However, the majority of ejaculation-activated cells in the MePD, PdPN, or mSDA of gerbils did not project to other members of the ejaculation-related circuit; the authors suggested that the majority of the Fos-IR neurons either were interneurons or projected to other brain areas.[538] Indeed, a later article reported that ejaculation-activated neurons in the PdPN and MePD projected to the anteroventral periventricular nucleus (AVPV), the dorsal portion of the principal part of the BST, and the retrorubral field.[699]

It is not clear whether the activated neurons primarily received sensory input or activated motor patterns leading to ejaculation. The similar pattern of Fos-IR in female rats following ejaculation by the male[700,701] suggests that these neurons are activated by sensory input rather than programming motor output. However, lesions of the PdPN or MePD decreased mounting and delayed ejaculation.[358] Thus, these data suggest a contribution of these structures to the motor control of copulation, but not a major specific role in triggering ejaculation. Lesions of the posterior thalamus that included SPFp and zona incerta completely disrupted ejaculatory behavior in male rats,[702] supporting a role for the posterior thalamus in control of ejaculation. In contrast, small lesions restricted to the SPFp in gerbils had no effect on copulation,[358] suggesting that the SPFp may relay copulation-related information, rather than triggering ejaculation. The SPFp receives ascending sensory inputs, either directly or indirectly, from the lumbosacral and cervical regions of the spinal cord, and in turn projects to the BSTpm and MePD of rats.[703] In gerbils the SPFp projects to the mSDA, PdPN, MePD, but does not receive reciprocal input from those structures.[699]

Yahr and her colleagues have provided information about the neurotransmitters used by ejaculation-activated neurons in gerbils. One-third to one-half of Fos-IR neurons in the lateral PdPN and MePD expressed NOS; in addition, half of the Fos-IR neurons in the MePD, lateral PdPN, and medial sexually dimorphic nucleus of the MPOA (mSDA) were GABAergic, and a quarter of those in the MePD and mSDA were glutamatergic; the PdPN appeared to have no glutamatergic cells.[380] The authors suggested that these neurons may influence the timing of ejaculation, the length of the postejaculatory interval, or release of LH or prolactin at the time of ejaculation.

Male hamsters show Fos activation in the BSTpm and MePD only after multiple ejaculations, or when they are reaching sexual satiety after only a few ejaculations, due to mating on previous consecutive days.[363] Moreover, small lesions directed at the lateral MePD increased the number of ejaculations necessary for satiety.[704] Hence, the MePD may contribute to ejaculatory behavior and promote sexual satiety in addition to other aspects of male sexual behavior.

Lesions of the lateral hypothalamus severely affect the display of ejaculations, but do not affect the ability to mount and intromit.[557] Thus, this area may play an excitatory role in the regulation of ejaculation. Interestingly, 5-HT is released in the anterior LHA at the time of ejaculation,[533] and microinjection of a selective 5-HT reuptake inhibitor into the LHA increased the latencies to mount, intromit, and ejaculate.[533] Hence, 5-HT in the LHA may influence sexual motivation as well as ejaculatory behavior.

A study by Holstege and coworkers[419] used positron emission tomography to study increases in regional cerebral blood flow during ejaculation in men. Increased blood flow was observed following ejaculation compared to sexual stimulation in the mesodiencephalic junction, which includes the location of the SPFp. In addition, increased blood flow was observed in cerebellum, lateral putamen, claustrum, and several cortical areas. Increased blood flow was not detected in the MPOA or BNST, which contrasts with studies in rodents but is in agreement with a study in male macaques that failed to detect Fos activation in the MPOA following ejaculation.[409]

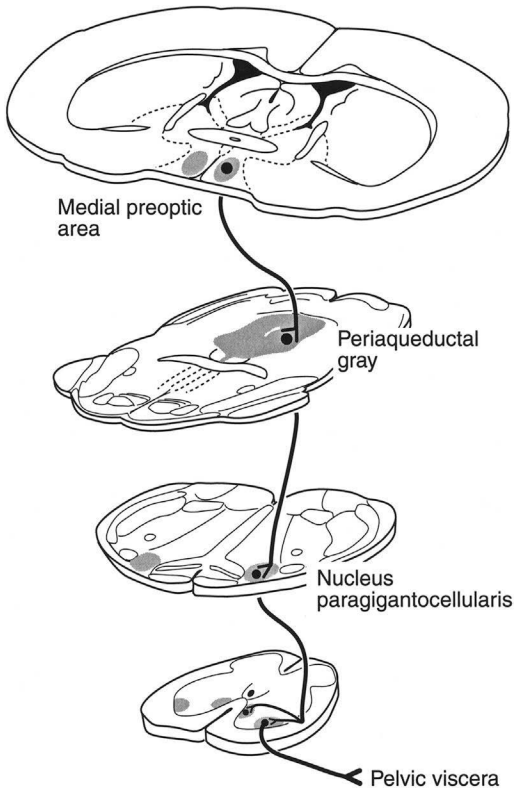

FIGURE 49.25 Summary schematic showing the MPOA-PAG-nPGi-spinal cord circuit. MPOA projections to the periaqueductal gray (PAG) terminate preferentially among PAG neurons projecting to the nucleus paragigantocellularis (nPGi). Descending projections from the nPGi terminate within the dorsomedial and dorsolateral motor pools of the ventral horn of the lumbosacral spinal cord. Motoneurons from these pools innervate the bulbocavernosus and ishiocavernosus muscles, which are essential for penile erection and ejaculation. *Source: Figure is from Ref. 633, with permission.*

Efferents from the MPOA

The primary efferents from the MPOA travel through the medial forebrain bundle to the midbrain.[705] However, we should emphasize that most of the afferent and efferent connections of the MPOA with other brain regions are reciprocal.[424] Therefore, "downstream" structures can both modulate MPOA processing and receive its output. Evidence for the importance of axons leaving the MPOA laterally to join the medial forebrain bundle include reports that knife cuts lateral to the MPOA disrupted copulation similarly to lesions of the MPOA itself, whereas knife cuts either rostral or caudal to the MPOA were ineffective.[706] Similarly, lesions along the extent of the medial forebrain bundle caudal to the MPOA permanently eliminated copulation, whereas lesions rostral to the MPOA did not affect copulation (reviewed in Ref. 3). Furthermore, contralateral lesions of the MPOA and medial forebrain bundle were as effective as bilateral lesions of either structure.[707]

The critical axons in the medial forebrain bundle provide reciprocal connections between the MPOA and the ventral pons and medulla (Figure 49.25).[708] Dense projections from the MPOA reach the nPGi and midline raphe nuclei. Lesions of the nPGi facilitated copulation,[643] touch-based erections and anteroflexions,[644] and the UG reflex.[646] 5-HT from the raphe nuclei is also generally inhibitory to male sexual behavior (reviewed in Ref. 576). Therefore, one means by which the MPOA can facilitate sexual behavior is by inhibiting these two areas. However, these areas may also send reciprocal input to the MPOA to inhibit sexual behavior. The MPOA also provides dense innervation to the PAG, which in turn projects to the nPGi. Thus, the MPOA can influence the nPGi through both direct and indirect connections. The PAG has numerous AR- and/or ER-containing neurons.[636] Furthermore, both the MPOA efferents to the PAG and the PAG efferents to the nPGi contain AR and/or ERα, and axons from the MPOA end in close juxaposition to PAG-to-nPGi efferents.[633] Therefore, gonadal hormones could affect the ability of the MPOA to disinhibit sexual behavior. However, it is unlikely that mere disinhibition can account for the elicitation of reflexes that has resulted from electrical or chemical stimulation of the MPOA (reviewed in Ref. 3). It seems likely that there is also a pathway that provides excitation to the spinal neurons that control the reflexes. Peripheral pathways that mediate that excitatory influence appear to include activation of both parasympathetic outflow, via the pelvic and cavernous nerves, and sympathetic efferents, via the paravertebral sympathetic chain and possibly the hypogastric nerve.[39] Although the parasympathetic system provides the main pro-erectile force, the sympathetic system may also contribute, perhaps by producing vasoconstriction in nongenital areas, thereby diverting blood to the penis.[39] (See the section Neural Innervation of the Penis earlier in the chapter.)

Sexual Behavior in the Context of Mammalian Social Behavior

The same brain areas that control male sexual behavior also regulate other social behaviors, including female sexual behavior, maternal behavior, aggression, and territorial marking. Newman[405] has suggested that these structures form a richly and reciprocally interconnected circuit subserving mammalian social behaviors. Most of the areas, except the midbrain, are copiously populated with steroid receptors, and all contribute to more than one behavior. Perinatal, adolescent, and adult hormones mold sexually dimorphic responsiveness to social stimuli. Substructures of these brain areas may be specialized for specific behavioral components. However, the circuit that is activated specifically by ejaculation in male rats, hamsters, and gerbils, also responds in female rats to ejaculation by a male. Therefore, this circuit may either "count" stimuli or regulate timing in both males and females to promote a successful pregnancy. It is unclear whether the same neurons contribute to different behaviors or whether behavior-specific neurons within each structure mingle with neurons specific for other behaviors. Organizational and activational effects of hormones may confer specificity in response to stimuli and thereby promote diversity in the network.

CONCLUSION

Our understanding of the neural mechanisms of male sexual behavior is based primarily on our understanding of the rat and other animal models. Nevertheless, as is evidenced in this chapter, there is considerable homology among species with regard to sex-relevant mechanisms, which permits us to extrapolate from the animal data while informing our understanding of the human condition.

The neural mechanisms of male sexual behavior are organized developmentally by hormones, primarily estrogens in rodents and primarily androgens in primates, including humans, and in guinea pigs. Those neural circuits are then activated by the same hormones, beginning in puberty. Sensory circuits relay information about sexually relevant stimuli to several brain areas that integrate those stimuli and program appropriate motor output. However, those integrative areas also send output back to the sensory areas to amplify the relevant sensory signals. Hormones have primarily slow, genomically mediated effects, including production of enzymes, receptors, and structural proteins, although they may also have rapid effects via membrane-associated receptors.

Chemosensory input arrives via the main and accessory olfactory systems and is processed by the medial and cortical areas of the amygdala and the BST; activation of hormone receptors is critical for the responsiveness of those areas. The amygdala and BST also receive sensory input from the genitals via the central tegmental field of the midbrain. The amygdala and BST also receive visual and auditory information.

The MPOA indirectly receives input from all sensory systems and sends reciprocal output back to those areas. Thus, hormone-concentrating neurons can bias the sensory input to favor sexually relevant information. Although the MPOA has primarily parasympathetic connections, which promote erections, it can also indirectly activate some sympathetic neurons, which can elicit seminal emission and ejaculation and also contribute to erections. DA is released in the MPOA as soon as the male detects the presence of an estrous female and is critical for mating to occur. Glutamate from the amygdala and BST activate production of NO, which is necessary for female-stimulated DA release and for copulation. A large spike of glutamate is released at the time of ejaculation. E2 is necessary to maintain NO synthase, which in turn maintains basal DA levels, but androgen is necessary for the DA increase in response to the female and for optimal copulation.

The PVN, which is caudal to the MPOA, can also elicit erections and ejaculation. It appears to be more important for NCE, elicited by the sight or smell of an estrous female, than for copulation itself, though it also contributes to copulation. DA, oxytocin, excitatory amino acids, and hexarelin peptides are excitatory to NO-producing neurons in the PVN, which release oxytocin in the hippocampus, pons, medulla, and spinal cord to stimulate erection and ejaculation. GABA and opioid peptides inhibit those neurons.

Other hypothalamic areas that contribute to mating include the perifornical LH, the site of orx/hcrt neurons, which project to both the MPOA and the mesocorticolimbic DA tract and activate those areas. 5-HT is released in the perifornical LH at the time of ejaculation and inhibits the orx/hcrt neurons, thereby inhibiting copulation. Activation of those 5-HT receptors would likely contribute to the sexual dysfunction that often results from SSRI antidepressants, although there are also inhibitory 5-HT receptors in the spinal cord, which normally receive input from the nPGi.

The mesocorticolimbic DA tract originates in the midbrain tegmentum and projects to the Acb and the prefrontal cortex. It is sometimes referred to as the "engine" that drives numerous motivated behaviors, including mating. DA is released in the Acb as soon as a male rat detects the presence of an estrous female, suggesting that it contributes to sexual motivation, not just motor activation. On the other hand, the nigrostriatal DA tract is activated only during actual copulation, suggesting that it is less important for sexual motivation. Oxytocin in the VTA appears to stimulate the DA-ergic neurons, and CCK released in the Acb potentiates the facilitative effects of DA. However, 5-HT agonists microinjected into the Acb inhibit ejaculation.

The PAG contains steroid receptors and receives output from the MPOA; in turn, it projects to the nPGi, which sends inhibitory 5-HT-containing axons to the spinal cord. Stimulation of the MPOA can override the normal inhibition of the UG reflex, apparently by inhibiting the nPGi.

The spinal cord provides initial processing of somatic and visceral information from the genitals and the autonomic and somatic nuclei that control the hemodynamic processes and striated muscles that produce erection, ejaculation, and detumescence. Both descending axons from the brain and local reflex loops are important for these processes.

The brain and spinal areas are heavily interconnected and form circuits that specialize in chemosensory, genitosensory, visual, and auditory inputs that elicit mating and that elicit approach to a female and trigger erection and ejaculation.

Answers to previous questions inevitably raise new questions to guide future research. These questions fall into several broad categories: anatomical interconnections, immediate and long-term neurotransmitter effects and their interactions, electrophysiological responses, roles of intracellular messengers and gene expression, similarities and differences within and between species in the control of male sexual behavior, and in the control of other social behaviors.

Questions concerning anatomical interconnections include the following: By which pathways do the main and vomeronasal olfactory systems promote sexual arousal? How do the pathways that control noncontact, touch-based, and *in-copula* erections differ and where do they converge? Similarly, what are the similarities and differences between pathways that elicit the UG reflex and *in-copula* ejaculation? Which neural efferents from the MPOA carry the disinhibitory and the excitatory influences on genital reflexes? What pathways mediate the parasympathetic and sympathetic proerectile effects of MPOA stimulation?

Issues related to neurotransmitters include: Which neurotransmitters, and which receptors, mediate the major effects in each of the sensory, integrative, and motor control sites? Which neuropeptides are co-released with classic transmitters, and under which conditions? Do changes in neurotransmitter release reflect primarily changes in cell firing or influences on presynaptic terminals? Which (combinations of) neurotransmitters elicit long-term changes in sensitivity, as opposed to immediate responses to stimuli?

Questions related to intracellular and genetic influences include the following: Which ion channels and/or second messengers mediate the immediate and long-term effects of neurotransmitters in brain areas that respond to sexually relevant stimuli? What changes in gene transcription are elicited by steroid hormones binding to classic steroid receptors? What are the effects on sexual behavior of rapid membrane responses to steroid hormones? How does sexual experience affect gene transcription? How does activation of immediate early genes facilitate subsequent sexual behavior? Are new neurons recruited by sexual experience, or are the facilitative effects of experience mediated by strengthening of previous connections? What do patterns of electrophysiological responses contribute to the neural control of copulation?

Questions concerning broader issues include: How do general activational systems, such as the mesocorticolimbic system, mesh with systems that promote specific behaviors? What *does* the MPOA do? What differences in neuroanatomical and physiological processes result in species differences in behavior? How are behavioral differences between species related to ecological niches? How are the neural elements of male sexual behavior similar to and different from those that control other social behaviors?

INTRODUCTION

Interest in female sexual behavior and reproduction is likely as old as our species. Indeed, one of the oldest known medical texts, the Kahun Papyrus, found near the pyramid in El-Lahoun, Egypt, in 1889 and dated to at least 1800 BCE, is a gynecological text that outlines causes and treatments for women's reproductive health problems, including problems of fertility, contraception, and pregnancy.[1] Ancient erotic texts, such as Vatsayana's *Kama Sutra* (compiled from Hindu writings in the second century BCE), Ovid's *Ars Amatoria* (c.1 BCE), and the Taoist *Art of the Bedchamber* books (compiled between 206 BCE and 24 CE), devoted large portions to understanding how to court women properly; how to stimulate arousal, desire, and pleasure; and how women's receptivity to such courting and stimulation shifted across the menstrual cycle.[2] The striking similarity in descriptions, despite vast differences in culture, suggests some degree of commonality in the way women's sexual physiology and psychology are constructed and altered, respectively, by ovarian hormones.

The *Hippocratic Corpus*, dating from the fifth century BCE, contains seven early volumes written by Hippocrates himself that were concerned with women's fertility and diseases specific to women.[1] The first of these contains an oddly modern account of midcycle rises in women's sexual lust and receptivity, driven of course by the lunear impact on women's "psychic pneuma" (the four endogenous fluids—blood, yellow bile, black bile, and phlegm—that were thought to mediate the four basic emotions of passion, anger, sadness, and calm). Hippocrates also notes that "hysteria" should be treated by gentle stimulation of the clitoris and/or vagina to orgasm (or sexual intercourse, if the woman is married or has a knowledgeable sex partner). It was believed that orgasm would center the uterus back into its normal position. The second contains a then-comprehensive list of contraception methods, including the use of small scrubbed stones as intrauterine devices. This practice was based on the experiences of Egyptian and Bedouin camel drivers, who routinely placed stones in the uteri of camels to prevent pregnancy. It is likely that animal sexual behavior and reproduction have been studied since humans started domesticating animals, but largely from a veterinary and/or animal husbandry perspective, and only in those species used as pack animals (camels, sheep, donkeys), for agricultural work (e.g., oxen, horses), or for food (e.g., sheep, cattle). In his work *Historia Animalium*, Aristotle (384–322 BCE) described the routine spaying (ovariectomy, OVX) of adult sows and camels as common agricultural practice, done specifically to eliminate sexual behavior and control reproduction.[3]

Rudimentary psychological understanding of sexual arousal, desire, pleasure, and inhibition in women can be found in art and prose, from ancient religious stories (e.g., "Song of Songs"), plays (e.g., Shakespeare's "The Taming of the Shrew"), to myriad love poems written throughout the ages, mostly by men about women, but also written by women (e.g., the "nine earthly muses"

Knobil and Neill's Physiology of Reproduction, Fourth Edition

of Ancient Greece, notably Sappho and Praxilla who wrote erotic, comic, and tragic poetry about the sexual desires of women and men). Most ancient polytheistic cultures had women depicted as goddesses of sex and fertility. The Aztecs had eight deities—seven of which were women—who controlled the intricacies of sex and reproduction. However, goddesses of love and carnality were associated with freedom, war, or mental illness. An example of the latter was the Moroccan lust goddess, Qandisa, who seduced men and then drove them insane.

Erotic art has existed for a very long time, starting with cave drawings of copulation (often between animals, but also heterosexual and homosexual copulation between adult humans). Fertility statues also exist, dating back well over 10,000 years, and almost always depicting a full-bodied, reproductively capable woman (e.g., the Venus of Willendorf). Erotic art from India, Japan, Greece, and Rome during ancient times depicts a variety of imaginable sex acts between two or more humans, humans and animals, and even humans and inanimate objects. Women were depicted masturbating and initiating sex. This did not change in Europe during the Middle Ages, Reformation, or Enlightenment periods, as Néret's[4] *Erotica* series depicts. Women are drawn by many artists with smiles and in full control of sexual interaction, again often initiating sex and in positions (e.g., female supine) that would maximize clitoral and inner vaginal stimulation. Women's orgasm was thought to be positively related to fertility; thus, hints of masturbation were found in artistic works throughout these periods. For example, Titian's "Venus of Urbino" of 1538 depicts her reclining sensually with her hand draped over her mons, her fingers easily in position to stimulate her clitoris. Ēdouard Manet's "Olympia" of 1863 has a similar depiction, this time with her hand outstretched over her pubis, but her forefinger hidden seductively between her legs. There is also a large portrayal of women in fetish circumstances during the eighteenth century, often controlling the man in the action. This is in stark contrast to the portrayal of women in a large part of nineteenth and twentieth century pre-Internet erotica as being either passive exposers of their genitalia or passive and emotionless recipients of male penetration.[5]

As science and rationalism took hold in Europe and the Americas, so did attempts at understanding behavior based on deductions about underlying physical causes. For female sexual behavior, this began with the nineteenth century phrenologists who attempted to understand the nature of female sex drive as a function of the size of bumps on the skull that they believed reflected the size of the underlying brain structure. Among these was the so-called amativeness center at the back base of the skull, just over the cerebellum, that allegedly controlled sexual and parental instincts in women.[6]

Early ethologists began to categorize reproductive behavior in the late 1800s. Notable among these descriptions was that of Darwin,[7] who discussed sexual selection in terms of flexible *female* choice for male epigamic and/or behavioral traits of strength. At the same time, physicians in France and the US began to define "hysteria" in women as a long-term complication of sexual frustration that should be treated with manual clitoral and/or vaginal stimulation. In the 1800s, "muscle beaters" used for massage were applied to the clitoris in the treatment of "hysteria". Some of these had long handles that women would use on their own to provide clitoral and vaginal stimulation. In the late 1800s, vibratory stimulation of the clitoris and/or vagina was seen as particularly effective in inducing orgasm, and was easily produced electrically using saline electrodes with faradaic current applied.[8] Thus the "vibrator" was used in clinical medicine explicitly as a means of "electrotherapy" for the treatment of "hysteria". Vibrators were sold by mail order (e.g., from successive catalogs of Sears, Roebuck and Co.) up to the start of World War II as "Aides that Every Woman Appreciates". Although these seemed to disappear in the 1940s and 1950s, they returned in the 1960s specifically as "sex toys" for women. A fascinating account of the development of the vibrator can be found in Maines.[8]

The ovaries had been known since the time of Aristotle to be involved in both the generation of offspring and in female sexual behavior (for a historical overview, see Ref. 9). Despite Aristotle's writings, it was not until 1672 that de Graaf explicitly described the ovarian follicle as an "egg" which turned into a corpora lutea when the female was impregnated. Van Leeuwenhoek in 1683 suggested that it was the egg itself that was impregnated with sperm. In the nineteenth Century, ovarian function was again the focus of scrutiny. The French physician Roberts reported that Indian women who underwent forcible OVX as prepubertal girls had no sex drive, no menstruation, and had retained a boyish appearance (meaning no breasts). Although Berthold in 1849 had suggested the existence of a floating substance secreted by the testes that masculinized body and behavior in roosters, nothing was mentioned about the ovaries until Brown-Séquard's claim in 1890 that multiple injections of guinea pig and rabbit ovarian extracts could refeminize and excite the passions of OVX, hysterectomized women.[1] Berthold's experiment was repeated in 1896 by Knauer, but this time grafting ovaries into the abdominal cavity of OVX dogs, rabbits, and guinea pigs, and restoring estrous cyclicity and sexual behavior.

The early twentieth century saw experiments aimed at discerning the function of the corpora lutea in the timing of ovulation and the maintenance of pregnancy. Heape in 1900 coined the terms estrus, proestrus, diestrus, metestrus, and anestrus to describe cytological changes in vaginal epithelium, which were used subsequently in 1922 by

Long and Evans to link the stage of the vaginal epithelial cycle with sexual ("estrous") behavior. In 1923, Allen and Doisey determined that vaginal cell cornification could be used as a bioassay to determine which of the ovarian secretions induced it. Parkes and Bellerby in 1926 referred to the active secretion, "oestrin", as the cause of cornification, and in 1930 abundant sources of oestrin had been found in the late pregnancy urine of Canadian women and sold by Ayerst Labs as an orally active source of the hormone. In 1929, Butenandt and Doisey determined the crystalline structure of estrogens, and in particular estradiol-17β, which was the same in the late-pregnancy urine of cows, sows, horses, and humans. Progesterone was isolated in 1934 and was found to inhibit pregnancy when injected alone to a variety of gonadally intact, ovulating animals. Work by Zuckerman in 1937 showed that menstruation was the result of atrophy of the corpora lutea. These findings together led to the creation of steroid biochemistry, and ultimately the isolation of different estrogens and progestins, and the formation of oral contraceptives in 1953 by Pincus and Chang.

The other important endocrine question was behavioral. In 1939, Boling and Blandau found that sequential injections of estradiol followed 48 h later by progesterone induced sexual "heat" (lordosis) in OVX female rats. This pivotal paper coincided with experiments throughout the 1930s–1950s by Stone, Ball, Beach, Larsson, Yerkes, and Young, among others, examining the sexual behavior of female rats, cats, and nonhuman primates, such as macaques and chimpanzees, and in particular its expression around the time of ovulation and how it declined after OVX, and was stimulated. An important comparative approach was taken to this, and careful analyses were made comparing the expression of hormone-driven sexual behavior in animals to humans (e.g., Ref. 10). Since the 1930s, oral estrogens derived first from urine, and then made synthetically, were used to treat menopausal symptoms such as hot flashes. With the advent of the birth control pill and its subsequent reformulations, hormone replacement therapy was born. In the late 1960s, binding sites for estradiol were found in the brain independently by Pfaff, Sar, and Stumpf, and localized largely in the mediobasal forebrain, notably in regions of the hypothalamus and limbic system. The molecular actions of those receptors were characterized in the 1980s and 1990s by McEwen, Pfaff, and others, and their molecular role in the generation of neurotransmitter actions was elucidated.

Drugs of abuse, such as heroin and cocaine, had been known since the 1920s to alter reproductive function in both women and men and to inhibit sexual arousal and desire, along with anorgasmia, in female addicts.[11] The effects of alcohol on sexual arousal, desire, and reproductive function were legendary.[12,13] The study of drug effects on sexual behavior began in the 1950s with the work of the Soulairacs in France. The role of the newly discovered monoamines, dopamine (DA) and serotonin, was examined on lordosis in female rats using systemic pharmacological treatments by Swedish pharmacologists Meyersson, Ahlenius, Södersten, and Malmnäs starting in the mid-1960s through the 1970s. The discovery of brain-born neuropeptides and their receptors in the 1970s and 1980s increased the complexity of the pharmacological targets, and individual brain regions, especially in the hypothalamus, began to be examined. Large brain lesion studies in the 1940s and 1950s showed that decorticate male rats could not copulate, but that OVX females receiving estradiol and progesterone could still display lordosis.[14] More specific brain lesion studies conducted largely in rats during the 1960s showed that ablation of the medial preoptic area (mPOA) reduced male mounting behavior[15] and lesions that included the ventromedial hypothalamus (VMH) reduced lordosis in female rats.[16,17]

The analysis of female sexual behavior in different species became more sophisticated during the 1980s and 1990s (see below), as did the pharmacological and molecular tools applied to its study. Transgenic mouse models were made with specific genes deleted (knockouts (KOs)) or overexpressed (knock-ins); antisense technology allowed researchers to KO specific gene products in different brain regions. Microdialysis and voltammetry allowed certain monoamines, such as DA and serotonin (5-HT), and small molecule neurotransmitters such as acetylcholine (Ach), glutamate, and GABA, to be analyzed directly in brain regions. Cellular techniques allowed cytoplasmic proteins or their mRNA to be labeled in brain slices, and the use of immediate-early gene products such as Fos allowed cell-level localization of activated neurons following copulatory stimulation.[18] Similar advances were made in human brain imaging using functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scanning. These techniques allowed clinical researchers to examine brain activation by erotic stimuli and orgasm in women (see below).

Sophistication also grew in behavioral analyses of sexual function and dysfunction in women, although not without heated controversy. In 1948, Kinsey and colleagues published *Sexual Behavior in the Human Male*,[19] which was greeted with a sense of accomplishment and intrigue in the postwar West. Five years later, their publication of *Sexual Behavior in the Human Female*[20] was greeted with scandal and denouncement. Nevertheless, Kinsey's work, along with the advent of *Playboy* as a mainstream publication, and the reaction a decade later to *Human Sexual Response* by Masters and Johnson,[21] gave rise to a "sexual revolution" during the 1960s and 1970s that had women question traditional sex roles and traditional sexual behavior, especially the role of the clitoris as *the* gland of women's orgasm and sexual pleasure, rather than the "mature" vaginal orgasm that Freud[22] had thrust

into psychoanalytical therapy and psychiatric medicine. Hite[23,24] wrote two reports on male and female sexuality in the sexually liberated 1970s, which saw changing female sexual attitudes. However, she still noted sex differences in which women were viewed as more "sensate focused" and needing more than visual erotic stimuli to arouse their sexual interest. Such sex differences in response to erotic visual stimuli, however, appear to have waned with the advent of the Internet, and with a new generation of women who have had easy access to such stimuli.

Sexual disorders, which had been cataloged by psychiatry in various editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) in North America and the *International Classification of Diseases* (ICD) in Europe, eliminated homosexuality as a disorder in the mid-1970s and reworked sexual behavior disorders in women as those of sexual arousal, desire, and orgasm, with sexual pain disorders, such as dyspareunia and vaginismus, and gender identity disorders as separate disorders. Work around the turn of the millienium sought to characterize those disorders as sets of symptoms and apply both physiological and subjective assessment techniques that could predict symptom severity. As with the Kinsey experience a generation before, the advent of oral treatments for erectile dysfunction in men was hailed in light of a new sophisticated neuropharmacology of sex, whereas the search for a "female Viagra" has been vilified by special-interest groups who are against the so-called "medicalization of women's bodies" by the pharmaceutical industry.[25,26] Although androgens were reported to increase sexual arousal and desire in both pre- and postmenopausal women with those disorders, a transdermal patch was rejected by the U.S. Food and Drug Administration. Despite this, more compounds entered clinical trials for the treatment of sexual arousal and desire disorders in the early twenty-first century. Part of that effort was aided by preclinical research in rodents and nonhuman primates, showing conclusively that drugs that elevated female solicitations in rats also increased measures of subjective sexual desire in women. The study of the neuroanatomy and neurochemistry of sexual behavior has become another "sexual revolution" of neurobiologically-relevant information about sex—one that moves almost seamlessly between species. This begins to realize the challenge put forth by Beach[27] to examine the physiology of behavior across different species and the dream of a truly translational clinical science.

COMMONALITIES, HOMOLOGIES, ANALOGIES, AND MODELS

Sexual function is required for the propagation of all mammalian species. It not only allows for reproduction, but it also provides a natural reward that is easily accessible to any sexually mature individual in good health. Its benefits can be short-term by instilling feelings of satiety, intimacy, and well-being, while long-term benefits may include the memory of the sexually satisfying event, bonding with the partner, in addition to the pregnancy and the delivery of offspring. Sexual dysfunction, in contrast, results in feelings of inadequacy and a loss of feelings of intimacy and well-being, which induces significant distress on individuals and their relationships. The etiology of the dysfunction can be due to physiological, psychological, or a mixture of factors. As such, sexual function in humans involves a complex integration of the individual's biology and physiology (including genetics, hormonal states, and neurochemical regulation), personal history, expectations, context, and culture—all of which impinge on the brain to create or inhibit a sexual response.

In all species, sexual behavior is directed by a complex interplay between steroid hormone actions in the brain that give rise to sexual arousability, and experience with sexual reward or pleasure that gives rise to expectations of competent sexual activity, including sexual arousal, desire, and elements of copulatory performance.[28] Sexual experience allows animals to form instrumental and Pavlovian associations that predict sexual outcomes and thereby direct the strength of sexual responding. Although the study of animal sexual behavior by neuroendocrinologists has traditionally been concerned with mechanisms of copulatory responding related to reproduction (e.g., lordosis in females and erections, mounts, intromissions, and ejaculations in males), more recent use of conditioning and preference paradigms, and a focus on environmental circumstances and experience, has revealed sexual behaviors in a variety of species that are driven by reward-related mechanisms in the brain and that are analogous or homologous to human sexual desire.[28–31] From both a biological and psychological perspective, this makes logical sense: animals must be able to respond to hormonal and neurochemical changes that signal their own sexual arousal and desire, and be able to interact with external sexual incentives. Animals must be able to identify external stimuli that predict where potential sex partners can be found and subsequently seek them out, solicit, court, or otherwise work to obtain them; distinguish sensory cues and behavioral patterns of potential partners from those that are not interested or receptive; and pursue desired sex partners once sexual contact has been made.

The Sexual Brain

The brain organizes sexual stimulation into an evolutionarily conserved set of pathways or "modules" (e.g., Ref. 32; see below for lordosis) that reflect different levels of processing and interpretation[33] (Figure 50.1).

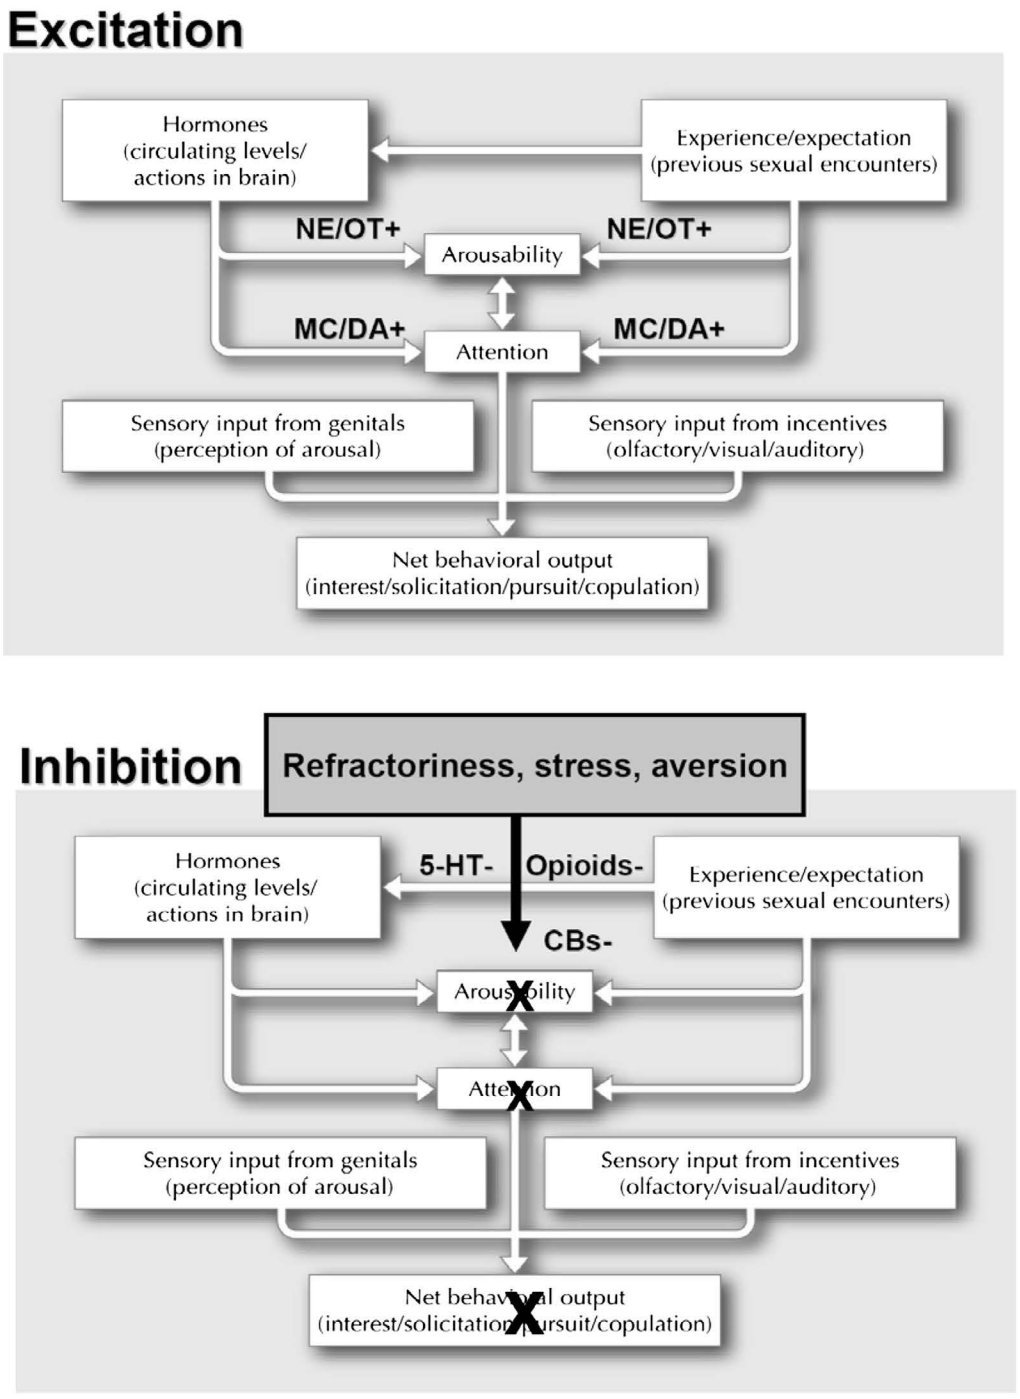

FIGURE 50.1 Interactive model depicting the regulation of sexual behavior by hormonal and associative learning (experiential) systems that subserve sexual arousal, desire, and behavior. Top: Excitation produced by hormone action and/or experientially derived activation of arousability (via activation of norepinephrine (NE) and oxytocin (OT)) and attention (via the activation of melanocortin (MC) and dopamine (DA)) that mixes with peripheral arousal and sexual stimuli to drive net behavioral output. Bottom: Inhibition from refractory states, stress, or aversion. Inhibitory systems activate serotonin (5-HT), opioids, and endocannabinoids (CBs) to induce satiety, pleasure, and sedation, respectively, although such systems are activated in stressful or aversive circumstances. *Source: Adapted from Pfaus and Scepkowski.*[33]

These pathways integrate endogenous sex "drive" (e.g., gonadal hormone status and energy metabolism) with autonomic arousal in the hypothalamus, the intensity of incentive sexual stimuli (unconditioned and conditioned stimuli that activate or "prime" attention and movement from distal to proximal to interactive) in the hypothalamus and limbic system, and the evaluation of sexual context and executive function as it relates to sexual excitation or inhibition overall in the cortex. In particular, cortical activation controls the coding of information

into "gestalts" (e.g., sets of physical or interpersonal characteristics that individuals find conditionally attractive or unattractive, contexts that are suitable or unsuitable for sexual activity, etc., following from Pavlov[34]) and involves the activation of medial prefrontal cortex (mPFC) and the descending inhibition of motor acts as part of executive function. Within each are excitatory and inhibitory neurochemical systems that control sexual responding at any given time. These systems are activated or suppressed by steroid hormones, as well as by experience-driven changes in gene expression and neurochemical function.[35] It is through these systems that priming stimuli or drugs alter sexual responding by changing the interpretation of stimuli and context.

Attentional and emotional components are encoded largely in limbic structures, notably in the nucleus accumbens (NAc), septum, and amygdala, which allow the animal to focus on pleasure- (or punishment-) related stimuli in the environment. The hippocampus provides spatial maps of the external world and episodic memory for important sexual encounters, and the paleocortex (e.g., anterior cingulate gyrus) regulates autonomic function along with anticipation of reward, decision-making, and empathy.[36,37] Along with limbic activation, hypothalamic structures, notably the mPOA and VMH, activate sexual responding in relation to hormonal status and metabolism, and in concert with regions, such as the paraventricular nucleus (PVN) and supraoptic nucleus (SON), coordinate autonomic activation with elements of sexual desire (e.g., solicitations, pursuit). Those structures also participate in the generation of partner and mate preferences. The mPOA is well suited as a central processor in the linking of metabolic need, hormonal status, and autonomic outflow, with the stimulation of mesolimbic DA neurons in the ventral tegmental area (VTA). The mesolimbic DA system projects to several important limbic and cortical structures, notably the NAc, corticomedial amygdala, lateral and medial septum, and mPFC, and is critical for all animals' attention to incentive stimuli.[38] Thus, regulatory, attentional, and emotional systems are engaged at the same time following the hormonal stimulation that occurs around ovulation, linking reward-related incentive motivation to reproduction.

Finally, although sexual responses can include thoughts and fantasies (at least in humans), they are reflected in all animals as behavior. Coordinated purposeful behavior comes from the activity of both fine and gross motor acts that are derived from the coordinated activation of motor cortex and the basal ganglia, along with other motor structures in the midbrain and the cerebellum. In addition to coordinating body movements in space and time, these structures crystallize motor memory, a function that is critical for motor habit formation (the phenomenon whereby motor acts at the beginning of behavioral learning are choppy and uncoordinated, but become virtually automated with practice). Although the formation of motor habits in males with extensive sexual experience protects sexual behavior against treatments or situations that might disrupt it, including novel environments, stress, genital anesthesia, brain lesions, and even castration or hypogonadism (reviewed in Pfaus et al.[28]), it is not yet known whether sexual experience provides females with similar protection.

Structure of Female Sexual Behavior

For all animals, sexual behavior occurs as a sequence or "cascade" of behavioral events. Beach[39] recognized the heuristic value of separating sexual behavior into *appetitive* and *consummatory* phases. Essentially, this scheme followed from the work of early twentieth century ethologists and experimental psychologists,[40,41] who defined appetitive (or "preparatory") behaviors as those which bring an animal from distal to proximal and into contact with goal objects or incentives, such as potential sex partners. In contrast, consummatory behaviors are performed once an animal is in direct contact with the incentive (i.e., to "consummate" the goal). Consummatory sexual behaviors tend to be species-specific, sexually differentiated, and stereotyped, whereas appetitive behaviors are more flexible. This also makes sense as survival often depends on behavioral flexibility—on an animal's ability to learn a variety of strategies to obtain goals in different environments or appetitive circumstances.[28,42] As in animals, human sexual desire and subjective sexual arousal fit into an appetitive framework,[28,31,43] whereas the more stereotyped patterns of copulatory behavior fit into a consummatory framework. Perhaps the most well-known description of human sexual response is that of Masters and Johnson's "EPOR" (Excitement-Plateau-Orgasm-Resolution) model[21] (Figure 50.2). This model flows in time as a cascade of behavioral and neurophysiological events, starting with sexual excitement (blood flow to the genitals and other erogenous erectile tissues), then plateau (parasympathetic maintenance of genital blood flow during sexual intercourse), culminating in orgasm (a defining moment of euphoria, ecstasy, and pleasure in which sympathetic systems move blood out of the genitals), followed by resolution (also called a refractory period during which inhibitory systems of the brain are activated to reduce the salience of external and somatosensory sexual stimuli). The EPOR model describes at least three distinct patterns for women that vary in the structure of the plateau, the intensity and number of orgasms, and the temporal offset of arousal during the resolution phase, although it does not differentiate the particular characteristics of the sexual stimuli used to achieve orgasm (e.g., external clitoral

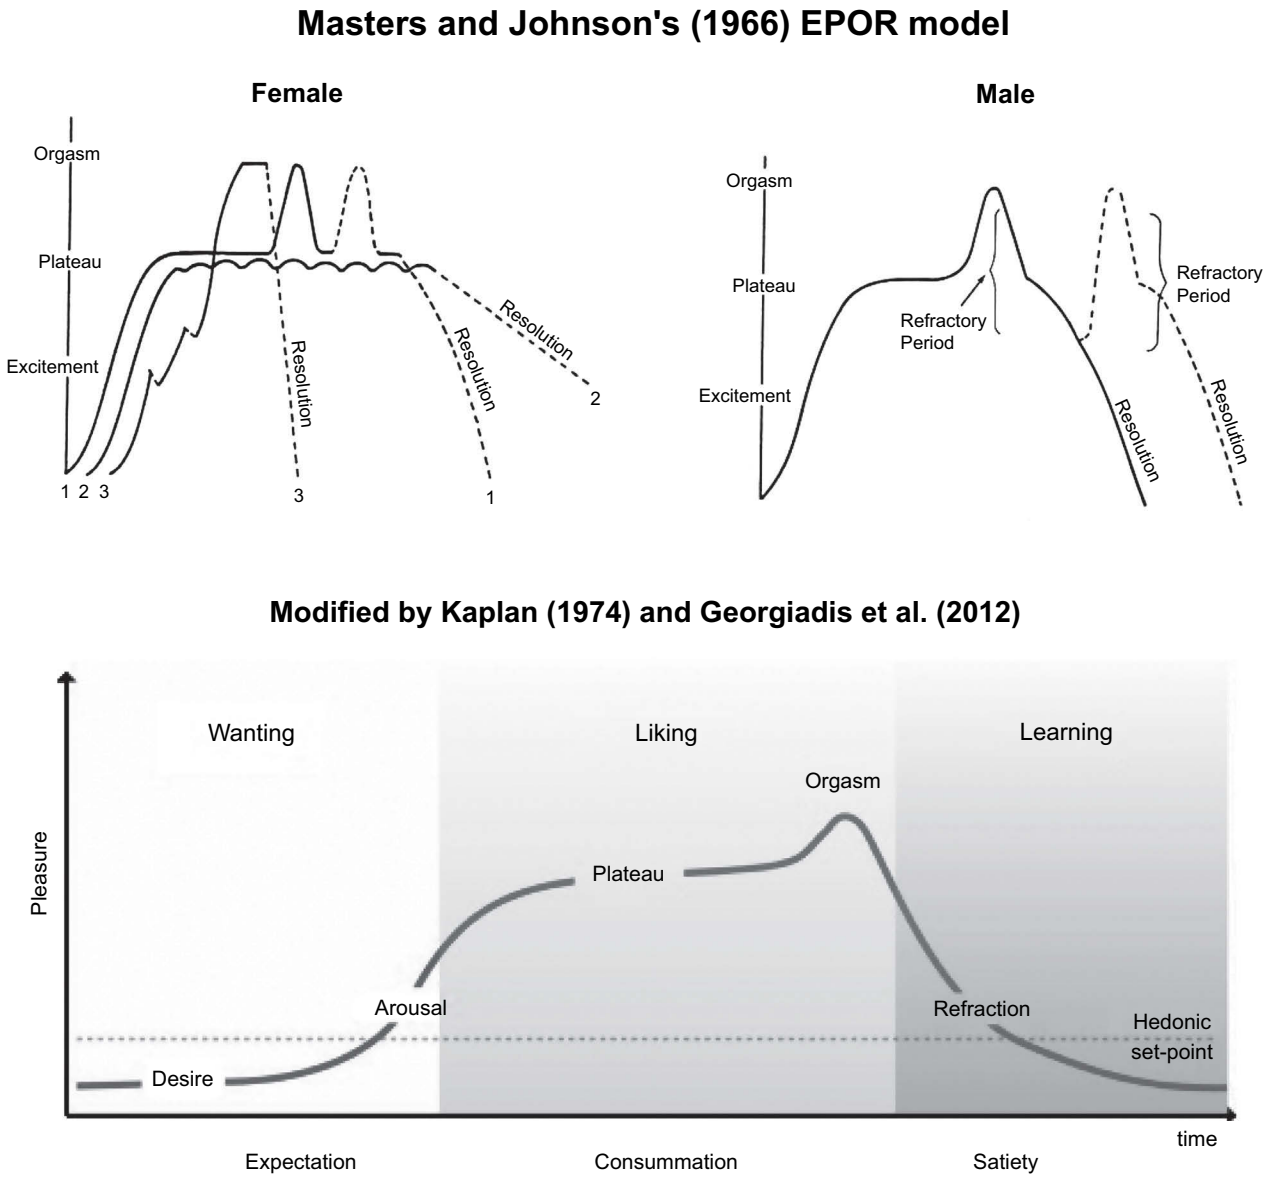

FIGURE 50.2 Top: The EPOR model of human sexual response by Masters and Johnson.[21] Bottom: Modifications of the model by Kaplan[44] to include sexual desire before arousal, and further modifications by Georgiadis et al.[45] to include theoretical phases of expectation, consummation, and satiety, along with the conceptual framework of Berridge et al.[46] of wanting, liking, and learning.

only, external and internal clitoral, cervical, blended clitoral and cervical, extragenital, etc.), nor was it based on an analysis of actual genital blood flow. Subsequently, Kaplan[44] added a phase of sexual desire, consisting of fantasies and thoughts about sexual activity, along with behavior aimed at obtaining sexual partners and/or sexual gratification.

Despite overarching theoretical models of human and animal sexual response that did not posit sex differences in the basic response structure, female sexual behavior has, until fairly recently, been considered "passive". This is due in part to a general social construction in Western society of female sexuality as something that is "done to", relative to more active male sexuality that "performs", and to the labeling of female sexual behavior in both animals and humans as "receptive", consisting largely in animals of estrogen- and progestin-dependent behaviors that allow females to accept male initiation (e.g., mounts) and be open to vaginal penetration by engaging in postural changes such as lordosis, the characteristic arching of the back that raises the rump to allow penile intromission. Similarly, in humans, hormone- and context-dependent "responsive desire" has been viewed as allowing females to be responsive to a partner's active pursuits.[47] However, it is clear that women and some other primate females can have sexual intercourse anytime during the ovulatory cycle. This can even occur without hormone priming in hypogonadal individuals and, indeed, without

prior desire or consent.[48] Although sexually receptive behaviors clearly exist in females of all species, they are far from passive when it comes to sex. Based on observations of a variety of species, Beach[39] proposed that female-initiated sexual behaviors can be partitioned into a cascade of essentially three temporal phases: *attractivity* (behaviors such as approach or scent marking that lure males to the females), *proceptivity* (behaviors that precede receptive behaviors and focus the male on pursuing the female), and *receptivity* (behaviors such as lordosis and lateral tail deflection in rats and hamsters, respectively, or leg spreading in the human) that allows the male to gain vaginal penetration. More recently, Basson[47] (Figure 50.3) described how innate sexual desire (potentially induced at ovulation, for example by the combined action of estrogens and androgens in the hypothalamus and limbic system) activates attention to incentive sexual stimuli, sexual arousal, and sexual receptive behaviors, that, if positively reinforced, lead to a sensitization of attention and sexual arousal in the presence of salient and competent incentive sexual cues. Her model is easily applicable to all species and is similar to incentive models for sexual motivation produced by others.[2,43] Inherent in all models of sexual behavior is the notion that the components are separable. This would require different brain regions or networks to control the components, feedback systems that link them together, and molecular mechanisms that allow their activation to be altered by steroid hormones and experience.

Clearly, females and males engage in mutual and complementary patterns of sexual activity; however, it is the females that initiate and control successful sexual interaction, including the initiation and temporal patterning of copulation. This occurs by a complex interaction of *appetitive precopulatory behaviors* that attract and solicit sex from males. These behaviors are taken to reflect sexual desire and may well be informed by or sum with sexual arousal. Once copulation begins, females engage in *receptive behaviors* such as lordosis, *pacing behaviors* that control the rate of sexual stimulation received during sexual interaction and copulation, and *defensive behaviors* used either to pace the copulatory contact if females cannot otherwise do so or to terminate the sexual interaction.[2,49,50] These behaviors serve to optimize the rate and strength of sexual stimulation received by females, which in turn initiates neuroendocrine reflexes associated with fertility and pregnancy.[51–53]

Ovarian Hormones Set the Stage

The cyclic actions of estradiol, testosterone, and progesterone in females leads to changes in sexual responding and increases in sexual arousal and desire around the time of ovulation in all vertebrate species, including humans,[54,55] although a smaller increase in arousal and desire has been reported around the time of menstruation.[56] Of the major steroids released from the ovaries of mammalian females, estradiol and testosterone are at their highest level in the circulation around the time of ovulation (Figure 50.4). Progesterone levels rise before, during, and after ovulation, depending on the species. This hormonal milieu during the periovulatory follicular phase alters the way in which visual sexual stimuli are processed in women,[58–61] which presumably leads to a shift in the incentive value of the stimuli. Analogous findings have been reported in other primates, for example, in approaches and solicitations made around the time of the mid-cycle estradiol peak in rhesus macaques,[57] and in the appetitive and consummatory sexual behaviors that characterize the periovulatory period of female rats.[31,32,39,49,50,62] Steroid hormones drive sexual arousal

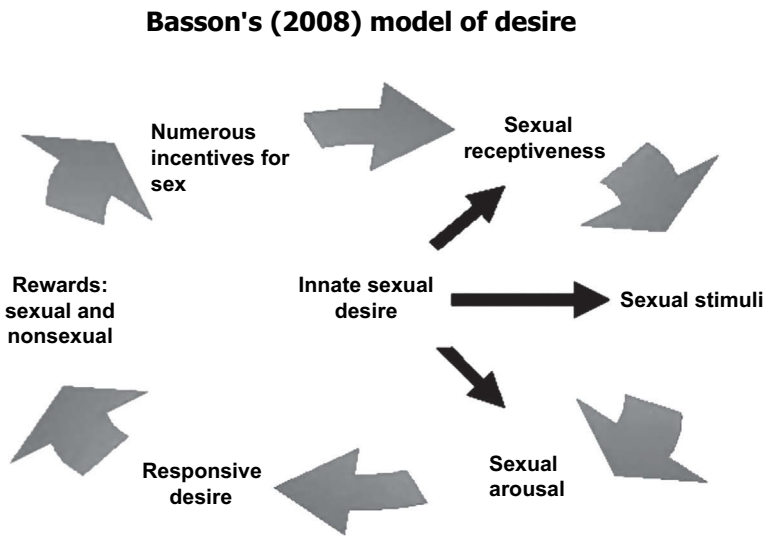

FIGURE 50.3 Circular model of female sexual response by Basson.[47]

and desire in response to competent incentive stimuli. In turn, experience with sexual reward (and inhibition) modulates the strength and trajectory of responses to incentive sexual cues. This is timed in most female mammals to the period around ovulation, thus stimulating females to engage in the most rewarding behaviors under the most reproductively relevant circumstances (see below). This contrasts with the relatively stable and continuous testicular androgen secretion in mammalian males (and its aromatization to neural estradiol in different regions of the brain) that maintains sexual arousability and responsiveness in a relatively continuous manner[63] (see Chapter 49).

Animal Models of Female Sexual Behavior

Although human sexual behavior is best studied in humans, it is often impossible to do so with experimental precision or at a level that allows any degree of finely-grained neural or molecular analysis. Recent advances in brain imaging and eye-tracking technology have allowed cortical and subcortical activation and visual gaze to be assessed in women viewing erotic visual stimuli, and some important paradigms have emerged to correlate aspects of subjective sexual arousal, desire, and orgasm to overall brain activation patterns.[64] Such data reveal a great deal about the cognitive and limbic control of different aspects of female sexual behavior under different hormonally-modulated, pharmacological, or experiential conditions, and in ways that confirm data from females of other species. Nevertheless, these paradigms lag behind the scope of neuroanatomical, neuropharmacological, histochemical, and molecular methods that can be utilized in situ with animal models.

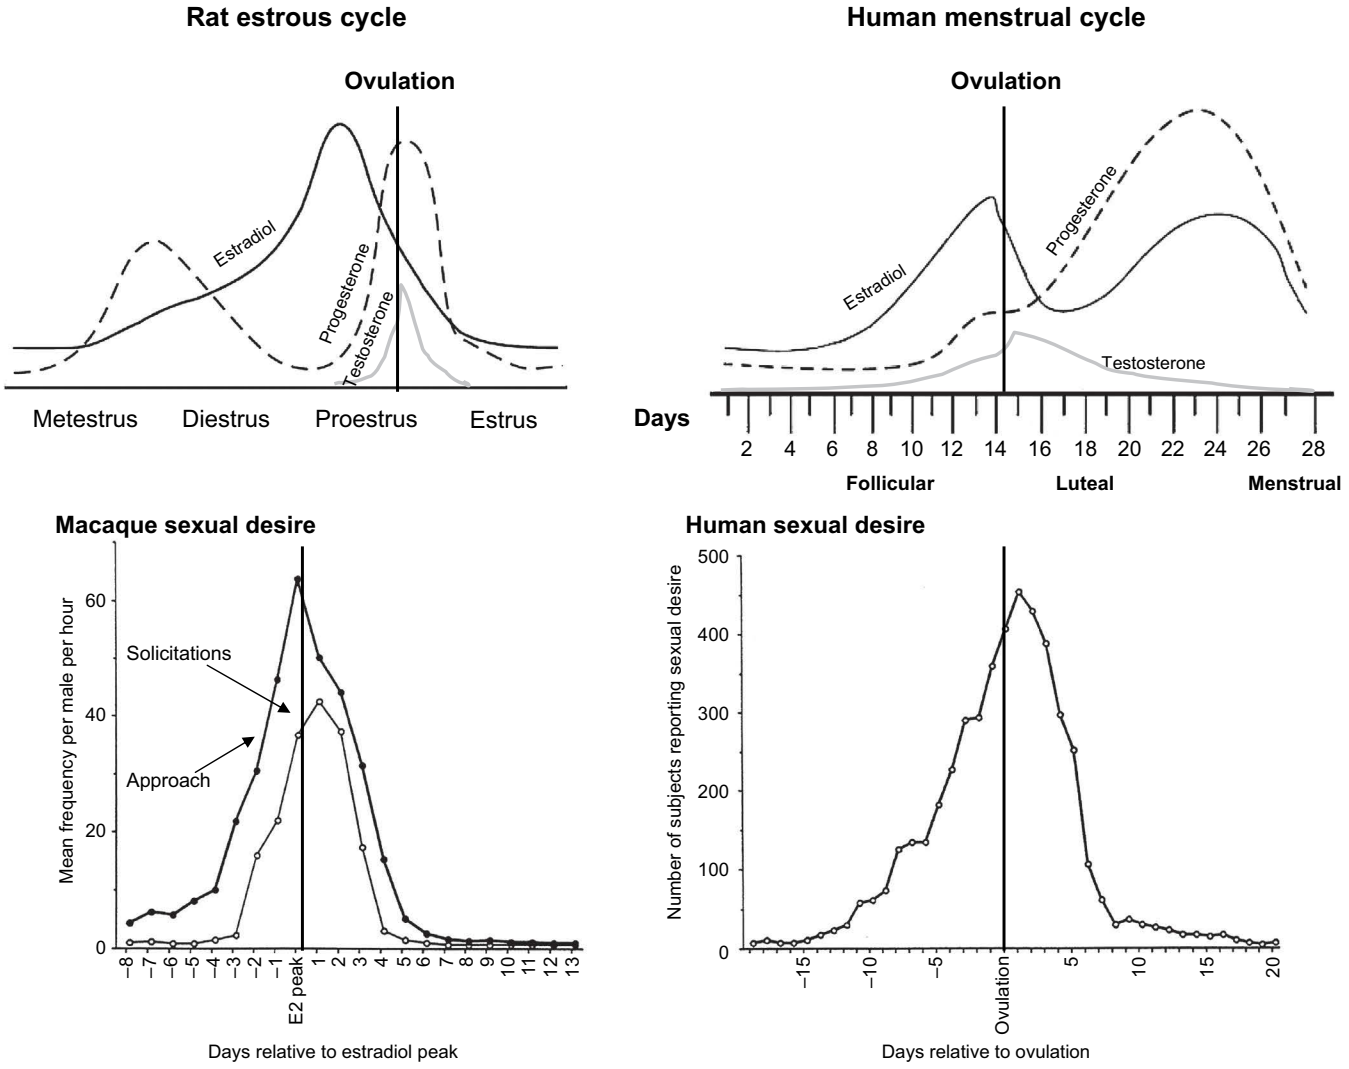

FIGURE 50.4 Top: Schematic changes in estradiol, progesterone, and testosterone in rats and humans across their respective estrous and menstrual cycles. Bottom: Sexual approaches and solicitations by female rhesus macaques, and expressed sexual desire of women, relative to ovulation. *Source: Adapted from Refs 54,57.*

Most of the research done on the neurobiology of female sexual behavior comes from rodent subfamilies, such as rats, mice, hamsters, gerbils, voles, and musk shrews, lagomorphs like rabbits and myomorphs like guinea pigs, less so from primates like rhesus and Japanese macaques, and even less so from humans. Understanding the behavioral structure of each species' appetitive and consummatory phases is vitally important for a sophisticated understanding of the neurobiological mechanisms that control it. In many studies the female's receptive lordosis posture is taken as an index of her copulatory or "mating" behavior, rather than the full repertoire of appetitive and consummatory sexual responses. It is often the case in laboratory settings that females are tested in small chambers that do not allow them to approach or escape the male or, in the case of females that pace the copulatory contact, allow them to regulate the timing and intensity of that contact. When appetitive responses are taken together with lordosis, it becomes immediately apparent that there is extensive conservation of the neurochemical mechanisms that control sexual behavior which generates homologies in the way that sexual stimulation is perceived by the brain and induces competent responses. Behavior is the ultimate arbiter, and can never be supplanted by the processes that underlie it. For example, release of the neurotransmitter DA in mesolimbic terminals like the NAc may be involved in all forms of appetitive motivation toward rewarding incentives like sex partners, but just observing DA released there does not allow the viewer to conclude that whatever the animal was doing is positively hedonic. Understanding the neurobiology of animal sexual behavior also allows the consideration of models of sexual function and dysfunction that are directly applicable in the preclinical testing of drugs or other treatments.

Rats

Female rats are cyclic ovulators whose sexual behavior is timed to the periovulatory period. The ovulatory cycle last approximately 4–5 days, and as mentioned above, is split into phases that reflect the actions of ovarian hormones on vaginal cell morphology and sexual behavior, including diestrus, metestrus, proestrus, and estrus. A rise in estradiol, during metestrus, followed by a peak in progesterone during the afternoon of proestrus, just prior to ovulation, primes the neural circuits necessary for sexual responding. As such, sexual behavior is expressed only during an approximate 12–20 h window, when she is fertile. As mentioned above, sexual behavior can be completely eliminated by bilateral OVX, but reinstated by priming with estradiol and progesterone (P) administered by subcutaneous injections, 48 and 4 h prior to testing, respectively,[65] to mimic ovarian steroid secretion.

A typical copulatory bout in rats begins by anogenital investigation by either the female or the male, followed shortly thereafter by a solicitation made by the female. Solicitations begin with a head-wise orientation toward the male followed by a runaway of varying lengths, some of which are short and in the male's vicinity and are typically referred to as "hops and darts".[30,31,49,50,66–71] This behavior entices the male to chase the female. As the female comes to a stop, she initiates a present posture, facilitating the ability of the male to mount the female when he arrives. Flank stimulation during a mount elicits lordosis, the concave arching of the back that raises the rump and anogenital region, and is absolutely critical for vaginal penetration, or intromission, to occur. Male mounts are almost always accompanied by pelvic thrusts which make direct contact with the female's clitoris. If the male has an erection, then the pelvic thrusts will push his penis into her vagina. Such vaginal intromissions provide the female with stimulation of the vagina, including the internal clitoris and possibly also the cervix. Immediately after a vaginal intromission the male dismounts and grooms his penis into detumescence. The female may run away again or stay in the male's vicinity and hop over him to induce another mount with intromission. In this way, the female regulates or "paces" the rate of vaginal penetration, which controls the rate of vaginal, clitoral, and possibly cervical stimulation. After several mounts with intromission regulated by the female, the male ejaculates. Ejaculation consists of a deep penetration that is held in the vagina as the ejaculate congeals into a "vaginal plug" that surrounds the cervix and protects sperm transport. This also produces a large and sustained amount of cervical stimulation and is responded to by the female with a bursting dismount and runaway. After a few minutes of absolute then relative refractoriness and behavioral quiescence, the female shows increasing interest in the male and stays in his vicinity. This is responded to by the male with the resumption of mounts with intromission and a second ejaculatory series. Males typically have 7–10 ejaculatory series before becoming "sexually exhausted".[72,73] However, long before male exhaustion, females display a progressive reduction in solicitations and enforce increased time between intromissions either by running away or fighting. In the wild, more dominant females tend to reenter the burrow after only a few ejaculations, whereas more subordinate females take more ejaculations before they stop copulating. The progressive decline in solicitations and increase in agonistic behavior is characteristic of "estrus termination", an inhibitory state that signals a period of female refractoriness and the endocrine transition to pseudopregnancy or pregnancy.[70,74,75]

Female and male rats have also been used in studies of sexual reward, and to understand the plasticity of appetitive responses and their neurochemical control under different sexual circumstances, including different contexts, experiences, level of sexual reward, and partner

density.[28,30,76–79] Indeed, rats will copulate in a variety of circumstances and testing chambers, including small cylindrical or square chambers,[80] unilevel pacing chambers,[49,77,78,81–84] bilevel pacing chambers,[70,75,85,86] and open fields[31,50,87] (Figure 50.5).

Mice

There are well over 1100 naturally-occurring species of mice, with a far larger number of transgenic lines made with specific gene deletions or insertions. Those lines have been useful in identifying the role of estrogen, androgen, and progestin receptors using lines with specific KOs of those receptors or their subtypes, e.g., estrogen receptor alpha (ERα) and ER beta (ERβ), or steroid synthesizing enzymes, e.g., aromatase or 5α-reductase. The sexual behavior of wild house mice (*Mus musculus*) was documented by Estep, Lanier, and Dewsbury,[87] and consisted of a period of appetitive courtship that included mutual grooming of the body and genitals, sniffing of the genitals, and rooting (in which one partner lifts up the body of the other with its head). Females were observed to orient away from the male prior to the males initiating mounts. Like hamster females, these wild mice hold lordosis for a long duration of male thrusts with intromission. Upon ejaculation, males typically fall over, pulling the females with them. Females then hold lordosis on their sides with the male's penis still inside the vagina for approximately 20–30 s, after which the male dismounts, and the two groom their own genitals. Unlike the female rat, the female mouse stays in close proximity to the male during his postejaculatory interval. Despite obvious differences in copulatory behavior

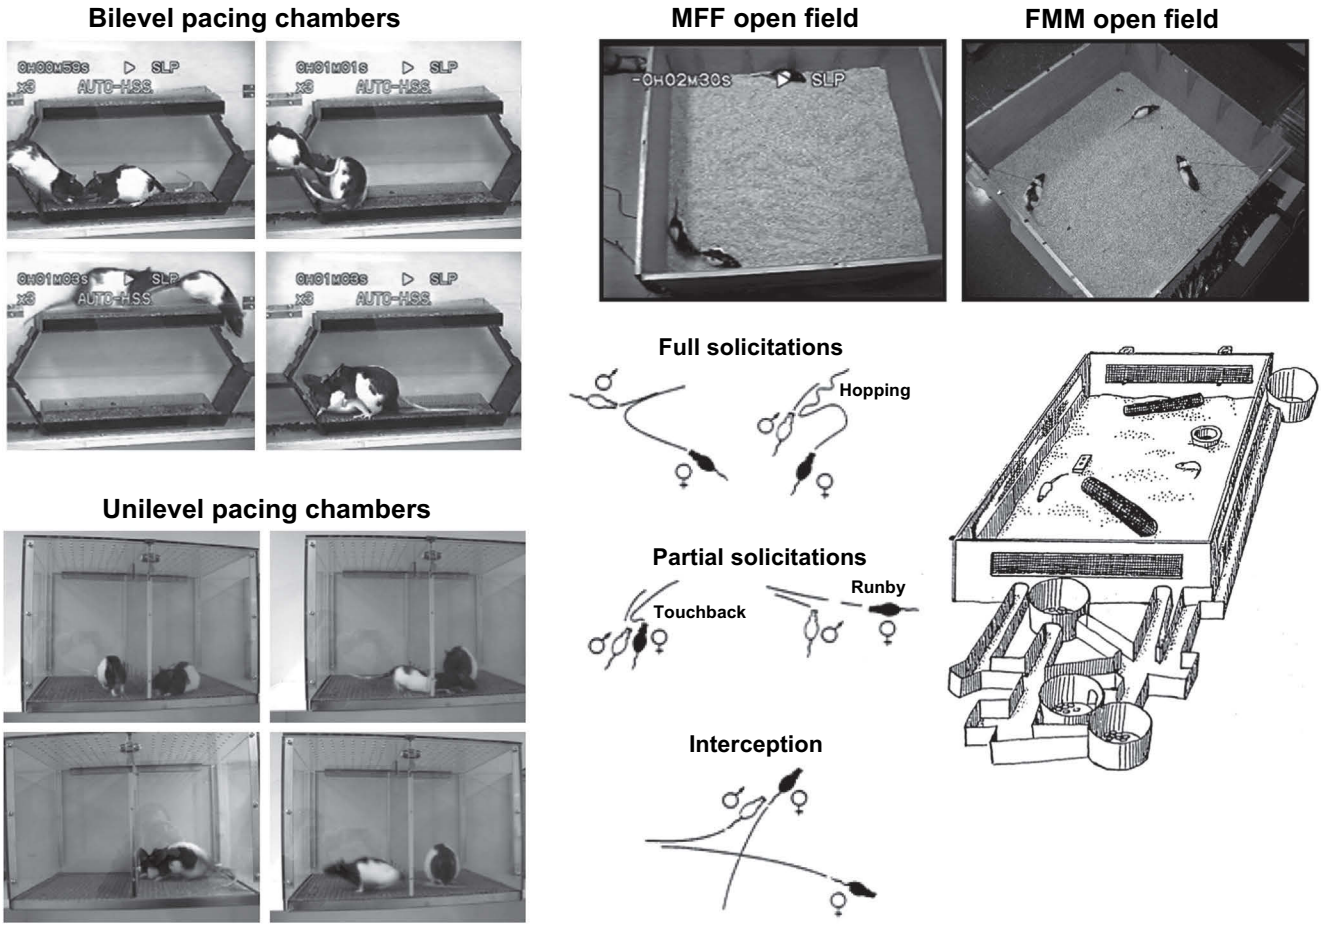

FIGURE 50.5 Rat copulation in several chambers. Top left: Bilevel pacing chambers. Bottom left: Unilevel pacing chambers. Bouts of copulation are typically initiated by the female through solicitations. In bilevel chambers the female solicits as she would in the wild by making a headwise orientation to the male and then either darting or hopping away on the same or other level. This forces the male to chase her and females regulate the rate of copulation by running from level to level. The endpoint of each solicitation and runaway is lordosis, allowing the male to mount and gain vaginal intromission, after which the male dismounts and grooms his penis. This is repeated several times until the male ejaculates. Unilevel pacing chambers are bisected by a Plexiglas or mesh partition with one or more holes cut out of the bottom that are big enough to allow the female to pass through but too small for the male. This restricts the male to one side. Females initiate copulatory contact by moving to the male's side, and regulate the rate of contact by running from side to side. Top right: Open fields used for tests of conditioned sexual partner preference for one male choosing among two free-ranging females (MFF) or for one female choosing between two tethered males (FMM). Bottom right: Large open field used by McClintock[50] to examine group mating patterns and preferences in female rats.

between mice and rats, nearly identical pacing behavior was observed recently in female mice.[88] Females placed into a smaller version of a unilevel pacing chamber bisected by Plexiglas dividers with four holes that only the females can pass through displayed exits and returns from the male's side after bouts of intromissions. This indicates that mice pace the copulatory contact like rats do when given the opportunity. It is not yet known whether female mice find sexual stimulation in paced conditions rewarding.

Guinea Pigs

Guinea pigs were used extensively to understand the role of ovarian hormones in the elicitation of lordosis, and also to understand the functions of progesterone. Both females and males engage in a courtship dance prior to copulation in which the female approaches the male swinging her hips back and forth and making a vibrating sound often referred to as "purring". Males respond in kind, and will often sniff and lick the anogenital region of the female, who does the same. Males have been observed to purr and sway their hips at nonreceptive females, but if the females do not respond sexually, then copulation is not attempted by the male.[89] This is similar to sexually experienced male rats that investigate sexually nonreceptive females but do not attempt copulation.[90] Females in heat express lordosis in response to male flank palpation during mounting. Like rats, males have a multiple intromission pattern prior to ejaculation and, as in rat pacing behavior, females run away from the males between intromissions causing the males to chase them. As the period of estrus terminates, females display more and more aggressive rejection responses to male pursuits and mounts.

