primary plexus of the hypophysial portal circulation, thereby providing the pituitary gonadotrophs with the pulsatile stimulation that, as first demonstrated by Knobil, is essential for maintaining gonadotropin secretion (see Chapter 28). Recently, these GnRH projections to the median eminence in mice were recognized to share characteristics of axons and dendrites and were accordingly termed dendrons[164]: it is speculated that communication among multiple GnRH neurons underlying synchronous peptide release may occur at the dendrons (see Chapter 11). While the neurobiological mechanisms that underlie GnRH pulse generation remain controversial, compelling evidence is emerging to indicate a fundamental role of KNDy neurons in the arcuate nucleus (also called infundibular nucleus).[165–168] These hypothalamic neurons, named because they coexpress *k*isspeptin, *n*eurokinin B (NKB) and *d*ynorphin,[169] project their axons to the median eminence where they mingle intimately with GnRH fibers en route to the portal vessels.[170] It is proposed that GnRH pulse generation is achieved by reciprocating stimulatory (NKB) and inhibitory (dynorphin) connections within the arcuate nucleus, while the output of the pulse generator is relayed to GnRH fibers projecting to the median eminence by an intermittent kisspeptin signal. Thus, these neurons may represent the anatomic site of the GnRH pulse generator. Loss of function mutations in the genes encoding for kisspeptin (*KISS1*) or *KISS1R* and for NKB (*TAC3*) or the NKB receptor (*TACR3*) in man lead to a profound hypogonadotropic state that is typically manifest by the absence of gonadal development at the expected age of puberty.[23,24,171,172] On the other hand, gain of function mutations of both *KISS1* and *KISS1R* has been implicated in the etiology of precocious pubertal GnRH-dependent gonadotropin secretion in man.[173,174] The mechanism of action of the receptor mutation has been attributed to delayed degradation of the KISS1R leading to a prolonged duration of action.[175] The importance of KNDy neurons has also been demonstrated by the finding that their ablation either nonselectively in the adult monkey or selectively in the postpubertal rat results in a loss in hypothalamic drive to LH secretion.[176,177] Contemporary models for GnRH pulse generation are discussed further in Chapters 27 and 28.

The hypothalamic GnRH pulse generator and the pituitary gonadotropes comprise the basic neuroendocrine unit responsible for basal/tonic LH and FSH secretion. Tonic gonadotropin release in the adult is regulated by negative feedback actions of the gonadal hormones on LH and FSH secretion that may be exerted either directly on the gonadotropes to suppress their responsivity to GnRH stimulation or indirectly at a suprapituitary locus to modulate the frequency and/or amplitude of pulsatile GnRH release. Removal of such negative feedback influences results in a chronic hypersecretion of both LH and FSH, which occasions a sustained elevation in circulating gonadotropin concentrations an order of magnitude higher than those observed in intact subjects. In the absence of feedback by gonadal hormones, the hypothalamic GnRH pulse generator of sexually mature male and female primates appear to exhibit an operational frequency of approximately one cycle per hour. This "adult" pattern of intermittent GnRH release, as measured directly in the monkey or reflected in the circhoral discharge of pituitary LH release, has been observed in male and female rhesus monkeys castrated postpubertally, in ovariectomized and post-menopausal women, and in men with primary gonadal failure or following castration (see Chapter 28).

The primary testicular components of the negative feedback loops governing gonadotropin secretion in the male are testosterone and inhibin B, which regulate LH and FSH, respectively. In the female, tonic gonadotropin secretion, which is observed during the greater part of the follicular phase and during the luteal phase of the menstrual cycle, is controlled by a negative feedback action of ovarian hormones (primarily estradiol) on LH and FSH release.

In addition to tonic gonadotropin secretion that drives folliculogenesis and maintains the corpus luteum, the female also requires expression of the surge mode of gonadotropin secretion to achieve ovulation. This mode of gonadotropin secretion is generated by a stimulatory or positive feedback action of estradiol on LH and FSH release. The positive feedback action of estradiol is elicited, at least in the human and macaque female, when circulating levels of this steroid secreted by the ovarian follicle destined to ovulate are maintained for approximately 36–48 h at a threshold concentration of 200–500 pg/ml during the late follicular phase of the cycle. The precise neuroendocrine mechanism that is activated by the positive feedback action of estradiol in highly evolved primates and that therefore underlies the preovulatory gonadotropin surge in these species is poorly understood. In this regard, the concept of

distinct anatomical centers in the medial basal hypothalamus (MBH) and rostral hypothalamus that govern tonic gonadotropin secretion and the preovulatory discharge, respectively, which was originally proposed to account for LH secretion throughout the estrous cycle of the rat, is generally omitted from current models of the primate menstrual cycle.[178] Whether the hypothalamic machinery responsible for the preovulatory gonadotropin surge in primates involves more than the GnRH pulse generator and the GnRH neurons that it regulates is unclear. However, there is considerable evidence from GnRH deficient human and monkey models to support the view that pulsatile GnRH stimulation, alone, is sufficient for the generation of the preovulatory gonadotropin surge. Moreover, the postnatal development of surge gonadotropin secretion has been scantly studied in primates. For the foregoing reasons, only the role of hypothalamic GnRH pulse generation in the development of tonic gonadotropin secretion and the onset of puberty will be considered in detail.

If GnRH pulse generator activity is compromised in the adult, as occurs, for example, in severe undernutrition and during strenuous exercise training, individuals become hypogonadotropic and hypogonadal (see Chapters 35 and 36). Thus, the pituitary gonadotrophs may be viewed as a slave to the hypothalamic GnRH pulse generator, and this analogy should be borne in mind as the developmental changes in gonadotropin secretion are considered.

DEVELOPMENTAL PATTERN OF GONADOTROPIN SECRETION

Fetal

Although descriptions of the circulating LH and FSH concentrations during fetal development in primates are incomplete, it has been established for humans and rhesus monkeys that secretion of these hormones is robust during mid- to late pregnancy,[9,179–181] when their levels in the fetal circulation may attain values comparable to those observed in adult castrates. The magnitude of the fetal rise in circulating FSH and LH concentrations is most striking in the female.[179–181e] An inhibitory action of fetal testicular hormones on LH and FSH secretion at the hypothalamic and/or pituitary level provides the most likely explanation for the relatively lower circulating LH and FSH concentrations in the male at this stage of development. This view is supported by the finding of Resko and Ellinwood,[182] demonstrating that orchidectomy between 98 and 104 days of fetal development in the rhesus monkey elicits a dramatic postcastration hypersecretion of gonadotropin that, within 3 weeks, results in a rise in circulating LH and FSH to concentrations observed in intact female fetuses of comparable age. Ovariectomy at this stage of fetal development does not appear to influence gonadotropin secretion.

During the latter half of human gestation, FSH and LH concentrations in the fetal circulation decline, and, at the time of birth, low gonadotropin levels are consistently observed in cord blood.[183] A similar suppression of gonadotropin secretion during late fetal development is also observed in the rhesus monkey,[181] although in the case of this species, elevated LH and FSH concentrations are sustained for a relatively greater proportion of fetal development before declining abruptly at the end of gestation.

Circumstantial evidence suggests that the principal stimulus to the fetal gonadotropes is provided, as in the case of the adult, by an intermittent pattern of GnRH discharge by the hypothalamus. In humans, the hypothalamic–hypophysial portal circulation and the major hypothalamic nuclei appear to differentiate by midgestation.[179] Interestingly, GnRH neurons, in contrast to other neurons in the CNS, originate outside the brain in the nasal placode and migrate to the hypothalamus during the first trimester of fetal development.[100] In the rhesus monkey, GnRH neurons reach the adult pattern of distribution within the hypothalamus early in the second trimester of gestation.[184,185] Immunoactive GnRH has been extracted from human fetal hypothalamus in the first trimester,[186] and at this stage of gestation the distribution of GnRH perikarya and their projections in the fetal brain of humans as revealed by immunocytochemistry appear similar to that in adults.[187,188] The gonadotropes in the fetal pituitary gland of humans and rhesus monkeys are able to respond to stimulation with synthetic GnRH.[189,190] Studies employing chronically catheterized ovine fetuses, a species in which the ontogeny of gonadotropin secretion during fetal development appears to resemble that in highly evolved primates,[191] have revealed the presence of distinct LH pulses during this phase of development.[192] Such discharges of LH are presumably occasioned, as in the adult, by the episodic release of GnRH by the hypothalamic pulse generator of the fetal brain.

The factors responsible for the characteristic bell-shaped time course in gonadotropin secretion during fetal development in humans are unclear. The best explanation for this phenomenon is that proposed by Grumbach and his colleagues.[9,179] These investigators suggest that differentiation of pituitary gonadotropes and the initiation of a hypophysiotropic drive to these cells are

[e] Although Kaplan et al.[179] did not observe a sex difference in fetal LH concentration in blood, the latter workers did observe that fetal pituitary LH content is greatest in females.

established early in fetal development and precede the ability of this neuroendocrine complex to respond to the inhibitory actions of gonadal and placental steroids on LH and FSH release. Thus, during the first half of fetal development, gonadotropin secretion is unrestrained and increases to a level reminiscent of that observed in the open-loop situation in adults. Thereafter, the fetal hypothalamic–pituitary unit presumably acquires the capacity to respond to the negative feedback actions of sex steroids, and circulating LH and FSH concentrations decline throughout the second half of fetal development as the placental production of estrogen and progesterone rises. That gonadotropin secretion in the primate fetus is restrained during late gestation by the inhibitory action of placental steroids is further suggested by the observation that, following parturition and the resulting removal of placental influences, circulating LH and FSH rise to concentrations markedly greater than those observed later in prepubertal development.[9,183,193–201]

Neonatal/Infant

Heightened gonadotropin secretion during neonatal development is observed in boys, and male chimpanzees, Old World monkeys, and marmosets, and is associated with marked elevations in testicular testosterone secretion that produce circulating levels of the steroid comparable to those observed in adults.[30,194,195,199,200,202] Continuous treatment of infantile male rhesus and marmoset monkeys with a GnRH receptor agonist results, as in adults, in a complete suppression of the pituitary–testicular axis,[203,204] and in normal infantile boys LH secretion is pulsatile[205,206]: findings indicating that gonadotropin secretion at this stage of development is driven by pulsatile hypothalamic GnRH secretion. Further study of the rhesus monkey has led to the notion that the hypothalamic component of the control system that governs testicular function is fully mature by the neonatal stage of development. Bilateral orchidectomy at 1 week of age elicits a post-castration rise in LH and FSH secretion seemingly indistinguishable from that observed after castration in sexually mature animals,[197] demonstrating the integrity of the negative feedback control of pituitary gonadotropin secretion during infantile development. Moreover, in such neonatal castrates, LH secretion is episodic and exhibits a pulse frequency typical of open-loop LH secretion in animals castrated postpubertally, namely, one pulse per hour.[207] The latter finding suggests that the hypothalamic GnRH pulse generator of the infantile male primate, like that of the postpubertal animal, is capable of generating the adult circhoral pattern of intermittent GnRH secretion. In addition, infantile male rhesus monkeys exhibit a diurnal variation in testicular testosterone secretion that is quantitatively similar to that typically observed in pubertal and fully adult animals and is correlated, as in adults, with a corresponding diurnal variation in LH release.[199,208,209] The latter observation suggests that the hypothalamic GnRH pulse generator of the infant is probably modulated by the same exteroceptive factors that regulate testicular function in the adult. Thus, in highly evolved primates the hypothalamic–pituitary unit that governs testicular function differentiates to full maturity during fetal development.

The hypothalamic–pituitary unit in female primates (humans, chimpanzees, and rhesus monkeys) also exhibits heightened activity during early neonatal development, resulting in an elevation in circulating LH and FSH concentrations, which are maintained for a variable period of time during infancy, depending on the species.[183,193,196,198,200,201,210] Although the foregoing findings support, at first sight, the view that the female hypothalamic–pituitary unit is also fully mature by birth, this question is worthy of further consideration. In infantile girls, circulating FSH concentrations are sustained at elevated levels for several years and often exceed, in dramatic fashion, those observed in adults during the follicular phase of the menstrual cycle, rising on occasion into the adult castrate range.[183,196,201] Circulating LH, on the other hand, exhibits a developmental pattern similar to that observed in the infantile boy, with a rise to low adult levels during the first few months of postnatal life.[183,193,196,200,201] This sex difference in gonadotropin secretion during infantile human development, which has been detected as early as the first day of postnatal life[211,212] and is observed in the late-gestation fetus,[180] results in an elevated ratio of FSH to LH in the peripheral circulation of the female. A similar sexual dimorphism has also been observed in the chimpanzee and the rhesus monkey.[182,198,208,213]

Studies of the rhesus monkey suggest that differential gonadal feedback signals cannot account for this sex difference in gonadotropin secretion: castration at 1 week of age does not abolish the difference in the time courses of gonadotropin secretion during the subsequent 40 weeks of life.[210] Similarly, in anorchic infantile boys, circulating FSH concentrations are lower than those in age-matched patients with Turner's syndrome.[212] Moreover, in agonadal infantile monkeys the relatively high FSH:LH ratio in the female is associated with a frequency of pulsatile LH secretion (one pulse every 4 h) that is markedly slower than that in age-matched castrated males (one pulse/h) (Figure 32.1). The latter finding, in turn, suggests that the hypothalamic GnRH pulse generator of the infantile female, in contrast to that of the neonatal male, is not capable of operating at the adult circhoral frequency. This may be of considerable conceptual importance, because if subsequent study establishes that the slow frequency of hypothalamic GnRH discharge in the infantile female reflects an "immature" pulse generator that fails to develop the capacity to operate at the adult

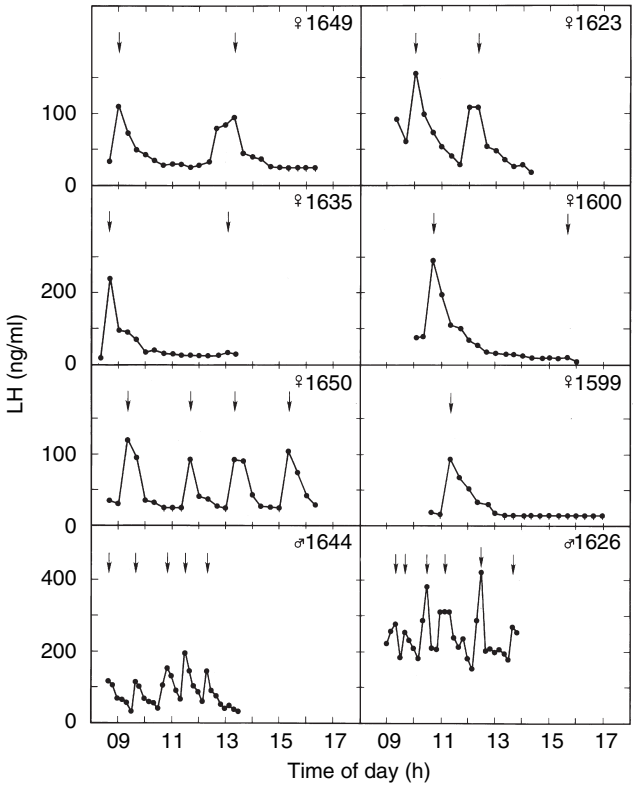

FIGURE 32.1 Moment-to-moment changes in circulating LH concentrations[f] at 4–7 weeks of age in six infantile female (top three panels) and two infantile male (lower panel) rhesus monkeys that were bilaterally gonadectomized at 1 week of age. *Arrows* indicate increments in LH identified as pulses by PULSAR. Note that the frequency of LH pulses, and presumably therefore of GnRH discharges, in agonadal infantile females is markedly slower than that in agonadal males of similar age. *Source: Reprinted with permission from Ref. 210.*

circhoral frequency during fetal development, then a postnatal maturation stage of the GnRH pulse generator will have to be added to the schemata of female puberty.

An early influence of testicular androgen on the developing fetal brain seems to be a reasonable mechanism to account for this sex difference in hypothalamic function during infantile development, and this view is supported by the finding that male infants with partial androgen insensitivity due to mutations of the androgen receptor exhibit a female pattern of gonadotropin release in association with elevated testosterone levels.[214] However, the concomitant observation that, in subjects with complete androgen insensitivity, circulating concentrations of LH and testosterone are very low during the first 3 months of postnatal life[214] is counterintuitive. Parenthetically we consider that resolution of this intriguing paradox is likely to be particularly informative.

It is to be noted that during infantile development, the gametogenic functions of the ovary and testis are not activated despite the "adult like" gonadotropin drive to the gonad. In the infantile testis, Sertoli cells and undifferentiated type A spermatogonia proliferate, but the production of differentiating type B spermatogonia, the initial step in spermatogenesis, does not occur.[33,61,62,215,216] This deficit in seminiferous tubular function is likely to be accounted for by the absence of responsiveness of the Sertoli cell to androgen and FSH stimulation.[217] The precise age at which the primate gonad acquires the full capacity to respond to LH and FSH stimulation has not been established, but when it does, the infantile phase of robust gonadotropin secretion has been terminated and the hypogonadotropic state of the juvenile guarantees the quiescence of the primate testis for the remainder of prepubertal development.

Juvenile

Studies examining pulsatile profiles of circulating LH concentrations during juvenile development in both humans and monkeys (reviewed in detail in the previous edition of this chapter)[124] indicate that this mode of gonadotropin release, and presumable GnRH pulse generator activity, is not abolished in the juvenile, but rather is heavily suppressed to a variable degree depending on sex, and, perhaps, species. Indeed, it is now universally accepted that the marked reduction in gonadotropin secretion during juvenile development in primates is the result of a corresponding hiatus in robust pulsatile GnRH release from the hypothalamus.[218] In the premenarcheal rhesus monkey, spontaneous ovulatory menstrual cycles may be precociously induced by a chronic intermittent infusion of exogenous GnRH[21]; see Figure 32.2, and, in cognate studies of the male macaque, premature initiation of testosterone secretion and spermatogenesis has been reported.[148,219] In agonadal male rhesus monkeys between 15 and 18 months of age, which is the phase of development characterized by very low levels of LH and FSH (see below), the chronic intravenous intermittent infusion of GnRH elicits a prompt hypersecretion of both gonadotropins.[208,220,221] These results in the macaque are consistent with clinical findings that pulsatile GnRH treatment results in the full activation of the pituitary–gonadal axis in human subjects, with delayed puberty occasioned by defects in endogenous GnRH release.[149–151]

Although the juvenile stage of development is a hypogonadotropic phase, nighttime elevations in LH (and testosterone secretion) are observed in juvenile boys.[128,131,132] Nocturnal secretion of gonadotropin in juvenile boys is also reflected in urinary LH and FSH excretion.[222] Thus, it seems that the neuroendocrine mechanisms that underlie the nocturnal elevation in

[f]Note that several LH standards have been used to measure circulating LH concentrations shown in this and subsequent figures, so direct comparisons of specific concentrations across figures cannot be made.

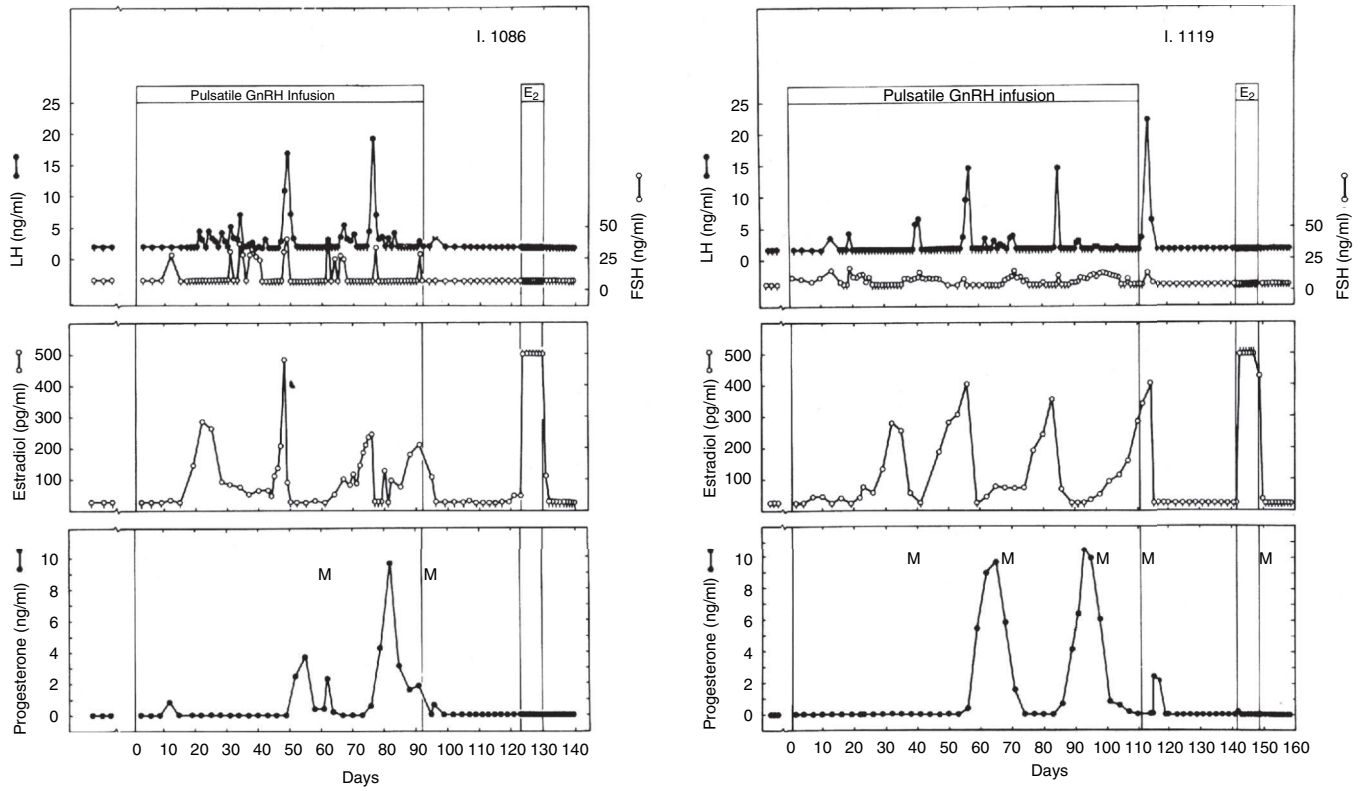

FIGURE 32.2 Ovulatory ovarian cycles in two premenarcheal rhesus monkeys induced by a chronic intermittent intravenous infusion of GnRH (1 pulse/h) initiated on day 0. Note that the pituitary–ovarian axis reverted to a prepubertal state following termination of GnRH treatment on days 92 and 111, respectively, and subsequent administration of estradiol (indicated by the unshaded bar labeled E2) failed to induce a gonadotropin surge. The occurrence of menstruation is indicated by M. *Source: Reprinted with permission from AAAS from Ref. 21.*

LH and testicular testosterone secretion during male puberty may be the same as those that are operative in infantile and juvenile primates. Studies of the agonadal female monkey indicate that the mechanisms for nocturnal modulation of hypothalamic GnRH release are also extant during infantile and juvenile development.[213,223]

Pubertal

During pubertal development there is a marked reaugmentation of pulsatile LH secretion that follows the reactivation of robust GnRH pulse generator activity, as directly demonstrated in one of the authors' laboratories by measuring pulsatile GnRH release in the region of the pituitary stalk–median eminence in the female monkey.[100,218,224]

Gonadotropin secretion during early human puberty is characteristically low during wakefulness and augmented in association with sleep, when large-amplitude LH pulses are observed (reviewed in detail in the previous edition of this book)[124]. Since marked circadian changes in pituitary responsivity to GnRH stimulation are unlikely, the large nocturnal LH pulses probably reflect high-amplitude GnRH discharges. The frequency of these discharges, originally observed only at night but later during the day, appears to increase noticeably from early to midpuberty in both boys and girls. The neuroendocrine basis of the nocturnal increase in LH release in pubertal boys, however, may differ from that in postpubertal males. In this regard, pulsatile LH secretion during the early hours of sleep in pubertal boys appears to be less responsive to the feedback action of testosterone,[225,226] and at this stage of development, in contrast to the situation in adults, the suppressive effect of testosterone on LH release that is observed appears independent of the endogenous opioids.[134,227] As is the case with the human male, the relationship between sleep and GnRH release appears to change with pubertal development in the female, with sleep inducing a deceleration in pulsatile LH release during the follicular phase of the human menstrual cycle.[228] An analogous situation appears to exist in the female monkey, since the GnRH pulse generator of the adult slows during the night.[229]