Hamsters and Gerbils

The copulatory behavior of these subfamilies have been studied in less detail than that of rats, and mostly for effects of hormones, drugs, or brain region lesions on lordosis,[91] but also to examine social conditions like group size on sexual receptivity,[92] and sexual recognition.[93] Like rats, hamsters become sexually receptive every 4 days during their ovulatory phase, but are much more consistent than rats in their estrous cycles. Gerbils are sexually receptive approximately every 6 days. Female hamsters and gerbils both display appetitive responses that attract and solicit males to chase them. Female gerbils, for example, display a rhythmic "thumping" of the hindlegs that attracts males to them (males display similar behaviors with other males, although typically in response to a threat). Females of both species also display lordosis upon somatosensory stimulation of the flanks and perineum by males. Although both species are seasonal breeders in the wild, sexual behavior can be induced at regular intervals by injections of estradiol and progesterone, as in the rat. True receptivity to intromissions in the hamster, however, is not assessed by lordosis alone. Female hamsters display the lordosis posture and remain in it while the male mounts, intromits, and dismounts several times. To allow vaginal penetration, the females' tails must deflect laterally or dorsally, making "tail displacements" the true measure of receptivity to vaginal penetration.[94] In addition, female hamsters do not run away from males, or if they do it is for a very short distance and still while in a semi-lordosis posture, so there is little chasing behavior. Males simply mount and intromit repeatedly until ejaculation. Like rats, female hamsters will attack males that attempt to mount them when they are not sexually receptive, when the period of sexual receptivity is terminating, and when they are OVX and primed with low doses of estradiol, with or without progesterone. Female gerbils engage in appetitive thumping, causing males to thump back, as the rhythmic leg thumps are a form of social communication. This typically occurs prior to the female presenting to the male, which is followed by the male mounting. Estrus termination in both species is induced by vaginocervical stimulation (VCS) and accompanied by an increase in female fighting if males persist in attempting to mount. It is more typical, however, for females to take themselves out of the situation by moving to a different space or into a burrow system.

Voles

Voles have been studied largely to understand the neurochemical and genetic basis of "monogamous" vs "promiscuous" sexual partner and mate preferences. Both female and male prairie voles show social and sexual partner preferences for their first sexual partner, relative to an unfamiliar partner, and they form relatively stable pair bonds for the nurturing of their pups. In contrast, closely related meadow voles do not display such preferences. However, prairie voles are not sexually exclusive and will copulate with other partners under certain circumstances. Differences in mating strategy have been linked to the differential actions of oxytocin (OT) in females and vasopressin in males,[95] in particular in males to the greater expression of the vasopressin 1a (V1a) receptor in the ventral pallidum, a motor structure that receives input from the NAc. DA is also important in driving the partner preference in the presence of familiar—and presumably olfactory—incentive cues.[96]

Female voles make precopulatory scent marks when they are sexually receptive, and they will spend more time near male scent marks. Females also approach males and both engage in side-by-side contact, sometimes referred to as cuddling. Males mount females who display lordosis, and although males appear to set the pace, females copulate with tethered males, suggesting that females can initiate copulation. Vole mating in the wild takes place over

several days, during which males ejaculate several times with either one (monogamous) or several (polygamous) females. Like rats, male voles display a multiple intromission pattern prior to ejaculation, suggesting that females receive clitoral stimulation (CLS) and VCS at a particular rate. It is not known which stimuli are responsible for terminating sexual receptivity in the vole.

Musk Shrews

Musk shrews are a primitive eutherian mammal. Female shrews are induced or reflex ovulators that require behavioral stimulation to ovulate and induce increases in circulating estradiol and progesterone. The torturous process of a male "taming" a female shrew into sexual receptivity has been known for a very long time. Indeed, Shakespeare's 1592 play of the same name is a comic analogy about human heterosexual marriage. Rissman and colleagues studied the copulatory behavior of musk shrews extensively in order to make comparative analyses of hormone-brain interactions. Their work established clearly that female musk shrews display a period of intense appetitive aggression toward males which includes biting and scratching, and if the females live in large natal groups, the aggression against potential suitor males sometimes results in death.[97] Virgin females attack males more frequently than sexually experienced females, and exposure to male olfactory cues reduce aggression in virgin females.[98] The most persistent male will eventually gain access to her flanks and mount, which induces tail-wagging, a first sign of sexual interest, followed by a lordosis posture thus rendering her sexually receptive to his intromissions. Testosterone produced by the ovaries and adrenal glands is the most abundant circulating steroid at the time the males begin their approach,[99] and may explain the increased female aggression during this appetitive period. Indeed, crystalline implants of testosterone in the mPOA or VMH of OVX shrews were more likely to induce a full complement of sexual behaviors compared to implants to the bed nucleus of the stria terminalis (BNST), whereas implants of estradiol in the mPOA or VMH induced lordosis and immobility, and reduced the time taken for females to become receptive. This suggests that aromatization of circulating testosterone into estradiol is necessary for the switching from aggression to sexual receptivity. High levels of cortisol are also observed during the induction of sexual receptivity, and blocking cortisol production reduces sexual receptivity.[100] As with rats, extended periods of sexual receptivity also facilitate the induction of pregnancy.[98] It is not known what type of sexual stimulation may contribute to this.

Rabbits

As with rats and guinea pigs, rabbits have been used to examine a host of female reproductive functions, from hormone and brain lesion effects on sexual behavior and scent marking to sexually dimorphic development of the olfactory system (e.g., Refs 101,102). Female rabbits typically approach males and stay motionless beside them. The two gradually rub noses and nibble at each other's fur. If receptive females are eating when a male approaches, he may rush past them and then gradually get closer, often circling stiff-legged with his rump and tail raised high in the air. If the female ignores the male's advances, he often scent marks her with urine. Once the male mounts and intromits, he typically bites the back of the female's neck. After a few thrusts he ejaculates, and like the rat often falls off the side of the female and remains motionless for a while. As the male approaches exhaustion and the female approaches estrus termination, the two start nibbling more and more at a food source.

Macaques and Other Nonhuman Primates

Rhesus macaques have been used in a variety of ways in sex and neuroendocrine research, notably like rats in the study of hormonal and neurochemical systems underlying appetitive and consummatory sexual behavior, but also to study the social conditions under which very different types of sexual responding are induced. Female rhesus macaques living in large natal groups approach males early in their appetitive phase, several days before their estradiol peak, followed by solicitations of males more closely linked to the estradiol peak.[57,103] Solicitations or "invitations" include characteristic "hand reach", "head-duck", and "head-bob" behaviors in the vicinity of the male.[104] Females also assume a lordosis posture when mounted, and males typically mount with a number of intromissions and pelvic thrusts, sometimes occurring in bouts prior to ejaculation. Females display a characteristic clutching reaction after ejaculation in which the female reaches back and clutches the face of the male.[105] These behaviors cease soon after copulation terminates, as plasma estradiol levels decrease. Like rats and dogs, female rhesus macaques also mount sexually inactive or naïve males as a supersolicitational behavior to induce the males to mount back.[106] In contrast to females living in large groups, single female rhesus macaques living in dyadic conditions with one male show a far greater propensity to submit to mounts on the part of the male throughout the ovulatory cycle, although there is an increase in successful mounts by the male around the time of the estradiol peak.[103] Thus, a dyadic context in which the female is always in the vicinity of the male and cannot escape stimulates more mounting behavior on the part of the male, which is reacted to by consummatory sexual behavior on the part of the female throughout her ovulatory cycle, although the number of male ejaculations still increases during ovulation. This suggests that contextual

cues and sexual stimulation interact with neuroendocrine systems to stimulate sexual responding in female rhesus macaques that appears to be less tightly-linked to ovulation, a situation generally not found in rats and mice. In laboratory settings, female rhesus macaques can also be trained to bar-press to obtain a male, behavior that increases during their ovulatory phase.[107]

Female Japanese macaques, and to a lesser extent Stump-tail macaques, engage in homosexual mounting of other receptive females, often to the point of displaying ejaculation—like facial grimaces prior to dismounting and a period of rest,[108] suggesting that female–female mounting leads to genital stimulation that induces an ejaculation-like state in the female. Female Japanese macaques form stable homosexual consortships during the breeding season[109–112] that is not due to, nor affected by, the availability of males. Females mount one another repeatedly, and males entering into this consortship engage in intrasexual competition, often trying to fight the dominant (mounting) female to gain access to the other female, who typically rejects him over 90% of the time.[109] Female bonobos also engage in female–female mounting, usually as a method of conflict resolution when males are fighting.[113,114] Notably this behavior can occur at anytime during the ovulatory cycle. Although the patterns of female approach and solicitation are similar in many primate species, the copulatory stance of the Bonobos includes face-to-face, male-on-top "missionary" positions not observed in other primates except humans.

Humans

Like other primates, the sexual behavior, and especially sexual arousal, desire, orgasm, and sexual inhibition of the human female are exquisitely sensitive to context and social learning.[47] However, despite the general view that sexual behavior in women is "freed" from the dependence on steroid hormones, women display a characteristic increase in self-reported sexual desire and arousal during ovulation.[55] Across the ovarian cycle of women, steroid hormone levels fluctuate in a cyclical manner. Circulating levels of estradiol, progesterone, and testosterone rise around the time of ovulation, correlating with an increase in sexual interest, activity and fantasies.[55,115–118] Removal of cyclic steroid hormone release by long-term administration of estrogen-containing oral contraceptives often results in a decline in sexual desire, activity, and genital blood flow.[115,119,120] It is unclear whether the blunting of the cyclical induction of sexual activity and fantasies is directly due to the removal of the cyclicity of the hormones acting on relevant tissues, or whether it is secondary to downstream effects of chronic administration of estrogens. Long-term exposure to estrogens has a number of physiological effects that might disrupt sexual behavior. For example, estrogens upregulate steroid hormone binding globulin (SHBG) production by the liver, which are transport proteins that bind androgens with higher affinity than estrogens.[121,122] A recent study on premenopausal women's steroid hormone levels using liquid chromatography-tandem mass spectrometry revealed that serum testosterone, free testosterone, estradiol, estrone, and SHBG levels peaked at midcycle and remained higher in the mid-luteal phase, whereas the 5-α reduced androgen metabolite dihydrotestosterone (DHT) did not change across the cycle.[123] Chronic use of oral contraceptives containing combined estrogens and progestins lowers free testosterone levels and upregulates SHBGs.[124] Given the importance of free testosterone for sexual desire in women,[125] its reduction by chronic oral contraceptive use may be one reason why some women experience a decrease in sexual desire on the pill.

A decline in sexual desire and activity also occurs following surgical and natural menopause. Surgically menopausal women, induced either by bilateral oophorectomy and hysterectomy, experience a sudden and drastic decline in sexual arousal and desire.[126–129] These symptoms can be restored following adequate hormone replacement regimens, particularly with replacement of estrogens in combination with testosterone.[126,127,130–139] As such, ample evidence suggests that fluctuating ovarian steroid hormone levels are important in normal sexual function in women, as they are in other species.

Sexual desire in women is a matter of great controversy. Although sexual arousal and desire can be defined by subjective reports, only arousal has been defined objectively (as increased genital blood flow). There is not yet an objective measure of desire, thereby forcing it to be inferred from subjective self-report or intuitively observed behavior (e.g., flirtations). Desire appears to occur spontaneously in some women whereas in others it occurs in response to the right male(s) or females(s) making the right verbal and nonverbal gestures in the right contexts. As mentioned above, self-reported desire peaks during ovulation. This makes antecedent hormonal conditions—effects of estradiol, testosterone, and perhaps also progesterone, in the brain—likely motivational variables in its stimulation. Responsive desire, or the ability of the "right" stimuli to activate incentive motivational pathways in the brain and excite attention and behaviors that are indicative of desire, is also activated by steroid hormones. Desire is then expressed both as a spontaneous motivation and an attention toward competent sexual stimuli.[2,43] In both cases, the emergent conscious awareness of sexual desire activates movement from distal to proximal to interactive, like the approach and solicitations of rats and macaques. Humans thus learn a baffling array of appetitive responses that work differently in different cultures and contexts, or differently within a single culture at different epochs, and indeed

differently with different people. And cultures constrain women's responses, and indeed their own knowledge of their own sexuality, to appropriate times and places. The brain must balance these excitatory and inhibitory influences to achieve some kind of optimal level for pleasure. And it must do this with hormonal influences weighing it toward excitation, especially during ovulation, and experience directing attention and behavior toward individuals and stimuli previously associated with sexual reward.

The copulatory patterns of women are also fraught with problems of interpretation. Although more behaviorally stereotyped than appetitive responses, consummatory patterns of copulation in humans are nonetheless extremely variable, even in cultures where certain positions (e.g., missionary) are proscribed.[10,20,140] Some heterosexual positions, e.g., woman on top, can maximize her ability to get optimal external and internal CLS, possibly along with direct stimulation of the cervix, from the male.[141] Other positions may embellish other stimulus zones, and thus engage different motor patterns to maximize the stimulation achieved. And of course, some women are extremely sensitive to external CLS, and can only achieve orgasm in that way, whereas others achieve orgasms with blended internal and external CLS.[142–146] Interestingly, there is no human analogue to the lordosis reflex, although lordosis-like positions can be observed in women being mounted from behind. The arching of the back, however, is not a hormone-induced and/or facilitated spinal reflex; those do not exist in humans, a fact that continues to limit the human clinical application of the neuroendocrine work done on lordosis in animals. Being "receptive" to vaginal penetration in women involves a conscious decision to expose the vulva and open it to penetration. Experience with orgasm or other types of sexual pleasure and intimacy leads to expectancies which also constrain the sexual positions and patterns of both men and women.[145]

ANATOMY AND PHYSIOLOGY OF SEXUAL SENSORY SYSTEMS

The autonomic and peripheral nervous systems work together to send sensory information about genital and erogenous sexual arousal and stimulation to the spinal cord and brain, from which conscious feelings of desire and pleasure are derived (Figure 50.6). Genital (clitoral and cervical, but also involving sensitive regions of the labia and anus), and erogenous (nipples, lips) stimulation typically requires the engorgement of erectile tissues with blood (a parasympathetic activation). This engorgement increases the somatosensory surface area upon which stimulation can induce a response, essentially making the female more sensitive to tactile stimulation. Copulation typically involves more focused and localized genital stimulation that culminates in the buildup of a threshold amount of sympathetic arousal that brings about orgasm (or homologous responses in animals), and immediate sexual pleasure that activates inhibitory mechanisms related to euphoria (e.g., orgasm/reward), satiety and refractoriness.

Autonomic Control

The autonomic nervous system[147,148] consists of three divisions, sympathetic, parasympathetic, and enteric (the latter of which controls the gut). The role of the sympathetic system is to up- or down-regulate homeostatic and cardiovascular mechanisms to prepare the body for action (sometimes referred to as "the stress response" or the "fight or flight response"). Such action can be defined in terms of good stress ("eustress") or bad stress ("distress") depending on the nature of the event.[149] In either case, the sympathetic system initiates immediate pupil dilation (allowing for greater processing of the visual field), increased heart rate and blood pressure, dilation of the bronchioles of the lungs (to increase oxygenation of the blood), constriction of blood vessels, and inhibited digestion. It also is responsible for orgasm once sexual stimulation is underway. The sympathetic system activates the adrenal gland (located just above the kidney) to induce a massive release of adrenaline from the adrenal medulla (which activates and potentiates sympathetic outflow in most organs all at once, except the gonads). Adrenocorticotropic hormone (ACTH) released from the anterior pituitary stimulates the secretion of glucocorticoids such as corticosterone or cortisol from the adrenal cortex (which increases glucose concentrations in the blood, inhibits inflammation that might occur in response to injury, and potentiates arousal in the central nervous system and phenomena like place learning in the hippocampus of the brain's limbic system). The sympathetic nervous system extends from the spinal cord between the thoracic and lumbar divisions, and consists of short preganglionic nerves that contain the neurotransmitter Ach which excites postganglionic neurons, and long postganglionic nerves that contain norepinephrine (which inhibits prolonged muscle contractions). The ganglia collect incoming preganglionic fibers and distribute the postganglionic fibers to the organs in the abdominal and pelvic regions.

In contrast, the parasympathetic nervous system opposes the actions of the sympathetic system at each organ within each division. Its role is to calm the system down after stress, although it can be activated within each division on its own (e.g., as bright sunlight induces constriction of the pupil). The parasympathetic division is literally around ("para") the sympathetic division, and extends long fibers of the cranial nerves III, VII, IX, and

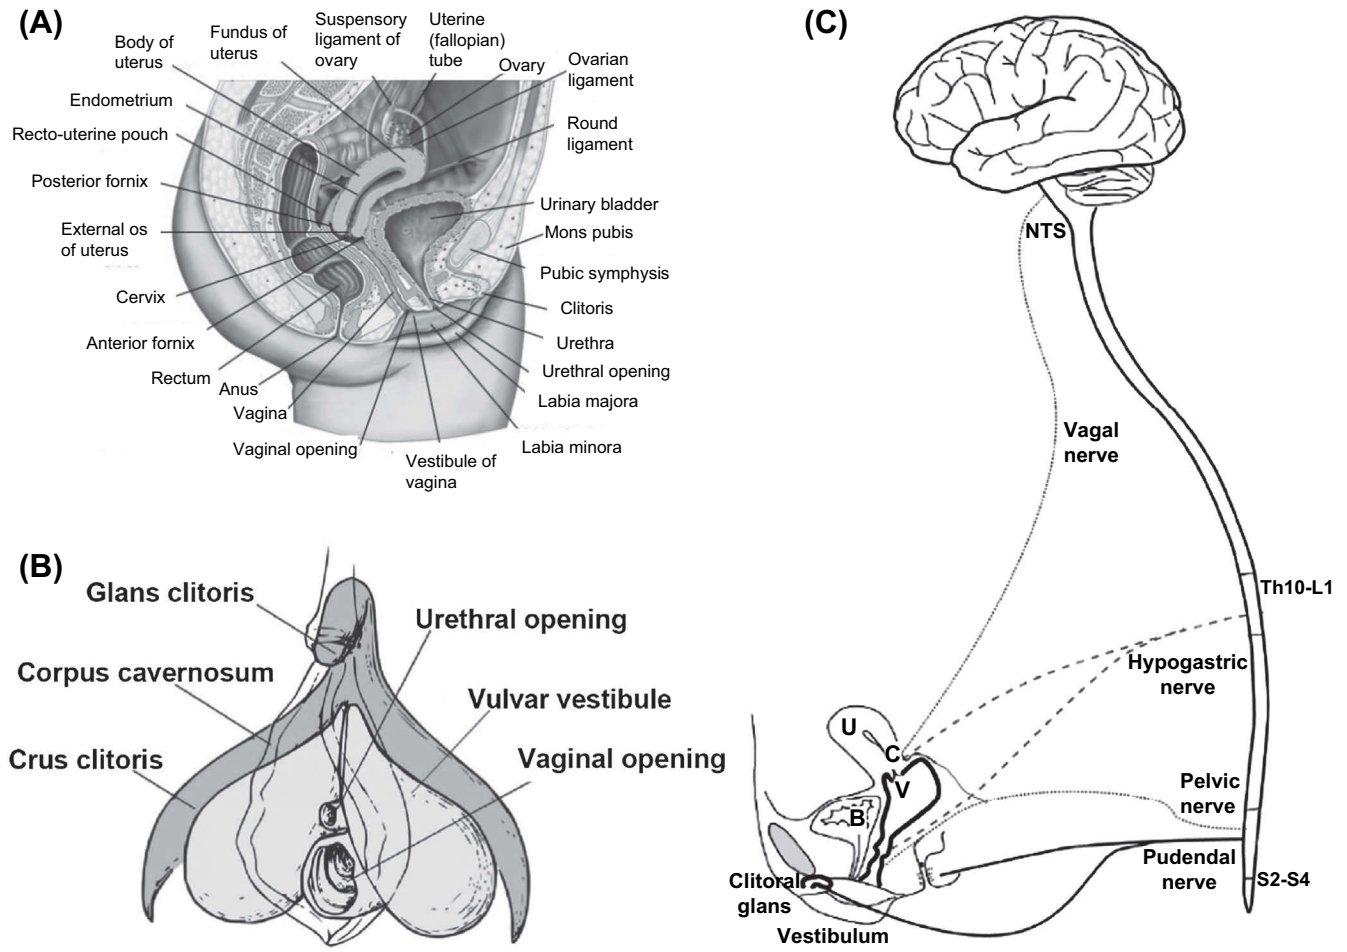

FIGURE 50.6 **Human female genital anatomy and neurophysiology.** (A) Cross-section of the human female genital and pelvic region. (B) The clitoral complex in relation to the urethra, vulva, and vagina. X (occulomotor, facial, glossopharyngeal, and vagus) to innervate ganglia close to the organs. The postganglionic fibers that innervate the organs are short. Both pre- and postganglionic fibers contain Ach, which excites neurons and contracts smooth muscle. The pre-to-post relationship is more specific (e.g., 1:3) compared to the sympathetic division (which is greater than 1:10). Because the parasympathetic division causes dilation of blood vessels, it is critical for the stimulation of erection in labia, clitoris, and the vaginal epithelium, along with other erogenous erectile tissues (e.g., nipples and lips), and for draining the blood out of erectile tissues after orgasm.

Physiological sexual arousal can be defined as increased autonomic activation that prepares the body for sexual activity. In females this includes activation of the parasympathetic system that keeps blood in genital and erectile tissues, in particular the clitoris, labia, vaginal epithelium, nipples, and lips, and sympathetic blood flow from the heart to striated and smooth muscle that participate in sexual responses (Figure 50.7). Sexual arousal also includes a central component that increases neural "tone" or preparedness to respond to sexual incentives, and forms around an intricate interaction of hormone priming and noradrenergic activity in different regions of the brain. Both peripheral and central arousal may be detected as part of the perception of subjective sexual arousal, and both clearly lead to changes in responsiveness in genital tissues and control certain copulatory responses, such as the latency to orgasm (with shorter latencies indicating an increase in arousal). Both aspects are sensitized by estradiol and testosterone,[150] and are thus more likely to be experienced during the periovulatory period.

Peripheral autonomic blood flow is typically experienced far more readily than internal flow. Thus, women are less likely to be consciously aware of blood flow to the labia and clitoris relative to blood flow to the nipples. The reliance on vaginal arousal as a measure of sexual arousal may well account for the relative lack of concordance between physiological and subjective measures of sexual arousal in women relative to the concordance observed between physiological and subjective measures of sexual arousal in men.[151]

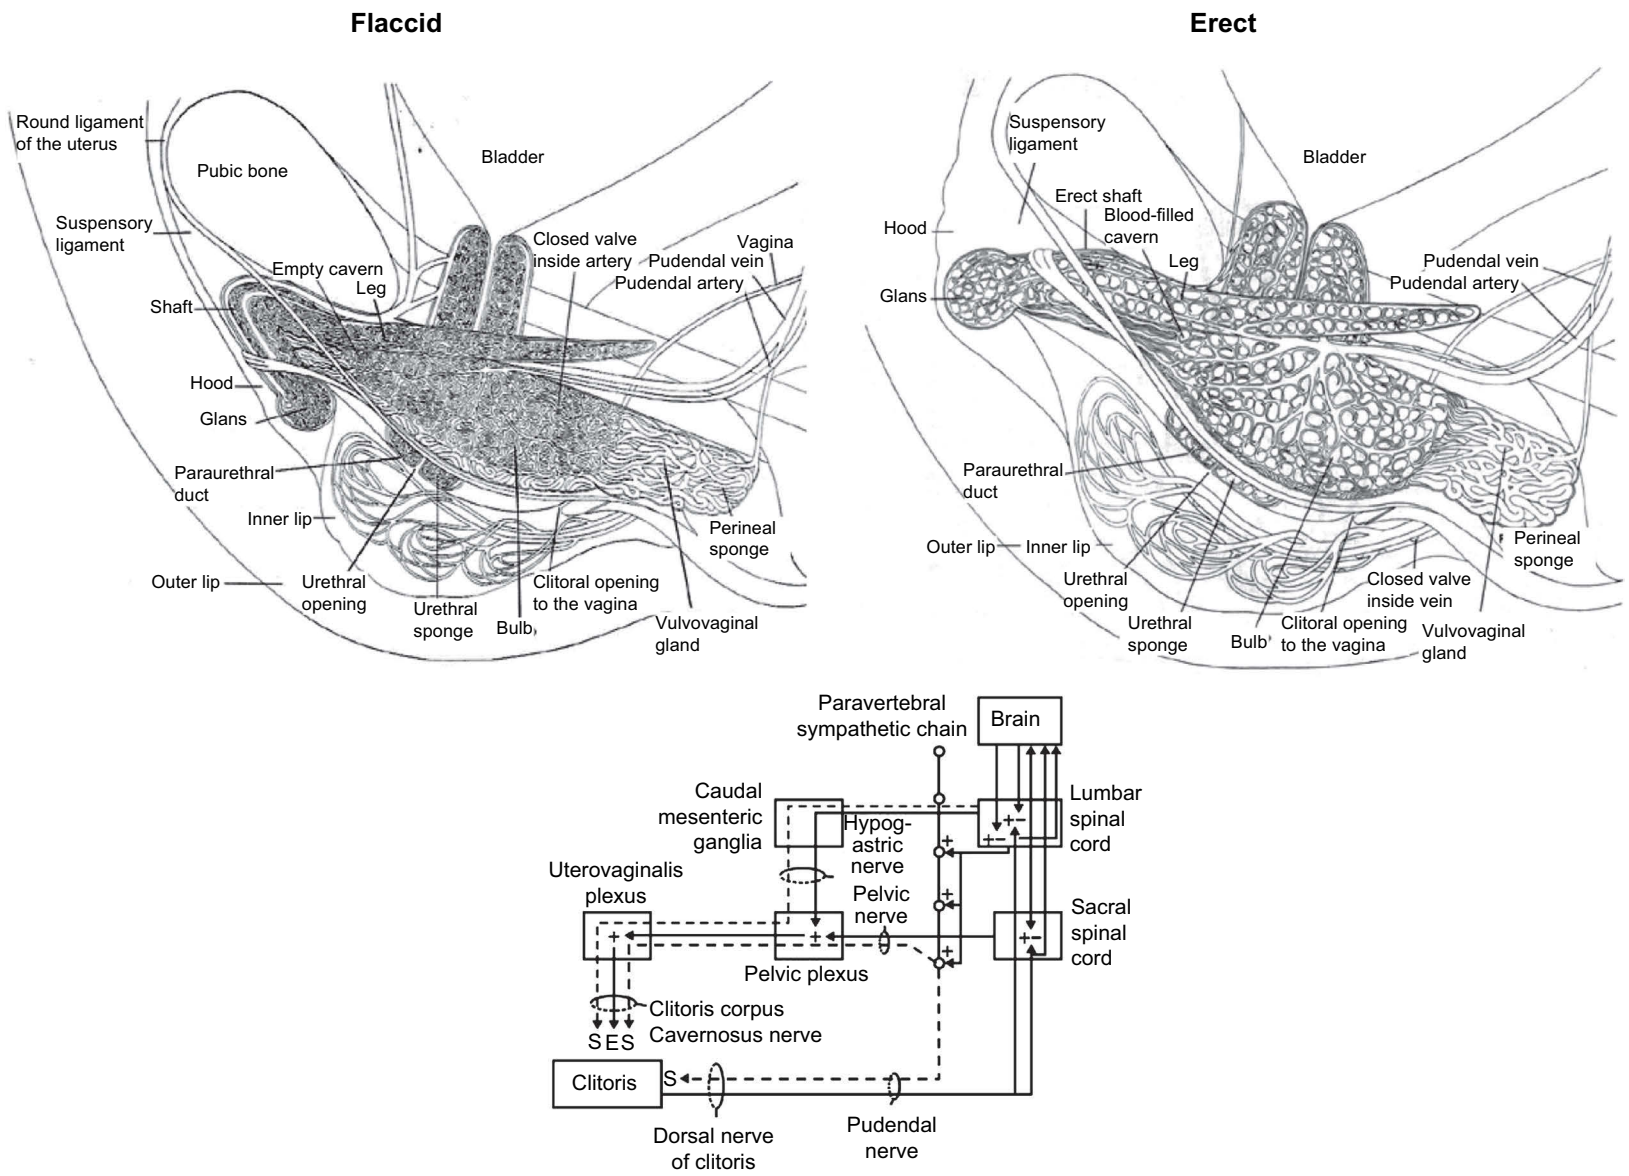

FIGURE 50.7 Top: The clitoral complex in its flaccid and erect states. Bottom: Wiring diagram of the sensory and autonomic pathways of the clitoral complex.

Genitosensory Stimulation

Both psychogenic and physical stimulation induce sexual arousal and desire that can lead to sexual behavior. Under normal conditions peripheral genital stimulation enhances excitability within sensory afferents that innervate spinal cord neural circuits. These spinal pathways contain the neural components for reflexive vasodilatation and orgasm and receive and send information to brain regions that perceive and modulate the signals that drive or inhibit sexual behavior. Although there are important differences in the brain and spinal pathways that mediate sexual function in males and females, largely related to sexual differentiation due to gonadal steroid hormone actions during fetal development (See Chapter 47), there is also substantial similarity between the CNS mechanisms mediating sexual desire, arousal and orgasm in males and females. In females, these include mechanisms involved in genital and psychological arousal, vasodilatation in the clitoris and vagina, smooth and skeletal muscle contractions, and rewarding sensations including orgasm.

Clitoral Stimulation

The clitoris is the main genitosensory organ of sexual pleasure in females,[130,132,134] and CLS influences vaginal muscle function.[152] It has been studied in rats with regard to its innervation and vasculature during sexual arousal[153–156] and its morphology in response to hormones.[157–159] However, its role in carrying sensory information during sexual activity in female rats has only recently been eludicated.[160–163] By engaging in lordosis, female rats not only receive vaginal intromission, but also CLS during mounts with pelvic thrusting. This interaction stimulates the female's flanks, rump, tailbase, perineum, and perivaginal surfaces which include the clitoris.[164] Intromission also stimulates the internal end of the clitoris in a region that overlaps in humans with the so-called "G-spot".[165–167]

In addition to CLS induced by male pelvic thrusting, direct CLS can be applied by an experimenter that mimics the distributed CLS a female rat might receive during copulation[160–163] (Figure 50.8, bottom left). Such stimulation on its own is rewarding in sexually naïve rats and stimulates preference for places and scents on partners associated with the reward state (see Section Consequences of Sexual Stimulation below). In contrast, CLS does not induce a preference in sexually experienced rats,[162] although it stimulates approach and solicitations of males behind a wire mesh screen.[161] Interestingly, the reward value of CLS is independent of steroid hormone priming, working as well in OVX rats as it does in OVX rats primed with estradiol alone or estradiol and progesterone.[162]

Clitoral afferents travel largely via the pudendal nerve (which branches into the dorsal penile nerve in males and dorsal clitoral nerve in females). This nerve provides the major sensory input from the external and internal clitoris and vagina, and provides the efferent (motor) innervations of the striated muscles of the pelvic floor and perineum.[170–172] Stimulation of the sensory branch of the pudendal nerve elicits vasodilation of the clitoris and vagina.[158,172–175] The increase in vaginal blood flow in response to sensory pudendal nerve stimulation was reduced by bilateral pelvic nerve cuts, suggesting that somatic afferents activate automatic spinal pathways to mediate the changes in vaginal blood flow that lead to vasocongestion.[174] The sensory field of the pudendal nerve is augmented by treatment with estradiol in OVX rats.[176]

Cervical Stimulation

The cervix is also stimulated during sexual interaction. Female rats, for example may receive VCS directly with each intromissive pelvic thrust from the male, whereas in humans the penis is generally not long enough to do this in most male-above positions, although it can occur in female-on-top positions.[177] Notably, however, orgasm in women also induces contractions of the cervix as part of what has been referred to as the "up-suck" reflex that aids sperm transport into the uterus.[178]

In rats small amounts of VCS potentiate lordosis whereas large amounts stimulate the termination of estrus. This stimulation-dependent excitation or inhibition depends on the hormonal status of the female and whether she can pace the copulatory contact with the male, as pacing increases the force with which the male intromits.[179–181] The augmentation of lordosis by small amounts of VCS is thought to be mediated at least in part, by the release of norepinephrine and possibly DA in the hypothalamus.[182,183] It may also be mediated by the release of OT in the spinal cord,[184] an effect that could also induce cervical dilation in preparation for sperm transport.

VCS can be applied by the experimenter using a smooth glass rod (Figure 50.8 bottom center) or plastic 1 cc syringe that approximates the width of the erect male rat penis. This stimulation can partially mimic the effects of intromissions by a male rat on reproductive physiology and behavior. This is somewhat surprising, however, because the probes provide pressure directly to the uterine cervix with mild distension pressure on the vaginal wall, whereas the erect rat penis is covered with keratinous spines,[185,186] which may more potently stimulate the vaginal wall even if the glans of the penis does not actually make contact with the cervix during intromission. Nevertheless, experimenter-administered VCS has many of the same effects on behavior and physiology as intromissions and is often used as a tool to simulate in a controlled manner the intromissions by the male. For example, experimenter-applied VCS increases heart rate[187] and elevates pain thresholds in both rats[188] and women.[189] VCS also

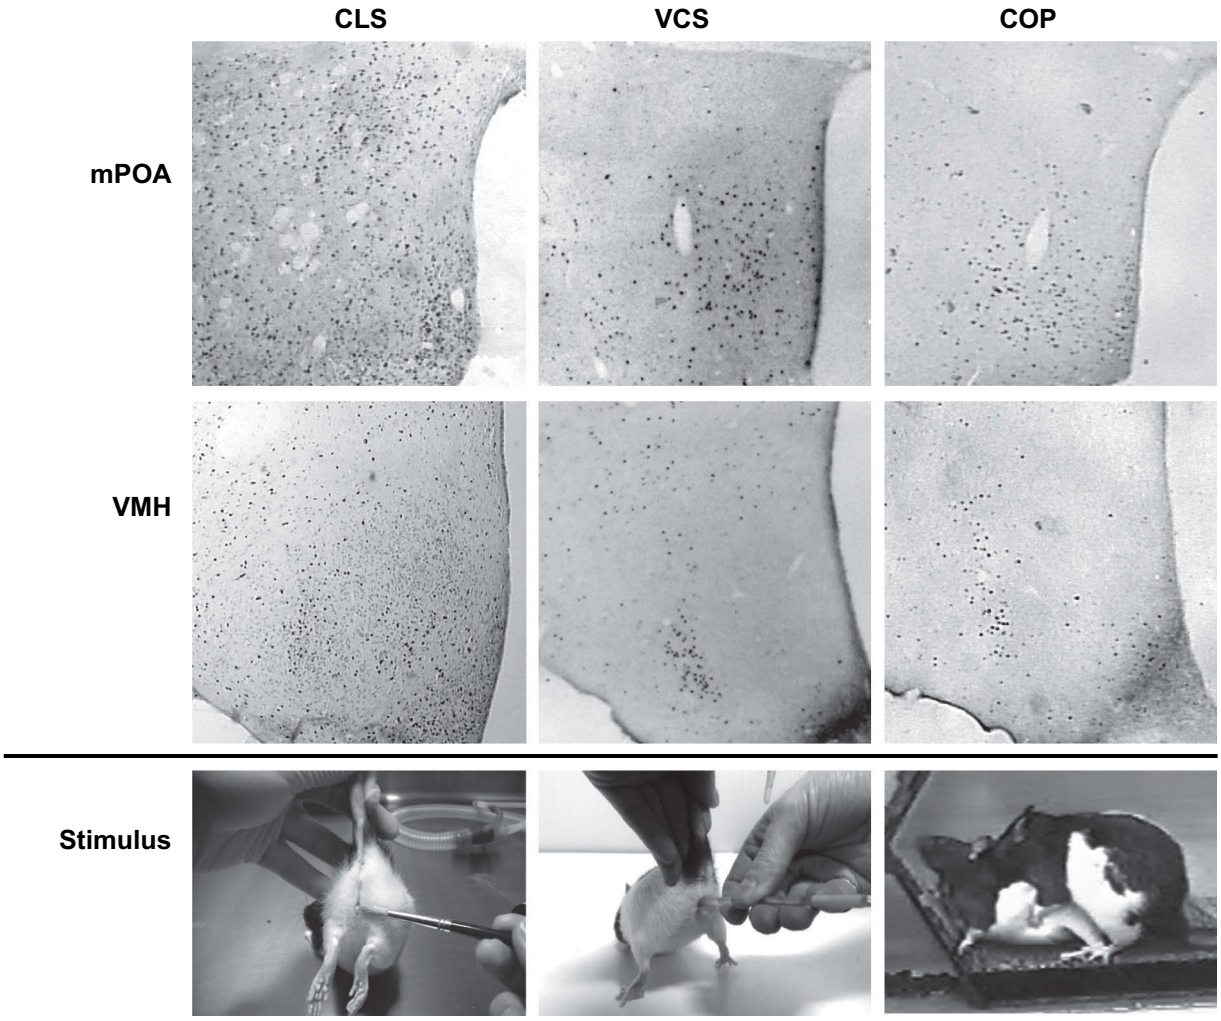

FIGURE 50.8 Fos induction in the mPOA (top) and VMH (middle) of OVX hormone-primed rats that received 50 distributed CLSs applied with a paintbrush,[160–163] 50 distributed VCSs applied with a lubricated glass rod,[75,168,169] or an hour's worth of paced copulation in bilevel chambers (bottom).

potentiates the ability of flank stimulation to induce lordosis in OVX rats not given hormone replacement,[190] and represents the only known stimulus, other than estradiol, to permit flank stimulation to induce lordosis.

Study of the relative contribution of intromissive, as compared to flank and perineal, stimulation provided by males suggested that nonintromissive stimulation is sufficient for mating-enhancement of lordosis, ear-wiggling and darting-and hopping in OVX/adrenalectomized (ADX) rats in a repetitive mating situation.[179] Therefore, VCS is not the proximate cause of mating enhancement in the repetitive mating situation, because, mounts without intromission were sufficient to enhance lordosis in OVX/ADX, estradiol-treated rats in the absence of progesterone. This makes logical sense; enhancement precedes the receipt of intromissions, because intromissions require that females display lordosis in response to mounts. Of course, the female does not show this posture until she is sexually receptive. In some experiments, rats have been OVX, and in others, they have also been ADX. Therefore, the interactions between adrenal ovarian hormones in the regulation of sexual responsiveness[182] and in the neuronal response to mating stimulation[191] must be considered. In some neuroanatomical areas, for example, OVX/ADX rats express the immediate early protein, Fos, in fewer cells in response to mounts without intromission than do OVX rats, but they express Fos in more cells in response to intromissions. This finding suggests that adrenal secretions may decrease sensitivity to low levels of mating stimulation.[191] Besides its influences on behavior, VCS influences luteinizing hormone (LH) release[192] and the twice daily surges of prolactin that then result in an extended period of diestrus[193] called pseudopregnancy or the progestational state.[194] More will be explained about the influences of VCS on estrus termination below. Cervical afferents travel largely via the pelvic nerve, and ablation of the pelvic nerve abolishes Fos induction in the brain by both VCS and copulation.[195]

Clitoral and Cervical Overlap

Both pelvic and hypogastric nerves convey sensory and noxious information from the internal reproductive organs, vagina and skin.[196] The cavernous nerve regulates both penile and clitoral erections. Stimulation of pelvic nerve afferents evokes an increase in vaginal blood flow, modeling genital arousal.[158] Vagal afferents from the uterus and cervix provide direct connections to the brainstem, and may sense orgasmic responses after spinal cord injury.[197] The distribution of the sensory afferents in the pelvis allows them to transmit considerable information relevant to mating, such as initiation and strength of sexual arousal, the location and movement of the penis inside the vagina, and orgasm or other pleasurable sensations derived from CLS. The clitoral glans contains specialized nerve endings that become very sensitive during erection and likely enhance sensation during intercourse, as is the case of the glans penis.[198,199]

Spinal Pathways

The sympathetic, parasympathetic, and somatic branches of the nervous system are coordinated and interconnected through important spinal pathways. This coordination allows sensory inputs to produce the appropriate sexual response, e.g., vasodilatation of erectile tissue, lubrication, increased sensitivity of erogenous zones, and muscle contractions during intromission and orgasm. In females the sympathetic spinal regions in lower thoracic-lumbar segments play a role in psychogenic arousal that occurs when distal cues (e.g., erotic visual cues in women; olfactory cues in rats) induce vaginal congestion.[200,201] However, genital responses occur only if the lumbosacral spinal cord that contains the pelvic and pudendal afferents and efferents is intact. Brainstem nuclei in the nucleus paragigantocellularis exert a serotonin-mediated tonic inhibition over the spinal pathways, and different regions of the brain (cortex, limbic system, mPOA) can be activated (directly or through visual or olfactory sexual stimulation) to initiate genital responses (reviewed in Ref. 196).

The pudendal nerve and pelvic nerve afferents course along the medial and lateral dorsal horn, respectively, of L5-S1 of the rat, with some afferent fibers penetrating into the dorsal gray commissure, and toward the parasympathetic preganglionic nucleus. In contrast, the hypogastric nerve afferents of the rat are relatively sparse and terminate in the superficial dorsal horn and medial gray of T13-L3.[171,195]

Fos Induction

Copulation, artificial VCS or CLS, urethral stimulation, or electrical stimulation of pudendal or pelvic nerves, all activate the immediate-early gene product Fos in neurons in similar spinal segments and subregions.[175,202] Activated spinal neurons are located in the superficial dorsal horn, the dorsal gray commissure of L5-S1 segments, overlapping with pelvic and pudendal sensory nerve innervations. Additional spinal neurons are activated in the intermediate gray and lateral gray dorsal to the parasympathetic preganglionic neurons. The distribution of activated spinal interneurons is similar in males and females. In parallel, electrophysiological studies identified similar spinal interneurons in the medial lumbosacral spinal gray matter after stimulation of the pudendal nerve and pelvic viscera.[203,204] However, VCS and CLS produce a different pattern of Fos activation in the rat brain (Figure 50.8, top). For example, distributed CLS that females find rewarding activates the medial nucleus of the mPOA,[160] whereas VCS activates a more medial region near the ventricles of the mPOA.[168,169] Paced copulation with a male (Figure 50.8, bottom right) activates both. In the VMH, CLS activates Fos throughout the dorsal and medial region, whereas VCS activates Fos exclusively in the ventrolateral region. Similarly, CLS activates Fos in limbic structures such as the posteroventral region of the medial amygdala (MEApv), whereas VCS activates Fos in the posteriordorsal region of the MEA.[18,160] In women, fMRI studies show that clitoral, vaginal, or cervical self-stimulation activates different regions of the sensory cortex.[205] Each of these are clustered in the medial paracentral lobe, a region that registers stimulation of the penis in the classic sensory homunculus of men.[206]

Tract Tracing

Neuroanatomical tract-tracing studies using neurotrophic viruses that are transported transneuronally through several synapses (for example, pseudorabies virus) have been used to map spinal and brain neurons that innervate the perineal muscles, clitoris, vagina, and uterus.[171,207–210] The majority of labeled neurons in the spinal cord are located in the dorsal gray commissure and in the vicinity sympathetic and parasympathetic preganglionic neurons, in the same regions as the Fos activated neurons. These neuroanatomical and electrophysiological studies reveal that genital afferents synapse on multiple interneurons in the spinal cord which then relay through a spinal pattern generator the preganglionic and postganglionic neurons and motoneurons to mediate, enhance, trigger, and maintain genital sexual responses. This complex spinal system allows coordination of sexual reflexes and sensorimotor modulation of these responses by different hypothalamic, midbrain, and brainstem regions (Figure 50.9).

Ultrastructural Changes in the Brain by Copulatory Stimulation

Sexual behavior itself influences neuronal morphology in rats[211] and hamsters.[94] After 1 h of mating in rats, there is a dramatic increase in expression of the cytoskeletal

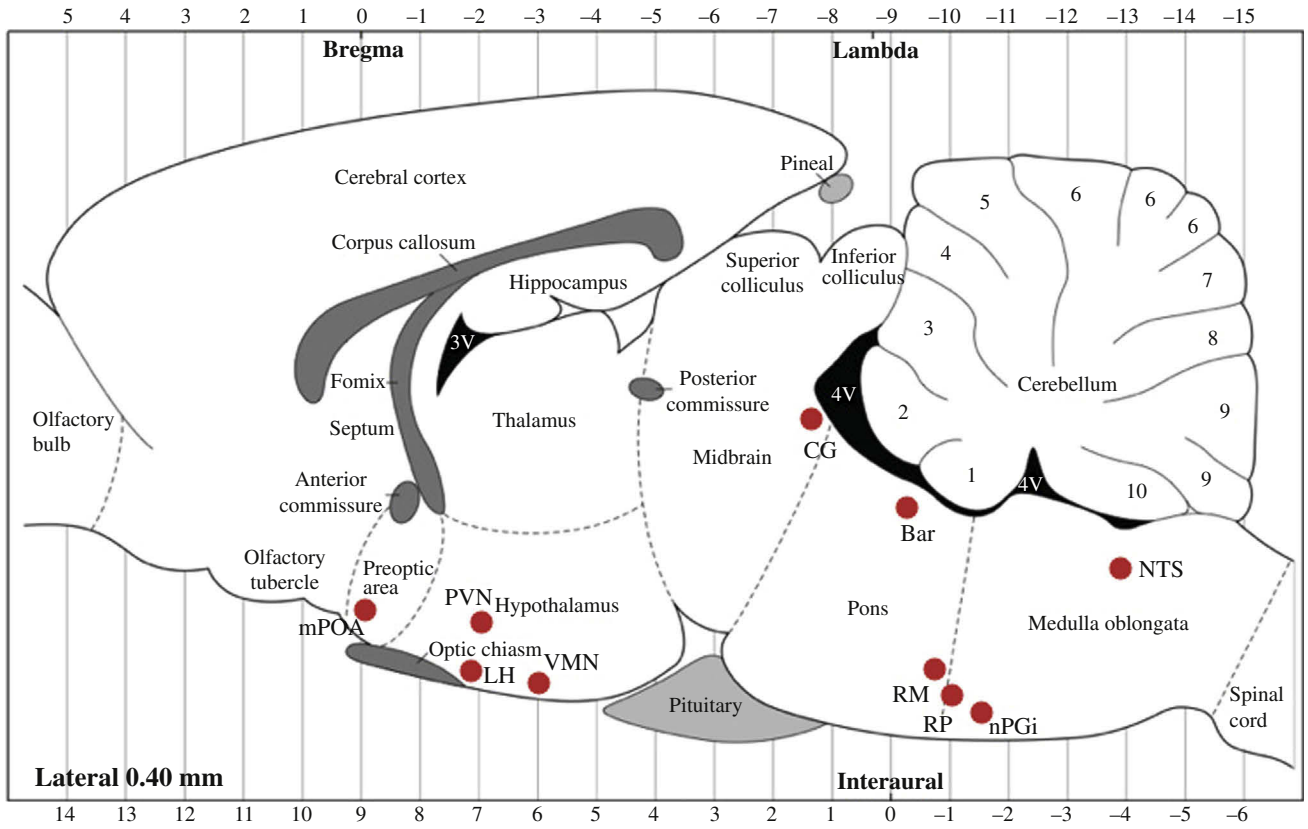

FIGURE 50.9 Dots depict areas of transneuronal staining in the brain 4 days after an injection of pseudorabies virus (a retrograde tracer) to the glans clitoris. *(Source: Adapted from Marson.[171,209])* mPOA, medial preoptic area; PVN, paraventricular nucleus; LH, lateral hypothalamus; VMN, ventromedial hypothalamus; CG, central gray; Bar, Barrington's nucleus; RM, medial Raphé; RP, posterior Raphé; nPGi, nucleus paragigantocellularis; NTS, nucleus of the solitary tract.

protein, Arc, in the ventrolateral VMH. Surprisingly, although the short-term effects were not assessed, this treatment also leads to a reduction 5 days later in secondary dendrites in this area. In hamsters, sexual experience increases the density of dendritic spines (membranous protuberences from the dendrite that typically receive a single synaptic input) in the prefrontal cortex (PFC), while decreasing it in the NAc.[94] Corresponding neurochemical changes have also been reported as a function of copulatory experience, including sensitization of D1 DA receptors[212] and Fos expression[213] in the NAc. It is clear that environmental stimulation, including that from mating, causes structural changes in neuroanatomical areas involved in sexual behavior. It is currently unclear how these changes relate to behavioral responses.

Other Erogenous Zones

Nipple and lip stimulation can be highly erotic during sexual arousal in both men and women, and can stimulate further sexual activity.[214,215] Nipple self-stimulation in women activates the genital sensory cortex (as well as the thoracic) region of the homuncular map in sexually experienced women.[205] The nipple/areola complex in women is innervated by the anterior cutaneous branches of the 1st to 6th intercostal nerves and laterally from the lateral cutaneous branches of the 4th intercostal nerve with additional innervation by cutaneous branches of the 3rd and 5th intercostal nerves (reviewed in Ref. 214). Innervation of the nipple appears to follow a pyramidal hierarchy, with most cutaneous sensory input in most women coming from the 4th lateral cutaneous branch, followed by the 3rd and 4th anterior branches.

Sensory innervation of the upper and lower lips comes from the maxillary and mandibular branches of the trigeminal (5th) cranial nerve, respectively.[216] Primary neurons send input to the trigeminal sensory nucleus, which is actually a sensory ganglion in the brainstem. Second order neurons project from there to the ventroposterolateral thalamus, and from there tertiary neurons carry input to the secondary somatosensory cortex (SII), in the lip region of the homunculus. The blood supply to the lips comes from the external carotid system,[217] which is aroused during parasympathetic activation of the lingual nerve. In the case of vasodilation in general for all genital and erogenous tissues, antihypertensive drugs

like nifedipine and propranolol can diminish erectile capability in both men and women.

In female rats, cutaneous stimulation of the flanks and perineum induces lordosis. Estradiol increases the area where cutaneous stimulation around the flanks and perineum induces lordosis, essentially sensitizing the somatosensory inputs to induce the reflex. This occurs by actions of estradiol in the periphery and within CNS modules that alter the propensity for cutaneous stimulation to induce lordosis.[32] Estradiol induces neurochemical and ultrastructural changes in the hypothalamic module (discussed below), notably in the VMH in concert with actions in other hypothalamic nuclei like the mPOA, that lead to an altered activation of neurons in the midbrain module of the central gray, which in turn activate neurons of the lateral vestibular nucleus in the brainstem module. This outflow activates the lateral vestibulospinal and reticulospinal tracts that synapse on motor neurons of the spinal module in the lower spinal cord (L5, L6, S1) to contract the lateral longissimus and transversospinalis muscles of the back, producing the characteristic arch of lordosis. However, such contractions are produced only when somatosensory afferents from the skin of the rump, tailbase, and perineum are activated by the male during anogenital investigation and more extensively during mounts with pelvic thrusting. Thus, although lordosis is essentially a spinal reflex, it is normally under tonic inhibition during periods of sexual nonreceptivity. The action of steroid hormones in the hypothalamic module is to constrain the lordosis reflex to an extended periovulatory period and disinhibit it in response to competent somatosensory stimulation of critical erogenous zones in the skin.

Primary Visual and Olfactory Senses

Sexual stimulation is often defined in terms of genital and erogenous somatosensory inputs (as those are explicitly and directly sexual), but largely separate from the main sensory systems that detect sexual incentives at a distance. In primates, and especially sighted humans, such stimuli are visual and auditory in nature. In other animals like rodents, they are olfactory in nature. Some stimuli are unconditionally arousing to human females (e.g., erotic pictures of attractive nudes or copulating couples[218,219]) or female rats (e.g., the smell of male rat fur[220]). Those unconditioned stimuli evoke attention and sexual approach behaviors like nose-pokes in rats. Treatments that disrupt olfactory input in rats, e.g., olfactory bulbectomy, zinc sulfate lesions of the olfactory epithelium, or olfactory occlusion with a polyethylene tube inserted into the nose, severely disrupt appetitive solicitations in females, but do not alter lordosis if the female is mounted.[221] Such treatments block copulation in male rats if they are sexually naïve, but not experienced.[28] Male olfactory cues alone activate Fos in the main olfactory (piriform) cortex, mPOA, VMH, and MEA of sexually experienced OVX rats primed with estradiol and progesterone.[221]

Erotic visual cues are used in studies of sexual arousal and desire in women (and men), and include still pictures or videos of nudes or different types of sexually explicit heterosexual or homosexual interaction. These are also used in brain imaging studies to correlate brain activation using fMRI or PET. Women experience cyclic fluctuations in sexual attention and arousability. For example, Mass et al.[60] reported pre-menopausal women's self-reported sexual desire and electromyographic responses of the facial zygomasticus major muscle (used for smiling and expressing joy) changed across the menstrual cycle during their exposure to pictures of naked men, with increases in smiling during the follicular phase and decreases during the luteal phase. Notably, these responses co-varied with increases and decreases in plasma progesterone, respectively. Similarly, event related cortical potentials (ERPs) recorded by scalp electrodes attached to the head that correspond to attention and stimulus processing for working memory increase in women following the presentation of sexually arousing pictures, but not pictures of babies or body care products, during the ovulatory phase.[59] The same pictures do not activate those ERP components during other phases of the menstrual cycle, or in women taking oral contraceptives.[222] Another study used fMRI to compare brain activation of premenopausal women in mid-luteal or menstrual phases of the cycle in response to erotic video clips relative to neutral video clips.[58,223] Increased activation by the erotic clips was observed in the anterior cingulate cortex (ACC), left insula, orbitofrontal (OFC), and parietal cortices, NAc, and hypothalamus, during the mid-luteal phase relative to the menstrual phase. These are virtually identical to the areas activated in men exposed to similar stimuli. The OFC is also activated by pictures of male faces, and the degree of activation is correlated positively with estradiol and progesterone levels in blood. The augmentation of the OFC response predicts the perceived attractiveness of the faces.[61] The ability of erotic visual stimuli to activate limbic and cortical structures is reduced after menopause, but can be restored to premenopausal levels following combined estradiol and testosterone treatment.[138] Thus, timing, context, and hormonal milieu, are extremely important variables to bear in mind when studying sexual arousal and responses to visual sexual stimuli in women.

HORMONAL PRIMING AND CONTROL

Steroid hormone synthesis in the ovaries is under the control of follicle stimulating hormone (FSH) and LH that are released from the anterior pituitary in response

to gonadotropin releasing hormone (GnRH) (see Chapter 28). FSH stimulates the growth of the ovarian follicle (and egg). When the follicle reaches a certain level of maturation it begins to secrete estradiol. LH causes the rupturing of the mature follicle to release the egg. The follicle becomes the corpora lutea ("yellow body") which then synthesizes and releases progesterone. The peak in estradiol secretion by the ovaries is followed by a small but critical rise in circulating androgens, notably testosterone, which is tightly linked in time to ovulation, and which, either alone in some species or in concert with the actions of preovulatory progesterone (from the follicle), activates appetitive approach and solicitation behaviors in many species. In humans, such behaviors are consonant with an increase in sexual desire. In most species, the expression of female sexual behavior is tightly regulated by ovarian hormones and occurs only during the periovulatory period.

Lordosis is perhaps the most-characterized and studied model of the hormonal regulation of behavior. In fact, the hormonal and neuroendocrine regulation of lordosis is similar in many species, including rats, mice, guinea pigs, hamsters, and gerbils. During the estrous cycle of these species, the secretion of estradiol followed by progesterone from the ovaries results in a period of sexual behavior that is tightly linked to ovulation.[65,224–226] Removal of the ovaries results in the loss of expression of female sexual behaviors.[65,227] High levels of sexual behavior in estrous cycling or OVX animals require estradiol priming followed by progesterone.[226,228] After behavioral estrus ends, sexual receptivity is not expressed until the next proestrous stage of the estrous cycle at which time estradiol secretion followed by progesterone once again induces sexual behavior. Although females of each of these species[229–232] may respond to estradiol alone, estradiol followed by progesterone is typically necessary for the expression of the full suite of female sexual behaviors closely resembling that seen in estrus-cycling animals.[14,65,225,227,233,234] The increase in both lordosis and appetitive sexual behaviors also occurs in OVX rats primed repeatedly with estradiol alone[84] and in ovary-intact, aged rats treated with testosterone.[235]

In some cases, after exposure to progesterone, rats,[236] hamsters,[231] guinea pigs,[237] and mice[238] become refractory to further stimulation of sexual behavior by either progesterone alone or, in some cases, to estradiol and progesterone. Although progesterone is believed to cause heat termination in guinea pigs, the role of progesterone in termination of sexual behavior during the estrous cycle of rats[239] is unclear. Based on work in guinea pigs to be discussed later, it has been suggested that progesterone desensitizes its response to itself, leading to termination of sexual receptivity and subsequent facilitation requires additional exposure to estradiol. Estradiol priming of behavioral response to progesterone generally takes about a day,[240,241] However, an intravenous injection of progesterone may facilitate the expression of lordosis within an hour of injection in estradiol-primed rats.[242–245] Interestingly, latencies as brief as 10 min for progesterone facilitation have been reported.[246]

Steroid Hormone Receptors

Although other hormones are involved, estradiol and progesterone have been the most extensively studied in the regulation of female sexual behavior in a variety of rodent species. This regulation involves a now "classic" steroid hormone action on specific intracellular receptors that act as transcription factors to induce gene expression (see Chapter 9). In turn, this sets up the excitatory and regulatory functions of the sexual brain, altering neurotransmitter synthesis, release, binding and reuptake, and altering synaptic connections in critical regions. Because of their role in the regulation of sexual behavior, understanding the regulation of these receptors is essential. A basic principle is the homologous and heterologous regulation of the receptors, each essential to ensure the critical timing of behavioral events with ovulatory events. This, in turn, sets up different neurochemical actions that time the onset, duration, and offset (inhibition) of the behavior.

A wide variety of steroid binding proteins has been described in the brain. These include the classic (so-called, nuclear) receptors that have been most extensively studied: ERα, ERβ, progesterone receptor A (PR-A; often referred to as progestin receptor A), progesterone receptor B (PR-B), and androgen receptor (AR). In addition to these classic receptors, other receptors, notably cell-surface receptors, have been described more recently that also mediate the effects of steroid hormones in the brain. Although these novel receptors are of great interest, much less is known about their role in the regulation of sexual behavior. As models of the regulation of female sexual behavior that involve the novel receptors develop, they must also be able to account for the data demonstrating the importance of the classic steroid hormone receptors as well.[247]

Classic ERs and Their Distribution in Brain

As described above, several subtypes of ERs exist, including the well-characterized classic (primarily) cell nuclear ERα and ERβ. Although relatively little is known about the neuroanatomical distribution of membrane-based ERs, a good deal is known about the distribution of ERα and ERβ. The following description of the brain localization of ERs focuses on the pattern of ERα and ERβ expression.

Four independent techniques have convergently revealed the distribution of ovarian steroid receptors

in the mammalian brain: in vitro binding, receptor autoradiography, immunohistochemistry, and in situ hybridization. These techniques measure the anatomical distribution of receptor binding activity, protein or mRNA expression, respectively, providing compelling evidence for regionally specific expression of these receptors. Table 50.1 summarizes the brain regions with the highest levels of ERs, based on these studies. Although most mapping studies have used rats, mice and guinea pigs, partial mapping of either ER protein or mRNA has been done in many other species, ranging from fish[248] and lizards[249] to musk shrews,[250] sheep,[251] human,[252,253] and nonhuman primates,[254,255] and the overall pattern is conserved.

The first studies delineating the anatomical distribution of estradiol binding used steroid receptor autoradiography with 3H-estrogens injected systemically. Although the initial observation of binding of an estrogen in the brain was made in cats,[256,257] in more comprehensive experiments,[258,259] regions of the hypothalamus and amygdala were especially rich in ERs. With the later discovery of distinct α and β subtypes of nuclear ER, autoradiographic studies were performed in transgenic animals with a "KO" of each of the subtypes of the ER.[260] These studies confirmed distinct neuroanatomical distributions for ERα and ERβ.

A great deal of the early work on the role of ERs in female sexual behavior and the biochemical characterization of them relied on in vitro 3H-estradiol binding in cell nuclear preparations of homogenates of particular brain areas.[261] In microdissection studies, the areas with the greatest density of ERs were in close agreement with autoradiographic studies showing ERs most abundant in the mPOA, VMH, and MEA.[262]

The early autoradiography and ligand binding studies on neural ERs relied on the binding of ^{3}H-estradiol to receptor proteins. Unfortunately, these techniques did not distinguish binding to each of the ER subtypes. However, the molecular cloning of the ERα and ERβ led to development of antibodies that could be used in immunocytochemical procedures that were able to distinguish the two subtypes. Immunocytochemical procedures were developed for both ERα[263–265] and ERβ.[266] Although immunohistochemistry provides the opportunity for superb subcellular localization, it has the disadvantage of not being able to distinguish between bound vs unbound receptors. This differs from autoradiography, which depends upon the receptor binding ligand. Thus, in addition to confirming the general pattern of receptor expression that had been revealed by receptor autoradiography, immunohistochemistry uncovered ERs in axons, dendrites, and terminals.[267,268] The presence of ER immunoreactivity in these nonnuclear sites complemented other evidence for nongenomic actions of estrogens, which will be discussed later.

The mRNA for ERα and ERβ has been mapped with in situ hybridization techniques,[269] and the neuroanatomical distribution of mRNA for the ERα and ERβ isoforms has been completed.[270] The results are in agreement with mapping studies based on receptor autoradiography in KO mice and subtype-selective immunocytochemistry. As a testament to the functional significance of the receptors in these regions, mating behavior produces a pattern of immediate early gene expression in the brain, a marker of neuronal activity, that corresponds to the neuroanatomical pattern of many locations of ER density.[168,271] Thus, ERs are well positioned to modulate the activity of the neural circuits that control mating behavior.

In summary, the neuroanatomical distribution of nuclear ERs is well documented, with the pattern of ERα expression coinciding well with brain regions known to

TABLE 50.1 The Dominant Pattern of ER Subtype Expression in Brain Regions Involved in Reproductive Behavior

	ER-Alpha	ER-Beta	Both

promote female sexual behavior. In a later section, we discuss the concept that in many areas with high levels of ERα expression, such as the VMH and POA, estradiol treatment increases the expression of the two forms of the progestin receptor (PR-A and PR-B).

Necessity of ERs for Hormonal Induction of Female Sexual Behavior

The notion that ERs are *essential* in order for estradiol to prime mice to become sexually receptive has been demonstrated by a wide variety of techniques, including: (1) injection of estrogen antagonists, which block the binding of estradiol nonselectively to ERs, or estrogen agonists that selectively activate either ERα or ERβ, (2) ER gene-disrupted mice (ER knockouts; ERKOs), in which the ERα or ERβ gene has been disrupted, and (3) RNAi silencing of ERα in specific brain regions.[272] The results of each approach are consistent with the conclusion that ERα is essential for the effects of estradiol on the expression of sexual receptivity, and that ERβ may have a modulatory role.

Effects of Estrogen Antagonists and Agonists

Early studies using estrogen antagonists to block the binding of estradiol to ERs were unequivocal in demonstrating the absolute necessity of binding to ERs in the mechanisms by which estradiol primes rats for female sexual behavior.[273,274] However, those antagonists were not specific for ER subtype. More recently, experiments using the ER subtype-specific agonists, propyl-pyrazole triol (PPT; ERα agonist) and diarylpropionitrile (DPN; ERβ agonist) indicate that ERα mediates the effects of estradiol on both appetitive and consummatory aspects of sexual behavior in female rats. Although the ERβ agonist is without effect when administered alone, it reduces the effects of the ERα agonist, suggesting that ERβ has a modulatory role in damping the effects of ERα activation.[275]

KOs and Knockdowns

KO strains of mice have been developed in which the gene for each form[276,277] or both forms[278] of ER is disrupted. Targeted disruption of the ERα gene (ERKO) completely eliminates hormonal induction of female sexual behavior.[279,280] In contrast, disruption of the ERβ gene (BERKO) was reported to be without effect in OVX, hormone-injected mice,[281] although it extended the period of behavioral estrus and enhanced receptivity.[282] Double KO mice with disruption of both, ERα and ERβ, exhibit decreased levels of sexual receptivity supporting the critical role of ERα in the sexual behavior of female mice.[281] Further support for involvement of ERα in female sexual behavior, and specifically its role in the VMH comes from the use of RNAi silencing of this gene in the VMH.[283] However, in a more recent study using the more complete ERβ-null mouse ($ER\beta_{ST}^{L-/L-}$),[284] complete elimination of ERβ resulted in a decrease in lordosis and attractivity in homozygous female mice.[285] Taken together, these experiments point to a critical involvement of both forms of the ER in the regulation of female sexual behavior in mice.

Regulation of ERs and ER Action

Because of the importance of ERs in the induction of female sexual behavior, it is essential to understand the ways in which levels of ERs in cells are regulated by estradiol and other compounds. There is some inconsistency among studies on regulation of ERα protein and mRNA levels by estradiol. However, estradiol has typically been reported to down-regulate ERα in most neuroanatomical areas.[286–291] Most studies find that estradiol also down-regulates ERβ in some neuroanatomical areas but is without effect in others.[289,292–294] Besides the homologous down-regulation of ERs by estradiol, ERs are down-regulated by progesterone[295–298] under some circumstances. Down-regulation in specific neurons that results from either hormone would be expected to decrease hormonal responsiveness in those neurons. The inconsistencies that exist in the literature with respect to the regulation of ERs by estradiol are to be expected, because there are numerous, important methodological differences between studies, such as doses of estradiol used, duration of exposure to hormone, time since OVX, etc. Furthermore, there is heterogeneity in the regulation of each form of ER, not just among neuroanatomical areas, but even among the neurons in a neuroanatomical area.[289] Nevertheless, such receptor down-regulation may help to explain why a substantial proportion of pre-menopausal women taking synthetic estradiol-containing oral contraceptives experience a blunting of their sexual desire, and an uncoupling of desire around the time that ovulation would normally have occurred.[299,300]

Pattern of Estradiol Exposure Sufficient to Induce Sexual Behavior

Acute Administration

The pattern of hormonal exposure is another critical variable in determining response to hormones. OVX rats need not be exposed to estradiol continuously during the priming period in order to express sexual behavior. Two pulses of a low dose of estradiol (e.g., 5 μg of estradiol benzoate, EB) spaced 24 h apart are more effective in inducing female sexual behavior after subsequent progesterone administration than a single higher dose of EB (e.g., 10 μg) or continuous exposure to estradiol from a silastic capsule implanted subcutaneously (sc) for several hours.[301–303] The behavioral effects of each pulse can

be blocked by either a protein synthesis inhibitor[304] or pentobarbital anesthesia,[305] suggesting that both protein synthesis and neuronal activity are required for each of the pulses of estradiol to be effective. The potential roles of classic and membrane receptors in these processes are discussed below.

Although continuous exposure to estradiol is not essential for the expression of sexual behavior, the continued presence of estradiol-bound ERs seems to be a requirement; administration of an estrogen antagonist that displaces receptor-bound estradiol inhibits sexual behavior, even when administered just prior to progesterone injection within a few hours of testing.[306] This finding suggests that the down-regulation of ERs by progesterone, which would then be expected to reduce ER-dependent estradiol action, may be part of the mechanism by which the period of estrus terminates.

Chronic Administration

Priming regimens in the literature vary, as do the strains of OVX rats used. It is clear, however, that a low dose of estradiol (e.g., 5 μg of EB) injected sc induces a moderate lordosis, but no appetitive approach or solicitation behaviors. The addition of progesterone (e.g., 100–500 μg sc) can increase lordosis further, and stimulate appetitive behaviors. However, continuous EB exposure through a silastic capsule implanted sc results in high and continuous levels of both appetitive sexual behavior and lordosis, as do frequent injections of EB, which sensitize both lordosis and appetitive sexual behaviors in sexually experienced female rats. Maintenance of serum estradiol concentrations above 15 pg/ml over a 5-week period with silastic capsules maintain normal body weight along with normal patterns of appetitive and consummatory sexual behaviors in female rats.[307] Serum concentrations below this cause increases in body weight and a dramatic suppression of appetitive responses with smaller decreases in lordosis.

The progressive elevation of appetitive and consummatory sexual behaviors by sc injections of estradiol is dependent on the dose and injection interval (Figure 50.10), such that as EB dose increases, behavioral sensitivity increases.[84,301,308–314] Notably, the sensitization is not blocked by ADX in OVX rats,[84] making it unlikely to be induced by facilitated release of adrenal progesterone. This finding is important because it further demonstrates that hormones can override inhibitory mechanisms that would otherwise act to inhibit sexual behavior as estrus terminates. A function of this increased sensitivity to the hormones, or decreased sensitivity to VCS, may be to ensure the female receives sufficient stimulation to maximize reproductive success.[75,84]

Estrogen sensitization is an important consideration in pharmacological studies that investigate compounds that might facilitate sexual behavior. Typically, OVX females are primed with a dose of EB that produces low-to-moderate amounts of appetitive sexual behaviors and lordosis. This is done to prevent ceiling effects that occur when animals are primed with EB and progesterone. However, animals are often tested repeatedly to reduce the number of animals used or because long-term treatment effects are of interest. The sensitization of sexual behaviors with chronic EB is confounding and makes data interpretation complex. This is particularly problematic in studies where the facilitative actions of a drug seem to disappear over time. EB dosing regimens have been characterized for OVX rats to achieve desired baseline rates of female sexual behavior across time[84] which will help overcome these problems. Stable baselines are vitally important in preclinical models of female sexual function. For example, 5 μg EB administered every 7 days, induces a stable baseline[84,315,316]; and when given in combination with flibanserin, a mixed 5-HT1A agonist/5HT2A antagonist, appetitive sexual behaviors were increased significantly by the drug following 3 weeks of treatment,[316] whereas the control group did not manifest any increase in behavior.

ER Co-regulators

Another level of regulation of response of a cell to a hormone lies in steroid receptor coregulators; intracellular proteins that allow for efficient regulation of the transcription of steroid receptors (see Chapter 9).[317] These proteins bridge the receptor and the general transcriptional machinery and modify promoter regions of the receptor by a variety of mechanisms. Although there are over 300 steroid receptor coregulators,[318] and we have much to learn about how they modulate the action of ERs, perhaps fine-tuning responses to steroid hormones, we do understand the role of three coactivators in regulation of female sexual behavior. Work using intracerebroventricular infusion of antisense oligonucleotides directed against the mRNA for particular steroid receptor coactivators in rats suggests that steroid receptor coactivator-1 (SRC-1) and cAMP response element binding protein (CBP) act together to modulate the induction of sexual receptivity by estradiol,[319] as well as the induction of progestin receptors[319] and progesterone-facilitated sexual behavior in female rats.[320] Likewise, SRC-1 and SRC-2 play an important role in the cellular action of estradiol in the induction of female sexual behavior in rats and mice.[321]

In order for coactivators to influence the activity of steroid receptors, they must be coexpressed in the same neurons as the receptors. In fact, SRC-1 and SRC-2 are expressed in most cells expressing ovarian steroid hormone receptors in the VMH, mPOA, and arcuate nucleus (ArcN) of female rats and mice.[317] Although

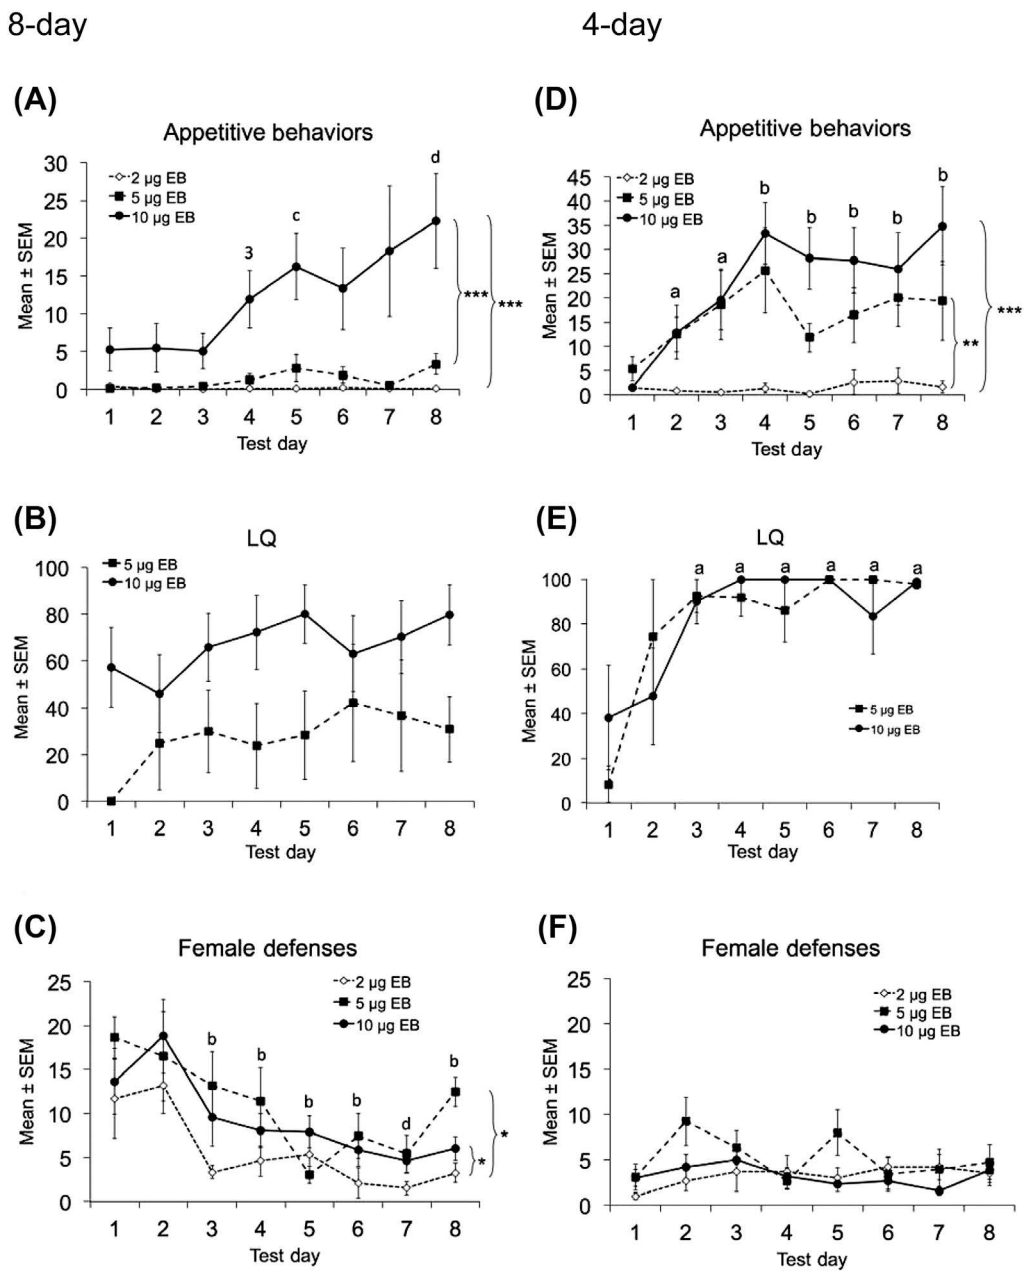

FIGURE 50.10 Sexual behaviors of OVX Long-Evans females treated with varying doses of estradiol benzoate (EB) at 8-day (left) or 4-day (right) intervals. (A) Appetitive sexual behaviors increased in females treated with 10 µg EB, but not 2 µg or 5 µg when treated at 8-day intervals. (B) Lordosis quotient (LQ) did not sensitize when treated with EB at 8-day intervals. (C) Collapsed across EB treatment group, females were less defensive toward males as of Test 3. (D) When treated at 4-day intervals sexually appetitive behaviors sensitized in females treated with 10 µg EB. (E) LQ sensitized in females treated with 5 and 10 µg EB when treated at 4-day intervals. (F) Defensive behaviors were unaffected when treated with EB at 4-day intervals. [a]Different from Test 1; [b]Different from Tests 1 and 2; [c]Different from Tests 1, 2, and 3. [d]Different from Tests 1–4. in vitro studies suggest that the relative expression levels of the coactivators and corepressors determine cell-specific, appropriate and graded responses to steroid hormones,[315] there has to date been no work on this subject in the brain and on behavior. It is however likely that this represents another level of fine-tuning of the hormonal regulation of female sexual behavior.

Is Binding of ERs to Estrogen Response Elements Essential?

Not all ER-mediated responses require the prototypical estrogen response elements on specific genes. A gene knock-in mouse model with a mutated ERα that does not bind to estrogen response elements (EREs)[322] expresses

negative, but not positive, feedback to estradiol on gonadotropin secretion, suggesting that negative feedback does not require binding of ERα to an ERE. While expression of masculine sexual behavior in males was shown to require binding to EREs,[323] results on female sexual behavior have not been reported. Nevertheless, this work suggests that some effects of estradiol that are relevant to female sexual behavior do not require binding the nuclear ER to an ERE, opening up the possibility that estradiol induces these effects through membrane ERs.

Role of Membrane ERs

Recent work has made clear that, while classic ERs are principal players in regulation of female sexual behavior by estradiol, membrane mechanisms are also involved. Although much less is known about membrane ERs than about the role of classic, so-called, nuclear ERs, there is now a good deal of evidence for the involvement of membrane mechanisms of action for the effects of estradiol on female sexual behavior. A variety of putative membrane ERs has been described,[324] including the classic ERα and ERβ, which can be translocated to plasma membranes,[325] ER-X, STX (a tamoxifen analogue that is estrogenic)-activated membrane ER, and GPR30 (G protein coupled estrogen receptor; GPER).

Although still in an early stage of research, the data argue strongly for the involvement of membrane ERs in the regulation of female sexual behavior by estradiol. For example, a biotinylated form of estradiol, which is impermeable to the cell membrane, interacts with metabotropic glutamate receptors in the mPOA, resulting in an increase in lordosis.[326] Specifically, membrane ERα[326] and/or the STX-activated membrane ER[327] is believed to interact with the metabotropic glutamate receptor 1a in the ArcN, resulting in the internalization of mu-opioid receptors in the mPOA and consequently an increase in lordosis via projections to the VMH. It should be noted, however, that while the STX compound facilitates the expression of lordosis in OVX rats, it only does so in rats administered a subthreshold dose of estradiol.[327] Therefore, the STX-activated mER participates in the process of estradiol priming of sexual behavior, but it is not sufficient to substitute for estradiol. As discussed earlier, administering estradiol in discrete pulses allows much lower doses of estradiol to be used to induce sexual behavior. However, little is known about the cellular basis for the enhanced response to pulsed exposure as opposed to bolus injection of estradiol. In some experiments, estradiol conjugated to bovine serum albumin (another form of estradiol which is impermeable to cell membranes), has been used.[328] The fact that this conjugated estrogen can substitute for either the first or later pulse of estradiol indicates that membrane ERs are capable of completing at least part of the priming for sexual behavior. Compounds that activate either protein kinase A (PKA) or PKC can also substitute for the conjugated estrogen,[328] suggesting involvement of these two intracellular signaling pathways in the priming action of estradiol on female sexual behavior. It should be noted that experiments using protein conjugates of steroid hormones must be interpreted very cautiously because of the possibility that the protein could be cleaved from the steroid molecule[329] and because the position of the protein on the steroid can have unexpected effects on function.[330] Nevertheless, the data argue for the ability of membrane ER mechanisms to substitute for interaction of estradiol with classic ERs.

With the exception of the work of Kow and others,[328] mechanistic studies have typically focused on the role of *either* nuclear ERs acting as transcriptional regulators or on the role of membrane receptors in regulation of sexual behavior. However in vitro, ERα and ERβ each may be processed to become associated with membranes, and are capable of signaling through the mitogen activated protein (MAP) kinase pathway.[331–333] This finding indicates that caution must be exercised in interpreting experiments which used hormone antagonists, antisense oligonucleotides or targeted gene disruption to test the involvement of ERs acting as transcription factors. If the ER genes that direct synthesis of the classic ERs also direct the synthesis of membrane receptors in the brain, then the manipulations that target the classic ER could disrupt membrane receptors as well as classic nuclear receptors.

As mentioned earlier, ERα immunoreactivity[267,334] has been observed in extranuclear locations within the guinea pig hypothalamus, including axon terminals and distal dendrites[267] (Figure 50.11). In some cases, this has been observed associated with synaptic densities and plasma membranes, which is consistent with the idea that classic ERs can be directed to membrane sites.

To summarize this section, in addition to actions of estradiol on classic ERs, estradiol may signal through a variety of membrane receptors to either substitute or perhaps, augment the behavioral effects of estradiol acting on classic ERs. There is still a great deal to be learned about the interplay of these various receptors in the fine-tuning of the hormonal induction of female sexual behaviors.

Classic PRs and Their Distribution in Brain

As with ERs, evidence from receptor autoradiography, immunohistochemistry, and in situ hybridization presents a coherent picture of the pattern of expression of nuclear PRs, although information about membrane receptors is still being gathered. Early receptor autoradiography experiments first revealed nuclear progesterone binding activity in the rodent brain.[335,336] Although progesterone binding was found in regions with an

abundance of ERs, such as the hypothalamus and amygdala, a few brain regions expressed PR in the absence of ER, suggesting separate functions. Double-label immunohistochemistry studies have shown that ERα and PR are often co-localized at the cellular level in brain regions known to control female sexual behavior.[289,337] The mapping of mRNA of the PR has been conducted using in situ hybridization techniques in rats, rabbits, lizards and fish.[338–341] Although there may be some species differences in regulation, the overall pattern of nuclear PR expression is conserved in regions associated with reproductive behavior, including the VMH, mPOA, median preoptic nucleus, anterior hypothalamic area, medial nucleus of the amygdala, anteroventral periventricular nucleus, lateral habenula, ArcN, and periaqueductal gray.[342,343] It should be noted many of the PR-immunoreactive cells in the VMH are located outside the Nissl-defined nucleus,[337] and these cells have been implicated in the facilitation of sexual behavior by progesterone, at least in guinea pigs.[344]

Although there is a great deal of overlap between neuroanatomical sites containing estradiol-induced PRs and those that contain ERs, immunocytochemical experiments demonstrated conclusively that estradiol-induced PRs are co-expressed in ER-ir cells in brain regions involved in regulation of female sexual behavior.[289,345] Virtually all cells expressing estradiol-induced PRs also express ERα (Figure 50.12).

The PR is synthesized from alternative, estrogen-inducible promoters on the PR gene, resulting in two isoforms of the receptor (PR-A and PR-B) with somewhat

different transcriptional activities.[346,347] Although our understanding of the differential distributions of these PR subtypes remains incomplete, the two isoforms are expressed in the rat brain,[348] and the ratio of the two isoforms varies under different hormonal[349–352] and behavioral[353] conditions. Experiments using antisense oligonucleotides directed at the mRNA for each or both of the isoforms demonstrate differential regulation of particular genes by each isoform.[354]

Necessity of PRs for Progesterone Regulation of Female Sexual Behavior

The characterization of neural PRs suggested the hypothesis that PRs are essential for the facilitation of sexual behavior by progesterone.[355] This hypothesis predicted that sensitivity to progesterone is determined by the concentration of unoccupied PRs available in neurons involved in progesterone-facilitated sexual behavior, and response is dependent on an adequate concentration of activated PRs in those cells. An increased concentration of PRs (e.g., after estradiol priming) would be expected to increase the sensitivity of the neural substrate for progesterone, presumably by increasing the concentration of receptors that become activated in response to progesterone treatment. Likewise, a decreased concentration of unoccupied PRs would be expected to result in decreased sensitivity to progesterone. This PR hypothesis[356] was corroborated in later work on the regulation of PRs that will be discussed. A central mechanism involving neuroprogestin activation of PR, or ligand-independent activation of PR, has not been determined.

Upregulation of PRs

As discussed, estradiol increases the concentration of PRs in the hypothalamus, mPOA, and a number of other brain regions (Figure 50.13). Coincident with the increase in the hypothalamus, behavioral responsiveness to progesterone increases. The increased concentration of PRs and behavioral responsiveness to progesterone are both transient.[358,359] In gonadally intact, estrus-cycling rats, the concentration of unoccupied PRs in the hypothalamus increases during proestrus in response to estradiol.[244] Collectively, these experiments suggested that PRs are a critical aspect of the cellular mechanism by which progesterone facilitates sexual behavior.

The duration of sexual receptivity for each species is tightly regulated, lasting about 8 h in guinea pigs[360] and about 14 h in rats.[361] The timing of the *duration* of sexual receptivity is referable at least in part to the regulation of activated PRs in particular neurons.[356] The presence of activated PRs in particular neurons presumably leads to the expression of neuropeptides and neurotransmitters described below, but the presence of the activated

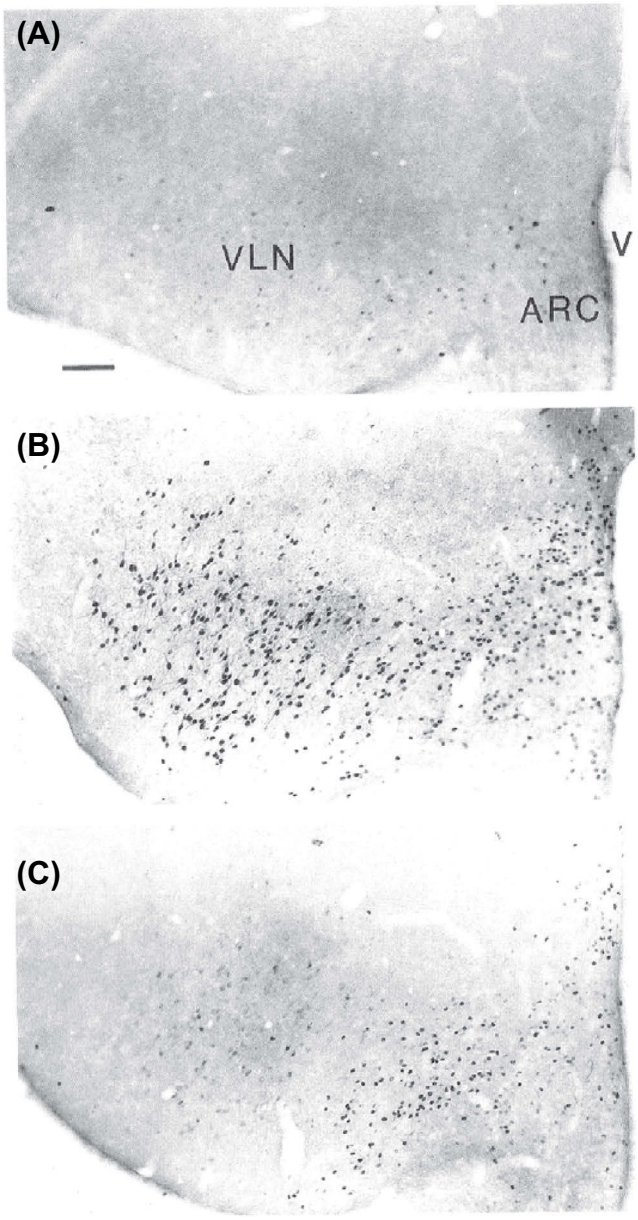

FIGURE 50.13 PR-immunoreactivity in the rostral aspect of the ventrolateral nucleus of the hypothalamus (VLN) and arcuate nucleus (ARC) of OVX guinea pigs injected with: (A) oil (0 h) and oil (42 h), perfused 24 h later, (B) estradiol benzoate (0 h) and oil vehicle (42 h), perfused 24 h later, or (C) estradiol benzoate (0 h) and progesterone, perfused 24 h later. Magnification bar = 100 μm. *Source: Reprinted from Blaustein and Turcotte,[357] with permission of Wiley.*

PR may act to gate the transcriptional activity of the relevant downstream genes. Progesterone injected in estrogen-primed, OVX guinea pigs and rats[244,362,363] or the preovulatory progesterone secreted during the estrous cycle[363] binds to and activates neural PRs. The presence of activated PRs in a pooled sample of the hypothalamus-preoptic area after progesterone injection correlates well with the ability of female rats to display lordosis.[362] Manipulations which prolong the period that

hypothalamic PRs remain occupied extend the duration of that period in female rats.[364,365] This temporal agreement between activated/occupied PRs and expression of lordosis suggests that it is maintained by elevated levels of occupied PRs, and that termination of lordosis is due at least in part to loss of these receptors.

Besides these correlational studies, a variety of techniques—injection of progestin antagonists, antisense oligonucleotides to PR mRNA and PR knockout (PRKO) strains of mice—has been used to demonstrate that PRs are *essential* for the facilitation of lordosis by progesterone. Systemic injection[366,367] or intracranial application[368] of a progestin antagonist inhibits the facilitation of lordosis by progesterone in rats and guinea pigs. However, because most antagonists are not completely specific, other techniques have been used to test the necessity of PRs for progesterone function in sexual behavior. Infusion of antisense oligonucleotides to PR mRNA, which inhibits PR synthesis, into the cerebral ventricles[369] or VMH[370,371] blocks facilitation of both appetitive sexual behaviors and lordosis by progesterone. Similarly a transgenic mouse strain with a targeted disruption of the PR gene (PRKO)[372] are completely unresponsive to progesterone for the facilitation of sexual behavior.[373] Using PR isoform-specific KO strains of mice to determine the relative contribution of each PR isoform to progesterone-facilitated female sexual behavior, Mani et al.[374] observed that progesterone-facilitated lordosis was completely eliminated in the PR-A null mutant mouse, and PR-B null mutant mice showed a trend of suppression of progesterone-facilitated sexual behavior. Although the specific function of PR-B is unclear, the data collectively suggest that PR-A is essential for progesterone-facilitated lordosis, and both isoforms are required for optimal facilitation by progesterone.

The question of which ER is involved in up-regulation of PRs has received some attention. The ERα selective agonist, PPT, induces PR mRNA, at least in the VMH and ArcN.[375] Although PR-ir induction in the brain by estradiol is dramatically reduced in ERαKO mice, KO of ERβ does not fully eliminate PR-ir induction.[281,376] Furthermore, genetic downregulation of ERβ (albeit in the incomplete ERβb KO mouse) was without effect on PR-immunoreactivity in the VMH. In subsequent work, in which it was confirmed that the ERα agonist, PPT, induces PR-ir in the VMH, it was also determined that the ERβ agonist, DPN does not. However, the sequential injection of an ERβ agonist after an ERα agonist induces PR immunoreactivity in more cells in the VMH than the ERα agonist alone.[377] Based on experiments using BSA-conjugates of estradiol, it has been suggested that membrane ERs are also involved in the induction of PRs in the VMH.[378] Collectively, these experiments point to a critical role for ERα, a possible role for a membrane ER, and a minor role for ERβ in the induction of PR immunoreactivity, at least in the VMH.

Membrane PRs and Nonclassic Mechanisms of P Action

The mechanism of action of progesterone is not as simple as activation of just PR-A and PR-B. Although the classic mechanism of hormone action plays an important role in the regulation of sexual behavior, membrane mechanisms are also involved.[379] Progesterone can also influence electrophysiology and facilitate sexual behavior within seconds and minutes, respectively. Some of these effects may be referable to activation of cell surface PRs, ion channels and cytoplasmic second messenger signaling cascades, and are independent of gene transcription.[380] Recently, membrane proteins unrelated to classic PRs have been characterized. The presence of membrane PRs (mPRs) and progesterone receptor membrane component 1 (PGRMC1) and PGRMC2 in the brain[342,381–384] provides a possible mechanism by which progesterone could have rapid effects on behavior and neurophysiology. mPRs are G-protein coupled receptor members of the seven trans-membrane adiponectin Q receptor family, and come in at least three subtypes.[385] In addition, PGRMC1 (also called 25Dx) is regulated by estradiol and progesterone in the VMH of female rats.[343,381] Although the direction of the regulation is not consistent between the two reports,[343,381] the hormonal treatments and methods used were quite different, which may explain the discrepancy.

PGRMC1, PGRMC2 and classic PR mRNAs are expressed at high levels and have a good deal of overlap in the mPOA and other hypothalamic nuclei and their projection sites.[342] Under some conditions, progesterone treatment results in an increase in PGRMC1 mRNA levels in the VMH and preoptic area.[343] Likewise, mPRα and mPRβ are present within the hypothalamus and preoptic areas, among other areas, and estradiol increases the expression of mPRβ[384] and the estrous cycle influences the expression of mPRα and mPRβ expression in some brain areas.[383] Although the functional role of each of these putative membrane receptors in hormonal regulation of sexual behavior remains to be determined, their presence in the brain suggests additional mechanisms by which progesterone could rapidly influence sexual behavior and possible interactions of mPRs and classic PRs within the same neurons.

Cross-Talk between Neurotransmitters and Steroid Hormone Receptors

Neurotransmitters Influence Concentrations of ERs and PRs

One of the most interesting aspects of the regulation of female sexual behavior is the interplay between external factors and the internal hormonal *milieu*. Because of the critical role of steroid hormone receptors in the

mechanisms of action of steroid hormones on female sexual behavior, studies of integration between afferent information and steroid-hormone sensitive systems have focused on the regulation of these receptors. The finding that catecholaminergic activity influences the concentrations of neural sex steroid receptors in rat and guinea pig brain[386] suggested that stimuli from the environment might regulate the concentration of steroid receptors in neurons involved in female sexual behavior, and consequently, behavioral response to hormones.

Drugs which either inhibit norepinephrine synthesis (dopamine-β-hydroxylase (DBH) inhibitors) or which block noradrenergic receptors (e.g., α-adrenergic antagonists) typically decrease the concentration of ERs in some neural areas[387,388] and/or inhibit induction of hypothalamic PRs by estradiol,[389–391] and α-adrenergic agonists reverse this suppression. Noradrenergic antagonists also decrease female sexual behavior in guinea pigs.[392] This, together with the finding that injection of an α_1-noradrenergic antagonist, which decreases ER concentrations in the hypothalamus, also decreases female sexual behavior,[393] suggests behavioral relevance of the neurotransmitter regulation of ERs. Finally, under some conditions, stimulation of DA receptors increases the concentration of ERs in the brain.[394,395]

A possible anatomical substrate for the integration between catecholaminergic neurons and steroid hormone-responsive neurons can be found in the catecholaminergic innervation of some ER-containing neurons,[396,397] and immunoreactivity for tyrosine hydroxylase and DBH, the enzyme that converts DA into norepinephrine (NE), varicosities are sometimes found closely associated with PR- or ER-immunoreactive neurons in the mPOA and hypothalamus.[398–400] The fact that those ER-immunoreactive cells with closely associated DBH-immunoreactive varicosities stain more darkly for ERs than other ER-immunoreactive neurons lacking this association suggests that noradrenergic input regulates the level of ERs in a population of these ER-immunoreactive cells,[400] and consequently, behavioral responsiveness to estradiol. It should be noted that neurotransmitter regulation of steroid receptor levels is not limited to the catecholamines. For example, muscarinic agonists and antagonists regulate the levels of neural ERs.[401]

Defined anatomical connections may influence steroid receptor levels and therefore, presumably, sensitivity to steroid hormones for their influence on sexual behavior. For example, anterior roof deafferentation using knife-cuts in female rats increases the behavioral response to estradiol, presumably referable to the resulting increase in the concentration of ERs in the mediobasal hypothalamus.[402] Conversely, olfactory bulb removal results in an increase in the concentration of ERs in the MEA in female rats, presumably related to the mechanism by which olfactory bulbectomy increases sexual behavioral response to estradiol.[403]

Input from the social environment also regulates steroid hormone receptors and hormonal response, presumably via neuronal pathways. The odor of male prairie voles induces estrous behavior in female prairie voles,[404] presumably in part due to the accompanying increase in the concentration of ERs in the mPOA.[405] Level of maternal care of pups induces long-term changes in the concentration of ERα in particular brain areas,[406] due to epigenetic changes (see Chapter 52) in the ERα gene promoter.[407] Likewise OT, injected systemically during the neonatal period, induces stable changes in the levels of ERα in prairie voles.[408,409] Therefore, regulation of steroid receptors by environmental stimuli working through neurotransmitters is another level of regulation of steroid hormone response in subsets of relevant neurons.

Ligand-Independent Activation of PRs

Steroid hormone receptors, such as ERs and PRs in addition to being activated by binding of their cognate ligand, steroid hormone receptors can be activated by a variety of intracellular signaling pathways.[410,411] Power et al.[412] first demonstrated in vitro that DA agonists also can activate PRs in vitro, which led to studies on alternate pathways to PR activation besides binding of progesterone, including pathways leading to the facilitation of sexual behavior in the absence of progesterone.

Intracerebroventricular infusion of D1 DA agonists substitute for progesterone in the facilitation of sexual behavior in estradiol-primed rats.[413] This facilitation by DA agonists is blocked by infusion of progesterone antagonists,[413] or antisense oligonucleotides directed at the PR mRNA,[369] or in PRKO mice,[373] providing strong evidence that DA facilitates the expression of sexual behavior by indirectly activating PRs in the brain in vivo.

Progesterone and DA both initiate second messenger signaling cascades involving increases in 3′-5′-cyclic adenosine mono phosphate (cAMP) levels, activation of PKA and phosphorylation of the neuronal phosphoprotein, DA and cAMP regulated phosphoprotein-32 (DARPP-32)[414,415] (Figure 50.14). These in turn result in alterations in phosphorylation of other proteins and activation of PRs and/or its coregulators in the hypothalamus. DARPP-32 KO mice express a decreased level of female sexual behavior in response to either progesterone or DA. This suggests that DARPP-32 is involved in ligand-independent activation of sexual behavior via PRs.[414] These results demonstrate the obligatory role that activation of DARPP-32 plays in the regulation of sexual receptivity by PRs, regardless of the route of activation of the receptors.

The mechanism of ligand-independent activation of steroid receptors by neurotransmitters and second messenger pathways provides a possible means by which afferent input from the male facilitates the expression

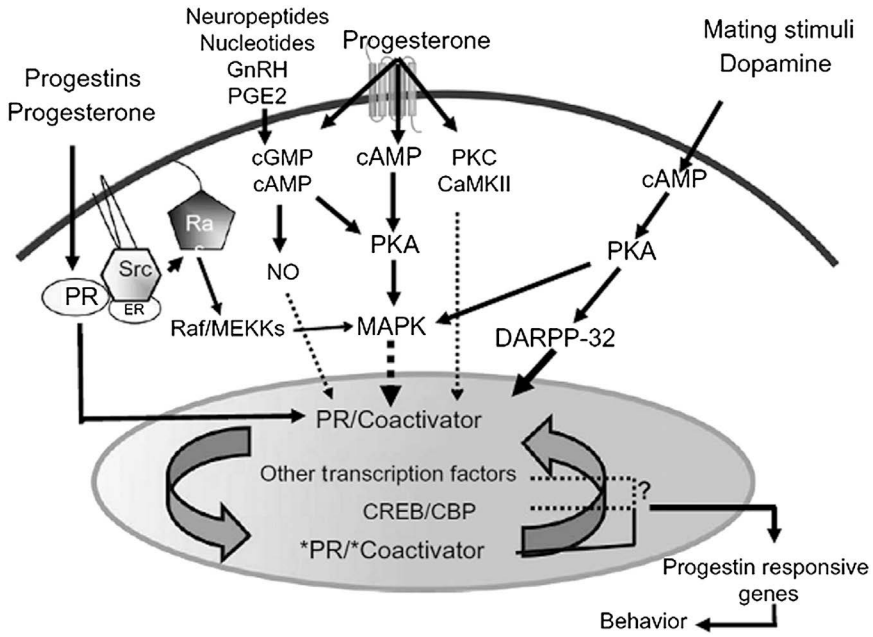

FIGURE 50.14 Cross-talk between progesterone and a variety of second messenger pathways converging on the PR leading to increases in female sexual behaviors. This schematic representation depicts a variety of interacting mechanisms. (1) Progesterone acts via a classic genomic mechanism of action mediated by classic (primarily) nuclear PRs. The ligands bind to their cognate receptors and activate PRs promoting interactions with coactivators; (2) Progesterone acts via second messengers (cAMP, cGMP) and signaling kinases (PKA, PKC, CaMKII), which then activate the MAPK signal transduction cascade, leading to phosphorylation of PRs and coactivators (CREB and/or its associated protein CBP shown here, as well as others); (3) Progesterone and progestins act via the Src kinase pathway to activate the MAPK cascade leading to activation of PR and coactivators. (4) Progesterone acts via the PKA/MAPK/DARPP-32 pathway to induce an increase in phosphorylation of PRs and/or its coactivators. (5) Mating stimuli and D1 agonists may stimulate PKA activation, which then phosphorylates DARPP-32 or MAPK leading to the activation of PR and/or its coactivators. (6) Neuropeptides, nucleotides, prostaglandin E2, and other molecules may act through various receptor- and/or second messenger pathways (cAMP, cGMP, NO) to activate nuclear PRs or other transcription factors. *PR/*Coactivator signifies activated progestin receptor and coactivators. Dashed lines indicate hypothesized, but as yet unproven, direct interactions. *Source: Reprinted from Mani and Portillo,[415] with permission of Elsevier.*

of sexual receptivity in the absence of progesterone. First some background information is necessary. When estradiol-injected, OVX or OVX/ADX rats are exposed intermittently to sexually active males, their level of sexual receptivity increases over the first few hours,[179–181,416–419] even if the ovaries and adrenal glands are both removed, presumably removing all sources of peripheral progesterone.[418] Progestin antagonists block mating-enhancement,[418] suggesting that the cellular mechanism by which the male's mating attempts facilitates sexual behavior is via ligand-independent activation of PRs.[418] It should also be noted that mating-related stimulation results in phosphorylation of DARPP-32 in areas associated with reproduction and reproductive behavior (mPOA, VMH, posterodorsal MEA, and BNST),[420] and a D1 DA antagonist eliminates Fos expression in response to mating-related stimulation in all areas investigated.[421] Although the evidence supports ligand-independent activation of PRs as the mechanism for mating-enhancement of sexual behavior, the possibility that neuroprogesterone is involved cannot be excluded at this time.[422]

Because sexual stimulation induces DA release,[423–426] immediate early gene response (Fos) in PR-containing neurons,[427] and DARPP-32 phosphorylation in relevant areas,[420] it is likely that mating-induced DA activates PRs via ligand-independent activation mechanism. The PR-dependent, ligand-independent relationship is involved in the mechanism by which a variety of compounds that substitute for progesterone facilitates sexual behavior. GnRH,[428] delta opioid receptors,[429] α_1-adrenergic receptors,[430] nitric oxide (NO),[431] MAP kinase,[429] PKA,[432] cAMP,[428] and cGMP[433] as well as prostaglandin E2[428] and epidermal growth factor[434] each facilitate sexual receptivity in estradiol-primed rats by a process that involves activation of PRs. Likewise, ligand-independent activation of PRs may be involved in the mechanism by which methamphetamine enhances the effects of ovarian hormones on female sexual behavior.[435] Thus, many of the numerous signaling pathways that induce female sexual behavior in estradiol-primed rats converge on ligand-independent activation of PRs.

Ring-A reduced metabolites of progesterone, 5α-dihydroprogesterone and allopregnanolone, as well as 5β-reduced progestins, in addition to GnRH, and prostaglandin E2, facilitate lordosis in OVX, estradiol-primed female rats.[436–440] Because these progestins and

hormones have relatively low or no affinity for PRs, it is unlikely that they facilitate lordosis by binding directly to PRs. However, facilitation of sexual behavior by these compounds is inhibited by a progestin antagonist, suggesting involvement of ligand-independent activation of PRs in the process by which they facilitate sexual behavior.[432,437,441] Further, it has been suggested that via ligand-independent activation of PRs, they, like progesterone,[442] then activate the Src/Raf/MAPK signaling pathway resulting in lordosis.[440] Therefore, even some progestins may facilitate the expression of sexual receptivity by ligand independent activation of PRs after which they converge on a signaling pathway in common with a pathway involved in facilitation by progesterone.

As mentioned earlier, progesterone facilitation of sexual behavior is dependent on the PR-A isoform. In contrast, ligand-independent activation of sexual behavior by a D1 DA agonist is reduced, but not eliminated in either PR-A or PR-B KO strains of mice.[374] Therefore ligand independent activation of sexual behavior is dependent on both isoforms. Sexual behavior facilitated by the PKA activator, 8-bromo-cAMP, is eliminated in PR-A KO mice. Therefore, each isoform is involved in the facilitation of sexual behavior, but the importance of each isoform may depend on the mode of activation. Although PR-A seems to have the primary role in most situations, PR-B has a larger role in ligand-independent activation of sexual behavior.

The fact that many neurotransmitters can both influence steroid receptor levels and activate steroid receptors raises questions in the interpretation of many pharmacological studies. Pharmacological experiments performed with the assumption that the drugs are stimulating or antagonizing output of steroid hormone-sensitive neurons. However, it is likely that some of the drugs are influencing steroid receptor-containing neurons, either activating steroid hormone receptors directly or regulating the concentration of receptors.

Ultrastructural Changes Induced by Estradiol and Progesterone

Hormonal Regulation of VMH Structure

The VMH is well established as a key site in the control of female sexual behavior by ovarian steroid hormones, as it has been extensively studied in rats, as discussed above. It should be noted that the borders of the VMH as defined by Nissl stain may not perfectly match the distribution of typical VMH markers, such as ERs, in some species. Nevertheless, the term "VMH" is useful as referring to a brain region with functional similarities across vertebrates, even if its borders and connectivity differ somewhat in various species.

Hormone-induced changes in VMH structure must be understood within the context of the VMH local circuit, which comprises several cell types. Unfortunately, phenotypic markers for these cell types are only partially defined (Table 50.2), and the direction of information flow between these cell types is not yet known. One cell type expresses nuclear ERα and estradiol-induced PR. Given that many studies have used nuclear labeling to identify the ERα-expressing cells, it remains unclear whether these same neurons also mediate the membrane-based effects of estradiol discussed above. Given that these neurons express OT receptors, their long dendrites manifest an estradiol-induced increase in synapses, as discussed below.

A second cell type, are neurons with axonal connections to the periaqueductal gray,[443,444] a critical relay in the control of the lordosis reflex. A small subset of PAG-projecting neurons expresses steroid receptors (15–25%). These neurons have a more elaborate dendritic tree, and estradiol treatment reduces spines on the long dendrites of these neurons.

A third cell type within the VMH is defined in part by the lack of ERα and axonal projections to the midbrain, and the presence of mating-induced Fos expression[427,444,445] These neurons exhibit a robust estradiol-induced increase in dendritic spines. In summary, the VMH microcircuit includes at least three cell types that exhibit differential patterns of neural plasticity after estradiol treatment.

Recent insights into the ovarian hormone-induced remodeling of neural circuits within the VMH in adult female rats provide insights into the neurological control of this behavior. It is worth noting that estradiol-induced synaptic changes have been observed in a number of

TABLE 50.2 Phenotypic Markers of Three Types of Neurons in the VMH Local Circuit

Cell Type	Features
ER/PR expressing neurons	Glutamatergic Co-express enkephalin Dendrite arbor not known Weakly activated by mating Express oxytocin receptors Estradiol increases synapses on LPDs
PAG projecting	Transmitter not known Five to six dendrites Weakly activated by mating Estradiol reduces LPD spines (length)
"Unidentified" (lack ER/PR and no projections to the PAG)	Transmitter not known Three dendrites Activated by mating Estradiol increases spines on short dendrites Estradiol reduces LPD length

other brain systems that are not directly tied to sexual behavior. These include the hippocampus[446] and the PFC.[447] Thus, it seems that estradiol's effect on synaptic organization in the VMH represents a typical mode of action for this hormone.

Estradiol has global structural effects on neurons in the VMH. Hours after OVX animals are treated with estradiol the size of neuronal cell bodies is increased, based in part on the hypertrophy of the nucleus, rough endoplasmic reticulum, and Golgi apparatus.[448] In addition, estradiol changes several parameters within the dendritic arbor (Figure 50.15). The size and shape of a dendritic tree are indicative of its ability to sample and weight afferent inputs. Neurons in the VMH exhibit

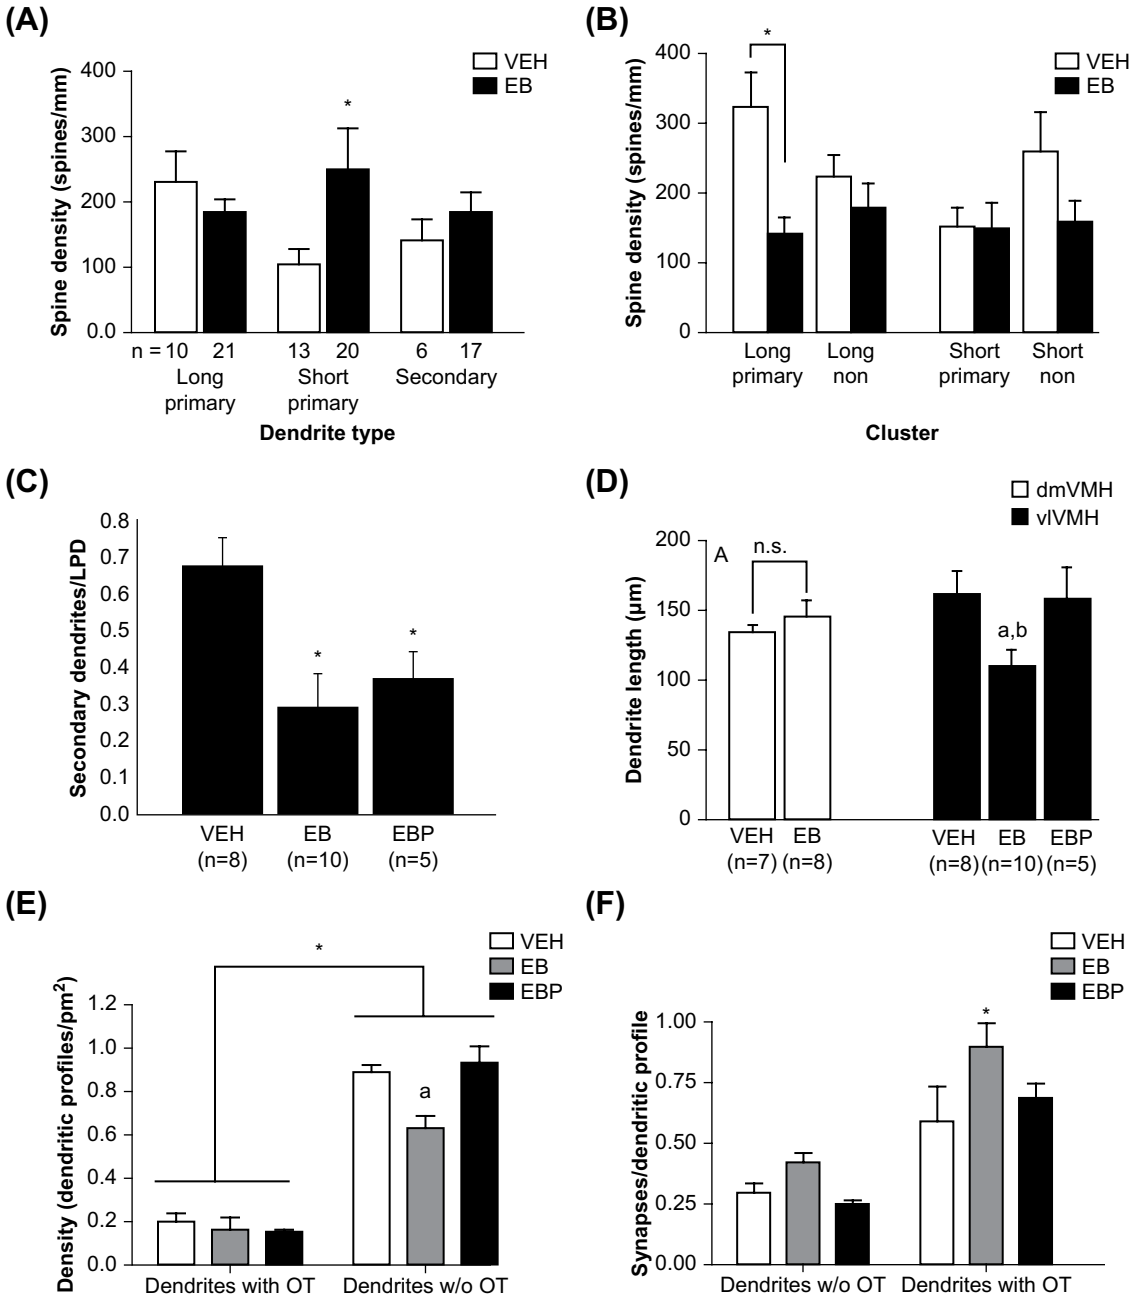

FIGURE 50.15 Complex effects of vehicle (VEH), estradiol (EB), or EB and progesterone (EBP) on the dendritic arbor of VMH neurons. Golgi impregnation and electron microscopy studies show that estradiol increases spines on short primary dendrites (Panel A); reduces dendritic spines on long primary dendrites of projection neurons (Panel B); decreases branches on long primary dendrites (LPD) (Panel C); retracts long primary dendrites (Panel D); selectively removes oxytocin (OT)-negative dendrites from the lateral fiber plexus (Panel E); and increases innervation on oxytocin-positive dendrites in lateral fiber complex (Panel F). *(Source: Adapted from Calizo and Flanagan-Cato,[443] Calizo and Flanagan-Cato,[449] Griffin and Flanagan-Cato,[450] and Griffin et al.[451])* vlVMH, ventrolateral VMH; dlVMH, dorsolateral VMH.

simple dendritic arbors, usually with three or four dendrites. Based on studies using various techniques to quantify neuronal morphology in intact estrous cycling rats and OVX females given ovarian hormone replacement, the number of dendritic spines correlates with hormonal states that increase reproductive behavior.[449,452–454] Thus, estradiol treatment increases local excitatory input onto VMH dendrites (Figure 50.16).

At the same time, long dendrites retract from the lateral afferent zone, a process that is reversed with subsequent progesterone treatment. This regulation of VMH dendrite length was first observed with Golgi analysis[450] and subsequently confirmed with electron microscopy analysis.[451] Ultrastructural evidence suggests that non-OT receptor-bearing dendrites retract, allowing for the transfer of afferent inputs to the OT-bearing dendrites.[455] Thus, estradiol treatment appears to simultaneously heighten local excitatory input and direct extranuclear afferent input to the OT-sensitive neurons, suggesting a substantial hormone-dependent shift in the computational activities of VMH neurons and their outputs that control sexual behavior (Figure 50.16, bottom).

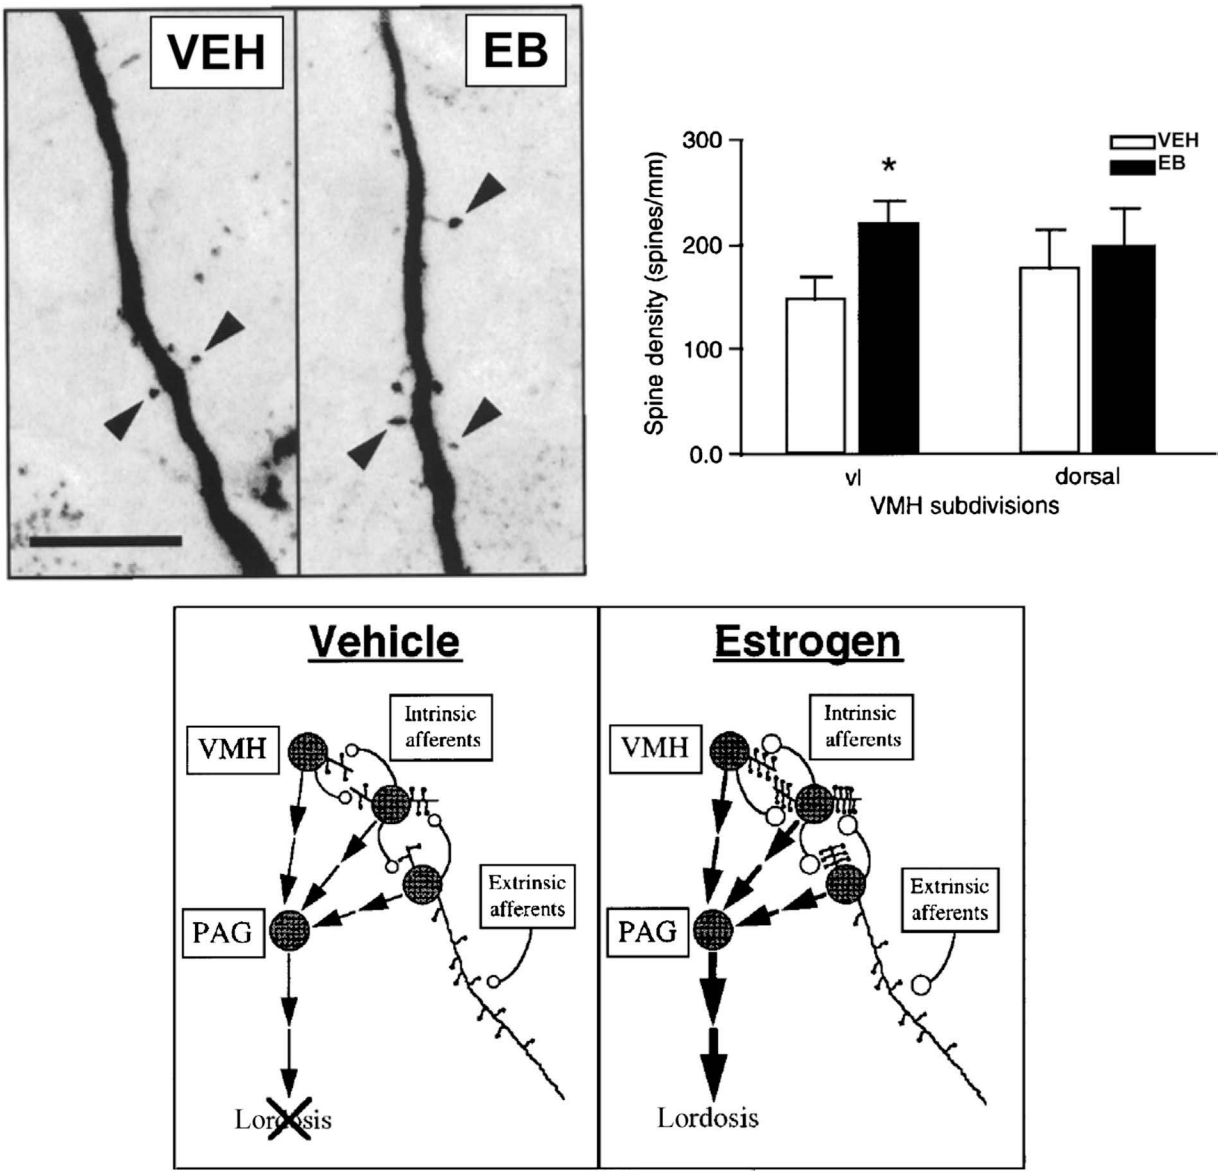

FIGURE 50.16 Top left: Confocal projections of representative female rat VMH dendrites illustrating the effect of estradiol treatment to increase the number of spines. Arrows indicate the locations of representative spines. Scale bar = 10 μm. Abbreviations: VEH, vehicle; EB, estradiol benzoate. Top right: Mean spine densities from vehicle- and EB-treated rats in the ventrolateral (vl) and dorsal regions of the VMH. *$p < 0.05$. Bottom: Model of possible mechanisms of spine induction by estrogen on short primary dendrites in the VMHvl. The output of the increased action of intrinsic afferents would be to increase the activation of the periaqueductal gray (PAG) to reach a critical threshold for lordosis to occur. *Source: Reprinted from Calizo and Flanagan-Cato,[449] with permission from the Society for Neuroscience.*

An important projection from the VMH terminates in the ventrolateral PAG,[456] a critical relay in the motor control of lordosis behavior. Estradiol treatment induced remodeling of synaptic organization in this region as well.[457] In particular, estradiol treatment increases the number of synapses and the number of dense-core vesicles per synapse. As mentioned above, ERα is abundant in the PAG. To date, little is known about hormone-induced plasticity in the medullary reticular formation or spinal motor neurons, although in the cat estradiol increases the innervation of the nucleus retroambiguus to the lumbar spinal cord.[458] It would not be surprising if dendrite structure in the lumbar ventral horn were also changed. Thus, ovarian hormones may promote lordosis by modifying the connections between several nodes in the descending lordosis pathway.

The relevance of synaptic reorganization of the VMH in human sexual behavior has been not been studied due to obvious technical and ethical limitations. However, hormone-induced regulation of VMH dendrite length has been documented in other rodents, namely hamsters[459] and prairie voles,[460] which indicates that it is not a phenomenon unique to rats. Studies in nonhuman primates would be helpful to assess the possible relevance to sexual behavior in women. The synaptic reorganization that has been observed with structural studies is associated with altered activity of VMH neurons (discussed below).

Genitosensory Stimulation Activates Cells with Steroid Hormone Receptors

Many of the cells that respond to mating-related stimulation also contain ERα-ir[444,445] and/or PR-ir[427] suggesting that they are part of the neuronal substrate for integration of hormonal signals with afferent input from the social environment. Mating- or VCS-induced Fos is extensively coexpressed with ERα-ir in the mPOA, bed nucleus of stria terminalis, posterodorsal MEA, midbrain central gray[445] and VMH.[444,445]

Although other areas were not investigated, extensive coexpression of Fos with PR-ir is seen in the mPOA, parts of the VMH, and the ArcN.[427,461] Within the VMH (primarily rostral), mating induces Fos-ir in a number of PR-ir cells that project to the midbrain central gray[462] consistent with a role for these neurons in female sexual behavior. The fact that they are responsive to mating stimulation and express PRs suggests that they may be a substrate for interaction between mating stimulation and PRs.

In some, but not all cells, VCS-induced Fos expression in estradiol-primed, OVX rats requires PRs, suggesting that ligand-independent activation of PRs is an obligatory step in the activation of the c-fos gene.[418,461] Although progestin antagonists block VCS-induced Fos expression in the mPOA, medial bed nucleus of stria terminalis, and caudal VMH, they were without effect in other areas studied, including the MEA, dorsomedial hypothalamus and PVN. Interestingly, a progestin antagonist blocks VCS-induced Fos expression in the rostral, but not caudal, mPOA.[461] Collectively, the data support the interpretation that in cells expressing PRs, VCS induction of Fos expression requires functional PRs; that is to say, neuronal response to particular stimuli seems to be gated by PRs. The mechanism is likely to be ligand independent activation of those PRs by the afferent input. Although olfactory stimuli are of great importance to reproduction and sexual behavior, unlike VCS-induced Fos expression[427] the neurons in which exposure to bedding soiled by male rats induces Fos expression do not contain PR-ir.[463]

In a study of responses of ERα and ERβ cells to mounts with and without intromission, Gréco et al.[464] reported that either mounts alone or mounts with intromissions induced Fos in ERα-ir cells within the rostral mPOA. However, Fos expression in ERα/ERβ coexpressing cells was induced only by mounts with intromission. The pattern in the amygdala was different. In the dorsal posterodorsal MEA, only mounts that included intromission induced Fos expression, and it did so only in ERα or in ERα/ERβ coexpressing cells, not in cells expressing only ERβ. In the ventral posterodorsal MEA, only mounts with intromission induced Fos expression, but the response was restricted to ERβ cells, but not cells expressing ERα. Although work in ERKO mice suggests primary involvement of ERα in female sexual behavior, these results suggest roles for both forms of ERs in integration of hormonal information and information relating to specific types of sexual or genital stimulation.

ARs and Aromatase

Androgens, principally testosterone and 5α-DHT, exert their effects by activating a specific AR. Thus far, a single subtype of AR has been described, a classic member of the steroid receptor superfamily, a hormone-activated transcription factor, with the canonical functional domains of proteins in this superfamily. Thus, upon ligand binding, AR undergoes phosphorylation, homodimerizes, interacts with DNA, and binds to androgen response elements. Transcriptional machinery and cofactors are then recruited to the site to promote or repress gene expression. In addition to this standard genomic mechanism, AR is found in dendrites and axons, suggesting short-term effects on neurotransmission.[465,466] Some brain regions respond to testosterone by converting it to estradiol, via the enzyme aromatase, also known as cytochrome P450 enzyme. Aromatase is found in the smooth endoplasmic reticulum of some populations of neurons. Thus, aromatase activity would direct

circulating testosterone to act via ERs rather than AR. Therefore, the expression of both AR and aromatase will be considered for a full view of testosterone action in the female brain.

Multiple techniques and animal models have helped describe the distribution of ARs in the vertebrate brain, including rats, mice, hamsters, and nonhuman primates; however, there is surprisingly limited information focused on adult female mammals. Available evidence suggests that females and males have similar neuroanatomical distributions of AR, with somewhat different levels in females. Table 50.3 includes a listing of the brain regions with the highest levels of ARs, based on these studies.

The first studies delineating the anatomical distribution of testosterone binding used steroid receptor autoradiography with 3H-testosterone injected systemically. Abundant testosterone binding was reported in the preoptic area, amygdala, and especially the VMH, in female rats[467,468] and female rhesus monkeys.[469] The molecular cloning of AR led to the development of antibodies that could be used in immunocytochemical procedures, although initial reagents were plagued with conflicting results. The messenger RNA for AR has been mapped with in situ hybridization techniques,[269] and these results nicely complement the distribution described with autoradiography. Studies in juvenile females indicate that AR mRNA is abundant in several brain regions associated with female reproductive behavior, including the lateral septum, BNST, mPOA, and VMH.[470] Although it has not been studied extensively, it appears that in some brain regions that co-express AR and ER, many neurons express AR only, but most neurons that express ER co-express AR.[471]

As with AR, most studies on aromatase in the brain have focused on developing males rather than adult females, but some basic information exists. Aromatase has been documented with in vitro enzyme activity assays of discrete brain regions, including the BNST, mPOA, MEA, and VMH.[472] This analysis also compared the levels of aromatase and AR in adult females. A striking finding was that AR binding activity is highest in the VMH, where aromatase activity is the lowest. The relatively low level of aromatase activity in the VMH is reflected in relatively low levels of aromatase messenger RNA.[473] This finding suggests that in the VMH testosterone may be more likely to act through the AR than the ER in females. Ovarian hormones do not regulate aromatase activity in female rat brains.[474] Overall, transcripts for aromatase are found in the BNST, the mPOA, the MEA, and the VMH in females.[475]

In summary, ARs are expressed in the female brain, including in brain regions that promote female sexual behavior. Although some brain regions may convert testosterone to estradiol, androgen-specific actions that affect female sexual behavior seem likely, especially in the VMH. Although not well studied yet, it is possible that 5-alpha reductase is also expressed in the VMH in female mammals, as it is in green anole lizards.[476] This enzyme converts testosterone to the more potent androgen, DHT. If so, females would have the potential to compensate for their relatively low circulating levels of testosterone by locally enhancing androgen action. Although there is little information about the role of androgens in female sexual behavior, ARs appear to be poised to contribute.

Hormone Replacement Therapy in Women

A decline in sexual arousal, desire, and/or activity occurs following surgical and natural menopause. Surgically menopausal women, induced by bilateral oophorectomy with or without hysterectomy experience a sudden and drastic decline in sexual desire and arousal.[126–129] Significant improvement in desire and arousal occur following adequate hormone replacement regimens,

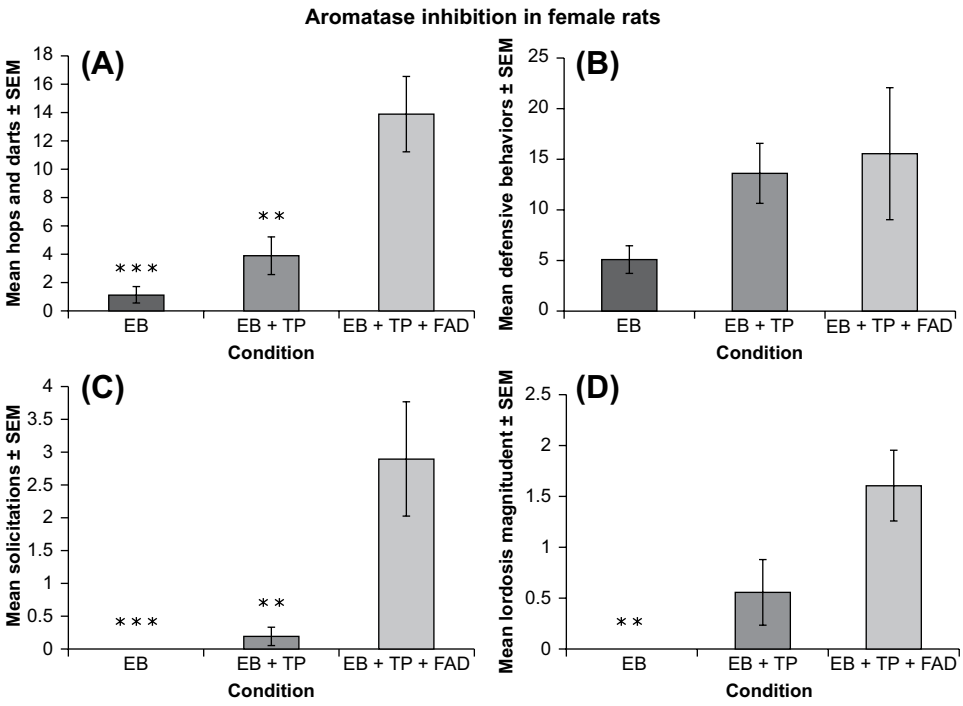

FIGURE 50.17 Hops and darts (A), solicitations (C), defensive responses (B), and lordosis reflex magnitudes (D) of OVX rats primed with estradiol benzoate (EB) alone, EB + testosterone propionate (TP), or the combination of EB + TP along with the aromatase inhibitor fadrazole to block conversion of testosterone to estradiol, thus augmenting the effect of the exogenously-administered TP on behavior. *(Source: From Rosenbaum, Jones, and Pfaus.[478])* $^{**}p < 0.05$, $^{***}p < 0.01$, from the EB + TP + FAD-treated rats.

particularly replacement with exogenous estrogens in combination with testosterone[126,127,131,133,135–139] relative to estrogen treatments alone. Although co-administration of estrogens and progestins (notably medroxyprogesterone acetate) also increased sexual arousal and desire, this formulation increased overall risk for secondary disease factors in the Women's Health Initiative randomized trials.[477]

An unresolved question is how co-therapy with estrogens and androgens works and why it offers greater therapeutic value over estrogen replacement alone. There are at least three possible scenarios. The first is that the induction of SHBGs by exogenous estrogens would likely decrease free estrogen concentrations, thereby limiting their ameliorative action in the brain and periphery. The addition of androgens like testosterone to this would compensate by binding to SHBGs with higher affinity, thus allowing more free estrogens to get to target tissues. The second possibility is that testosterone induces actions on its own through binding to ARs in the brain and periphery. Indeed, a significant proportion of untreated postmenopausal women reported increases in sexual desire and activity following double-blind administration of testosterone for 6 months through a transdermal patch that released approximately 300 μg/day of testostereone.[137] This treatment increased free testosterone to within normal physiological premenopausal levels without any concomitant increases in plasma estradiol or SHBG levels. Placebo control conditions did not induce this increase. These data suggest that testosterone alone is able to reverse the decline in sexual arousal and behavior in postmenopausal women. However, the presence of aromatase in the brain could convert exogenous testosterone into estradiol locally in different hypothalamic or midbrain regions, despite no increases in plasma estrogens. Long-term OVX rats treated systemically with the aromatase inhibitor fadrozole and given hormone replacement with the combination of estradiol and testosterone displayed significantly greater numbers of appetitive solicitations and lordosis responses compared to females given the combination of estradiol and testosterone alone (Figure 50.17). Females treated with estradiol alone displayed low numbers of solicitations and lordosis responses.[478] Thus, blocking the aromatization of testosterone into estradiol induces a greater facilitation by testosterone of both appetitive and consummatory aspects of female sexual behavior relative to estradiol alone or the combination of estradiol and testosterone. This suggests strongly that testosterone acting at ARs facilitates female sexual behavior. The final possibility of course is that both testosterone and estradiol exert distinct actions on ARs and ERs, respectively, that combine to facilitate sexual desire and behavior.

NEURAL ORGANIZATION

As mentioned above, sexual behavior has a beginning, middle, and end, each of which is controlled by different, but integrated, brain systems. The function of many of those systems is altered by steroid hormones, such that sexual incentive stimuli come to the foreground

of attention and action. These neural systems must be able to process rudimentary sensory components of sexual stimulation (e.g., olfactory, visual, somatosensory, auditory), and sum them into Gestalts or "wholes" that represent contextual and/or discrete unconditioned incentives (e.g., suitable receptive partners, partner odors, individual facial features, etc.) or unconditioned inhibitors (nonreceptive partners, predators, or parents, or competing incentives like food if hungry), and do the same for conditional incentives or inhibitors (e.g., neutral cues that become predictors of the unconditioned incentives, e.g., a favorite sex toy, odor or place cue associated with sexual reward, or inhibitors, e.g., same stimuli associated with thwarted sexual behavior or sexual nonreward). They must be able to compute competent responses to those cues so that sexual behavior is timed correctly and appropriate to the circumstances, and automate those responses so that they become more optimal with experience (e.g., faster initiation of solicitations in the presence of highly valued partner cues). At each level of analysis, there are excitatory and inhibitory neurochemical systems that regulate the intensity of the perceived incentive or inhibitory stimuli and that modulate the timing and intensity of the responses.[35] These are also modulated by steroid hormones and by feedback from positive and negative sexual experiences (see Section Consequences of Sexual Stimulation).

Excitation, Inhibition, and Disinhibition of Sexual Responses

The notion of separate, but interactive, neural systems for behavioral excitation and inhibition (Figure 50.18) goes back to the work of early neurophysiologists like Sechenov, Sherrington, and Pavlov, and more modern psychologists like Gray, who applied the idea to the study of fear and anxiety.[480] It has important implications for sexual behavior because it posits that behavior can commence either due to direct excitation or through a process of disinhibition. This concept was advanced further by Bancroft and Janssen[481] and Perelman,[479] who presented dual control models of human sexual response in which the net expression of sexual behavior is based on the influence of excitatory and inhibitory mechanisms in the brain and periphery, set around a "sexual tipping point". As in Gray's theory, this model stressed the adaptive nature of both excitatory and inhibitory processes. For example, the adaptive nature of sexual excitement would drive individuals to seek out sex partners for reproductive or reward purposes. The adaptive nature of sexual inhibition would guard against situations that threaten the individual, including chronically stressful life events. It would also be important to keep the optimal expression of behavior constrained to the "right time", as in the case of females that display sexual behavior only during a periovulatory period, when they are most likely to become pregnant. Bancroft and Janssen viewed the propensity for sexual excitement or inhibition as an individual tendency based on the genetic makeup and/or behavioral expectations of the individual: Those whose propensity for central inhibition of sexual response is too high have increased vulnerability to sexual dysfunction, whereas those whose inhibitory propensity is too low would be more likely to engage in hypersexual or high risk sexual behavior. Indeed, the study of sexual inhibition is also critical if we are to understand how certain events or drugs like alcohol, cocaine, or amphetamine, may induce sexual disinhibition and the propensity to engage in risky sexual behaviors.[482]

Excitation

We may view excitation from autonomic arousal and genitosensory/erogenous stimulation as a "bottom-up" phenomenon in which individual sensory modules come together at higher levels of processing. This occurs in the thalamus, but also in each domain of the hypothalamus, limbic, system, and cortex, that make up the excitatory sexual system of the brain.[35] At the hypothalamic level, genitosensory and olfactory information is integrated in both the mPOA and VMH, which have outputs to the PVN, SON, and ArcN of the hypothalamus. In turn, those regions control the release of OT, vasopressin both in brain and from the posterior pituitary, and the release of melanocortins (MCs), opioids, and corticotrophin releasing factor (CRF) from the anterior pituitary. The mPOA also sends lateral efferents to the VTA, which stimulate DA neurons and DA release in mesolimbic and mesocortical terminals, such as the NAc, ACC, lateral septum, corticomedial amygdala, and mPFC. Thus, the mPOA is well situated to "drive" the DA-mediated incentive motivational system in the presence of salient unconditional and conditional external sexual cues, and also to register and perhaps link those cues to genitosensory and autonomic input. In addition, noradrenergic inputs to the hypothalamus coming from the locus coeruleus are themselves stimulated by the reticular activating system, which is stimulated by general autonomic and somatic inputs from the spinal cord. For females, sensitivity to sexual arousal is enhanced during ovulation, and thus excitatory systems in the CNS appear to require steroid hormone priming.

Estradiol regulates a variety of neurotransmitter and second messenger systems in brain areas involved in sexual behavior.[483,484] Estradiol priming induces the synthesis of α_{1B}-adrenergic receptors in the VMH[485,486] and augments the release of DA in the striatum, NAc, and mPOA during copulation.[90,425,487,488] Extracellular DOPAC (3,4-dihydroxyphenylacetic acid), a DA metabolite, increases in the mPOA in the afternoon to the early evening of proestrus, around the time that sexual

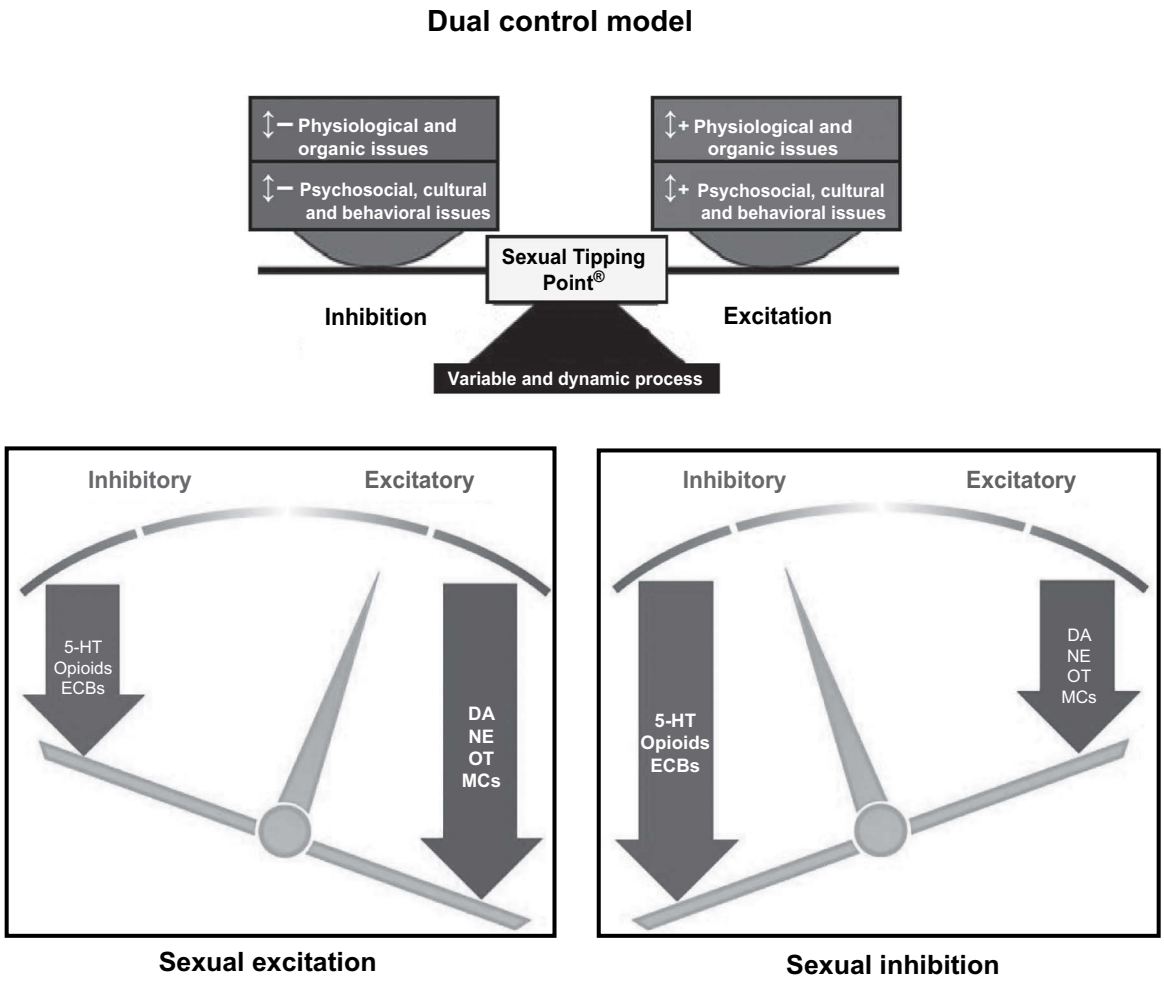

FIGURE 50.18 **Dual control model of sexual excitation and inhibition around a "sexual tipping point".** Activation of excitatory neurotransmitters, such as dopamine (DA), norepinephrine (NE), oxytocin (OT), and melanocortins (MCs), within midbrain, hypothalamic, and limbic regions occurs in response to steroid hormones, sexual incentive cues, and sexual stimulation. Activation of inhibitory neurotransmitters, such as serotonin (5-HT), opioids, and endocannabinoids (ECBs) in cortical, limbic, hypothalamic, and brainstem regions occurs during and after orgasm or in response to stress or aversion, resulting in a net decrease in excitatory tone. *Source: Adapted from Perelman*[479] *and Pfaus.*[35]

behavior is activated.[482,489] DA is also released within the mPOA in OVX females treated with EB and progesterone, however this release is not detected in females treated with EB alone.[424,490] Hormone dependent differences also occur with the application of DA agonists to the mPOA, such that in females primed with EB-alone, D2 receptor subtype agonists facilitate sexual behavior, whereas in EB + progesterone primed females D1 receptor subtype activation facilitates sexual behavior.[482,491,492] Tonic DA release activates D2 receptors, whereas phasic DA release stimulates D1 receptors. Thus, priming with EB-alone may tonically activate D2 receptors, whereas subsequent progesterone administration may stimulate phasic DA release within the mPOA, and activate D1 receptors, to facilitate sexual behaviors. Estradiol also stimulates the synthesis of MC type four receptors in the hypothalamus[493] and synthesis of proopiomelanocortin (POMC) in ArcN neurons[494] and stimulates the synthesis of cholinergic receptors and enkephalin within the VMH.[495,496] GABA and glutamate activation are also stimulated by estradiol in these regions (see below).

Inhibition

Inhibitory synapses make up a large part of the CNS, and local inhibitory networks can hone a response by eliminating competing responses that would interfere with it (e.g., as happens in the visual system with lateral inhibition by amacrine cells[497]). Such inhibition can be observed when behavior comes in bouts or phases, or in Masters and Johnson's EPOR model would be consonant with the "R" phase, a period of postorgasmic refractoriness in which further sexual interest is diminished.[21] Local inhibition can also play a role in the timing of behavior to make it occur only during optimal periods. Female desire and lordosis behavior are obvious examples, and the role of steroid hormones may well be

to suppress the behavior during reproductively nonoptimal (nonovulatory) periods.

General behavioral inhibition, however, is typically viewed as a "top-down" phenomenon involving the cognitive process of "executive function".[498] Animals always have to choose among different drives and motivations (e.g., between feeding and copulation), and indeed between several possibilities per motivational system, to achieve an optimal outcome. The mPFC organizes this by creating behavioral hierarchies based on expectancies, planned actions, and calculations. The mPFC, (and likely other cortical areas) therefore, must inhibit a complex and ongoing interplay of motor tendencies to arrive at planned and sustained actions. People or rats with disrupted prefrontal function, either due to lesions or neurochemical imbalance, have great difficulty focusing attention on tasks, are unable to inhibit competing responses, and experience retroactive and proactive interference.[498] With regard to sexual behavior, such top-down inhibition can be activated as "morality" and would be based on a cultural value system that imposes "right" and "wrong" on certain behaviors, such that some that feel good are "right" and can be experienced without guilt, whereas others are "wrong" and carry the weight of guilt and/or rule of law against them.[28,35] This type of inhibition gives rise to the classic "approach-avoidance" conflict, where the expectation of reward drives the desire, but the inhibition imposed by the real or perceived aversive consequences of engaging in sexual activity blunts the initiation of behavior. Such inhibition may well lie at the root of the inhibited sexual response experienced by women who are not taught to express their sexual desires without some form of guilt. Such inhibition would likely be reinforced if women experienced sexual nonreward during copulation, and such reinforced inhibition would likely overlay itself on desire components to suppress them directly. Some women may be more susceptible to this type of inhibition than others. Accordingly, the "prosexual" nature of drugs such as alcohol, cocaine, and methamphetamine may be a function of their ability to disinhibit such suppressed sexual responding.