As puberty progresses, LH pulse frequency has been reported to decrease in both boys and girls.[230–233] In boys, this phenomenon has been attributed[231] to the action of rising testosterone concentrations to decelerate the frequency of the GnRH pulse generator. However, not all studies of LH pulse frequency during puberty in boys and girls have revealed the foregoing changes in the frequency of intermittent LH secretion.[234] Additionally,

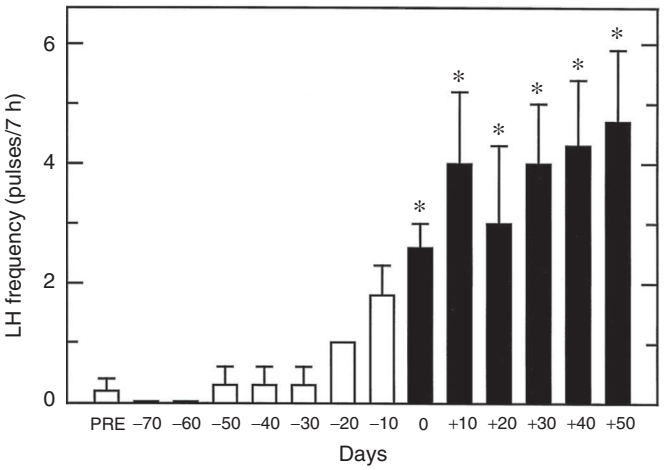

FIGURE 32.3 Peripubertal developmental changes in GnRH pulse generator activity, as reflected by nocturnal frequency of LH secretory episodes, obtained by aligning data for five agonadal male monkeys to the onset of the pubertal resurgence in pulsatile GnRH release (day 0). Heightened pituitary responsiveness to GnRH stimulation was maintained by a "priming" infusion of pulsatile GnRH between assessment windows. Ages of animals at day 0 ranged from 24 to 29 months. PRE, values for the earliest assessment window examined in each monkey, which ranged from 14 to 22 months of age; *asterisk*, significantly different from PRE ($P < 0.05$). *N* for each time point varies from 3 to 5. *Source: Reprinted with permission from Ref. 221.*

direct measurement of hypothalamic GnRH release during puberty in the female monkey indicates that both frequency and amplitude increase at the time of puberty onset: from early to midpuberty the amplitude further increases, whereas the frequency remains constant.[218] Similar pubertal changes in the GnRH pulse frequency occur in the absence of the ovary.[224] Moreover, the pubertal increases in baseline GnRH release and GnRH pulse amplitude are greatly exaggerated in ovariectomized females compared to those in gonadally intact counterparts.[224] Longitudinal studies of agonadal male rhesus monkeys, in which pituitary responsiveness to endogenous hypothalamic GnRH discharges was heightened with a "priming" infusion of the synthetic decapeptide, have provided insight into the time course of the pubertal resurgence in pulsatile GnRH release in the absence of testicular steroid feedback.[221] As reflected by pulsatile patterns of LH secretion in such animals, nocturnal GnRH pulse generator activity accelerates explosively at the termination of the juvenile phase of development from <1 pulse/7 h to approximately 4 pulses/7 h over a period of less than 6 weeks (Figure 32.3). While this rapid tempo of the pubertal reawakening of the GnRH pulse generator in agonadal animals is presumably dampened in the normal situation by testicular inputs, it seems reasonable to propose that, in male primates, the acceleration of the GnRH pulse generator during puberty is an early and rapidly completed neurobiological event in the initiation of this phase of development.[221]

Indirect estimates of GnRH pulse amplitude during puberty have been made by comparing the amplitude of endogenous LH pulses with those elicited in the same pubertal subjects by bolus infusions of GnRH (previously shown to provide the pituitary with a hypophysiotropic stimulus comparable to that generated by the hypothalamus following puberty). Using this approach, two groups have concluded that GnRH pulse amplitude is similar in adult men and pubertal boys during sleep.[56,235] From the foregoing considerations it seems reasonable to conclude that the earliest detectable pubertal mode of operation of the GnRH pulse generator is composed of a high-amplitude, intermediate-frequency discharge at night that probably reflects an amplification of a comparable preexisting prepubertal mode of activity. As pubertal development continues, intermittent GnRH discharge occurs during the day, and the integrated 24 h frequency of the GnRH pulse generator accelerates. The time course of GnRH pulse generator activity during the mid- to postpubertal phase of development that is associated with increasing secretion of gonadal hormones is less clear.

A schematic representation of GnRH pulse generator activity from fetal development until the entry into adulthood in a representative male and female highly evolved primate is shown in Figure 32.4. The timing of primate puberty may therefore by conceptualized by the operation of two postnatal switches. The first is an "off" switch that is activated during infancy, resulting in the restraint of GnRH pulse generator activity that guarantees the gonadal quiescence of the child (human) and juvenile primate. The second is an "on" switch that leads to a reactivation of robust GnRH pulse generator activity and the onset of puberty.

GONADAL INDEPENDENCE OF THE POSTNATAL SWITCHES AND THE HYPOGONADOTROPIC STATE OF JUVENILE DEVELOPMENT

As described in the previous section, the postnatal pattern of gonadotropin secretion in highly evolved primates is characterized by elevated LH and FSH release during infancy and puberty (continuing into adulthood) separated by a relatively hypogonadotropic state during juvenile development. An important feature of this characteristic "primate" pattern of gonadotropin secretion postnatally is that its fundamental temporal aspects are preserved in the absence of the gonad. As shown in Figure 32.5, this feature of primate development is exemplified by the rhesus monkey rendered agonadal at birth by either ovariectomy or orchidectomy.[49,213] The non-gonadal reduction in LH and FSH secretion during juvenile development is also readily apparent from data obtained with agonadal boys and girls.[141,236–242] In the latter group of individuals, which comprise primarily phenotypically female subjects with Turner's syndrome, circulating LH concentrations that exist between 4 and 10 years of age are often in the range reported for normal children and are always well below values reported for postmenopausal subjects.

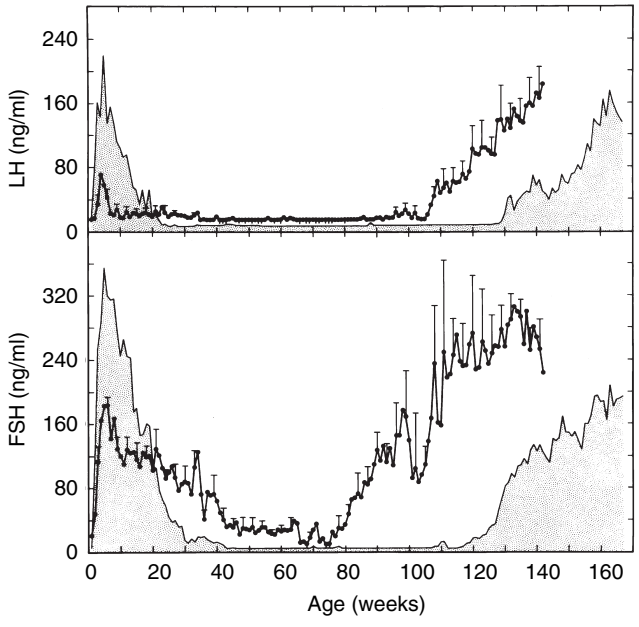

FIGURE 32.5 Time courses of circulating mean LH (top panel) and FSH (bottom panel) concentrations determined in blood samples collected in the morning from birth until 142–166 weeks of age in rhesus monkeys ovariectomized (•, $N=6$) and orchidectomized (*stippled area*, $N=4$) at 1 week of age. Note that the prepubertal hiatus in the secretion of FSH, and LH to a lesser extent, in agonadal females is truncated in comparison to that in castrated males. This difference between agonadal males and females, which presumably underlies the earlier onset of female puberty, is further exaggerated when nighttime concentrations of LH and FSH are examined (not shown). *Vertical bars* above data points indicate SEMs. *Source: The data for males are redrawn with permission, from Ref. 49.*

Taking the foregoing considerations together, it may be concluded that the low levels of circulating gonadotropins during juvenile development, which guarantee the relative quiescence of the gonad at this stage of primate development, are governed by a nongonadal brake, the effects of which are amplified, particularly in the female by inhibitory gonadal feedback. The site of action of the nongonadal brake is exerted at the level of the hypothalamus via GnRH release, and this issue will be explored in the next section.

While the nongonadal brake is waxing and waning during infancy and at the termination of the juvenile phase of development, respectively, inhibitory feedback actions of gonadal hormones on gonadotropin secretion, in both sexes, will play major roles in setting the quantitative level of FSH and LH secretion, and in modulating the precise duration of the hypogonadotropic juvenile state. Such feedback control during removal of the nongonadal brake at the termination of the juvenile phase of development will affect the tempo of gonadal maturation during puberty. For example, the negative feedback action of estradiol on gonadotropin release has been proposed as an important component of the neuroendocrine mechanisms that account for the temporal delay between menarche and first ovulation.[243–245] In this regard, it has been demonstrated for the rhesus monkey that the circulating estradiol concentrations required to prevent an elevation in gonadotropin following ovariectomy during the immediate postmenarcheal period are lower than those required to inhibit a postcastration hypersecretion of LH and FSH in adult females.[243,244] Similarly, in teenage girls with gonadal dysgenesis, the dose of conjugated estrogen required to suppress urinary excretion of LH and FSH into the normal range is less than that required for postmenopausal women.[246] Such steroid-imposed restraint on tonic gonadotropin secretion, which, according to studies of the pubertal monkey, is mediated at least in part by a hypothalamic site of action of estrogen to inhibit GnRH release,[224,247] is associated with, and is probably responsible for, the reduced efficacy of estrogen to exert its positive feedback action on gonadotropin secretion during this phase of pubertal development.[104,139] This latter view is consistent with the finding that estrogen-induced LH surges may be elicited in agonadal female monkeys at an earlier age than in intact animals.[248] Moreover, the onset of positive feedback in ovariectomized monkeys is observed in association with the initiation of the pubertal rise in tonic gonadotropin secretion.[248] Thus, it is reasonable to infer that ovulation does not generally take place immediately following menarche because the reawakening hypothalamic–pituitary unit is held in check by the relatively small amounts of estradiol produced by the ovary at this stage of development. A detailed discussion of these ideas

has been presented by Foster and his colleagues.[244] The operation of a similar feedback mechanism may also be invoked to account for the observation in the male rhesus monkey that the pubertal postcastration rise in LH and FSH secretion at 2 years of age precedes, by approximately 6 months, a detectable increase in testicular testosterone secretion in intact monkeys.[49]

In both man and the rhesus monkey, the degree and duration of the juvenile reduction in gonadotropin secretion are noticeably more marked in the male (Figure 32.5). The relatively weaker and shorter application of the agonadal brake or restraint on gonadotropin release during juvenile development in the female, which presumably underlies the earlier onset of puberty in this sex, is most clearly reflected by FSH secretion. In agonadal female monkeys and girls, plasma concentrations of this gonadotropin during the juvenile phase of development are consistently greater than those in normal age-matched subjects. As in infancy, the relatively high circulating FSH:LH ratio in the agonadal juvenile female is associated with a low LH pulse frequency.[223,238,240]

The sex difference in the degree to which gonadotropin secretion is restrained by the nongonadal brake during juvenile development is reinforced by studies in juvenile monkeys of the effect of castration on the subsequent pattern of LH and FSH secretion. Orchidectomy at this stage of development fails to elicit a postcastration rise in either LH or FSH.[75,249,250] Instead, plasma levels of these gonadotropins are maintained for many months at values that are indistinguishable from those of intact animals. Although the results of analogous studies in the prepubertal female are somewhat inconsistent,[75,213,223,243,249,251] it is now generally accepted that, in contrast to the male, ovariectomy of juvenile rhesus monkeys between 12 and 15 months of age results in a small postcastration increase in gonadotropin secretion, which is most marked at night and most noticeable for FSH.[213,223,251]

Before leaving the role of sex steroids in the developmental control of gonadotropin release, it is worth noting that the possibility that adrenal sex steroids exert an inhibitory action on LH and FSH release in the juvenile primates is, at best, remote. Bilateral adrenalectomy in agonadal infantile male rhesus monkeys at 1 month of age does not interrupt the prepubertal hiatus in gonadotropin secretion,[124,252] and human subjects with primary adrenal insufficiency do not exhibit precocious puberty.[3,9]

NEUROBIOLOGICAL BASES OF THE JUVENILE HIATUS IN PULSATILE GnRH RELEASE AND INITIATION OF PUBERTY

In contrast to what might be anticipated, there is little evidence to suggest that the ability of the GnRH neuronal network to respond to potent secretagogues, such as glutamate, is at all compromised in the juvenile hypothalamus. Trains of intermittent GnRH discharges with a periodicity and amplitude similar to those generated by the hypothalamus of the adult may be provoked from the brain of juvenile male monkeys in response to hourly stimulation with NMDA.[22,220,253] NMDA is an analog of the acidic amino acid glutamate, a major excitatory neurotransmitter of the mammalian CNS.[254] Although studies of NMDA action on the hypothalamus of the prepubertal female monkey have utilized only single bolus administration of the glutamate receptor agonist,[255,256] repetitive stimulation of the stalk–median eminence region of the juvenile female monkey electrically or by direct application of an α_1-adrenergic receptor agonist will also elicit a train of GnRH discharges.[257,258]

These physiological findings are largely consistent with those describing GnRH mRNA and peptide content. In the agonadal male macaque, hypothalamic GnRH content as estimated by bioassay and RIA remains unchanged throughout postnatal life.[250,259] Moreover, in the rhesus monkey and some other species of primate, the distribution of GnRH neurons and their peptide content, as reflected by immunohistochemical analysis, are comparable in infant, juvenile, and adult animals,[260–266] Figure 32.6. The data on GnRH mRNA levels are less consistent. In the agonadal male rhesus monkey, the levels of this transcript as determined by RNAse protection are indistinguishable in the MBH of infant and juvenile animals,[267] but at the time of the pubertal resurgence of GnRH release, such animals show a modest increase in this mRNA.[250] In the intact male macaque, the pubertal increase in *GnRH* expression has been reported to be either exaggerated (qPCR)[268] or absent (in situ hybridization).[269] Although in one study of female monkeys, GnRH mRNA levels in the MBH of juvenile and pubertal aged animals were reported to be similar,[270] in another a robust increase in this mRNA has been noted during the juvenile—pubertal transition (Terasawa et al., unpublished observation).

These findings suggest that GnRH neurons in the juvenile hypothalamus are endowed with the molecular machinery required for generating an intermittent discharge of the peptide. Moreover, this molecular machinery may be prematurely activated with apparent ease either experimentally[22] or pathophysiologically, as in GnRH-dependent precocious gonardarche.[3,9,143,144,154] The biosynthetic properties of hypothalamic GnRH neurons in the juvenile may be contrasted with those of the gonadotroph at a comparable stage of development (Figure 32.7). In most instances, the magnitude of biosynthesis of a given secretory product is strongly coupled to the degree of cellular activation.[271] Thus, as expected in the absence of a GnRH drive during the juvenile phase of development, LH content of the gonadotroph and circulating levels of LH are at least an order of magnitude

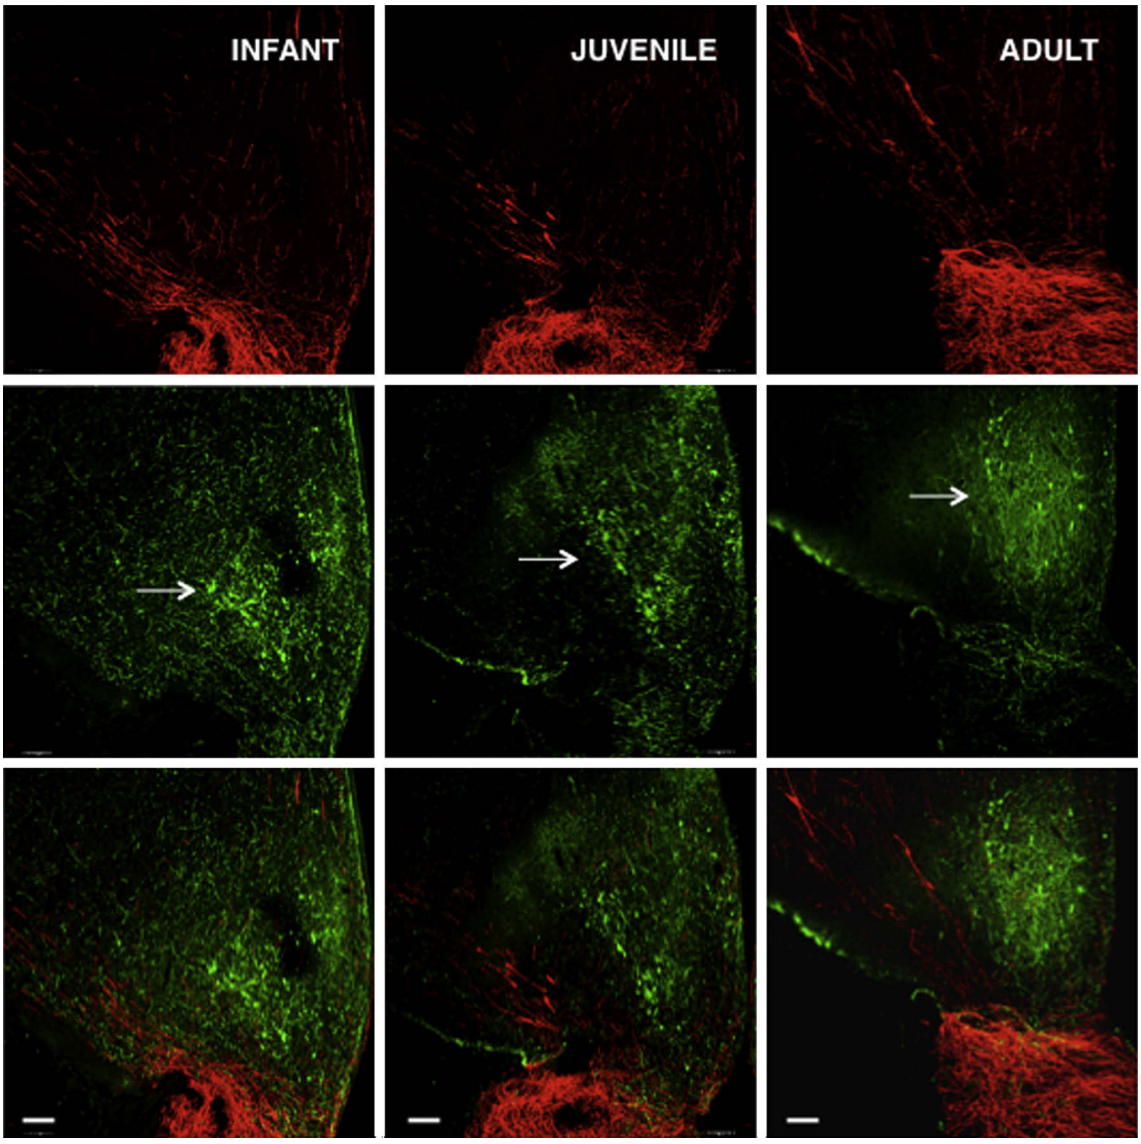

FIGURE 32.6 This figure is reproduced in color in the color plate section. Confocal images illustrating developmental changes in GnRH (top panels) and kisspeptin (middle panels) neurons (immunopositive perikarya and fibers) in the MBH at the mid-tuberal level during postnatal development in the agonadal male rhesus monkey. The lower panels show the merged images. A hemi-hypothalamic section is shown for an infant (left-hand panels), juvenile (center panels), and adult (right-hand panels) animal; stages of postnatal development corresponding to the on-off-on pattern of GnRH pulse generator activity in primates. Note that kisspeptin immunoactivity is reduced in the juvenile MBH at a time when GnRH pulsatility is arrested but GnRH immunoactivity in the median eminence is maintained during this phase of development. In most cases the ependymal lining of the third ventricle is visible on the right-hand boundary of each hemi-section. *Arrow* indicates kisspeptin neurons in the arcuate nucleus. lower than those observed in the infant or adult.[259] In addition, the mRNA levels encoding the LHβ and FSHβ gonadotropin subunits are low (Winters and Plant, unpublished observations), and the pituitary requires weeks of intermittent GnRH stimulation before an adult-like pattern of gonadotropin secretion is elicited.[221] From these data, it is reasonable to posit that (1) the GnRH neurons in the hypothalamus of the juvenile monkey are receiving stimulatory afferent input (thereby maintaining the cell's biosynthetic potential), and (2) the GnRH pulse generating system that leads to the intermittent discharge of the peptide into the hypophyseal portal circulation during infancy and puberty is restrained during juvenile development.

Kisspeptin

As described previously, compelling evidence is emerging to indicate that the output of the hypothalamic GnRH pulse generator is relayed to the GnRH neuronal network by an intermittent kisspeptin signal generated by KNDy neurons in the arcuate nucleus. That intermittent kisspeptin release in the region of the median eminence is attenuated during juvenile development in the

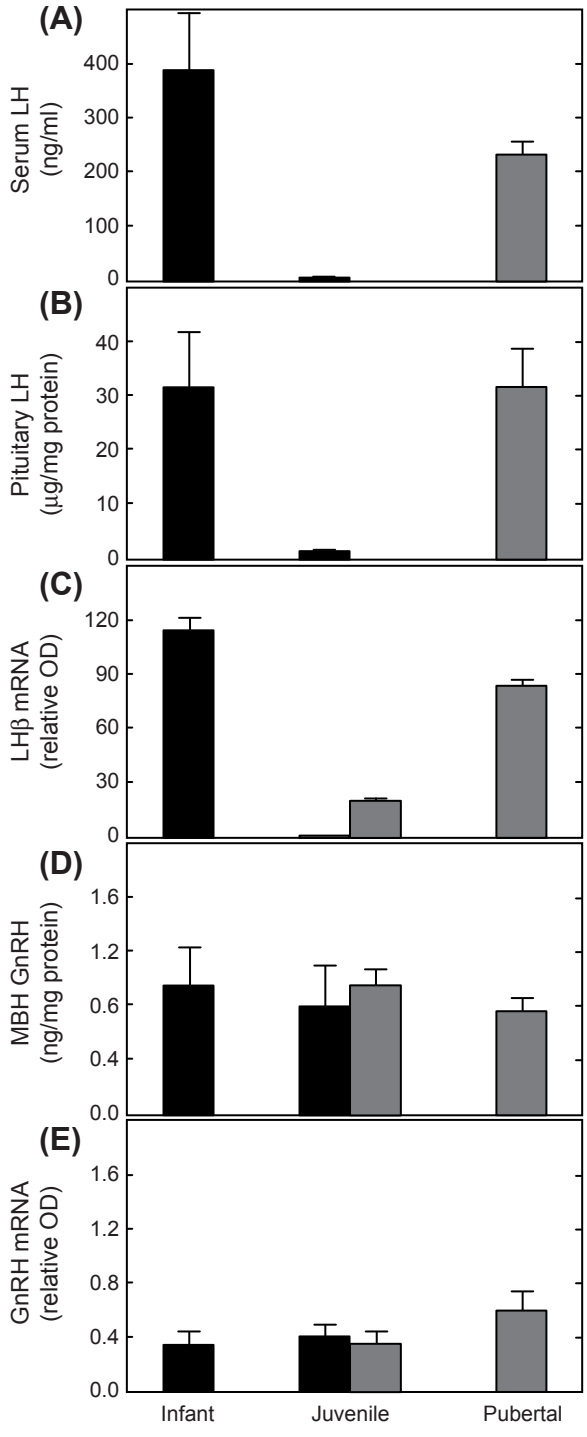

FIGURE 32.7 The hypogonadotropic state of the agonadal juvenile male monkey in comparison with that of the infant and pubertal state (panel A) is associated with a correspondingly low pituitary LH protein and LHβ mRNA content (panels B and C, respectively) but, interestingly, the content of GnRH peptide and mRNA in the MBH at this stage of development is maintained (panels D and E, respectively). Two histograms are shown for the juvenile stage of development because two separate groups of animals at this stage of development were studied: one was used in a study comparing infants and juveniles[267] (closed histogram) and one was used to compare juvenile and pubertal monkeys[250] (gray histogram). Means and SE are shown. *Source: Data for serum LH concentration, pituitary LH content, MBH GnRH peptide, and mRNA content redrawn from Refs 250, 259, 267. Data for LHβ; Winters SJ, Plant TM, unpublished observations.*

female monkey has been directly demonstrated[272,273] (Figure 32.8). Application of microdialysis to sample peptide release in the median eminence revealed that discharges of kisspeptin in this region of the hypothalamus during juvenile development were of low amplitude and occurred with a long interpulse interval, a pattern of release that contrasted to high amplitude and frequency release of kisspeptin in pubertal monkeys. This developmental change in pulsatile kisspeptin release was observed in both intact and ovariectomized females[273] and was similar to that of GnRH release in this region of the basal hypothalamus.[218,224] Importantly, the frequencies of kisspeptin discharges at the two stages of development were independent of the ovary. An impact of the ovary on kisspeptin release, as to be expected, was evident in the pubertal monkey, where both pulse amplitude and mean release of kisspeptin were markedly increased by ovariectomy, presumably due to loss of negative feedback from ovarian estradiol. Indeed, replacement of estradiol in pubertal ovariectomized animals suppressed kisspeptin release, while in prepubertal monkeys kisspeptin release was not affected by estradiol replacement.[273] Thus, peripubertal changes in ovarian steroid regulation of kisspeptin release are similar to those seen with GnRH release.[247] The attenuation in pulsatile kisspeptin release in the median eminence in the juvenile monkey is associated with a low level of *KISS1* expression in the MBH (presumably in the arcuate nucleus) in ovarian intact female and agonadal male monkeys.[274]

The changes in *KISS1* expression during the juvenile–pubertal transition in the agonadal male is paralleled by changes in the peptide (Figure 32.6).

Studies of KNDy neurons in the infant and of how their function changes in the transition to the juvenile stage of development when robust activity of the GnRH pulse generator is being brought into check by the "off" switch are scant. However, a recent study of the agonadal male monkey has shown that the number of immunopositive kisspeptin neurons in the MBH is greater in the infant than in the juvenile, thus paralleling the decline in GnRH pulsatility during this developmental transition,[266] Figures 32.6 and 32.9. The latter result is consistent with the notion that the reduction in pulsatile GnRH release during the infantile–juvenile transition may be causally related to a decrease in the kisspeptin output of the GnRH pulse generator, an idea further supported by the finding from human genetics that an infant boy with loss of function mutation in KISS1R was reported to be hypogonadotropic.[275] Taking the foregoing considerations together, it seems reasonable to propose that the neurobiology underlying the switch that leads to the attenuation of pulsatile GnRH release during the transition from infantile to juvenile is thrown into reverse at the termination of the juvenile phase of development.

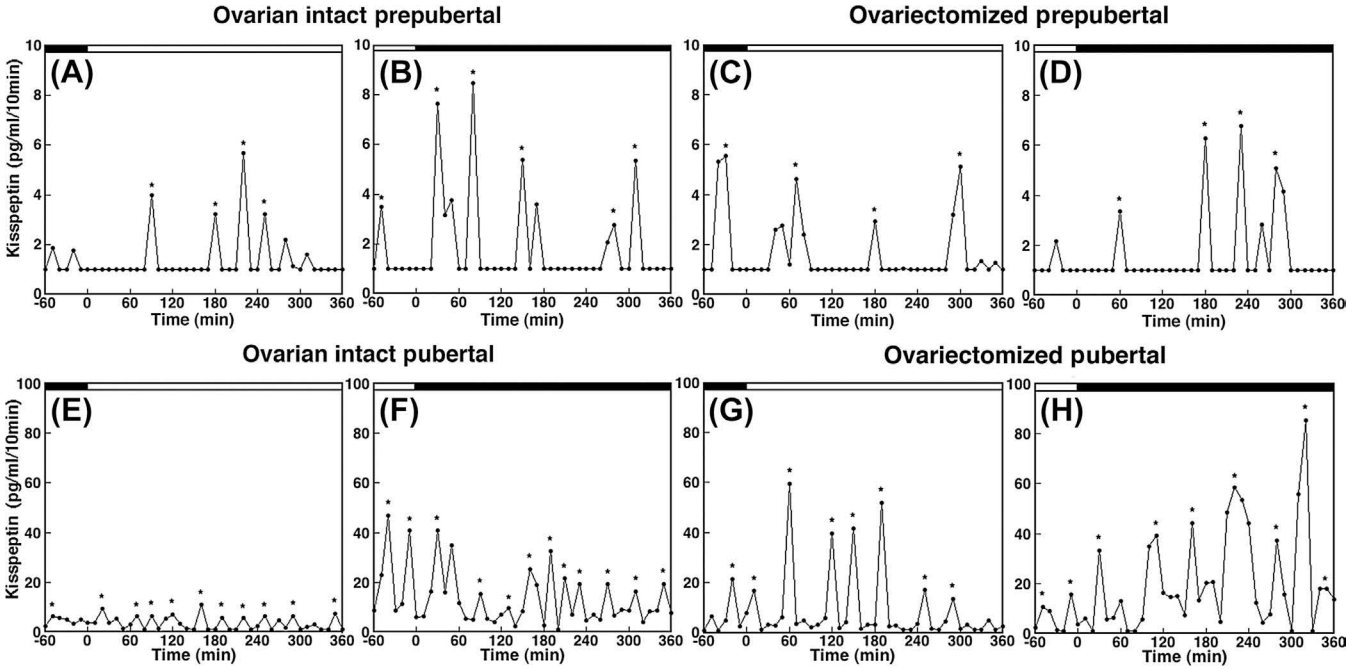

FIGURE 32.8 Pulsatile kisspeptin release in the region of the pituitary stalk and median eminence of ovarian intact prepubertal (panels (A) and (B)) and pubertal (panels (E) and (F)) monkeys, and ovariectomized animals at similar stages of development (panels (C) and (D), and (G) and (H), respectively) as assessed by microdialysis. Note that the scale on the *y*-axis in panels (E)–(H) (pubertal monkeys) is 10-fold higher than that in panels (A)–(D) (prepubertal monkeys). The dark phase of the light–dark cycle is indicated on the top of each of the eight panels with a dark solid line. *Asterisks* indicate increments in kisspeptin identified as pulses by PULSAR. *Source: Modified with permission from Ref. 273.*

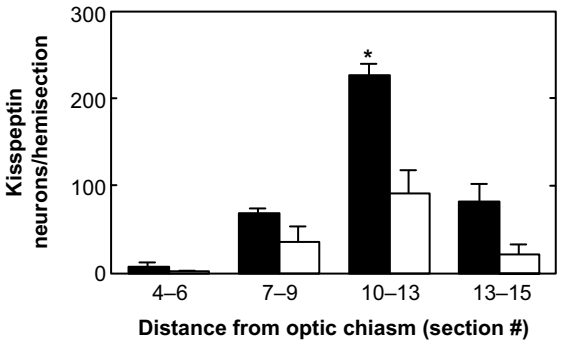

FIGURE 32.9 The number of kisspeptin neurons per hemi cross-section throughout the arcuate nucleus of the agonadal infant male monkey (closed histograms) is greater than that in juveniles monkeys of similar gonadal stature (open histograms). Section number indicates distance posterior from the optic chiasm with section 1, the first retrochiasmatic section. The distance between two sequentially numbered sections was 250 μm. * $p < 0.05$. *Source: Reprinted with permission from Ref. 266.*

That an attenuated kisspeptin output from the GnRH pulse generator is the proximal cause of diminished GnRH release in the juvenile is also supported by the finding that in the agonadal juvenile male monkey (with a GnRH primed pituitary), repetitive stimulation of the GnRH neuronal network with hourly intravenous injections of kisspeptin is able to induce a premature and sustained train of LH discharges similar to that produced by spontaneous GnRH pulse generator activity in pubertal animals,[276] Figure 32.10. It is important to note that in this model the kisspeptin-induced train of LH pulses is abolished by concomitant administration of a GnRH receptor antagonist, confirming a hypothalamic action of kisspeptin.[276] Dose-dependent kisspeptin-induced GnRH release in the median eminence of the juvenile female monkey has been directly demonstrated using microdialysis,[277] further suggesting a causal relationship between the reduced kisspeptin output and low levels of GnRH release during this phase of prepubertal development.

From the foregoing discussion it is apparent that the critical role of kisspeptin in the initiation of puberty can be accounted for entirely by the role of this neuropeptide in mediating the output of the GnRH pulse generator. This realization led us to recently propose a new model for the control of the timing of puberty in primates.[168] According to this model (Figure 32.11), kisspeptin neurons in the arcuate nucleus play no regulatory role in dictating the timing of puberty. Rather, as a component of the hypothalamic GnRH pulse generator, they are a slave to the upstream regulatory mechanisms that determine puberty onset.

Expression of *KISS1R* by GnRH neurons has been demonstrated in non-primate species using in situ hybridization,[278] and therefore the question of whether changes in KISS1R signaling in GnRH neurons also contribute to the hiatus in kisspeptin tone to the GnRH neuronal network during juvenile development merits

consideration. KISS1R mRNA levels in the MBH increase during puberty in the intact female monkey, although this was not observed in the agonadal male[274] and studies of expression of this receptor specifically by primate GnRH neurons have not been conducted. Nevertheless, kisspeptin-induced GnRH release in the female monkey is larger in pubertal animals than in juveniles,[277] indicating that an increase in responsiveness of the GnRH neuronal network to kisspeptin stimulation contributes to the pubertal resurgence of pulsatile GnRH release.

Amino Acid Neurotransmitters

γ-Aminobutyric acid (GABA) and glutamate are the major inhibitory and stimulatory neurotransmitters, respectively, in the CNS,[279] and both appear to be intimately involved in the regulation of the postnatal pattern of pulsatile GnRH release.

As described previously, sustained trains of GnRH-induced LH discharges may also be elicited from the MBH of the juvenile male by repetitive activation of hypothalamic NMDA receptors.[253] Moreover, the time course of these LH discharges is essentially identical to that induced by intermittent intravenous infusion of kisspeptin,[276] and, as with kisspeptin, hypothalamic glutamate release increases at the time of puberty in the female rhesus monkey[280]; Figure 32.12. Furthermore, a preliminary study indicates that the competitive NMDA receptor antagonist, DL-2-amino-5-phosphono-pentanoic acid, can interrupt GnRH pulse generator activity in the adult monkey.[281] The exact relationship between the excitatory amino acid and the neuropeptide in the context of GnRH pulse generation, however, remains to be elucidated. Although non-NMDA receptors, and in particular kainate receptors, are most highly expressed in the region of the arcuate nucleus/median eminence in the monkey (T.M. Plant, unpublished data), intermittent stimulation of the juvenile hypothalamus with kainic acid, in contrast to that with NMDA, fails to sustain a train of GnRH-induced LH discharges.[282]

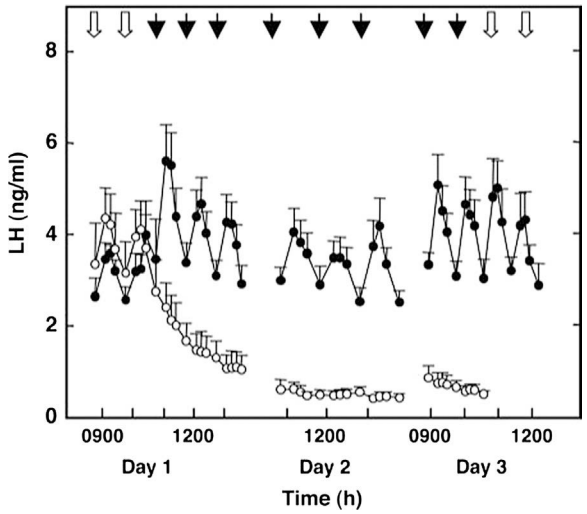

FIGURE 32.10 LH responses in agonadal GnRH primed juvenile male rhesus monkeys ($N=4$) during the last two priming infusions of GnRH (administered on Day 1 at 0900 and 1000 h, open arrows) and during brief hourly intravenous infusions of either kisspeptin or vehicle (black arrows) initiated on Day 1 at 1100 h and maintained for 48 h. The response to the experiment in which kisspeptin was administered is shown by the black data points. Note that although the kisspeptin and vehicle injections were administered without interruption for 48 h, only those injections to which the LH response was monitored are indicated. The LH response to the first two repriming pulses of GnRH are shown for the kisspeptin experiment (administered on Day 3 at 1100 and 1200 h, open arrow). The priming infusion before and after the kisspeptin infusion produces a pulsatile discharge of LH comparable to that observed spontaneously in pubertal animals. The response to repetitive kisspeptin administration was abolished by concomitant treatment with a GnRH receptor antagonist (data not shown), indicating the intermittent kisspeptin infusion provides the GnRH network of the juvenile hypothalamus with a stimulus similar to that produced endogenously by the GnRH pulse generator in pubertal animals. Vertical lines above data points indicate SEM. *Source: Reprinted with permission from Ref. 276.*

In the case of GABA, a series of studies of the female monkey has provided unequivocal evidence that this amino acid plays a critical role in maintaining the suppression of pulsatile GnRH release throughout juvenile development.[100] In one study, chronic repetitive administration of bicuculline (a $GABA_A$ receptor antagonist) into the base of the third cerebroventricle in the juvenile female led to precocious puberty, as reflected by premature menarche and first ovulation.[283] That this precocity was the result of premature and sustained GnRH pulsatility is supported by the following studies. Employing push–pull perfusion or microdialysis of the stalk–median eminence to quantitate neuropeptide and neurotransmitter release in the hypothalamus of the female monkey, the pubertal rise in GnRH secretion and, interestingly, the associated increase in glutamate release were demonstrated to be temporally coupled to a decrease in GABA release in this region of the brain.[280,284] Moreover, an acute reduction of GABA signaling in the stalk–median eminence region of the juvenile monkey induced by local administration of bicuculline, or antisense oligodeoxynucleotide for the mRNA encoding the GABA-synthesizing enzyme, glutamic acid decarboxylase 67 (GAD 67), elicited an immediate discharge of GnRH,[284,285] which was associated with an increase in glutamate release.[280] More recently, similar bicuculline injections to juvenile female monkeys have been shown to induce kisspeptin release,[286] Figure 32.13. In contrast, bicuculline infusion into pubertal female monkeys failed to stimulate either GnRH or kisspeptin release.[284,286] The elevated levels of GABA release in the juvenile hypothalamus of the female are associated with an increase in GABA synthesis, as infusion of antisense oligodeoxynucleotide for the mRNA encoding GAD 67 into the median eminence greatly stimulates GnRH release in juvenile monkeys,

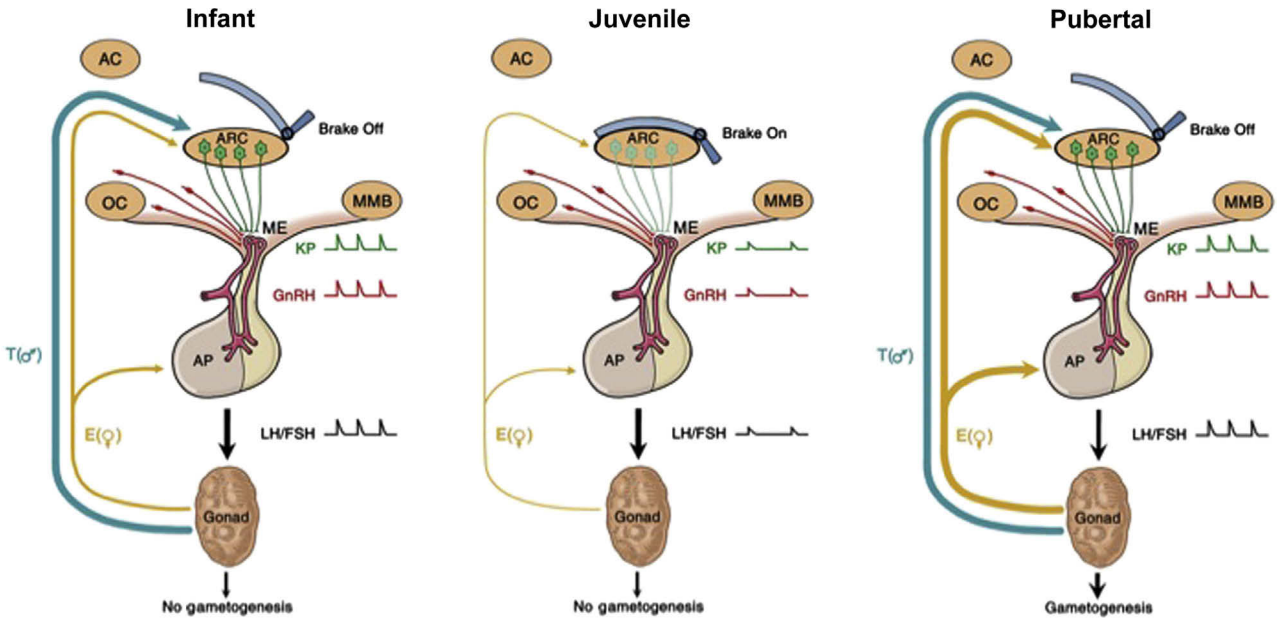

FIGURE 32.11 A model for the control of the timing of puberty. The role of kisspeptin signaling is posited to be a critical component of the neural machinery that generates pulsatile gonadotropin-releasing hormone (GnRH) release from the hypothalamus (the hypothalamic GnRH pulse generator). In this model, the hypothalamic GnRH pulse generator resides in the arcuate nucleus (ARC) and the output of the pulse generator is relayed to GnRH terminals in the median eminence (ME) by kisspeptin projections arising from KNDy neurons in the ARC. During infancy (*left panel*), GnRH pulse generator activity is robust, leading to intermittent release of kisspeptin in the ME, resulting in a corresponding pattern of GnRH release into the portal circulation. This, in turn, drives pulsatile gonadotropin secretion. In the transition from infancy to the juvenile phase of development (*middle panel*), a neurobiological brake restrains the GnRH pulse generator and pulsatile release of kisspeptin in the ME is markedly suppressed. This leads to reduced GnRH release and to a hypogonadotropic state in the juvenile period. Puberty is triggered when the neural brake is released and GnRH pulse generator activity with robust intermittent release of kisspeptin in the ME is reactivated (*right panel*). According to this model, the mystery of primate puberty lies in the nature of the neurobiological brake and in the mechanism that times its application during infancy and its release at the end of the juvenile phase of development. It should be noted that the ability of the postnatal gonad to respond fully to gonadotropin stimulation is not acquired until the juvenile stage of development, by which time luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion is low as a result of the GnRH pulse generator being brought into check. The thickness of the arrows (T, testosterone and E, estradiol) from gonad to ARC indicating negative feedback by the testis and ovary, respectively, reflects the degree of gonadal steroid inhibition exerted on LH secretion at these three stages of development. whereas the same antisense oligodeoxynucleotide infusion in pubertal monkeys results in significantly smaller GnRH increase.[285,287] Importantly, there is a temporal relationship between the decrease in GABA and the increase in glutamate when antisense oligodeoxynucleotide is infused into the median eminence.[280] Specifically, a decrease in GABA release in the stalk–median eminence triggers a GnRH discharge with a subsequent increase in glutamate release in this hypothalamic region that further contributes to the pubertal increase in GnRH. In the male monkey, on the other hand, it is unclear whether GABA inhibition is responsible for the juvenile hiatus of GnRH release, as equivalent experiments have not been conducted and the expression of GAD 65 and GAD 67 mRNA[250,288] does not change across puberty. In the infant–juvenile transition during the attenuation in GnRH pulse generator activity, however, GAD 65 and GAD 67 mRNA levels increase in the male hypothalamus.[267]

Additional support for a role of GABA comes from clinical observations in which administration of loreclezole, a GABA agonist, to an 11-month-old girl with epilepsy and precocious gonadarche, led to decreased LH secretion and regression in pubertal development.[289] Pubertal delay has also been reported in epileptic boys treated with valproic acid, a drug with GABAergic activity.[290] It should be noted, however, that the pharmacology of valproic acid is complex, and others have reported that this drug, like other antiepileptic agents, does not invariably delay sexual maturation.[291]

While the foregoing considerations provide compelling evidence in support of the view that both GABA and glutamate play an important role in dictating the kisspeptin output of the GnRH pulse generator during juvenile development and the transition into puberty in females, it is likely that additional regulatory factors are yet to be identified. In this regard, the induction of precocious menarche in response to repetitive bicuculline administration to juvenile female monkeys (see above) appears to be related to the age at which GABA antagonism is initiated: the younger the age the longer

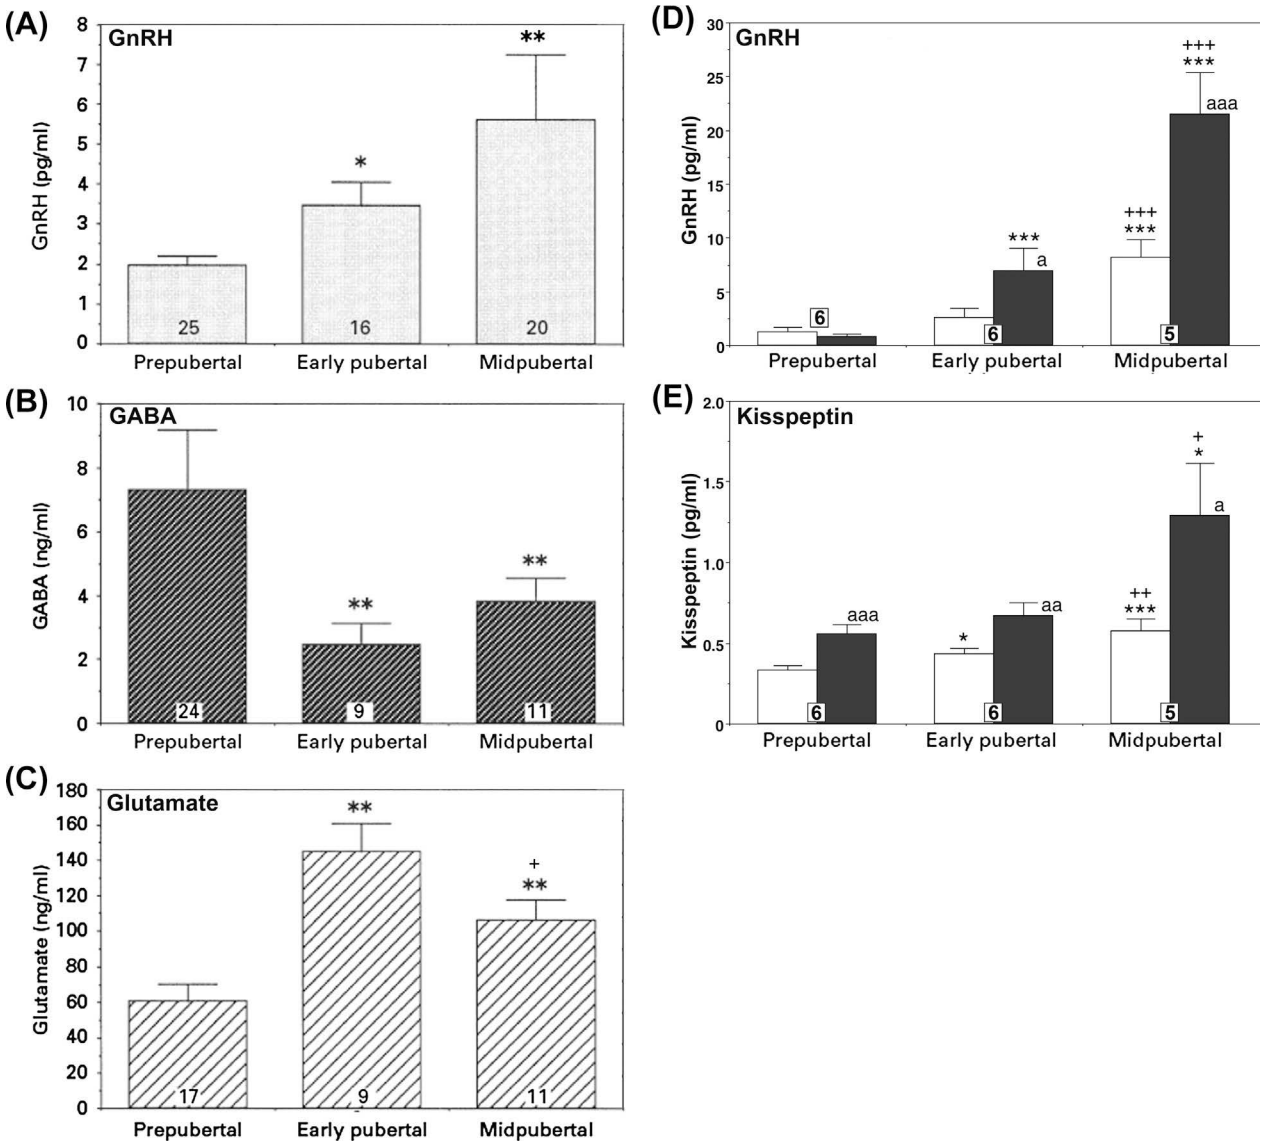

FIGURE 32.12 Release of GnRH (A) and (D), GABA (B) glutamate (C), and kisspeptin (E) in the stalk–median eminence of ovariectomized pre-, early- and mid-pubertal female rhesus monkeys, as measured in hypothalamic perfusates. GnRH (A), GABA (B), and glutamate (C) were measured in the same samples obtained in one study[280] and GnRH (D) and kisspeptin (E) were measured in the same samples obtained in another study.[272] In the first study (A)–(C), samples were collected in the morning only, whereas in the second study (D and E), samples were collected in the morning (open bars) and evening (closed bars). *$p<0.05$ versus prepubertal; **$p<0.01$ versus prepubertal; ***$p<0.001$ versus early pubertal; +$p<0.05$ versus prepubertal; ++$p<0.01$ versus early pubertal; +++$p<0.001$ versus early pubertal; a $p<0.05$ versus AM; aa $p<0.01$ versus Am, aaa $p<0.001$ versus AM. $N=5$–25 (see individual bars). *Source: Reproduced with permission from Refs 272,280.*

the duration to precocious menarche (Terasawa, unpublished observations).