Refractory inhibition that comes after orgasm involves the activation of at least three neurochemical systems: opioids that induce pleasure, euphoria, and ecstasy; endocannabinoids that induce sedation; and serotonin that induces satiety.[35] The reward states induced by CLS, VCS, or paced mating in rats appear to be independent of steroid hormone priming, although the priming is necessary to activate the excitatory systems that bring about the behavior in the first place.[28,162] At present it is not known where such inhibition actually takes place. Indeed, the mPOA and VMH have receptors for all three transmitter systems, indeed for all three opioid systems. Activation of delta opioid receptors in the mPOA inhibit lordosis,[499] whereas activation of mu opioid receptors in the VMH inhibits lordosis.[485] Inhibition also comes in the form of estrus termination. This is discussed in more detail below.

Disinhibition

As noted above, certain prosexual drugs can disinhibit sexual responding, but only in individuals with sexual inhibition. This has been modeled in male rats.[90] Male rats trained not to copulate with sexually nonreceptive females will attempt copulation with them under the influence of alcohol. Cocaine, amphetamine, and methamphetamine can do the same in males,[482] and Frohmader et al.[490] provided evidence that methamphetamine could do this after males were inhibited from making sexual approach responses toward scented, sexually receptive females using LiCl-induced gastrointestinal distress as the inhibitory outcome. Alcohol and cocaine stimulate appetitive behaviors in females primed with estradiol alone.[482] Intermittent amphetamine or methamphetamine administration sensitizes sexual approaches and solicitations in female rats[435,500] and increases Fos activation in the MEA and VMH following copulation.[435] However, methamphetamine treatment also makes female rats less selective in preference for particular males.[501]

Disinhibition may also occur as a function of hormone priming. Systems that normally maintain inhibition over female sexual behavior during nonovulatory periods likely must be inhibited to allow the behavior to occur. This appears to be the case for some systems in the VMH that help to time the behavior and that help to bring about estrus termination (see below). Thus the brain is set up with modules that gather and interpret sensory input and generate competent motor outputs at optimal times. This allows reward systems to be activated when females engage in the right behaviors at the right times, and allows such behavior to optimize the reproductive outcomes. The fact that paced copulation is both rewarding to females and results in stronger copulatory stimulation from males, leading to a greater chance of successful impregnation, is a good example of the intricate timing systems that blend the two. Far more is known about the neural and neurochemical control of lordosis than appetitive sexual approach, solicitation, or pacing behaviors. These are outlined below.

Sexual Approach Behaviors

Mesolimbic DA is involved in the sensitization and crystallization of incentive responding,[38] especially within terminals in the NAc. Microdialysis studies have shown that DA in the NAc increases during copulation in OVX female rats or hamsters primed fully with EB and progesterone. In rats the increase is approximately 150%

of baseline when females are presented with a gonadally intact, sexually vigorous male rat behind a screen, and increases to approximately 180% when the screen is removed and copulation ensues.[488] The temporal resolution of microdialysis (e.g., 10-min samples), however, does not permit specific behaviors to be correlated with the rise in DA especially during copulation. However, the degree of release is positively correlated with the number of attempts made by the female to nose-poke through the wire-mesh divider. DA release increases more in the NAc and dorsal striatum in hormonally-primed females that must make an operant response to gain access to males compared to females that do not,[487] suggesting that mesolimbic and striatal DA release helps orient the female toward a sexually active male and make approach responses in anticipation of sexual stimulation and reward.

Solicitations

The pioneering work of Wallen et al.,[57] McClintock,[50] and Erskine[49] refined Beach's[39] general category of "proceptive" behaviors in female macaques and rats into species-specific descriptions of sexual approach, solicitation, and pacing. In rats, solicitations could be defined as full (headwise orientation to the male followed by a runaway) or partial (hops and darts, and perhaps also ear-wiggles) depending on how close in proximity the female was to the male, and whether she had room to run away (e.g., Figure 50.5). Pacing could be operationalized as an intermount or inter-intromission interval imposed by the female, and could be assessed in open fields or as exits and returns to the male's side in a unilevel pacing chamber (e.g., Ref. 49), or level changes per mount or intromission in bilevel pacing chambers (e.g., Ref. 75). Female mounting of sexually sluggish or naïve males was considered by Beach[106] to be a "super-solicitation behavior" that would allow females to "show" the male what they wanted. Such behavior has been studied extensively in rats using sexually experienced OVX females primed with EB alone or EB + progesterone and given access to castrated male rats.[221,502–504]

Hoshina et al.[505] were the first to show that axon-sparing excitotoxic lesions of the mPOA abolished both full and partial solicitations, but enhanced lordosis, in sexually-experienced OVX rats primed with EB and progesterone. Lesions of the mPFC inhibited the temporal patterning of full solicitations, disrupting the runaway component.[506] In contrast, lesions of the lateral septum or VTA did not alter the frequency of hops and darts.[507,508] Lesions of the mPOA, VMH, or MEA, abolished the mounting of sexually sluggish males in OVX rats primed with EB + progesterone, whereas crystalline implants of estradiol to the VMH, but not the mPOA or MEA, induced the behavior in OVX rats.[221]

Role of Incertohypothalamic DA

As with lesions of the mPOA, systemic administration of DA antagonists such as haloperidol abolish solicitations but augment lordosis.[509,510] This effect does not appear to be mediated by mesolimbic DA, as 6-OHDA lesions of VTA DA neurons projecting to the NAc did not alter solicitations in small chambers.[511] However, DA in the mPOA plays a key role in the stimulation of solicitations, with D2 receptor activation facilitating solicitations in OVX rats treated with EB alone, and D1 receptor activation facilitating solicitations in OVX rats treated with EB and progesterone.[491,492] DA projections to the mPOA originate in the zona incerta (ZI). DA turnover in the ZI increases with estradiol administration.[512] Extracellular DOPAC, a DA metabolite, increases in the mPOA in the afternoon to the early evening of proestrus, around the time that sexual behavior is activated.[489] DA is also released within the mPOA in OVX rats treated with EB and progesterone, but not in rats treated with EB alone.[81,160,424,513] Infusions of SCH-23390, a D1 antagonist, to the mPOA of OVX rats primed with EB + progesterone significantly reduced solicitations selectively.[492]

Role of MCs

MCs like α-melanocyte stimulating hormone (α-MSH) are derived from POMC, a precursor peptide made largely in the ArcN from which is also derived the opioid β-endorphin and ACTH.[514] α-MSH synthesis is stimulated by estradiol[515] within ArcN neurons. Projections of those neurons terminate in the mPOA and secrete α-MSH. Two MC receptors exist in the brain, MC3 and MC4, of which the latter is found in the mPOA. Bremelanotide (formerly PT-141) is a synthetic analogue of α-MSH and is the active metabolite of melanotan-II (MT-II). Systemic administration of bremelanotide stimulates solicitations selectively in female rats primed with EB or EB + progesterone.[516] MT-II produces a weaker effect,[517] although five consecutive days of MT-II administration produces an effect similar to bremelanotide in magnitude.[518] The enhancement of solicitations by bremelanotide is duplicated by infusions to the lateral ventricles or mPOA, but not the VMH.[30] Systemic bremelanotide also stimulates DA release in the mPOA, but not NAc or dorsal striatum of OVX rats treated with EB and progesterone. Finally, the stimulation of solicitations by systemic bremelanotide can be reversed by infusions of a selective MC4 antagonist (HS019) to the mPOA, but not VMH.[30] It can also be reversed by infusions of the D1 antagonist SCH-23390 to the mPOA,[30] suggesting that incertohypothalamic DA terminals in the mPOA contain MC4 receptors that drive DA release which in turn stimulates solicitations by acting on D1 receptors in this brain region. Thus the integration between MC and DA systems in the mPOA is a critical component in the regulation of solicitations.

Glutamate in the Ventrolateral VMH

Full and partial solicitations are also under the control of the VMH. In a series of studies, Georgescu et al.[519,520] investigated the inhibitory role of glutamate neurons in the ventrolateral VMH on the sexual behavior of female rats. Both full and partial solicitations were inhibited dramatically by infusions of glutamate, and also by infusions of the selective ionotrophic receptor agonists AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) and kainite to sexually experienced OVX rats primed with EB and progesterone.[519] Conversely, infusions of the dual AMPA/kainite receptor antagonists CNQX (6-cyano-7-nitroquinoxaline-2,3-dione) and DNQX (6,7-dinitroquinoxaline-2,3-dione) to the ventrolateral VMH of sexually experienced OVX rats primed with EB alone increased full and partial solicitations.[520]

Differential Effect of Opioid Receptors

Pfaus and Pfaff[521] reported that infusion of the delta opioid agonist DPDPE, but not the kappa opioid agonist U50-488h, or the mu opioid agonist DAMGO, to the lateral ventricles of sexually experienced OVX rats primed with EB alone or EB and a low dose of progesterone (to induce moderate lordosis and low solicitations) increased solicitations in bilevel chambers significantly over control infusions. It is not known at present where in the brain this facilitation of solicitations may occur.

Taken together, these data suggest that the connections between the VMH and mPOA are critical in the regulation of solicitations relative to lordosis. This is evident from the fact that mPOA lesions suppress solicitations but augment lordosis, and is an example of the kind of mutually-exclusive behavioral patterns discussed by Konorski.[522] Females cannot hold a lordosis posture while making a forward-directed solicitation and vice-versa. Mutually interactive inhibitory subsystems in the two regions likely regulate the timing of solicitations and lordosis.

Pacing Behavior

The ability of female rats to pace the copulatory contact is critical for the timing of intromissions. This timing leads to distributed stimulation of the clitoris, vagina, and possibly also the cervix, stimulation that female rats find rewarding,[81,160,513] and that facilitates pregnancy or the induction of pseudopregnancy,[49,523] and partner preference.[77,78] Female rats pace at a faster rate early in the copulatory interaction, but with successive ejaculations, the number of level changes per mount in bilevel chambers (Figure 50.5) increases dramatically, thereby increasing male inter-intromission intervals.[75] A similar effect is also observed in large open fields, and is more pronounced in wild rats compared to domesticated laboratory rats.[50] In unilevel pacing chambers, the latency to return to the male's side after mounts, intromissions, and ejaculations shows a progressive increase in time, which increases with successive ejaculatory series.[49,74] Low, steady rates of pacing are induced in OVX rats by EB and progesterone, whereas OVX rats administered EB alone show higher rates of pacing and rejection responses. Fully primed female rats tested in small chambers that offer no escape from the male also display rejection responses (e.g., rearing and boxing postures[524]) at a higher rate than females tested in chambers where they can escape. It would appear that females use rejection responses to pace the copulatory contact if they cannot do so otherwise. However, in those conditions, copulation does not induce reward and does not facilitate pregnancy or pseudopregnancy (see below).

Very little work has been done examining the neural control of pacing. However, Xiao, Kondo, and Sakuma[525] found that bilateral radiofrequency lesions of the lateral septum, but not the mPOA, disrupted the pattern of female exits from the male side of a 3-hole unilevel pacing chamber. In general, females with lateral septal lesions did not leave the male side after mounts, and took significantly more time than sham-lesioned females to leave the male side after intromissions or ejaculations. This suggests that activation of the lateral septum by copulatory stimulation is an important component of the regulation of pacing. It is not known whether such lesions would facilitate or inhibit the development of place or partner preferences. Guarraci, Megroz and Clark[526] found that cell body lesions of the mPOA, but not MEA or BNST, increased the intromission and ejaculation contact-return latencies of females in pacing chambers, and increased the number of withdrawals from the male's side following intromissions, suggesting that mPOA activation is critically involved in keeping females with males, consistent with its role in solicitations. Interestingly, clitoral anesthesia induced by lidocaine injections also increased the number of exits and returns displayed by OVX, EB and progesterone-primed rats in a 4-hold unilevel pacing chamber, decreased the amount of time spent with males, and increased the ejaculation return latency.[163] This indicates that CLS maintains low rates of pacing, which increase if the stimulation is blunted. As noted above, polysynaptic clitoral afferents project to the mPOA and CLS activates Fos in medial regions of the mPOA of female rats. It is not known if the reward induced by CLS is eliminated by mPOA lesions, although such lesions disrupt the reward induced by VCS[527] (see below).

Lordosis

More is known about lordosis than any other behaviorally relevant spinal reflex with supraspinal control, except perhaps the control of penile erection[172] and the conditioned eye-blink response.[528,529] The seminal work

of Pfaff[32,62] merged electrophysiology with anatomy and pharmacology and behavioral neuroendocrinology with molecular biology to determine the modular supraspinal components of the lordosis reflex and its control by ovarian hormones acting on receptors in the brain (Figure 50.19). The action of steroids on those receptors alters the brain's neurochemistry and activates the excitatory sexual systems reviewed above. This activation then alters the reaction of the female to incentive sexual stimuli, which leads her to being attracted to male cues. Similarly, it results in approaches and solicitation of sex from the male and, upon simple palpation of the flanks and perineum, the female no longer reacts with violent intense rejection but rather with ear wiggles and sexual receptivity. Thus, the behavioral reflex is linked by the mechanics of gene transcription and translation in critical hypothalamic circuits to the timing of ovulation so that the two can co-occur.

Coordinating physiological responses with behavior requires timing. Hormone priming essentially sets up a timing system for lordosis onset and offset. Although some of the neurochemical systems involved in onset are part of the excitatory system, others are actually inhibitory and keep lordosis from occurring too soon. Likewise, activation of the excitatory neurochemical systems keeps the potential for lordosis on long after the female has taken herself out of the mating game. In general, the hypothalamic targets of estradiol include neurosecretory neurons such as GnRH and DA neurons that affect both pituitary secretion and sexual behavior, and local circuitry neurons such as POMC, GABA, and glutamate.

Given the pivotal role that the VMH and the surrounding area plays in the control of lordosis behavior, our discussion will focus on this region, with the understanding that estradiol also affects the neurochemistry within the broader network of brain regions with ERs. Based on the global effects of estradiol and progesterone on VMH activity, as described below, ovarian hormones clearly transform neural processing in this brain region.

Lordosis Onset

Activation of Excitatory Systems

Estradiol and progesterone activate gene expression for a number of neurochemicals systems in the hypothalamus, most notably in the mPOA and VMH, which stimulate female sexual behaviors including lordosis (Figure 50.20). This includes an upregulation of specific neurotransmitter receptors by estradiol, e.g., progestin preceptors, OT receptors, adrenergic α_1 receptors, muscarinic receptors, MC three and four receptors, and delta opioid receptors, GnRH receptors, GABA-A receptors, and D1 DA receptors.[62,484] This changes how the circuit between the two regions operates. Enzymes are also upregulated in this system, including NO synthase, prostaglandin-D synthase, and DBH, leading to an upregulation of the end products. NO in particular is a critical and ubiquitous player in neurotransmitter release, so its upregulation is important in helping to set the stage for the upregulated neurochemical systems to play a functional role in the generation of the behavior. Pharmacological studies help to confirm the role played by these neurochemical substrates:

GABA AND GLUTAMATE

Throughout the central nervous system, many synapses include excitatory or inhibitory amino acids as neurotransmitters, namely glutamate and GABA, which bind to ionotropic receptors, allowing brisk changes in the postsynaptic potential. Both glutamate and GABA, and their ionotropic receptors, are present in the VMH.[531–538] Several methodological approaches have demonstrated ovarian hormone regulation of these neurotransmitter systems and implicated their actions in the VMH in the control of lordosis behavior (reviewed in Refs 536,539–541), providing insight into the neurological control of mating behavior.

Glutamate neurotransmission in the VMH has been studied with many technical approaches. Double-label immunohistochemical studies indicate that the ERα-expressing neurons in the VMH are glutamatergic, based on the colocalization of the vesicular glutamate transporter-2.[542] Ultrastructural analysis of the VMH has revealed abundant excitatory inputs, including axospinous synapses, which comprise approximately one third of the total VMH synapses. Based on hormone replacement regimens, estradiol treatment increases glutamate levels in the VMH, and this is reversed with subsequent progesterone treatment.[543] The number of AMPA and NMDA (N-methyl-D-aspartate) receptor subunits are likely to increase with estradiol treatment.[538,544] Although the behavioral pharmacological evidence is not complete, glutamate action in the VMH acutely inhibits female sexual behavior during the time window of receptivity.[541] This may be mediated by a combination of kainite, AMPA, and NMDA receptors.[519,520] Thus, it appears that female reproductive behavior depends on the inhibition of glutamate neurons in the VMH.

Whereas glutamatergic neurons in the VMH are the direct target of ovarian hormone action, the specific functions of GABAergic cells in the VMH are not yet clear. Nevertheless, GABAergic activity in the VMH is clearly modulated by estradiol. Estradiol treatment increases GABA levels in the VMH, based on hormone replacement regimens, and subsequent progesterone treatment returns GABA back to vehicle-treated levels.[545,546] Similarly, estradiol treatment may also increase GABA turnover.[546] The estradiol-induced increase in GABA production may be based on transcriptional regulation of GAD65, an enzyme involved in GABA biosynthesis,

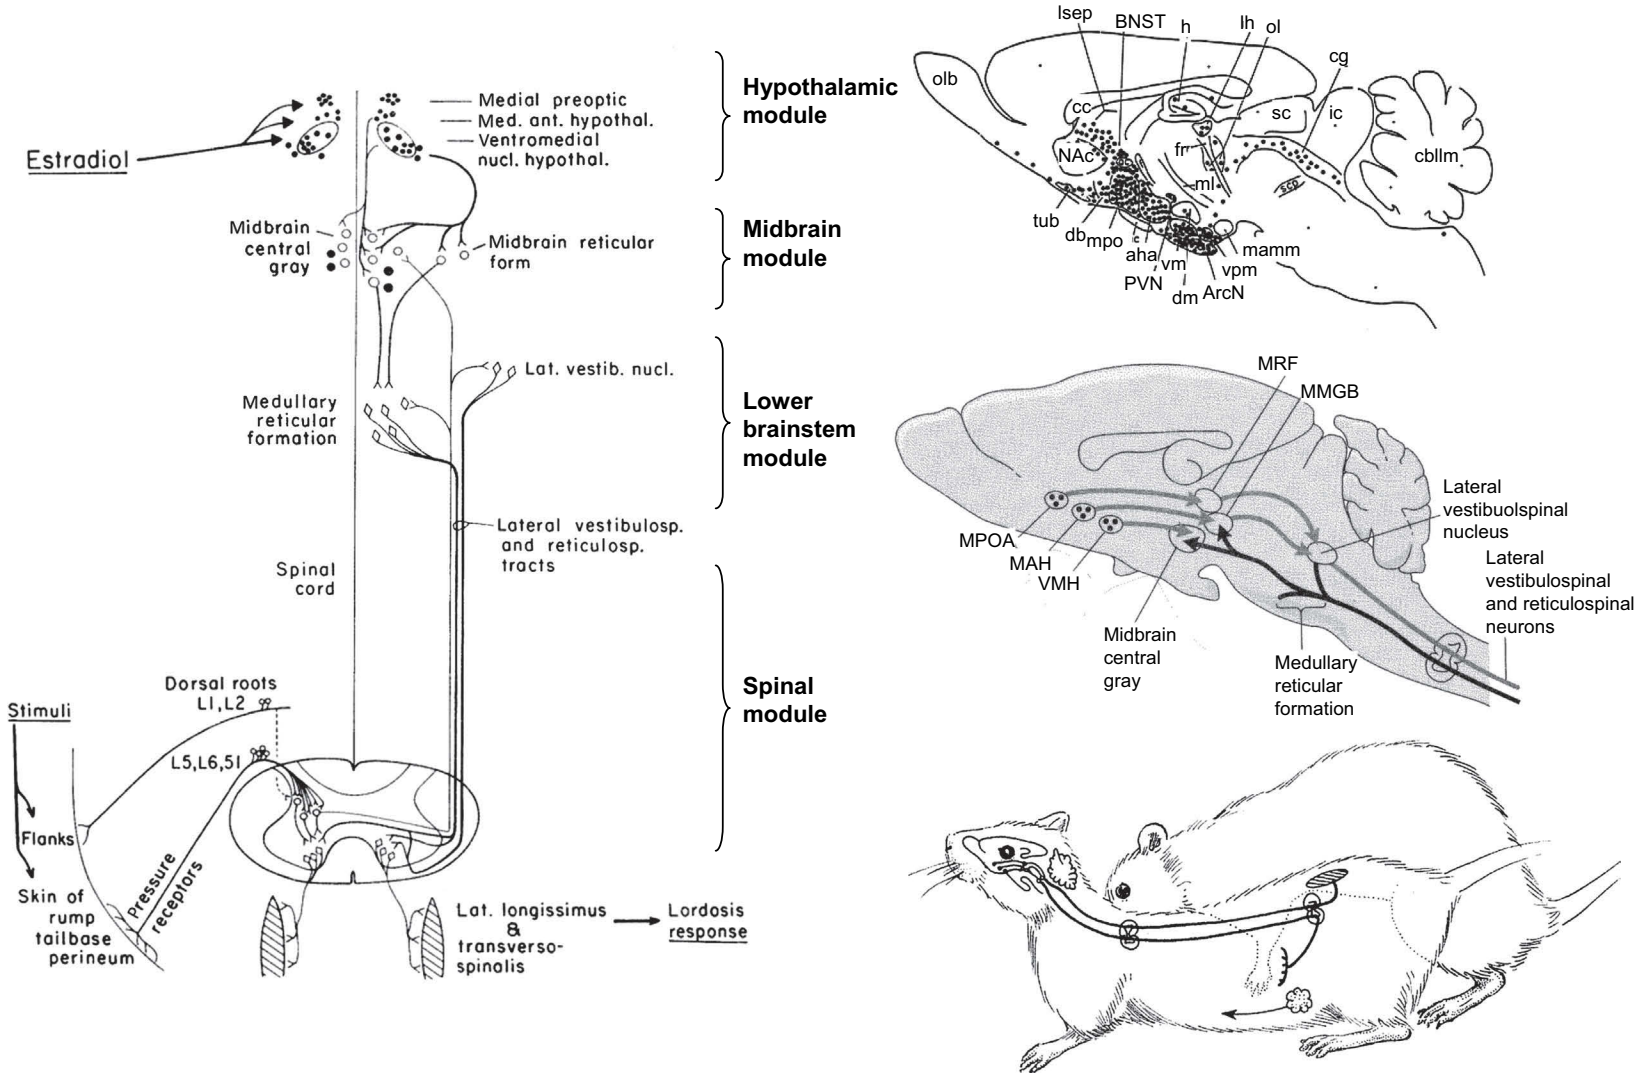

FIGURE 50.19 **Modular control of lordosis.** Left: Estradiol binds at the level of the hypothalamic and midbrain modules, altering the way that incoming somatosensory inputs from flank and perineal stimulation via the spinal cord to brainstem are processed and responded to. This alters the response of the female to palpation of the flanks, switching her from fighting to lordosis (bottom right). Right top: estradiol binding in the mediobasal hypothalamus, and midbrain of female rats. Right middle: critical elements of the lordosis circuit depicting regions of estradiol binding in the medial preoptic area (mPOA), ventromedial hypothalamus (VMH), and anterior hypothalamus. Motor pathways for the circuit include the lateral vestibular nucleus (for postural orientation) and lateral vestibulospinal and reticulospinal neurons that control contractions of the lateral longissimus and transversospinalis muscles of the back, which raises the base of the tail and head. Estradiol activates both nuclear and membrane-bound receptors in the hypothalamus to induce these changes, which include the augmentation of neurochemical systems that are excitatory for sexual behavior (see text). Abbreviations: aha, anterior hypothalamic area; ArcN, arcuate nucleus; BNST, bed nucleus of the stria terminalis; cblm, cerebellum; cc, corpus callosum; cg, midbrain periaqueductal gray; db, diagonal band of Broca; dm, dorsomedial hypothalamus; fr, fasciculus retroflexus; h, hippocampus; ic, inferior colliculus; lh, lateral habenula; lsep, lateral septum; MAH, medial anterior hypothalamus; mamm, mammillary bodies; MMGB, medial region of the medial geniculate body; mpo, medial preoptic area; ml, medial lemniscus; NAc, nucleus accumbens; ol, nucleus of the lateral olfactory tract; olb, olfactory bulb; PVN, paraventricular nucleus; tub, olfactory tubercle; vm, ventromedial hypothalamus; vpm, ventral premammillary nucleus. *Source: Modified from Pfaff.*[32]

by ERα and ERβ.[547] Behavioral pharmacology experiments suggest that GABA activity may facilitate female sexual behavior,[543] thus exerting disinhibition.[539] GABA may work, in part, by inhibiting local serotonin release, which tonically inhibits lordosis behavior in the VMH,[543] and also by inhibiting glutamate neurons (see below).

These neurotransmitter systems also work in concert to exert opposite effects in the mPOA and VMH on lordosis. In the VMH, infusions of the GABA-A receptor agonist muscimol to OVX, EB-primed rats facilitates lordosis,[548,549] whereas infusions to the POA inhibit lordosis.[549] Infusions of muscimol also reduce extracellular 5-HT concentrations in the VMH.[548] Conversely, infusions of the GABA-A receptor antagonist bicuculline to the mediobasal hypothalamus resulted in an inhibition of lordosis. VMH infusions of antisense oligodeoxynucleotides that flank the start codon for two isoforms of the GABA synthesizing enzyme glutamic acid decarboxylase (GAD; GAD65 and GAD67) inhibited lordosis in rats primed with continuous diffusion of crystalline estradiol in sc silastic capsule implants.[550] These data suggest that GABA in the mPOA inhibits lordosis by an action at GABA-A receptors, but facilitates lordosis in the VMH.

Glutamate was first reported by Kow et al.[540] to inhibit lordosis in OVX, EB-primed rats following infusions to the VMH. This effect was replicated and extended by Georgescu and Pfaus[519,520] who showed that infusions of glutamate or its ionotrophic receptor agonists AMPA, NMDA, and kainate, to OVX rats primed with EB and progesterone inhibited lordosis. NMDA and kainate infusions also increase the display of rejection responses. In contrast, infusions of the NMDA antagonist AP-5 or the AMPA/kainate antagonists, CNQX or DNQX, each facilitate lordosis in OVX rats primed with EB alone.[520] Interestingly, an electrophysiological depolarization signature due to glutamate release in VMH slices was shown by Booth, Weyman, and Jackson[551] to be inhibited by the same treatments. Moreover, pharmacological agents known to inhibit lordosis systemically, such as the 5-HT1A agonist 8-OH DPAT, the mu opioid agonist DAMGO, bicuculline, and CRF all potentiate the in vitro VMH glutamate EPSP (excitatory postsynaptic potential) signature.

The local VMH GABA and glutamate circuits are modulated, in part, by major afferents arriving from the hindbrain somatosensory-arousal systems providing serotonergic, noradrenergic, histaminergic and cholinergic projections to the area lateral to the VMH proper,[426,552–559] innervating the long primary dendrites that extend into the lateral fiber plexus. The brainstem nuclei of origin for these neurotransmitters all express estrogen receptors.[269,397,560,561] In summary, the key neurotransmitters of fast synaptic neurotransmission, glutamate and GABA, are regulated by estradiol within the VMH and have opposing effects on female sexual behavior.

DOPAMINE

Systemic administration of DA agonists can facilitate or inhibit lordosis behavior in OVX rats primed with EB and progesterone or EB alone. Paradoxically, systemic administration of a range of doses of DA antagonists also facilitates lordosis, although the behavioral signature of the effect is different. As mentioned above, whereas DA agonists produce a small increase in lordosis, but a large increase in solicitation behaviors, DA antagonists produce a large increase in lordosis quotients but abolish solicitations. Both the inhibitory and facilitatory effects of systemic DA agonists appear to act through D2 receptors in OVX, EB primed rats, but on D1 receptors in OVX rats primed with EB and progesterone. DA release in the VMH facilitates lordosis. Infusions of apomorphine or DA to either the mPOA or VMH facilitate lordosis behavior in OVX rats primed with low doses of estrone, whereas infusions of the DA receptor antagonists haloperidol or α-flupenthixol to these regions inhibit lordosis, but only in OVX rats made highly receptive with high doses of estrone. DA release is also increased in the VMH during copulation.[426] As discussed above, crosstalk between D1 receptors and steroid hormone receptors in the VMH appears to play a role in the facilitation of lordosis by a cellular process of ligand-independent activation of steroid hormone receptors. Mani et al.[413] reported that the D1 agonist SKF-38393 facilitates lordosis in OVX, EB-primed rats following infusions to the lateral ventricles, and that this effect is blocked by the progesterone receptor antagonist RU-38486 or by infusions of and antisense oligodeoxynucleotide directed against the start codon of the PR-A. These data indicate that activating D1 receptors in the VMH is capable of activating PR, possibly by altering the phosphorylation of the PR or a specific transcription coregulator. Thus, in addition to progesterone altering the activity of diencephalic DA systems, DA in the VMH appears to facilitate lordosis by the indirect activation of PR.

NOREPINEPHRINE

There is considerable evidence that the hormonal changes that underlie lordosis behavior and certain neuroendocrine reflexes, such as the preovulatory LH surge and pseudopregnancy, are associated with altered norepinephrine transmission. Early studies suggested that hindbrain noradrenergic projections to the hypothalamus provide critical visceral and somatosensory cues for female sexual behavior.[555] Extensive work by the Etgen laboratory has demonstrated that estradiol and progesterone enhance norepinephrine release in the vicinity of the VMH.[562] From a postsynaptic perspective, ovarian hormones reconfigure the populations of subtypes of noradrenergic receptors in the VMH, substantially altering signal transduction pathways and neurophysiological responses.[563] These changes in responsiveness and signal transduction channels appear critical for allowing the relevant sensory information to the VMH to promote the lordosis reflex.

Although systemic treatment with α or β noradrenergic receptor agonists and antagonists modulate lordosis, no clear picture emerges. Central effects of adrenergic drugs on female sexual behavior have not been studied in detail. Infusions of the α_1 antagonist prazocin into the VMH, but not the mPOA, inhibit lordosis, whereas infusions of the α_2 antagonist idazoxan or the β antagonist metoprolol to the VMH have only small inhibitory effects in some animals. Infusions of metoprolol to the mPOA inhibit lordosis in most rats. These results indicate that stimulation of α_1 receptors in the VMH facilitates lordosis, whereas stimulation of β receptors in the mPOA may inhibit lordosis. Consistent with this, in vivo microdialysis studies have shown that copulation with intromission increases extracellular norepinephrine concentrations in the VMH.[426]

ACH AND HISTAMINE

Both Ach and histamine have similarly been implicated as arousal neurotransmitters acting in the VMH to promote female sexual behavior, based on behavioral pharmacology studies.[564,565] As with serotonin and norepinephrine, specific subtypes of receptors for both of these signals are regulated by ovarian hormones.[566,567] Electrophysiological studies indicate that during estradiol exposure these signals have an enhanced excitatory effect on VMH neurons.[530,567] Histamine, in part, acts through H3 receptors to inhibit spontaneous GABA release.[532] The overall pattern that arousal transmitters that facilitate lordosis are also excitatory to VMH neurons would seem paradoxical, given that glutamate, a major excitatory transmitter, appears inhibitory for female sexual behavior within the VMH. In this regard, it is important to remember that the VMH includes several cell types that may be differentially regulated and exert excitatory vs inhibitory effects on behavior.[444] In addition, the effect of glutamate on neurotransmission may not be as straightforward as "excitatory". The net effect of glutamate on the membrane potential may be

dependent on the general state of excitability.[551] Nevertheless, there is a strikingly consistent pattern for hindbrain arousal pathways to converge on the VMH, with effects being modulated by estradiol.

OXYTOCIN

One of the most studied neuropeptides in female sexual behavior is OT, which acts in both the mPOA and VMH to promote female sexual behavior.[568,569] OT immunoreactivity is present in the lateral fiber complex, in axons arising from the PVN, colocalized with glutamate.[451] These OT axons innervate the long primary dendrites that extend into the lateral fiber complex.[451] Receptors for OT in the VMH undergo striking regulation by estradiol and progesterone in the VMH.[570] In general, ovarian hormones increase OT signaling by increasing levels of the receptor in the vicinity of the OT fibers. Electrophysiological studies suggest that OT has excitatory effects on VMH neurons.[571,572] Thus, OT may be co-released with glutamate in the area surrounding the VMH to signal social and sexual cues, and ovarian hormones sensitize specific VMH neurons to this information.

Within the VMH, estradiol stimulates OT receptor transcription. Lordosis is facilitated dramatically following systemic and intracerebroventricular administration of OT, and OT receptors in the mPOA and VMH appear to facilitate the frequency and duration of lordosis, respectively.[573] OT infusions to the VMH of OVX, estrogen-primed prarie voles reduces rates of aggression and increases the amount of physical contact that the females made with males, although it also leads to a faster termination of estrus. Copulation with intromission induces Fos within OT neurons of the paraventricular hypothalamus, but not the SON,[574] suggesting that endogenous OT systems are activated during copulation and may participate in the facilitation of lordosis following intromission. Interestingly, masturbation to orgasm increases plasma OT levels in women.[575]

GnRH, PROLACTIN, AND CHOLECYSTOKININ

Like OT, GnRH and prolactin have various effects that promote reproduction in females, including the promotion of female sexual behavior.[576–579] GnRH-labeled neurons reside in more anterior regions of the rat hypothalamus, but axonal fibers surround the VMH[580] and GnRH receptors are expressed in the VMH.[581] Likewise, prolactin receptors are expressed in the ventrolateral VMH,[582] and prolactin-immunoreactive axons are found in the mediobasal hypothalamus.[583]

GnRH produces a dramatic facilitation of lordosis in OVX, estradiol-primed rats following systemic or ventricular administration. Infusions of GnRH into the anterior POA, arcuate, and PAG, also facilitate lordosis in estradiol-primed rats, whereas infusions of a GnRH antibody into the MCG reduce lordosis quotients. Copulation with intromission, or manual VCS induces Fos within GnRH neurons of the anterior POA,[584] indicating that these neurons are activated during copulation. Interestingly, estradiol enhances the proportion of GnRH cells that express Fos following VCS, possibly through long-term noradrenergic activation. These results suggest that the activation of OT and GnRH neurons may form part of the system that facilitates lordosis following VCS. The behavioral effects of prolactin have not received as much experimental attention as GnRH, although there is a perception that sexual satiety is induced by prolactin in both men and women because prolactin release from the anterior pituitary into the general circulation occurs with orgasm.[585] Recently, it was found that women's self-reported satisfaction from orgasm is correlated positively and significantly with the concentration of postorgasmic prolactin found in serum.[586] Additional studies are needed to understand the neural circuitry, neurochemical coding, and neurophysiological targets of both GnRH and prolactin.

Another peptide that robustly innervates the VMH and mPOA is cholecystokinin (CCK). Immunoreactive terminals for CCK innervate VMH soma and dendrites, arising from the lateral parabrachial nucleus,[587–589] a region with strong ERα expression, and making symmetric synapses suggestive of inhibition.[590] Likewise, CCK receptors are found in the VMH.[591,592] However, the significance of CCK action in the VMH for lordosis and the type of information being relayed remains unclear.

DELTA OPIOIDS AND SUBSTANCE P

Two peptides intrinsic to VMH neurons are enkephalin and substance P. Enkephalin immunoreactivity is present in inhibitory axons terminating on GABA-containing VMH neurons. Thus, enkephalin may modulate these intrinsic GABAergic VMH neurons, thereby disinhibiting VMH output.[534] Enkephalin itself is upregulated by estradiol and progesterone in the VMH,[496] like its apparent co-transmitter GABA. Electrophysiological studies suggest that enkephalin has excitatory effects on VMH neurons. As with GABA, the delta opioid receptor agonist DPDPE inhibits or facilitates lordosis following infusions to the mPOA or VMH. Infusions of DPDPE to the lateral or third ventricles facilitates lordosis in OVX rats primed with EB alone or EB and progesterone.[521,593] A similar action was found when low doses of DPDPE were infused directly to the VMH.[593] However, higher doses inhibit lordosis. These effects were blocked by the delta opioid receptor antagonist naltrindole, and infusions of naltrindole alone to the VMH inhibited lordosis. Infusions of antisense oligodeoxynucleotides that flank the start codon for pre-proenkephalin mRNA to the VMH reduced lordosis quotients in OVX rats primed with estradiol.[594] As mentioned above, estradiol stimulates the synthesis of pre-proenkephalin in the VMH

which could act as an endogenous ligand for delta receptors there.[595] However, infusions of DPDPE to the lateral mPOA inhibit lordosis.[499]

Substance P is intrinsic to VMH neurons, and many substance P-labeled neurons express ER.[596,597] These substance P neurons are thought to project to the periaqueductal gray to promote sexual behavior.[598,599] Substance P-labeled terminals are likely to be excitatory, based on ultrastructure.[600] Thus, although both enkephalin and substance P are present in the VMH and promote lordosis, evidence suggests that they comprise distinct elements within the lordosis circuitry, with enkephalin modulating local inhibitory connections and substance P modulating the descending excitatory outflow.

In sum, the local VMH circuit includes glutamatergic and GABAergic neurons, which are directly and indirectly responsive to estradiol, and which have acute effects on lordosis behavior. The neuropeptides substance P and enkephalin are co-localized with these amino acids, and are likely to modulate their actions. The VMH also receives ascending influences from the hindbrain carrying arousal and sensory information, which is also modulated by ovarian hormones. Although the neurochemistry of many hypothalamic connections is not known, peptides associated with reproduction, such as OT, GnRH and prolactin may also affect lordosis by acting on VMH neurons. Taken together, the VMH is transformed by exposure to estradiol to change its internal pattern of activity, and at the same time, the salience of various inputs to the VMH is drastically recalibrated. As we better define the neurochemistry that controls the lordosis circuit, it will be important to understand how these neurotransmitters and neuromodulators work in concert to affect neurophysiology and behavior.

Inhibition of Inhibitory Systems

Tonic inhibitory systems exist for lordosis in the mPOA and VMH that must be overridden to activate lordosis. This action then constrains lordosis to the periovulatory period. Local actions of both mu and delta opioids, and glutamate, appear to keep lordosis constrained until such time as those systems are either inhibited directly, or the action of excitatory neurochemical systems overcomes the inhibitory tone.[35]

Serotonin is the most intensely studied transmitter in this category, and as might be expected, projections from the raphé to the VMH inhibit female sexual behavior.[601,602] Treatment of OVX rats with behaviorally effective doses of estradiol plus progesterone significantly reduces the turnover of serotonin in the VMH in a manner that correlates with changes in lordosis behavior.[603] Decreased serotonin in parallel with increased sexual behavior is also seen across the estrous cycle.[489] This inhibitory effect of serotonin on female sexual behavior is associated with an inhibitory effect on VMH neuronal activity, although the affected cell types have not been described. The serotonin receptor subtype 2C has been localized to the VMH and its neuropil.[533] Acute systemic treatment with the selective serotonin reuptake inhibitor fluoxetine disrupts estrous cyclicity, and reduces lordosis and the amount of time OVX rats primed with EB and progesterone spend with males, with Sprague-Dawley rats being less sensitive to these effects than Fischer rats.[604–606] The reduction in lordosis by fluoxetine was attenuated by progesterone,[607] and by chronic daily exposure to males.[606]

Timing Mechanisms

There are at least two timing mechanisms that have been explored, one that keeps the onset of sexual behavior in females tightly linked to ovulation, and another that allows females to receive a requisite amount of genitosensory stimulation before they fall out of heat. Sinchak et al.[608] have carefully provided evidence for a hypothalamic timing microcircuit in which estradiol acting at ERα in the ArcN stimulates neuropeptide Y release locally within the arcuate that in turn stimulates the activation of POMC neurons that project to the mPOA. These neurons release β-endorphin which activates mu opioid receptors in the mPOA, internalizing them and effectively inhibiting lordosis for the duration of its action. The maintenance of the mu opioid receptor internalization is provided by the activation of GABA-B receptors in the arcuate. This mechanism would also be expected to inhibit appetitive solicitations derived from activation of DA in the mPOA. However, this transient inhibition is itself inhibited by subsequent progesterone actions at PRs, and/or by higher doses of free estradiol acting at membrane receptors in the ArcN (linked to Gq-coupled activation of Srx) and/or in the mPOA (linked to GPER-30 receptors) to deactivate mu opioid receptors in the same membrane.[609,610] Together, these mechanisms create a biochemical timer that keeps sexual behavior from occurring until requisite physiological changes have taken place to support pregnancy. It may also be an important mechanism to investigate for estradiol-induced negative feedback, which may augment opioid actions in the mPOA while reducing the GPER-30 linked disinhibition.

Lordosis must also be maintained long enough for females to receive sufficient CLS for reward and potentially cervical stimulation to induce the neuroendocrine reflexes (e.g., upsuck for sperm transport, increased prolactin surges) that facilitate pregnancy and the progestational state. Glutamate neurons and glutamate transmission in the VMH are activated by VCS and inhibit lordosis as part of a local hypothalamic circuit that terminates estrus (see below). Estradiol augments GABA turnover in the VMH, and glutamate neurons

have GABA-A receptors, making them a target of inhibition by GABA. Such a mechanism likely extends the period of sexual receptivity before glutamate release in the VMH reaches a critical threshold for estrus termination.

It is tantalizing to consider that estradiol tips a balance between energy regulation and sexual behavior by modulating hypothalamic systems that promote feeding, utilizing them to inhibit both appetitive solicitations and lordosis until ovulation, at which time mechanisms that normally inhibit feeding (e.g., MCs) are activated that stimulate sexual behavior (e.g., Refs 611,612). For example, infusions of antisense oligodeoxynucleotides to GAD, which stimulate lordosis, inhibit food intake in rats.[613] This contrasts dramatically with the ability of food and sex to activate the central nucleus of the amygdala and stimulate mesolimbic DA release similarly in the NAc.[614,615] This suggests a fundamental difference in the way that hypothalamic regulatory systems and more general mesolimbic incentive motivational systems regulate different motivational states. Hypothalamic systems appear to regulate different motivations as if each possesses its own separate and mutually exclusive drive state. In contrast, the mesolimbic incentive system treats external stimuli associated with those drive states as essentially similar in the induction of forward-directed locomotion. However, it is also the case that glutamate in the VMH inhibits both feeding[616] and sex,[519,520,540] and may be involved in satiety-related mechanisms that terminate both motivational systems.

Estrus Termination

The offset of appetitive sexual responses and lordosis occurs as the period of sexual receptivity terminates. This is typically referred to as "estrus termination". Part of this process accompanies the natural decline in hormonal titers, whereas more immediate inhibition stems from an abbreviation of the sexually appetitive and receptive period brought about by VCS from intromissions and ejaculations.[617] Abbreviated estrus induced by mating stimulation or VCS has been shown to occur in rats,[75,617,618] guinea pigs,[619] and hamsters.[620] Indeed, allowing females to pace sexual contacts increases the inhibitory effect of intromissive stimulation on estrus duration in estrus-cycling rats[74,523] presumably because males make deeper and more powerful thrusts that could stimulate the cervix. In fact, OVX rats primed with EB and progesterone and given 50 distributed VCSs with a glass rod (that approximates the number of intromissions they would receive in an hour from a male) display no solicitations, low levels of lordosis, and high numbers of rejection responses when tested 12 h later.[75] In that study, rats given sham stimulation 12 h before testing displayed normal rates of solicitations and lordosis, and no rejection responses. Females allowed to copulate freely with males in bilevel chambers show changes in the intensity of appetitive and consummatory behaviors, such that by the fourth ejaculatory series, fully primed female rats show few solicitations, lower lordosis frequencies and reflex magnitudes, longer pacing intervals, and higher numbers of rejection responses, compared to the first ejaculatory series.[70] It is around this time that naturally-cycling female rats in large semi-natural environments will take themselves out of the open area and back into the burrow system, effectively ending their participation in sexual activity. However, in experimental settings where sexual stimulation is not controlled adequately by the female, she displays longer periods of sexual receptivity than would be predicted from studies in the wild or in semi-natural environments. This is similar to the observation by Wallen et al.[621] of female rhesus macaques displaying nearly constant receptivity when paired in small enclosures with a single male, relative to females in large natal groups that take themselves out of a sexual interaction by retreating to the female territory.

Role of PRs

Inhibition of protein synthesis by infusion of a protein synthesis inhibitor into the mPOA in hamsters[622] or following systemic administration to guinea pigs[619] blocks mating-induced abbreviation of the period of sexual receptivity. Likewise, inhibition of protein synthesis delays heat termination.[623] Recent work suggests that heat termination that is hastened by mating stimulation is referable to more rapid down-regulation of PRs (specifically PR-B)[354] than the down-regulation in response to progesterone. Thus, although there is still much that is not known about the role of PR-A and PR-B in particular neurons, it is clear that PRs play a key role in the timing of sexual receptivity in a variety of circumstances by serving as a gatekeeper for the transcriptional processes within those neurons involved in sexual behavior.

Although, there is a temporal correlation between decreased blood levels of progesterone and termination of behavioral estrus,[362] the two events are not causally related. That is to say, the period of sexual receptivity ends even when levels of progesterone are maintained.[624,625] Because of the importance of PRs to the facilitation and maintenance of sexual behavior, the cellular basis for heat termination requires looking at the regulation of PRs. Progesterone down-regulates its own receptors. Loss of behavioral response can typically be attributed to either a declining concentration of activated/occupied hypothalamic PRs[356] or the absence of a sufficient level of progesterone to interact with the particular level of unoccupied receptors. The decline in concentration of unoccupied PRs can come about in a variety of ways; a decrease in estradiol levels results in the loss of induction of PRs, and exposure to

progesterone down-regulates PRs. Both processes typically occur in tandem.

It has been suggested[356,626] that the refractory period, which follows termination of sexual receptivity[236,627,628] comes about as a result of the same mechanism that causes heat termination—down-regulation of PRs by progesterone. During the refractory period, the concentration of hypothalamic PRs is depressed in relevant brain areas,[357,358,629,630] and progesterone treatment results in low levels of activated PRs.[362,631] In addition, a supplemental estradiol injection, which offsets the decrease in the concentration of unoccupied PRs, resulting in high levels of occupied PRs in response to progesterone,[364] causes the animals to regain response to a second progesterone injection.[236,628,632] The refractory period can also be overcome by injection of a large dose of progesterone,[631,633] which, unlike a lower dose, results in a large increase in progesterone-occupied PRs in the hypothalamus.[631] Therefore, with a variety of conditions, there is a strong concordance between the level of activated PRs and the expression of lordosis.

There have been conflicting reports of progesterone involvement in estrus termination in rats. However, although rats may not become completely insensitive to progesterone after estrus termination, they do in fact become hyposensitive to it[634] The hypothesis that estrus termination and the refractory period are both due to loss of activated PRs may explain the conflicting opinions concerning progesterone's role in estrus termination.[224,635,636] Perhaps behavioral response is critically dependent on an adequate concentration of PRs, rather than progesterone per se.

Role of Disinhibited VMH Glutamate

As mentioned above, VCS that induces estrus termination activates a population of glutamate neurons in the ventrolateral VMH[637] (Figure 50.21). When OVX rats are given 0, 1, 5, 10, 20, 30, 40, or 50 distributed VCSs, the activation of Fos in those neurons is delayed by prior treatment with EB or EB and progesterone, relative to the oil-treated control, such that fewer neurons reach a threshold for activation until animals receive between 10 and 20 VCSs.[169] This blunted activation indicates that steroid hormones have suppressed the ability of VCS to activate these inhibitory glutamate neurons, although by 50 VCSs there is no difference in the number activated between steroid-treated and control groups. How might estradiol with or without progesterone do this?

Virtually all the glutamate neurons that co-express Fos after VCS also contain GABA-A receptors which are up-regulated by EB treatment.[638] The stimulation of GABA synthesis by EB in GABA neurons that project to the VMH would be expected to bind to GABA-A receptors on the inhibitory glutamate neurons and induce IPSPs for an extended period of time, long enough perhaps for the female to receive enough intromissions and ejaculations to ensure pregnancy, or at least the progestational state consonant with pseudopregnancy. Extracellular concentrations of glutamate in the VMH during copulation in OVX females are very high in females injected only with oil (which reject male advances), and lowest in females primed with EB and progesterone who display full appetitive and consummatory sexual responses.[638] Indeed, infusions of the AMPA/kainate receptor antagonist DNQX to the VMH prior to the application of 50 distributed VCSs delayed the induction of estrus termination observed in saline-treated controls 12 h later.[639] The source of the GABA input to glutamate neurons has not been identified, although preliminary findings suggest it comes largely from the mPOA.[640] Thus blocking glutamate receptors in the ventrolateral VMH blocks the abbreviation of estrus induced by VCS, an effect that may occur naturally by estradiol-induced inhibition of glutamate neurons. The net effect would be for females to remain sexually receptive long enough to receive a requisite number of intromissions and ejaculations to ensure pregnancy.

Disorders of Sexual Desire or Interest in Women

An important example of how basic research translates into clinical treatments comes from the study of the neurochemistry of sexual desire. At least three potential treatments for disorders of sexual desire or interest in women are being considered, including the MC agonist bremelanotide, the serotonergic mixed 5-HT1A agonist/5-HT2A antagonist flibanserin, and a combined pill containing testosterone and a phosphodiesterase-5 (PDE-5) inhibitor called Lybrido®. Acute bremelanotide increases solicitations selectively in preclinical models using OVX rats primed with low doses of EB, or low EB and progesterone.[30,516] Likewise chronic flibanserin increases solicitations and reduces rejection responses in OVX rats primed with EB or EB and progesterone.[316] Microdialysis samples from the mPFC, NAc, and mPOA showed that acute flibanserin increased basal levels of NE in all areas, along with DA in the mPFC and mPOA, but not the NAc. Acute flibanserin also decreased serotonin levels in all areas. However, chronic flibanserin increased DA and NE significantly in the mPFC, but did not alter serotonin, glutamate, or GABA relative to chronically injected controls. Finally, acute treatment of OVX rats primed with low EB with testosterone and a PDE-5 inhibitor increased solicitations and hops and darts.[641] All three drugs have shown significant efficacy in increasing self-reported sexual desire in pre- and post-menopausal women diagnosed with hypoactive desire disorder.[30,642–646] The ability of these three drugs to stimulate solicitations in a rat model of hypoactive sexual desire predicts their functional application in women with hypoactive sexual desire. This suggests strongly that the neurochemical systems underlying

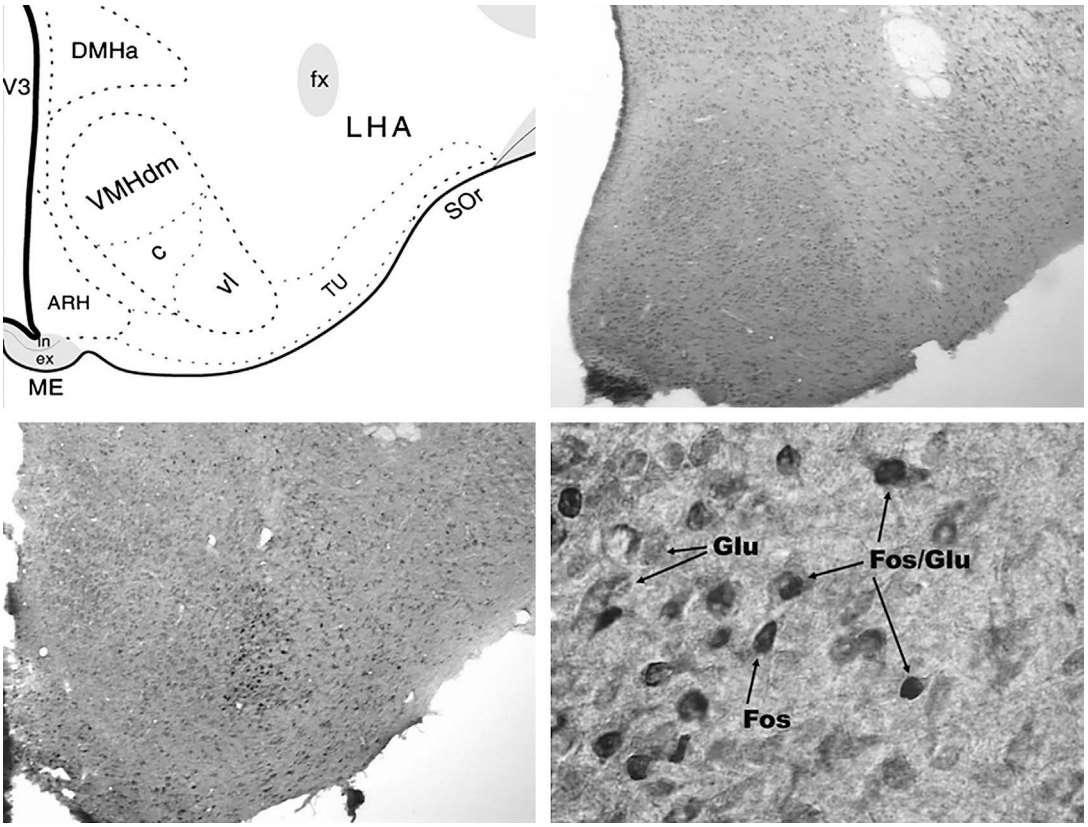

FIGURE 50.21 Activation of glutamate neurons in the VMH by 50 artificial vaginocervical stimulations over the course of 1 h. Top left: schematic drawing of the VMH and its substructures. appetitive sexual behavior are conserved between at least rats and humans, and that translational work on the neural and hormonal systems that mediate sexual responses in women can be derived from basic and clinical research in other species.

CONSEQUENCES OF SEXUAL STIMULATION

In addition to estrus termination and the activation of neuroendocrine reflexes associated with pregnancy and pseudopregnancy, stimulation of the clitoris and possibly also vagina and cervix induce a state of pleasure or reward. As with many rewarding stimuli, a neurobiological "preference" can be established for physical elements associated with the original pleasure-inducing event. For things such as pleasure-inducing drugs this can include the place in which the drug effect is experienced. In animal models this can be manipulated so that an individual's preference for one distinctive environment in which the drug effect was experienced, vs a different environment in which the effect of vehicle or placebo was experienced, can be quantified and used as an indicator of how rewarding the drug is.[647] This same principle can be applied to sexual stimulation received in one distinctive environment vs no stimulation in another environment. In both cases the location in which the rewarding event occurred becomes a conditioned stimulus in the classic sense and thus this phenomenon (or behavioral assay) is referred to as conditioned place preference (CPP). Specifically in the context of sexual reward experienced with a distinctive partner, the same principle can be applied such that salient partner-related cues become conditioned stimuli that induce a partner preference. Research into the role of conditioning as a result of sexual stimulation brings together three important observations in females (and males) of a variety of species.

First is the phenomenon of mate choice, observed naturally in female prairie voles that display monogamous social and sexual partner preferences with the first male they mate with (see Chapter 48). This phenomenon traces its cause in large part to the particular way that OT is activated in regions of the limbic system and hypothalamus that create an incentive sexual preference for a particular

male with whom the female has mated with.[648,649] The male of this species also displays monogamous social and sexual preferences,[650,651] and the two will form a partnership around care and raising the young. It has been assumed that most other species are polygamous, and in particular, sexually promiscuous. If there are preferences at all (especially in males) it is for a different partner every time in order to spread the genes far and wide in the pool. Both male and female rodents are assumed to be polygamous and promiscuous, with both showing "Coolidge effects" in which sexual activity is more vigorous with new compared to familiar partners.[72,652]

The second phenomenon is sexually CPP, as referred to above. In these studies rats or hamsters are placed into the start chamber of a CPP box (Figure 50.22) that contains two distinctive environments to either side that vary by floor pattern or some other distinctive characteristic but one that will not, in and of itself, invoke a preference. The sequential pairing of sexual stimulation or a reward state induced by sexual interaction with a partner is then experienced in one side, and no stimulation is experienced in the other side, and occurs for several trials after which the rat is placed into the start chamber and allowed to roam freely between the two distinctive environments. If the sexual stimulation has positive reinforcing (i.e., rewarding) properties then the rat will spend significantly more time on the side of the chamber where it previously experienced the rewarding sexual stimulation (UCS (unconditioned stimulus)).

Seminal work by Paredes and colleagues starting in the mid-1990s asked if female rats "liked" sex. Prior to this work, lordosis and other sexual behaviors were seen as being "driven" by estradiol and progesterone, but given the existence of penile spines it was far from clear that female rats found sexual interaction with males rewarding. And given the anesthetic properties of progesterone, it was indeed possible that they did not, but that the potential pain of sex was merely reduced to endurance levels by hormone action. In fact, in some

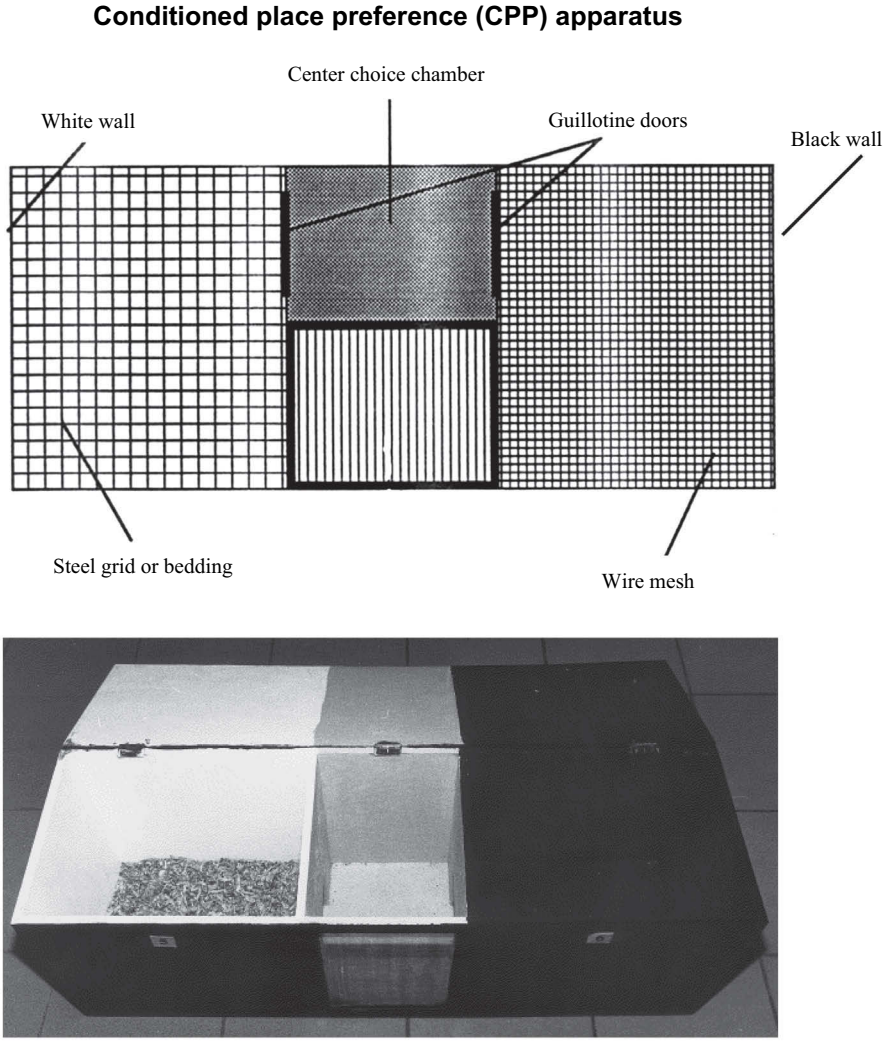

FIGURE 50.22 Typical conditioned place preference (CPP) apparatus used to determine the rewarding properties of drugs or sexual stimulation. *Source: Adapted from Paredes and Vazquez.*[81]

studies prior to Paredes' work, female rats were observed to run away from the male after ejaculation, or to choose to spend more time with a castrated male relative to an intact male.[653] Two important papers by Paredes' group changed that perception (see below).[81,513]

The third phenomenon merged the first two, showing that polygamous and promiscuous female rats are capable of developing sexually conditioned partner and mate preferences based on the degree of reward experienced during their first sexual encounters, and whether this sexual reward had been paired with a discrete odor cue (e.g., almond) on the male they had their first rewarding sexual experience with.[28,78] This effect was also demonstrated for the strain of the male with which the female had her first sexual experience.[77] Female rats also display mate guarding behavior, just as female prairie voles do, if they are sexually receptive and placed into a situation with their male and another competitor female who is sexually receptive. Together, these phenomena link reward and reproduction, and bring them to a more cognitive level of analysis that translates extremely well to human sexual behavior. One significant advantage to the use of neutral stimuli such as an odor of a place being paired with a sexual reward state is that the stimuli can be presented alone—as a priming cue—and the activation of brain areas in response to the conditioning cue in the absence of the actual rewarding stimulus can be identified. This has led to important insights into the neurological underpinnings of reward, both in response to pleasure inducing drugs and sexual stimulation.[63]

Sexual experience in females also changes cellular morphology in critical regions of the reward circuitry. In female golden hamsters, for example, copulatory experience increases dendritic spine density in the NAc, but decreases it in the PFC[94] (Figure 50.23). An augmentation of synapses in the NAc, concomitant with a decrease in the PFC, would be expected to enhance the ability of distal sexual incentives to focus a female's attention and activate excitatory appetitive sexual responses. Thus, the ability of sexual experience to augment the activation of sexual reward, and in turn sexual desire, is most likely rooted in molecular, structural, and neurochemical changes that sensitize females to competent sexual incentives and cues that predict sexual reward or pleasure.

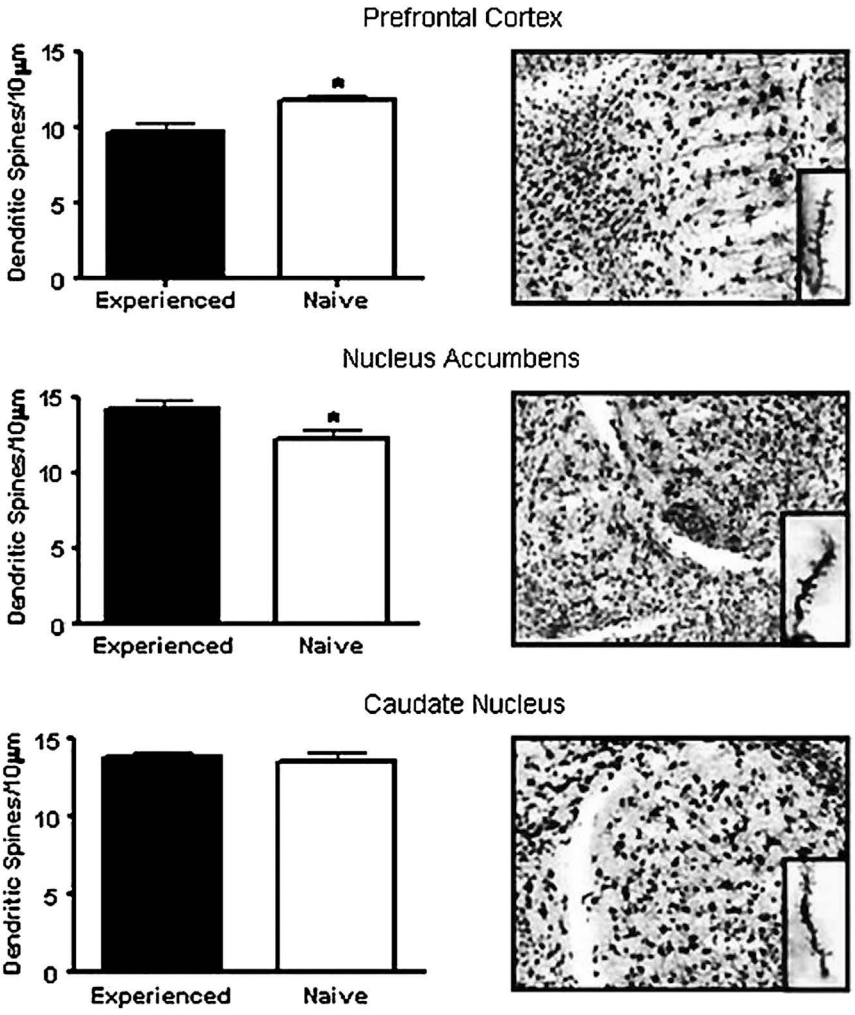

FIGURE 50.23 Spine densities of Golgi-stained neurons from the prefrontal cortex (PFC), NAc, or caudate nucleus (dorsal striatum) in sexually experienced or naïve female hamsters. Sexual experience induces a significant reduction in spine density in the PFC, but a significant increase in the NAc. This pattern of synaptic alteration would be expected to enhance reactivity to both unconditioned and conditioned sexual incentives. *Source: Reprinted from Meisel and Mullins,[94] with permission of Elsevier.*

Sexual CPPs in Females

Oldenburger et al.[654] found that when copulation occurred within one of the distinctive compartments of a CPP apparatus, female rats showed a weak preference for the chamber in which mating occurred. Subsequently, Paredes and Alonso[513] and Paredes and Vazquez[81] demonstrated a robust place preference in female rats when they were able to pace the rate of copulation without having to employ defensive behaviors. This was accomplished using unilevel pacing chambers bisected by a Plexiglas divider with one or more small holes that only the female can pass through.[74,81,513,523] The male was sequestered on one side of the chamber and the female was then free to pace the copulatory contact by running from side to side. Like males, females acquired a strong preference for a distinctive environment only if they were placed into the CPP box after paced copulation. No preference was found if the copulation was unpaced prior to placement in the CPP box (meaning that it had occurred in the same pacing chamber but without the divider). Thus, for a female rat, place preference develops only if she has been able to control the initiation and rate of copulation freely without having to use defensive behaviors.

There is an alternative interpretation of the place preference induced by controlled paced mating in females. Rather than paced mating being rewarding per se, it may be that under conditions in which the female has little control over the interaction, such as is usually the case in tests of animal mating behavior performed in small constrained arenas such as glass aquaria, that these interactions are actually aversive. To examine this possibility, Afonso, Woehrling, and Pfaus[504] allowed female rats to copulate in two unilevel pacing conditions using Plexiglas dividers that had either four holes or one hole. This was done to eliminate the possibility of an "aversive" state resulting from unpaced copulation. Trials were conducted sequentially at 4-day intervals and each pacing condition was paired with one of the distinctive sides of a CPP apparatus, in a counterbalanced fashion. Control groups contrasted the 4-hole or 1-hole condition with a no-divider condition (as was done by Paredes and Alonso[513]). Control females developed significant CPP for either the 1-hole or 4-hole condition, relative to unpaced copulation with no divider. These data replicate the findings of Paredes and Alonso[513] and indicate that both the 4-hole and 1-hole condition were rewarding relative to the unpaced (no divider) condition. However, they do not rule out the possibility that the real distinction being made was between an aversive condition (unpaced copulation) and a rewarding condition (paced copulation). This was addressed in the group allowed to contrast the 4-hole vs 1-hole condition, in other words females that could control the pace of the sexual interaction freely (in the 4-hole chamber, females can move freely from side-to-side) vs those that could not (in the 1-hole chamber, males often obstruct the hole with their heads, forcing the females to wait longer to get to the male's side). Females developed significant CPP for the 4-hole relative to the 1-hole paced copulation experience. Thus free control over the rate of copulation appears to be a crucial variable in the rewarding aspects of pacing. Similarly, Jenkins and Becker[655] found that female rats developed significant CPP for paced relative to unpaced mating, but also for unpaced mating in which the experimenter removed the male for a period that approximated the female's imposed interintromission interval, relative to unpaced mating in which male removal did not occur. Thus, female rats develop CPP for sex at their own preferred intervals. Taken together with the results of Matthews et al.,[656] these data suggest that reward comes from the sexual stimulation that females receive, namely mounts with intromission, so long as that stimulation occurs at the desired time intervals.

What is it about paced copulation that leads to CPP in females? Meerts and Clark[657] reported that VCS applied with a 1 ml syringe plunger at 200 g of pressure for 2 s at 30-s intervals, for a total of 15 stimulations, induces a reliable CPP in OVX females primed with estradiol and progesterone. Given that VCS could stimulate the internal clitoris as well as the cervix, we asked whether external CLS could induce CPP.[160,658] As mentioned above, in these studies CLS was administered either with a lubricated paintbrush or a small cotton-tipped vibrator at preferred intervals for 10–15 min over five to six reinforced sessions. Both types of stimulation induce robust CPP. Importantly, reward as a consequence of CLS can be induced in OVX females with or without hormone priming,[162] indicating that sexual reward is independent of steroid priming, although such priming would normally be required for females to experience CLS from mounts with pelvic thrusting, as it would be necessary to induce lordosis which exposes the clitoris to the male's perineum during pelvic thrusts.[164] Indeed, females primed sequentially with EB and progesterone, or its ring A-reduced metabolites, show enhanced CPP from paced copulation relative to females primed with EB alone, presumably due to the greater degree and frequency of lordosis induced in females receiving progesterone in addition to estradiol.[659] OVX rats primed with low doses of EB that induce low to moderate lordosis do not develop CPP,[660] OVX, hormone-primed rats given exitotoxic lesions of the nucleus paragigantocellularis of the brainstem have attenuated lordosis and appetitive behaviors.[661] Interestingly these females also do not develop CPP to artificially-applied VCS.

Maintenance of the memory of paced sexual reward does not require exposure to hormones. Parada et al.[162] attempted to extinguish paced copulation-induced CPP

by exposing OVX rats in three priming conditions (oil, EB alone, and EB+progesterone) to the CPP box without prior copulation. Only females primed fully with EB+progesterone shifted their preference back to the original preconditioning side. At first glance, this would appear to be counterintuitive, given that the reward state induced by distributed CLS (and possibly also paced copulation) is not hormone dependent. However, *desire* is hormone-dependent, and only the females that had hormone-induced activation of appetitive sexual motivation, but did not receive sexual stimulation, showed extinction of the CPP. Nonprimed, or EB-primed, females did not extinguish the CPP. This makes sense from a conditioning viewpoint: animals that are not in a state of desire do not need that state satisfied, whereas animals in a state of desire seek satisfaction of that desire. Extinction thus occurs only when a state of desire or need exists and there is no satisfaction.

Finally, the CPP induced by paced copulation in females can be blocked by systemic injections of naloxone,[662] or following infusions of naloxone to the mPOA, VMH, or MEA, but not the NAc.[663] Similar data have been reported for males, suggesting that common opioid systems in the brains of male and female rats are activated by sex-related cues[662] and constitute a primary reward signal. Bilateral lesions of the nucleus paragigantocellularis in the brainstem decrease the amount of time females spend with males, which in turn, attenuates the CPP induced by paced copulation.[621] Such lesions also attenuate the CPP induced by artificial VCS, suggesting both a behavioral and sensory deficit induced by the loss of the nucleus paragigantocellularis.

Conditioned Sexual Partner Preferences

As outlined above, female rats also show olfactory conditioned partner preference for males associated with a pacing-induced reward state.[78] This was accomplished in unilevel pacing chambers in which the paced condition involved the placement of either a 1-hole or 4-hole Plexiglas divider through which the female could regulate the initiation and rate of copulation. The nonpaced condition involved copulation in the same chamber but without the divider. Females in the paired group were given paced copulation with males that had almond odor applied to their necks and anogenital area vs nonpaced copulation with males that had distilled water applied to the same areas. After four paced vs nonpaced trials, females were placed into a large open field with two tethered males, one scented and the other unscented, and choice of male to solicit, copulate with, and receive ejaculations from, was recorded. Females for which the odor was paired with the paced condition selectively solicited, copulated with, and received ejaculations from the scented male. Females that had the odor explicitly unpaired or paired randomly with pacing did not display a preference (Figure 50.24).