Neuropeptide Y

Evidence obtained primarily with the male rhesus monkey indicates that neuropeptide Y (NPY) may be an important component of the neurobiological brake responsible for restraining pulsatile GnRH release during juvenile development.[250] First, changes in hypothalamic *NPY* expression and NPY content during the transition from the infant to the juvenile and to the pubertal phase of development in agonadal male monkeys are inversely related to those in pulsatile GnRH release; namely *NPY* expression is elevated during the juvenile phase of development and low in association with robust GnRH pulse generator activity during infancy and at puberty. Second, a marked inhibition of pulsatile GnRH release is observed in agonadal postpubertal male and female monkeys following central administration of NPY.[292–294] Although the inhibition of GnRH release in the postpubertal situation is mediated, at least in part, by the NPY

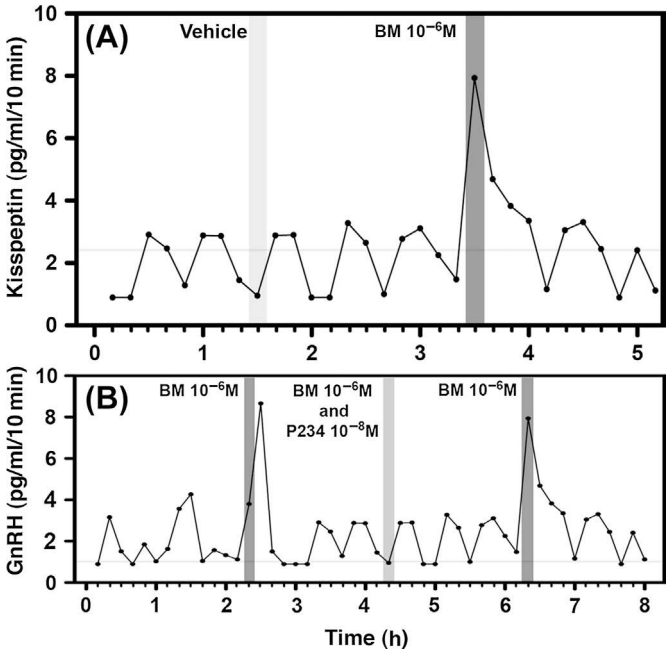

FIGURE 32.13 Panel (A): A brief 10 min infusion of the $GABA_A$ antagonist, bicuculline (BM) into the stalk–median eminence region (dark shaded vertical bar) stimulates kisspeptin release in a prepubertal female monkey. Panel (B): Coinfusion of the kisspeptin receptor antagonist, peptide 234 (P234), and BM (light shaded vertical bar) blocks the action of the $GABA_A$ antagonist and elicits GnRH release. *Source: Reprinted with permission from Ref. 286.*

Y1 receptor, the pharmacological data supporting a role for this receptor sub-type in the prepubertal attenuation of pulsatile GnRH release are tenuous.[292] Also, the search for inactivating mutations of the NPY Y1 receptor gene in children with GnRH dependent precocious gonadarche (see below) has not been successful.[295,296]

In addition to the posited inhibitory action of NPY on GnRH release during juvenile development (discussed previously), this neuropeptide has also been implicated in the stimulation of GnRH release at the time of puberty and in adulthood. In both pubertal and postpubertal female monkeys, but not in prepubertal subjects, NPY infusion in the region of the median eminence stimulates GnRH release,[294,297,298] and infusion of NPY antibody or antisense oligodeoxynucleotide for NPY mRNA in this hypothalamic area suppresses GnRH release.[297,299] The pubertal emergence of this stimulatory action of NPY on GnRH release is associated with an amplification of pulsatile release of NPY in the median eminence that is temporally coupled to that of GnRH.[297,300] The most parsimonious explanation to account for the paradox of the inhibitory and excitatory actions of NPY on GnRH release is to posit two subsets of NPY neurons.[301] One subset comprises a component of the brake that holds the GnRH pulse generator in check during juvenile development. The other subset comprises a component that appears to be related to GnRH pulse generation and is only manifest after the juvenile brake on the GnRH pulse generator has been lifted. Whether these two putative subsets of NPY perikarya are anatomically distinct has not been examined.

Opioid Peptides

The opioid peptides were the first to attract attention as potential candidates responsible for the attenuation of pulsatile GnRH release in the juvenile because of their established inhibitory action on GnRH secretion in sexually mature monkeys and human beings,[302–306] and because endogenous opioid peptides are known to exert presynaptic inhibition in the magnocellular system.[307] Administration of opioid antagonists such as naloxone and naltrexone, however, has consistently failed to release the prepubertal brake on the GnRH pulse generator as reflected by the failure of these drugs to elicit LH secretion in prepubertal children,[308–311] chimpanzees,[312] and rhesus monkeys.[255,313,314] The failure to detect naloxone-induced GnRH release during the prepubertal period cannot be accounted for by the decreased sensitivity of the gonadotrope during this phase of development since, in studies of the monkey, the responsivity of these pituitary cells to GnRH was greatly heightened prior to the studies with exogenous GnRH.[313] Additionally, puberty in the male monkey appears to be associated with an up-regulation of the POMC gene.[269] Consistent with this report, preliminary data in female monkeys indicate that β-endorphin release in the stalk–median eminence region increases in association with puberty onset.[315]

Other Neuronal Factors

Peripheral intravenous administration of cholecystokinin (CCK), like that of kisspeptin is also able to elicit precocious GnRH release in the agonadal juvenile male monkey.[316] In the context of the timing of the pubertal resurgence in GnRH release, this action of CCK, which is associated with a generalized activation of the neuroendocrine hypothalamus, has not been further examined. Finally, acute central administration of methoxamine, an α_1-adrenergic receptor agonist, can elicit a GnRH discharge in the premenarcheal rhesus monkey,[258] whereas intravenous injection of the α-adrenergic receptor antagonist phentolamine blocks GnRH pulsatility in the adult female.[317,318]

Glial-Derived Growth Factors

Glial-derived growth factors, such as transforming growth factor (TGF) α, neuroregulins, and their cognate ERBB transmembrane tyrosine kinase receptors, play a role in the timing of puberty in the rat (see Chapter 30).

The actions of these growth factors on GnRH neurons are stimulatory and indirect, involving autocrine/paracrine actions of factors such as prostaglandin E2 released from neighboring astrocytes. Studies of the monkey in this regard are limited: TGFα mRNA in the hypothalamus of the female rhesus monkey is increased dramatically at the time of puberty,[270] although in the agonadal male expression of this gene is only marginally increased at a corresponding stage of hypothalamic development.[250] Further support for the view that glial factors may play a role in the pubertal resurgence in GnRH release in highly evolved primates is provided by findings that hypothalamic lesions result, on the one hand, in an astrocytic response that includes activation of TGFα and expression of ERBB receptors,[319,320] and, on the other hand, may be associated with precocious gonadarche in children[321–323] and in juvenile monkeys.[324] Thus, precocity in primates associated with hypothalamic lesions, and in children who have been subjected to chemotherapy or cranial irradiation, or who have sustained head trauma,[321–323] may result from increased ERBB signaling rather than by interruption of inhibitory inputs to the GnRH network, as was previously proposed.[325] Additionally, hamartomas removed from two patients with precocious gonadarche have been found to be rich in astrocytes containing TGFα, but devoid of GnRH neurons,[325] again indicating a role of increased ERBB signaling in the etiology of this precocity. These arguments, which have been primarily articulated by Ojeda and his colleagues,[325] are consistent with the finding in the rat that infusion of an ERBB receptor antagonist at the site of the hypothalamic lesion prevents the puberty-advancing action of the lesion.[319]

Structural Remodeling

Regardless of the relative importance and identities of transynaptic and astroglial systems that underlie the neurobiological brake on the GnRH pulse generator during juvenile development, it is reasonable to propose that this brake will involve a reorganization of the anatomic substrate that governs the control of the GnRH pulse generator. The capacity for structural plasticity within the mammalian brain appears to be associated with the expression of the "embryonic" or polysialic acid—neural cell adhesion molecule,[326] and a study of the rhesus monkey employing immunocytochemical and immunoblot analysis has demonstrated that this cell surface glycoprotein is expressed in the region of the arcuate nucleus and median eminence.[327] Although it is not known whether the arcuate nucleus is remodeled during postnatal development in primates, quantitative ultrastructural studies have demonstrated that synaptic input to GnRH perikarya in the MBH of the agonadal male monkey declines in association with the pubertal resurgence in pulsatile GnRH release. Interestingly, this structural remodeling during peripubertal development in the monkey has only been observed in the MBH.[328] On the other hand, the degree of glial ensheathment of GnRH neurons in the MBH of agonadal monkeys did not appear to be developmentally regulated,[328] although peripubertal changes in glial ensheathment have been reported in the preoptic area in the female rhesus monkey.[329]

It will be obvious from the foregoing discussion of the neurobiological basis of the juvenile hiatus in GnRH pulse generator activity that our understanding of this phenomenon is at best fragmentary. Moreover, in some cases, for example, that of the role of GABA, studies have been restricted primarily to the female, while in others the male has been the primary sex examined. As such, it is not possible to provide a useful summary of either (1) the relative importance of various neurotransmitters, neuropeptides, and glial factors underlying the hiatus, or (2) whether there are qualitatively sex differences in the neural mechanisms utilized to achieve the hiatus.

THEORETICAL PHYSIOLOGICAL CONTROLS GOVERNING THE DURATION OF THE PREPUBERTAL HIATUS IN GnRH SECRETION

Two theoretical physiological control systems may be invoked to account for the prepubertal hiatus in GnRH pulse generator activity in highly evovled primates. One involves the concept of a central neural timekeeping mechanism able to measure age and programmed to operate a gating system that would interrupt GnRH pulse generator activity from infancy to puberty. The other model requires positing a central neural mechanism capable of tracking one or more hormonal signals that reflect somatic size/growth/maturation.[330] Such a somatometer would, in turn, govern the postnatal ontogeny of GnRH release in much the same fashion proposed for the first model of a pubertal clock.

Attempts to examine the anatomic location of such putative control systems have been made using a classical technique known as surgical deafferentation, whereby the MBH is isolated from the rest of the brain and the impact on the pituitary–gonadal axis is monitored. When this procedure was performed on juvenile female monkeys, the age at the onset of puberty was similar to that of control monkeys.[331,332] In contrast to surgical deafferentation of the MBH in adults,[333] however, the diurnal variation in cortisol secretion was not abolished in the pubertal animals,[331,332] suggesting that isolation of the GnRH network from extrahypothalamic inputs may have been incomplete. Thus, it is premature to conclude that the entire neural component of the puberty control system resides within this area of the hypothalamus.

Somatometer

In considering a somatometer, it has been long viewed as axiomatic[334] that growth to maturity is required before an animal can breed. Thus, the notion that the attainment of a particular body size or composition provides the trigger for initiation of puberty has attracted considerable attention. Examination of the relationship between physical growth and the onset of puberty in primates has been restricted primarily to the human female, with menarche providing the usual endpoint. Attention was first drawn to a close correlation between the age of menarche and the rate of skeletal maturation.[335,336] Later, Frisch and Revelle,[337] stimulated by studies of the relationship between body weight and the onset of puberty in rats,[338] drew attention to their observation of a relationship between menarche and the attainment of a mean body weight of approximately 47 kg. This association led the latter workers[337] to propose the hypothesis "that attainment of a body weight in the critical range causes a change in metabolic rate, which, in turn", is responsible for an increase in hypothalamic drive to the pituitary gonadotrophs.

Shortly after the formulation of this so-called "critical weight hypothesis", Frisch and her colleagues modified their views to include the concept of threshold or critical body composition for puberty.[339] Specifically, menarche was argued to be most closely correlated with attainment of a particular proportion of body fat. According to such hypotheses, the secular trend toward an earlier age at menarche (see previously) is attributed to attainment of a threshold body weight or composition at a progressively younger age as a result of a corresponding secular improvement in the standard of living, including better nutrition and health care. Although the specific hypotheses of Frisch and her colleagues have been criticized on the basis of methodological and statistical grounds,[340–344] the isolation in 1994 of leptin, a protein that is secreted by adipocytes and regulates feeding behavior and body weight by providing the hypothalamus with information on fat mass,[345,346] rekindled interest in the Frisch hypotheses. Indeed, an enormous effort was expended over the ensuing decade to examine the role of this adipocyte hormone in the timing of gonadarche. Next we consider the evidence for a role for leptin and other putative endocrine and metabolic signals that might relay information on somatic development to the brain.

Leptin

Leptin, encoded by the leptin gene (*LEP*), is primarily secreted by adipocytes and regulates feeding behavior and body weight by providing the hypothalamus with information on fat mass and energy status (see Chapter 35). Leptin action is mediated by leptin receptors, which are single transmembrane domain receptors. Six isoforms of the leptin receptor have been described; all represent alternatively spliced products derived from a single gene (*LEPR*) located in man at chromosome 1p31.3.[347] The phenotype of individuals with deficits in leptin signaling, resulting from loss of function mutations in either *LEP* or *LEPR* include morbid obesity, abnormal eating behaviors, and lack of spontaneous pubertal development.[348–350]

Cross-sectional and longitudinal studies of both boys and girls indicate that circulating leptin concentrations increase during pubertal development.[351–355] Moreover, the pubertal increases in circulating leptin concentrations in children are inversely related to changes in levels of the soluble leptin receptor,[356,357] indicating that the rise in bioavailable leptin at this stage of development may be more robust than that of total immunoactive leptin. The binning of leptin data with respect to Tanner stages of pubertal development in the foregoing studies, and the paucity of detailed longitudinal information on both leptin levels and LH pulsatility during transition from Tanner stage 1 to stage 2, however, does not allow the question of whether circulating leptin increases immediately prior to the initiation of gonadarche to be addressed. One exception to this situation has been provided by the longitudinal study of eight boys in whom increments in circulating leptin concentrations over a period of several months to a year were reported to occur prior to nocturnal elevations in testosterone secretion.[358] As previously noted,[359] however, the leptin levels reported in the latter study were extremely variable, and the seemingly tantalizing increments of circulating levels of leptin were actually rather trivial in many of the subjects. Moreover, in contrast to normal puberty, circulating leptin concentrations were unchanged at the time gonadarche was initiated in boys with constitutional delay in growth and puberty.[360]

The relationship between circulating leptin levels and the onset of gonadarche in other species of highly evolved primates has been examined in the rhesus monkey. In the female, circulating leptin levels at the initiation of gonadarche, as identified by increased nocturnal LH secretion, have been reported to be greater than those observed at 14 months of age.[361] In the male monkey, however, the longitudinal relationship between the onset of nocturnal testosterone secretion and plasma leptin levels is unremarkable.[362] Results from cross-sectional studies of the male monkey[363,364] are also consistent with the view that gonadarche in the male is triggered in the absence of a rise in circulating leptin. Moreover, studies of the agonadal male rhesus monkey suggest that both the restraint and the resurgence of GnRH pulse generator activity during infancy and at the end of the juvenile phase of development, respectively, occur in the absence of changes in circulating leptin concentrations.[362,365]

Daily administration of recombinant human leptin in intact female rhesus monkeys, starting at 1 year of age, was associated with increased circulating LH concentrations at 14 months of age, when compared to those in the control group.[361] Nocturnal LH secretion was also detected earlier in the leptin-treated group, and this was associated with a 2-month earlier menarche, although premature menstrual cyclicity was not observed. In agonadal males, however, a continuous 16-day intravenous infusion of recombinant human leptin did not trigger precocious activation of GnRH pulse generator activity.[366]

In contrast to the lack of compelling data to support the hypothesis that increased leptin signaling provides the pivotal cue timing the pubertal resurgence of pulsatile GnRH release, several clinical observations support the idea that this hormone is nevertheless obligatory, in a permissive sense, for initiation of this critical developmental event.[359] Over the last 15 years, leptin replacement has been administered to several patients with leptin deficiency due to *LEP* mutations. When administered at an age appropriate for puberty, leptin promoted pubertal development. Importantly, there has been no evidence of premature puberty in younger children following replacement treatment.[349,367–369] Moreover, among children with GnRH-dependent precocious puberty, leptin concentrations correlated with body mass index and not pubertal status.[370] These findings provide compelling evidence that the action of leptin, albeit obligatory for the onset of puberty, is nevertheless permissive.[371–374] This action of leptin may require only low circulating levels of the adipocyte hormone because normal pubertal development in both male and female subjects with various lipodystrophies has been reported despite low leptin concentrations.[375,376] Similarly, regular menstruation in underweight postpubertal women has also been observed in the face of marked hypoleptinemia.[377]

The neuronal targets for leptin's action in the hypothalamus to permit puberty to unfold and allow GnRH pulsatility to be maintained postpubertally are an area of considerable contemporary interest, but one that is being pursued primarily in non-primate models (see Chapter 35). While it is generally recognized that GnRH neurons do not express *LEPR*, data obtained in rodents and sheep regarding expression of this receptor by KNDy neurons are inconsistent, and the site of action of leptin may be upstream to the GnRH pulse generator.[378] Interestingly, recent studies of transgenic mice[379–381] indicate that GABA neurons expressing leptin receptors may play a role in puberty onset in this rodent. Since GABA plays a critical role in the control of primate puberty, it will therefore be important to examine whether hypothalamic GABA neurons in the monkey express leptin receptors and, if so, their role in controlling gonadarche is established.

Growth Hormone and Insulin-like Growth Factor-1

Growth hormone (GH) plays a major role in the regulation of somatic growth, and, therefore, the finding that puberty is markedly delayed in children with isolated GH deficiency[382] raises the possibility that GH may be involved in the interface between somatic development and the timing of the onset of puberty. Although this is an attractive notion, it has been generally recognized that changes in GH secretion during puberty, at least in man, are the consequence, rather than the cause, of the underlying neurobiological events triggering puberty.[9,383] Thus, the pubertal rise in GH secretion in humans[384–388] and the concomitant increase in circulating insulin-like growth factor-1 (IGF-1) concentrations,[389–392] which has also been reported for the rhesus monkey,[393,394] baboon,[47] and chimpanzee,[26] are absent in agonadal subjects of pubertal age[395] and may be mimicked in sexually infantile children or in subjects with delayed puberty by treatment with sex steroids.[396–399] Moreover, the enhanced GH secretion that is observed in precocious puberty is suppressed when the drive to the pituitary–gonadotrope axis is interrupted with GnRH analog treatment.[391,400]

The notion of a causal relationship between the neuroendocrine axis governing growth and that regulating gonadarche has been championed by Wilson and his colleagues at the Yerkes National Primate Research Center, based primarily on their studies of the female rhesus monkey. This was prompted by the finding that, in the perimenarcheal female rhesus monkey, the onset of the pubertal rise in LH secretion was preceded by about 6 months with a marked daytime rise in the circulating GH concentration.[83] Moreover, the same temporal relationship between the pubertal LH increase and GH secretion was observed in animals that were ovariectomized premenarcheally and subsequently treated with estradiol,[83] suggesting that, in contrast to man, the increase in GH secretion at this stage of development may not be triggered by the rise in estrogen secretion. An increase in GH secretion in association with the pubertal resurgence in pulsatile GnRH release has also been reported for the agonadal male rhesus monkey.[401,402]

The effects of perturbing GH status on the timing and tempo of puberty in the female rhesus monkey have been reported on several occasions. Treatment of premenarcheal monkeys with human GH was associated with a premature increase in pubertal LH secretion, menarche, and first ovulation.[403] On the other hand, IGF-1 administration to premenarcheal female rhesus monkeys advanced only first ovulation,[404] and attempts to suppress GH and IGF-1 in premenarcheal females by treatment with somatostatin delayed only first ovulation.[394,405] Moreover, the timing of the pubertal LH increase in ovariectomized estrogen-treated monkeys was not influenced by GH treatment,[403] and IGF-1 administration to untreated agonadal females was

without effect on this parameter of pubertal development.[243] Taking the foregoing observations together, it seems reasonable to conclude that it is unlikely that GH secretion dictates the timing of the pubertal resurgence in pulsatile GnRH release, but rather it modulates the tempo of pubertal development following activation of the critical neurobiological event triggering increased GnRH release. One mechanism whereby GH accelerates the tempo of pubertal development in the female monkey appears to involve an action of IGF-1 at the hypothalamic and/or pituitary level to impair the negative feedback action of estradiol secreted by the pubertal ovary on gonadotropin secretion[243]; Figure 32.14.

Melatonin

Several lines of indirect evidence have been employed to support the idea that pineal melatonin may provide a signal that is read by the putative somatometer. Circulating concentrations of this indolamine in prepubertal children and female monkeys are higher than those in adults, and a decline in this plasma hormone occurs during juvenile and pubertal development.[406–412] The production rate of melatonin, as reflected by studies of the urinary excretion of 6-hydroxymelatonin, the principal metabolite of this pineal hormone, either declines or remains constant during childhood and puberty.[413–416] It has been known since the beginning of the twentieth century that pineal tumors may be associated with sexual precocity in man,[417] and the argument is made that those pineal tumors that destroy the parenchyma of the gland suppress the release of melatonin[418], which, in turn, leads to a premature reactivation of pulsatile GnRH release. It should be noted, however, that pineal tumors may themselves secrete gonadotropic substances[419,420] and may

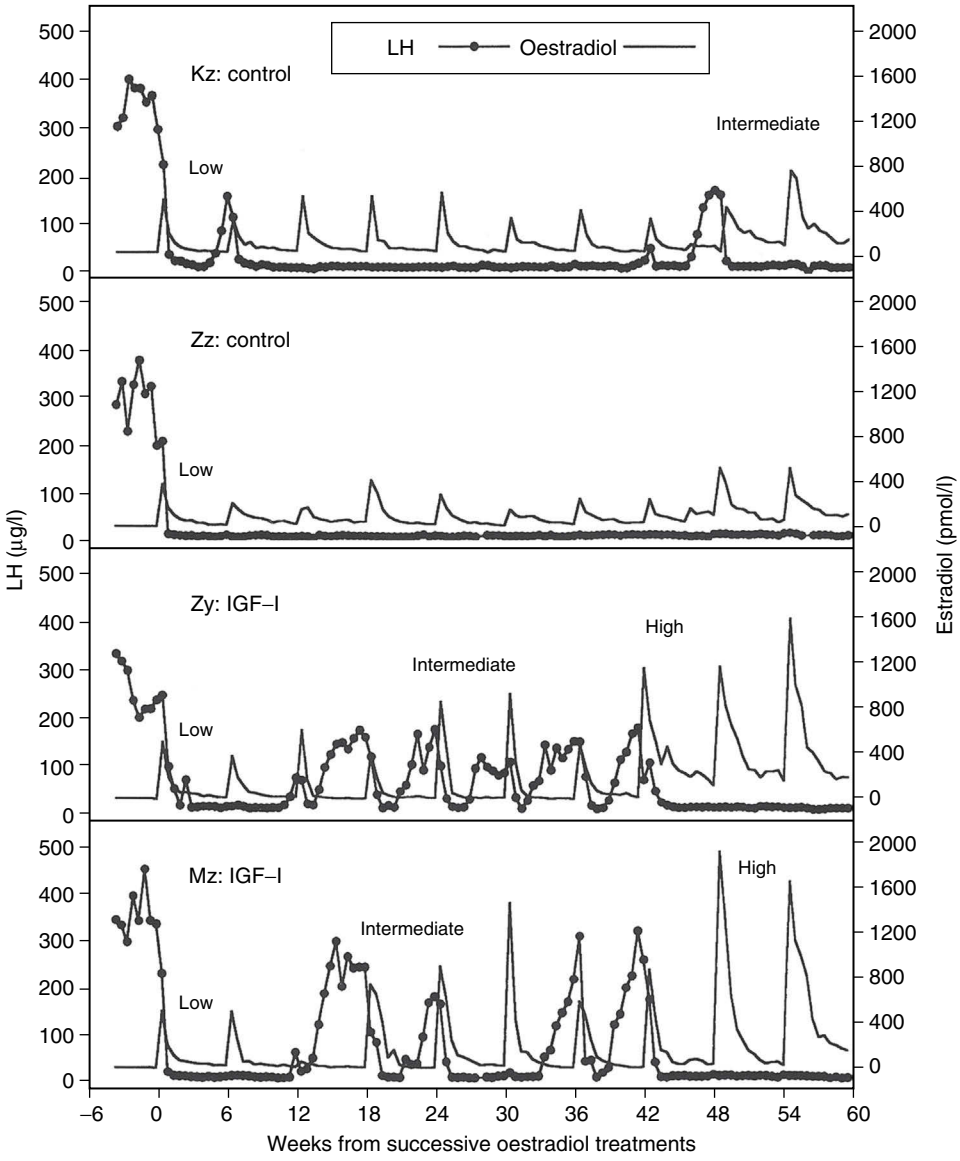

FIGURE 32.14 Developmental changes in serum LH concentrations (solid circles) in four female monkeys ovariectomized at approximately 13 months of age: two served as control (top two panels) and two were treated with IGF-1 (60–300 μg/day) from 16 to 18 months of age (bottom two panels). All four animals were replaced with estradiol starting at approximately 25 months of age (week 0). For this purpose, steroid-containing pellets were implanted subcutaneously every 6 weeks and resulted in "spikes" of circulating estradiol (continuous line) lasting approximately 3 weeks. The doses of estradiol used (low, intermediate, and high) are shown for each monkey. *Reproduced by permission from Ref. 243. © Society for Endocrinology 2005.*

impinge on adjacent areas of the hypothalamus and, thus induce premature sexual development by the same mechanism that leads to other forms of lesion-induced precocious gonadarche (see above). In patients with idiopathic precocious gonadarche, circulating melatonin concentrations are lower than those in age-matched individuals and similar to those of normal pubertal subjects.[421] Moreover, the suppression of circulating melatonin concentrations in patients with this form of precocity is not the consequence of elevated gonadal hormones, since down-regulation of the pituitary–gonadal axis following treatment with GnRH analogs fails to restore melatonin to normal levels.[421,422] The latter result is consistent with the finding that the prepubertal decline in circulating melatonin concentration in the female rhesus monkey is independent of the changes in estradiol secretion at this stage of development.[423]

If elevated circulating melatonin levels during prepubertal development are indeed monitored by a somatometer, which, in turn, holds pulsatile GnRH release in check, then removal of the pineal gland during this phase of development should lead to a premature reactivation of the GnRH pulse generator. Studies in the monkey, however, suggest that this is not the case.[208,424] Pinealectomy in agonadal males during the prepubertal hiatus in pulsatile GnRH release does not appear to influence the timing of the pubertal reactivation of the GnRH pulse generator (Figure 32.15), and the decline in GnRH pulse generator activity during infancy in pinealectomized monkeys is indistinguishable from that in sham-castrated animals.[424] Moreover, increasing the duration of the nocturnal elevation in circulating melatonin in the female rhesus monkey during the third year of life advances the age of menarche and ovulation.[425] This latter finding probably reflects an action of the control system governing seasonal influences on the hypothalamic–pituitary–ovarian axis, rather than a perturbation of the neurobiological brake that dictates the duration of the prepubertal hiatus in pulsatile GnRH release. Thus, it must be concluded that there is no compelling evidence for the view that the signal for the pubertal resurgence of pulsatile GnRH release is provided by a decline in circulating melatonin concentrations.

Metabolic Hormones and Substrates

Steiner and his colleagues have proposed that the reduction in GnRH secretion from infancy to puberty may be the consequence of decreased availability of certain metabolic hormones or substrates.[426,427] These investigators proposed that, in the juvenile primate, the GnRH pulse generator is subjected to a metabolic milieu similar to that associated with fasting states in adults, such as in anorexia nervosa, in which hypothalamic GnRH release also appears to be compromised.[428,429] In a somewhat similar vein, Winterer et al.[430] have proposed that recognition of a critical level of available calories by the primate brain leads to the reawakening of the dormant GnRH pulse generator and, therefore, to the initiation of gonadarche. According to the latter hypothesis, a reduction in available calories below the critical level in adults could lead to impairment in GnRH release.

Several lines of circumstantial evidence, which have been reviewed by others,[426,427,430] may be used to support such metabolic theories for the onset of puberty. The inhibition of gonadotropin secretion in adult monkeys and human beings that result from restricted food intake may be observed, as in the case of the prepubertal hiatus in LH and FSH release, in the absence of gonadal steroids.[431,432] Moreover, the pattern of hypothalamic GnRH pulse generator activity, as reflected by pulsatile patterns of LH secretion in female anorectics, appears to resemble closely those described for prepubertal and pubertal girls.[428] Anorexia nervosa and its related disorder,

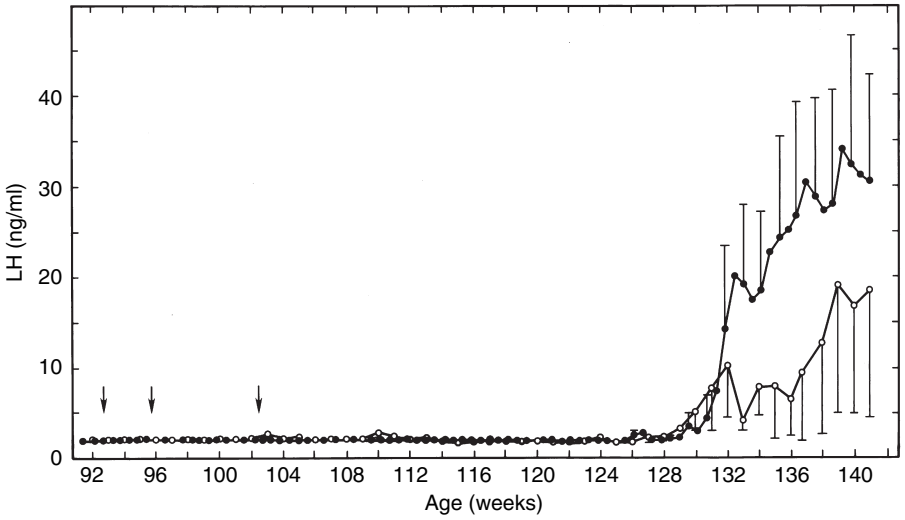

FIGURE 32.15 Failure of pinealectomy to induce a precocious pubertal reactivation of the GnRH pulse generator (as reflected by circulating LH concentrations) in agonadal male rhesus monkeys. Data for pinealectomized animals (•-•, $N=3$) are compared to those from a similar group of pineal-intact monkeys (O–O, $N=3$). *Arrows* indicate the age at pinealectomy. The time courses of FSH secretion in the two groups of animals (not shown) were similar to that of LH. *Redrawn with permission from Ref. 208.*

bulimia nervosa, however, are complex diseases characterized by psychosocial features, including difficulties with emotional regulation and adult autonomy, and tendencies toward obsessive-compulsive personality disorder in addition to weight loss. Moreover, dysregulation of the hypothalamic–pituitary adrenal axis, characterized by elevated cortisol concentrations in the face of normal ACTH concentrations, reduced peripheral metabolism of cortisol, and lack of suppressibility of ACTH by dexamethasone, is common.[433] Overactivity of the serotonergic system is also present.[434] Although no specific genes have been identified, family and twin studies support the hypothesis that genetic factors influence the risk for both these disorders.[435] Thus, anorexia nervosa represents the outcome of complex interaction between multiple genetic factors, early life experiences, and environment during the peripubertal years.

Although many of the metabolic sequelae of short-term fasting (such as the decline in circulating levels of glucose, amino acids, and insulin, as well as the increase in plasma concentrations of free fatty acids and β-hydroxybutyrate) tend to be more pronounced in juveniles than adult primates,[436–438] these metabolic adaptions do not, in general, appear to emerge until 12 h or more into a fast. Thus, it is difficult to envisage how such a nutritional signal would be relevant to pubertal timing in well-nourished monkeys or children.

With the exception of Steiner and his colleagues, few investigators have attempted to address directly the foregoing metabolic hypotheses of puberty. In a technically difficult study, the latter workers examined the gonadotropin response to a sustained intravenous infusion of glucose and amino acids administered to castrated male crab-eating monkeys between 18.5 and 31 months of age.[426,427] This hyperalimentation, which resulted in a 75% increase in daily caloric intake and, presumably, stimulated insulin secretion, was associated with an elevation in circulating LH concentrations in approximately 50% of the animals studied. In evaluating this tantalizing observation, it should be noted that in the closely related rhesus macaque, gonadotropin secretion in prepubertally castrated males may be first detected as early as 2 years of age.[49] It is, therefore, not inconceivable that spontaneous reawakening of the hypothalamic GnRH pulse generator may have been initiated during hyperalimentation in the older crab-eating macaques. The latter possibility would be excluded, of course, by a return of circulating LH to preinfusion control levels following termination of hyperalimentation, but such data were reported for only one animal. Unfortunately, these observations made 30 years ago have not been pursued.

It has long been recognized that insulin resistance increases during puberty in children,[9,439–441] although it has generally been considered that this phenomenon, like the pubertal elevation in GH, is a consequence of gonadarche. A recent longitudinal study of a modest number of children, however, suggests that the increase in insulin resistance may be a prepubertal event.[442] The notion that insulin may serve as a metabolic trigger for puberty is reinforced by the proposal that, in the context of the regulation of appetite, the primate hypothalamus has the capacity to monitor circulating insulin levels.[443,444] Further credibility would be given to the foregoing speculation by the demonstration that fasting insulin levels also rise in agonadal children and monkeys concomitantly with the reawakening of the GnRH pulse generator.

Ghrelin is a small peptide secreted predominantly by the stomach, and resistin and adiponectin are two recently described hormones secreted by adipocytes[445–450]: all three factors play a role in nutritional/metabolic homeostasis, but a role in the onset of gonadarche or adrenarche has not been established.

Other Factors

Although adrenarche typically precedes puberty,[3] the possibility that, in man, a putative somatometer responds either directly or indirectly to maturation of the adrenal appears to be very unlikely. The most compelling evidence that may be cited for the latter view is the finding that the onset of gonadarche does not appear to be noticeably delayed in children with primary adrenal insufficiency present before the age of adrenarche.[451] Conversely, premature adrenarche is not associated with any apparent signs of precocious gonadarche,[451] and idiopathic GnRH-dependent precocious gonadarche is typically observed prior to adrenarche.[452] From a comparative perspective, it is also difficult to argue that a rise in adrenal androgen secretion is a critical event in the pubertal reawakening of the hypothalamic GnRH pulse generator in other primates, since adrenarche, when noted in Old World monkeys (rhesus macaque), was observed to occur during infancy[3,6]; also see above. Moreover, adrenalectomy during the first week of life in agonadal male rhesus monkeys did not delay the timing of the reactivation of the GnRH pulse generator (Figure 32.16). As with many other factors, the prepubertal status of circulating adrenal androgen levels have been reported to be correlated to pubertal timing in children and therefore these steroids may modulate the precise timing of the reactivation of pulsatile GnRH release at the termination of juvenile development.[453,454]

Exposure to supraphysiological concentrations of plasma androgens during juvenile development may lead to premature reawakening of the hypothalamic GnRH pulse generator. Children with congenital adrenal hyperplasia (CAH) and advanced skeletal maturation may exhibit signs of GnRH-dependent precocious puberty (e.g., sleep-augmented LH release[455]) or, more frequently, may progress into a state of true sexual maturity despite

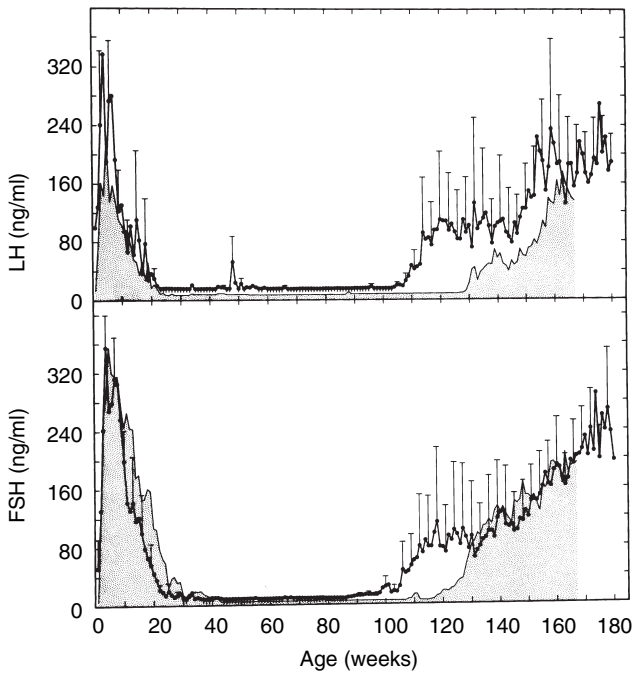

FIGURE 32.16 Time courses of circulating mean LH (top panel) and FSH (bottom panel) concentrations from birth until 166–180 weeks of age in a group of rhesus monkeys orchidectomized at 1 week of age (*stippled area*, $N=4$) and in a group of similar agonadal males adrenalectomized at 4 weeks of age (•: $N=3$, birth to 40 weeks; $N=5$, 41–180 weeks). The apparent earlier initiation of the pubertal mode of open-loop gonadotropin secretion in adrenalectomized animals is attributable to one animal. In the remaining four adrenalectomized animals, the pubertal rise in FSH secretion was not observed until 136 weeks of age or later. Vertical lines above data points indicate SEMs. *The data for castrated males are redrawn with permission from Ref. 49, and those for castrated/adrenalectomized males are, in part, redrawn with permission from Ref. 252.*

appropriate corticosteroid replacement treatment.[451,456,457] Interestingly, long-term testosterone treatment of rhesus monkeys during the first year of life mimics the effects of adrenal hyperplasia in man. In the female monkey, Van Wagenen[458] found that the age of menarche was advanced by 1 year, and in the agonadal male monkey, one of the authors' laboratories reported that early testosterone treatment led to a remarkably precocious pubertal increase in LH secretion.[459] The mechanisms whereby supraphysiological and early exposure of androgens appear to result in the premature reawakening of the hypothalamic GnRH pulse generator are not known. Since treatment of agonadal male monkeys during the first year of life with high levels of estradiol or dihydrotestosterone did not accelerate the onset of the pubertal resurgence in LH release[459], it seems reasonable to postulate that the effect of testosterone may be mediated by high levels of estradiol produced by local aromatization within the specific hypothalamic areas. Alternatively, the influence of excess androgen on the timing of the pubertal process may be mediated indirectly by a metabolic signal induced by steroid action on peripheral structures.[330] In this regard, it is becoming increasingly apparent that bone serves as an endocrine organ subject to the influences of sex steroids and, in males, the osteoblast-derived hormone osteocalcin promotes testosterone biosynthesis.[460] Whether osteocalcin influences the central component of the hypothalamic–pituitary–gonadal axis has not been examined. In any event, the appeal of the notion that attainment, by whatever mechanism, of a critical level of somatic maturation provides a trigger for the initiation of puberty is again reinforced.

In summary, the notion of a growth-tracking device in the brain that monitors body size and synchronizes the attainment of a degree of somatic development sufficient to bear and nurture offspring with the pubertal reactivation of GnRH pulsatility and therefore the onset of reproductive competence continues to be an attractive proposal. However, at the time of writing, there are no compelling candidates for the circulating signal that is read by the putative somatometer, and until such cues are identified the idea will remain hypothetical.

Pubertal Clock

Only scant attention has been paid to the possibility that the timing of the onset of puberty is governed by an endogenous biological clock. Although there is no doubt that the mammalian CNS is endowed with timekeeping systems capable of tracking both circadian and circannual periods (see Chapters 26 and 34), the role, if any, of such mechanisms in dictating the ontogeny of the primate hypothalamic GnRH pulse generator has not been established. It is to be expected, however, that if such endogenous clocks are involved in the regulation of hypothalamic GnRH secretion throughout development, then selective damage to the timing mechanism would lead to a major alteration in the age at which puberty is initiated. In this regard, it is generally recognized that important timekeeping functions of the mammalian brain are subserved by the suprachiasmatic area of the hypothalamus.[461] As noted earlier, attempts to dissociate the hypothalamic GnRH pulse generator in the prepubertal female rhesus monkey from the influence of more rostral brain regions, including the suprachiasmatic nucleus, by surgically transecting neural pathways between these two areas have not consistently resulted in a major alteration in the timing of menarche and other indices of puberty.[331,332] However, this surgical intervention in juvenile animals failed to abolish the diurnal rhythm in cortisol secretion.

Placement of lesions in the anterior hypothalamus of premenarcheal female rhesus monkeys has also been reported to be without effect on the age of menarche.[462] In a subsequent study of the same problem, however, a significant number of prepubertal female monkeys with

anterior hypothalamic lesions failed to thrive, and, when data from these animals are excluded from numerical analysis, a lesion-induced advancement in menarche and first ovulation emerges.[324] In humans, on the other hand, lesions of the anterior hypothalamus have generally been observed in association with delayed sexual maturation or hypogonadism.[463] Moreover, the specificity of the neurosurgical procedure employed for the placement of anterior lesions in the monkey is unclear, because similar lesions in the posterior hypothalamus also advance menarche and first ovulation in intact animals and the pubertal reinitiation of open-loop LH secretion in ovariectomized monkeys.[324] The latter finding is consistent with the generally accepted view that posterior hypothalamic lesions that involve the tuber cinereum and mammillary bodies result in precocious puberty in humans.[9,464,465] As discussed previously, the puberty-advancing action of some lesions may result from increased expression in the vicinity of the lesion of glial-derived growth factors, such as TGFα and neuroregulins. Although further study of the sequelae of destructive hypothalamic lesions in the primate brain should not necessarily be discouraged, such an approach to date has not provided significant insight into the nature of the control system that times the pubertal reawakening of the hypothalamic GnRH pulse generator.

GENETICS, EPIGENETICS AND PUBERTY GENES

As with other complex developmental processes, multiple genes are likely to contribute to the timing and tempo of puberty, and some of these may be coassociated with parameters of pubertal growth velocity and others not.[100,466,467] In this regard, the recognition that genetics play a role in regulating the timing of gonadarche has been highlighted.[468] Greater concordance in age of menarche and other indicators of the progression of gonadarche, such as peak height velocity and plasma LH concentrations, have generally been found in monozygotic twins when compared to dizygotic twins.[469–476] The impact of genetics on the timing of gonadarche is further indicated by the findings of a high degree of heritability in the age of menarche[473,475] and, in the United States, of a significantly earlier age of menarche in Afro-American girls than in their white counterparts.[119,477–479] Similarly, girls in London of Afro-Caribbean and Indo-Pakistani parentage have an earlier age of menarche than white girls of British parentage.[480] In addition, precocious gonadarche in girls may be familial and appears to be transmitted in an autosomal dominant mode.[481]

We have earlier suggested that the term "puberty" gene should be restricted to those genes that are specifically involved in the timing of either gonadarche or adrenarche.[3] The most likely, although theoretically not only, site for expression of "puberty" genes would be the brain, and probably the hypothalamus. In the case of gonadarche, the proteins encoded by these genes would determine the age of the pubertal resurgence of pulsatile GnRH release by regulating the timing of the application or withdrawal of transynaptic and/or glial inputs to the GnRH pulse generator of the juvenile hypothalamus. Conceivably, such putative "puberty" genes could time the resurgence of pulsatile GnRH release not only by triggering a hypothalamic signal at puberty but also by determining the duration of the prepubertal brake on pulsatile GnRH release or by timing the "turn off" of the GnRH pulse generator during infancy.

The foregoing definition of a puberty gene would eliminate *KISS1* and possible *TAC3*, which, as discussed previously, are currently viewed to be GnRH pulse-generating genes. Similarly, mutations of many genes involved in the differentiation and early development of the hypothalamic–pituitary–gonadal axis have been reported.[482] Mutations in these genes, which include *FGFR1*, *FGF8*, *KAL1*, *PROK2*, *PROKR2*, *CHD7*, *NELF*, and others, have profound effects on pubertal development. However, as previously argued,[483] such mutations have not clarified our understanding of the control system responsible for the timing of gonadarche. For example, mutations of the X-linked *KAL-1* gene, which encodes anosmin, an extracellular glycoprotein that is necessary for the early embryonic migration of GnRH neurons into the hypothalamus,[484] are associated with hypogonadotropic hypogonadism and absence of puberty. While such mutations have provided significant insight into the fetal development of the reproductive axis, they have contributed little to our understanding of the control system that governs the timing of the pubertal resurgence of pulsatile GnRH release.

Recently, genome-wide association studies indicate that several specific loci on the human genome are associated with variations in the age at menarche (AAM).[485–489] A locus with a high frequency of single nucleotide polymorphisms (SNPs) that was consistently and strongly associated with an earlier AAM was found on chromosome 6 (6q21) in the region of *lin-28 homolog B (Caenorhabditis elegans) LIN28B*: a gene that encodes for a micro-RNA binding protein.[490] The differences in AAM in subjects with and without variants in the region of *LIN28B* are relatively small (1–2 months) compared to the recognized range for the AAM in the population at large that may extend from 10 to 16 years of age.[3] In one of the foregoing studies, an association between the *LIN28B* locus and advanced voice breaking and/or advanced pubic hair stage was also reported for boys.[486] It should be noted, however, that when an association between either a genetic locus or a specific gene and the timing of puberty is established, it remains to

be determined whether the relationship is causal, and if so whether the genetic parameter is directly determining the timing of the pubertal resurgence of GnRH release, or simply influencing permissive factors such as those that reflect metabolic and growth status, and that are required for this developmental event to be triggered.

Another contemporary and powerful genomics technique that has recently been applied to examine the genetic basis of puberty onset is whole exome sequencing. Using this methodology, the entire coding region of the genome of members of families with a particular disorder of pubertal development may be sequenced and compared to a "normal" genome. Using this approach, central precocious puberty in seven girls and five boys from 12 families has been found to be associated with mutations in the gene encoding for makorin RING finger protein 3 (*MKRN3*).[491] All affected individuals inherited the disorder-associated allele from their fathers, indicating that only the paternal allele is expressed.[491]These mutations are predicted to result in loss of function of the protein. While the function of MKRN3 is not fully understood,[492] the makorin family of proteins contains a particular zinc-finger motif that has been associated with ubiquitination, a process that is involved in protein trafficking, which in some cases leads to protein degradation. Puberty in these individuals was observed as early as 5–6 years of age in both sexes, and therefore *MKRN3* may well be a puberty gene. Clearly, examination of expression of this gene in the monkey hypothalamus throughout postnatal development is likely to be very informative.