As with males, females showed a similar preference for strain cues associated with paced copulation,[77] although it was stronger if the strain associated with paced copulation was their own. Interestingly, in that study, pigmented or albino females solicited whichever strain of male was associated with paced copulation, but received ejaculations preferentially from males of their own strain and only if that male had been associated with paced copulation. This also revealed a degree of assortative choice, especially for mating, and showed that females, like males, can differentiate copulation from mating. Finally, female rats that experienced manual distributed CLS in the presence of a cotton gauze pad soaked in almond extract chose to copulate selectively with almond-scented males over unscented males during their first sexual experience in a large open field with both males.[161] Interestingly, they did not show a preference to receive the scented male's ejaculations, suggesting that the VCS received from males during paced copulation induced a further reproductive or mate choice. It is not yet known whether this stems from specific stimulation of the cervix (and pelvic nerve) or from full stimulation of internal and external aspects of the clitoris,[166] or other sensory regions inside the vagina. Experience with paced, relative to nonpaced, copulation in unilevel chambers induces significant neurogenesis in the granular layer of the accessory olfactory bulbs,[664] a region known to contain intrinsic memory systems related to pheromonal stimulation and recognition of conspecifics.[665,666]

Female rats also learn inhibitory associations. Coria-Avila et al.[83] found that administration of the opioid receptor antagonist naloxone blocks the development of sexually conditioned partner preference in OVX female rats primed with estradiol and progesterone. Subsequent analysis of the naloxone training sessions revealed that by the 6th or 7th trial, most females display significantly fewer, if any, solicitations, a low frequency and magnitude of lordosis, and a far higher number of rejection responses, as if they were in a state of estrus termination (Figure 50.25). In some females this occurred before any intromissions were achieved by the males, although such stimulation was often reacted to violently by the females who would box and push the males onto their sides or backs. *And this was despite full hormonal priming with estradiol and progesterone.*

In addition to the inhibitory effect of sex without opioid reward induced by naloxone, thwarted sexual activity in the presence of an inaccessible male can also induce an inhibitory state. Parada et al.[161] gave sexually naïve female rats five trials of CLS in the presence of a sexually active male scented with almond behind a screen. On alternating days, the females received sham CLS in the presence of an unscented male behind the screen. During

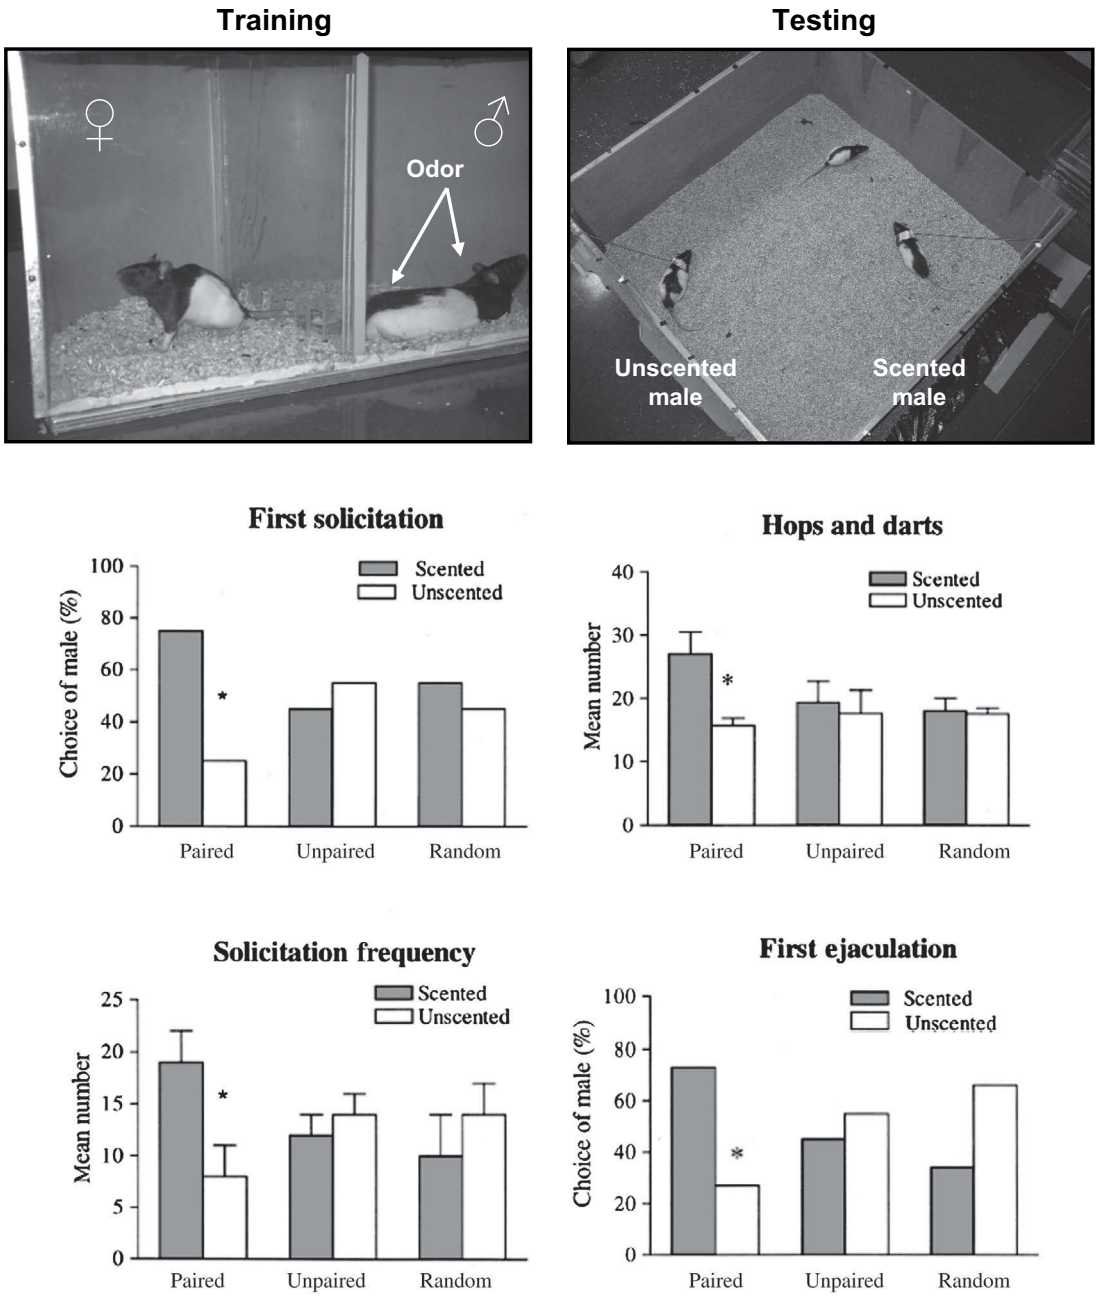

FIGURE 50.24 Conditioned partner preference in the female rat. Top: Paired females are given their first sexual experiences in a unilevel pacing chamber with a male behind a 1- or 4-hole divider scented with a neutral odor (e.g., almond). This is followed 4 days later by exposure to an unscented male but with the divider removed. After several sequential exposures of scent and paced copulation and no scent and unpaced copulation, females are tested in a large open field with two tethered males, one scented and one unscented. The choice of male for solicitations, hops and darts, mounts, intromissions, and ejaculations is recorded. Unpaired females are given the opposite order of association during training, no scent with paced copulation and scent with unpaced copulation. Random paired females are given scented and unscented males randomly associated with paced and unpaced copulation. Bottom: Choice of male for first solicitation, frequency of solicitations, hops and darts, and choice of male for first ejaculation, from paired, unpaired, or random-paired groups. *Source: Adapted from Coria-Avila et al.*[78]

the final open field test with two males, one scented and the other unscented, females solicited selectively the *unscented male* and showed a trend to receive that male's ejaculations preferentially. At first glance, these data seem at odds with the fact that CLS induces a reward state. However, it was noted that females attempted to solicit the males behind the screen following CLS during the training trials, which, of course, were not successful because the male was behind a screen. Thus, it is likely that the female was in a state of thwarted sexual nonreward that she associated with the odor and generalized to the choice of male for her first sexual experience.

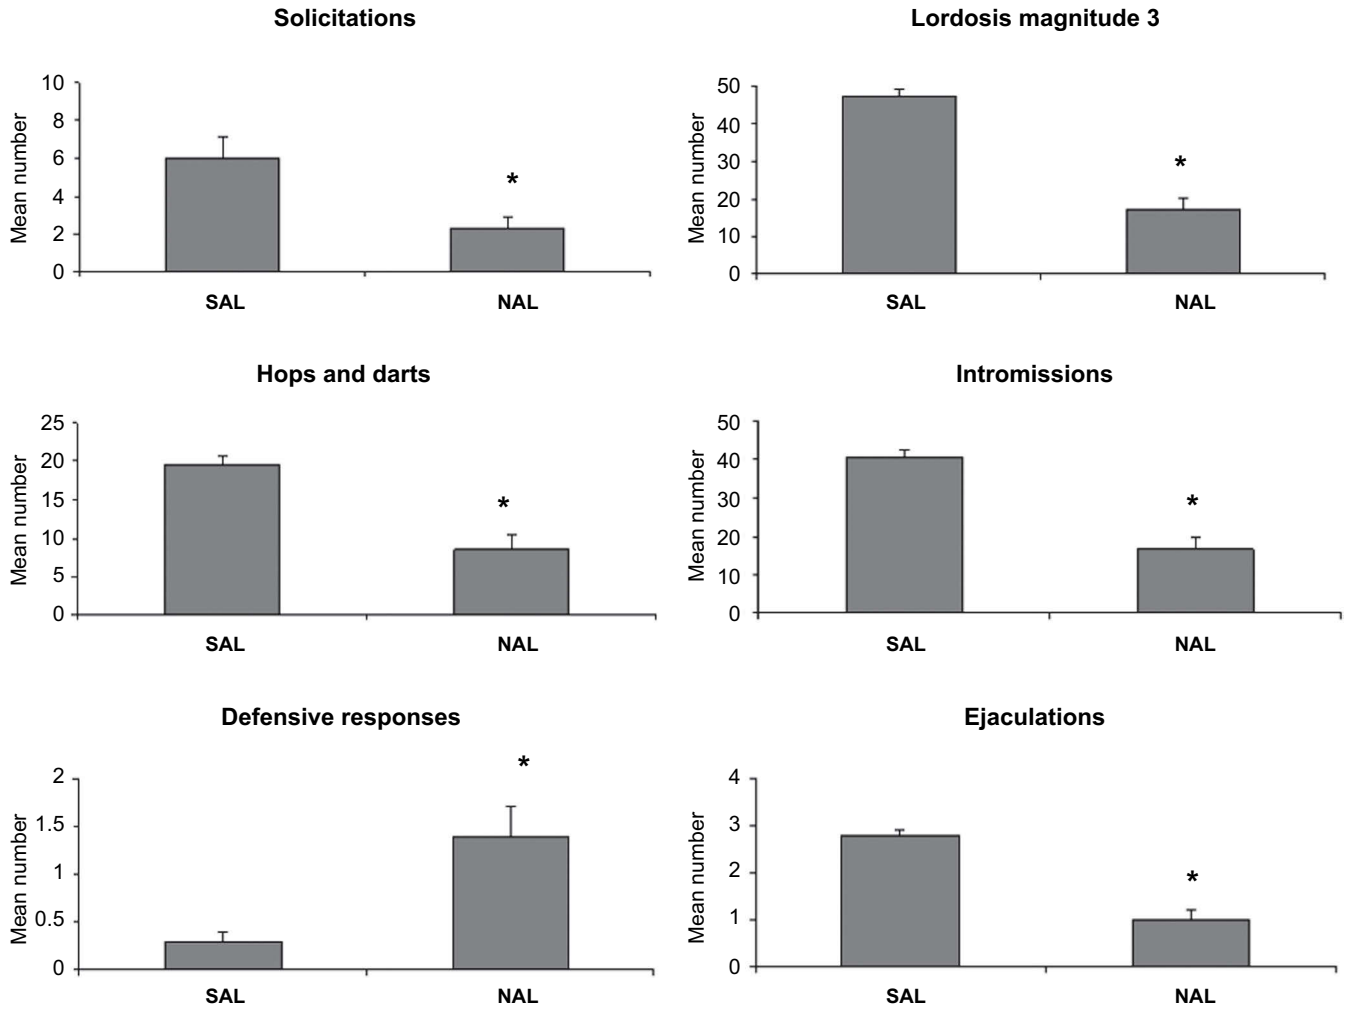

FIGURE 50.25 Effects of acquiring sexual experience under the influence of saline or naloxone (5 mg/kg, ip) on appetitive and consummatory sexual behaviors in OVX female rats primed fully with estradiol and progesterone. Females received six multiejaculatory experiences at 4-day intervals prior to the final test in which all rats received an injection of saline. *Source: Adapted from Pfaus et al.*[28]

After conditioning, the odor cue can be presented alone to examine its priming effect in the brain. Relative to the unpaired group, the odor presented to females in the paired group activates Fos (Figure 50.26) in a circuit that is strikingly similar to that observed in fMRI brain scans of women during the presentation of erotic pictures, and especially pictures of their partners.[64] These regions include: olfactory tubercle, piriform cortex, ACC, insula, NAc, dorsal striatum, lateral septum, mPOA, PVN of the hypothalamus, ArcN, VMH (scattered), and VTA.[76] Presentation of strain cues behind a wire-mesh screen also activated Fos. Relative to unpaired rats, Fos protein was activated in significantly more cells in the piriform cortex, mPOA, VMH, and VTA.[76] Areas of common activation by odor and strain related cues associated with paced copulation are shown in Figure 50.27.

Finally, OVX, hormone-primed female rats given their first 10 multiejaculatory sexual experiences with the same unscented male display agonistic behavior toward an OVX, hormone-primed competitor female (CF) when the three are placed into an open field. Sexually receptive female rats have generally been observed to compete with one another in large mating arenas[50]; however this behavior is reminiscent of the mate guarding displayed by Prairie voles.[667] The partner female (GF) typically mounts the competitor female (HO) and pushes her into corners of the open field, sometimes with aggressive postures, prior to running back to the partner male with her ears wiggling. Occasionally she positions herself between the male and the competitor, making it nearly impossible for the male to gain access to the other female.[668] These observations have been replicated and extended,[669] and brain activation by the encounter compared between the GF and the HO. In both cases, Fos activation of CLS and VCS zones in the hypothalamus and limbic system have been detected; however in GFs that position themselves more frequently between the male and the HO, Fos protein was induced in a greater number of cells by the copulatory stimulation.

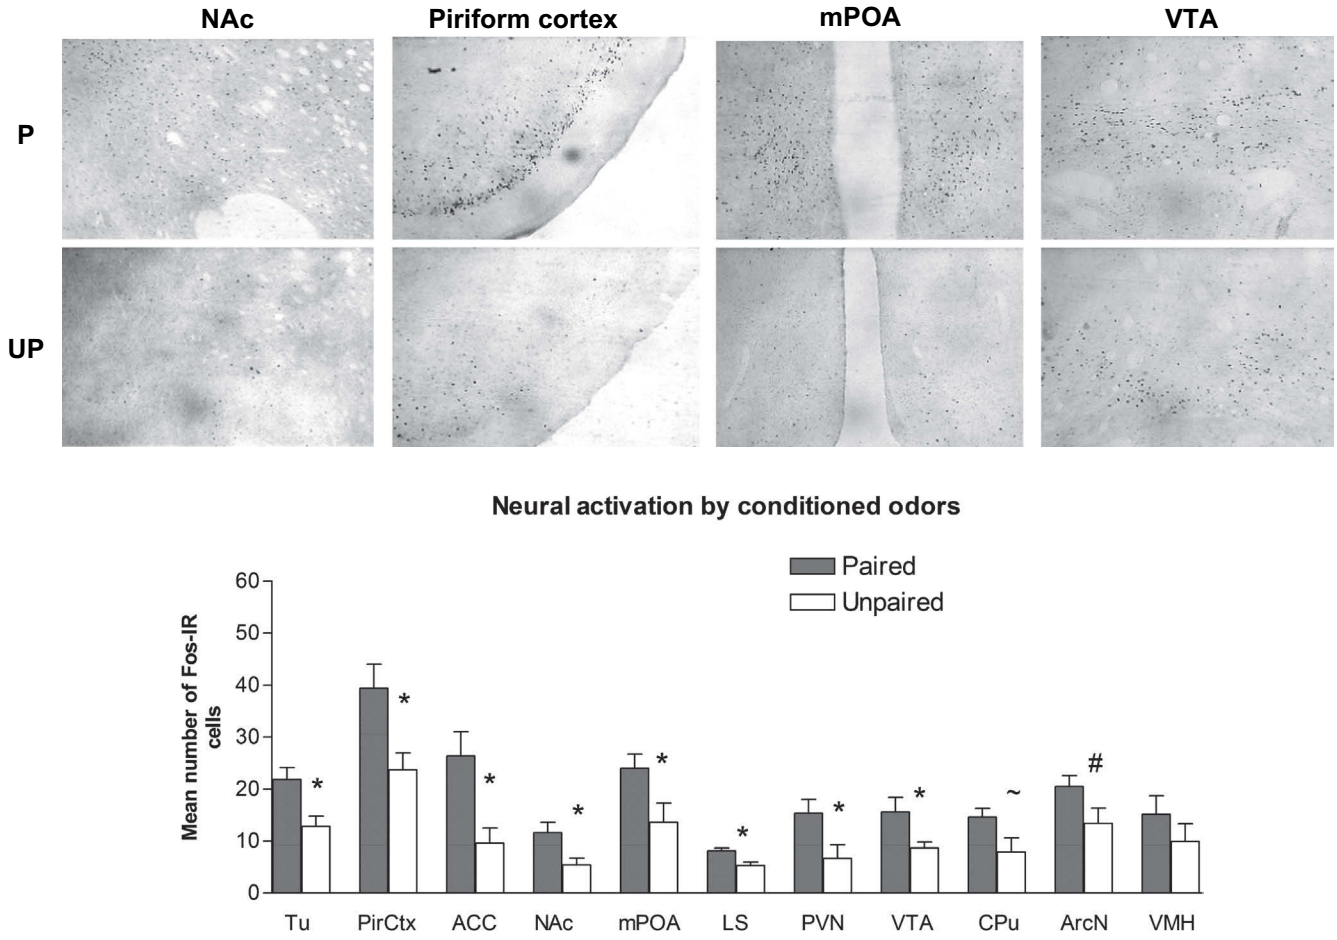

FIGURE 50.26 Selective activation of Fos by an almond odor paired (P) or unpaired (UP) with paced copulation. Note the activation of the central DA cell body-rich region of the VTA by the odor cue. However, only the GF shows significant activation of Fos within OT and vasopressin neurons of the paraventricular and supraoptic nuclei, and within regions of the hippocampus and corticomedial amygdala that could indicate an additional stress response.

It would appear that female rats possess the ability to show behavioral and neuronal rudiments of either selective or promiscuous mating depending on their early sexual experience. Such experience seems to crystallize sexual response patterns and preferred sexual stimuli by sensitizing a circuit similar to that activated in monogamous prairie voles during their formative sexual experiences[96,651,670] and following parturition.[671] The results of Aragona et al.[96] are particularly instructive, as the sexual bond formation was inhibited by activation of D1 receptors, but facilitated by the activation of D2 receptors. This suggests a neural reorganization in mesolimbic terminals after formative sexual experiences that "seals the bond", making it less likely for other stimuli to acquire associative strength.

Such an effect is consistent with modern theories of learning (e.g., Refs 672,673) and has been implicated in the susceptibility to drug addiction, especially in terms of responding to cues that predict drug reward,[674] and more generally in response to food-related cues.[614,675] The interaction of OT and DA in the PVN, mPOA, VTA, and NAc of male rats induces penile erections and links them to appropriate appetitive sexual behaviors.[676] Thus, opioid reward states may form the rudimentary mechanism of bonding because they sensitize DA release in the presence of reward-related cues compelling animals to focus their attention and goal-directed behavior toward those cues. Activation of brain OT systems (by DA or other means) adds a reduced social distance and bonding to this neurochemical reward state. Given that pharmacological activation of opioid receptors induces a direct suppression of both hypothalamic and pituitary OT secretion,[677] sensitized and potentially reorganized mesolimbic and hypothalamic DA systems must be a necessary intermediary. This is consistent with a

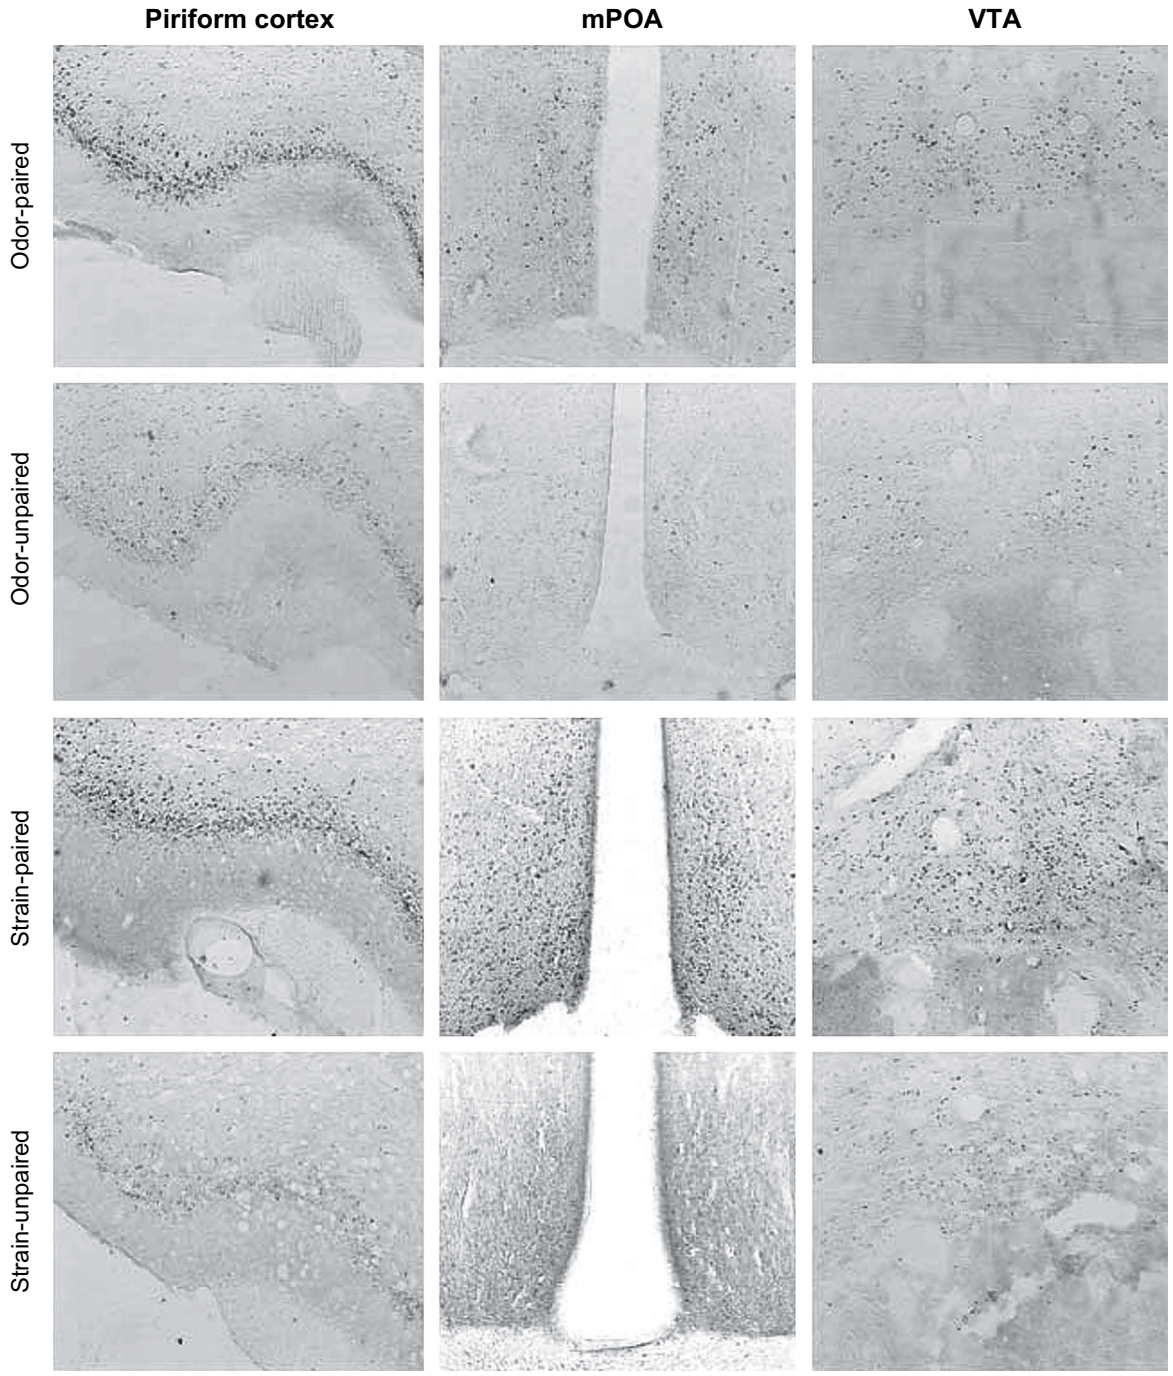

FIGURE 50.27 Comparison of Fos in the piriform cortex, mPOA, or VTA, by almond odor or strain cues (pigmented vs albino) paired with paced copulation. *Source: Reprinted from Coria-Avila and Pfaus,[76] with permission of Elsevier.*

multifaceted role of mesolimbic DA in incentive salience and response initiation.[38]

Conditioned Sexual Arousal in Women

It is difficult to condition sexual arousal or desire in adult humans as they have likely already had their sexual preferences set by experience long before. This is especially true in women when using erotic films or pictures as the UCS that are rated as mildly or moderately stimulating (e.g., Ref. 678). More recent attempts have been more successful using UCSs or CSs of higher incentive quality. For example, Both et al.[679,680] found that neutral pictures of male headshots paired with 2 s of intensely pleasurable vibrotactile CLS produced greater vaginal pulse amplitude (VPA) during extinction in the

paired vs unpaired groups. In another study, stimuli were presented briefly (30 ms).[681] Although only the paired group showed increased VPA to the CS during the first extinction trial, there was no increase in the conscious affective value of the stimulus. Finally, Hoffmann, Janssen, and Turner[682] varied the duration and relevance of a CS (abdominal area vs a gun) that was paired with short erotic film clips in both men and women. Interestingly, when the stimuli were presented subliminally for brief durations, the relevant abdominal stimulus increased arousal in both men and women. However, when the stimuli were presented for longer periods prior to the erotic film clips, a sex difference emerged in which the relevant CS alone (abdominal area) induced genital arousal in men, but the presumably irrelevant stimulus alone (gun) induced genital arousal in women. This latter effect may indicate that women require CSs that increase autonomic arousal to a higher extent than men, a potential corollary of the "discordance" experienced by women, but not men, between genital and subjective sexual arousal.[151] It may also be the case that anything that activates the sympathetic nervous system sufficiently in women may generate a genital blood flow response, regardless of whether the stimulus is sexual in nature. This may occur at anytime during the menstrual cycle, but may be interpreted as more "sexual" when women are periovulatory.

An Integrative Model of Conditioned Sexual Responding

The model proposed by Pfaus, Ismail, and Coria-Avila[683] and shown in Figure 50.28 accounts for both unconditioned and conditioned sexual responding, integrating a number of important regions that regulate female sexual responses by the hypothalamus, limbic system, and cortex. With reference to conditioning, CSs associated with sexual reward state UCSs act as "priming

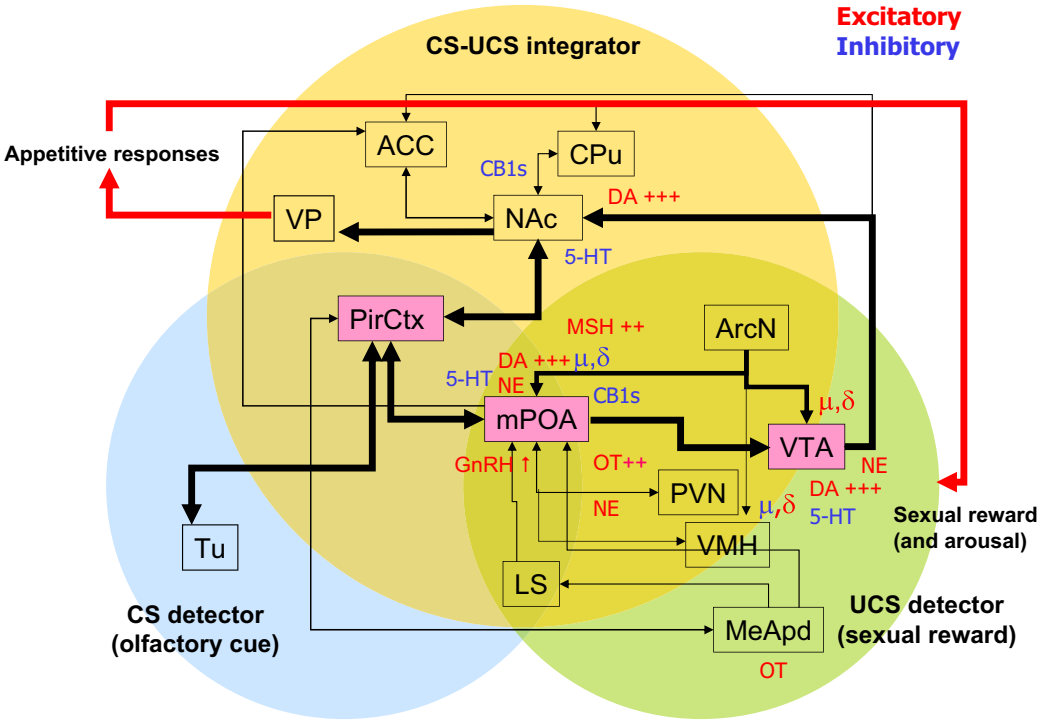

FIGURE 50.28 Neural systems critical for the display of sexual behavior in the rat. This figure is reproduced in color in the color plate section. Appetitive behaviors made toward unconditioned or conditioned sexual incentive stimuli lead to sexual reward that is processed by three interactive systems. Two systems process olfactory stimuli and sexual reward relatively independently, whereas a third, mesolimbic DA system, acts to integrate both the conditioned olfactory cue and its rewarding sexual outcome. Three common regions, the piriform cortex, mPOA, and VTA, are activated in male and female rats by conditioned olfactory stimuli. Opioid actions in the VTA potentiate mesolimbic DA activation, whereas opioid actions in the mPOA inhibit sexual arousal and desire. Neurotransmitter systems or their receptors in red are excitatory for sexual motivation whereas those in blue are inhibitory. Black pathways signify major inputs and outputs of the system. Note that opioids can be excitatory in the VTA, inhibitory in the mPOA, or either in the VMH (depending on the receptor type). A similar system is activated in humans.[63] Abbreviations: ACC, anterior cingulate cortex; ArcN, arcuate nucleus of the hypothalamus; CB1, cannabinoid Type 1 receptor; CPu, caudate-putamen (striatum); DA, dopamine; δ, delta opioid receptors; GnRH, gonadotropin releasing hormone; LS, lateral septum; MeApd, posterior-dorsal nucleus of the medial amygdala; mPOA, medial preoptic area; MSH, melanocyte stimulating hormone; μ, mu opioid receptors; NAc, nucleus accumbens; NE, norepinephrine OT, oxytocin; PirCtx, piriform cortex; PVN, paraventricular nucleus of the hypothalamus; Tu, olfactory tubercle; VMH, ventromedial nucleus of the hypothalamus; VP, ventral pallidum; VTA, ventral tegmental area; 5-HT, serotonin. *Source: Adapted from Pfaus et al.*[683]

stimuli" to activate cortical, limbic, and hypothalamic circuits involved in the facilitation of sexual arousal and desire and/or in the suppression of inhibitory systems (Figure 50.28). Some of those circuits involve selective processing of the sexual stimulation that generates the reward state (UCS), the olfactory stimulus (CS), and a system that integrates the CS and UCS so that animals can focus their attention and engage appropriate forward-directed locomotion toward the CS when it is present.[38,46] What becomes apparent is that systems for sexual reward and incentive responding overlap with systems proposed for sexual (and maternal) bonding (e.g., Ref. 670). These involve the interaction of at least three neurochemical systems, including mesolimbic DA, hypothalamic OT, and opioids that inhibit hypothalamic structures like the mPOA, but sensitize mesolimbic DA systems through a process of disinhibition.[684] This is strikingly similar to Fisher's[685] proposal of three primary emotional systems for mating, reproduction, and parenting, to the mechanism proposed for romantic love in humans,[686] and to the models of human sexual responding proposed by Georgiadis and colleagues.[45,64]

During conditioning, female rats display solicitations indicative of their desire to copulate. If they receive the appropriate stimulation (i.e., distributed CLS during paced copulation) UCS-detector centers become activated (green circle). The posterior-dorsal nucleus of the medial amygdala is sensitive to paced copulation and projects information about it to the mPOA which serves as a main integrator area. The VTA is activated to provide DA to areas important for motivation and decision making (e.g., NAc, ACC) and motor activity (caudate-putamen, ventral pallidum). POMC cells in the ArcN project to the VTA and release opioids that hyperpolarize inhibitory GABAergic neurons (not shown), and therefore increase DA cell firing in mesolimbic and mesocortical terminal regions. The ArcN also projects α-MSH and opioid terminals to the mPOA to facilitate solicitations and reward, respectively. OT terminals from the PVN may release OT into the mPOA to facilitate reward and bonding. Concurrently the Tu (blue circle) and PirCtx sense the CS. PirCtx projects olfactory information to the mPOA and to the NAc to strengthen the incentive value of the CS. Exposure to the conditioned odor alone will activate the common core areas (pink boxes) which trigger motivation and integrate information (yellow circle) about males that bear the CS. Serotonin (5-HT) and endocannabinoid (CB) release and binding in the cortex, limbic structures, and hypothalamus, is associated with an inhibition of the excitatory mechanisms. In animals with a well-developed visual system, like humans, visual CSs likely provide the dominant priming cues, although auditory and olfactory cues should not be overlooked.

CONCLUSION

The study of sexual behavior in animals and humans has come a very long way since the mechanisms of sexual arousal and copulatory responding, and their hormonal and rudimentary neural bases, began to be studied in the 1960s. In particular, the advent of PDE-5 inhibitors for the treatment of erectile dysfunction in men opened up new vistas in the pharmacology of sexual behavior that thrust previous "basic science" studies of the role of different neurotransmitters in sexual behavior into the light of translational clinical science relating to human sexual function and dysfunction. Animal models of a variety of human sexual responses were determined that had predictive validity.[31] It became clear from brain imaging studies in a variety of species using immediate-early gene expression as a measure of activation, and from fMRI or PET studies as measures of activation in humans that a conserved set of neural pathways and neurochemical systems exist in vertebrates to excite and inhibit sexual behavior. Some of those systems are general, and modulate responses to all unconditioned and conditioned excitatory stimuli (e.g., the mesolimbic DA system and its role in incentive motivation) or inhibitory stimuli (e.g., the mPFC and other cortical systems that mediate behavioral inhibition as part of executive function). Other systems are more specific and mediate the autonomic control of genital arousal and the sexual approach and solicitation behaviors that females display as ovulation approaches. Those pathways share functions for parental behavior, feeding, and drug addiction although some, like feeding and sex, may be mutually inhibitory. To what extent do drugs of abuse utilize and usurp the sex and bonding pathways? Understanding the interrelation of these systems, how they are activated by hormones and/or experience, and how experience can override hormonal priming, is a very promising avenue of cross-translational research. Understanding the similarities of bonding to addiction may well prove useful in the treatment of drug abuse or other obsessive-compulsive addictions.

New data always raise new questions but also reframe some very old ones in the literature that have never been resolved. Several of these are outlined below.

What Can Studies of Female Sexual Behavior in Other Species Tell Us About Hormonal Influences on Sexuality in Women?

Much has been learned concerning the neuroendocrine processes and cellular mechanisms by which steroid hormones influence reproductive behaviors in rodents and other animals. Although cellular studies in humans are presently impossible to perform, mechanistic studies in rodents may provide clues about the

neuroendocrine mechanisms by which hormones act and interact in the brain to influence behavior in all species, including humans. A number of basic principles have been derived from work in nonhuman species. For example, these studies demonstrate the importance of considering the timing of hormone treatments, the dosage of hormone, specific hormone used within a particular class of hormones, form of hormone (e.g., long-acting esterified estradiol or nonesterified estradiol), interactions between hormones, the role of steroid receptor coactivators, route of administration, peripheral factors that may influence hormonal response, and the possible mechanisms of action by which hormones and other factors may influence hormone action and subsequently, sexual behaviors.[687]

These major advances in our knowledge belie a continuing gap in our understanding. In particular, scientists are usually forced to measure either behavior, neurochemistry, electrophysiology or neuronal structure, often in a limited time window or with a specific neuroanatomical focus. A major frontier is to understand the causal sequence of these dynamic, network-wide events. Another major frontier is to understand the relative contribution of each of these hormone-induced changes to behavior, given that so many systems are being regulated simultaneously.

At a more granular level of analysis, recent work has identified different cell types in the VMH; however, the wiring diagram for these neurons is unclear. A better understanding of the neurochemistry and connectivity of these neurons would explain in a concrete manner the apparent excitatory and inhibitory controls of lordosis behavior. At present, the functional significance of the diverse effects of estradiol on the dendritic arbors of these cell types is unclear. Detailed knowledge of VMH microcircuitry would help explain how and to what end estradiol exerts these cell-type-specific effects. Furthermore, our present understanding of estradiol-induced changes in VMH dendrite structure is largely divorced from our knowledge of changes in neurochemistry and electrophysiology. A fascinating future direction will be to determine the interplay between changes in synaptic connections and neurotransmission.

What is the Nature of Female Orgasm?

A critical question that continues to generate controversy concerns the existence of a "G-Spot" that when stimulated properly leads to a "deep vaginal orgasm".[688] Still others argue that such an anatomical entity does not exist[689] citing clinical or case studies of women who have never found theirs despite trying. It may well be the case that not all vaginas are constructed the same way, and that internal sensory inputs come in various sizes and shapes. The "G-Spot" may correspond to an internal portion of the clitoris that has differential sensitivity in different women. It is also the case that experience with external CLS as a sole source of sexual stimulation and orgasm may well preclude the exploration of other stimulation points, especially those that might be hard to get to and are never stimulated adequately by a sex partner. fMRI studies of external and internal clitoral/G-Spot stimulation and subjective awareness could help to solve this issue. Indeed, Komisaruk and colleagues have used fMRI to examine brain activation in women self-stimulating to orgasm[690] and it would appear that orgasms can be induced from external clitoral, internal clitoral, and/or cervical stimulation,[691] despite differences in the areas of activation. How these differ in subjective quality could be examined using validated measures such as Orgasm Rating Scale.[692]

A similar problem exists in the animal literature. Although it is clear that VCS and not CLS potentiates estrus termination, it is not known whether paced CLS, VCS, or both, lead to the reward state necessary for the induction of CPP and/or partner preference. Moreover, it has not been established that the penis of the male rat actually makes contact with the cervix during intromission, although the ejaculatory plug of the male forms around the cervix and pubic bone, which would provide intense and continuous VCS when it occurs and until the plug is removed from the vagina. However, the rate and duration of intromissions is higher in paced vs nonpaced conditions.[523] This, and not the presence or absence of ejaculations, is key in the induction of estrus termination and in the neuroendocrine responses (e.g., nightly prolactin surges) that facilitate pregnancy. Erskine[74] has argued that paced copulation results in stronger intromission thrusts, which may well stimulate both the clitoris and cervix.

How Does Awareness of Sexual Incentives Change across the Menstrual Cycle?

More attention needs to be paid to the menstrual cycle and how it affects women's reactions to sexual incentive cues. These could build upon and extend current knowledge about autonomic, emotional, and cognitive changes across the cycle as they relate to the perception of, and reaction to, external sexual stimuli. Those perceptions could then be examined in terms of brain activation following the presentation of stimuli through goggles worn by the subjects. In this vein, cognitive tasks that examine changes in relative attention toward explicitly sexual visual cues presented either above or below conscious awareness could be used in conjunction with physiological measures of sexual arousal to examine how the two are altered across the cycle (see below).

Will There be Drug Treatments for Sexual Arousal, Desire, and Orgasm Disorders?

Disorders of sexual arousal, desire, and orgasm affect a sizable proportion of pre- and post-menopausal women world-wide depending on the criteria used to define the disorder.[693] This can occur as a function of hormone or neurochemical imbalance, genetic "proneness" to inhibition, depression and other mental illness, and the use of oral contraceptives that generate negative steroid feedback.

As noted above, the development of treatments for sexual disorders in women has benefited greatly from preclinical analyses provided by animal studies. Such studies can examine mechanisms at different levels of analysis (e.g., neuropharmacological to molecular) in ways that simply cannot be done in humans. This requires a complete analysis of the behavior of the animal "models", and some degree of predictive validity that what is being observed in the particular animal model corresponds to the sexual process that requires treatment. In turn, this requires a conceptual understanding of the functional endpoint. For example, approach and solicitation in female rats or macaques serves the same purpose as approach, flirtations, and maintenance of eye-gaze in women who have found someone sexually alluring, This is a critical behavioral juncture: in those with desire disorders such behavior simply does not occur. In extreme cases it is not even thought of. What remains in many women is arousal without a proper context and no sexual incentive to blame it on. Others lose the arousal component as well. And of course, without this there is little chance of sexual gratification, leading to sexual interactions that are likely aversive. This may especially be the case if the woman is prone to inhibition (e.g., Ref. 694).

In some women this is remedied easily by psychodynamic therapies, whereas in others it is not. Such women may well have a physiological blunting of response that is due to hormonal or neurochemical systems that either are no longer operating properly to excite arousal and desire (as may occur in many women during and after menopause), or overactive inhibitory systems that have come online for a variety of reasons, some of which may be genetic and due to an increased sensitivity to sadness and depression (e.g., overexpression of the long allele form of the promoter regions of the serotonin transporter gene[695]).

The discovery of potential pharmacological treatments for arousal and desire disorders in women have been largely serendipitous, with the prosexual effects of the MC-4 receptor agonist bremelanotide discovered during clinical trials of the potential tanning drug MT-II[696] and the sexual effects of flibanserin discovered during its trials as a potential antidepressant.[642] The potential of testosterone as a therapy for the treatment of sexual arousal and desire disorders after menopause was first shown in studies where it was added as an adjunct to estradiol.[138] Current treatments with testosterone include a transdermal testosterone patch (Intrinsa) and labial gel (Libigel), both of which produce rather continuous penetration of testosterone into the circulation. Although these have positive efficacy in the treatment of arousal and desire disorders,[697] they do not mimic the normal testosterone rise during ovulation.[698] The efficacy of applying testosterone as a sublingual bolus was advanced by Tuiten et al.[699] and recently shown in clinical trials that applied it in conjunction with a PDE-5 inhibitor or 5-HT1A agonist to treat hypoactive desire induced by either a "bottom-up" lack of genital sensitivity[700] or an abundance of "top down" inhibition over sexual incentive cues.[694] The first effect has been modeled in female rats.[71] The dose of testosterone is extremely small, making it likely that its action is only in the brain. The PDE-5 inhibitor acts in the periphery to relax smooth muscle in the genitals, allowing for more rapid and complete engorgement. Approximately 4h after administration, the brain is "ready" for sex, having undergone genomic changes induced presumably by testosterone that allow both genital arousal and sexual incentive stimuli to be registered and integrated. Essentially this "tricks" the brain into thinking that ovulation has just occurred. The combination is reported to be well tolerated and devoid of untoward side-effects in a number of treatment regimens. A major advantage is that the combination can be taken "on demand" prior to sexual activity.

It is impossible to know at this point whether any of these drugs will be approved for the treatment of hypoactive sexual desire, interest, and/or arousal. However, as work continues to enhance our understanding of the neurochemical systems involved in sexual excitation and inhibition, it is likely that other drugs will be subjected to clinical trials. It has been predicted that combined pharmacological and traditional talk therapies will have better efficacy than either alone.[701] However it is not yet known whether some women, pre- or post-menopausal, will retain their restoration of sexual arousal and desire if the pharmacological treatment is discontinued. All of this could be modeled in rats or other species using appropriate behavioral analyses. It will also become vitally important to understand how testosterone or other androgens are working in the female brain. Although a good starting point is to examine whether they operate on classic intracellular or membrane bound receptors, it may also be the case that they are aromatized into estrogens to induce their actions. This will be important in determining how testosterone sets up the neurochemical substrates that bring sexual incentive cues into conscious awareness in the female brain. Likewise, a greater understanding of the roles played by OT and prolactin in women is critical in helping to elucidate

the mechanisms of orgasm and its aftermath. This may help to differentiate women with orgasm difficulties who have either never experienced them or experienced them fleetingly vs those that have sluggish brain and/or autonomic reactions to sexual stimulation.

How Does Sexual Responding Change with Age?

As the so-called "Baby Boomer" generation is aging and millions of women world-wide are reaching menopause and beyond, more research must be focused on how the aging female brain and body change in response to the hormonally unstable and ultimately hypogonadal condition that menopause engages (see Chapter 37). Women experience changes in cognition and emotional reactions, in addition to bone density and fat deposition as a function of altered metabolism. Sexuality changes during aging as a function of experience and expectation, relationship status, hormonal alterations, and changes in genital sensitivity. Very little is understood about age-related changes in the brains of women in regards to sexuality, and little has been studied in this regard in animals. Aging brings about cardiovascular and metabolic changes associated with conditions such as diabetes and hypertension, which can blunt sexual arousal and desire in both men and women.[35] The treatments for those conditions also have sexual "side effects" that blunt sexual arousal and possibly desire and orgasm,[35] so treatments that restore sexual function must be able to operate independently of those mechanisms and not exacerbate them.

Can We Infer Mechanisms in Females from Similar Mechanisms in Males?

There is no question that substantial sex differences exist in morphology and brain neurochemical function[702] that underlie differences between females and males in response to sexual stimuli,[703] motivation,[704] control of pituitary hormone systems in rodents,[705] pain,[706] and mental health.[707] Some of these mechanisms have their origin in the initial sexual differentiation that occurs in the neonatal brain,[708,709] whereas others do not.[710,711] In particular, McCarthy et al.[711] note that a common strategy in the experimental approach taken by many neuroendocrinologists is "after I understand the phenomenon in males, I'll check whether it's there in females". This approach has also been taken in understanding the hemodynamic of sexual arousal in men and women, often with the assumption that anything that induces penile erection in men should also work the same way for the induction of labial, clitoral, and vaginal erection in women. Certainly PDE-5 inhibitors do increase vaginal vasocongestion but many women are unaware of that, leading to the phenomenon of "discordance" between subjective reports of sexual arousal and physiological measures of such arousal.[151] Such discordance between subjective and physiological sexual arousal is not observed in men unless they have consumed a threshold dose of alcohol that blunts erection but disinhibits subjective arousal and desire.[13,712] There may be several reasons for this. Sex differences likely exist in the cellular response to cyclic vs continuous gonadal hormone output; in the reaction to context; and in individual responses to preexisting stressors. Individual differences also exist in terms of experiences with, and attitudes toward, different types of erotic stimuli that are presented to provoke a genital response. These sex and individual differences conspire to create differences in conscious sexual response which is reflected in brain activation (e.g., laterality in amygdala responsivity[703]). Although it is difficult to find sex differences in the human sexual response cycle, other than the ability of some women to have multiple orgasms relative to men's inability to do so, there are obvious sex differences in the behavior of female and male rodents. Those differences are typically "reverse-engineered" back to differences in differentiation of brain and body, and to specific differences in brain area, for example, the sexually dimorphic nucleus of the preoptic area. Indeed, lesions of the POA in male rats disrupt erection, ejaculation, and mounting behavior, whereas lesions in female rats disrupt solicitations and pacing, and may affect the hemodynamics of clitoral engorgement or the ability of genital stimulation (clitoral and/or cervical) to induce reward. At one level, those functions and the behaviors they subserve seem very different. At another, however, they both involve the responses to genital stimulation that bring about direct sexual contact: solicitations and pacing in females and mounting in males. In fact, in the human brain activation literature, there is an overwhelming preopoderance of sex *similarities* in regional responses to erotic visual stimuli.[45,713] Thus, in rats, the same regions may respond similarly to sexual stimulation but induce output that appears different at a behavioral level. In humans, the behavioral differences may well have disappeared, or been impinged upon by a greater executive cortical/cognitive control over sexual behavior that is mediated more by context and social learning. However, rats clearly have the capacity to make both Pavlovian (stimulus–stimulus) and operant (response-reinforcer) associations between sexual stimuli and sexual responses that can span first- and second-order conditioning, even to the point of conditioning of sexual fetishes for rodent tethering jackets.[28,714]

Context is also an important component of sexual behavior in both female and male rats.[50,70,668] It may well be the case that sex similarities exist in rats, as they do in humans, especially at "higher" emotional and cognitive processing levels that include cortical processing. It

is the case that human neuropsychology and brain imaging studies on incentive sexual responses have focused on cortical and limbic structures, usually with a mention that the hypothalamus is or is not activated, whereas animal studies have focused largely on hypothalamic and some limbic activation of immediate-early gene products, or microdialysis/voltammetric analyses of neurotransmitter turnover. Rarely do neuroendocrinologists study the cerebral cortex, nor do neuropsychologists delve into the hypothalamus, and this confounds our understanding. In fact, analysis of both animal and human brain activation to sexual stimulation reveals nearly identical cortical responses,[64] suggesting that even "higher processes" have been conserved, and that the sexual brain is not simply reducible to hypothalamic processing.

How Does Environmental Context Modulate Hormonal Action on Female Sexual Behavior?

A number of examples were given earlier of nonsteroid hormone factors that can influence steroid receptors, and subsequently behavioral response. In addition, we discussed the idea that stimuli from the environment (mating stimulation) can activate steroid receptors indirectly by ligand-independent activation. This mechanism provides a means by which an array of environmental influences could alter sexual response. Do these mechanisms come into play in the real world of a wild rat? Do attempted mounts by conspecifics or other environmental factors alter the timing of the commencement of sexual behaviors? And might particular contexts or types of stimulation activate steroid receptors in women thus influencing sexual response? It is also important to consider whether incentive cues associated with sexual reward alter steroid ligand–receptor interactions and whether such changes, if any, can compensate for the loss of hormonal priming that occurs in hypogonadal individuals.

Final Remarks

Our understanding of the neurobiology of female sexual function is fast reaching a level of depth and sophistication that rivals that of male sexual function. Animal models of human female sexual function and dysfunction have been proposed that emphasize reward-related learning and cognitive assessment of context. Within these new paradigms, the role of ovarian hormones, gene expression, neurochemical mediation, and the impact of brain lesions (both surgical and accidental) are beginning to be assessed. The sexual brain integrates sensory and hormonal inputs to the hypothalamus to activate incentive motivation and emotional responses in limbic structures. These are under cortical control to inhibit unnecessary or competing responses, or indeed to inhibit sexual responding altogether in inappropriate contexts or situations. The combined actions of these systems optimize female sexual responding, so that what is most rewarding is also likely to be the most reproductively efficient. That these systems are essentially conserved in all mammals—and perhaps all vertebrates—is a testament to our continued survival on this planet, survival that depends critically on the ability of females to approach, solicit, pace, and engage in rewarding sexual activities under their control.

Acknowledgments

Work from JGP's laboratory was funded by grants from the Canadian Institutes for Health Research, Natural Sciences and Engineering Research Council of Canada, and by Fonds de recherche du Québec-Santé (FRQS Groupe de recherche) to the Center for Studies in Behavioral Neurobiology at Concordia University. Work from LFC's laboratory was supported by the National Institutes of Mental Health. Work from JDB's laboratory was funded by several institutes of the National Institutes of Health, including NINDS, NIMH, and NICHD, the National Science Foundation, and the Isis Fund from the Society for Women's Research. SLJ was funded by a doctoral research scholarship from Fonds québécois de la recherche sur la nature et les technologies. The authors would like to thank Drs Sarah Ferri, Bob Meisel, and Mayte Parada for their assistance with figures and Dr Margaret McCarthy for comments and editing on an earlier draft. Finally, the authors are indebted to the scores of trainees and colleagues who contributed to work in their laboratories and to the ideas expressed in this chapter.

INTRODUCTION

The reproductive venture in mammals typically begins with the task of choosing a mate and is followed by the copulatory interactions that culminate in the joining of ova and sperm. For almost all mammals, reproduction and its behavioral correlates do not end there. Most mothers give birth to young that are unprepared for an independent life ex utero, thus requiring that the neonates receive prolonged and intense parental care for their sheer survival. Caregiving by most animals is highly sexually dimorphic,[1,2] so for the majority of offspring this nurturance is provided by their mothers and is termed *maternal behavior*. In animals that have a relatively rare reproductive strategy involving biparental care, fathers will provide *paternal behavior*. In addition, caregiving may not be restricted to the parents and can be displayed by other willing participants, including the neonate's older siblings or other close relatives, who provide beneficial *alloparental behavior*.

Potential caregivers are often not spontaneously interested in young or may not be able to adequately care for them even if interested in doing so. Through the process of pregnancy and parturition, a profound neurobehavioral transition occurs in maternally inexperienced female mammals such that any clumsiness or indifference to neonates, or even outright aggression toward them, is replaced by skillful and tender caregiving. Of course, caregivers other than biological mothers do not gestate and give birth to offspring, so there must be alternative means that promote their nurturant behaviors.

The literature detailing the physiology of mammalian parental behaviors has been reviewed numerous times with tremendous thought and detail. The goal of this chapter is not to again exhaustively review this large literature, and we refer readers elsewhere for details not found herein.[3,4] We instead highlight what we view as the major scientific advances in our understanding of the endocrinology, sensory regulation, and neurobiology of nurturant behaviors displayed by mothers, fathers, and sometimes alloparental "helpers." Similar to the reductionistic study of most mammalian behaviors, the physiology of parenting is best understood in laboratory rodents. This is justified by their exceptionally successful breeding within a laboratory environment, the broad social acceptance for their use in basic research, a wealth of existing knowledge about their endocrinology and neurobiology, and the important belief that such an evolutionarily conserved behavior as parenting will have similar biological underpinning across mammals. Indeed, sufficient investigation of nonrodent parents, including sheep, rabbits, and primates, provides richness to this literature and ample data that allow one to detect potential universals, as well as species-specific mechanisms, involved in this biologically complex, incredibly motivated, and evolutionarily essential mammalian social behavior.

Historical Perspective

Studying the biological mechanisms underlying parental behavior has a century-long history. Some of the earliest research on this topic refers to observational or experimental work on the endocrine, sensory, or neural basis of copulation in rodents and other small mammals; thus, we can presume that the study of parenting behavior arose from and was informed by the study of mating behavior. Cross-fertilization between these fields still occurs today, which is understandable given the discrete set of sensory, endocrine, and neurobiological faculties that animals have available to conduct a wide range of reproductive and other social activities. Contemplating the similarities or differences among behaviors, such as parenting and mating, will continue to provide valuable insight into the biological mechanisms underlying them both.[5,6]

Questions asked in the very early studies of mothering were quite similar to those asked today. For example, the search for bloodborne factors that are released during pregnancy or lactation and involved in maternal caregiving was studied as early as 1925 by Stone,[7] who surgically conjoined virgin and pregnant female rats in hopes of finding accelerated maternal responding in the conjoined virgin. Stone's study was unsuccessful, but reasonable given that parabiotic methods had previously shown that bloodborne factors could travel from one animal to affect the physiology of another.[8] Such parabiotic studies were resurrected by Terkel and Rosenblatt almost 50 years later, who did find enhanced maternal responding in the conjoined virgins (see the section Hormones Most Significant for the Onset of Maternal Behavior in Rodents, Sheep, and Humans).[9,10] The 1920s also saw reports that particular patterns of ovarian activity were correlated with mating in female rats and that ovarian hormones could induce copulation when exogenously administered.[11,12] Either in response to these studies, or simply consistent with the zeitgeist, a flurry of studies emerged soon thereafter reporting that mothering would be displayed by dogs given extracts from the urine of pregnant women[13] and that maternal behavior could be seen in a nulliparous monkey[14] or in virgin rats[15] given crude extracts of the pituitary gland.

The next few decades saw numerous, but often methodologically compromised and contradictory, studies attempting to pinpoint the ovarian and pituitary secretions that could induce or inhibit mothering. Some reported that ovarian hormones could only inhibit mothering,[16] while others found that seemingly any ovarian, pituitary, or thyroid hormone could promote maternal behavior when given alone or in combination.[17] Buried amongst such discrepant results were findings that later became fundamental concepts in the current field studying parenting behavior. For example, prolactin (PRL) has been known for decades to promote the onset of maternal behavior in ovarian hormone–primed nulliparous rats.[18] Also, it has long been known that after hormones promote the onset of maternal behavior in many species, endocrine factors are unnecessary for maintaining the behavior (through a process termed "eroticization" by Steinach[19]) such that ovariectomy or hypophysectomy has little effect on postpartum mothers' general interest in pups.[15,20] Early studies also demonstrated the still often-used paradigm of maternal "sensitization" (see the section Hormones Most Significant for the Onset of Maternal Behavior), in which nulliparous rats with no exogenous hormone treatment and no interest in pups begin to perform caregiving behaviors after repeated exposure to neonates.[15,21] Some early misconceptions about the endocrinology of mothering were not clarified, however, until as late as the 1960s. These included that neither PRL nor progesterone could alone promote maternal behavior in virgin female rats and instead required the assistance of other endocrine factors.[22–24] One of these factors is now known to be estradiol, although at least two studies from the 1960s (which can retrospectively be seen as the beginning of the "modern era" for the biological study of maternal behavior) could not demonstrate estradiol's effects, probably because the temporal sequences of the exogenous hormones given were endocrinologically incorrect (see the section Hormones Most Significant for the Onset of Maternal Behavior).[24,25]

Extant research on the hormonal regulation of caregiving behaviors shown by male mammals also began almost a century ago, but often had the goal of inducing maternal-like behaviors in species of males that were not naturally paternal. These studies included observations of female-like interest in pups by guinea pigs and rats that were peripubertally castrated and given ovarian grafts[19,26] and the display of maternal-like behavior in male rats given anterior pituitary implants during adulthood.[27] Brown has more recently criticized this strategy as misguided for understanding paternal behavior in any naturally biparental species because a female-oriented focus leads one to incorrectly assume that the endocrine and neural factors underlying maternal behavior are similarly responsible for paternal behaviors in fathers.[28] As far as we can determine, the earliest work manipulating the endocrine system of any spontaneously paternal male mammal was studies from the 1930s that found no effects of hypophysectomy on the paternal behavior of male laboratory mice.[20] Studies of the steroid hormones involved in a paternal male primate came much later, with Wilson and Vessey's 1968[29] report that castrated male rhesus macaques (*Macaca mulatta*)—albeit a species that is still not particularly paternal in natural environments—are particularly prone to exhibit paternal behaviors and Alexander's 1970[30] suggestion that the androgen withdrawal occurring across seasons in the

more naturally paternal male Japanese macaque (*Macaca fuscata*) was associated with males' increased paternal play with young. As seen in the section Hormones Most Significant for Paternal Behaviors, endocrinological studies of the now exemplar rodent models used to study the natural occurrence of fathering—California mice (*Peromyscus californicus*), prairie voles (*Microtus ochrogaster*), and dwarf hamsters (*Phodopus campbelli*)—began to emerge just less than two decades ago.

With regard to the sensory control of parenting, there was evidence 80 years ago that blinding or anosmia had little effect on nest building or other maternal behaviors in postpartum rats. Beach and Jaynes[32] later systematically provided many additional insights into this question, again partly drawing on previous work studying the sensory control of copulatory behavior in rats and other small mammals.[33,34] By studying the effects of individual and multiple desensitizations on retrieval of pups, Beach and Jaynes laid the groundwork for our understanding that maternal responding in rats was under "multisensory control." More recent studies re-examining the sensory control of retrieval and other maternal behaviors in primiparous laboratory rats, and the responses of human mothers to infant sensory cues, support many of Beach and Jayne's early conclusions that no single sensory modality is indispensable for most mothering behaviors (see the section Sensory Control of Maternal Care).

Starting in the 1930s, electrolytic or aspiration lesions were employed to study the central nervous system control of maternal behavior, but these studies produced discrepant results for decades.[35] The cerebral cortex was the first focus of this work and, once again, it took some lead from research that had unsuccessfully sought to find the cortical "sexual center" in male rabbits.[36] In his studies examining cortical control of mothering as an exemplar innate behavior, Beach found that the amount of cortical tissue loss was proportional to the temporospatial disorganization of the females' maternal behaviors but that the location of the cortical loss was mostly irrelevant.[37,38] Around the same time, Stone[39] and Davis[40] also reported that substantial decortication abolished maternal behavior. Later experiments did indicate cortical specificity for mothering,[41] though, and suggested that earlier cortical lesion effects on maternal behavior were partly due to subcortical damage.[42,43]

The first clear evidence for a subcortical influence on caregiving behaviors came from Fisher in 1956,[44] who described how nest building and sometimes retrieval and licking the pups could be elicited in a small number of male rats that received infusions of sodium testosterone sulfate into the medial, but not lateral, preoptic area. Prepartum lesions of the ventromedial preoptic area were later reported to have no consequence on postpartum maternal behavior, while ventromedial nucleus lesions elicited infanticide.[45] Given what we now know about the roles of the preoptic area and ventromedial hypothalamus in maternal behavior (see the section Brain Control of Maternal Behaviors), both of these findings would be surprising if reported today. Other studies around this time found that lesions of the lateral hypothalamus, septum, hippocampus, or mammillary bodies disrupted mothering in female rats[42,43,46,47] and that lesions of the septum and cingulate cortex could sometimes produce negative consequences on mothering in postpartum mice.[48,49] It will be seen in this chapter that significant advances in experimental methodology—including more widespread use of and greater sophistication in neuroanatomical tracing, the ability to use genomic responses or regional oxygen utilization to visualize the activity of multiple brain sites simultaneously, and the development of techniques to manipulate the rodent genome—have permitted the field to move away from using lesions to conduct this type of site-by-site analysis of the neural structures required for parental behavior and instead provide a more network- or integrative systems-level understanding of how the brain controls caregiving behaviors (see the section Brain Control of Maternal Behaviors).

COMPONENTS OF PARENTAL CARE

Successful parenting results from parents' increased attraction to infants, the perfection of infant-directed caregiving behaviors, and modification of existing capabilities that are not even oriented toward the offspring but nonetheless promote their survival. Some of these modifications in non-offspring directed behaviors include blunted emotional reactivity that may help parents focus on the needs of their young,[50] enhanced cognitive skills that may optimize parental responding to the neonates and other aspects of the environment,[51] and aggressiveness toward potentially infanticidal intruders. This last modification is outside the scope of this review, so we refer readers elsewhere for information about the hormonal and neural control of maternal aggression.[52,53]

It is important to begin the discussion about the components of parental care by first highlighting that the nature of parental attraction to infants differs considerably among species. Polytocous rodents such as laboratory rats, mice, and rabbits that give birth to many offspring can discriminate between their own and unrelated pups, but form no exclusive bonds with them. In laboratory environments, these mothers will indiscriminately care for any conspecific or even nonconspecific neonates. Such generous mothering could be a laboratory artifact, but

instead might be relevant in natural environments when lactating mothers communally nest.[54,55] In contrast to these rodents, maternal sheep form an impressively selective bond with their offspring at parturition that prevents foster caregiving. Unlike either example, most human mothers form an intense bond with their infants, but this bond is not exclusive and the possibility of caregiving toward other infants of course remains.

There are also considerable differences among species in their parental repertoires, which often lies in the fact that parent–offspring interactions are necessarily dyadic, involving reciprocal stimulation between the participants,[56] so adult responses tremendously depend on the characteristics of the offspring. These include the newborn's neurobehavioral competency for independent survival. Neurobehaviorally undeveloped neonates (termed *altricial offspring*) are often offspring of small, short-gestationed mammals, such as rodents, rabbits, dogs, and cats; at birth, they have a limited ability to thermoregulate, locomote, see, or hear. Even more extreme are the altricial young of some species that appear almost embryonic at birth, such as some marsupials that are born after an unusually brief gestation and spend their early postnatal life within their mother's pouch to seemingly finish up what was unaccomplished during in utero development.[57] In contrast to these altricial offspring, relatively neurobehaviorally developed neonates (termed *precocial offspring*) often arise from longer gestating mammals such as sheep, horses, and guinea pigs; they are born furred, with eyes wide open, and are surprisingly mobile. Such differences between altricial and precocial young are relevant for understanding the relationships among the hormonal profiles of nonhuman animals, that of our own species, and females' caregiving behaviors. One salient example is that while both the sheep (~147 days) and human (~280 days) have lengthy pregnancies, sheep give birth to precocious offspring, whereas human offspring are relatively altricial. The durations of hormone exposure in these species are more similar to each other than, say, to that of laboratory rats, but maternal interactions with young at parturition differ tremendously. Thus, the hormonal patterns during and after pregnancy, and the developmental state of the young at birth, must all be considered to accurately uncover the neurobiological mechanisms driving maternal care in any given species.

Based on their developmental stage, one might expect that maternal care is frequent and protracted toward altricial young, but infrequent and brief toward precocious young. This is not necessarily the case. Startlingly, whereas altricial rat pups are in the nest with their mothers for 70–90% of the time,[58] altricial rabbit pups receive only 3 min of maternal care each day.[59] Similarly, precocious ungulates are either "cached" away and visited by the mother just a few times per day[60] or are members of species that follow close behind their mothers and remain within steps of her most of the time.[61] Species differences in the fat, protein, and water content of maternal milk allow such variation in the frequency of mammalian caregiving to exist.[62]

Regardless of the neonate's developmental stage at birth, offspring-directed behaviors may seem to be a seamless thread of activities, but a closer look reveals that they are instead a collection of behavioral routines and subroutines that are appropriate to study both individually and collectively. This study is often facilitated by careful observation of the individual behaviors displayed, and then grouping them into meaningful categories of activities that might involve particular parts of the parents' bodies, are most often temporally associated, or appear to have similar or interdependent purposes. This task can be difficult because not all mammalian parents display the same repertoire of behaviors and universal categorization of parental activities may be impossible. Even so, many researchers have distinguished *active* parental behaviors from *inactive* parental behaviors. Active parental behaviors include many of the hallmarks of caregiving, including establishing a place where mother–offspring interactions can occur, which is often called nest building. For many animals, including most small rodents with altricial young, this involves transporting suitable materials to a central location and manipulating them into a safe and secure nest. Active parenting also often involves carrying displaced offspring from one place to another using the mouth, hands, or arms, or more passively allowing the offspring to cling to the parent's fur to hitch a ride. Carrying or retrieving neonates is easily quantifiable in both the field and laboratory, but it is important to note that its propensity is not universal. It is mostly unnecessary and even impossible in precocious species with heavy or highly mobile young, and it is also rare even in some relatively altricial species. These include prairie voles (*M. ochrogaster*), whose pups are born with teeth that help maintain attachment to the mother,[63] and rabbits who nurse at the bottom of a deep burrow from which the pups cannot easily escape.[64] Cleaning the offspring is another common active parental behavior and is performed by nonprimates by using the mouth to lick or gently nibble, but in primates it also involves the parents' hands.

In many mammals, these active maternal behaviors are often performed in preparation for prolonged periods of inactive nursing, the behaviors involved in transferring mother's milk to the infants. Lactation (i.e., milk production and letdown) is not a behavior, and there is a tremendous amount of information known about this physiological process that can be found elsewhere. (see Chapter 46; and Refs 65,66). With regard to nursing behavior, in response to offspring suckling some mothers undergo a transition from a highly active state to one of inactivity and quiescence, which in laboratory rats, cats, and primates

involves slow-wave sleep.[67–69] Only during these periods of quiescence does milk letdown occur in rats.[70] In rabbits and pigs, suckling elicits behavioral inactivity, but it is associated with increased cortical firing rather than a depression.[71,72] Many four-legged mothers that are simultaneously nursing multiple offspring will assume a distinctive posture, termed *kyphosis*,[73] which involves limb rigidity and an upward flexion of the spinal column. This nursing posture provides additional room for young to breathe, move, and suckle while underneath their mother. Kyphosis is more likely to occur earlier in lactation than later and is the optimal position for milk letdown during early lactation in laboratory rats.[74] In addition to kyphosis, mothers can be readily observed lying prone on top of the young with little limb support or found lying in a supine position next to or under the pups. These latter postures may be especially common when mothers are either fatigued by the rigidity of kyphosis, when offspring are too large for the entire litter to fit under her, or when older pups initiate nursing from a recumbent mother.[73]

CONSIDERATIONS FOR UNDERSTANDING THE HORMONAL REGULATION OF MATERNAL CARE

The hormonal profile of pregnancy and the peripartum period is crucial for supporting the developing fetus, while at the same time prepares "the expectant brain" and the periphery for the expression of maternal behavior and other required physiological processes such as lactation (see Chapter 44). Extensive experimental evidence has demonstrated that estradiol, progesterone, PRL, and sometimes oxytocin (OT) can play crucial roles in the onset of maternal behavior in rodents and ungulates, with the addition of cortisol important in primates. A remarkable feature of the hormonal profiles over a wide range of species is the similarity of the hormones and their temporal course during pregnancy, parturition, and the postpartum period. Another remarkable feature is that not only do the maternal ovaries, adrenals, and anterior pituitary act as hormonal sources during pregnancy, as they do during all reproductive phases, but the placenta and fetus individually and together are also powerful sources of hormones unique to pregnancy that can act peripherally and perhaps centrally.

Basic information about this hormonal profile is essential for understanding the state changes in the female brain that increase maternal motivation and her readiness to provide care to the young. Because these hormones act on the periphery and brain via their respective families of hormone receptors, it is also critically important to understand how reproductive state alters hormone receptor expression, affects the dominance of particular subcategories of receptors, and how these receptors are influenced by their ligands to influence neuronal activity and maternal responding.

In pregnant and postpartum mammals, the hormonal profiles of rodents and humans have been the best studied, but some additional models including sheep have significantly added to our understanding of this topic. Each nonhuman animal model possesses different features of face, construct, and predictive validity for the hormonal basis of parenting in humans, but no single model provides a complete picture homologous to what is known from humans. Even so, each model holds uniquely useful characteristics for examining the emergence and continuation of maternal behavior. For example, a valuable feature of the laboratory rat model is that while rats do recognize their own young, their assiduous and rapid care for the young of other individuals facilitates many laboratory studies. On the other hand, a crucial and fascinating feature of caregiving in sheep is the selective mother–offspring bond, which is based on individual recognition and memory of lamb cues, and which may inform some aspects of maternal bonding in humans.

Correlating hormone levels in the pregnant and parturient female with the expression of maternal behaviors is an important approach to examining the hormonal basis for maternal behavior in all species examined, and really the only approach available to do so in humans. When considering the major changes in the hormonal milieu for the three exemplar species discussed in detail below, it is absolutely crucial to consider the extent to which the maternal brain is bathed in this milieu: that is, whether the blood–brain barrier does or does not prevent the hormones of interest from reaching the brain. It is generally accepted that steroid hormones readily access the brain, but most peptide hormones of peripheral origin are more highly regulated or almost completely restricted from access. Some peptides, including those in the PRL family, gain access via peptide-specific transporter systems that result in cerebrospinal fluid levels being highly correlated with plasma levels.[75] However, less than 3% of most other peripherally circulating peptides without such transporter systems, including OT and arginine–vasopressin (AVP), enter the brain.[76] While there is limited evidence that the blood–brain barrier is not altered by pregnancy,[77] the access of such peptides to the brain during this time has not been experimentally examined in detail, so great caution is warranted when attempting to extrapolate peripheral (plasma and saliva) peptide hormone titers to what may be found in the brain. In addition, the marked advantages of animal models for examining the hormones necessary for the onset of maternal behavior allow experiments that provide causal evidence because the removal of glands

and supplementation of hormones are readily possible. There are substantial limits to such reductionist approaches, however, because disrupting the endocrine and physiological demands of pregnancy, parturition, and lactation can inadvertently confound analysis of the behavioral outcomes of most interest.