A third novel approach to explore the genetic basis underlying the timing of puberty is to first describe global changes in hypothalamic gene expression using either microarrays or RNAseq across peripubertal development; then, computational (in silico) biology is applied to examine whether the genes that are empirically determined to change with pubertal development are likely to be members of networks of functionally linked hypothalamic genes.[493,494] To date, this approach, which has been pioneered by Ojeda and his colleagues, has been applied only to non-human primate models. In this regard, it is proposed that developmental changes in a network of genes encoding for cohorts of transcription factors, such as tumor suppressor genes, lie—in a molecular sense—upstream of the GnRH pulse generator.[493] It is further argued that such gene networks serve as a governing hierarchy to orchestrate the increase in pubertal GnRH release and therefore the timing of puberty. However, until information is forthcoming on the phenotype and location of the neurons/glial cells in which the puberty associated genes are expressed, it will be difficult to integrate such in silico hypotheses into our thinking of puberty that has evolved from more classical approaches. Nevertheless, the potential significance of this approach is indicated by the finding that one of these transcriptional regulators, enhanced at puberty 1 (EAP1), is expressed in kisspeptin neurons in the arcuate nucleus of the monkey, and its expression in the hypothalamus increases at the time of puberty in the female.[495,496] Moreover, knockdown of *EAP1* using a lentivirus approach interrupts menstrual cyclicity in the female monkey,[497] and an SNP upstream of the *EAP1* gene has been associated with irregular menses in this primate.[498]

The recent finding that global inhibition of DNA methylation by intraperitoneal injections of 5-azacytidine in prepubertal rats resulted in the delay of vaginal opening, indicating that epigenetic regulation of gene expression may be important for timing puberty, has led to yet another strategy for interrogating the genetic basis of this developmental process,[499] i.e., to search for hypothalamic genes that are epigenetically regulated during peripubertal development. In this regard, studies of the rat have led to the identification of a cohort of genes that encode for either a group of transcriptional "silencer" proteins known as the polycomb group or proteins with which the polycomb group interact.[499] In the pubertal rat, expression of these polycomb genes is downregulated by DNA methylation leading to a reduction in the silencer proteins they encode. Interestingly, two genes of the polycomb group were found to be expressed in neurons of the rat arcuate nucleus (some of which coexpressed *Kiss1*), and overexpression of one of these genes in neurons of this nucleus, which was targeted by a lentivirus construct, resulted in a decrease in *Kiss1* expression in association with delayed vaginal opening and a disruption of GnRH pulsatility in MBH explants.[499]

As argued previously, we consider that *KISS1* is a GnRH pulse-generating gene and not a puberty gene.[168] Moreover, GnRH pulse generator activity is robust during infancy in monkeys and man, and in these species puberty is triggered by a reactivation of this neurobiological mechanism after a prolonged period of relative dormancy during juvenile development. It would therefore be of great interest to establish whether epigenetic silencing is involved in the "turn off" of pulsatile GnRH release during infancy in the monkey. While the specific question of whether postnatal epigenetic changes in polycomb genes occur in the primate hypothalamus remains to be addressed, one of the authors' laboratories has recently found that DNA demethylation of the *GnRH* gene in the MBH occurs across puberty in male rhesus monkeys in association with a pubertal increase in GnRH mRNA.[268] Therefore, epigenetic regulation of hypothalamic gene expression is likely to be a contributing factor for the mechanism of puberty onset.

It is highly likely that the number of puberty genes that are expressed in the primate hypothalamus will expand dramatically over the next few years as high throughput

approaches to genomics are increasingly applied to investigate this developmental process. Whether these new anticipated data will solve the fundamental nature of the physiological control system timing the onset of primate puberty—i.e., whether the pubertal reactivation of the GnRH pulse generator activity and therefore the onset of gonadarche in primates is timed by a pubertal clock or a somatometer is less clear.

FETAL PROGRAMMING AND THE ONSET OF PUBERTY

Epidemiological observations and subsequent clinical and experimental data have demonstrated an association between intra-uterine growth retardation and increased risk for several endocrine and non-endocrine disorders in adulthood.[500] In the case of pubertal development, adrenarche has been reported to be precocious and/or exaggerated in both boys and girls born small for gestational age (SGA), particularly those who show accelerated weight gain during early childhood. In contrast to adrenarche, the timing of menarche in girls born SGA does not appear to be markedly different from girls born at an appropriate size for gestational age.[501–503] In boys born SGA the timing of puberty appears to be normal, although sub-fertility has been reported postpubertally.[503,504]

The role of fetal androgen in programming the neural component of the hypothalamic–pituitary–gonadal axis, and therefore potentially in timing the onset of gonadarche, merits consideration. Testosterone secretion by the fetal testis is presumably responsible for the greater frequency of pulsatile GnRH release in infant male monkeys compared to that in age-matched females (Figure 32.2), and for the subsequent dimorphism in the developmental pattern of GnRH release as reflected by gonadotropin levels in agonadal monkeys and humans (Figures 32.4 and 32.5). Prenatal exposure of female monkeys to elevated levels of androgens administered in large quantities to their mothers has been associated with increased LH pulse frequency, post-natal hyperandrogenism, insulin resistance, and decreased pancreatic beta cell function.[505] These data suggest that the prenatal androgen milieu may influence the risk to develop polycystic ovary syndrome. Additionally, androgen exposure early during gestation in the monkey has been reported to impair oocyte developmental competence.[506] Girls with classical congenital adrenal hyperplasia due to 21-hydroxylase deficiency are exposed to elevated levels of androgens during fetal development. Despite appropriate glucocorticoid replacement therapy, women with CAH can develop ovarian hyperandrogenism, irregular menses, and infertility.[507]

EXTEROCEPTIVE CUES AND THE TIMING OF PUBERTY

Season

Reproduction in many species of primate involves a seasonal pattern in breeding,[508] which is presumably dictated, as in nonprimate species, by photoperiod and possibly other environmental cues (see Chapter 34). The rhesus monkey living outdoors provides a striking example of a seasonal breeding primate: ovulation generally occurs during the fall, and births are usually restricted to the spring.[509] Thus, as previously noted by Rowell[97] and graphically demonstrated by Wilson et al.[393] and Terasawa et al.,[82] the typical feral female experiences her first and second breeding season as an infant and juvenile of approximately 6 and 18 months of age, respectively; menarche occurs during the third breeding season, at approximately 30 months of age, and puberty is completed with first ovulation and conception by approximately 42 months of age during the fourth breeding season. Spring-born females that exhibit unusually early or late first ovulation do so 1 year before or after the age at which ovulation typically occurs.[393] Moreover, when females that are born in the fall, because of contrived laboratory conditions, are reared from birth in an outdoor environment, first ovulation and conception typically occur in the fall at the end of the third year of life rather than at 3.5 years of age as in spring-born animals.[393] Thus, under natural conditions, season imposes a quantum effect on the timing of puberty in the rhesus monkey, and, as previously remarked by Rowell,[97] the onset of menarche or first ovulation is better predicted by counting time in breeding seasons than in months. An analogous quantal relationship between breeding season and the initiation of puberty has also been reported for male rhesus and bonnet macaques[45,510] and for male squirrel monkeys.[46]

That the hypothalamic GnRH pulse generator is an important relay station in mediating the influence of season on the timing of puberty is indicated by the finding that testicular quiescence during the nonbreeding season may be reversed in the monkey by intermittent stimulation of the pituitary–gonadal axis with exogenous GnRH.[511] The finding that menarche and first ovulation are advanced in spring-born female monkeys by imposing a short-day pattern of circulating melatonin during the long days of the summer preceding the third breeding season[425] suggests that the pineal gland is an important component of the interoceptive mechanism mediating the seasonal influence on the timing of the onset of puberty in this species as in other seasonal breeders (see Chapter 34).

Although the foregoing discussion underlines the robust effect seasonally related exteroceptive cues

may have on the timing of the onset of puberty in non-human primates, it is important to remember that there is no evidence to indicate that such cues actually regulate the fundamental control system governing the onset of puberty, namely, the neurobiological brake that switches the GnRH pulse generator off in infancy and on at the termination of prepubertal development. It appears that irrespective of season, the latter control is independently programmed, and the capacity for puberty is achieved independently of season. However, in a seasonal breeding species, puberty may be manifest only when the capacity for puberty and the breeding season coincide.

Social Factors

In nonprimate species, it is well established that social cues influence the timing of the onset of puberty.[512] Cognate mechanisms appear extant in certain species of primates, and this is exemplified by the South American marmosets and tamarins. These small equatorial primates live in family groups consisting of a monogamous pair of adults and their offspring.[105] Interestingly, the breeding female appears to suppress the ability of her adult daughters to reproduce,[105,513] possibly by inhibiting ovulation.[514] In Old World monkeys, socially dominant juveniles of both sexes reach puberty earlier than their subordinate peers.[515–518] The neuroendocrine mechanisms responsible for this intriguing relationship between social dominance and the neuroendocrine axis governing reproductive function in macaques is probably related to elevated "social" stress associated with subordinate status.[518] Furthermore, it is to be anticipated that stress impairment of hypothalamic GnRH pulse generator activity is involved in the delay of puberty in subordinate individuals (see Chapter 36). In man, social subordinance prior to puberty also represents one of several "pediatric" stresses (see Ref. 519 for a comprehensive review of this subject), and the role of psychosocial or socioemotional stressors generated by family dynamics and impacting upon children, particularly girls, in timing the onset and tempo of puberty is an area of sociology receiving increasing attention.[519,520] Interestingly, in this regard, some presumed socioemotional stressors, for example, father absence and insecurity as an infant, appear to be associated with an acceleration in the timing of puberty.[519,521–523] The reasons for the opposite effect of "stress" prior to puberty on the timing of this developmental event in Old World monkeys on the one hand and in boys and girls on the other are unclear but have been posited to be related to differences in diet.[518,524] Specifically, children raised under conditions of high stress may consume foods high in fat and sugars.[525]

Another interesting association between behavior and the onset of human puberty first reported in 1981 is the precocious gonadarche that has been reported in children, particularly girls, adopted by European parents from developing world regions such as Asia and South America.[120] Ethnic background does not appear to be involved, and a similar phenomenon has also been observed in immigrant girls arriving with their parents.[120] The mechanisms responsible for the association between adoption and/or migration and puberty in girls remain unclear.

Food Availability

In addition to the impact of food availability during prepubertal development on somatic growth, and therefore the signals posited to be tracked by the putative somatometer (see above), the balance between energy intake and energy expenditure is a critical environmental factor determining whether puberty will progress once growth has reached a pubertal threshold.[110,519,526] In girls menarche is delayed in malnourished individuals,[111,527] while obesity is associated with early breast development and menarche,[528] although this phenotypic prematurity may not be directly related to GnRH pulse generator activity.[529] On the other hand, the increased metabolic demand that may be imposed by strenuous exercise such as long-distance running, gymnastics, and ballet is often associated with delayed or interrupted pubertal development.[530,531] In such individuals, in whom deviation from ideal body weight may be minimal, the frequency of pulsatile LH secretion is less than that in sedentary women during the follicular phase of the menstrual cycle.[532–535] Male wrestlers lose body weight, fat mass, and lean body mass during the competitive season and disruption of the neuroendocrine axes governing testicular function and growth may be observed at this time.[536] These changes reverse within months following conclusion of the wrestling season. Together these findings suggest that metabolic signals, at least those associated with restricted food intake and/or increased exercise, have the capacity to impair the pubertal activity of the hypothalamic GnRH pulse generator. While the impact of undernutrition on gonadarche in boys has received less attention, there is no reason to suspect that the male axis is unaffected in this regard.

The effects of food availability/nutrition on the timing of puberty in non-human primates have received only scant attention. In the female rhesus monkey, high calorie diets were associated with a precocious increase in nipple volume, sex-skin swelling, and menarche in association with increased concentrations of leptin and IGF-1 concentrations, and an increased BMI.[123]

Chronic disease is often associated with inadequate nutrition (and in all probability with stress) leading to impaired GnRH secretion and delayed or interrupted puberty. Children with sickle cell anemia, perinatally acquired HIV infection, diabetes mellitus, chronic renal disease, and inflammatory bowel disease tend to have delayed puberty.[537–539] Among girls with cystic fibrosis, age at menarche was delayed, but correlated with nutritional status and maternal age at menarche.[540] Effective treatment of the underlying disorder is generally associated with restored pubertal progression. For example, following successful renal transplantation, children with chronic renal disease manifest resumption of gonadotropin secretion and progressive pubertal development.

Restricted food intake, imposed experimentally in the post-pubertal rhesus monkey or voluntarily in human subjects with anorexia nervosa, appears to inhibit gonadotropin secretion primarily by an action at a suprapituitary level that is mediated by suppression of the hypothalamic GnRH pulse generator.[432,541] Thus, in the undernourished juvenile, the same inhibitory mechanisms that arrest the hypothalamic GnRH pulse generator in food-restricted adults are presumably activated, and therefore any waning of the neurobiological brake on intermittent GnRH secretion in the juvenile would not become manifest because of the additional and independent check imposed by restricted food intake. Thus, gonadarche—the consequence of the reawakening of the GnRH pulse generator—is further delayed.

In summary, it is reasonable to conclude that those exteroceptive cues associated with season, social status, and nutrition that impact the reproductive axis of adults are unlikely to be affecting the fundamental neuroendocrine changes driving puberty, just suppressing their expression.

DISORDERS OF PUBERTAL DEVELOPMENT

To date, with the exception of one report in the chimpanzee,[542] disorders of puberty in primates have been described only for man, and these have been recently reviewed in detail.[3] Here, we restrict our discussion to those particular disorders that, when their etiology is fully established, are most likely to add major advances to the understanding of the physiology of primate puberty. Also, certain disorders of human puberty that have provided major insight into key signaling pathways (e.g., kisspeptin-KISS1R) regulating pulsatile GnRH secretion have already been discussed earlier and will not be considered in detail in this section. Since the key events in regulating the onset of puberty are the switches that first turn off the GnRH pulse generator in infancy and subsequently reactivate this neural component to initiate gonadarche at the end of juvenile development (see above), examination of the underlying causes of GnRH-dependent disorders of human puberty will likely be the most revealing. Indeed, discovery of novel genes associated with such conditions provides an ever-expanding appreciation of the complexity of the neurobiology of this critical developmental event. This is not to say that GnRH-independent disorders of pubertal development are neither of physiological interest nor of clinical importance. In fact, disorders of gonadal and adrenal steroidogenesis, or the failure of the pituitary gland to undergo normal development, may have profound impacts on growth and sexual development.

Disorders of human pubertal development fall into the broad categories of precocious and delayed puberty, and both may be either familial or sporadic. In the latter, patterns of inheritance include autosomal recessive, autosomal dominant, and X-linked recessive. For affected patients and their families, molecular genetic diagnosis improves identification of asymptomatic affected family members and enables prediction of associated features.

Precocious Puberty

Precocious puberty may be classified as being either GnRH-dependent or GnRH-independent. GnRH-dependent precocious puberty, or more accurately precocious gonadarche, is the result of a premature resurgence or incomplete suppression of the hypothalamic GnRH pulse generator. GnRH-independent forms represent a group of disorders associated with increased gonadal or adrenal sex steroid secretion that occurs in the absence of GnRH-stimulated gonadotropin secretion.

In GnRH-dependent precocious gonadarche, the normal pubertal sequence of hypothalamic events appears to be recapitulated, but the process starts at an inappropriately early age. This disorder is diagnosed more often in girls than in boys, perhaps because suppression of the GnRH pulse generator during childhood and juvenile development in girls is less robust than in boys (see above). While often considered to be idiopathic in girls, an organic etiology can usually be identified in boys. Despite the relative mature physical appearance of children with precocity, their cognitive and emotional development is normal for chronologic age. Thus, the guilelessness and naïveté of such children exposes them to an increased risk of sexual abuse, with affected girls at risk of becoming pregnant.

Hypothalamic hamartomas, congenital malformations comprised of heterotrophic neural tissue usually located on the floor of the third ventricle or attached to the tuber cinereum, are a common etiology of precocious gonadarche.[9] The tumors can be classified as parahypothalamic when attached or suspended from the floor of the third

ventricle, or as intrahypothalamic, in which the mass is enveloped by the hypothalamus and distorts the third ventricle. Hamartomas do not grow over time and do not metastasize. Although gelastic or laughing seizures can be associated with precocious puberty due to hypothalamic hamartomas, the majority of patients do not exhibit neurologic symptoms. Interestingly, histological examination of hypothalamic hamartoma tissue has shown immunoactive GnRH perikarya in association with capillary networks[543–546] and/or astroglial-derived growth factors such as TGFα.[547] The surgical removal of such small peduncled hamartomas in infants with precocious puberty has been reported to result in a complete arrest of sexual development.[543–546] The intriguing possibility that such hamartomas contain an ancillary GnRH pulse generator that is emancipated from normal developmental controls must therefore be considered. On the other hand, astroglial factors such as TGFα may provide an ectopic drive to GnRH neurons with a normal distribution in the hypothalamus.

Other CNS lesions, hydrocephalus, meningomyelocele and certain neurodevelopmental disorders, previous head trauma, CNS infections, CNS granulomatous disease, and CNS radiation may also be associated with GnRH-dependent precocious gonadarche.[548,549] CNS radiation used to treat intracranial tumors or used prophylactically for malignancies can induce precocious GnRH-dependent gonadarche, perhaps as a result of an astroglial response with increased TGFα production.[325]

Precocious GnRH-dependent gonadarche may also be observed in children with virilizing disorders such as CAH and familial male-limited precocious puberty (testotoxicosis) in whom skeletal maturation is significantly advanced. This particular pathophysiological condition can be replicated experimentally in the monkey by exogenous testosterone administration.[458,459] Whether the action of testosterone to prematurely reawaken the GnRH pulse generator is exerted on the CNS or on peripheral tissue such as, for example, the skeleton, is unclear.

The treatment of choice for children with GnRH-dependent precocious gonadarche is a GnRH receptor (GnRH-R) agonist.[549] GnRH-R agonists are modifications of GnRH having greater resistance to degradation and increased affinity for the GnRH-R than the native decapeptide. They are, therefore, perceived by the pituitary as a continuous GnRH stimulation, which induces desensitization of GnRH-R function and leads to decreased gonadotropin secretion. GnRH-R agonists are available as daily injections or depot forms, the latter including leuprolide acetate and histrelin.[550] The major goals of treatment are to prevent further pubertal progression until appropriate for chronological age, and to attain normal adult height. In situations of coexisting GH deficiency, combined treatment with recombinant human GH may be helpful to preserve height potential.

Delayed Puberty

In the context of understanding the timing of normal puberty, constitutional delay of growth and puberty is of most interest, because this condition, which is currently considered an extreme of the normal variation of pubertal timing, aggregates in families and therefore must have a genetic basis (see above). Typically, gonadarche, adrenarche, and skeletal maturation are delayed. Constitutional delay is a diagnosis of exclusion because no definitive diagnostic test exists.

Delayed or absent pubertal development secondary to hypogonadotropic hypogonadism is reported to affect one in 7500 males and one in 70,000 females.[551] Investigations of families with this disorder have identified mutations in several genes. Phenotypic heterogeneity of clinical presentations has become evident. Thus, there is variation regarding sense of smell, non-reproductive clinical features, patterns of endogenous GnRH secretion, and severity of clinical features. Kallmann syndrome is the eponym used to describe anosmic/hyposmic hypogonadotropic hypogonadism. Detailed investigation of human fetuses with *KAL1* mutations verified the extra-CNS embryonic origins of GnRH neurons and the failure of olfactory and GnRH neurons to migrate to the CNS.[552]

Mutations associated with the hyposmia/anosmia phenotype include genes discussed above that influence GnRH neuron migration as well as those that influence GnRH neuron function and action. Specifically, mutations have been identified in the *KAL-1, FGFR1, FGF8, KISS1, KISS1R*, and *GnRHR* genes.[23,24,171,484,553,554] Non-reproductive clinical features can accompany specific gene defects. Synkinesis is typically associated with *KAL1* mutations, but can occur with mutations in *PROK2/PROKR2* genes. Cleft lip/palate was associated with *FGF8, FGFR1*, and *CHD7* mutations.[555] Some individuals with hypogonadotropic hypogonadism carry genetic variants in two or more different genes and represent examples of oligogenic disorders.[556]

Curiously, approximately 10–15% of individuals diagnosed to have hypogonadotropic hypogonadism show reversal of the condition in early adulthood following replacement therapy with sex steroids. This reversibility has been described in association with mutations in the *CHD7, GnRHR, FGFR1, TAC3*, and *TACR3* genes.[557,558] It has been suggested that plasticity of the neuronal network governing GnRH pulsatility exists and is influenced by exposure to sex steroids. Indeed, patients diagnosed to have constitutional delay may show onset of puberty following sex steroid treatment to "kickstart" the pubertal process. Reversal in patients with loss of function mutations in the NKB signaling pathway is of particular interest (see Ref. 3) because as described earlier this pathway has been posited to comprise an integral component of the hypothalamic GnRH

pulse generator. In this regard, it is tempting to speculate that other tachykinins may be able to compensate for the abrogation of NKB signaling. Consistent with this idea is the recent finding that NKB may activate kisspeptin neurons in the arcuate nucleus of the mouse via multiple tachykinin receptors.[559]

CONCLUSION

The study of the neuroendocrine mechanisms regulating the onset of puberty in primates has been restricted almost exclusively to the infraorder Catarrhini, and primarily to Old World monkeys and man. In such highly evolved primates, puberty may be viewed as manifesting itself as a result of the cascade of physiological and behavioral processes that are set in motion by the reawakening of a restrained, but functional hypothalamic GnRH pulse generator. In males, maturation of the hypothalamic GnRH pulse generator appears to be completed during fetal development, but in the female the capacity of this system to generate an adult frequency of one pulse per hour may not be completed until after birth. The protracted hiatus in gonadotropin secretion from late infancy until puberty is viewed to result from an action of a neurobiological brake that is imposed on the GnRH pulse generator during juvenile development. The application of this brake on GnRH pulse generation, which may be achieved by a decrease in excitatory input, an increase in inhibitory input, or a combination of both, is achieved by extragonadal mechanisms. The rising circulating concentrations of sex steroids produced as a result of gonadarche, however, retard the pubertal resurgence in pulsatile GnRH release. Thus, the tempo at which puberty unfolds once it has been initiated is dictated by an interplay of central and gonadal factors, together with metabolic cues and environmental factors.

The components of the neurobiological brake on the hypothalamic GnRH pulse generator remain poorly understood. Although the kisspeptin—KISS1R signaling pathway has attracted unprecedented attention in this regard since the last edition of this book, it is likely that this neuropeptide's role in the onset of puberty is that of a GnRH pulse-generating signal, and as such is slave to the upstream components of the neurobiological brake, which dictates the "on-off-on" pattern of GnRH pulsatility during postnatal primate development. Although an increase in GABA signaling and a decrease in glutamate tone in the MBH appear to be a component of the brake, the neurobiological switches that first restrain and then reactivate GnRH pulse generator activity in the infant–juvenile and juvenile–pubertal transitions, respectively, remain poorly understood, and the developmental cues that time the activation of these switches remain a fascinating mystery. The notion that these developmental cues are governed by a program of sequential expression of "puberty" genes or gene networks in the hypothalamus (a puberty clock) in analogy to the genetic control of embryonic development has been fueled by the emergence of high throughput technologies to sequence genomes and transcriptomes. At the present time we prefer the alternative idea that the two switches controlling the postnatal activity of the GnRH pulse generator are controlled by a central growth-tracking device, termed a somatometer, that is able to respond to peripheral cues reflecting the status of somatic development. In either model, many hypothalamic genes are likely to be involved and their expression will be governed by both classical transcriptional regulation and by DNA methylation.

Also, regardless of the model, puberty will only be manifest once the neurobiological brake has been lifted at the end of juvenile development if metabolic status, as reflected by such peripheral signals such as leptin, is not compromised by undernutrition or disease. Although the actions of metabolic signals are in many cases essential for puberty onset, they should be viewed as permissive and not as components of the timing mechanism that activate the pubertal switch that leads to reaugmentation of the hypothalamic GnRH pulse generator.