The brain itself is also a source of steroid hormones and peptides that act as neuromodulators, including OT and AVP. As would be expected for neuromodulators, site-specific release of OT and AVP has been confirmed and can be independent from plasma levels.[78,79] Although independent brain and peripheral release has been demonstrated, it is also the case that OT and AVP are released intracerebrally at parturition and during suckling in apparent coordination with peripheral release, suggesting a hormonally coordinated linking of central and peripheral events in mothers.[80]

A great deal of recent research on laboratory rats and mice has been devoted to studying how naturally occurring genetic variation among individuals or genetic manipulations reveal important features about the endocrine and other neurochemical bases of mothering. The most gene-specific manipulations for probing the endocrine and neuroendocrine basis of maternal behavior have been carried out with transgenic laboratory mice, and most of these have used global and lifelong knockout (KO) of specific endocrine system genes.[81] It is invaluable to realize that transgenic manipulations of receptors of ligands that mediate the hormonal underpinnings of maternal behavior can have the unintended consequence of altering fertility or the capacity to maintain pregnancy and undergo parturition. This makes it impossible to examine the hormonal and other factors involved in naturally occurring postpartum behavior, but does permit investigation of how these females respond to pups after repeated exposure to them in a maternal sensitization paradigm (described in detail below), which is thought to be non–hormonally controlled. It is also important to recognize that the neurobiological control of maternal-like responses in females that have not undergone pregnancy and parturition could differ from those that have experienced these reproductive events. Furthermore, because different strains of nulliparous rats and mice vary in their baseline maternal responsiveness,[2,82,83] careful consideration of the variability in these baselines is crucial because high spontaneous maternal behavior may be confused with the impact of endocrine system gene KO, which may be subtle in strains with spontaneous maternal caregiving. Thus, there is a heightened requirement in studies of transgenic models to make a faithful comparison of the impact of the genetic manipulation on the baseline postpartum or virgin maternal performance in the same strain. This issue of "background matters" has also been demonstrated for male sexual behavior in gene-disrupted mice,[84] making this a generalizable consideration important for all studies examining the genetics of behavior.

Regardless of the form of genetic or other manipulation, experiments impacting natural postpartum maternal behavior offer the most interpretable data when quantitative information is included about parturition behavior to verify that offspring are delivered alive and cleaned of amniotic membranes, that offspring viability is measured soon after parturition (including litter size and weight in rodents), and that the mothers are lactating normally (including repeated measurement of offspring weight or postmortem mammary gland weights). Because of the dyadic nature of mothering, further crucial inclusions include regularly assessing offspring vigor and replacing any sickly young with healthy foster young of a similar age, and maintaining a species-typical number of offspring for each mother to interact with.

For studies of behavior after global or lifelong knockouts of any protein, it is also necessary to consider the possibility that behavioral resilience or alteration might be due to redundant proteins that take a larger than usual role or compensation by functionally associated molecules that otherwise would not be involved. A further complication is the case in which a ligand normally regulates the expression of its own receptor, for example regulation of the OT receptor by its ligand, but where the receptor is normal even in the absence of OT, suggesting that other molecules have taken over its usual role.[85] Also importantly, the absence of some proteins during development may generate very different functional alterations than if the proteins are absent only during adulthood. While conditional gene inactivation approaches may limit some of these problems by allowing temporal or spatial restriction of the KO or knockin, they bring other issues that have recently been discussed in the context of the androgen receptor KO models.[86,87] Frequently encountered limits of the conditional activation systems include the completeness of the excision (i.e., a knockout that is really a knockdown), the confounding influence of the floxing itself, and the leakiness of Cre activation into off-target cells or tissues. In the best circumstances, proof of effectiveness and target specificity can mitigate these problems, while in the worst cases the KO model being studied does not allow one to make interpretable conclusions.

HORMONES MOST SIGNIFICANT FOR THE ONSET OF MATERNAL BEHAVIOR IN RODENTS, SHEEP, AND HUMANS

Harking back to Stone's early parabiotic studies examining if bloodborne factors were involved in mothering behaviors,[7] Rosenblatt and Terkel reported in 1968 and 1972 that injecting plasma from early-postpartum laboratory rats into virgins, or commingling their

circulatory systems, dramatically reduced the latency to show maternal responding (Figure 51.1).[9,10] Transferring periparturitional blood was by far the most effective. An almost innumerable number of endocrine events occur across the weeks or months of pregnancy and parturition, and up to years of lactation depending on the species. Are they all required for mothering behaviors? Responding to foster pups by laboratory rats increases dramatically in the final days of pregnancy, presumably in preparation for the litter's appearance at parturition.[88] In laboratory rats, the duration of pregnancy before surgically terminating it via Caesarean procedures is positively associated with females' maternal responsiveness, and at least 16 days of rising estrogens and exposure to placental hormones followed by the withdrawal of progesterone is needed for a robust onset of maternal behavior.[89,90] Of course, successful pregnancies normally terminate with parturition, when offspring would naturally first be available to the female. Because some aspects of maternal behavior appear prepartum and are displayed by late-pregnancy terminated rats, the physical processes of parturition are clearly not required for the onset of maternal behavior.

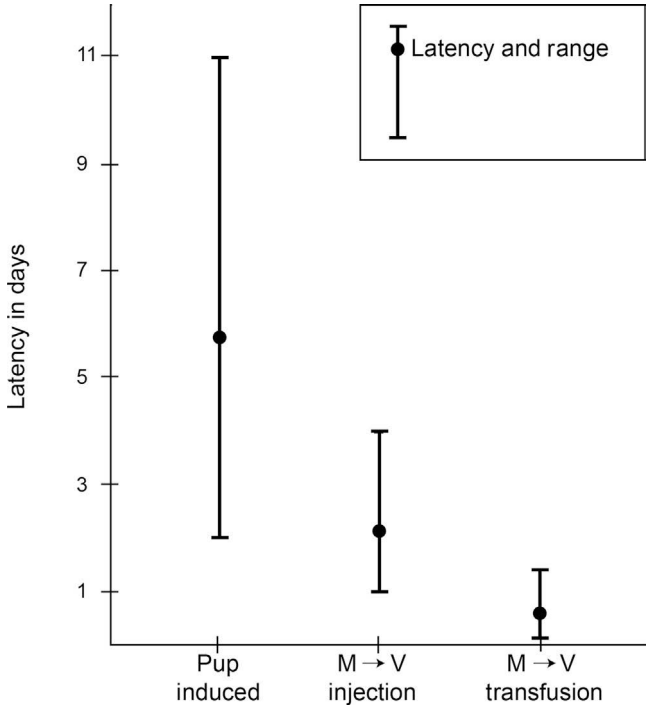

FIGURE 51.1 Mean and range of the number of days of pup exposure for nulliparous female rats to begin retrieving pups. Females were exposed to pups alone (Pup Induced), were exposed to pups after receiving an injection of blood plasma from a recently parturient and maternal female (M→V Injection), or were exposed to pups during and after a 6 h transfusion of blood from a recently parturient and maternal female (M→V Transfusion). Transfusion from a parturient female very rapidly induced retrieval in the nulliparous rats. *Source: Modified from Terkel and Rosenblatt, 1972.*[10]

Even though the onset of mothering does not require the sensory input of parturition, including vaginocervical stimulation, or the ingestion of placentae and amniotic fluid, these factors can still have positive effects on mothering in some laboratory rats.[91,92] Vaginocervical stimulation naturally received during parturition is required, however, for the onset of mothering in many female prairie voles (*M. ochrogaster*)[93] and wild house mice[94] that remain unresponsive to pups or even infanticidal through the end of pregnancy.

In contrast to most laboratory rats, sheep do not become more maternal as parturition approaches and the visceral events of either natural delivery or experimentally produced vaginocervical stimulation are needed for motherhood and development of the mother–young bond. Indeed, epidural anesthesia is a major impediment to the onset of their maternal behavior,[95] and receipt of vaginocervical stimulation must occur within a short time frame before the appearance of a lamb to avoid its total rejection by the ewe.[96] While treatment with exogenous estradiol, progesterone, and central OT can induce maternal responsiveness even without vaginocervical stimulation in ewes, this is much more difficult to achieve than in the rat. In the natural situation, both peripheral and central systems are coordinated by the processes of parturition, and vice versa, for maternal behavior in ewes (discussed further below). In humans, the now common use of Caesarean delivery has revealed that vaginal delivery is not required for their maternal responsiveness, but vaginal delivery is associated with greater maternal neural and behavioral sensitivity to infant cues as well as more positive maternal mental health,[97,98] all perhaps related to the endocrine and other chemical factors released during parturition.

While the hormonally induced changes to the maternal brain instituted by pregnancy and the peripartum period are vital for neural sensitivity to offspring cues and the display of maternal behavior in the early postpartum period, after parturition the presence of hormones becomes progressively less important. The maintenance of maternal behavior is instead regulated by interaction with the offspring, with the dyad becoming an interactive duo that produces changes in maternal behaviors according to the needs of the developing offspring. Indeed, mothers and offspring of probably all mammalian species spend progressively less time with each other as the offspring become more physically and motorically independent.[99,100] A nonhormonal maintenance of maternal behavior is supported by many studies showing that removal of the pituitary, ovary, or adrenal glands does not terminate postpartum maternal behavior.[3] There may be some changes in postpartum maternal behavior after removal of these glands, but they are quite subtle compared to their role in the onset of maternal behavior. For example, adrenalectomy has

little effect on retrieval, nest building, and nursing in postpartum rats, but it does increase how long mothers lick their pups and alters where licking is focused on the pups' bodies.[101] Similarly in the ewe, after postparturitional acceptance of the lamb, hormones are not required for maintaining maternal care and the mother's interaction with the lamb is instead crucial.[102] In humans, postpartum interaction between the mother and infant optimizes ongoing mothering, although there seems to be continuing modulatory roles for maternal OT and cortisol in regulating this interaction.[103,104]

Mothering without Pregnancy or Parturition?

In some species, mothering-like behavior is possible without undergoing pregnancy and parturition—which is sometimes common in parental males, juvenile siblings, or genetically related nulliparous adult females—indicating that there are multiple means by which the neural substrates for parenting can be activated. Most virgin adult and juvenile laboratory rats of both sexes can be experimentally stimulated to perform some maternal behaviors simply by continuously exposing them to pups. Because these caregivers cannot lactate, the health of the foster pups is maintained by once- or twice-daily rotation to lactating surrogates. The emergence of such pup-induced or sensitized maternal behavior in nulliparous female rats usually takes up to 6–10 days of exposure and alters females' behavior from avoiding the pups to avid caregiving. This sensitized maternal caregiving is thought to be hormone independent because it is not prevented or even greatly delayed by removing the adult subject's gonads, pituitary gland, or adrenals before initiating the exposure to pups.[105] The maternal-like behavior of sensitized rats may be impressive, but it does differ from the behavior of naturally parturient females in its deficient retrieval, pup licking, and nursing (Figure 51.2).[106,107] The relationship between sensitized and postpartum maternal behavior has also been compared within subjects, and there is a positive correlation between how rapidly adult nulliparous rats sensitize and how often they later lick their own offspring after giving birth,[108] but there is no relationship between sensitization during juvenile life and postpartum behavior in the same female rats.[109]

Sensitization has also been used in various strains of mice, but both laboratory house mice (*Mus*) and deer mice (*Peromyscus*) have high levels of baseline caregiving, again an important but sometimes overlooked consideration regarding their use for studying the hormonal or neural basis of maternal behavior. There is no evidence that nulliparous sheep are susceptible to any sensitization of maternal behavior, and sensitization has been demonstrated to not be readily achievable in other species, including rabbits.[110]

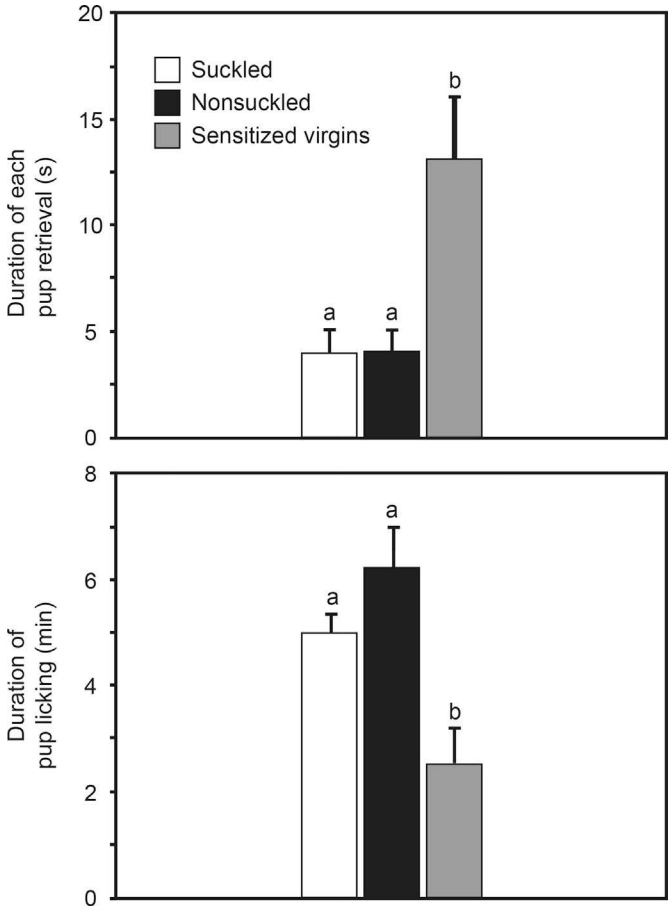

FIGURE 51.2 Duration of time (Mean + SEM) that suckled and nonsuckled postpartum rats, and maternally sensitized nulliparous rats, took to retrieve each pup to the nest (top panel) and spent licking the pups (bottom panel). Different letters above bars indicate significant differences between groups. Maternally sensitized nulliparous rats were deficient in both measures compared to postpartum mothers. *Source: Modified from Lonstein et al., 1999.*[107]

The sensitization paradigm has been combined with knowledge about the hormonal progression of pregnancy to establish that after days 17–19 of pregnancy, female rats are fully maternal within one day of pup exposure. Additionally, treating nulliparous female rats with exogenous hormones for 2 weeks using a profile roughly mimicking that of mid- to late pregnancy can quickly induce mothering. This can even be accomplished in male rats! The optimal sequence of hormones that can instill mothering in laboratory rats, and probably numerous other species, is now known to involve (1) first exposing animals to estradiol, (2) subsequent introduction of progesterone, (3) administering PRL near the conclusion of the ovarian steroid treatment, and (4) the withdrawal of progesterone at the very end of treatment.[111–115]

Hormones are clearly not required for human parenting. The most salient evidence for this is that the adoption of human children in times of need, or simply by preference, yields fully parental adults obviously without

pregnancy or parturition in the adoptive parent. As discussed in the work of Fleming and her colleagues,[4,104] human parental behavior is more heavily influenced by experiential and cultural factors that parents bring to caregiving. Cultural conditions can introduce factors that are unique and in some cases more difficult to the adoptive parent–child dyad (e.g., preadoptive abuse, abandonment, or long-term institutionalization), but adoption in humans is a remarkably robust and successful process for both parents and children under a wide range of circumstances.[116–118]

Endocrine Profiles of Pregnancy Involved in the Onset of Mothering

Laboratory Rodents

Estrogen: Circulating estrogens during pregnancy in rats and mice are generally low and similar to diestrus until about 16 days after insemination, after which there is a gradual increase until parturition,[112,119,120] when plasma levels of estradiol meet and exceed those found during the estrus cycle peak.[121] Soon after parturition, there is a further brief increase during the postpartum estrus (leading to sexual receptivity ~9 h later), but circulating estrogens are otherwise low during early lactation, then slowly rise across midlactation and even more as weaning and the resumption of estrus cyclicity approaches (Figure 51.3).[122,123] In early pregnancy, the corpora lutea resulting from the liberated ova produce the steroidogenic substrates for estrogen synthesis, as well as the estradiol itself, so only estrogens are produced in large amounts.[124] This differs from late pregnancy, when the placentae produce the androgens that are released into the general circulation and from which estradiol is then produced by the corpora lutea.[125–127] During lactation, the corpora lutea of pregnancy regress, and the corpora lutea of the postpartum ovulation become functionally dominant.[123]

The presence of estradiol always induces a more rapid onset of maternal behavior than that observed in its absence.[3,4] It has a crucial role in the preparatory nest building displayed prepartum and for the immediate onset of all other maternal behaviors at parturition. A rapid onset of maternal behavior can be induced by just the first 10–13 days of pregnancy, or in nulliparous rats by 10–13 days of treatment with exogenous estradiol, if the animals are then given a triggering dose of estradiol.[89,102,128,129] In fact, depending on the females' endocrine state, even a single high dose of estradiol benzoate can shorten the latency for nulliparous rats to show maternal behavior.[129] In studies using a surgical model involving hysterectomy of pregnant females with or without ovariectomy, there is a much more rapid onset of maternal behavior when the ovary and its secretion of estradiol remain intact.[102] However, this does not occur

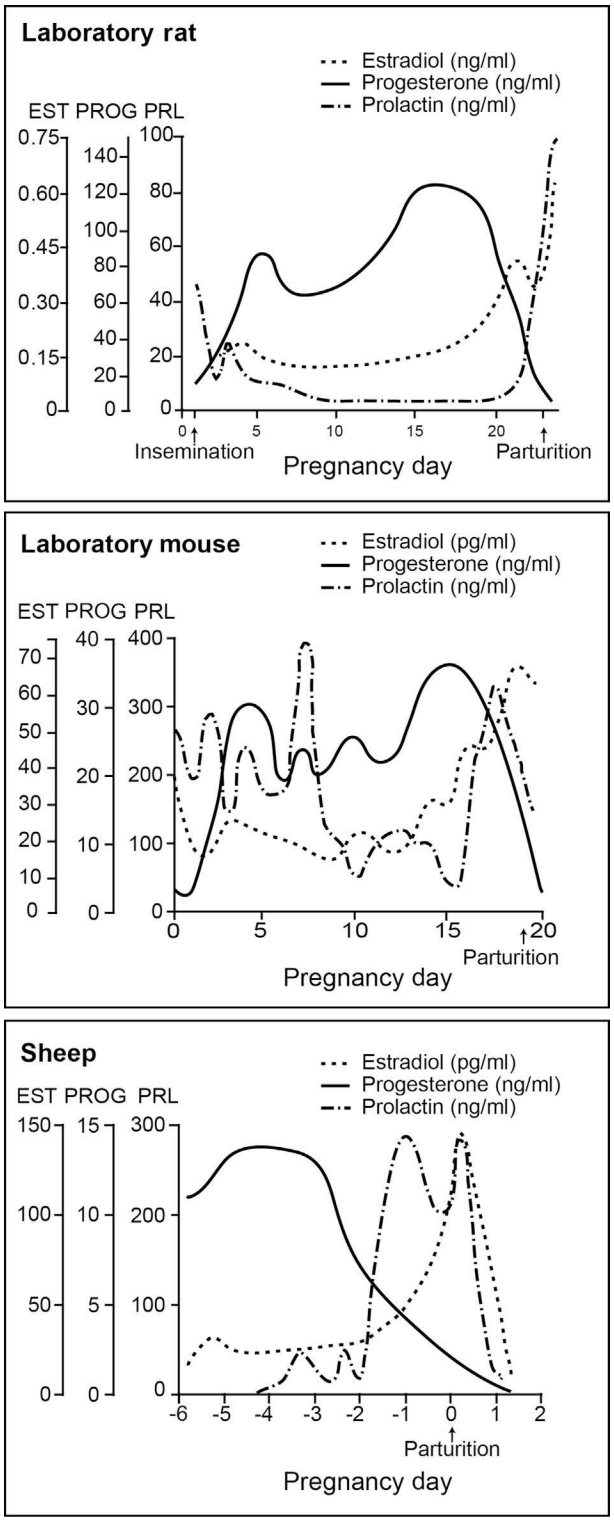

FIGURE 51.3 Schematic representation of circulating plasma levels of estradiol (EST), progesterone (PROG), and prolactin (PRL) across pregnancy and parturition in laboratory rats, laboratory mice, and sheep. *Source: Modified from Rosenblatt and Siegel, 1981.*[102]

until after day 13 of pregnancy and is sensitive to the postsurgical timing of when young are introduced.[90,130] Most of estradiol's effects on the maternal brain and behavior have long been assumed to occur genomically through activation of estrogen receptors, which have been well characterized in their distribution and density in relevant brain regions across pregnancy.[131,132] Indeed, most of the manipulations used to induce a rapid onset of maternal behavior involve a long time course of action consistent with that required for steroids to act genomically. More recently, however, Stolzenberg et al.[133] revealed the argument that estradiol also appears to act over a shorter time course, theoretically via nongenomic membrane estrogen receptors, for a rapid onset of maternal behavior.

Mice of both sexes with a lifelong and total absence of estrogen receptor alpha (ERα KO) have profoundly impaired reproductive function.[81,134] Thus, testing maternal behavior in these infertile virgin ERα KO females, which have a high rate of infanticide (40–80%),[135] is necessarily restricted to sensitization. Responding to pups appears to be reduced in ERα KO females,[81] but others have demonstrated in aromatase KO mice of a similar background strain that maternal responding does not depend on estrogens.[136] Neuron-specific conditional KO of ERα or estrogen receptor beta (ERβ) indicates that the global reproductive deficits are primarily due to the loss of ERα.[137] While global ERα KO and double ERKO (i.e., both α and β isoforms) limit the ability to study maternal behavior in naturally parturient animals, these ER knockouts have revealed valuable information about estradiol's influence on anxiety[138] and its molecular mechanisms. It had been suggested that estrogens can still act in these classical ERKO models via a membrane receptor or other novel ER-binding molecule (a possible novel ER transcript),[84] but others have found from another global ERKO model that does not contain this transcript that it has a limited role in reproduction.[134]

Although ERKO models generally have notable limits on the questions they can be used to ask, they do inform our understanding of maternal behavior in the larger context of emotional state and the neurobiological mechanisms of steroid action. The hope is that as transgenic applications develop,[139] the temporal and spatial limits of these earlier models will yield more specific information. For example, a conditional ERKO aimed only at the gonadotrophs of the anterior pituitary has been developed and resulted in subfertile females that completed pregnancy and parturition, but had smaller and fewer litters; unfortunately, no analysis of maternal behavior was included.[140] Downregulating ERα using RNA interference is another promising approach to achieve higher temporal and spatial resolution for studying estradiol's influence on mothering.[141]

Testosterone: Testosterone is an obligatory precursor to estradiol synthesis in the ovary and brain, usually in a paracrine or intracrine manner that rapidly produces estradiol, so there is usually no increase in plasma testosterone.[142] During late pregnancy, however, the rat placenta produces the androgenic substrate for synthesis of most estrogens. This results in a lesser known rise in circulating androgens (testosterone and dihydrotestosterone) from very low levels (0.4–0.8 ng/ml) early in pregnancy to sustained and remarkable levels (2.8 ng/ml) during the second half of pregnancy.[125,143] These levels are very high compared to that seen in cycling females, in which testosterone and dihydrotestosterone are found at 0.2 ng/ml to 0.4–0.5 ng/ml preceding the surge in luteinizing hormone.[127,144] These levels in late-pregnant females are even higher than those seen in male rats (1.1–2.3 ng/ml).[145] Immediately after parturition, androgen levels drop and remain low until estrus cycling recommences.

Such elevated plasma testosterone has not been reported in pregnant sheep, but high testosterone titers have been observed in pregnant mice[146] and rabbits,[147] where again the locations of estradiol synthesis and its testosterone precursor are in different tissues. While no studies have examined the effect of this androgen surge on maternal behavior in rats or mice, in rabbits it is perhaps uniquely involved in their nest building because it loosens chest hairs that females pull out and use to line the maternal nest.[148]

Androgens act on androgen receptors (ARs) located in specific tissues of the reproductive system and sites within the brain. In the brain, ARs exist in abundance in both males and females, are found on both neurons and glia, and act genomically as well as possibly nongenomically.[149,150] The AR has been a target in KO models for studying parenting and other aspects of reproduction. The first models were naturally occurring—complete androgen-insensitivity syndrome (CIAS, also known as testicular feminization mutation) in males and the XO genotype in females in which the single X chromosome had a mutated AR gene—but conditional gene-targeting approaches more recently yielded both global and tissue and cell-specific ARKO models.[86,87] One conditional model targeting the brain revealed that AR-mediated androgen action is not required for ovulation, mating, pregnancy, or lactation.[151] These females are less fertile and have fewer pups, but lactation is sufficient for normal growth of the smaller litters. No studies using these ARKO models have provided a detailed analysis of the females' maternal behavior.

Progesterone: Beginning as early as days 3–5 of pregnancy in the laboratory rat, circulating progesterone levels climb as high or up to 10-fold higher than the peak values seen during the estrus cycle and remain there for 17–18 days. Thus, a sustained high level of progesterone is one of the most remarkable features of the endocrine milieu of pregnancy. Beginning around day 19 of

pregnancy, progesterone levels markedly fall such that at parturition, they are lower than that seen at any point in the estrus cycle (Figure 51.3).[120,152,153] The temporal course of circulating progesterone in pregnant laboratory mice varies somewhat among strains, but generally peaks at days 15–17 of pregnancy and falls on the day before parturition (day 18) to half their peak levels.[146,154] On the day of parturition in rats and mice, levels fall even further after a brief postpartum estrus to very low levels, but at least in laboratory rats there is a mostly ignored elevation again between postpartum days 3 and 10, and thereafter it remains low until postweaning cycling resumes.[155]

Progesterone is the *sina qua non* for maintaining pregnancy in mammals, and withdrawal of progesterone at the end of natural pregnancy or a pregnancy-like regimen of hormones is necessary for the onset of maternal behavior. Progesterone has been demonstrated in pregnancy-terminated (hysterectomized and/or ovariectomized) and at-term pregnancy models to prevent an inappropriately early display of maternal behavior, and withdrawal of progesterone prepartum facilitates a rapid onset of mothering.[130,156] Similarly, nulliparous rats treated with exogenous progesterone require its removal for estradiol to potently stimulate mothering.[157] Evidence that progesterone at the end of pregnancy masks heightened maternal interest, rather than itself increases maternal interest simply by its withdrawal, is indicated by the fact that nulliparous rats given only progesterone followed or not by its withdrawal remain disinterested in pups.[158]

Importantly, progesterone only masks maternal behavior during late pregnancy or near the end of a pregnancy-like hormone regimen because during the early phase of estradiol exposure, progesterone synergizes with estradiol to promote maternal responding. In nulliparous rats, progesterone pretreatment reduces the dose of estradiol needed to reduce maternal sensitization latencies, and the combination of estradiol and progesterone followed by withdrawal of the latter is more effective in stimulating maternal responding than providing estradiol alone.[112,157] In laboratory mice, prepartum nest building depends on high circulating progesterone.[159] The onset of lactation also requires the presence and withdrawal of progesterone.[65,66] It was noted above that progesterone rises again beginning around the third postpartum day in rats. Early work suggested that the absence of the ovaries has no effect on postpartum maternal behavior,[160] although recently it was reported that postpartum ovariectomy slightly reduces maternal licking of pups and that nursing is somewhat impeded when circulating progesterone is experimentally elevated during early lactation.[161] The opposite result, increased nursing, is found when progesterone is elevated during later lactation, so perhaps the second decline in progesterone starting around day 10 postpartum contributes to the decline in maternal behavior in rats.[162]

The first progesterone receptor KO (PRKO) mice were designed to delete both the A and the B forms of the receptor, and both sexes sustained numerous endocrine deficits, including that females were unable to ovulate.[163] Subsequent work with isoform-specific deletions of either PR form A or B has demonstrated that PR-A KO alone leads to sterility in female mice, as well as severe uterine dysfunction, while hormonal responses of the mammary gland are mediated by PR-B.[164] Homozygous PR-B KO females are fertile, maintain pregnancy, and deliver viable, full litters of pups.[165] Unfortunately, nothing has been reported regarding the maternal behaviors of any PRKO females.

Adrenal steroids: Normal adrenal function and circulating levels of adrenal steroids optimize fertility and other needs of the female and her offspring during pregnancy, parturition, and lactation. Basal glucocorticoid levels rise in rats during late pregnancy and particularly at parturition, and thereafter return to levels more typical of early pregnancy, although there may be a flattened circadian rhythm of glucocorticoid release.[166] A notable condition of the postpartum period is that it is a time of stress hyporesponsiveness. When confronted with a variety of potential physical or psychological threats, females during mid- to late lactation exhibit a blunting of the hypothalamic–pituitary–adrenal response (see Chapter 44; and Ref. 167). An interesting feature of this hyporesponsive period is that some stressors, such as predator odor and intruders, evoke a normal stress response when the dam is in the presence of the pups,[168] suggesting a gating of the response that involves the cognitive capacity of the mother and her assessment of immediate threats to the litter.

Despite these complex alterations in glucocorticoid release in mother rats, there is no evidence that they are absolutely required for maternal behavior, as adrenalectomized females initiate and then maintain maternal behavior.[169] Detailed early studies of maternal behavior showed that the presence of the adrenal glands does facilitate the speed and completeness of caregiving in naturally pregnant females,[170,171] but others found that adrenal secretions inhibited maternal behavior.[172,173] More recent work demonstrates small but significant decreases in some components of mothering after adrenalectomy, including licking (rarely measured in early studies) and the duration of time spent in the nest, both of which could be increased by exogenous corticosterone obtained through the females' drinking water (Figure 51.4).[101] However, chronically high postpartum corticosterone via daily injections of the hormone reduces nursing,[174] and it has also been recently seen that an acute injection of the synthetic glucocorticoid, dexamethasone, impairs retrieval of pups and reduces the duration of nursing over a 30 min period following injection. Acute injection of dexamethasone also reduced peripheral PRL

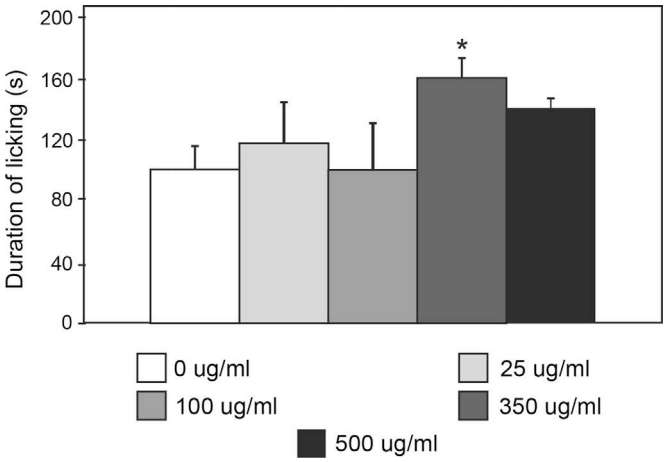

FIGURE 51.4 Duration of time (Mean + SEM) spent licking the pups by adrenalectomized, postpartum rats that received various doses of corticosterone in their drinking water. *Significantly more pup licking compared to dams that received no replacement corticosterone. *Source: Modified from Rees and Fleming, 2004.*[101]

and OT levels measured in the dams after a 15 min suckling interaction with pups, which may be a cause or consequence of the deficit in maternal behavior.[175]

In nulliparous rats, higher endogenous circulating corticosterone tends to delay maternal sensitization, and after adrenalectomy exogenous corticosterone given through drinking water or a subcutaneous pellet reduces pup licking and time spent in the nest by sensitized females that are already maternal.[176] The different consequences of adrenalectomy and/or chronic corticosterone replacement on the maternal behavior of parturient and sensitized rats clearly highlight that the endocrine and other physiological determinants of their mothering are not identical. It also appears from these studies that the effects of adrenal steroids on maternal responses may have a sphere of subtle influences that require careful consideration, including whether foster or related pups are used during testing and the postpartum stage and degree of experience of the mothers. In sum, the literature supports the view that corticosterone is not necessary for the initiation or maintenance of maternal behavior in rats, but that it modulates the intensity and timing of caregiving behaviors. It is essential to note that even such subtle influences on maternal behavior can have a significant impact on offspring development.[177]

Prolactin and its family members: PRL and three functionally related but less well-known hormones, decidual luteotrophin and placental lactogens I and II, are important during rat pregnancy because they help maintain steroidogenesis in the corpus lutea of pregnancy and prepare the mammary glands for lactation.[66] Despite their structural differences, all four protein hormones exert their effects by binding to the short or long form of the PRL receptor. Both forms of the PRL receptors are expressed and regulated differentially across reproductive states in the corpus lutea, mammary gland, and brain (see Chapter 12; and Refs 178–182).

The source of PRL itself during the estrous cycle and during early pregnancy is the anterior pituitary. During early pregnancy, PRL is secreted in two daily surges, one nocturnal and one diurnal.[183,184] At the same time, decidual luteotrophin is secreted by the decidua of the uterus, so PRL is thereafter no longer required to maintain pregnancy even though the anterior pituitary continues to release it.[181] Subsequently, in midpregnancy serum PRL from pituitary origin is substantially lower than what is found in cycling females, and decidual luteotrophin disappears while placental lactogens, first I and then II, become the predominant lactogens in the general circulation.[120] During the second half of pregnancy in rats, pituitary PRL secretion is inhibited by placental lactogens through negative feedback on the brain, but this is alleviated in the last few days of pregnancy. The pituitary then releases a substantial prepartum surge of PRL (Figure 51.3).

During the postpartum period, PRL has a critical role on the mammary gland for milk production and in the corpus lutea for progesterone synthesis.[123] Of course, suckling stimulation by pups is a powerful regulator of PRL release, such that there is a sharp increase especially when a female rat is separated from and then reunited with her pups. This is observed even after transecting the galactophores (milk ducts), which leaves the sensory capacity of the nipples intact but prevents suckling-induced milk letdown.[185] Maternally sensitized nulliparae do not respond to the presence of pups with an elevation in PRL, though.[186] Across the first 4 days after parturition, PRL levels rise such that they are 2–3 times higher than the maximum of the estrous cycle and remain so during the first 10 days of lactation, after which they decline quickly and remain relatively low until the end of the postpartum period and when estrus cycling resumes.[121,123,183]

PRL greatly facilitates the onset of maternal behavior that is initiated by ovarian hormones. Systemic injection of PRL included in a regimen of exogenous estradiol and progesterone, followed by withdrawal of the latter, notably reduces maternal sensitization latencies.[111,112,187] Moreover, Bridges and colleagues demonstrated that administering these ovarian hormones cannot decrease maternal sensitization latencies in ovariectomized female rats if they have also been hypophysectomized, and that ectopic pituitary grafts can reinstate the hormones' effects.[188] Even so, late-term hypophysectomy does not interfere with parturition or the onset of maternal behavior, which is presumably because by that time placental lactogens have assumed the major role in providing PRL to the maternal brain and periphery.

Access of PRL to the brain occurs via an active transport mechanism, possibly related to the abundant PRL receptors in the choroid plexus.[189] Grattan and colleagues

report that there may also be differential sensitivity, and possibly increased brain access, of PRL to some hypothalamic regions involved in the feedback regulation of PRL by dopaminergic neurons of the arcuate nucleus.[190] There is also evidence that PRL is synthesized by intracerebrally projecting neurons within the brain and in the neurons of somatosensory ganglia, and that it can be released site specifically in the female rat brain independent of peripheral release.[78,191]

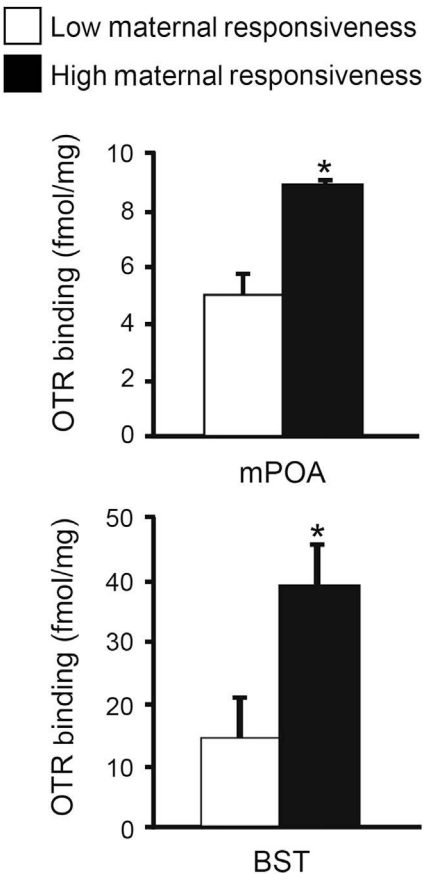
In laboratory mice, postpartum maternal nest building is facilitated by PRL,[159] but estradiol-mediated retrieval in ovariectomized mice that do not already spontaneously retrieve is unaffected by PRL depletion.[192] Mouse models exploring the role of PRL in maternal behavior have included the use of complete knockouts of either PRL or its receptors. As reviewed in depth by Kuroda et al.,[81] the earliest studies of PRL KO mice showed that the maternal responding of the virgin females is normal. Either another PRL-like ligand must be engaged in a compensatory mechanism in the adults or PRL is not absolutely required for maternal behavior in the virgin laboratory mouse. An ontological consideration is that PRL family ligands may crucially act during fetal development in brain regions needed for maternal behavior and that this remains intact because the numerous ligands are not eliminated by the PRL KO alone. These limitations highlight the importance of choosing background strains of mice for KO that are not spontaneously maternal as virgins, and so might not require the hormone in question in the first place. In contrast to eliminating the gene coding for PRL, KO of the PRL receptor gene does diminish maternal behavior.[193] Thus, it has been speculated that there is a role for PRL in these mice that can be filled by other ligands, possibly the placental lactogens acting during pregnancy in subjects with normal PRL receptors, but not in the absence of the PRL receptors.[4]

Oxytocin: OT is released during the beginning of pregnancy as a result of mating stimuli, and it may participate in the twice-daily PRL surges that maintain the corpus lutea necessary for steroid secretion,[85] but any relevance for this early OT in later maternal behavior is unknown. Preparturitional restraint of peripheral OT secretion is important to avoid premature contractions of the uterus or milk ducts, but during pregnancy OT does rise up to twofold over that observed in nonpregnant males and female rats and humans, with a peak at parturition and later peaks during suckling in all species examined.[194,195] During pregnancy, there are modifications of the hypothalamic magnocellular system involving retraction of astrocytic processes separating OT cells, thereby allowing more synchronous firing when a bolus of OT is needed for peripheral processes, including parturition or milk letdown (see Chapter 13; and Refs 196,197).

There is considerable evidence that OT can promote the onset of maternal behavior but it is not required for maintenance of the behavior once established. Prepartum destruction of the hypothalamic sites containing OT cells impairs all aspects of mothering after parturition, but lesions performed postpartum have only small effects.[198,199] OT from peripheral plasma is probably not involved because its access to the brain is extremely limited.[76] Some have argued that peripherally secreted OT as measured in plasma predicts release within the central nervous system,[200,201] but there can be brain-site-specific OT release and action independent of plasma levels.[79,202] The best evidence clearly indicates that OT facilitates maternal behavior by acting as a neuromodulator within the brain, and is released from a well-described network of neurons sometimes in association with other events, including parturition and nursing.[80,203,204]

Evidence of OT's modulatory role in postpartum maternal caregiving has been established by classical approaches, including infusing it into the brain or, conversely, infusing OT antiserum or receptor antagonists into the cerebral ventricles or relevant brain regions. These studies in rats involve postpartum females, pregnancy-terminated females, and pup-sensitized virgins.[108,204–207] There are also positive relationships between facets of the brain's OT systems with the propensity to display some postpartum maternal behaviors, including kyphosis and licking of pups (Figure 51.5).[108,208] Early studies of the role of OT in maternal behavior sometimes compared it with the effects of the closely related "control" neuropeptide, AVP. In contrast to these early works, where the effects of AVP were explained by its actions on the OT system, more recent research indicates that AVP acting on its own receptors also regulates maternal behaviors toward pups and maternal aggression.[204]

Transgenic mice have revealed a tremendous, often surprising, body of evidence about OT's modulatory role in maternal behavior. Mice with total global KO of the gene coding for OT give birth normally but have marked deficits in milk letdown. No deficits in maternal behavior were initially reported in these KO mice,[209] but more detailed analysis of OT KO mice subsequently revealed deficits in both retrieval and licking.[210] Because maternal behaviors are less affected in these OT KO mice than probably was expected, compensation by other systems (e.g., AVP) may have occurred or the strain used to create these particular KO mice has a high baseline level of spontaneous maternal behavior that was only slightly blunted.[209] In fact, it is valuable to note that in female wild house mice that are infanticidal as virgins, intracerebral infusion of OT dramatically promotes mothering.[211] Knockout of the *CD38* gene that codes for a protein critical for calcium-induced OT release does not impair the fertility, pregnancy, or parturition, and curiously also does not affect lactation in laboratory mice. This may be explained by the fact that while these mice have reduced circulating OT, it is sufficient for milk letdown.



FIGURES 51.5 **[^{125}I]OTA binding in the mPOA and BSTv (adjacent brain sites critical for active maternal behaviors; see the section Hormones Most Significant for the Onset of Maternal Behavior) of postpartum female rats that had previously displayed high or low maternal responsivity (i.e., high or low licking and nursing).** Highly responsive females had greater [^{125}I]OTA binding in both brain sites compared to less responsive females. *Source: Modified from Champagne et al., 2001.*[108]

This *CD38* KO does produce behavioral deficits, including slower retrieval, disorganized retrieval, and slower return to nursing after a disruption,[212] suggesting that brain OT release in these animals is insufficient to maintain normal mothering.

The most specific action of OT in the brain and periphery is via a single isoform of the OT receptor, which increases in number as pregnancy progresses and at parturition.[213] A total KO of the OT receptor in the brain and periphery revealed that parturition is surprisingly normal, but that lactation is not possible, and some aspects of postpartum or spontaneous virgin maternal behavior are reduced but not absent.[214] The maternal behavior deficits in this OT receptor KO are also probably more subtle than expected, again suggesting compensatory responses by other systems. Using a conditional OT receptor KO confined to the forebrain, and hence sparing the peripheral receptors and their function, others reported no impairment in maternal behavior, although pup licking was not assessed.[213] While these mice have apparently normal lactation, they are plagued by pup mortality of unknown etiology. The surprising retention of maternal function of these OT receptor KO mice may depend upon residual OT receptors within the forebrain, or possibly compensation from other brain regions outside the targeted brain region. An example of such compensatory mechanisms comes from the periphery and is related to OT's luteotrophic effect, such that prostaglandins take over this function in the absence of the OT receptor, calling attention to the fact that compensatory responses in the KO models may be more wide ranging than is currently proposed in many studies.

Sheep

Estrogen and progesterone: Virgin ewes are either indifferent or aggressive toward lambs, and, unlike rodents, they remain so even if they have prolonged exposure to young. This is radically changed by pregnancy, parturition, and a brief interaction with the offspring postpartum. Levels of estrogens are low during pregnancy and rise only very late and briefly in the peripartum period to a level approximately five times that seen at the peak of the estrus cycle. They then fall within hours after delivery.[102,215,216] Circulating progesterone levels are also very low in early pregnancy but rise later in pregnancy and are sustained at approximately four times the peak amounts found during the estrus cycle.[102,216] As pregnancy progresses in sheep, the source of progesterone shifts from the ovary to the placenta.[217] The progesterone rise as pregnancy progresses in ewes is similar to what is found in rats, such that levels are high until they rapidly fall a few days before parturition, and then remain at low levels through the early postpartum period (Figure 51.3).[102,215]

The high estradiol and low progesterone during very late pregnancy and the early postpartum period are positively related to maternal responsiveness in ewes, including lamb grooming, acceptance of suckling attempts, and maternal vocalizations by the ewe.[102,215] Maternally experienced ewes show increased responding to newborn lambs about 10 days before parturition,[218] presumably facilitated by the change in circulating hormones during late pregnancy. The hormones of late pregnancy also mediate the process where sheep withdraw from their herd before parturition, and give birth to and bond with their offspring in relative isolation. This isolation behavior is considered one of the earliest signs of maternal responsiveness in the pregnant ewe.[219] Fifty to sixty percent of multiparous ewes can be stimulated into maternal acceptance using 7–30 days of exogenous estradiol and progesterone treatment, with the best acceptance found with regimens involving high estradiol and low progesterone.[219–221] Unlike rodents, physiological levels of estrogens alone are insufficient to stimulate complete maternal behavior in sheep, but

together with the sensory input and OT release during vaginocervical stimulation (which is also insufficient alone), most primiparous ewes will completely and rapidly accept lambs.[96,221–223]

During the postpartum period, there is a hormonally established window of sensitivity to offspring during which the ewe must physically interact with the lamb and display placentophagia in order for them to form a preference for their own lambs. These activities have to occur within 4–12 h after parturition, and their effects usually begin to wane within 6 h of parturition.[218,224] The hormonal and visceral somatosensory stimuli, the chemosensory stimulation from the newborn lamb and amniotic fluids, and the auditory stimuli provided by low-pitched "lambing" bleats from the ewe provide the basis for bonding between the ewe and her offspring.

Adrenal steroids: Plasma cortisol levels are elevated during late gestation and lactation in ewes.[220] Cortisol levels during parturition are negatively associated with the onset of affiliative behaviors exhibited by the ewe to the lamb, but breeds that are more maternally responsive have higher levels of cortisol during the postpartum period.[220] It remains to be seen whether these higher levels simply do not interfere with maternal attentiveness, or possibly promote it, as has been suggested for humans (discussed further in this chapter). In support, hypothalamic–pituitary–adrenal (HPA) axis stimulation in sheep, along with additional hormonal treatments, can facilitate maternal acceptance by nulliparous ewes.[4,220] There is also evidence that the induction of parturition with exogenous dexamethasone shortens the sensitive period for bonding with the lamb due to reduced postpartum estrogens, which normally maintain this sensitive period.[218,224]

Prolactin and its family members: Similar to other species, basal PRL is low during most of pregnancy in sheep, but there is a substantial increase in the days immediately before parturition to reach levels somewhat higher than those seen in cycling females.[102,225] Placental lactogens also follow a similar pattern to that seen in other species, with sustained levels during later pregnancy and higher levels when two or more fetuses are being gestated.[226] An important difference between the scientific literature on rodents and ewes is that there is little evidence that PRL is required for the ewe's maternal behavior or bonding with the lamb.[4,219]

Oxytocin: Plasma OT levels peak at parturition in ewes, then fall to levels similar to prepartum levels within 24 h after parturition. They remain low during the postpartum period except for peaks associated with suckling by the lamb.[220] Plasma OT does not vary across breeds of sheep with higher versus lower maternal care, and peripheral OT is not thought to be relevant for the onset or maintenance of their maternal behavior.[220] Instead, Kendrick and colleagues have used microdialysis to assess OT release and infusion of OT to demonstrate that the location of OT action to promote mothering is intracerebral, particularly the olfactory bulb and paraventricular hypothalamus (PVN).[95,202,227] These investigators and others have also demonstrated that opioids acting within the brain facilitate maternal responsiveness, including regulating OT release, which is dissimilar to the disruptive effects of opioids on mothering in laboratory rats (see the section Brain Control of Maternal Behaviors).[228]

Humans

Due to the dramatic expansion of the cerebral cortex that occurred during primate evolution, mothering by humans is thought to be more cognitively based and greatly emancipated from the hormonal events often necessary for the stereotypical and reflexive caregiving behaviors displayed by many other animals.[229] Studying the hormonal basis of maternal or parental behavior in nonhuman and human primates is, of course, much more difficult than studying the nonprimate models described in this chapter. Some very significant work has been possible in nonhuman primates, though, and demonstrates roles for estrogens, cortisol, PRL, and OT that echo information found in nonprimates as well as some findings in humans.[230] The greatest limits to studying this question in humans is that most experiments can only investigate circulating levels of hormones assayed in plasma or saliva and correlate those measures to naturally occurring variance in behavior. An additional difficulty is the complex and highly varied nature of human maternal responsiveness, which limits generating an operational definition of maternal behavior that is relatively simple in animals with more stereotyped behaviors. Nonetheless, some laboratories have created useful observer-based operational scales that are appropriate for defining features of human mothering and they have correlated those measures with hormone levels.[231,232] The complicated issues introduced by our emotional states and traits affecting our behavior have usually been addressed by statistically considering data obtained by self-report or clinically administered psychological scales examining state (current affective state, postpartum depression, and anxiety) or trait features of our personalities (depression across life, personality, and pathology).[233]

Given the demonstration from animal models that hormones are important for the initiation of maternal behavior, many studies of maternal behavior in humans pay close attention to hormone levels during pregnancy and soon after giving birth. Indeed, this strategy has provided the best clues about possible hormonal influences in humans.[231,234] While the role of hormones in human mothers is mostly without the causal proof available

from studies of nonhumans, the natural endocrine patterns during this period have been well documented, which is essential for uncovering any role for hormones in human mothering.

Estrogen, testosterone, and progesterone: As with other mammals, the human placenta and the fetus contribute to the endocrine state of the mother, particularly during the late second and third trimesters, so delivery results in a rapid reduction in many circulating hormones within 24–48 h. Humans and nonhuman primates have been consistently reported to have a temporal course of estrogens and progesterone during pregnancy that is similar, but not identical, to those described in the rat and sheep models described here. Estrogens rise more steadily across pregnancy in humans so that in the second and third trimesters, plasma levels are 10–100 times those seen at the highest points of the menstrual cycle (e.g., the midluteal phase).[75,235–238] These levels remain high at delivery but fall substantially by the third postpartum day, such that they are below menstrual cycle levels by day 14 postpartum and remain low for up to 12 weeks postpartum in lactating women.[238,239] In nonbreastfeeding women, the endocrine changes consistent with the resumption of cyclicity begin in the first month postpartum (Figure 51.6).[240]

Less frequently analyzed or discussed for human pregnancy and the peripartum period is plasma testosterone. Similar to the rat, human circulating testosterone during the third trimester is three times the level found at the highest point in cycling women (i.e., midluteal).[238] While concentrations of testosterone are substantially less than those of estradiol during pregnancy (3 versus 82 nm/l), it remains at these levels for much longer than that occurring during the menstrual cycle, and so is a unique feature of the endocrine milieu of pregnancy.

Progesterone levels rise steadily across human pregnancy such that in the second and third trimesters, they are about 100 times higher than the levels found during the follicular phase of the menstrual cycle and 6–50 times higher than the maximal levels of the luteal phase of the cycle.[75,237,238] In terms of relative concentration, progesterone is the dominant gonadal steroid hormone in human pregnancy, being 10-fold that of even the substantially elevated estrogens.[237,238] Until late pregnancy, progesterone levels follow a pattern similar to that discussed here for other animal models.[235,236] Unlike other placental mammals such as rats, mice, and rabbits that have precipitous drops in plasma progesterone just before parturition, human circulating progesterone does not drop so substantially until after the fetus and placenta are expelled. In fact, only on the first day postpartum does progesterone fall precipitously to levels similar to what is found during the luteal phase of the cycle.[239,241–243]

The absence of a dramatic withdrawal of circulating progesterone before parturition in humans is intriguing because when labor begins, there is both high circulating progesterone and the formidable onset of myometrial contractility. There is thought to be a functional "progesterone block" that is alleviated prior to the onset of labor when the myometrial contractions are otherwise held in check by progesterone.[244] Mechanisms for how progesterone's function in the uterus is blocked during labor include a change in the dominant form of the genomic progesterone receptor, from the B to the A form, and subsequent release of myometrial contractility.[245–247] Interestingly, nongenomic progesterone receptor activity may favor myometrial contractility rather than inhibit it.[244]

Adrenal steroids: Primarily due to the contributions by the fetus and placenta, cortisol levels rise substantially across human pregnancy, rising 30% in the first trimester and by nearly threefold in the last two trimesters.[237,238,243] In the last trimester, plasma cortisol is nearly double that found in nonpregnant women.[75] In a within-subject longitudinal study, it was found that cortisol fell to slightly higher than prepregnancy levels within 2 days postpartum,[248] resulting in about half that seen during late pregnancy and labor,[243] and that the levels remained there for at least part of the postpartum period.[249] Walker and coworkers recently showed that the daily rhythm of cortisol returns to its normal circadian course and to nonpregnant levels in weeks 5–20 postpartum and that these

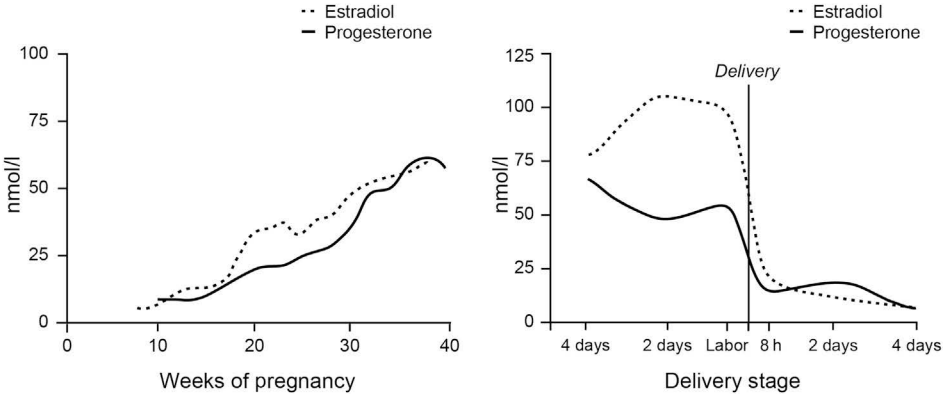


FIGURE 51.6 Schematic representation of circulating plasma levels of estradiol and progesterone across pregnancy and parturition in humans. Note that the levels of progesterone shown are divided by a factor of 10. For example, the immediate prepartum progesterone level is actually approximately 500 nmol/l. *Source: Modified from Brett and Baxendale, 2001.*[749]

levels are not altered by the mother's parity or whether she breastfeeds or bottle feeds the infant.[250,251]

Prolactin and its family members: Plasma PRL levels rise about 10-fold during pregnancy, without significant changes in cerebrospinal fluid levels.[75,238] As in other mammals, placental lactogens rise across pregnancy in humans to levels much higher than those of PRL itself. There have been no measures of PRL levels in the brain itself, but because PRL transporters are present in the choroid plexus, the human maternal brain is probably chronically exposed to high amounts of all PRL-type hormones from the periphery and may also be affected by PRL of purely central origin. The structurally similar placental growth hormone is also present at high levels in maternal blood, but less is understood about its access to her brain.[252] Placental lactogen is involved in lactogenesis and steroidogenesis, but human pregnancy is fine without it, possibly due to compensation by the structurally similar growth hormone.[252,253] However, data from mice deficient in growth hormone that are also lactogen resistant suggest that these hormones have distinct functions.[254] Within a day after parturition in women, placental hormones disappear from the blood stream and PRL itself is thereafter the dominant hormone supporting lactation.[236] Because PRL has a role in onset of maternal behavior in most animals examined, it seems possible that this is true for humans, but it has not been established in correlational studies. Whether such PRL effects would depend on peripheral PRL acting on the brain, or by PRL both made and acting within the brain, is a viable question.

Correlations among circulating hormones and human maternal behavior: There is a positive relationship between the ratio of the levels of estrogens:progesterone in human mothers and higher levels of feelings of attachment in the peripartum period, as well as increased approach and appropriate contingent responsiveness to infant cues, further providing evidence that these hormones in nonhuman primate females are related to behaviors thought to typify a good mother.[4,104,230,255] There is also work from psychologists and anthropologists supporting a role for circulating estrogens for maternal tendencies (i.e., interest in and desire to have children) and other features often associated with feminization.[256]

As discussed in detail in the section Hormones Most Significant for Paternal Behaviors, the first findings concerning testosterone and parental behavior were that lower circulating testosterone correlates with higher responsiveness in human fathers. A similar correlation has also been reported in women, with lower testosterone levels associated with motherhood and long-term social attachment such as that found in marriage,[257,258] whereas lower scores on maternal interest and reproductive ambition were found in women with higher circulating testosterone.[259] Circulating testosterone was not correlated with general career ambition, suggesting a restricted realm of influence for testosterone in women.

Novel work from Fleming and colleagues demonstrates that, among the steroid hormones, adrenal steroids are the most highly and positively correlated to high maternal responsiveness in women.[104,232] Specifically, mothers with higher levels of circulating cortisol interact more sensitively with their infants,[260] are more sympathetic to cries,[261] and are more attracted to and can better discriminate among infant odors (Figure 51.7).[232,261] This may indicate that higher cortisol contributes to a level of arousal that is optimal for maternal responsiveness, although overarousal would presumably interfere with appropriate mothering. These data were obtained on a single afternoon (a circadian point of decreasing levels) in a hospital setting, which may itself increase basal cortisol, 2 days after delivery when cortisol would be expected to have fallen to a point somewhat above prepregnancy levels. In contrast to these results, Feldman et al. reported that higher cortisol levels were associated with lower maternal behavior in a population of both primiparous and multiparous women of diverse socioeconomic status.[231] These findings were based on repeated measures taken in a clinical setting during the first and second trimesters and then 4 weeks postpartum (the time of day of cortisol sampling was not specified).

Lactating women, like other mammals, have attenuated HPA axis responses to stressors.[262] While some have reported reduced HPA axis responses to a social stressor immediately after nursing compared to women who simply held their infants,[263,264] others find this only in multiparous women[250] or if the time between feeding the

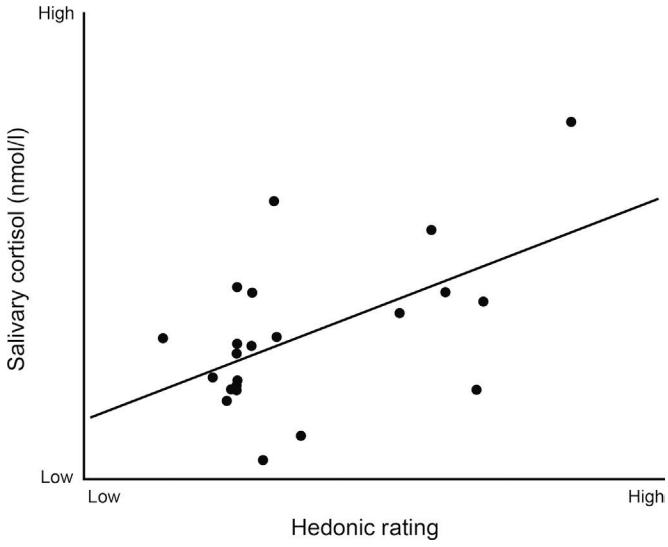

FIGURE 51.7 Correlation between salivary cortisol and the hedonic ratings (i.e., how pleasant or unpleasant) made by first-time mothers about the odor from their own infant's shirt. Mothers with higher cortisol rated the odors as more pleasant. *Source: Modified from Fleming et al., 1997.*[232]

infant and exposure to the stressor was relatively long.[265] Furthermore, suckling by the infant exerts a shorter term restraint on the HPA axis in humans compared to the longer term effect lasting even a day or two after litter contact seen in laboratory rats.[263]

Differences among studies in the relationship between adrenal steroids and mothering or stress responsiveness in parturient women highlight how sensitive such results are to a myriad of factors. This includes when the hormones are measured, which is particularly relevant for adrenal steroids that show marked circadian rhythm and very dramatic changes across pregnancy, parturition, and the postpartum period. Further influences include socioeconomic status (which is inversely correlated with basal cortisol), cultural and social conditions, infant feeding choices, and parity.[250,251] Also relevant is the potential for personality trait dependence of such findings, possibly including those underlying variations in basal and reactive cortisol responses.[104,249] In any case, while the bases of the discrepant findings are unknown, they are worthy of further exploration.

Among the peptides, OT has been the most studied for a relationship with human maternal care. OT released into the peripheral circulation has well-known roles for uterine contractions at parturition and postpartum milk letdown, with plasma levels of OT elevated during late pregnancy and in response to postpartum suckling.[75,266] While a few findings suggest that peripherally available OT has the potential to alter human maternal behavior, these studies do not provide any mechanism by which these effects occur as OT cannot cross into the brain. Intranasally administered OT does substantially raise salivary OT levels, with a short-lived peak after administration, but more work needs to be done in humans to determine the relationship between naturally occurring brain and peripheral OT.[267]

Without being able to define whether brain or peripheral OT is involved, there appears to be a role for the extended OTergic system in maternal attachment and care of infants. Circulating OT levels across pregnancy and the postpartum period are higher in women who are the most attached to their infants, and these women also exhibit higher levels of some maternal behaviors.[231] Additionally, mothers who are highly affectionate with their infants have higher circulating OT following an interaction with them compared to women rated as providing low levels of affectionate contact.[200] Polymorphisms in the genes coding for the OT receptor or CD38 are also associated with mother–infant bonding,[268] a finding reminiscent of the relationship between variation in OT receptor expression and some maternal behaviors in laboratory rats.[208] Furthermore, 6–14-week postpartum mothers with the greatest increase in plasma OT in response to a play interaction with their infants score highest on orienting sensitivity and attention to the mood, sensory cues, and emotions of their infants. Conversely, women who scored highest in trait measures of effortful control and focus on executive plans have lower levels of OT.[233] These interesting results suggest that the quality of certain mother–infant interactions are related to OT even during the later postpartum period, and that stable personality traits may predict some of these interaction qualities and their relationship with OT release.

HORMONES MOST SIGNIFICANT FOR PATERNAL BEHAVIORS

Paternal care is found across a large swath of the animal kingdom, from insects to humans. Birds are the most paternal vertebrates, with over 90% of species displaying biparental care, and the endocrinological basis of caregiving in avian fathers is quite well studied.[269,270] Fathering in mammals is much rarer, seen in only approximately 5–10% of species,[1,271] and is most commonly found in rodents, canines, and about 40% of primates. Laboratory studies of male rodents, such as laboratory rats, that are not parental in their natural environments reveal that the behavior can still be induced after manipulations that include early feminization by neonatal castration, treatment with very high doses of ovarian hormones during adulthood, and/or prolonged exposures to neonates.[2,28] Thus, the conclusion can be made that many male brains contain the necessary substrates for expressing paternal behaviors, regardless of natural history, and that this latent system can be uncovered under precise laboratory conditions.

Natural paternal involvement in caregiving is often coupled with a monogamous mating system and its associated increase in, but not absolute certainty of, paternity. Paternal involvement is also more likely expressed in relatively harsh environments in which food resources are sparse or temperatures are extreme, such that caregiving from two parents can greatly contribute to offspring survival and reproductive success.[1,271] Fathers of biparental species can also provide additional protection and supervision of the offspring. Studies of the benefits of fathering within a laboratory setting probably underestimate its importance given the undemanding environment,[28] although litter growth and survival have still been observed to be compromised in the absence of a sire even within the laboratory.[272–275] In humans, many studies have shown that the absence of a biological father or a second highly invested caregiver can contribute to negative social, psychological, and physical health consequences for children.[276]

We here review the endocrinology of paternal behavior in some exemplar parental mammals, with a focus on species displaying obligate paternal behavior within their natural environments, meaning that paternal care is

continually displayed by most sires of the species. This can be contrasted to the facultative fathering that is expressed more sporadically by sires in other species only during times of particular need and when mothering alone is inadequate.[28] For example, with approaching winter temperatures, many typically nonpaternal meadow voles (*Microtus pennsylvanicus*) nest with females and interact positively with their pups.[277] Such facultative fathering is not very often studied endocrinologically or neurobiologically, but is particularly intriguing because it requires the behavior to be switched on and off, sometimes repeatedly in the same individual across their lifespan. These transient plastic changes in the brain necessary for facultative fathering may involve the same systems necessary for paternal behavior in obligate fathers.[278] It is also interesting to consider that the behaviors of these more flexible facultative fathers are more likely susceptible to environmental influences compared to the relatively hard-wired behavior of obligate fathers.[279]

Studies of the endocrinology of fathering have often followed the heuristic that changes in steroid and peptide hormones that compel males to act paternally are similar to those necessary for females to display the same behaviors (i.e., elevated E, PRL, and OT). It will be seen that this assumption is not always correct and that the hormonal profiles associated with fathering considerably differ across species, especially among rodents.[28]

California Mice

The California mouse, *P. californicus*, is an important model system for investigating the hormonal control of paternal behavior. In contrast to most other socially monogamous species, including prairie voles,[280] DNA fingerprinting and paternity analysis suggest that wild California mice have extremely low rates of extra-pair fertilizations and are essentially strictly monogamous.[281] Equivalent levels of caregiving behaviors are expressed by males and females, with the obvious exception of nursing,[282,283] and offspring survival relies tremendously on the care provided by their father.[284] Virgin male California mice are not particularly attracted to pups and often attack them, but they become more paternal in response to olfactory cues they receive while living with their pregnant mate and are very paternal after the pups are born.[2] The hormones and neuropeptides studied for paternal behavior in California mice are numerous, with testosterone and its intraneuronal aromatization to estradiol receiving the greatest attention.

There is a classical inverse relationship between circulating testosterone and parenting that was first established in paternal birds[285] and that alters males' time allocation to other reproductive endeavors, including aggression, attracting mates, mate guarding, and an increased focus on their mate.[286] Further studies reveal plasticity in this hormone–behavior relationship, particularly when there is temporal overlap among mating, aggression, and paternal behaviors.[282,287] For example, California mouse pairs mate during the postpartum estrus, but males need to coordinate this with mate guarding and behavior toward their young pups in the nest. Behavioral conflicts do arise, as in one case observed in which a male California mouse removed the pups from the nipples of his female mate and placed them in the corners of the cage prior to mating with her (Marler, unpublished data).

As predicted from this classical perspective, testosterone levels in male *P. californicus* peak at courtship and significantly drop when they become fathers (Figure 51.8).[288] However, there is a *positive* correlation between testosterone and huddling with and grooming of pups in experienced fathers, and this relationship is not seen in virgin males.[289] A similar positive relationship between circulating testosterone and huddling with young pups has been found in another biparental male rodent, the Mexican volcano mouse (*Neotomodon alstoni*).[290] This positive hormone–behavior association is further supported in California mice by the detrimental effects of castration on their paternal care and the resumption of fathering after reintroduction of testosterone.[291,292] At first glance, it seems difficult to assimilate these seemingly contradictory findings, but there is an interesting evolutionary twist in male California mice because testosterone influences paternal behavior through activity of estrogen receptors rather than androgen receptors. Testosterone is aromatized into estradiol locally in specific brain regions to influence paternal behavior in California mice, as first suggested by the finding that implants of estradiol are as

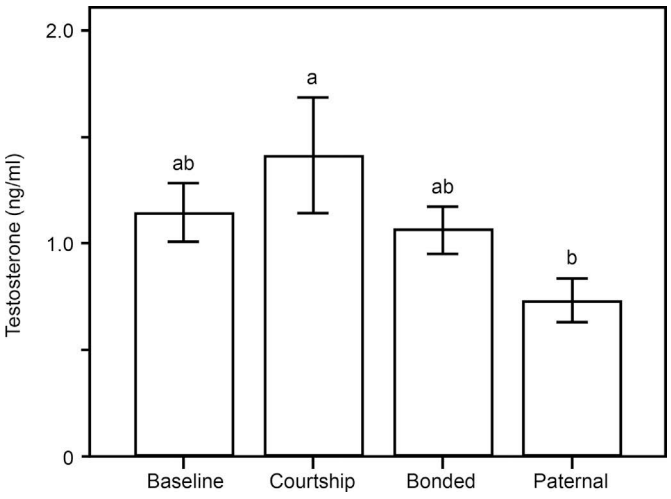

FIGURE 51.8 Circulating testosterone (Mean +/- SEM) in male California mice before pairing with a female (Baseline), an hour after pairing (Courtship), 3 weeks after pairing (Bonded), and 4 days after the birth of their pups (Paternal). *Source: Modified from Gleason and Marler, 2010.*[288]

effective as testosterone in maintaining paternal behavior in castrated males.[292] In addition, aromatase activity in the medial preoptic area (mPOA), a brain area critical for expression of most parental behaviors in all species studied (see the section Sensory Control of Maternal Care), is significantly elevated in fathers compared to mated males without pups.[293] Evolutionarily, it is possible that *P. californicus* males have successfully co-opted some of the mechanisms used in maternal care while avoiding some of the high costs of testosterone.

The relationships between glucocorticoids and the physiology and behavior of rodent mothers were reviewed above in the section Hormones Most Significant for the Onset of Maternal Behavior, but studies of male California mice indicate they may be mostly resistant to such glucocorticoid effects. This is suggested at a physiological level by their very high basal corticosterone levels, the inability of even moderate doses of dexamethasone to suppress this endogenous release, and the fact that several stressors are unable to further raise corticosterone levels but instead lower them at the time of the high diurnal peak.[294] Nonetheless, males' corticosterone does increase in response to a predator odor at times during the day when corticosterone levels are naturally lower,[294] as in response to social defeat at any time of day.[295] With regard to a relationship between glucocorticoids and paternal behavior, the published data are conflicting. A single injection of corticosterone administered in a manner that mimics an acute stress response has no effect on males' paternal behavior.[296] However, a complex analysis that included corticosterone, dehydroepiandrosterone (DHEA), and interruption of behavioral patterning in response to exposure to a novel object found greater levels of circulating corticosterone and DHEA but less behavioral disruption in fathers compared to sexually inexperienced males.[297] Others have found no difference in basal circulating corticosterone among males assessed as virgins, mated but without pups, and fathers.[298] In a study examining immediate-early gene activity of cells in the hypothalamic PVN that produce corticotropin-releasing hormone (CRH), there was no difference between paternal and nonpaternal males in response to stress.[299] Overall, male California mice appear to be resistant to stressors through both behavioral and HPA axis changes. What is unclear is whether this relates to the transition from being sexually inexperienced to becoming a father. Even if it does not, there may have been general selection for these males to respond less to stress because of the monogamous nature of their mating system. Males that mate for life and that have few offspring per litter are predicted to have buffers against stressors, unless a stressor strongly impacts the survival of the family unit or their ability to mate guard. Whether this also involves a change in emotional state in California mice is unclear because there are variable results regarding the effects of fatherhood on anxiety, fear, and neophobic behaviors,[297,299,300] even though fatherhood does appear to suppress activity in brain areas underlying these emotional behaviors.[301]

Correlational analyses of other plasma hormones in male California mice indicate little evidence that OT is important for paternal behavior. OT levels are high in males the day following mating, but then remain low throughout the mate's pregnancy and later development of the offspring.[302] More compelling are the findings that PRL rises within 2 days after the birth of a litter[303] and that progesterone levels drop with the onset of paternal behavior.[293] Exogenous PRL has been seen to rapidly induce paternal responding even in the typically nonpaternal male laboratory rat,[304] but additional studies are needed to assess cause-and-effect relationships between PRL or progesterone and paternal behavior in *P. californicus*.

Wild House Mice

Feral wild house mice live in extended social groups that often consist of an adult breeding male, several females and their litters, and a number of subordinate males.[305] Similar to other rodents living under such conditions, the expression of paternal behavior is likely in their natural environment. In the laboratory environment, almost all virgin males are infanticidal but can be parentally sensitized, and after mating they will refrain from killing pups when tested early or late during their mate's pregnancy.[82,306] The stimuli capable of inhibiting infanticide in mated wild male house mice are numerous, and this inhibition can occur from copulation alone[82] or by cohabitation with a pregnant female.[306] Hormonal factors contributing to high infanticide in wild male house mice followed by its decrement after mating have not been examined in great detail, but they involve unusually high endogenous testosterone release during neonatal development and a later decrease in circulating testosterone after mating or cohabitation,[82] the latter being similar to numerous other mammalian fathers.

Laboratory Mice

Paternal responding in virgin male laboratory mice is now very often studied, but as discussed earlier in this chapter for the study of female laboratory mice, levels of spontaneous paternal behavior strikingly vary among mouse strains.[83] This indicates the tremendous importance of genetics on males' responses to neonates, but does not make it easy to reach universal conclusions about the endocrine bases of fathering in laboratory mice. Early studies reported that individual differences in circulating testosterone do not correlate well with paternal responses in male Rockland Swiss albino mice,[307] but infanticide is still reduced by castrating males with

no prior killing experience.[308] It has also been seen that neonatally castrated males are *more* likely than males not neonatally castrated to kill pups after being treated with testosterone as adults,[309] suggesting that neonatal testicular hormones render the albino mouse brain to be less responsive to the infanticide-inducing effects of later androgens.

Similar to wild house mice and gerbils (see the section Mongolian Gerbils), mating eventually reduces infanticide and increases paternal behaviors in numerous strains of male laboratory mice that are not already highly paternal as virgins. This effect is maximal soon before their mates give birth and is due to the stimuli associated with ejaculation during copulation. Cohabitation with the mate or another pregnant female is neither necessary nor sufficient for this increase in paternal responsiveness in some strains of mice,[310,311] and in these cases the behavioral change appears to be based only on the number of light–dark cycles experienced by the male after ejaculating.[312] In other strains of mice, both ejaculation and cohabitation with a pregnant female may be needed to promote fathering.[313–315]

The only genetic manipulations of neuroendocrine systems in male laboratory mice that provide information about their paternal behavior involve KO of the progesterone and PRL receptors. The fascinating findings from the PRKO model included a tremendous reduction in infanticide and increased parental behavior by the males, which are of a strain that is normally aggressive toward pups (Figure 51.9).[316] Consistent with these results, wild-type male mice chronically treated with the PR antagonist RU486 are highly paternal,[316] while a history of chronic exposure to exogenous progesterone increases the percentage of males that attack pups even without progesterone "on board" at the time of testing.[317] Progesterone is a primary inhibitor of the onset of maternal behavior in female rats (see the section Hormones Most Significant for the Onset of Maternal Behavior), and this work suggested for the first time that PR activity can also interfere with paternal behavior in a male rodent. With regard to PRL, and in contrast to females, PRL signaling is expendable in male mice and the absence of the PRL receptor gene does not prevent males from interacting normally with pups. These males do not show the PRL-mediated neurogenesis necessary for later recognition of their own adult offspring, but the importance of such late offspring recognition in this species is also not obvious.[318]

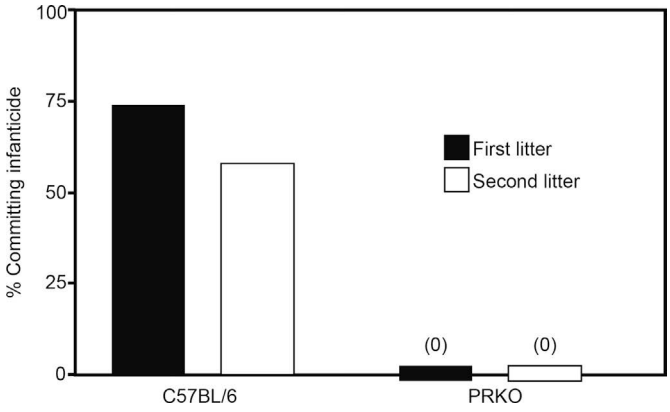

FIGURE 51.9 Percentage of male wild-type (C57BL/6) and progesterone receptor knockout (PRKO) mice committing infanticide after the birth of their first or second litters. PRKO mice do not attack pups. *Source: Modified from Schneider et al., 2003.*[316]

Mongolian Gerbils

Virgin male Mongolian gerbils are either spontaneously paternal[319] or at least become less infanticidal soon after mating.[320] Housing with a pregnant female promotes males' interest in pups,[319] making Mongolian gerbils similar to some laboratory mice and California mice. Like many paternal rodents, circulating testosterone rises in Mongolian gerbils after mating but drops dramatically after pups are born,[321] which is functionally significant because castrating adult virgin males increases paternal behavior, and providing replacement testosterone reduces it.[322] Circulating PRL in male Mongolian gerbils generally rises across their mate's pregnancy and continues to rise as the pups age,[321] although no manipulations of PRL have been conducted to determine any relevance of this change for paternal behavior.

Prairie Voles

Prairie voles (*M. ochrogaster*) are socially monogamous rodents that form lifelong pair bonds after mating and display biparental behavior after the birth of pups. This has been inferred from field studies where both parents are found with offspring in the natal nest or directly observed within seminatural or laboratory environments.[323–326] Plasma testosterone in male prairie voles increases in response to mating and cohabitation with a female,[327,328] and males' paternal behavior then increases across her pregnancy,[328] but it is not known if these events are causally associated.

Unlike unmated California mice, most virgin male prairie voles respond very positively to pups.[329,330] The consequence of castration during adulthood on parenting in these virgin males is equivocal. One study found that half of virgin prairie voles castrated as adults were infanticidal and the remaining voles weakly parental,[331] while a later study reported that castration had no significant effect on parental behavior when the virgin males were tested 4 or 8 weeks after surgery.[330] Differences between the two prairie vole colonies studied in their basal paternal responsiveness (lower in the first study compared to the second) and the presence of a litter effect in the first study probably account for the discrepancy. However, gonadal hormones are not completely irrelevant for

paternal behavior in male prairie voles, but they may be particularly important during early development. Neonatal castration reduces the percentage of virgin male prairie voles acting paternally during adulthood, even when testosterone is replaced weeks before testing.[332] In addition, alloparenting by weanling male prairie voles is reduced by inhibiting aromatization of testosterone to estradiol with 1,4,6-androstatriene-3,17-dione (ATD), or blocking androgen receptors with flutamide, during the second week of life.[333] Consistent with the study showing that adult castration has no effect on paternal behavior in male prairie voles,[330] and very different from studies of male California mice, work by Cushing and colleagues has revealed that neural ERα expression and signaling (presumably from binding estradiol generated by the aromatization of testicular testosterone) has a negative relationship with paternal behavior in prairie voles (detailed in the section Brain Control of Maternal Behaviors). Preliminary data indicate that blockade of progesterone receptors with RU486 has no effect on prairie vole paternal behavior.[2]

The influence of exogenous glucocorticoids on prairie vole paternal behavior is unknown, but Bales et al.[334] found that a single swim stress increases males' later huddling with pups, possibly because males seek out pups as social buffers to dampen their elevated HPA axis activity. Relatedly, stimulation of CRH2 receptors by intraperitoneal injection of urocortin also increases huddling with pups in male prairie voles.[335] A stress-associated increase in huddling with pups may help explain why RU486, which is also a glucocorticoid receptor antagonist, had no effect on pup-directed behavior in unstressed virgin male prairie voles from a colony that was highly paternal.[2]

Only a small amount of research has examined roles of peripheral peptides for paternal behavior in male prairie voles. Preliminary data indicate that their paternal behavior is unaffected by inhibiting pituitary PRL release with the dopamine receptor antagonist bromocryptine.[2] OT is very quickly released into the general circulation when juvenile or adult male prairie voles interact with a pup.[336] Whether this peripheral OT can cross the blood–brain barrier to facilitate ongoing paternal behavior, or is associated with concurrent OT release in the central nervous system, requires further study. Peripheral AVP levels are not affected by pup exposure and corticosterone release is blunted, again indicating that the presence of pups reduces stress.[336]

Dwarf Hamsters

The endocrine basis of caregiving behavior displayed by a subspecies of dwarf hamster that is biparental and monogamous, *P. campbelli*, has been extensively studied. Male *P. campbelli* are transiently alloparental as juveniles but become infanticidal as they age.[337] Reproductively experienced males are unlikely to attack pups, though, and are very paternal by the time their pups are born. In fact, they even contribute to delivery by pulling pups from their mate's vagina and by cleaning the pups of birth membranes and amniotic fluid.[338] Unlike California mice that become more paternal in response to urinary cues from their pregnant mate,[339] the suppression of infanticide and expression of midwifery in *P. campbelli* does not require that males receive any postcopulatory cues from their mates.[340]

Years of detailed work by Wynne-Edwards and colleagues have led to the conclusion that peripheral hormones do fluctuate in *P. campbelli* males across the transition to fatherhood, but that these hormones have very little if any role in regulating their paternal behavior. Correlational work reveals that males' circulating testosterone increases after mating but precipitously drops in concert with a spike in PRL just before pups are born.[341] Furthermore, expression of the long form of the PRL receptor in the choroid plexus falls and then rebounds in anticipation of the pups' birth.[342] Unlike most female mammals, circulating basal estradiol levels in male *P. campbelli* are consistently very high across the peripartum period, and their progesterone levels rise rather than fall associated with birth of a litter.[343] Because testosterone has been thought to impede nurturant behavior,[285] and high PRL and estradiol facilitate mothering in female rats, these patterns of endocrine changes could be reasonable facilitators of fathering in *P. campbelli*. Compellingly, none of these endocrine events occur after mating in the nonpaternal, but closely related, male *Phodopus sungorus*.[344]

While castrating male *P. campbelli* after mating reduces their circulating testosterone and estradiol to almost nondetectable levels, and reduces territorial aggression, it has no effect on retrieval of pups or viability of the litters.[345] Similarly, chronic inhibition of males' estradiol synthesis with the aromatase inhibitor, letrozol, beginning during their mate's pregnancy also has no effect on paternal care.[346] Experimental manipulations of PRL have revealed similar negative results—dopamine D2 receptor antagonism that reduces circulating PRL a few days before and after the birth of pups has no consequence on paternal behavior in *P. campbelli* (Figure 51.10).[347]

In sum, there appears to be a pattern of low testosterone and high PRL in *P. campbelli* and many other rodent fathers, and these hormones can sometimes be correlated with particular aspects of their paternal behavior. These correlative relationships are not found in all rodent fathers, and the cause-and-effect relationships between circulating hormones and paternal behavior in some species remain to be examined.[348,349] In species where experiments have been conducted to manipulate

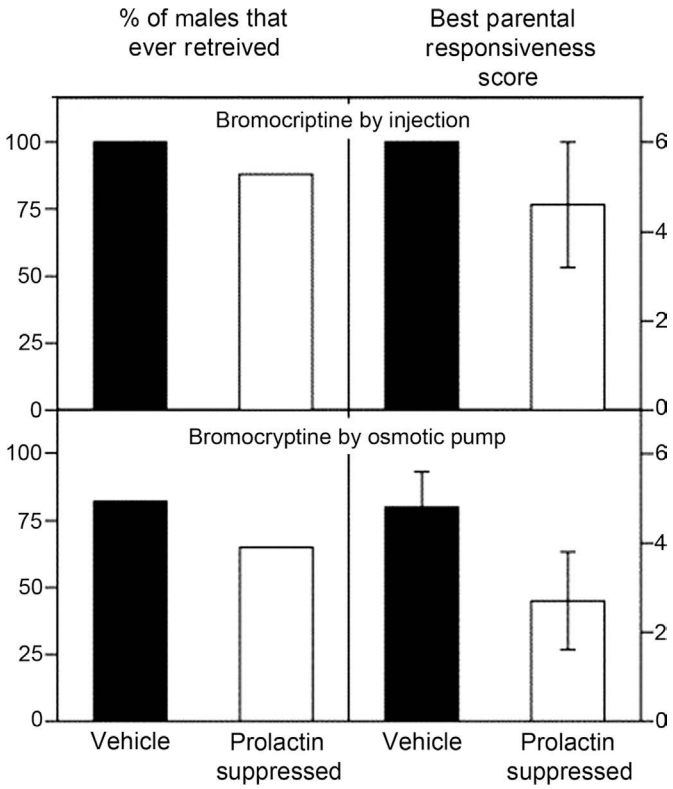

FIGURE 51.10 Percentage of male Djungarian hamsters that ever retrieved a pup, and their highest overall parental responsiveness score, after administration of vehicle or bromocryptine for the 3 days before birth of their pups via subcutaneous injection (top panels) or chronically via osmotic minipumps (bottom panels). Prolactin suppression had no effect on paternal responding. *Source: Modified from Brooks and Wynne-Edwards, 2005.*[347]

males' endocrine status, paternal behavior may or may not be affected. Thus, there is no universal endocrine basis of fathering in paternal rodents, suggesting that the behavior has evolved numerous times via numerous endocrine and nonendocrine mechanisms.

Primates

The small arboreal New World monkeys, the Callitrichids, are the best studied nonhuman primates for examining relationships between hormones and paternal behavior. They are cooperative breeders that live in family groups consisting of a monogamous male–female pair and their offspring of various ages, all of whom help care for the youngest infants in the family.[350] Paternal involvement in some Callitrichids and other nonhuman primates is so impressive that fathers may be the primary nonnutritive caregiver and can be observed to carry their infants considerably more than the mothers![351,352]

Testosterone and PRL were the first hormones examined for an association with paternal care in any primate. Dixson and George reported that most, but not all, male common marmosets (*Callithrix jacchus*) cohabitating with their mate and young offspring had lower circulating testosterone compared to males living with a nonpregnant or a pregnant female.[353] This result was bolstered by later work showing lower testosterone in common marmoset fathers after the birth of the infants compared to beforehand and a drop in males' testosterone during acute exposure to infant-related cues.[354,355] Testosterone was also inversely associated with infant carrying in black tufted-ear marmoset fathers (*Callithrix kuhlii*).[356] On the other hand, there is no significant relationship between circulating testosterone and paternal behavior in white-faced marmosets (*Callithrix geoffroyi*),[357] although this does not eliminate the possibility that the relevant testosterone is converted to estradiol within the brain to influence their behavior.[292]

Along with their decreased testosterone, common marmoset fathers sometimes have tremendously high circulating PRL.[353,354] PRL levels are elevated in these fathers only if they very recently carried an infant, and the levels are positively correlated with how long they carried the infant; these findings are not specific to fathers because they occur in male marmoset alloparental "helpers."[353,358–360] In contrast to marmosets, father Goeldi's monkeys (*Callimico goeldii*) do not have higher PRL levels than their adult nonreproductive sons, but PRL in fathers rises after the birth of their neonates and drops after they begin expressing paternal behavior.[361] Also different from marmosets are Pithecid fathers (Titi monkeys; *Callicebus cupreus*), which have higher urinary PRL compared to their nonreproductive sons a few weeks before the infants' birth, but show no changes in urinary PRL from a few weeks prepartum to 3 weeks postpartum, even though they carry their infants almost exclusively.[361]

In rare experimental studies manipulating hormones in monkey fathers, it was found that suppressing pituitary PRL release reduced infant carrying by alloparental marmoset males,[362] but that experienced fathers showed no such reduction in carrying after PRL suppression and were instead slightly more interested in infants compared to controls.[363] In fact, experience is an important determinant of whether endocrine fluctuations even occur in some nonhuman primate fathers. For example, there is no prepartum to postpartum hormonal change in mated male cotton-top tamarins (*Saguinus oedipus*) that have no parenting experience, but experienced males undergo rises in estrogens (estradiol and estrone), androgens (testosterone and dihydrotestosterone), PRL, and cortisol as their mate's pregnancy progresses, perhaps triggered by olfactory or other cues from the female.[364] These hormonal changes in male fathers can have important peripheral effects, in addition to any central effects. This can be seen in male tamarins that experience a PRL-mediated increase in body weight across their mate's pregnancy, which may be necessary for the metabolic demands of later infant carrying.[354]

The only nonhuman apes that exhibit paternal care are members of the family Hylobatidae, which consists of the socially monogamous and pair-bonding "lesser apes," commonly known as gibbons and siamangs. They provide an interesting comparison between closely related species because gibbons mostly ignore infants while siamangs readily carry their offspring.[365] In a study involving small numbers of three species of paternally experienced Hylobatidae, fathers' fecal androgen and estrogen metabolites did not significantly change from 1 month prepartum to 7 months postpartum in the nonpaternal gibbons, but androgen metabolite levels in the paternal siamangs rose across the mate's pregnancy and decreased after she gave birth. Males' estrogen metabolites also increased across pregnancy and were maintained at high levels through the postpartum period,[365] which is reminiscent of changes in estrogenic activity in paternal California mice.

It is probably unnecessary to state that many human fathers can be engaged and engrossed with their infants to the degree typically found in mothers.[366] Intense paternal behavior is common in humans, but not ubiquitous, with fathers having moderate to high contact with young infants in about half of the cultures examined.[367] As with naturally paternal rodents, high paternal involvement in humans is most likely to be found in cultures characterized by monogamy in which assurance of paternity is relatively high. It is also more likely to be found in cultures that conduct only small-game hunting and where animal husbandry is absent—the cultures perhaps with the least reliable food resources in which paternal assistance can have the greatest impact on offspring survival.[367] Even so, paternal involvement in childrearing other than basic "breadwinning" is still highly variable within most cultures where fathering commonly exists.[279] Furthermore, in societies where paternal interaction with infants is considered high, the average duration of time that fathers spend each day in physical contact with their infant or toddler can be quite small (15–90 min per day in the United States), even though fathers' general availability to offspring is usually considerably higher.[368] It is also true that human paternal behavior differs from maternal behavior in numerous ways, including that fathers are more arrhythmic in their interactions with infants, are more physically stimulating to them, respond more to infant motor cues than social cues, and are most likely to be touching their infants when play is occurring than during other types of interaction.[366]

Research on the endocrinology of human fathering has often hypothesized homology across species and between the sexes, and so predicts that fathers will have low circulating testosterone but high estradiol and PRL. In the first study of its kind in a now-burgeoning literature, Storey et al.[369] used a longitudinal design to find that plasma testosterone levels in men did drop after their partners gave birth, and others soon thereafter

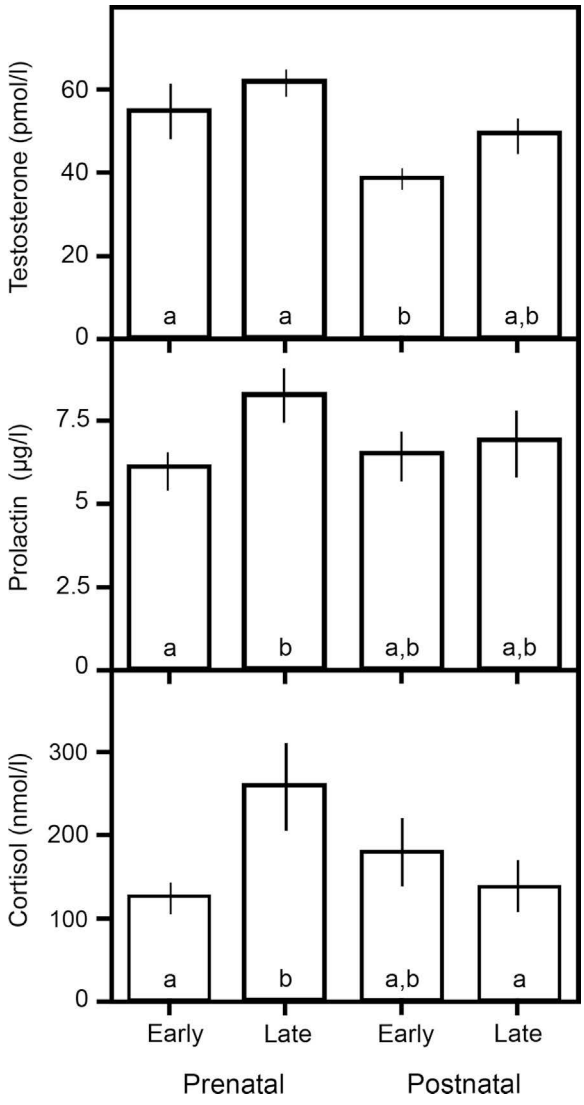

FIGURE 51.11 Plasma concentrations of testosterone, prolactin, and cortisol in human fathers before and after the birth of their infant. Different letters at base of bars indicate significant differences compared to the early prenatal group. *Source: Modified from Storey et al., 2000.*[369]

reported similar results (Figure 51.11).[370] Later studies in numerous cultures indicate significantly or at least notably lower testosterone in partnered fathers compared to partnered nonfathers or unpartnered nonfathers[370–375] and this difference is greatest when they are compared against the most involved fathers.[372] Even though human fathers' baseline testosterone is lower than that of nonfathers, fathers respond acutely with a rise in testosterone after hearing infant cries, although this acute increase is less in men expressing the greatest sympathy and concern to those cries.[369,371] In contrast, testosterone levels fall in fathers during a 30 min face-to-face interaction with their 2 year olds, but this depends on the context because it is only found in the fathers who spend *more* time interacting with the child during testing and

whose partners spend *less* time interacting with their toddler during the test, and only if it is a day when fathers have already spent considerable time with their children.[376] An important consideration for evaluating the results of these studies is that testosterone concentrations are stably lower in men who eventually pair bond than in single men who do not form such a relationship,[377] so the longitudinal studies and the studies comparing partnered fathers with partnered childless men are particularly valuable for determining relationships between men's testosterone and their fathering status or behavior.

Estradiol also changes across fatherhood in men. A longitudinal study of men becoming fathers for the first time found that estradiol was more likely to be detected in their saliva samples than it was in samples from nonfathers. Fathers' estradiol was also more likely detectable a month after the infant was born compared to a few weeks before the birth, even though absolute levels of estradiol did not significantly differ in men before and after their infant's birth.[370]

PRL levels in men rise across their partner's pregnancy,[376] resulting in fathers having higher PRL than nonfathers, particularly for men who are first-time fathers or are fathers of very young children.[371,378] Furthermore, PRL levels are correlated with paternal responsiveness, with greater PRL levels in men who report more alertness to and concern with recorded infant cries, as well as who show greater attention and coordination in their behavior with the infant.[369,371,379,380] Levels of PRL drop while first-time fathers interact with their child, though, indicating that not only do the most paternally sensitive men have the highest PRL but their hormones probably predict their upcoming behavior rather than are a result of it.[371,376,379,381] An interesting parallel is found in male meerkats, where PRL levels predict which males are the most likely to initiate a bout of caregiving.[382] Fascinatingly, PRL is also higher in fathers who report more couvade symptoms, the sympathetic somatic and emotional events characteristic of females' pregnancy, further reflecting these men's greater investment in the upcoming birth and higher sensitivity to their partner's experience.[369]

There is no evidence that circulating or plasma OT is higher in fathers than nonfathers, which is also true for postpartum women who have not recently breastfed, but OT levels in fathers are associated with emotional synchrony, engagement, and positive communication with the infant.[200,380] These men with high OT are prone to this type of social interaction because they also report greater attachment in social relationships throughout their lives, including with their parents and romantic partners.[200]

Perhaps related to apprehension about the upcoming birth of an infant, glucocorticoid levels rise in expectant fathers during their partner's late pregnancy and peak the week before the delivery.[369,370] Similar to PRL, these high glucocorticoid levels drop across time while fathers interact with their infants[381] or toddlers.[376] Fathers with showing the smallest drop while interacting with their toddler are the most attentive fathers,[376] which is similar to the greater maternal responsiveness sometimes found in postpartum women with higher cortisol,[232] again suggesting that elevated cortisol at reasonable levels can positively contribute to parental attention. Because glucocorticoids (and PRL) have a reactive component to their release, these studies can be difficult to interpret and depend on the environment in which the samples were taken and the possibility that interacting with an infant can itself be acutely stressful.

In sum, unlike studies of rodents, the extant studies of primate fathers are generally consistent among each other, and the observed hormone profiles in these fathers generally support the hypothesis of homology between the sexes in their endocrine release before and during parenthood. This is particularly true for PRL. Given that, there are conflicting data regarding whether there are significant correlations between the hormone levels of individual father-and-mother pairs.[200,369,383] As with our discussion about the relevance of the correlations between hormones and behavior in human mothers (see the section Hormones Most Significant for the Onset of Maternal Behavior), a greater understanding of how and how much these changes in circulating hormones affect paternal behaviors in primate fathers is a critical area of future research.

SENSORY CONTROL OF MATERNAL CARE

Parents must accurately recognize infants at either short or long distances to initiate contact seeking and establish the physical proximity required for the execution of parental duties. As already noted in the Introduction, parenting is not a unitary process but is composed of numerous individual behaviors, and these behaviors differ in what sensory inputs elicit and maintain them. Studies of the sensory control of parenting traditionally focus on the senses involved in maternal recognition of young and contact-seeking behaviors, rather than the senses required to maintain or terminate physical proximity after its establishment. In laboratory rodents, the senses involved in maternal approach to offspring, followed by carrying them to the nest, are most often studied. Although retrieval is probably rare in undisturbed environments with young, mostly immobile pups, how rapidly dams approach offspring during a retrieval test can provide particularly valuable information about factors modulating maternal motivation to initiate contact with pups, as well as the ability to pick them up, hold them in the mouth while transporting them, and finally release them in the nest.

In some of the earliest studies investigating the sensory requirements for retrieval in multiparous postpartum laboratory rats, Beach and Jaynes[32] reinforced the important concept of "multisensory control" for how the senses act individually and together for a mother's behavioral responding. Dams appeared to use both olfactory and visual cues to orient toward pups, but retrieval remained rapid after cauterizing the olfactory bulbs and was only slightly slowed by surgical removal of the eyes. Furthermore, loss of tactile input (i.e., anaptia) by severing any one of six sensory nerves subserving the face and head only slightly affected dams' retrieval capabilities. A small number of animals tested after two desensitizations displayed somewhat greater impairment, and only after three desensitizations (blind–anosmic–anaptic) did performance notably suffer, even though some still retrieved a few pups. From these results, it was concluded that dams may normally use all available senses to fine-tune their behavior, but any individual sensory modality was mostly expendable as long as there was sufficient input from the other senses to compensate. More recent studies on this topic from primiparous laboratory rat and human mothers discussed below support many of Beach and Jaynes's early conclusions.

Vision and Hearing

Vision and hearing are still thought to be mostly unnecessary for maternal behavior in rats. Rats that are enucleated before giving birth or had their eyes temporarily sutured closed after parturition are competent mothers and raise healthy pups.[384,385] Consistent with this, blind nulliparae are just as likely to become maternally sensitized as sighted ones,[386] all of which may not be surprising for this nocturnal, burrowing rodent. With regard to sound, mother rats and mice can detect pup sonic and ultrasonic vocalizations, and can discriminate the sex of the pup based on their vocalizations,[387] but will not use sound alone to guide their behavior.[388,389] Dams also do not absolutely require sonic inputs, and deaf postpartum or Caesarean-sectioned rats still retrieve pups although do so more slowly compared to hearing females.[15,384] Similarly, dams orient to and retrieve dead, chilled, or anesthetized pups but do so more slowly than when presented with active and vocalizing pups.[390–392] Deaf postpartum rats also exhibit normal licking and nursing,[385] and deaf virgins are just as likely to become maternally sensitized as hearing females, but are more likely to accidentally step on and injure a pup.[386] The combination of blindness and deafness decreases nursing frequency in rats, but is not inconsistent with rearing viable pups.[393]

Diurnal ungulates living in large, mobile groups can also dispense with visual or auditory cues for maternal identification of or behavior toward their lambs. Blindfolded ewes and beef cows can identify and accept their young,[394,395] and ewes continue to prefer the vocalizations of their own lamb even if they cannot see them.[396,397] This does not mean that auditory cues from the lamb are what is required for maternal identification, because ewes successfully find their lambs even after surgical removal of the ewe's auditory canals[394] or when the lambs are contained in a soundproof chamber.[398] In both cases, the ewes may act by sight, although ewes are unable to readily learn to use photographs of their lamb's faces as discriminative stimuli to gain access to their offspring.[399] Importantly, when both vision and hearing are eliminated, ewes are much less likely to immediately choose their own lamb over alien lambs. Moreover, most ewes cannot find any lambs at all when the sense of smell is simultaneously impaired with vision and hearing.[394] It was once thought that at short distances from the lamb, sound and sight have little role in ewe's acceptance of the lamb at the udder and that olfaction was primarily responsible,[394] but this has more recently been questioned after the finding that anosmic ewes do recognize their own lambs within hours after giving birth and later use the remaining available cues to selectively nurse them.[400]

How a lack of vision influences maternal care in human and nonhuman primates has rarely been studied. This is surprising because human mothers and infants are innately interested in each other's faces, normally spend a tremendous amount of time looking at each other, use eye-to-eye contact and its disengagement to modify their interactions, and the foundation of their bonding usually involves face-to-face interactions.[401,402] After spending as little as an average of 5 h with the neonate, mothers (as well as fathers) can accurately identify photographs of their infant's face.[403,404] These infant visual cues, including the infant's physical attractiveness, are unconsciously associated with differential maternal responses to and attributes made about the infant.[405] In the absence of vision, however, maternal interactions with infants appear to be normal, and blind mothers use a variety of flexible strategies to interact and communicate with their infant.[406,407] Compared to the study of maternal vision, maternal hearing has received more investigation. Most human mothers distinguish between the cries of their own and other infants within 48–72 h after parturition, and many can do so even before then.[408,409] Some analyses of deaf mothers interacting with their hearing infants indicate no differences,[410] while others report that deaf mothers have less vocal interaction with their infants,[411] and yet others find that deaf mothers vocalize more often than do hearing mothers during face-to-face interaction with their hearing infants.[412] In the absence of incoming auditory cues, deaf mothers may compensate by briefly touching the infant and using hand gestures more often, which is thought to help maintain the connection with and attention by the infant.[413,414]

Olfaction

Over the past four decades, there has been a tremendous amount of research devoted to understanding the olfactory control of maternal behavior in rodents, consistent with the thought that olfaction is the primary sensory mediator of social information in nonprimate mammals.[415] A distillation of this literature is that olfactory cues from rat pups are unattractive or even aversive to nonpregnant or nonparturient rats, and that a primary consequence of peripartum ovarian and pituitary hormones is to alleviate this olfactory aversion and permit attraction to the sensory cues from neonates. After hormones have completed this task, olfaction is thereafter mostly unnecessary for ongoing maternal care. These hypotheses were partly based on anecdotal observations of differences in behavior of parturient and nonparturient females after young pups are placed in their home cage.[10,416] While mothers rapidly seek out and retrieve or lick the pups, nonparturient females exposed to pups for the first time approach and sniff them, but usually make a hasty retreat. Nulliparous females also actively avoid previously preferred parts of their home cage if pups are placed there,[417] but such avoidant responses wane after a few days of exposure, and maternal responses often emerge thereafter.

Early work from Fleming and colleagues provided further supporting evidence that olfaction inhibited mothering in rats. They found that virgin female rats exhibit a rapid onset of maternal behavior after being olfactory bulbectomized, with latencies of ~2–3 days versus ~7 days in controls.[418] Moreover, 70% of bulbectomized responders were maternal within 24 h after their first exposure to pups. In subsequent studies, they further demonstrated that peripheral anosmia induced by irrigating the nasal cavity with zinc sulfate also elicited rapid mothering in most virgin females and that sectioning the vomeronasal nerve reduced sensitization latencies by 50%.[419] Because combining vomeronasal section with olfactory bulb damage stimulated the behavior even faster (Figure 51.12),[420] both pheromonal and volatile olfactory appeared to inhibit maternal responding. Similar hastening of caregiving behaviors in virgin rats occurs after destroying the medial amygdala (MeA), stria terminalis, or bed nucleus of the accessory olfactory tract,[421,422] which transmits olfactory information to the hypothalamus and other areas of the basal forebrain. Disruption of olfactory paths even promotes maternal responding in virgin male rats,[423,424] which are less positively disposed to pups than are virgin females.[2] Although maternal responding in olfaction-disrupted nulliparous rats is impressively hastened, it is not the only inhibitor of mothering because administration of ovarian hormones makes anosmic females even more responsive to pups.[425]

A number of points are relevant for interpreting the literature on olfaction and mothering. First, the ability

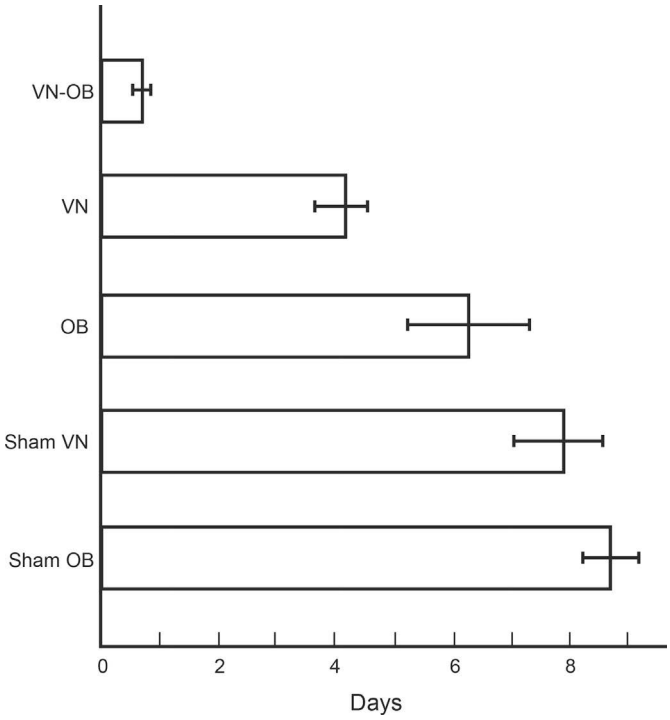

FIGURE 51.12 Mean latency for nulliparous female rats to display maternal behavior after receiving cuts to the vomeronasal nerve (VN), olfactory bulb (OB), or both (VN–OB). Control animals received a sham section of the VN or OB. Note the particularly fast sensitization in the VN–OB females. *Source: Modified from Fleming et al., 1979.*[420]

of intranasal irrigation of zinc sulfate to produce anything other than a brief (<72 h) and incomplete anosmia in rats has long been questioned.[426,427] In fact, one early study indicated that the loss of olfactory discrimination after intranasal zinc sulfate did not correspond well with maternal responding, given that most females were probably no longer anosmic 2 days after treatment but still exhibited very rapid onset of maternal behavior at that time.[428] Second, the concept of segregated main and, accessory olfactory systems has been questioned because they functionally overlap more than is often considered. For example, both systems can respond to volatile odors and pheromones, and the difference between them is in their degree of responsiveness to particular odorants, rather than their ability to respond to them at all.[429,430] Third, olfactory disruption in mammals broadly affects endocrine function, including thyroid, pineal, pituitary, gonadal, and adrenal hormones.[431] Olfactory bulbectomy also increases the expression of estradiol receptors in the female rat MeA,[432] which may contribute to faster sensitization; there is a relationship between ERα expression in numerous other brain areas and the propensity to sensitize in olfactory-intact virgin female rats.[433] Whether or not such changes in hormone release or expression of their receptors occur in a time frame consistent with studies of maternal behavior that can initiate pup exposure days or weeks after a manipulation

should be considered. Interestingly, Gonzales-Mariscal and colleagues found that disrupting main or accessory olfactory input dramatically hastens maternal responsiveness in virgin rabbits, but not if females were ovariectomized.[434,435] A similar need for the ovaries is found for the facilitated maternal behavior after cell-body-specific chemical lesions of the MeA in nulliparous rats.[436] Lastly, if olfaction is a primary inhibitor of maternal responding, it is surprising that sensitization is not necessarily hastened in nulliparous rats by habituating them to distal cues from pups encased in a wire mesh box and placed in the home cage before sensitization begins.[437,438] On the other hand, female rats reared from birth to weaning in a colony room that housed other dams with pups do sensitize faster during adulthood than females raised without this exposure.[439] This could indicate that exposure to distal pup cues, especially during early development, establishes a strong, long-lasting habituation to these cues compared to what can be achieved when exposure occurs during adulthood.

It is also valuable to note that two studies sometimes cited as evidence that mothers are attracted to pup odors while nonmothers find them aversive did not demonstrate report data leading to that conclusion. Bauer reported that late-pregnant and early-postpartum rats preferred their own soiled bedding, or bedding soiled by other postpartum rats, over bedding soiled by virgins or clean bedding.[440] Because peripartum females also equally preferred bedding of late-pregnant rats, the source of the preferred odor could very well be from mothers rather than from pups. Furthermore, nulliparous virgin females in this study did not have an aversion to soiled bedding from maternal nests, but rather had no preference for it over clean bedding. Similarly, Fleming et al. reported that steroid hormone–primed nulliparous rats had a strong preference for soiled nest material over clean bedding, but the control females given cholesterol did not show an aversion to the soiled bedding—if anything, they had a slight preference for it.[441]

Any need for olfaction during ongoing postpartum maternal behavior in rats is unclear. Most studies find little effect of olfactory bulbectomy performed before mating or during pregnancy, but a few have reported high pup mortality at parturition or impaired maternal behaviors thereafter (see Refs 442–444). Discrepancies might be explained by the nonsensory consequences of bulbectomy because neither peripheral anosmia nor vomeronasal nerve damage has much effect on postpartum pup care.[442]

In contrast to its inhibition of mothering in virgin rats and likely irrelevance in postpartum rats, olfaction is essential for maternal behavior in female mice. Because most strains of virgin laboratory female mice are spontaneously parental to varying degrees, it must be the case that no pup sensory cues invariably need to be overcome. Both virgin and postpartum mice can use pup odor to find and retrieve them, and olfactory bulbectomized virgin mice show no maternal care and often cannibalize pups.[389,445,446] Bulbectomy before mating, during pregnancy, or postpartum produces similar effects in parturient females.[447–449] Less dramatic impairments in mothering are observed after peripheral anosmia with zinc sulfate,[449] and maternal experience can mostly compensate for this peripherally induced loss of olfaction[450] but it cannot overcome bulbectomy.[447] Inducing general anosmia by deleting the *SCN9A* gene in olfactory sensory neurons, thereby eliminating the Nav1.7 voltage-gated sodium channel, abolishes retrieval but apparently does not induce cannibalism.[451] This genetic manipulation helps clarify the effects of anosmia on mouse maternal care by avoiding the known side effects of surgical intervention or nasal irrigation with zinc sulfate. The importance of the main olfactory system in mouse mothering seems to also be supported by the severely impaired retrieval and nest building of virgin or postpartum mice with a targeted deletion of the adenylyl cyclase type 3 (*AC3*) gene,[452] which is necessary for second-messenger cascades in main olfactory neurons, but presumably also in any of the brain sites underlying maternal behaviors.

Vomeronasal organ removal in female mice leaves maternal behavior intact,[453] as does eliminating a suite of putative pheromone receptor genes.[454] However, deleting the *Trpc2* gene that codes for an ion channel found in the vomeronasal organ deforms the accessory olfactory bulb, reduces the frequency of postpartum nest building and nursing,[455] and results in an early decline in nest attendance as postpartum time ensues.[456]

Olfactory control of mothering in ewes involves a prepartum inhibition perhaps similar to rats, followed by a postpartum facilitation that differs in purpose from that found in mice. Amniotic fluid is aversive to nulliparous female sheep, but the aversion can be relieved by peripheral anosmia with zinc sulfate or, of course, by the hormonal milieu of pregnancy.[457] Mothers' strong attraction to amniotic fluid at parturition is observed even toward a bowl containing the liquid.[458] Ewes reject and are even aggressive toward their own lambs if the offspring are washed immediately after delivery,[459] and they are more prone to accept alien lambs wearing a jacket soaked in amniotic fluid.[460] When examined immediately after parturition, the lack of olfaction produces small detriments to, but does not prevent, mothering in primiparous ewes and has no effect in multiparous ewes.[461] Anosmic ewes do show indiscriminate mothering toward any lamb and[461] anosmic postpartum goats are similarly indiscriminate.[462] Severing the vomeronasal nerve does not produce such effects in ewes, so main olfactory cues are probably more relevant than pheromones for early maternal responding and identification of the lamb.[461]

The enlarged cortex of primates has diminished the importance of olfactory communication to guide their behavior,[229] resulting in only a small literature on olfaction and primate mothering. This is despite the fact that body odors can both convey and influence emotional states in humans and other primates,[463] which helps set the stage for maternal caregiving (see the section Sensory Control of Maternal Care). It is well known that infant human and nonhuman primates are attracted to and can identify their mother by her olfactory cues alone, and use those cues to guide their contact-seeking behaviors.[464,465] In the reverse direction, early postpartum human mothers find the odor of T-shirts worn by infants more attractive than nonmothers do, and this attraction is associated with individual differences in maternal behavior—mothers who rate their infant's odor as highly attractive spend more time in close physical contact with their infant than do mothers who give lower ratings.[466] Women can also use the sense of smell to selectively identify clothing worn by their infants even after surprisingly little interaction with them after parturition,[467,468] but maternal recognition of her own odor profile, which may be inherited by infants, could contribute to this ability. It would be fascinating to study if the inability to detect infant odors disrupts human mothering, but anosmia in reproductive-aged women is uncommon conditions that do not otherwise compromise reproduction and parenting (e.g., Kallman syndrome, schizophrenia, and multiple sclerosis). There are no readily found studies of mothering by anosmic monkeys, and one might predict that the absence of olfaction would have little consequence.[469]

Taste

It has not been examined in detail if taste influences any maternal behavior in any species, but anesthetizing the tongue significantly decreases maternal licking but does not affect retrieval.[470] This finding is difficult to interpret because tongue anesthesia impairs both taste and somatosensory inputs, and may impede motor control of the tongue by the hypoglossal nerve in a way known to reduce other types of licking (i.e., nonpup).[471]

Somatosensation

After being drawn to their offspring via distal cues, perioral and ventral somatosensory inputs that mothers receive from the pups are essential for the normal pattern of mothering to continue (Figure 51.13).[73] Retrieval is inhibited if the texture of pups' skin is altered by making it greasy or tough,[32] or if the pups' skin temperature is abnormally low,[390] but not if it is too high.[472] Dams detect these pressure and thermal skin qualities through the infraorbital branch of the trigeminal nerve—which mediates the tactile function of the snout, whiskers, nose, and mucous membranes of the mouth—in order for the mouth-opening reflex that is needed for retrieval to occur. Reducing or eliminating tactile inputs to the perioral region by anesthetizing dams' mystacial pads or severing the infraorbital nerve impairs or even abolishes retrieval and licking of pups.[73,473] Such deficits are not observed after severing the mental nerve serving the chin and lower lip. Importantly, although dams with infraorbital denervation or anesthesia cannot retrieve, they still self-groom (and even do so more than controls), indicating differential sensory control of retrieving and some other oral behaviors.[73]

The mostly abolished retrieval and licking seen after perioral anesthesia or nerve cuts are greatly lessened if rats have pretreatment experience retrieving pups or trying to retrieve pups under previous lidocaine treatment,[473,474] suggesting compensation by other sensory inputs. Indeed, experienced dams spend additional time sniffing pups between retrievals, perhaps to maximize the input from remaining sources of stimulation.[474] The maternal experience of multiparous females could explain why early studies indicated little effect of sensory denervation of the snout or mouth on rat mothering.[32] This is reminiscent of the effects of olfactory bulbectomy on postpartum behavior, which, when found, are diminished in multiparous compared to primiparous dams.[475]

Perhaps unexpectedly, Stern and colleagues found that perioral tactile inputs facilitate not only dams' oral maternal behaviors, but also their quiescent nursing.[470] Dams separated from their litters for 4–6 h and then subjected to perioral anesthesia shortly before reunion did not continually attempt to interact with pups but ignored the individual offspring scattered around the cage. Even if the litter was manually placed directly in the nest, perorally anesthetized animals still ignored the pups and rarely nursed them. Thus, just having the pups in a single location without tactile input to the dams' snout is insufficient to maintain maternal interest or eventually lead to nursing of young pups. Because older and more motorically capable pups are persistent in seeking out their mother and can burrow under their perorally desensitized dam to search for a nipple, nursing can be elicited. Interestingly, if anaptic dams are deprived of contact with offspring for a rather long period of time before testing (~24–36 h), mothers do remain with a young foster litter and nurse,[476,477] suggesting that high maternal motivation overrides the lack of perioral inputs for nursing to occur.

The skin of the snout is not the only tactile regulator of mothering in laboratory rats. Nursing behavior, involving cessation of motor activity and often kyphosis (crouched posture over pups), is closely tied to the

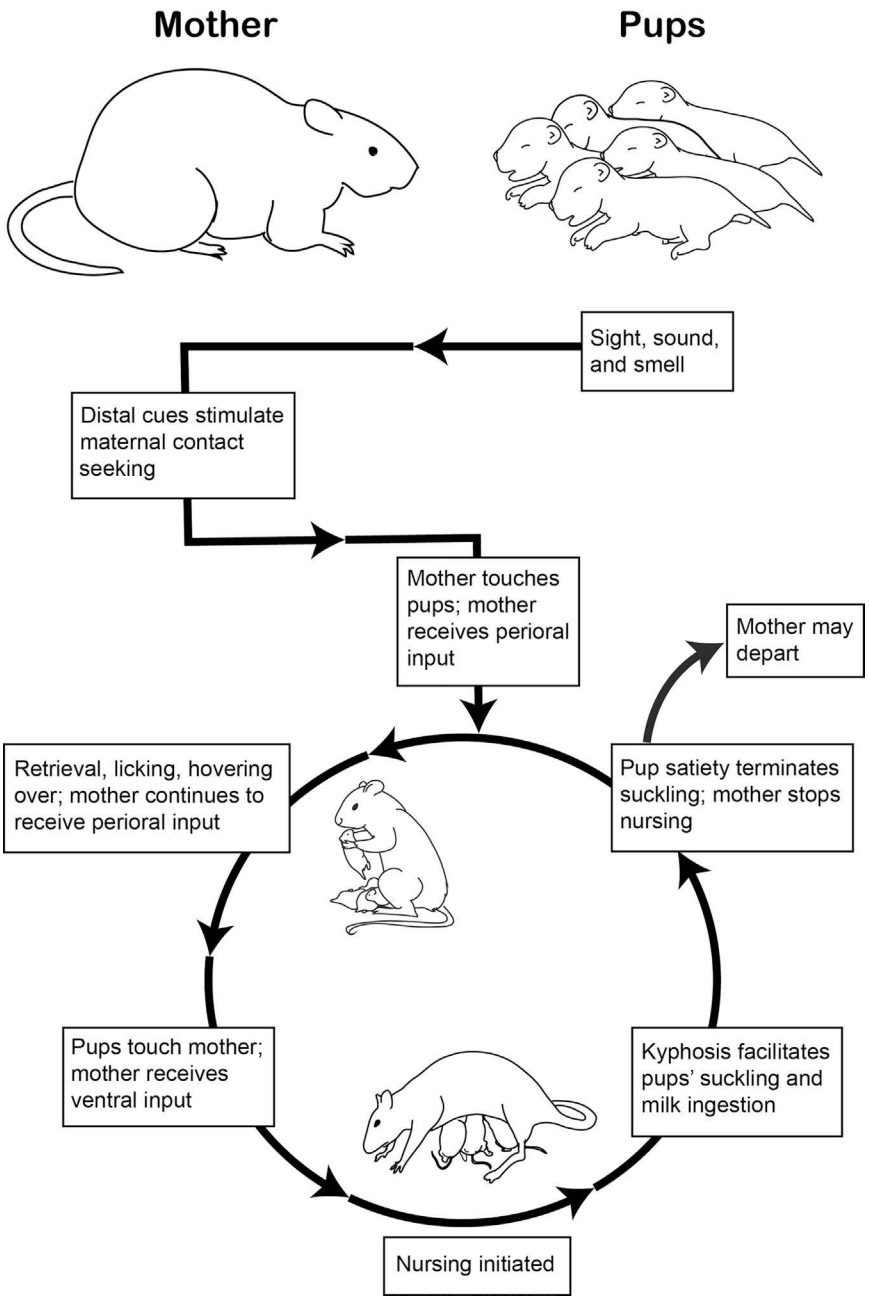

FIGURE 51.13 Sensory events regulating maternal behavior in laboratory rats. In this dyadic interaction, distal cues from pups elicit maternal contact seeking, which then permits the mother to receive perioral tactile inputs required for retrieval. Perioral tactile cues that dams receive while in the nest, mostly obtained while licking the pups, maintain her interest in interacting with the litter and stimulate the litter to search for nipples. Once a sufficient number of pups attach to nipples and begin suckling, these ventral inputs that the dam receives elicit her to show prolonged bouts of quiescent nursing and eventually let down milk. Sated pups will detach from nipples, and the loss of suckling inputs will often result in either the dam resuming active maternal behaviors while hovering over the litter or the dam leaving the nest. *Source: Modified from Stern, 1996.*[73]

somatosensory inputs that dams receive to their ventrums while pups search for and suckle on a nipple. This requisite ventral stimulation must come from a relatively large number of active pups. Indeed, dams are unlikely to nurse if interacting with fewer than four pups or if the pups are immobilized by anesthesia, chilling, or warming.[73] Furthermore, the pups must be not only active but also capable of suckling because normal nursing cannot occur if the pups' mouths are closed shut or anesthetized, or if the dams cannot detect pup suckling because her ventrum is anesthetized or her nipples were surgically removed (a procedure termed *thelectomy*).[390,478] In the absence of adequate ventral stimulation and the quiescence it instills, mothers often continue to actively hover over the litter while exhibiting oral behaviors (licking, repositioning the pups within the nest, and self-grooming) until eventually lying flat on top of the litter without assuming kyphosis or simply leaving the nest.

The termination of a nursing bout also depends on sensory inputs from the pups. The intensity and rhythm of pup suckling reflect their nutritional state, with hungry pups attaching to nipples faster, maintaining attachment longer, and sucking more vigorously and synchronously than do sated pups.[479,480] Because pup suckling induces dams' quiescence, more suckling

results in longer nursing bouts. If hungry pups are suckling a dam that cannot provide milk because her nipples are ligated, or because she is treated with the PRL release inhibitor bromocryptine, nursing bouts are prolonged.[73,481] Conversely, if pups are artificially fed through a gastric tube before interacting with their mother, nursing is truncated.[386] Termination of nursing behavior in rabbits, which typically occurs once per day for only a few short minutes, is also at least in part controlled by suckling inputs from the young.[59]

Given the importance of suckling for the initiation and continuation of nursing bouts in lactating rats, it is surprising that some aspects of the nursing-like behaviors displayed by sensitized nulliparous rats (which are naïve to pregnancy's endocrine influences on skin sensitivity and have no developed nipples upon which pups can suckle) are more similar to those of suckled postpartum dams than those of postpartum thelectomized rats.[107] Perhaps once a postpartum female rat experiences suckling pups, the range of sensory inputs required for quiescence and nursing behaviors is narrowed, but maternal virgins without such experience remain responsive to nonsuckling inputs from the litter.

A number of studies have revealed a critical role for somatosensation in establishing and maintaining maternal responsiveness more generally. One of the earliest events indicating upcoming successful maternal sensitization in nulliparous rats is not a sudden onset of retrieval, but females' tolerance of physical contact with pups that had crawled to them.[386,482] This is consistent with the unusually fast sensitization of virgin rats housed in small cages that do not allow her to avoid physical contact initiated by the pups.[482] In mated female rats, if physical interaction with pups at parturition or relatively soon after a Caesarian delivery is prevented, the mothers are later unresponsive to pups even if they had earlier received distal cues from them.[437,483,484] This early somatosensory input that establishes later interest in pups is diffuse and can be satisfied by either perioral or ventral inputs. If both sources are blocked during the initial interaction with pups, via perioral anesthesia combined with a "jacket" covering the trunk, females are as unresponsive to pups as Caesarian-sectioned females who have never before seen pups at all.[477]

Tactile sensitivity of the human breast, nipples, and areolae is higher during the first few days postpartum compared to during pregnancy.[485] It is unknown if this is also true for other highly sensitive skin, such as the fingertips or face, but it is not found on the back of the hand.[486] The power of this sensitivity is indicated by the ability of postpartum women to identify their own infant just by stroking the infant's hand.[487] Such changes in tactile sensitivity are surely the consequence of ovarian and other hormones,[488,489] and are important for successful breastfeeding and perhaps early bonding between mothers and infants.[490,491] Disorders associated with tactile hypersensitivity (e.g., fibromyalgia or chronic pain) or hyposensitivity (e.g., multiple sclerosis or spinal cord injury) may be expected to interfere with mother–infant interactions through both sensory and cognitive mechanisms, but this remains to be extensively studied.

These findings about how the tactile senses are critical regulators of mothering in laboratory rats are not necessarily universal. For example, the inability to touch the lamb after parturition has little effect on ewes' later maternal acceptance of them as long as they had been able to smell the lambs at a distance.[492] Another possible example is related to the fact that rabbits do not retrieve displaced young and rarely lick them during their brief once-daily interaction,[493] so presumably the absence of perioral sensations would have little or no effect on rabbit mothering.

BRAIN CONTROL OF MATERNAL BEHAVIORS

Brain Control of Maternal Behaviors in Nonhuman Animals

Most of what we know about the neurobiological mechanisms regulating maternal behaviors is derived from laboratory research investigating nonhuman mammals. Laboratory rats have traditionally been the model of choice, but other rodents (mice, voles, gerbils, and hamsters) as well as sheep, rabbits and monkeys have been invaluable additional models that provide essential comparative information. Because at least some of the sensory, motivational, and motor aspects of maternal behaviors are taxonomically conserved, converging evidence gathered across species has outlined a core neural network for mothering. Recent functional magnetic resonance imaging (fMRI) studies in humans have confirmed and extended much of what we originally gleaned from research on nonhuman animals. Studies on this topic in the recent past have often separately considered the functions of a handful of brain structures commonly associated with regulating maternal behavior. However, it needs to be emphasized that such structures belong to interacting neural networks that integrate many processes contributing to successful mothering. These include neurobiological systems involved in sensorimotor integration, motivation, arousal, emotional processing, attentional selection, decision making, learning and memory, and inhibitory control. Together, they orchestrate the effective expression of behaviors appropriate to the needs of both mother and young.

Conceptualizations of the neurobiological underpinning of parental behaviors originally involved a single system that required a particular threshold of

hormonal and/or sensory stimulation from neonates to be reached before an appropriate caregiving response could be triggered.[416] Early detailed analyses of the behavior shown by female rats toward pups were not completely consistent with this conceptualization, though. Particularly inconsistent was that inexperienced nulliparous rats exposed to pups in a maternal sensitization paradigm are not simply neutral toward young and then spontaneously attracted to them a few days later, but instead exhibit what appear to be fearful responses and will actively avoid the offspring. As days of pup exposure progress, these females approach and investigate the pups more often without recoiling, tolerate physical contact from and even lick the pups, and then eventually seek them out. This can easily be contrasted with the wholly positive responses to pups displayed by almost all naturally parturient mothers.

These observations led to an alternative "approach–avoidance model" of mothering.[56,416] This model could be applied to any behavior involving a conflict between competing motivations and a shift in attraction to a social or even presumably nonsocial stimulus. Within this framework, the hormonal events of late pregnancy and parturition do act on the brain and peripheral sensory structures to shift the valence of pup sensory cues from negative to positive, but instead two distinct neurobiological systems are simultaneously modified for this to occur—an excitatory network promoting approach to and interaction with neonates, and an inhibitory system that promotes avoidance and withdrawal from them.[4] The balance of activity in these networks resolves the conflict between avoidance and attraction to pups such that mothering can be expressed. As discussed in detail below, in an attempt to match this model to the known neural systems regulating maternal behavior, the mPOA and adjacent ventral bed nucleus of the stria terminalis (BSTv) have been considered the primary "excitatory" nuclei that project facilitatory information to the mesolimbic dopamine system for the execution of maternal behavior. The MeA and its connections with the dorsal hypothalamus–anterior hypothalamic area (DH/AHA) and ventromedial nucleus (VMN) of the hypothalamus have been suggested to be the primary "inhibitory" nuclei with respect to maternal behavior.[4] In accordance with this model, the onset of maternal behavior is facilitated by a switch from functional dominance of the inhibitory MeA-to-DH/AHA–VMN system to the excitatory mPOA–BSTv-to-mesolimbic system.

It will be seen that the approach–avoidance model has been a very useful heuristic for understanding the neurobiology of maternal behavior, but there are caveats that must first be mentioned. Most problematic is that some brain sites can promote as well as inhibit the behavior, depending on the subpopulation of cells involved or the context in which the behavior is being studied. Thus, it is too simplistic to suggest that some neural sites or systems always promote maternal behavior while others inhibit such responses. Also, the evidence supporting this approach–avoidance model of mothering is heavily based on the inexperienced laboratory rat, in which avoidance of pups is very high and is alleviated by anosmia or sometimes continual exposure to their sensory cues. The model is not readily applied to other animals where parental behavior is spontaneously expressed at very high levels even by inexperienced members—they show no avoidance that needs to be overcome.

Importantly, there is probably also no such avoidance that needs to be overcome in many mammals living in their natural environments. Many animals live in large social groups containing numerous reproducing females. Juveniles in such groups are usually extremely interested in neonates and often have the opportunity to interact with young siblings or nonsibling conspecifics.[350] Similarly, in species like rats and other rodents with a postpartum estrus, lactating females living in natural environments commonly give birth to a subsequent litter before the older litter has reached the age of dispersal from the nest.[54] In either case, juveniles gain parental experience that may permanently obviate most of the aversion to offspring because this experience produces long-term effects on the brain that enhance later parental responding.[494–497] This early experience can affect later behavior to the point that, in its absence, some primate mothers are much more likely to kill or neglect their young.[498] Even in humans, previous experience with infants is a strong predictor of a new mother's positive responses to her own infant and feelings of maternal competency.[499–501]

Medial Preoptic Area (mPOA)

The brain site most studied for an involvement in parenting behaviors in mammals is the mPOA of the ventral forebrain, which lies just rostral to the anterior hypothalamus and caudal to the diagonal band of Broca. As mentioned in the section Components of Parental Care, it has been known that the mPOA was involved in parental behaviors since Fisher's work on testosterone-infused male rats in 1956.[44] A tremendous number of later studies from numerous laboratories have greatly expanded upon these findings by showing that a functional mPOA is essential for both the onset and early expression of maternal behavior. Premating, preparturitional, pre–Caesarean delivery, or postpartum destruction of the mPOA with electrolytic or excitotoxic lesions severely disrupts many components of maternal behavior in female rats, especially retrieval of pups and nest building.[3,4] A similar effect is produced by severing the dorsolateral axons coming to and emanating from the mPOA,[502–504] or by pharmacologically inactivating

the mPOA.[505,506] Licking the pups has not always been quantified in these studies, but when it is, it appears to be less negatively affected by mPOA lesions or knife cuts than other oral maternal behaviors.[504,507–509] The disrupted maternal behavior after mPOA lesioning is not due to endocrine disruption because such lesions impair the onset and expression of sensitized mothering in female and even male rats, whose maternal-like behavior is presumably independent of hormones.[3,4] Electrically stimulating the mPOA promotes maternal responsiveness in maternally experienced rats and in virgin female rats,[510] further supporting the idea that activity in the mPOA promotes mothering. Importantly, the behavioral effects of depressed mPOA activity are relatively specific, since it does not affect females' locomotor activity, sexual behavior, ingestive behavior, and ability to carry pup-sized inanimate objects around their home cage. The importance of the mPOA for many components of maternal behavior is conserved across species and these include laboratory mice,[511] California mice,[509] hamsters,[512] rabbits,[110] and sheep.[513]

Most studies agree that interfering with the mPOA severely to completely disrupts the active oral components of maternal behavior, but only moderate or mild alterations are found in nursing behaviors.[3,4] As discussed in the section Components of Parental Care, when deficits in nursing are found after mPOA manipulations, they may be secondary to the deficit in retrieval and the associated absence of a sufficient number of pups in the nest that can stimulate nursing. It is noteworthy in this context that mother rats with mPOA lesions or dorsolaterally severed axons approach and sniff pups in a manner similar to controls,[502,504,507,514] indicating that the mothers remain interested in pups and initiate physical contact with them. Additional lines of research further support the notion that the mPOA is involved in motivational processes associated with mothering. For instance, in an operant procedure, bar pressing for access to pups in early postpartum females is substantially reduced after mPOA lesions, whereas food-reinforced bar pressing is unimpaired.[508] Similarly, transient inactivation of the mPOA completely abolishes conditioned place preferences to pup-associated incentives.[515]

Relevant to understanding the role of the mPOA, or any other component of the brain's maternal behavior network, is that mammalian maternal care is provided over a long period of time lasting from weeks to years depending on the species. Across this period, the mother's responsiveness to her growing and maturing young changes to match their evolving needs. The temporal dynamics of mother–infant interactions have been described for numerous mammalian species,[99,100] and it is typical for mothers to relax their care in accordance with the increasing physiological and behavioral independence of the young. Indeed, as weaning approaches, mothers leave older young unattended more often and at greater distances, will reject their attempts for physical contact and nursing, and no longer restrain them from leaving the nest. Recent research has revealed that a substantial functional reorganization of the maternal circuitry occurs, probably sculpted by the continuous experience of interaction with the developing pups, to allow such changes in the mother's behavior across the postpartum period that are attuned to the needs of her young.

Specifically, Pereira and Morrell revealed that the mPOA is differentially engaged throughout the postpartum period to orchestrate maternal responses to the changing needs of the developing pups, from a necessary facilitatory role during early postpartum period to an inhibitory role during the late postpartum period.[506,516] Transient inactivation of the mPOA with the anesthetic bupivacaine during the first week postpartum was found to produce the expected loss of maternal responding in rats (Figure 51.14). The same mPOA inactivation during late lactation did not, and instead it increased maternal responding during this time when responsiveness has waned (Figure 51.14).[506,516] Fascinatingly, such changes in the mPOA could be occurring simultaneously with the demonstration of the full pattern of maternal behavior toward a new litter of pups born as a result of mating during the postpartum estrus,[15,496] and may involve even a different pattern of activity in the mPOA and elsewhere to allow dams to both ignore the older litter while remaining interested in the recently born pups. There is also some evidence from immediate-early gene studies that some cells in the mPOA and also the BSTv respond to the aversive qualities of pups, possibly inhibiting maternal behavior, because nonmaternal nulliparous rats have almost as much Fos expression in the mPOA–BSTv after forced exposure to pups as do maternal rats in some studies.[517]

Another consideration for a more comprehensive view of the mPOA in mothering is that long after weaning of the litter, the female brain remains primed for future maternal responding, and experienced females are more resistant to sensory and neural insults compared to inexperienced females.[418,508,513,518] Even nulliparous sensitized female rats are more likely to act maternally at a future date than inexperienced females, indicating that experiential effects do not require endocrine factors.[519,520] The neural basis of this may be related to the finding that second-time mothers have more glial fibrillary acidic protein (GFAP)-immunoreactive cells (i.e., astrocytes) in the mPOA compared to virgins or first-time mothers, and this parity difference requires that females maternally interact with pups after parturition.[521] The functional implications of an increased number of astrocytes are unknown, but perhaps they contribute to a mother's long-term interest in pups by modulating the adjacent

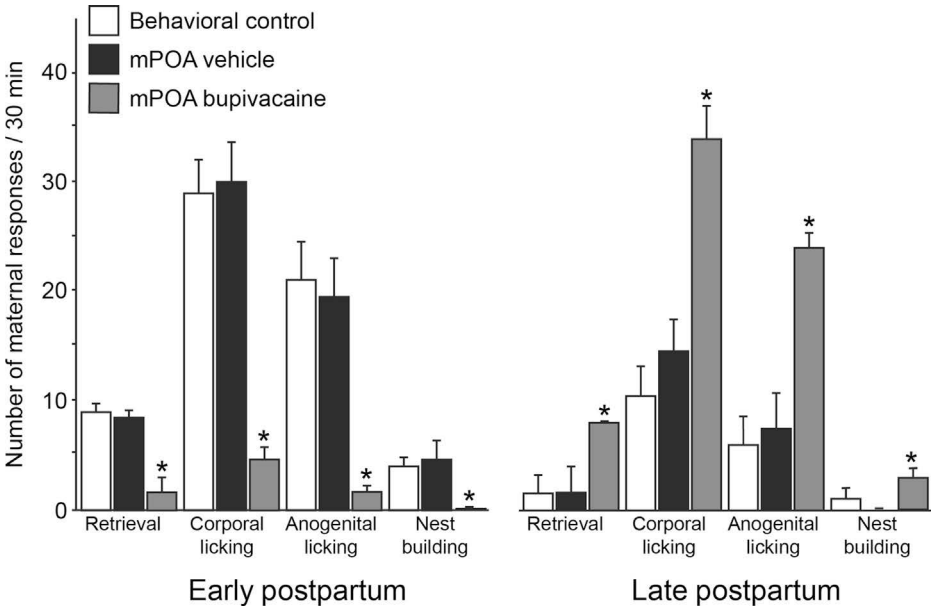

FIGURE 51.14 Frequencies of maternal behaviors (Median ± SIQR) shown by female rats tested early postpartum (days 7 and 8) or late postpartum (days 13 and 14) after transient inactivation of the mPOA with 2% bupivacaine or no inactivation by infusing saline. The behavioral control group received no stereotaxic surgery or infusion. Inactivating the mPOA disrupted all measures of active maternal behavior when performed early postpartum, but facilitated the same behaviors when performed late postpartum, indicating the differing role of the mPOA for maternal behavior across the postpartum period. *Source: Modified from Pereira and Morrell, 2009.*[506]

preoptic area neurons necessary for maternal motivation or behavior. Other types of structural plasticity in the mPOA, such as changes in the size of its somata and the number of basal dendritic branches, occur across pregnancy and in response to exogenous ovarian hormones but are not permanent,[522,523] so they are more likely involved in the onset of maternal behavior rather than long-term experience effects.

Numerous neurotransmitters are released in the intact mPOA to promote or inhibit maternal behaviors. Compared to nonmaternal nulliparous rats, mother rats have greater dopaminergic and serotonergic activity in the mPOA,[524,525] and when they interact with their offspring, AVP is locally released at high levels.[526] In ewes, the release of dopamine, gamma aminobutyric acid (GABA), and OT increases in the mPOA during interaction with the lamb, but there is no change in serotonin release.[227] Infusion of pharmacological agents that mimic or block the activity of a number of neurochemicals alters maternal behaviors. For example, various aspects of maternal behavior are disrupted by mPOA administration of a $GABA_A$ or $GABA_B$ receptor agonist,[505] D1 or D2 receptor antagonists or a dopamine reuptake inhibitor,[527–530] α2-autoreceptor antagonists that increase norepinephrine release,[531] and a nitric oxide synthesis inhibitor that could blunt the release of a number of neurotransmitters.[532] Serotoninergic signaling is essential for maternal behavior in rodents,[533,534] but the effect of serotonin receptor modulation specifically in the mPOA has not yet been investigated.

While most of the research on the mPOA shows little effect on nursing, does the mPOA really have nothing to do with this essential component of mammalian maternal behavior? A subset (~5%) of mPOA cells that express Fos during maternal behavior project to the midbrain periaqueductal gray (PAG),[535] and this projection has been proposed to regulate nursing behavior in postpartum rats.[536] Neurons in the ventrocaudal PAG uniquely show very high Fos expression in response to suckling inputs from pups,[537,538] and lesioning this site greatly interferes with kyphosis while leaving nursing in other postures and appetitive maternal behaviors such as retrieval intact.[537,539] Kyphosis is tonically inhibited by GABA release in the ventrocaudal PAG, but the posture is disinhibited by suckling inputs impinging on PAG cells that are involved in postural control.[540] Because dams cannot simultaneously show immobile nursing and active maternal behaviors, it has been proposed that inhibitory reciprocal projections between the mPOA and ventrocaudal PAG ensure the suppression of inappropriate maternal responses depending on the presence or absence of pup suckling.[537]

Immediate-Early Gene Expression

Studies using expression of the immediate-early genes *c-fos*, *FosB*, and *Egr-1* as markers for cellular modulation in response to cues from pups or behavioral interactions with them have helped confirm and further explicate the role of the mPOA in mothering behaviors. Very large increases in immediate early-gene expression are found in the mPOA when sensitized virgin or postpartum female rats interact with pups,[443,541–545] and this increased expression can persist for many hours (Figure 51.15).[546] If postpartum females are only distally exposed to pups at testing, however, Fos is not increased in the mPOA compared to unexposed controls.[443,542] The same is true for virgin and postpartum laboratory mice,[547,548] but postpartum rabbits require only distal

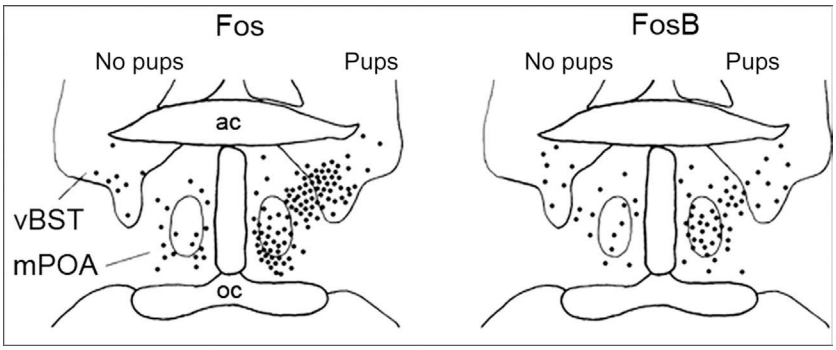

FIGURE 51.15 Schematic representation of frontal sections through the postpartum rat medial preoptic area (mPOA) and ventral bed nucleus of the stria terminalis (BSTv) showing the location of Fos-immunoreactive (left) and FosB-immunoreactive (right) cells after no interaction with pups (left half of each panel) and after an interaction with pups and the display of maternal behavior (right half of each panel). cues from pups for peak Fos expression.[549] The importance of the behavioral interaction with offspring rather than their distal cues in rats is further supported by the inability of olfactory bulbectomy, peripheral anosmia, thelectomy, or general ventral anesthesia to reduce Fos-immunoreactive cells in the mPOA as long as the females behave maternally.[443,444,544] Nonetheless, the development of fMRI for use in live rodents has revealed that even when postpartum rats are restrained and cannot actively interact with pups, the maternal mPOA still exhibits positive blood oxygenation level–dependent activation (often thought to reflect the increased blood flow and metabolism associated with elevated cellular activity) in response to pups' ventral probing and suckling.[550] In multiparous sheep, the vaginocervical stimulation associated with parturition induces Fos in the mPOA, but Fos is not further increased by the presence of the lamb.[551,552] This could indicate little involvement of the mPOA in response to lamb cues or the expression of maternal behavior soon after parturition, but a more reasonable interpretation is that parturition generates a ceiling effect in Fos-immunoreactive cells in the ewes' mPOA. This is reasonable because inactivation of the mPOA during parturition with the anesthetic lidocaine does prevent the onset of maternal behavior in primiparous ewes. Lidocaine in ewes' mPOA also reduces some aspects of ongoing mothering when infusions begin hours after parturition.[513]

This immediate-early gene activity in the maternal mPOA is a convenient marker for genomic activity in response to offspring cues or the expression of parenting, but the specific function of these Fos-immunoreactive cells in the mPOA remains an important question. Half to 75% of the mPOA cells expressing Fos after postpartum rats and mice interact with pups also express glutamate decarboxylase 1 (GAD_{67}), so these cells are likely GABAergic.[511,553] Activation of so many potentially inhibitory cells in the maternal mPOA could reflect the removal of tonic inhibition on downstream cell groups necessary for maternal behavior, or that activation of these GABAergic cells is suppressing other cell groups that would otherwise interfere with the behavior.[553] A recent anatomically refined study found that the subregional location of the densest Fos in the mPOA after the display of maternal behavior by postpartum mice was not the same mPOA subregion where maternal behaviors were the most disrupted by excitotoxic lesions, suggesting that many of the mPOA cells are responding to maternal interaction with pups for some other behavioral or physiological purpose.[511] A major limitation of these immediate-early gene studies is that this approach has little temporal resolution. Progress in understanding maternal behavior is hindered by the lack of understanding of the real-time events and the coordinated and sequenced activity across neural components necessary for mothering. Particularly useful would be functional circuit analysis with electrophysiological approaches and continued use of fMRI in mother laboratory rats.