There are obviously major hurdles to overcome before the mystery of puberty in primates is resolved. Perhaps most importantly, the neurobiological mechanisms underlying GnRH pulse generation need to be fully elucidated before the developmental control of this system can be established. In this regard, the hypothesis that KNDy neurons in the arcuate nucleus represent the hypothalamic GnRH pulse generator is attractive, but at the present time that is all that it is: a hypothesis. Species differences in the postnatal development of the GnRH pulse generator need to be recognized and models sought that will address the fundamental questions related to the timing of the onset of human puberty, namely what are the neurobiological mechanisms underlying the switches that first turn off pulsatile GnRH secretion during infancy and later reactivate this pattern of neuroendocrine activity to trigger puberty, and what is the biological system that has evolved in Old World monkeys, apes and humans to dramatically separate these two critical postnatal events in these species.

Acknowledgments

We are most grateful to Dr. Robert Goodman for the excellent suggestions he made while editing our manuscript. Work from the authors' laboratories described in this chapter was supported by the NIH [Grants U54-HD08610 (TMP), R01 HD13254 (TMP), R01 HD16851 (TMP), R01 HD11355 (ET), R01 HD15433 (ET), P51 OD-011106 (WNPRC), R29-HD34808 (SFW), and 5M01-RR-00084 (GCRC)].

CHAPTER

33

Neuroendocrine Control of Gonadotropin Secretion: Comparative Aspects

Robert L. Goodman

Department of Physiology and Pharmacology, West Virginia University, Morgantown, WV, USA

INTRODUCTION

One objective of this new edition of *Knobil and Neill's Physiology of Reproduction* is to increase the consideration of species similarities and differences in each of the chapters. However, it was also recognized that the chapters describing the neuroendocrine mechanisms underlying puberty and ovarian cycles in rats, sheep, and humans and other primates were particularly useful in previous editions and could not realistically be combined. Therefore, these species-specific chapters have been retained (with the chapters on rats being expanded to include mice), and this new chapter has been added to provide a brief species comparison of the neuroendocrine mechanisms controlling gonadotropin secretion. This chapter will focus primarily on the female because species differences in function of the hypothalamo–pituitary–testicular axis are less striking and have not been as well studied as those in females. Because many of these concepts are firmly established, much of the material covered will be more distant than topical, but I will touch on current controversies and overlooked conundrums where appropriate. I will also not duplicate detailed discussions of mechanisms underlying puberty and ovarian cycles in rats, sheep, and primates (readers are referred to the species-specific chapters for this information), and include only selected references from these species (a more comprehensive bibliography being available in those chapters); more complete citations will be provided when discussing other species, primarily rabbits and guinea pigs.

Before considering the neuroendocrine control of gonadotropin secretion, it is useful to review the major similarities and differences in the pattern of ovarian function among species. In general, control of gonadal function is more complex than that of other endocrine tissues because the gonads produce two products: hormones and gametes. Moreover, within reproduction, the female reproductive system is more complicated than that of the male because the female has two distinct reproductive functions: (1) make gametes and ensure they are fertilized (analogous to that of the male), and (2) maintain the developing young in utero throughout pregnancy. These two functions require different endocrine environments, with estradiol (E_2) from the follicle being most important for the former, and progesterone from the corpus luteum (and placenta) for the latter. The second system becomes fully active only during pregnancy, but in many mammals progesterone secretion from the corpus luteum (CL) occurs during the normal cycle to help prepare the uterus for implantation if fertilization occurs. Ovarian cycles arose in part because these two systems must function sequentially: a mature ovum (ova) must develop before pregnancy can occur.

This sequential function is clearly evident in the phases of the menstrual cycle in women and most other primates, which can be easily divided into 2-week-long follicular and luteal phases.[1] During the follicular phase, a follicle (and ovum) develops and produces increasing amounts of E_2 (Figure 33.1(A)). The follicular phase ends with ovulation of the mature ovum (which is accompanied by a precipitous fall in E_2), and the remnants of the follicle in the ovary differentiate into the CL, initiating the luteal phase. As the CL grows, progesterone (and E_2 in women) concentrations increase to a peak about a week later. If implantation does not occur, the CL begins to die in the latter part of the luteal phase, with the subsequent fall in progesterone (and E_2) inducing menstruation, which signals the start of the next follicular phase. Although there are thus clear follicular and luteal phases, it is important to note that follicular development lasts longer than 2 weeks in primates (Chapter 28),[5] so it is not confined solely to the follicular phase preceding ovulation.

Ovarian cycles in other mammals can, in general, be divided into three additional groups based on the duration of the cycle. One group, typified by domestic animals (cow,

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00033-8

sheep, and pig) and guinea pigs, has a luteal phase similar in length to that of primates (13–16 days), but a relatively short 3–6-day follicular phase; thus, ovarian cycles last between 17 and 21 days (Figure 33.1(B)), depending on the species. In these species, considerable follicular development occurs during the luteal phase, often evident as two to three follicular waves, but the final stages only occur after luteolysis. The most obvious outward sign of ovarian cycles is the occurrence of estrous behavior, which is coupled to ovulation. Thus these are referred to as estrous cycles, and the day of estrus is taken as day 0 of the cycle. The third group of animals, which consists largely of rats, mice, and hamsters, has shortened both the follicular phase and luteal phase to 1 or 2 days and has estrous cycles that are 4 or 5 days in length.[3] The 4 days of the estrous cycle are usually referred to as estrus (ovulation and estrous behavior), metestrus (increasing progesterone), diestrus (falling progesterone and increasing E_2), and proestrus (peak E_2). There is also a peak in follicular progesterone secretion on the afternoon of proestrus (not shown in Figure 33.1) that induces estrous behavior early the next day. In these species, a neural signal induced by coitus prolongs the lifespan of the CL to 9–14 days (Figure 33.1(C)). This condition, known as pseudopregnancy because it can be induced with a vasectomized male, provides sufficient progesterone to allow implantation if fertilization occurs. The final large group of mammals, exemplified by rabbits, domestic cats, mink, and ferrets, has eliminated the luteal phase completely unless coitus occurs.[6,7] Females of these species that are isolated from males show waves of follicular development and sufficient E_2 secretion to produce estrous behavior, but never ovulate. Mating of estrous females, even with sterile males, will induce ovulation and a subsequent luteal phase (Figure 33.1(D)) lasting 14–40 days, depending on the species. In some species (e.g., cats and rabbits), pseudopregnancy is terminated if implantation does not occur, but in others (e.g., ferrets) the duration of pseudopregnancy is the same as pregnancy. Because ovulation is induced by a neuroendocrine reflex triggered by coitus, these animals are referred as "reflex ovulators" to distinguish them from the other three categories, all of which are "spontaneous ovulators."

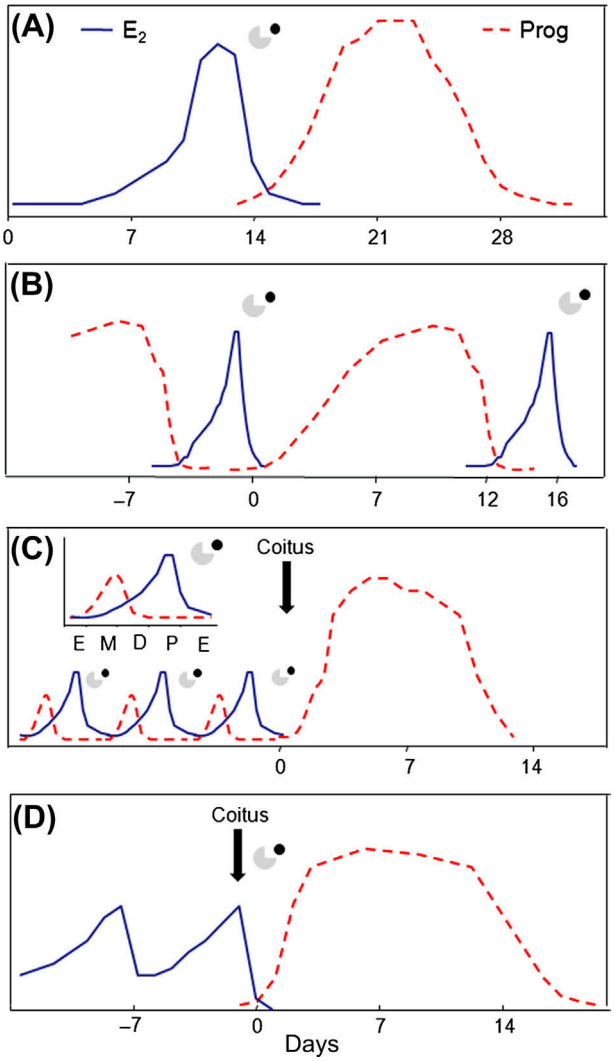

FIGURE 33.1 Patterns of follicular estradiol (E_2: solid lines) and luteal progesterone (Prog: dashed lines) to illustrate ovarian cycles of women and other primates (panel A); domestic animals and guinea pigs (panel B); mice, rats, and hamsters (panel C); and reflex ovulators (panel D). Ovulation (ovary–ovum symbol) occurs on day 14 of the primate menstrual cycle and day 0 of the estrous cycle in other mammals. In most rodents, and all reflex ovulators, coitus (arrow) is needed to induce a full-length luteal phase. Also note that in some species (e.g., rodents and primates), the follicles also secrete progesterone, while in others (e.g., some primates, and rabbits) the corpus luteum also produces E_2; these steroid patterns have been omitted from this figure in the interests of simplicity. Hormonal patterns taken for panels A–D are based on data in women,[1] sheep,[2] rats,[3] and rabbits,[4] respectively.

HISTORICAL DEVELOPMENT OF CONCEPTS FOR FEEDBACK CONTROL OF GONADOTROPIN SECRETION

Despite the diversity in ovarian cycles among mammals, the underlying events are controlled by the same basic feedback relationships between ovaries and the hypothalamo–hypophysial unit. Our understanding of these complex feedback relationships developed gradually over half a century, in parallel with the development of models to account for ovarian cycles. Indeed, much of the experimental work during this period appears to have been driven in part by a search for the mechanisms responsible for cyclic ovarian function.

Early Models

The first endocrine model for cyclic ovarian function was proposed by Loeb in 1910, based on observations

that removal of the CL of the guinea pig advanced ovulation, while prolongation of luteal function in pregnancy delayed it.[8] He thus proposed that a hormone from the CL "prolongs… the interval between two successive ovulations by preventing rupture of the follicles" and that spontaneous luteolysis in nonpregnant animals allows a new cycle to begin. While this provided a simple explanation for ovarian cycles, its basic assumption that follicular development and rupture occurred independently of extra-ovarian influences was soon disproven by the discovery of the gonadotropic action of the pituitary.

In 1927, Smith and Engle[9] demonstrated that hypophysectomy caused gonadal atrophy that could be prevented by implants of anterior pituitary tissue, and suggested that "the hypothesis of the periodic liberation of gonadal-stimulating hormone of the pituitary may explain the periodic ripening of groups of follicles more satisfactorily than any other heretofore advanced."[9] These results immediately shifted attention to the role of the pituitary and triggered studies leading to the first description of the inhibitory actions of gonadal hormones on gonadotropin secretion by Moore and Price.[10] These workers proposed that a negative feedback loop existed between the gonads and the pituitary. A negative feedback loop in which one hormone (i.e., gonadotropin) stimulates secretion of a second hormone (i.e., E_2), which in turn inhibits secretion of the first hormone, is the most common control system in endocrinology because it is designed to maintain homeostasis in the system. However, Moore and Price proposed that appropriate lag times in the negative feedback loop between the ovaries and the pituitary could account for ovarian cycles: "Starting with hypophysial secretion of gonad-stimulating substance, the ovary is stimulated and follicles grow and mature. During follicular activity large amounts of oestrin are liberated… [which] leads to depression of the hypophysis, causing it to lag in the secretion of the gonad-stimulating substance, which accounts for cessation of further follicular development. When oestrin is no longer produced in large amounts… the depressing action upon the hypophysis ceases and it again responds by a secretion of more gonadal-stimulating hormone and the cycle is repeated."[10] We now know that this feedback relationship would reach a steady state rather than cycle; in fact, this was first demonstrated in 1936 by Pfeiffer, who induced just such an equilibrium by "masculinizing" female rats with testicular implants during the neonatal period.[11] When these females matured, they failed to cycle, instead showing a condition known as "constant estrus," with large follicles in the ovary, and vaginal histology indicative of continuous E_2 secretion. Nevertheless, the basic concept of a negative feedback loop proposed by Moore and Price is still applicable to the relationship between testes and hypophysis, although of course the importance of the hypothalamus and both testosterone and inhibin is now incorporated into it. In fact, this negative feedback theory for ovarian cycles was short-lived largely because it was overtaken by the simultaneous discovery that the pituitary produced two hormones: one that stimulated follicular activity and E_2 secretion (follicle-stimulating hormone (FSH)), and another that induced ovulation and luteinization (luteinizing hormone (LH)) and thus favored progesterone production.[12] This discovery, in turn, led to the first long-lived model for the ovarian cycle.[13]

The Sequential Secretion of FSH and LH Model

One logical inference from the proposed actions of FSH (follicular development and E_2 secretion) and LH (CL formation and progesterone secretion) is that FSH is important for the follicular phase and LH for the luteal phase of the cycle. Moreover, two new lines of evidence provided a possible explanation for the sequential secretion of FSH and LH during the cycle. First, a negative feedback relationship between E_2 and FSH was supported by reports that: (1) ovary-intact rats, parabiotically connected so that blood from an ovariectomized (OVX) animal was transferred into them, showed constant estrus suggestive of elevated FSH release in the OVX rat[14]; (2) low doses of E_2 inhibited follicular development in immature rats[15]; and (3) urine from postmenopausal women with low E_2 contained FSH-like bioactivity.[16] Second, several studies provided evidence that E_2 stimulated LH secretion. Namely, injection of high doses of estrogen to immature rats[17] and seasonally anovulatory sheep[18] induced formation of CL; since LH was responsible for luteinization, these workers suggested a stimulatory action of E_2 on LH release. In contrast, progesterone administration blocked ovulation in rats,[19] guinea pigs,[20] and rabbits.[21] These data supported the hypothesis that progesterone inhibited LH release, and they would eventually lead to development of the contraceptive pill 20 years later.[22]

In 1939, Fevold[13] synthesized these new observations into the following model for the ovarian cycle: at the beginning of the follicular phase, FSH concentrations are high and initiate a wave of follicular development. As the follicles grow, the increasing serum E_2 inhibits FSH secretion and stimulates LH secretion. Ovulation and luteinization occur once LH release is dominant. During the luteal phase, the increasing progesterone and low E_2 result in gradual decreases in LH (high progesterone) and increases in FSH (low E_2), so that at luteolysis a new wave of follicular growth can begin. Although Fevold recognized that this model might not apply to rabbits and guinea pigs,[13] it appears to have been generally accepted, and it became the dominant model for the next two decades.

Over that period, several lines of evidence undermined the basic assumptions of this model. First, as more purified LH and FSH preparations were developed, it

became evident that LH as well as FSH were needed for E_2 secretion from the follicle.[23] Second, Everett demonstrated that the properly timed administration of progesterone to rats could induce ovulation,[24] with acute progesterone treatments being stimulatory and chronic treatments inhibitory. Third, careful studies demonstrated that E_2 had two effects on LH secretion, with low doses being inhibitory and high doses stimulatory.[25] At the same time, interest was growing in the possible role of the brain in control of gonadotropin secretion. Early work had clearly demonstrated a role for the nervous system in reflex ovulation in rabbits[26] and provided indirect evidence for a hypothalamic "sexual center" in rats (see the discussion in Sawyer et al., 1949[27]). However, it wasn't until the late 1940s, when Harris and others established the functional importance of the hypophysial portal circulation,[28] that studies on the neural control of ovarian function began in earnest. One of the earliest of these was a pivotal set of studies that ultimately led to the current model for ovarian cycles.

The Tonic and Surge Secretion Model

This model postulates that a relatively constant, or "tonic," secretion of FSH and LH is responsible for follicular growth and E_2 secretion and, in turn, is regulated by the negative feedback action of this steroid. Ovulation and luteinization are the results of a surge of gonadotropin (LH) superimposed on this basal secretory rate; in reflex ovulators the LH surge is triggered by coitus, while in spontaneous ovulators it is initiated by high E_2 concentrations at the end of the follicular phase. Tonic secretion occurs in males and females, whereas the LH surge only occurs in females. The ability of E_2 to induce the LH surge in spontaneous ovulators became known as the positive feedback action of this steroid to distinguish it from the negative feedback action of E_2 on tonic LH and FSH secretion, although it is technically not a positive feedback loop. A positive feedback loop consists of two elements (i.e., LH and E_2), both of which stimulate the other, and is inherently unstable because once initiated it leads to continuous increases in both elements until an outside force breaks the feedback loop. Although tonic LH secretion stimulates E_2 secretion, the LH surge inhibits E_2 secretion, while increasing progesterone secretion, from the preovulatory follicle.

In 1949, Everett, Sawyer, and Markee laid the foundation for this model in a paper examining the possible role of adrenergic and cholinergic transmission in ovulation.[29] In this work, they demonstrated that receptor antagonists (dibenamine and atropine, respectively) blocked ovulation in rats if given before 1400 h on proestrus, but were ineffective if given at 1600 h (Figure 33.2). They thus concluded that a neurogenic signal from a hypothalamic "sexual center" on the afternoon

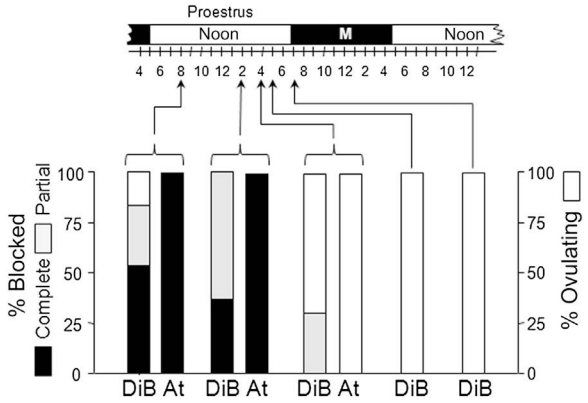

FIGURE 33.2 Administration of the α-adrenergic receptor antagonist dibenamine (DiB) and the cholinergic receptor antagonist atropine (At), at or before 1400 h of proestrus, blocks ovulation in rats. If given at 1600 h or thereafter, these drugs have little or no effect on ovulation. M: midnight. *Source: Data redrawn from Everett et al.*[29]

of proestrus triggered the preovulatory discharge of LH in rats. They also suggested, based on earlier work, that elevated estrogen initiates the "ovulation stimulus" from this center, although progesterone may synergize with E_2 under some circumstances. In a subsequent study, using pentobarbital blockade, they established that there was a "24 h periodicity in the 'LH-release apparatus' of the female rat,"[30] setting the foundation for current work on the circadian control of this system in rodents.[31]

As they had already demonstrated that dibenamine and atropine blocked ovulation if given shortly after coitus in rabbits,[32] this work in rats established a common link between control of ovulation in reflex-ovulating and spontaneously ovulating species. In addition, by limiting the time of LH release to a short period in the afternoon of proestrus, the data strongly indicated that the signal for ovulation in the rat, as in the rabbit, was an abrupt discharge of LH from the pituitary. Importantly, these authors extended the analogy between these two species by comparing rabbits to rats in constant estrus: "one direct cause of such aberrant occurrences is the failure of the hypothalamus to discharge an adequate stimulus to the hypophysis. As a result, the hypophysis continues more or less steadily to secrete only small amounts of gonadotrophin, which are nevertheless sufficient to maintain estrogen secretion. This steady state is normal in such species as the rabbit," and "the steady secreting male type is determined [in rats] by early action of androgen during infancy."

Although this model contained all the basic elements of the current tonic and surge model for the control of gonadotropin secretion, it was slow to gain acceptance. One major milestone in its progress was the work by Barraclough and Gorski[33] in 1961 on the site where neonatal androgen acts to disrupt ovulation. Although their experimental conclusion that androgen blocked the ability of electrochemical stimulation of the preoptic area (POA)

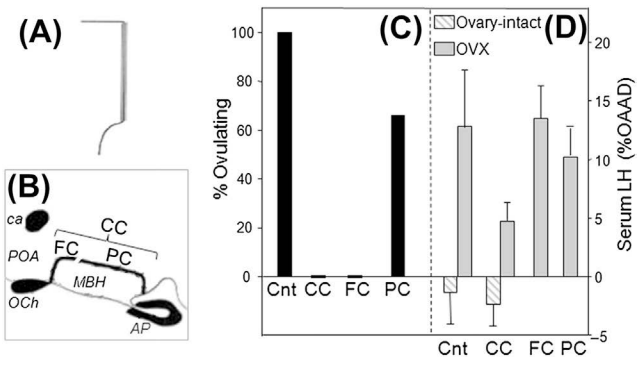

FIGURE 33.3 Effects of different neural de-afferentation procedures on ovulation in ovary-intact rats and serum LH in OVX rats. Panel A: schematic of Halasz knife that was lowered down between the two hemispheres to perform de-afferentations. By combining rotation of the knife 90° so the blade is parallel to the third ventricle and moving it in the anterior–posterior plane, the cuts in panel B were performed. Panel B: Illustration of three types of knife cuts on a parasagittal schematic of the rat hypothalamus. Complete cuts (CC) severed all connections to the mediobasal hypothalamus (MBH), while frontal cuts (FC) severed inputs from the preoptic area (POA) and posterior cuts (PC) severed inputs entering laterally and posteriorly. Effects of cuts on ovulation rate (panel C) and on tonic LH secretion (panel D), illustrated as mean (±SEM) serum LH concentrations in samples collected from OVX (shaded bars) and ovary-intact (striped bars) rats during the morning; Cnt: controls. Note that LH was measured using the ovarian ascorbic acid depletion bioassay. Serum from ovary-intact rats produced a slight (nonsignificant) increase in ascorbic acid content of the ovaries, which is plotted as a negative value. Panels A, B, and C taken from a review by Haslaz[35]; panel D is based on data presented in Halasz and Gorski.[36] AP: anterior pituitary; ca: anterior commissure; OCh: optic chiasm.

to induce LH secretion was later proved to be incorrect,[34] the hypothesis of "dual hypothalamic control of adenohypophysial gonadotropin secretion," with the arcuate–ventromedial nuclei of the mediobasal hypothalamus (MBH) controlling the "tonic discharge of gonadotropins in sufficient quantity to maintain estrogen production" and the POA producing the "cyclic discharge of gonadotropin to cause ovulation," was conceptually important. Moreover, it soon received strong support from the neural de-afferentation studies of Halasz, which clearly demonstrated that the MBH was important for tonic secretion, while input from the POA was essential for ovulation (Figure 33.3).[35–37] By placing control of tonic and surge secretion in two different hypothalamic areas, these studies provided a concrete visualization of the model that facilitated its general acceptance. The application of bioassays to the measurement of gonadotropins (primarily LH using the ovarian ascorbic acid depletion assay) in the 1960s provided further support for this model, which was formalized in its present form by Schwartz toward the end of this decade.[38] It is interesting to note that this model was essentially fully developed before radioimmunoassays (RIAs) were used to measure circulating gonadotropins and ovarian steroids, which is a tribute to the careful experimental designs and interpretations of these early workers. The subsequent RIA measurements of LH and FSH concentrations during the ovarian cycles of several species,[39,40] including humans,[39] and the application of the concept that different mechanisms control tonic and surge secretion of gonadotropins to the rhesus monkey[41] demonstrated its general applicability and solidified its acceptance.

While the tonic and surge model for control of gonadotropin secretion is now generally applied to all mammals, it should be kept in mind that it has been rigorously tested in only a few of these. In this regard, the estrous cycle of the mare is a cautionary example. At a superficial level, it closely resembles that of other domestic animals, with a length of 22 days divided into a 15–17-day luteal phase and 5–7-day follicular phase.[42] However, closer examination of the preovulatory LH surge indicates a marked difference from other animals in this group. It is prolonged, lasting about 5 days, and of relatively low amplitude, with peak levels only fivefold (compared to 50- to 100-fold increases in rats, sheep, and primates) higher than basal concentrations.[42,43] Moreover, follicular ablation studies demonstrate that it is not induced by increasing E_2 during the follicular phase, but is more likely caused by a withdrawal of steroid negative feedback due to luteolysis.[43] Thus, this ovarian cycle may depend more on changes in negative feedback, as first suggested by Moore and Price,[10] than on the differential control of tonic and surge secretion.

MODIFICATIONS IN THE MODEL: SPECIES DIFFERENCES IN GONADAL FEEDBACK

One apparent deficiency in this model is the lack of any role for progesterone beyond its ability to inhibit the preovulatory LH surge, which is evident in all species. Indeed, the model focuses much more on events during the follicular phase than on those in the luteal phase, most likely because it was based largely on work in rats, a species that does not have a functional CL in the absence of coitus. It was also recognized that there are major species differences in control of luteal function, with prolactin being the primary luteotropin in rodents, but LH performing this role in most other species (Chapter 23).[44] Moreover, in many species in which LH is luteotropic, uterine prostaglandin-$F_{2\alpha}$ is the key determinant of luteal lifespan, so the feedback actions of progesterone were thought to be of little importance. However, with the availability of RIAs and the development of physiological replacement regimens, two additional feedback actions of progesterone were identified, although the importance of these varies among species.

Control of the LH Surge: Stimulatory Actions of Progesterone

As noted in this chapter, earlier evidence in the rat indicated that progesterone could act acutely to induce ovulation[24]; later measurements of endogenous progesterone secretion indicated that it increased at the time of the LH surge in many species and raised the possibility that this action might be physiologically relevant. In rats,[45] guinea pigs,[46,47] monkeys,[48] and women,[49] the preovulatory LH surge induces an increase in progesterone secretion from the ovulating follicles, although the increment is modest in primates compared to the dramatic increase in rats and guinea pigs. This response to the LH surge is not seen in sheep[50] (although it does increase progesterone levels within the follicle), other domestic animals,[40] and reflex ovulators,[6] except for the rabbit, in which the primary steroid released is 20α-hydroxyprogesterone.[51]

While acute stimulatory effects of progesterone on LH can be demonstrated in rats,[52] guinea pigs,[53,54] rabbits,[55,56] monkeys,[57] and humans,[58,59] there are species differences in the physiological role of these endogenous progestin increments. They are not important in rabbits because ovariectomy 15 min post coitus does not alter the subsequent increment in LH.[60] Likewise, in guinea pigs,[61] sheep,[62] and rhesus monkeys,[63] exogenous estrogen alone produces normal gonadotropin surges in OVX animals. Similar replacement studies in women indicated that progesterone may produce a modest stimulation of LH secretion, and a more dramatic increase in FSH secretion, during the surge.[58,59] In rodents, the stimulatory actions of progesterone appear to be important in amplifying the LH surge.[64,65] It should also be noted that the chronic inhibitory actions of this progesterone increment limit the LH surge to proestrus,[66] instead of occurring daily as is seen in estrogen-treated OVX rats.[64] Interestingly, the stimulatory action of progesterone in rodents may well be one biological consequence of a key role for progesterone receptors (PRs) because they appear to be necessary for the preovulatory gonadotropin surge in rodents, even when it is induced by E_2.[67,68] Whether PR signaling is critical in other species has yet to be determined, but this does not seem to be the case for the ewe.[69] Thus in most, but not all, species, progesterone can synergize with E_2 to facilitate the preovulatory gonadotropin surge, but the physiological importance of this action varies across species.

Control of Tonic LH Secretion: Inhibitory Actions of Progesterone

Careful studies with physiological hormone replacement clearly demonstrate that progesterone can synergize with low E_2 levels to inhibit tonic LH secretion in rats,[70] sheep,[71] monkeys,[72] and humans.[73] Not surprisingly, this appears not to be the case for reflex ovulators[6]: E_2 is sufficient to hold LH secretion in check in OVX ferrets,[74] cats,[75] and rabbits,[76] and tonic LH concentrations during pseudopregnancy are similar to those in estrous rabbits.[4] In those spontaneous ovulators in which synergistic effects occur, it is also clear that progesterone usually has little or no effect in the absence of E_2, and the responses to the negative feedback actions of steroids change with time after OVX. These data, together with observations that LH concentrations during the cycle are not obviously negatively correlated with progesterone in monkeys[41] and rats,[77–79] supported the conclusion that E_2 is the primary negative feedback steroid in these species. In contrast, Karsch et al.[71,80,81] presented strong evidence that progesterone is the primary negative feedback hormone during the estrous cycle of sheep. They[82] and others[83] also proposed that the fall in circulating progesterone concentrations at luteolysis, by allowing a sustained increase in tonic LH secretion that drives the preovulatory E_2 rise needed to induce the LH surge, was the key event controlling the timing of ovulation in this species. Interestingly, some of the strongest support for this hypothesis was analogous to the early work of Loeb in the guinea pig[8]: removal of the CL caused premature initiation of these events, including ovulation, while prolongation of elevated progesterone delayed them.[80,83] Thus, there are species differences in which steroid is the primary negative feedback hormone during the ovarian cycle: it appears to be E_2 in reflex ovulators, rats, and primates, but progesterone in sheep, cows, and probably guinea pigs.

Control of Tonic LH Secretion: Steroid Inhibition of Episodic LH Secretion

The advent of RIAs soon led to the discovery that tonic LH secretion was not the "steady" continuous type of release originally envisioned, but instead was secreted episodically. The initial report of episodic LH secretion in OVX monkeys[84] was soon extended to include a large number of species and endocrine conditions.[85] When the negative feedback control of episodic LH secretion was examined, an interesting pattern emerged: in primates and domestic animals, progesterone inhibited LH pulse frequency, while E_2 inhibited pulse amplitude.[85–87] These actions were evident when pulse patterns in ovary-intact females were compared with those in OVX animals or postmenopausal women (Figure 33.4) and provided a simple explanation for differential patterns of episodic LH secretion during the ovarian cycle of these species, with low-amplitude high-frequency pulses in the follicular phase, and high-amplitude low-frequency pulses in the luteal phase.[88–90] The two exceptions to this general pattern are reflex ovulators and rats. LH pulse frequencies are similar in estrous and pseudopregnant rabbits,[4] and E_2 inhibits LH pulse frequency in OVX rabbits[76] and ferrets.[74]

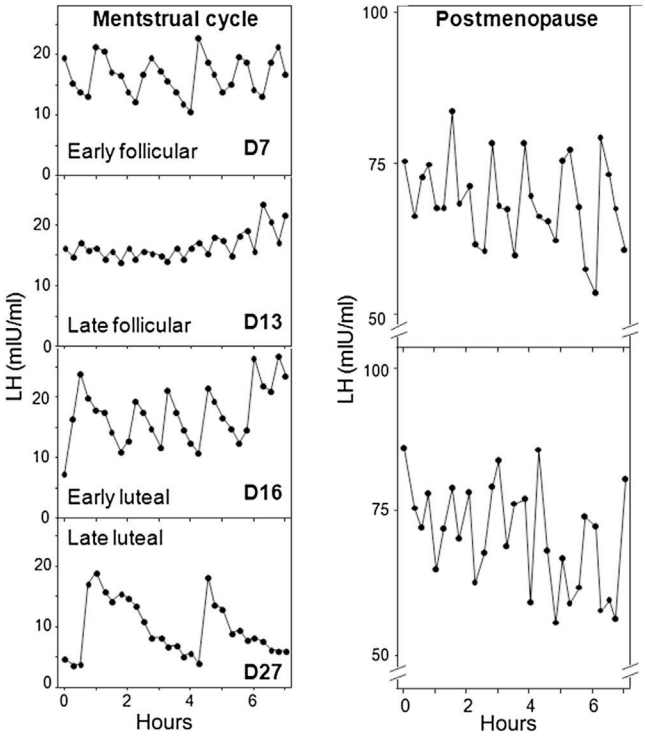

FIGURE 33.4 LH pulse patterns on four different days of the menstrual cycle (left) and from two postmenopausal women (right). Note that y-axes on the right have been adjusted to start at 50 mIU/ml so that pulse amplitudes can be directly compared with those on the left. *Source: Redrawn from Yen et al.[88] with permission from the Endocrine Society.*

In rats, there are no changes in episodic LH secretion during most of the 4-day estrous cycle except on the morning of estrus when few,[77] or no,[78,79] LH pulses are observed. When progesterone negative feedback on LH pulses is examined in rats, the primary effect appears to be on LH pulse amplitude,[91–93] although there is strong evidence that the proestrus surge in progesterone secretion suppresses pulsatile LH secretion on the morning of estrus.[94] Inhibitory effects of E_2 on either LH pulse frequency[91,95] or amplitude[78,91,95] have been reported, probably due to differences in steroid concentrations or treatment regimens. For example, careful comparison of the effects of physiological E_2 concentrations indicated that the higher levels on proestrus inhibited LH pulse frequency,[95] while lower concentrations seen on diestrus-2 did not.[93] The species difference in progesterone negative feedback may reflect the absence of a prolonged luteal phase in the rat, as progesterone (when combined with E_2) strongly inhibits LH pulse frequency on days 6 to 8 of pregnancy.[96]

One fairly consistent but still unexplained observation from these studies is that steroid replacement in OVX animals appears to be more effective than the same concentration of steroids produced by the ovaries, at least in rats and monkeys. Thus, the combination of physiological E_2 and progesterone replacement completely suppresses LH secretion in OVX monkeys and rats, a phenomenon not evident in ovary-intact animals. Similarly, E_2 treatment completely eliminates episodic LH secretion in OVX animals,[78,97,98] even though clear LH pulses are evident in the presence of the same E_2 concentrations in the follicular phase. This led to the proposal that an ovarian factor acts to ameliorate the negative feedback actions of E_2 and/or progesterone.[98] There is still no evidence as to what this factor is, and other possibilities have been suggested. For example, replacement regimens do not match the dynamic pattern of steroid secretion produced by the ovary. If such a factor exists, it is unlikely to be important in sheep since physiological E_2 and progesterone replacement results in LH concentrations indistinguishable from those in the normal ovine estrous cycle.

Control of Tonic FSH Secretion: Inhibins, Activins, and Follistatin

In many early RIA studies, LH and FSH concentrations generally changed in parallel so it was assumed that they were controlled by the same ovarian feedback mechanisms. This assumption appears to still hold for surge secretion of FSH, which is induced by the positive feedback action of E_2, supplemented by progesterone in some species. In contrast, it is now clear that tonic secretion of FSH is controlled, in part, by negative feedback actions of inhibin in many species. "Inhibin" was initially described in 1932 as a water-soluble testicular extract that inhibited castration-induced changes in the cell structure of gonadotropes.[99] Inhibin was subsequently associated with selective inhibition of FSH secretion based on positive correlations of urinary FSH, but not LH, with the degree of damage to spermatogenesis in infertile men.[100] However, this concept gradually fell into disrepute because the initial observations could not be replicated and attempts to purify inhibin were unsuccessful. Interest in inhibin was rekindled by RIAs, which demonstrated clear instances of differential secretion of FSH and LH, which included selective declines in FSH secretion (in the latter half of the follicular phase in primates and domestic animals) and selective increases in FSH release (during the peri-menopausal period in women, and "second FSH surges" in rodents and domestic animals). This ultimately led to the identification of two inhibins, inhibin A (α-β_A) and inhibin B (α-β_B), that inhibit FSH; activins (dimers of β_A and β_B) that stimulate FSH secretion; and follistatin, a binding protein that inactivates activin.[101,102] It was also soon recognized that these proteins are produced in a variety of tissues, including the anterior pituitary, and play important physiological roles beyond regulation of FSH secretion.

Although the ovaries produce inhibin A and B, activins, and follistatin, inhibins are probably the only important hormonal product because most of the circulating activin and follistatin form an inactive complex and the free forms show little, if any, variation that correlates with changes in FSH secretion.[103] Thus, paracrine actions of activin and follistatin at the pituitary are probably much more important to control of FSH secretion than their endocrine actions from the ovary. While inhibin is now recognized as an important inhibitory hormone, there are species differences in the relative roles of inhibin and ovarian steroids in the control of tonic FSH secretion. In rats[104] and sheep,[105] inhibin plays an important negative feedback role because physiological concentrations of progesterone and E_2 produce normal levels of LH, but only partially suppress FSH concentrations in OVX animals. Moreover, passive immunoneutralization of inhibin in rats[106] and cows[107,108] produces dramatic increases in FSH secretion that are often greater than those seen when antibodies to E_2 are administered. Thus, a negative feedback loop between follicular inhibin and FSH secretion controls follicular development and ovulation rates in these species.[109] The importance of inhibin in primates is less clear; physiological replacement with ovarian steroids in OVX monkeys maintains normal concentrations of both FSH and LH,[72] but similar treatments in women with premature ovarian failure produce normal LH, but elevated FSH, concentrations.[110] It is clear that a negative feedback loop between the developing follicles and FSH secretion is important to the control of follicular development in primates,[109] and some evidence points to an important role for inhibin,[111] but the preponderance of data (reviewed by Zeleznik and Plant[1]) indicates that E_2 is the primary negative feedback hormone in the follicular phase of the menstrual cycle.

There are species differences in the ovarian sources of inhibin A and inhibin B and thus differences in secretion patterns of these proteins. In rats and primates, follicles secrete similar amounts of both inhibins, while in sheep,[112] pigs,[113] cows, and horses[109] only inhibin A is secreted in biologically important amounts. In the species whose ovaries produce both inhibins, inhibin B originates primarily from small antral follicles, while inhibin A comes from preovulatory follicles.[114–116] This results in differential secretion of the two inhibins as the follicular phase progresses,[109,117,118] which may be useful in monitoring follicular development but is unlikely to be important to control of FSH because inhibin A and inhibin B have similar biological effects.[119] A more important species difference may be that the corpora lutea of Old World monkeys[115] and women[116] produce inhibin A, while those in most other species do not.[102,112,113] It is tempting to speculate that luteal secretion of inhibin A holds FSH release at minimal levels in these primates, thus preventing the follicular waves seen in other species during the luteal phase, and producing the relatively long follicular phase seen in primates. However, inhibin A does not appear to play such a role in monkeys because antibodies against this peptide did not alter FSH secretion in the luteal phase[120] and exogenous inhibin A failed to prevent the FSH increase that follows luteolysis in stump-tailed macaques.[121] Instead the combination of E_2 and progesterone likely accounts for changes in FSH concentrations during the luteal phase in primates.[1] In light of this conclusion, the production of E_2 by the primate CL, but not by the CL of domestic animals, may account for species differences in follicular development during the luteal phase, and thus the longer follicular phase of the menstrual cycle.[122]

NEUROENDOCRINE SYSTEMS MEDIATING STEROID FEEDBACK

For many years now, one major focus of reproductive neuroendocrinologists has been to identify the components within the hypothalamo–pituitary unit responsible for tonic and surge secretion of gonadotropin-releasing hormone (GnRH) and their control by ovarian steroids. These studies required invasive, and often complicated, experimental manipulations and have largely been limited to three species: rats, sheep, and monkeys. Therefore, in this section, I will compare the considerable information currently available on these three species with the more limited data available on humans and other species. I will first describe the effects of ovarian steroids at the level of the pituitary and then consider hypothalamic systems controlling tonic and surge secretion of GnRH.

Effects of Ovarian Steroids on the Pituitary

One enduring controversy, which has yet to be completely resolved, is the relative importance of hypophysial and hypothalamic sites of action of E_2 and, to a lesser extent, progesterone. A clear determination of the actions of ovarian steroids on the pituitary in situ is complicated because it is difficult to distinguish between direct effects on gonadotropes and indirect effects via changes in hypothalamic release of GnRH secretion. An increase in endogenous GnRH can affect the response to exogenous GnRH via several mechanisms, including an induction of GnRH receptors on gonadotropes[123] and a self-priming action, whereby a second injection of GnRH produces a larger increment than the first injection.[124] It is also clear that LH pulse amplitude is inversely related to GnRH pulse frequency[125] and directly related to GnRH pulse amplitude, and that changes in frequency can alter the relative secretion of FSH and LH, with high frequencies favoring the latter.[126,127] To eliminate possible confounding changes in endogenous GnRH secretion, workers developed

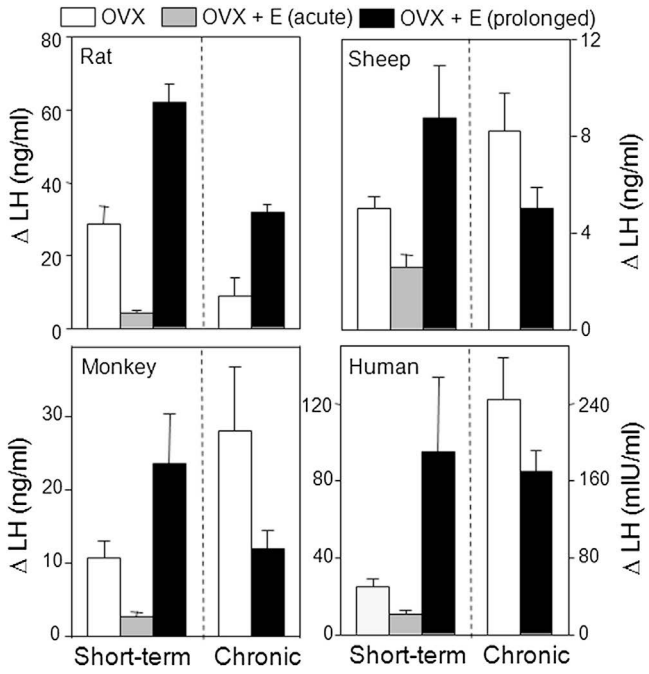

FIGURE 33.5 Effects of short-term and chronic treatment with E_2 on the pituitary response to GnRH (plotted as mean ± SEM ΔLH) in rats,[131] sheep,[129,132] monkeys,[128,133] and humans.[134,135] With short-term treatments of E_2, an initial (acute) suppression in response to GnRH is followed by stimulation of the response (prolonged treatment); in these panels, the nadir and peak responses are presented (see the text for approximate times of each). Chronic treatments with E_2 were for 48 h in rats,[131] 7 days in sheep[132] and women,[135] and 13 days in rhesus monkeys.[133] Data from sheep and short-term treatments in monkeys were collected using a hypophysial clamp approach; all other data were from animals or patients with an intact hypophysial–pituitary unit. Note that in most cases, data for short-term and chronic effects of E_2 are from different studies and cannot be directly compared.

techniques in monkeys,[128] sheep,[129] and pigs[130] to eliminate endogenous secretion by either lesioning the MBH or surgical disconnection of the MBH from the anterior pituitary so they had complete control of the exposure of the in situ pituitary to GnRH given exogenously (often referred to as a "hypophysial clamp").

Although not all studies have controlled for endogenous GnRH release, very similar patterns emerge (with one exception) when the effects of E_2 on the GnRH-induced increment in LH concentrations are examined across several species (Figure 33.5). In all cases, a short-term exposure to this steroid initially inhibits the response to GnRH, but with continued exposure to E_2 an augmented increment in LH is observed. The exact time course varies among species, being shortest in rats (nadir at 4–5 h and peak at 12 h),[131] intermediate in sheep (nadir: 6–10 h; peak: 20–28 h),[129] and longest in primates (nadir: 16–24 h[128,134]; peak: 3–4 days[128,135]). A similar pattern has been reported in cows[136] and guinea pigs,[137] but the stimulatory effects observed in the latter are fairly modest, particularly when compared to the dramatic effects of E_2 on the self-priming action of GnRH.[137] The one exception to this general pattern is the pig, in which E_2 appears to have inhibitory, but no stimulatory, effects on the pituitary.[130] It should be noted that very rapid inhibitory effects can be observed in several of these mammals with intravenous infusion of E_2,[138–141] although these studies sometimes used supraphysiological E_2 treatments. Interestingly, the latency to the stimulatory effects of E_2 on the pituitary generally corresponds to the time needed to induce an LH surge, and is positively correlated with the length of the follicular phase in these species. With more chronic exposure (i.e., at least several days) to E_2, inhibitory effects on the response to GnRH are observed in rabbits,[76] sheep,[132] monkeys,[133] and women.[135] On the other hand, the stimulatory effect observed in the rat with short-term exposure is maintained with chronic exposure to E_2 (>24 h).[131] These species differences are consistent with observations that a chronic increment in E_2 induces only a single LH surge in sheep and primates, but daily LH surges in rodents.[64]

The physiological importance of progesterone actions on gonadotropes remains unclear. These have not been as extensively studied as those of E_2 and vary considerably among species. In rats, these actions generally correlate with the effects of progesterone on LH secretion, with acute exposure (for 3–8 h) enhancing the response to GnRH, and prolonged exposure (at least 48 h) inhibiting this response.[3] In women with deficient GnRH secretion, progesterone increased LH pulse amplitude in response to exogenous GnRH pulses,[142] an action that may contribute to the elevated response to GnRH observed during the normal luteal phase.[143] In monkeys, stimulatory effects of progesterone on the pituitary have been reported,[1] but these are not reflected in an increased response to GnRH in luteal phase animals.[133] The situation is equally confusing in the sheep since both stimulatory[129] and inhibitory[144] effects of progesterone on the GnRH-induced increment in LH have been reported using similar models. Thus, in contrast to the effects of E_2 on the pituitary, which generally correlate with its negative and positive feedback actions in most species, the effects of progesterone are more variable and their physiological relevance remains unclear.

Hypothalamic Systems: General Considerations

There is evidence in most species that E_2 and progesterone also have important feedback actions in the brain to control episodic GnRH secretion. The inhibition of LH pulse frequency by progesterone clearly implies that this steroid inhibits GnRH pulse frequency, and this has been confirmed by direct measurements of GnRH. However, inhibition of LH pulse amplitude by E_2 could reflect actions solely at the pituitary, and there is considerably more controversy as to whether this steroid also inhibits GnRH pulse amplitude in some species, but clear evidence for

this in rabbits and sheep (discussed later in this chapter). It is also clear that E_2 induces a preovulatory GnRH surge in spontaneous ovulators, but there may be important species differences in the physiological significance of this positive feedback action of E_2. Furthermore, there are major species differences in the anatomical substrates and sites of action of ovarian steroids, so this section will consider the comparative aspects of each of these in some detail.

Anatomical Aspects

When considering neural aspects of these control mechanisms, it is also useful to distinguish between anatomical areas and specific neuronal phenotypes. At the outset, it should be emphasized that experiments focused on the neuroanatomy of these control systems were designed to determine the minimal neural areas required for normal function, and did not exclude other regions providing physiologically relevant modulatory input. It is thus important to remember that redundancy is one hallmark of the reproductive neuroendocrine system. This is evident in estimates of the number of GnRH neurons needed for normal episodic GnRH secretion, which range from 70–80 neurons in mice[145] to approximately 100 in sheep[146]; indeed, 1–28 GnRH neurons in hypothalamic grafts are apparently sufficient to produce episodic LH secretion in castrated male *hpg* (hypogonadal) mice.[147] Similar, if not greater, redundancy is seen in regard to ovulation. Thus, much more LH is released during the preovulatory surge than is required for ovulation,[148] and only a small fraction of the preovulatory GnRH surge is required to produce a normal LH surge, at least in sheep.[149] Similar redundancy is evident in other neural systems controlling GnRH release.[150,151] Thus, as exemplified by evidence from monkeys for a preovulatory GnRH surge that is not required for normal menstrual cycles,[152] determination of the minimal systems required for normal function is likely to exclude mechanisms that function under physiological conditions.

Neural Systems Mediating Feedback Actions of Steroids

Although a multitude of neurotransmitters have been implicated in the control of both tonic and surge secretion of GnRH (see Chapter 11),[153] a consideration of most of them is beyond the scope of this chapter. However, sufficient information is available on three of these to allow useful species comparisons: norepinephrine (NE), the endogenous opioid peptides (EOPs), and kisspeptin. This focus does not imply that these neurotransmitters are more important than others. For example, it is clear that both gamma-aminobutyric acid (GABA) and glutamate play important roles in controlling GnRH secretion, and a considerable amount of information is available on the effects of these transmitters on GnRH neural activity in mice.[153,154] However, no clear picture has emerged on their role in other species. Similarly, neuropeptide Y (NPY) appears to be important for the full preovulatory LH surge in rats[124] and rabbits,[6,7] but its physiological actions and roles in other species remain unclear. With NE, EOPs, and kisspeptin, a fairly consistent role has been identified across several species in the control of tonic and/or surge secretion of GnRH. The consideration of kisspeptin will be limited to a brief overview of species similarities and differences, with only a few references to the primary literature. A number of recent reviews on these actions of kisspeptin are available,[31,155,156] and they are also covered in detail by several chapters of this book.

Hypothalamic Control of Tonic Gonadotropin Secretion

Anatomical Sites of Action