Some insight into the role of the immediate-early genes themselves in maternal behavior, other than just being convenient markers for cellular modulation, comes from virgin female mice with a targeted deletion of the *FosB* gene. These mice are less likely to spontaneously retrieve pups as virgins, and even after mating and giving birth to healthy pups still will not care for them; most pups die within days after birth.[554,555] Inhibiting phosphorylation of the extracellular signal-regulated kinase protein (ERK), which is part of the intracellular cascade triggered by growth factors and necessary for *FosB* transcription, also inhibits spontaneous retrieval in inexperienced virgin female mice, but does not do so in experienced postpartum mothers.[556] Because *FosB* knockout mice are hyperactive, impulsive, and possibly hyperemotional, and their brains contain markers of neuropathology, the relationship between *FosB* and maternal behavior may be nonspecific.[555]

Relationship of the mPOA with the BSTv

The cells relevant for maternal behavior extend out of the cytoarchitectorally defined borders of the mPOA and into the adjacent BSTv (including parts of the dorsomedial, dorsolateral, magnocellular, and anteroventral subnuclei of the BST). Because of the close proximity of

the two sites, many mPOA lesion and hormone infusion studies have probably also affected cells of the BSTv,[557] and the mPOA and BSTv have sometimes been presented as a common functional unit for maternal behavior because distinguishing their individual roles is difficult.[3,557] Nonetheless, it has been observed that whereas retrieval does not recover after mPOA lesions,[514,558] it does reemerge in some postpartum rats with neurotoxic lesions of the BSTv.[557] Similarly, in primiparous sheep, the onset of maternal behavior at parturition is almost completely prevented by temporary inactivation of the mPOA, while almost no deficits are seen after BSTv inactivation.[513] Differences between the function of the mPOA and BSTv are also indicated by the findings that retrieval is more greatly impaired after mPOA than BSTv infusion of idazoxan (an α2-autoreceptor antagonist that increases norepinephrine release)[531] and that dampening AVP V1a receptor activity in the mPOA reduces retrieval and nursing in postpartum rats while having no effect in the BSTv.[526,559]

These results distinguishing between the two sites are probably related to the different projections of mPOA and BSTv cells that are stimulated during the performance of maternal behavior. The termination sites of almost half of all Fos-expressing neurons in the mPOA and BSTv of maternally acting female rats have been identified and involve just six brain areas—the lateral septum, ventromedial hypothalamus, lateral habenula, retrorubral field, ventral tegmental area (VTA), and lateral PAG. While most of the identified mPOA Fos-containing cells projected to the two forebrain sites (the ventromedial hypothalamus and lateral septum), the identified BSTv Fos-containing cells projected more widely to the six targets.[535] This functional and anatomical information could suggest that mPOA output primarily modulates activity in brain sites that would otherwise inhibit maternal behaviors, including the ventromedial hypothalamus and lateral septum, whereas the BSTv functions more to activate midbrain motor and motivation systems necessary for maternal behaviors to be displayed.

mPOA as a Site for Hormone-Sensory Integration

The mPOA is an essential component of the maternal behavior network, in part because it is perfectly situated to integrate an animals' endocrine state with incoming sensory cues from young, and then transmit this information to motivation and motor effector pathways that orchestrate the expression of maternal behaviors. Indeed, the mPOA is exquisitely sensitive to ovarian and pituitary hormones and a primary neural site for their effects on the onset of maternal behavior. It contains very high densities of receptors for ER, PR, PRL, and OT, all of which fluctuate in their expression near the end of pregnancy and in the early postpartum period in many animals.[110,131,180,560–562] When estradiol is implanted or repeatedly infused into the mPOA of nulliparous rats, the onset of retrieving is rapid, although other maternal behaviors are not necessarily so quickly established.[205,563,564] In rabbits, which do not retrieve young, estradiol implanted into or very near the mPOA stimulates components of maternal nest-building behavior.[565]

Even though estradiol in the mPOA stimulates components of maternal behavior in virgin animals, implanting the selective ER modulator tamoxifen (often traditionally used as an estrogen receptor antagonist in the brain) into the mPOA 2 days before parturition does not prevent the onset of maternal behavior.[566] Tamoxifen implants into the mPOA do somewhat reduce the percentage of females showing maternal care (by ~33%) if litters are delivered by Caesarian section,[566] suggesting that the experience of parturition and release of its hormones may override the need for late-pregnancy estrogenic activity in the mPOA. Recently, this question was re-examined by studying the maternal behavior of female laboratory mice after mPOA delivery of a short hairpin RNA (shRNA) that interferes with the mRNA for ERα. When testing began 4 days after parturition, these females displayed rather severe deficits in almost all maternal behaviors.[141] Unfortunately, it remains unknown how soon after parturition maternal behavior began to be impaired, if these mothers were lactating normally, or what the mothers were doing in the absence of spending time with the litter. Once ER signaling in the mPOA helps establish maternal behavior, it may continue to help maintain the behavior even in the absence of estrogen. A large percentage (~33%) of the mPOA cells expressing Fos during the display of postpartum maternal behavior also contain ERα,[567] and in the absence of high levels of circulating estrogen during lactation, activation of ERα in these cells may instead occur through a ligand-independent mechanism involving stimulation of the receptors by classic neurotransmitters.[568]

The sites where PRL acts to hasten maternal behavior are certainly within the central nervous system, as daily intracerebroventricular infusion of PRL or placental lactogens facilitated the behavior in steroid-primed females.[188] Bakowska and Morrell presented similar conclusions from pregnant female rats that were hysterectomized and ovariectomized on day 16 of pregnancy.[569] Conversely, a PRL receptor antagonist delivered into the cerebral ventricles delays the onset of mothering in parturient rats.[570] The mPOA is one site mediating these effects. Similar to ventricular infusion, PRL or placental lactogens infused into the mPOA can act along with ovarian hormones to hasten the onset of maternal behavior in nulliparous rats;[188,571] antagonism of PRL receptors in the mPOA delays the onset of

mothering in nulliparous steroid-treated rats.[572] Other brain sites where PRL acts to promote maternal behavior are unknown.

The mPOA is also a target for the effects of OT and its receptor antagonist on maternal behavior,[207] and fMRI activity in the POA is blunted by pretreating mother rats with an OT receptor antagonist before exposing them to pups.[550] Surprisingly, OT release in the mPOA does not increase during mother–infant interactions,[526] even though OT acts there to promote maternal behavior and individual differences in OT receptor expression in the mPOA are associated with the frequency of postpartum maternal licking.[208] Other forebrain sites where OT promotes mothering are mostly unknown, but maternal behavior can be stimulated by infusing OT into the olfactory bulb[573] and impaired by OT receptor antagonism in the VTA.[207] It was noted in the section Hormones Most Significant for the Onset of Maternal Behavior, that reducing OT signaling to the mPOA and elsewhere by lesioning the PVN of the hypothalamus, the major source of OTergic projections in the brain, disrupts the onset of maternal behavior at parturition but has little effect on its maintenance.[198,199,574] Other neuropeptides or their receptor antagonists that can influence maternal behavior after mPOA infusion include AVP,[207,559] endogenous opioids,[575] cholecystokinin,[576] and melanin-concentrating hormone.[577]

Progesterone is a strong inhibitor of maternal behavior (see the section Hormones Most Significant for the Onset of Maternal Behavior), and the mPOA has been studied as its target for this effect, but hysterectomized and ovariectomized pregnant female rats with progesterone implanted in the mPOA at the time of surgery are still rapidly maternal.[578] Perhaps progesterone acts elsewhere or on multiple sites simultaneously to produce its inhibitory effects on maternal behavior, but Sheehan and Numan did find that progesterone prevented the increase in Fos expression in the mPOA (and BSTv) of hysterectomized and ovariectomized pregnant female rats given an injection of estradiol that would have rapidly stimulated maternal behavior.[579] Circulating progesterone levels begin to rise a few days after parturition and remain very high through the second week of lactation in rats (see the section Hormones Most Significant for the Onset of Maternal Behavior), but it is unknown why this endogenous progesterone acting in the mPOA or elsewhere does not interfere with the maintenance of maternal behavior. Maybe this can be avoided because basal progesterone receptor expression is very low in the postpartum mPOA,[560,580] rendering it insensitive to progesterone's potential inhibitory effects on mothering.

With regard to sensory inputs from pups, the mPOA receives converging information from virtually all sensory modalities and sends input back to those sources. Olfactory information from the main and accessory olfactory bulbs reaches the mPOA via the MeA,[581,582] and the mPOA receives ventral trunk somatosensory inputs directly from the peripeduncular nucleus of the lateral midbrain[582] and perioral tactile inputs through a direct trigeminohypothalamic projection[583] and indirectly via brainstem relay nuclei.[582] Gustatory input can reach the BST,[584] which, in turn, is densely interconnected with the mPOA. Moreover, olfactory, gustatory, somatosensory, auditory, and visual regions within the insular cortex project to several limbic and sensorimotor regions and densely to the infralimbic region of the medial prefrontal cortex (mPFC), which, in turn, also projects to the mPOA.[582]

Connections of the mPOA for the Elicitation of Maternal Behaviors

Motivation Systems

Primary efferents from the mPOA traveling through the lateral hypothalamus allow it to interact with components of the mesolimbic dopamine (DA) system for the motivational aspects of maternal responsiveness to pups. The mesolimbic DA system, which is composed of DA cell bodies in the midbrain VTA that project to the nucleus accumbens (NA) in the forebrain, has been recognized for its central role in several behavioral functions related to motivation.[585,586] The NA receives converging excitatory inputs from most cortical and limbic structures, and hence has long been considered an interface linking those corticolimbic structures to behavioral output systems, under the modulatory influence of DAergic inputs from the VTA.[587] Neurophysiological and neuroanatomical studies suggest that DA in the NA may select and integrate the effects of limbic and cortical afferents, thus influencing the transmission of information to output areas, and ultimately modulating goal-directed behaviors.[586,588]

Anatomically and functionally, the NA can be divided into two distinct regions, the core and the shell.[589,590] Each receives different but overlapping excitatory glutamatergic projections from corticolimbic structures, including the basolateral amygdala (BLA), hippocampus, and prefrontal cortex (PFC).[589,591] The core and shell also differ in their downstream targets. The NA core projects primarily to the dorsolateral portion of the ventral pallidum, the substantia nigra pars reticulata, and the subthalamic nucleus.[590,592] Projections from these targets travel to the motor thalamus and then to cortical motor areas for the execution of behavior. The NA shell, in contrast, sends projections mainly to the ventromedial ventral pallidum, substantia innominata, mPOA, several hypothalamic nuclei, substantia nigra pars compacta, VTA, and PAG.[592–595]

In the context of maternal behavior, several pieces of evidence indicate that DA released in the NA shell and core

participates in activating maternal behavior. For instance, many laboratories have used microdialysis to find that DA release in both the core and shell of postpartum mother rats is enhanced during interactions with pups.[596–599] It appears that the hormones associated with pregnancy and parturition bias the mesolimbic DA system to respond to pups by reducing mother's basal DA levels in the NA shell. As a result, the magnitude of pup-evoked DA release is more striking.[596,600] In a very recent study, DA responses in the NA were further characterized during a fine-grained analysis of mother–pup interactions across the postpartum period. It was found that during the early postpartum period, the presentation of pups behind a screen that elicited maternal pup-seeking behavior resulted in a robust increase in DA release in the NA core, which was further augmented during active but not passive maternal interaction with pups. Although this pattern of DA release was also found in late-postpartum females, the magnitude of release was considerably attenuated in those mothers.[601]

Finer temporal analysis using in vivo voltammetry has also revealed that the DA signaling in the NA shell and core increases with the initial presentation of pups after a brief separation, and also immediately before as well as during active maternal behaviors such as pup retrieval and licking (Figure 51.16).[597,602] Furthermore, the magnitude of DA release is related to individual variation in maternal licking, such that high-licking mothers show a greater increase in DA release before or during a licking bout compared to low-licking mothers.[597] Levels of DA receptor expression in the NA are also positively correlated, and DA transporter levels negatively correlated, with mothers' levels of licking.[597] Together, these studies suggest that changes in NA DA activity associated with mother–pup interactions may serve as a neural substrate for the dynamic motivational aspects of maternal behavior among individuals and across postpartum time.

Interfering with this DA neurotransmission by electrolytic or DA-depleting lesions of the VTA, pharmacological manipulation of VTA activity, or core or shell administration of D1 or D2 receptor antagonists each selectively and severely disrupt most active maternal behaviors in early-postpartum rats.[529,603–609] The amount of time these mothers spend with the pups is normal, indicating that they remain interested in approaching the pups and maintaining physical contact with them. Indeed, these VTA or NA manipulations can even facilitate nursing behavior if pups are manually placed in the nest,[536] which is consistent with studies showing that manipulating accumbens DA selectively influences

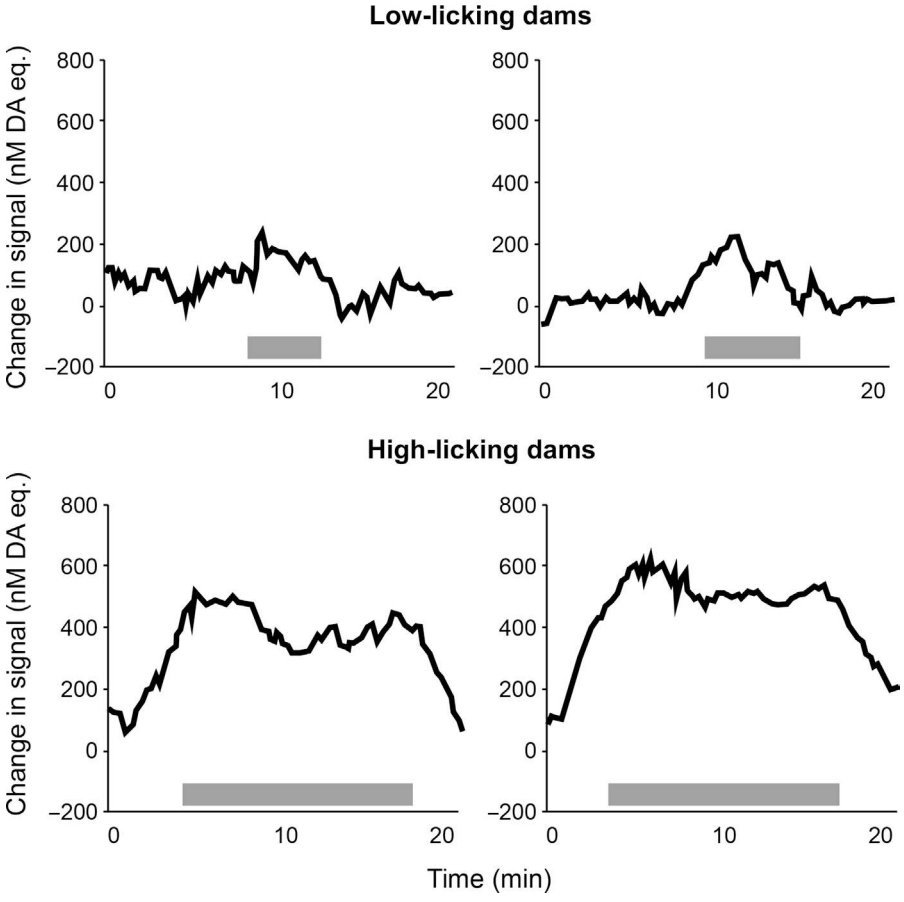

FIGURE 51.16 Changes in dopamine (DA) signaling in the shell of the nucleus accumbens of two representative high-licking and low-licking postpartum rats before, during, and after a bout of licking their pups. The gray bar indicates the duration of the licking bout. Note the greater increase in high-licking rats and that the rise in DA signaling begins to occur before licking is exhibited. *Source: Modified from Champagne et al., 2004.*[597]

the activational or effort-related aspects of motivated behaviors, while leaving the directional aspects relatively intact.[586,610] The disruptive effects of DA receptor antagonism on active maternal behaviors are not exclusive to rats and occur in both sexes of the biparental prairie vole.[611] Consistent with these studies, D1 receptor stimulation of the NA promotes the onset of maternal behavior in hysterectomized, pregnant female rats.[530] Of course, DA in the NA does not activate maternal behaviors in chemical isolation and the purine nucleoside, adenosine, and the adenosine A_{2A} receptor have been found to modulate DA-mediated maternal behavior.[612]

The nature of the impairments seen after interfering with DAergic activity is thought to mostly reflect deficits in maternal motivation, which is demonstrated by the fact that the deficits can be overridden if dams are separated from pups for 3–12 h[605,613] or if the motivational salience of the pups is increased by presenting mothers with hungry, demanding pups.[614] In both cases, active components of maternal behavior are restored to levels characteristic of control dams. Also, if postpartum rats are muzzled so they cannot retrieve pups, they spend considerable time pushing at the pups with their snouts and handling them with their paws, but such compensatory behaviors are not displayed if mesolimbic DA transmission is reduced.[615] Furthermore, DA release in the NA contributes to the rewarding aspect of the pups, as mothers can form a conditioned place preference for an environment in which they interacted with pups, but not if DA release in the NA is impaired.[599,607,616]

Given the results of the studies described immediately above, it is probably surprising to read that lesioning the NA produces no deleterious effects on maternal behaviors in rats.[508,617] To reconcile this, it is essential to consider prevailing models of how the NA is involved in basal ganglia function. These models propose that the NA consists of distinct populations of medium spiny GABAergic projection neurons that selectively express either D1 or D2 receptors.[618] These neurons respectively project directly or indirectly to basal ganglia output nuclei, namely, the substantia nigra pars reticulata and pedunculopontine tegmental nucleus.[619,620] Through these opposing direct and indirect output pathways, NA neurons are proposed to select appropriate behavioral responses while inhibiting competing ones. Manipulations that interfere with DA neurotransmission in the NA (inactivating the VTA, intra-NA DA receptor antagonism, and depletion of DA within the NA) all result in a marked impairment in behavioral responding to pups and related stimuli. By contrast, transient inactivation or permanent cell body lesions of the NA uniformly inhibit all its neurons, regardless of the medium spiny neuron subtypes or their efferent destination, and have virtually no effect on motivated behaviors. Given the distinct populations of medium spiny neurons within the NA, eliminating all NA activity might produce effects that negate each other at the level of basal ganglia output, with no net change in behavior.

In an elegant series of studies, Numan and collaborators have provided substantial evidence supporting the idea that activation of hormonally primed and offspring-stimulated mPOA projections to the VTA and NA promotes maternal behavior.[621] The mPOA can influence NA function through a direct projection to it and indirectly through projections to the VTA.[622,623] The mPOA projections to DAergic neurons in the VTA include OT-expressing cells,[624] providing a neuroanatomical substrate for how OT modulates maternal behavior.[207] Moreover, infusion of OT into the VTA can trigger DA release into the NA,[625] and this promotes the onset of maternal behavior and probably influences its ongoing display.[207] Intact bilateral connections between the mPOA and the VTA and NA are essential for maternal behavior in rats. In a study using an asymmetrical lesion design,[606,626] unilateral mPOA lesion paired with a contralateral lesion of the VTA severely disrupted maternal retrieval of pups, while various control lesions were relatively ineffective. Consistent with these results, the NA shows increased Fos expression during the display of maternal behavior in rats,[542] but not if the ipsilateral mPOA is lesioned.[627]

After hormone and pup sensory information has reached the NA via the mPOA, and probably to a minor degree via the basolateral amygdala,[628,629,630] this information is transmitted to the ventral pallidum. The ventral pallidum is reciprocally connected via GABAergic neurons to the NA and responds to the pleasurable qualities of stimuli such as pups.[588] The ventral pallidum also projects to motor networks necessary for the execution of behavior.[631] Lesioning or infusing a $GABA_A$ receptor agonist into the ventral pallidum causes a dramatic disruption in maternal responsiveness,[558,617] as does a unilateral lesion of mPOA paired with a contralateral lesion of the ventral pallidum.[617] Together, these studies demonstrate the importance of the mPOA interactions with the VTA–NA–ventral pallidum circuitry in the activational aspects of maternal motivation and behavior.

Emotion Regulation Systems

The approach–avoidance model of maternal behavior in rats suggests that neophobia of pup-related cues is a primary impediment to maternal responding in inexperienced rats, theoretically by high neural activity in brain sites involved in aversion or negative emotional reactivity that do not allow the mPOA and its connection to the brain's maternal motivation systems to dominate.[416] Because the odors of pups have traditionally been thought to be the basis of this neophobia, the locus of inhibitory control of mothering has been on the MeA,

which receives projections from both the main and accessory olfactory bulbs.[581] The MeA very densely and reciprocally innervates the mPOA, and each site can inhibit or excite the other. Estradiol reduces excitatory input from the mPOA to the MeA, which may be the basis of how estradiol regulates this projection to facilitate mothering.[632]

Similar to the effects of anosmia, nulliparous or pregnancy-terminated female rats sustaining electrolytic or cell body–specific lesions of the MeA, and sometimes also the cortical amygdala, are faster to act maternally than unlesioned controls.[422,436,633] These lesioned females do not actively avoid pups placed in their nest and are more tolerant of contact with them even if not yet expressing maternal behavior.[422] An intact mPOA is required for this facilitation, suggesting that the absence of the MeA does not alone promote maternal behavior but instead removes an inhibitory input to sites that do.[634] The onset of maternal behavior in MeA-lesioned animals can still take a few days, so it is not as effective as peripheral anosmia, suggesting that some olfactory inputs inhibiting maternal behavior are transmitted elsewhere in the brain. As opposed to the positive effects of MeA lesions in nulliparous rats, repeated kindling-like electrical stimulation of the MeA inhibits the future resumption of mothering in experienced postpartum rats. Furthermore, MeA kindling also somewhat reduces the preference for pup-related cues by inexperienced nulliparous rats, but it does not further affect their already low maternal responding in a sensitization procedure.[510] Nulliparous ewes also find offspring olfactory cues aversive, but it remains unknown if deactivating the MeA elicits maternal behavior. It is known that temporary chemical inactivation of the MeA or nearby cortical amygdala (but not the basolateral amygdala) beginning at parturition does not affect the onset of maternal behavior, but it does render ewes non-selectively maternal when tested hours later. Later MeA inactivation in already-selective ewes does not produce this effect, indicating that the MeA must process cues necessary for establishing an olfactory memory of the lamb (Figure 51.17).[635]

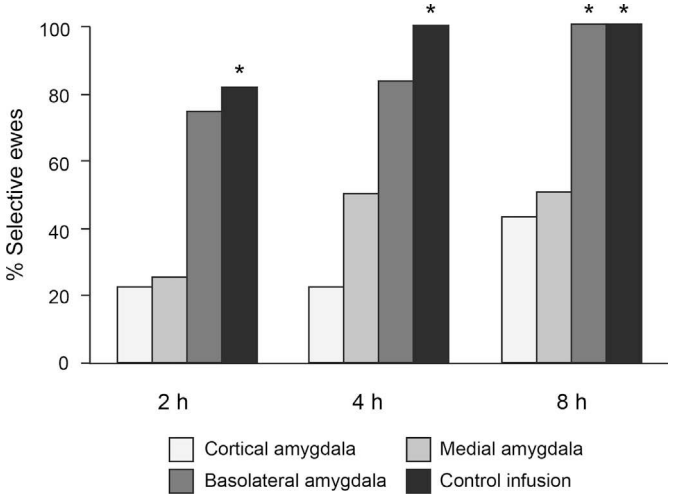

FIGURE 51.17 Percentage of ewes that selectively interacted with their lamb after 2, 4, or 8 h of inactivation of the cortical (Co), medial (Me), or basolateral (Bl) amygdala with lidocaine beginning at parturition. Inactivation of the cortical or medial nuclei, but not the basolateral nucleus, disrupted selectivity for the lamb. *Source: Modified from Keller et al., 2004.*[635]

Note that in animals requiring olfaction for the expression of maternal behavior, such as voles and mice, MeA lesions could be expected to produce blunted interest in pups, but this has not been examined in female voles, and lesion studies in mice have not targeted the MeA.[49,636,637] Another consideration regarding the MeA mentioned earlier in this chapter is that cell body–specific lesions of the MeA are incapable of promoting maternal responding in nulliparous female rats if their ovaries had been removed,[436] suggesting that the endocrine events involved with pseudopregnancy that can be induced after some types of MeA lesions are responsible for the effects on maternal behavior. In support, pharmacologically inhibiting pituitary PRL release prevents the facilitation of maternal behavior after excitotoxic MeA lesions. In addition, by delaying testing until well after postlesion pseudopregnancy has terminated, there is only a modest facilitation of maternal responding.[436] Such results might suggest that the negative influence of the MeA on maternal behavior in rats has been overemphasized, although it is interesting that in another series of studies using ovariectomized nulliparae tested 5 days after receiving electrolytic MeA lesions, there was still a dramatic onset of mothering compared to controls.[422] This apparent inconsistency could be related to differences between the studies in the neuroanatomical extent of the lesions or the lesion methods used (electrolytic versus excitotoxic).[638]

The MeA not only projects heavily to the mPOA but also provides major efferent projections to the DH/AHA and VMN of the hypothalamus, which are thought to partly mediate the MeA inhibition of maternal behavior. The DH/AHA and VMN are more generally components of the neural network mediating aversive and defensive behaviors,[639] and electrical stimulation of at least the VMN inhibits the firing of many mPOA neurons.[640] Aversive pup stimuli do not elicit Fos in the VMN of nonmaternal rats, but they do in the DH/AHA,[517] and MeA neurons that are activated in nonmaternal rats by aversive pup stimuli project to both hypothalamic regions.[633] Important direct evidence for the inhibitory role of these sites is that excitotoxic lesions of the DH/AHA or VMN stimulate maternal responding in steroid-primed nulliparous rats.[641] An indirect route through which AHA–VMN output may regulate avoidance of pups in nonmaternal rats is through projections to parts of the midbrain PAG involved in defensive responses. It would be valuable to

determine if lesioning any subregion of the PAG can alter defensive responding and promote maternal behavior in nulliparous rats. Ventrocaudal PAG lesions do reduce anxiety in postpartum rats,[74] and destruction of the rostral lateral PAG reorients the focus onto pups in morphine-treated postpartum rats that would rather hunt than mother.[642] Other brain sites, including the septum, central amygdala, mammillary region, and midbrain raphe serotonin system, could also interact with the MeA, DH/AHA, and VMN to instill aversion to pups in nonmaternal rats.[4,643] Of particular mention in this context is the lateral habenula, which regulates midbrain raphe cells to elicit or suppress aversive responses,[644] and is known to be necessary for the onset but not maintenance of natural or sensitized maternal behavior in rats.[645,646]

The function of the MeA has been suggested to switch after female rats give birth, by acting at that point to transmit olfactory inputs to the mPOA to increase attraction to pups and maternal behaviors.[4] There is little experimental support for this; on the contrary, olfaction is not needed for postpartum maternal behavior in rats (see the section Components of Parental Care), and increasing inhibitory tone in the MeA with the $GABA_A$ receptor agonist muscimol has no effect on postpartum mothering.[629]

The MeA regulates innate fear responses to olfactory stimuli,[647] which is consistent with the promotion of maternal responsiveness after MeA lesioning, but these lesions also reduce emotional reactivity unassociated with social odors. Female rats with corticomedial amygdala lesions not only are more maternal but also spend more time in the center of an open field, indicative of reduced general anxiety.[422] A regimen of exogenous ovarian hormones that presumably acts in part on the MeA to induce maternal behavior also increases time in the center of an open field.[441] Conversely, nulliparous female rats that received kindling-like electrical stimulation of the MeA spend less time in the center of the open field, indicative of higher anxiety.[510] The question arises whether MeA lesions promote maternal behavior by removing the ability to process aversive pup odors, or because of a more general dampening of emotional reactivity. It seems that for the onset of maternal behavior in laboratory rats, the olfactory modification is the most relevant. This is supported by data indicating that maternal interest increases in the final few days of pregnancy in female rats,[89] but their general anxiety-related behaviors in an open field or an elevated plus-maze are not lower than those of cycling females.[648,649] Second, if a general reduction in emotional reactivity was necessary for the onset of maternal behavior, treating rats with anxiolytics would be predicted to hasten maternal sensitization in nulliparous rats, but it does not.[650] Third, olfactory bulbectomy or peripheral anosmia very quickly induces maternal behavior, but does not in all studies reduce anxiety-related behaviors.[651,652] Lastly, nulliparous female rats that had juvenile experience with pups show very low adult anxiety-related behavior, meeting the low levels found in most postpartum rats. These adult nulliparae still avoid pups, though, and require a days of exposure to young before acting maternally, although they do sensitize faster than females not exposed to pups during juvenile life.[497]

A generalized reduction in anxiety or other aspects of emotional reactivity may not critically contribute to the natural onset of maternal behavior in laboratory rats, but there is such a reduction in anxiety after females have given birth. Lower anxiety behavior can be found in many behavioral paradigms within 24 h after parturition, lasts for about 1 week postpartum, and requires recent physical contact with the litter but not their suckling.[50] This mitigated reactivity to anxiogenic stimuli in maternal animals that have recent litter contact is reflected by lower Fos expression in some brain areas traditionally associated with emotional regulation.[653] The effectiveness of mother–offspring touch to suppress anxiety or other negative affective behaviors is further seen by the blunted reactivity of nulliparous, maternally sensitized female rats.[654–656] This blunted anxiety accompanying motherhood in rats also occurs in women,[50] but mother rhesus monkeys appear to be more anxious when they have infants to care for.[657]

As discussed elsewhere,[3,50] this general reduction in anxiety may affect numerous other postpartum behaviors. A suppression of anxiety could reduce dams' reactivity to intruders to the nest site in a way that is permissive for maternal aggression, although some data do not support this.[52] Low anxiety may also help maintain maternal attention to pups under mildly threatening conditions, but this suggestion is complicated by the findings that mother rats genetically selected for high anxiety spend more time with pups under undisturbed conditions and are faster to retrieve them under either undisturbed or challenging conditions compared to low-anxiety dams.[658] Others have found no relationship between "trait" anxiety in female laboratory mice and their later maternal behavior.[659] It has also been reported that noradrenergic manipulations in the BSTv, long associated with anxiety-related behaviors in addition to maternal behaviors, can impair mothering but not necessarily alter anxiety in postpartum rats.[531] It may be the case that within a natural environment, low postpartum anxiety is most important for achieving the metabolic demands of lactation, by allowing dams to forage further from the nest and take greater risks to obtain food. The more time that the dam spends away from the nest would lead to a gradual loss of the sensory "trace" instilled by pups that is needed for her low anxiety, and the resultant rise in anxiety could drive her to return to the familiar environs of the nest where she would then reunite with the pups.[660]

Interestingly, some of the emotional consequences of motherhood persist long after lactation, and anxiety can be lower in mothers tested many months after weaning of the litter.[661,662] This depends on when previous mothers are tested because cycling, primiparous female rats are less anxious than nulliparous females during the afternoon of proestrus but not during other phases of the estrous cycle.[662] This suppression of anxiety is clearly not due to recent contact with pups but instead due to the enduring neuroendocrine effects of parity, including lower PRL and estrogen release in previous mothers compared to nonmothers, but enhanced sensitivity to estradiol from greater ERα expression in the pituitary gland and brain—including in the mPOA.[663]

Cognitive Systems

Maternal behaviors emerge once the mPOA–mesolimbic pathway is activated and the MeA–DH/AHA–VMN inhibitory pathway is deactivated, but caregiving and its associated behaviors can be further improved by fine-tuning other neurobiological systems, including those underlying cognitive functioning. New parents must plan and be organized, but also prepared to respond to sudden change. That is, environmental cues need to be freshly evaluated, attended to, and efficiently processed so that the parent's behavior can be rapidly initiated or inhibited. New types of social interactions and physical features in the environment must be remembered to best guide future activities. Many such cognitive skills are enhanced in parental animals, and this involves a "resculpting" of their brain. This resculpting occurs to an impressive degree. For example, on a gross structural level, total brain volume shrinks by over 5% in pregnant women and this is accompanied by a 30% increase in the size of their ventricles.[664] These measures revert to prepregnancy values within 6 months after parturition, and at the same time the volume of women's gray matter in the prefrontal cortex and parietal lobe selectively increases.[665]

Research by Kinsley and Lambert was the first to discover that mothering enhances female rats' spatial memory, which is now known to involve striking hippocampal neuroplasticity. In an eight-arm radial maze, maternally experienced rats who had weaned their pups learned the location of baited arms after fewer trails than nulliparous females, and in a dry-land analog of the Morris Water Maze, the experienced females more rapidly reached a baited food well. The mothering experience, rather than pregnancy and lactation, is responsible for this benefit because nulliparous-sensitized females also show enhanced spatial memory.[666,667] Amazingly, these cognitive benefits of previous motherhood in rats can last for years.[668] Later work by Pawluski and colleagues extended this memory improvement in rats to current motherhood and found that it requires at least some contact with pups after parturition.[669,670] Similar behavioral results have been found in postpartum laboratory mice, and brain OT is one regulator of these effects in this species.[671] There is evidence that reproductive and maternal experience improves some memory capabilities in women,[672] and spatial memory improvements can also be found in rodent fathers.[673]

These results suggest that parental interactions with offspring, and in some cases exposure to hormones, induce plasticity in brain sites associated with learning and memory. Studies in rodents have focused on the hippocampus. One aspect of hippocampal plasticity in the maternal brain involves changes in the proliferation of new cells, including neurons. Cell birth in the brain was once thought to occur only during early development in mammals, but it is now well established in many adults, and altered cell proliferation is particularly common during times of hormone-mediated neurobehavioral flux, such as parenthood.[674] New brain cells are often visualized with the use of the cell birth date marker bromodeoxyuridine (BrdU), a thymidine analog readily incorporated into cells that are synthesizing DNA in preparation for mitosis.

One of the traditional areas for cell proliferation in the adult brain in many models is the granule cell layer of the hippocampal dentate gyrus (DG). Cell proliferation in the DG decreases during the middle and end of pregnancy in mice,[675,676] and during the first week postpartum in laboratory rats; the latter is a result of suckling-induced corticosterone release.[677–679] A similar decrease in DG cell proliferation is observed in parturient and maternal sheep.[680] The hormone dependence of this phenomenon is demonstrated by the finding that mothering experience alone in sensitized rats without the endocrine consequences of lactation *increases* cell proliferation in the DG (Figure 51.18).[678] A similar decrease in cell genesis during the first week postpartum also occurs in the midbrain dorsal raphe of laboratory rats,[643] which may be related to changes in serotonin output necessary for maternal behavior and lactation.

In forebrain sites more traditionally studied for roles in maternal behavior, increased numbers of BrdU-labeled cells are found in the dorsal BST and shell of the NA of postpartum rats that had brief maternal experience with pups compared to those without experience,[681] but females of various reproductive states do not differ in the number of BrdU-labeled cells in these sites or in their mPOA, ventral BST, or shell and core of the NA.[643] If new cells in these forebrain sites are not generated locally, they likely have migrated from the other classic neurogenic region, the subventricular zone (SVZ). The rodent SVZ shows pregnancy and early-postpartum changes in the number of BrdU-labeled cells, and this is a result of high circulating PRL.[682,683] In contrast, neurogenesis in the SVZ of sheep *decreases* after parturition and interaction with the lamb, which might somehow reflect differences between species in their need for

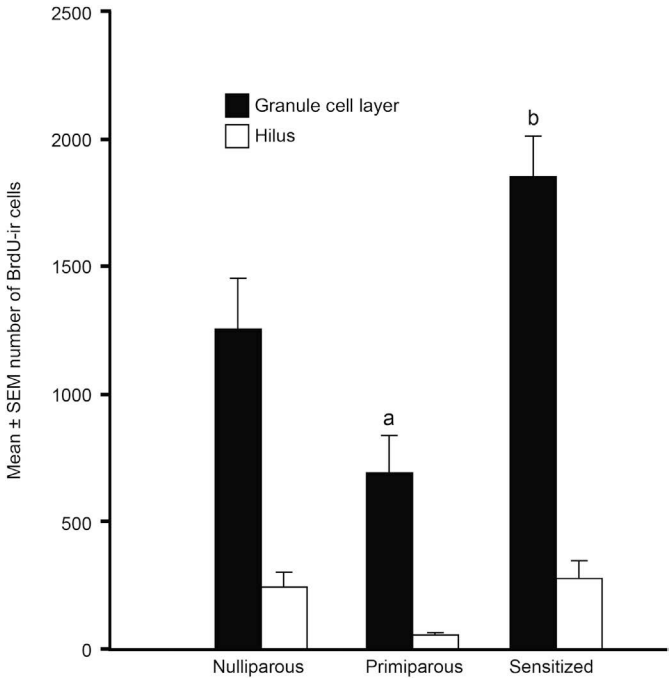

FIGURE 51.18 Number (Mean ± SEM) of BrdU-immunoreactive cells in the granule cell layer of the dentate gyrus of female rats measured 21 days after BrdU injection. Primiparous rats were injected with BrdU on postpartum day 1 and had fewer new cells surviving 21 days later compared to nulliparous control females. However, maternally sensitized nulliparous females had more new cells surviving 21 days after the beginning of pup exposure compared to controls. Groups did not differ in BrdU-immunoreactive cells in the hilus of the dentate gyrus. a = significantly different from nulliparous control females; b = significantly different from all other groups. *Source: Modified from Pawluski and Galea, 2007.*[678]

individual recognition of the offspring.[680] Many of these newly born cells in the SVZ of mice appear to migrate to the olfactory bulb, suggesting a role in the olfactory control of maternal behavior, but suppressing endogenous PRL during early pregnancy to block this neurogenesis impairs maternal behavior only when mice are tested under novel conditions, suggesting a nonsensory effect. Anxiety is increased in these PRL-suppressed dams, which may offer an explanation.[184]

The plasticity of the maternal hippocampus also involves structural changes in neuronal dendrites. CA1 pyramidal cells of late-pregnant and early-postpartum rats have a higher density of apical dendritic spines compared to that found in virgins, but, by the time of weaning, mothers have shorter CA1 and CA1 apical dendrite length and a lower number of branch points than virgins. This increase in apical dendrite spines depends on ovarian hormones,[684,685] and the later reductions in dendrite length and branch points may depend on adrenal corticosterone as it is not observed in multiparous females, which have lower circulating glucocorticoids compared to first-time mothers.[685] These results and the postpartum decrease in hippocampal cell proliferation discussed here might appear inconsistent with the improvement in short-term memory during lactation, but even regressive events in the brain could indicate an enhancement or refining of the neural circuitry involved in memory, and warn against a "more brain equals more behavior" type of logic. The functional significance of hippocampal plasticity may relate to maternal behavior toward pups. Lesioning the hippocampus before mating results in poor nest building, disorganized retrieval, and fewer pups surviving to weaning.[42] Similarly, mother rats with lesions of the fimbria, one of the major output paths of the hippocampus, build multiple small nests and retrieve some pups to each of them.[686] Unmated female rhesus monkeys that received hippocampal lesions during infancy, however, are normally affiliative toward unrelated infants,[687] which could reflect a species difference in the need for an intact hippocampus for mothering-like behavior or that other neural systems could eventually compensate for its loss in female monkeys. Peripartum hippocampal plasticity could also be involved in other functions in the females, including their altered negative feedback of the HPA axis response to stress.[167]

The cerebral cortex also exhibits peripartum plasticity, and cortical involvement in maternal behavior has recently received increased attention. Lactating rats have a thicker somatosensory cortex than cycling rats,[688] and twice as much somatosensory cortex is devoted to dams' representation of the skin of their ventral trunk, which is probably related to their enhanced sensitivity to pup probing and suckling.[689] This expansion of the somatosensory cortex requires physical contact with pups, and within 2 weeks after weaning its size reverts back to a prepartum state.[690] First-time mothers also have greater GFAP immunoreactivity in the cingulate cortex, a change that appears within hours of parturition if females are allowed to interact with pups, and this lasts through lactation.[691] Virgin female rats that are given exogenous hormones and interact with pups have a similar increase in cingulate GFAP immunoreactivity.[692] In addition, mother rats have a greater number of dendritic spines in the mPFC, an effect that coincides with their enhanced behavioral flexibility.[693]

Research on primates following lesions of the PFC or the anterior temporal cortex in postpartum rhesus monkeys demonstrated severe maternal behavior deficits, including an absence of contact seeking with infants, lack of retrieval from threatening situations, and only passive tolerance or active rejection if contact was infant initiated.[694,695] As discussed in the section Components of Parental Care, early work incorrectly suggested that no one area of the cortex was crucial for the expression of maternal behavior in rats but that the size of the cortical lesion was most relevant. We now know that specific regions of the PFC are activated by offspring cues and expression of parenting behaviors in rodents[628,696,697] and

that lesions of the medial PFC have profound effects on maternal behavior.[516,698,699] The PFC receives polymodal sensory input and has been implicated in stimulus recognition and executive functions contributing to attentional selection, optimal organization and planning, flexibility, and decision making in relation to complex goal-directed behaviors. The mPFC receives DA input from the VTA and has reciprocal connections with several subcortical structures, including many involved in maternal behavior such as the mPOA, BST, VTA, NA, and PAG. Thus, the mPFC can initiate a descending cascade though which the behavioral expression of a motivated or rewarding response results from outflow of the mPOA and limbic structures via the ventral pallidum and mesencephalic locomotor regions of the brain.[569]

The rodent mPFC can be functionally and anatomically subdivided into three distinct subregions—anterior cingulate (ACC), prelimbic (PrL), and infralimbic (IL)—each with distinct and dissociable contributions to the expression of maternal behavior across the postpartum period.[516] Permanent lesions and transient inactivation of the dorsal mPFC or ACC affect the organizational aspects of maternal behavior during both early- and late-postpartum periods, likely by inducing deficits in attention and behavioral inhibition processes, although mother rats remain very interested in pups.[41,43,49,516,698] Other studies have shown that depression of ventral mPFC activity severely disrupts maternal behaviors.[516,699] Specifically, transient inactivation of the infralimbic cortex, the most ventral part of the mPFC, severely disrupted all components of early postpartum maternal behavior, whereas inactivation of the prelimbic subregion did not.[516] It is worth noting that IL–mPFC inactivation, unlike mPOA inactivation that produced selective disruption of active maternal behaviors, resulted in females not directing their behavior toward pups at all but instead engaging in other activities such as eating, drinking, and resting. The IL–mPFC was also necessary for the dams' choice of pups over competing alternative conditioned incentives.[516] Together, it is tempting to speculate that the IL–mPFC is in a nodal position to integrate exteroceptive pup-related information with interoceptive information related to the maternal state, and to exert executive control to guarantee behavioral allocation toward pups and associated stimuli. By contrast, the mPOA is more a key component in motivational processing of pups and related incentive stimuli. Pereira and Morrell further demonstrated that, as the postpartum period progresses, the necessary facilitatory role of the IL–mPFC wanes, whereas the PrL–mPFC then contributed to the expression of late-postpartum maternal behavior.[516] This role transfer within subregions of the mPFC across lactation might be related to the transition from goal directed to habitual responding that probably occurs over time when dams continually interact with pups.

In summary of this subsection, the mPOA has a multifaceted role in promoting as well as inhibiting maternal behaviors. The mPOA is one of the most sensitive brain sites to ovarian and pituitary hormones and has reciprocal connections with neural sites processing all five sensory systems. It has dense connections with areas for the brain involved in motivated behaviors, emotion regulation, and cognition. The mPOA is perfectly situated to act as an integration site for the hormonal and sensory inputs required for the triggering or inhibiting of maternal interest, and then communicates that information with the motor, motivation, and cognitive systems necessary for the planning and performance of maternal behaviors (Figure 51.19).

Brain Control of Maternal Behaviors in Humans

Advances in fMRI to assess subregional changes in metabolic activity in the human brain have resulted in a small, but fascinating, collection of studies of how the postpartum human brain responds to infant-related auditory or visual cues. Because of the physical constraints involved with fMRI imaging, these studies do not reveal changes in brain activity during maternal behavior per se, but more about the perception and integration of sensory cues from infants and their rewarding or aversive properties. As discussed earlier in this chapter, heightened immediate-early gene expression in most brain sites involved in rodent mothering requires behavioral execution rather than distal stimulation from infants.[542,543,628] Evaluating the human brain response to infants in the absence of the ability to behave maternally

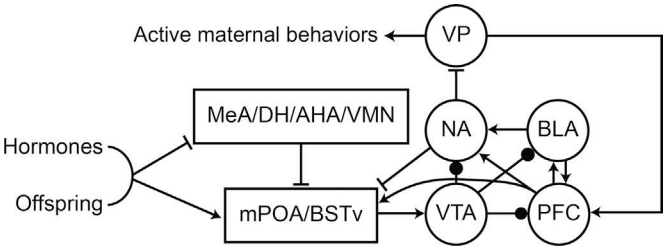

FIGURE 51.19 Hypothetical neural model for the stimulation of active maternal behaviors. The hormones of pregnancy and sensory cues of offspring suppress inhibitory input from the MeA–DH/AHA–VMN to the mPOA–BSTv while simultaneously stimulating mPOA–BSTv output to the VTA. This elicits dopamine release in the NA, PFC, and BLA. DA release in the NA inhibits VP output, thereby promoting the active components of maternal behavior. The NA, VP, PFC, and BLA can modulate this pathway by their connections to the MPOA–vBST or NA. AHA: anterior hypothalamic area; BLA: basolateral amygdala; BSTv: ventral bed nucleus of the stria terminalis; DH: dorsal hypothalamus; DA: dopamine; MeA: medial amygdala; mPOA: medial preoptic area; NA: nucleus accumbens; PFC: prefrontal cortex; VP: ventral pallidum; VTA: ventral tegmental area. is nonetheless particularly appropriate because human parenting involves more higher-order cognitive and emotional integration compared to that required for the parental behavior of rodents and other subprimates.[229]

Experiments exposing mothers to the cries of their own infant or the cries of an unfamiliar infant reveal widespread cortical and subcortical activation. Reliability about what brain regions are activated by infant cries will increase as more studies emerge, but the sites most frequently reported across studies to be activated by infant cries are areas involved in sensory perception and processing (the thalamus and superior temporal and auditory cortex), those involved in reward (the striatum and nucleus accumbens), and numerous regions of the cortex involved in emotion and cognition (the insular, orbitofrontal–inferior frontal, medial frontal, temporoparietal, and fusiform cortices).[700] A smaller number of studies have reported activation in response to a familiar or unfamiliar infant cry in the anterior cingulate and ventral prefrontal cortices, amygdala, hypothalamus, hippocampus, and septum–preoptic area.[700] Other series of experiments using infant photographs or videos as stimuli have most often reported greater activation to one's own infant over an unfamiliar infant in many of the same areas activated by cries (e.g., the thalamus, striatum and nucleus accumbens, orbitofrontal and inferior frontal, and fusiform cortices). Activation in response to infant visual stimuli is also sometimes found in the insular and temporoparietal cortices, lentiform nucleus–globus pallidus, midbrain, and cerebellum. Thus, regardless of the modality of the distal infant cue, there is considerable overlap in the sites of the maternal brain that respond to these cues, and this may reflect the core neural network necessary for the sensory, emotional, reward, and cognitive processing involved in human mothering.

Metabolic deactivation is rarely found in the maternal brain during exposure to infant cues, but two groups have each reported deactivation of the medial frontal gyrus when subjects are exposed to the cry of their own infant when compared to the cry of an unfamiliar infant or when comparing the response to an infant cry and infant laughter.[700,701] Interestingly, lower activation of the medial frontal gyrus is also found when mothers view their own infant versus another infant.[702] The medial frontal gyrus is implicated in functions that include mood regulation,[703] self-referential processing,[704] and behavioral decision making.[705] In psychologically healthy and motivated mothers, this deactivation in response to cues from their own children could be associated with suppressing negative affect and the intention of providing to provide selfless caregiving to their infant.

Unfortunately, not all human mothers are healthy and motivated, and women are heterogeneous in their emotional and cognitive appraisals of infants. This is reflected by their fMRI activity. For example, mothers who are more sensitive have greater activity in their anterior prefrontal cortex, inferior and superior frontal cortex, and amygdala while hearing their own infant's cry compared to that seen in less sensitive mothers.[706,707] Studies examining how maternal mental health influences fMRI activity in response to infant cues demonstrate that poor maternal mood and high distress, which impair mother–infant interactions and bonding, are associated with lower amygdalar activity when mothers are viewing their infant's face.[708] Mothers with posttraumatic stress disorder, which is also associated with impaired bonding and interaction with infants, show limbic hyperactivity and lower prefrontal cortex activity than controls when watching videos of their children in a stressful situation.[709] Similarly, reduced prefrontal cortex activity is found in substance-using mothers exposed to infant pictures or cries.[710] Maternal brain activation in response to the cry of one's own infant compared to those from other infants is also lower in multiple cortical regions (superior and middle temporal, superior frontal, medial fusiform, and superior parietal) and in the caudate, thalamus, hypothalamus, and amygdala in women who deliver via Caesarian section rather than vaginally (Figure 51.20).[98] Interestingly, breastfeeding is associated with greater fMRI activity in some of these same regions (superior frontal cortex and amygdala) compared to the activation seen in mothers who bottle feed their infants,[707] and these differences have been proposed to reflect the neuroendocrine consequences of vaginal delivery and suckling, as well as differences in maternal sensitivity to the infant.[711]

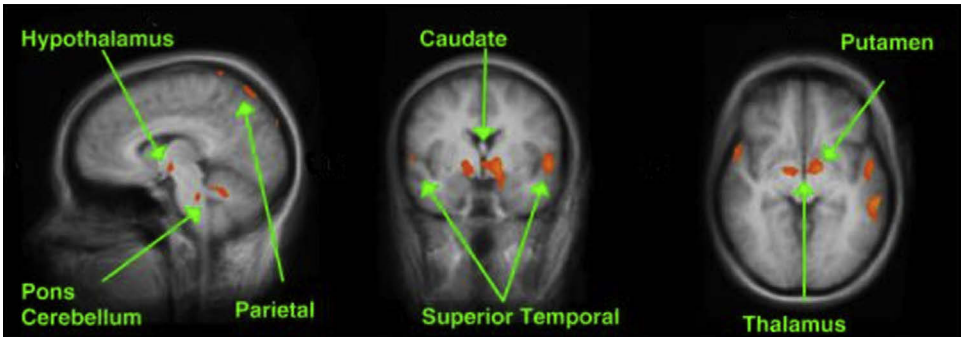

FIGURE 51.20 **Sites of the maternal brain where fMRI activity was higher (indicated by red) in mothers who delivered vaginally compared to via Caesarean section while listening to their own infant crying.** This figure is reproduced in color in the color plate section. *Source: Modified from Swain et al., 2008.*[98]

BRAIN CONTROL OF PATERNAL BEHAVIORS

Brain Control of Paternal Behaviors in Nonhuman Animals

Fathers in most biparental species show the same repertoire of caregiving behaviors as their female mates, including nursing-like postures, even though suckling by pups and milk letdown cannot occur.[326] Thus, it is parsimonious to think that brain networks controlling these behaviors are homologous to those in females, and immediate-early gene studies in prairie voles and California mice suggest this is mostly true. There has been no direct comparison of the immediate-early gene expression between female and male parents in either species, but patterns of immediate-early gene expression in parentally inexperienced virgin male and noninfanticidal virgin female prairie voles are very similar to those found in postpartum female rats and mice. For example, exposure to a single pup increases Fos expression in both the male and female prairie vole mPOA, BST, MeA, and lateral septum compared to the expression found after exposure to candy.[712] In California mouse fathers, Fos expression is elevated in the mPOA after exposure to just the distal cues from a pup.[713,714]

With regard to sex differences in Fos response, the magnitude of the increase in Fos expression in the prairie vole mPOA after exposure to a pup is much higher in virgin males than in virgin females, possibly reflecting the higher spontaneous parental responsiveness in males found in most studies.[330,715] Additionally, the paraventricular thalamus expresses Fos in paternally acting virgin male prairie voles, but it does not in females.[712] The relevance of this sex difference in prairie voles is unknown, but the paraventricular thalamus also expresses high Fos in postpartum mother rats,[542] and it could be related to sex differences in the role of the paraventricular thalamus in reward seeking[716] or HPA axis regulation.[717]

There have been relatively few studies manipulating the paternal rodent brain. Excitotoxic lesions of the virgin male prairie vole MeA and surrounding region slightly reduced sniffing and licking of pups, but greatly reduced huddling over and lying next to them. The effects were specific in that side-by-side contact with a familiar female was not affected by the lesions.[636] The role of the MeA in these males' behavior must be more complex than just processing olfactory stimuli from pups because olfactory bulbectomy produced much more dramatic deficits that included infanticide and disruption of other social and nonsocial behaviors.[718] In male California mice, electrolytic lesions of the mPOA produce results somewhat similar to those found in mPOA-lesioned female rats, including longer latencies to retrieve pups, less licking, and less time spent near offspring.[509,637]

The neurochemicals released from or acting in these sites in the paternal brain are surely numerous, but mostly unknown. In paternally experienced California mice, Fos is expressed in some serotonergic cells of the dorsal raphe.[714] A small number of the Fos-expressing cells in the BST and MeA of virgin male prairie voles contain tyrosine–hydroxylase and may release L-DOPA or dopamine to modulate their paternal behavior.[719] Fos is also expressed in the paternal prairie vole PVN, and quite a few of these cells synthesize OT or AVP.[336] In fact, numerous studies have focused on the role of AVP in paternal behavior. It has long been recognized that male prairie voles differ from nonpaternal species of voles in the density of V1a receptor binding in many areas of the forebrain, including having greater expression in their accessory olfactory bulb, cingulate cortex, BSTv, VP, central amygdala, and paraventricular thalamus but lower V1a binding in their lateral septum, lateral habenula, and PAG.[720] Correlational studies supporting a role for intracerebral AVP in fathering include that male prairie voles have plexuses of AVP-immunoreactive fibers in their lateral septum and lateral habenula (sites implicated in maternal behavior rats; see the section Components of Parental Care) that decrease in density after males cohabitate and mate with a female, and this decrease somewhat parallels the increase in their paternal responding. No changes were observed after mating in the AVP fiber plexuses of the nonpaternal male meadow vole.[328,721] Because mating increases AVP mRNA in the male prairie vole BST, which is the source of this fiber innervation, this drop in fiber density probably reflects increased AVP release.[327] Any causal link between this mating-induced change in AVP content and behavior is unclear because long-term castration of male prairie voles almost eliminates AVP synthesis in this system, but in some studies castration has no effect on their paternal behavior.[330]

Studies examining direct manipulations of central AVP on the paternal behavior of prairie voles have produced mixed results. Infusion of AVP into the border of the lateral and medial septum has been reported to increase males' time spent in contact with pups compared to saline-infused controls, while infusion of a V1a receptor antagonist reduced pup licking.[722] Some of these results could not later be reproduced,[723] and intracerebroventricular infusion of a V1a receptor antagonist has also been seen to have little effect on pup licking or other paternal behaviors,[724] but this latter null finding may be due to the nontargeted infusion. Even so, males receiving simultaneous intracerebroventricular infusion of a V1a receptor antagonist along with an OT receptor antagonist did display greater infanticide and reduced huddling over pups.[724] The effectiveness of the combined treatment may be related to the greater OT receptor expression in the frontal cortex, nucleus accumbens, BST, and paraventricular thalamus of prairie voles

compared to species of nonpaternal voles.[725] Lastly, intracerebral administration of AVP increases licking and huddling with pups and decreases pup-directed aggression in male meadow voles, which suggests that changes in central AVP are involved in switching on and off their facultative paternal behavior.[278]

Several correlations suggest that AVP is also associated with paternal behavior in male California mice. Within the hypothalamic PVN, there is a positive association between levels of AVP mRNA and males' approach toward a pup, but not other paternal behaviors.[726] Moreover, California mouse fathers have more AVP-ir cells and fibers in the PVN and supraoptic nucleus (SON) than do fathers of a nonpaternal *Peromyscus* species, *P. maniculatus*.[301] Within California mice, fathers that retrieve their pups more often have higher levels of AVP-ir in the SON.[727] There is also a transgenerational relationship between AVP and paternal behavior, with offspring raised by castrated fathers that display less huddling and grooming toward them later expressing higher AVP in the PVN.[728] These offspring raised by castrated fathers also display less huddling and grooming toward their own pups.[729] Together, these results from California mice suggest that AVP in the PVN is involved in adult and developmental plasticity of paternal behavior, perhaps related to the hypothalamic systems involved in stress.

Several lines of evidence also link AVP in the BST with developmental plasticity in paternal behavior. Cross-fostering litters between the more paternal California mouse and the less paternal and promiscuous white-footed mouse, *Peromyscus leucopus*, produce male offspring that are more similar to their foster parents with respect to pup retrieval.[730] AVP immunoreactivity in the offspring BST is positively correlated with the frequency of paternal retrievals that these cross-fostered male young had received and with their fathers' huddling, grooming, and time spent in the nest.[727] When retrieval by their fathers was increased by purposely displacing the litters from their nests, these offspring later retrieved their own pups more frequently (Becker and Marler, unpublished data) and also displayed higher paternal aggression after becoming fathers.[728] These male offspring that were retrieved more often by their own fathers also had more AVP immunoreactivity in the dorsal fiber tracts of the BST.[728] Moreover, there is a potential link between these results and testosterone because pups have an acute rise in testosterone when they are retrieved by their fathers,[731] and this could influence both their AVP system and future paternal behavior as adults. Paternal behavior in *P. californicus*, therefore, appears to mediate the behavioral transmission of both paternal retrieval behavior and aggression and may do so via plasticity of numerous central AVP pathways.

Central estrogen synthesis and presumably estrogen receptor signaling are required for paternal behavior in male California mice,[292] but estrogenic activity instead inhibits fathering in male prairie voles and possibly some other rodents. Correlational studies show that the paternal pine vole (*Microtus pinetorum*) has lower ERα expression in areas of the brain involved in paternal behaviors, including the MeA and BST, compared to the polygamous and nonparental montane vole (*M. montanus*).[732] Similarly, the highly parental male Djungarian hamster (*Phodopus sungorus*) has lower ERα expression in the BST compared to the less parental male Siberian hamster.[732] In prairie voles, regional populations of males that are more alloparental have lower ERα expression in numerous brain regions, including the mPOA, BST, and VMN, compared to populations of less alloparental males.[733] These differences in ERα expression in the MeA are functionally relevant for parenting because male prairie voles with viral vector-mediated overexpression of ERα in the MeA, but not in the BST, are much less likely to act paternally than controls.[734,735] This negative relationship between paternal behavior and ERα is specific to this steroid receptor because there are no associations between the brain distribution and/or density of androgen receptors[733] or progesterone receptors[736] and paternal behavior in adult male prairie voles.

Brain Control of Paternal Behaviors in Primates

The handful of studies of the paternal monkey brain have focused on neuropeptides, and the relationship between OT and maternal behavior in rodents appears to extend to male common marmoset fathers. OT levels released from hypothalamic explants of paternally experienced male common marmosets is significantly higher compared to those of inexperienced males,[737] and intracerebroventricular infusions of OT decreases the number of refusals that fathers made for food transfers to their offspring.[738] There are two studies associating central AVP with paternal behavior in common marmosets. One did not identify any changes in AVP release from hypothalamic explants based on paternal experience,[737] and the other found that fathers have a greater number of AVP V1a receptors in their prefrontal cortex, that they have a greater density of dendritic spines on pyramidal neurons in the prefrontal cortex, and that more of these spines contained V1a receptors compared to paternally inexperienced males.[739]

Because human fathers are more variable in their parental involvement and interact differently with infants than do mothers, the three published studies of fMRI activity in the paternal brain during infant cue exposure are an important contribution to the human parental brain literature (see the section Brain Control of Maternal Behaviors). Seifritz and colleagues found no specific sites activated in fathers compared to mothers listening to infant laughing or crying, but they did

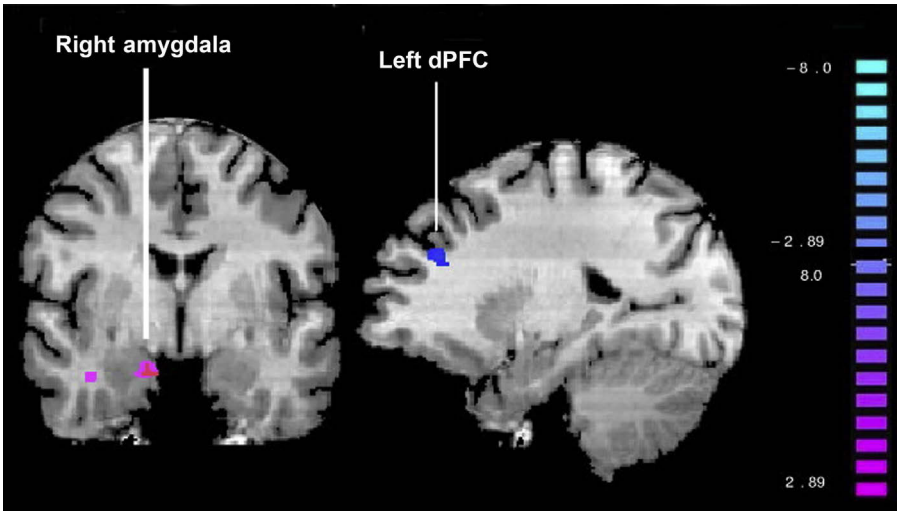

FIGURE 51.21 Sites in the parental brain where mothers (left) or fathers (right) showed greater fMRI activity in response to their own infant video compared to viewing an unfamiliar infant. This figure is reproduced in color in the color plate section. Mothers showed greater activity in the right amygdala and temporal, occipital, and parietal cortices compared to fathers, while fathers had greater activity in the dorsal prefrontal cortex (dPFC). *Source: Modified from Atzil et al., 2012.*[711]

discover a few overall sex differences in activity, with women (mothers or nonmothers) showing deactivation of the anterior cingulate cortex and mesial prefrontal cortex during cue exposure, whereas men (fathers or nonfathers) showed no such change.[701] The authors attributed the findings to sex differences in how these cortical areas control sensory gating and worrying or anxiety. They also found that compared to nonparents, parents of both sexes exhibited greater activation to infant crying in the amygdala; the cingulate, ventral prefrontal, and insular cortices; and the temporoparietal junction—all perhaps related to socioemotional regulation. A recent study comparing fMRI activity while fathers viewed video clips of a doll or their own infant's emotionally neutral face found greater activation to the infant in a host of cortical regions that are also often activated in mothers (orbitofrontal, lateral frontal, superior parietal, and midtemporal). Some cortical regions (orbitofrontal, inferior and superior frontal, supramarginal, and midtemporal) were also more metabolically active when fathers viewed their own versus an unfamiliar infant.[740] By imaging both mothers and fathers watching the same videos of their infant playing alone or a previous interaction with them, Atzil et al. found that functional activity was correlated between father-and-mother pairs in numerous cortical areas involved in empathy and social information processing (anterior cingulate, inferior frontal, inferior parietal, medial and lateral prefrontal, and insula).[711] Unlike the findings of Seifritz et al. indicating no father–mother differences in fMRI activity in response to infant vocalizations,[701] Atzil and colleagues further found that mothers showed higher activation to their own infants' visual cues than did fathers in areas of the cortex (temporal, postcentral, and fusiform), caudate, and amygdala (Figure 51.21).[711] Also only in mothers, activity of the amygdala, cingulate cortex, and nucleus accumbens was positively correlated with their plasma OT levels. Paternal plasma OT was instead negatively correlated with activation in cognitive cortical regions (dorsolateral PFC, dorsal ACC, IPC, and precentral gyrus),[711] and these results could possibly be related to sex differences in limbic and cognitive control of parenting.

CONCLUSION

A substantial amount of information clearly exists regarding the endocrine, neuroendocrine, sensory, and neural substrates necessary for the onset and maintenance of parental behaviors in rodents, sheep, and primates. We believe there are still numerous broad and specific areas for future research, and a few points to consider about the existing literature, that would improve the understanding of the physiology of parental care. Specifically, these might include:

- Increased investigation of the involvement of some steroid hormones in mothering. There is a very notable gap in our comprehension of how and where in the brain progesterone inhibits or facilitates caregiving behaviors. Since the early studies by Numan,[578] in which progesterone implanted into none of the hypothalamic or midbrain sites examined could delay the onset of mothering, there has been no direct investigation of this question. Studies using targeted implants of progesterone into brain sites not examined in that study, or brain site–specific knockout of PR, would be informative. There is also almost nothing known about any behavioral implications of the very high androgen secretion during pregnancy or where in the brain androgen receptor activity might influence the onset of mothering.

- A more informed perspective is needed on the redundancy existing among the endocrine factors underlying parenting. As discussed in this chapter, knockout models in which parental behaviors are unaffected or less impaired than expected suggest that such redundancy exists and provide insight into the systems most valuable for further analysis of this question.
- The neurobiological mechanisms involved in how parental behaviors are maintained by pup sensory cues after the endocrine effects have waned have not been well studied. Are the cells that were affected by hormones the same cells that are later responding to pup sensory cues? How is the physiology of these cells altered by hormones to assume this function? A somewhat similar question arises regarding how the multiparous brain differs mechanistically from the primiparous brain. The neural systems involved in mothering have been permanently altered to require reduced or no hormone exposure and less sensory input to elicit maternal behavior, but additional research into how this occurs would be tremendously valuable.
- We and many others have reviewed the scientific literature on the numerous neural systems involved in the suite of behavioral alterations that are necessary for successful parenting, but how these systems interact as a larger neural network for seamlessly integrated behavioral responding is not well understood. Furthermore, because these systems are involved in almost every social behavior,[6,741] it would be important to know how they selectively respond to offspring. Are different populations of cells within these structures involved in particular behaviors? How do the unique endocrine events of pregnancy versus other endocrine events involving the exact same ovarian and pituitary hormones (e.g., the estrous cycle) affect cells in ways that determine what social cues are responded to and what cues are ignored?
- As translating information from nonhuman animals to humans continues to become an important goal of the field studying maternal behavior, animal models must be chosen wisely. For example, while studying nonhuman female primates is admirable, it is obviously difficult or impossible for most researchers. A cogent argument has been made that one of the animal models closest to humans in their peripartum endocrinology, delivery of a small number of precocious offspring, mother–offspring communication, and social attachment is the now rarely studied guinea pig.[742–744]
- Carefully consider the existing and future literature in the context of the natural display of parenting behavior. Beginning with some of the foundational work in this field on laboratory rats[15,32,37] there has sometimes been an emphasis on retrieval of offspring as the most relevant, or sometimes the only, outcome measure. Retrieval is convenient to assess because it is usually rapid and clearly displayed by a subject or not, but it is problematic for a more holistic understanding of parenting because retrieval is uncorrelated with other parental behaviors of the same animals after retrieval has concluded or when the subjects are observed under undisturbed conditions.[745,746] It is also problematic because this type of long-distance carrying of young is probably rare in nature unless the nest site is disturbed.[747] Importantly, because parenting is not a unitary process, but instead involves a collection of individual behaviors with different sensory, endocrine, and neurobiological determinants, factors influencing retrieval will not translate to all other components of offspring care.
- With few exceptions,[661,678,748] we as a field focus on first-time parents with no previous experience with young. As discussed in part in this chapter, this is unnatural because most adult mammals are unlikely to approach parturition with no previous parenting experience because they would have received it during juvenile alloparenting and/or had given birth multiple times before. Under natural conditions, therefore, the relevant endocrine and sensory cues most often act upon an already heightened baseline to promote maternal behavior. Thus, laboratory studies may reveal how powerfully hormones, pup sensory cues, and other factors can influence parenting, but their importance for the majority of mothers and fathers living in natural environments is probably overemphasized in a literature that is mostly based on laboratory studies of inexperienced animals.

Parental behaviors directed toward offspring can tremendously help or materially harm the young, and can do so with lifelong consequences. As researchers who benefit from and struggle with the advantages and limitations of our models, we must not lose sight of the idea that our knowledge obtained from nonhuman models of parental behavior is both incredibly useful in its own right for a comparative perspective about social–behavioral endocrinology, and also informs the human condition in ways that can immensely benefit both parents and offspring during this critical phase of mammalian reproduction.

INTRODUCTION

Historical Overview

The idea that gene expression is modified by environmental and experiential factors is not new. Waddington first articulated the developmental dilemma that all cells have the same DNA and yet they are differentiated to perform vastly different functions.[1] Psychologists such as Irving Gottesman observed that identical twins were hardly clones, and their behavior and appearance was even more divergent when reared apart.[2] Thus, the fact that genes are not the only source of phenotypic variability has been well accepted for many years. What is new is that advances in molecular biology have provided us with the tools to discover mechanism that mediate changes "above the genes".

Figure 52.1 illustrates the exponential growth in publications on epigenetics since the first papers were published in 1958.[3,4] Work on reproduction in the context of epigenetics is also accelerating and has grown markedly in the early twenty-first century. Recognition of hypermethylation as the major cause for X chromosome inactivation pushed the area ahead.[5] Silencing of the X chromosome is now one of the best examples of epigenetic regulation of gene expression. In the early 1990s, David Barker and colleagues discovered that infant birth weights were correlated with risk for a variety of adult-onset diseases, including diabetes and hypertension[6–8] (see also Chapter 45). This hypothesis, now interpreted broadly as developmental origins for adult disease, has been extremely influential and has been a major intellectual breakthrough in reproduction as applied to environmental antecedents of well-being. Recognition of the important role that maternal care has in behavioral phenotypes is also a breakthrough—and with it, the application of epigenetics to neuroscience.[9] In neurons, changes in cellular morphology (synapses, spines, etc.) can influence cell function in a highly plastic manner, and environmental variables are known to cause these changes. Thus, in the brain, the important distinction between epigenetic modifications that may only last for a generation vs those that are permanent and inherited is particularly relevant to studies of reproductive physiology and behavior. The short-term epigenetic modifications can be thought of as "socially transmitted" as compared with germline transmission of long-lasting changes. The coming years will prove to be an exciting time for epigenetics and reproduction. We now know that nearly all epigenetic enzymatic reactions are reversible. New levels of epigenetic modification are being revealed; as they emerge and are tested, most have applications in reproduction. Not only is epigenetics providing us with solutions to long-standing problems in reproduction, it also has caused us to rethink some long standing dogmatic notions.

Nowhere is the importance of epigenetic regulation of gene expression more self-evident than in reproduction. Only through restrictive modifications of the genome that tightly control the expression of one suite of genes over another can a single fertilized egg give rise to the rich diversity of cell and tissue types found in mature organisms. This fantastic panoply of development is orchestrated both temporally and spatially by epigenetic

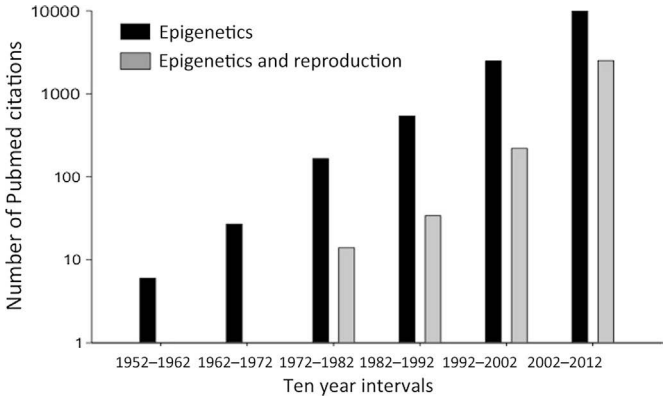

FIGURE 52.1 Publishing trends for epigenetics. A survey of the digital scientific data base PubMed Central from the National Library of Medicine USA (http://www.ncbi.nlm.nih.gov/pmc) reveals a continuous rise in the number of citations in which the term *epigenetics* is a key word and a parallel increase in the number that include both epigenetics and reproduction.

regulation of gene expression. Once complete, this process further serves to imprint upon the new organism features of its environment and experience and, if salient enough, to ensure that the impact of these features are passed on to the next generation in anticipation of similar circumstances. The centrality of epigenetics to reproduction is further evident in fundamentals such as X inactivation, parental imprinting, and the organizational actions of steroids on almost all tissues and organs, including the brain. The goal of this chapter is to review the basic mechanics of epigenetics and then to place them in the context of reproduction. We will review the two best described processes: histone modifications and DNA methylation. We will also describe some of the techniques now in use in the field and we will provide a survey of epigenetic mechanisms in selected topics.

Reproduction is the main mechanism that implements evolution. Evolution acts by natural and sexual selection, favoring individuals that are able to adjust to the ambient environment and then survive for long enough to reproduce successfully and pass genetic material on to subsequent generations. When the environment is stable and energetic demands are not severe, reproduction may be a rigidly encoded process. For example, the yeast *Saccharomyces cerevisiae* has two mating types that participate in different forms of reproduction: asexual budding and sexual reproduction. In predictable environments, mitosis is the predominate form of population growth. However, in complex environments, sexual reproduction, meiosis, and gamete formation are favored. In multicellular organisms that have obligate sexual reproduction, the capacity to respond to environmental pressures and to change breeding strategies can occur via maintenance of some genes accompanied by silencing of others, via long-term adaptation. However, when environments change in real time, other processes and rapid accommodation are required. Epigenetics is undoubtedly one way that organisms respond to changes in the environment and accomplish rapid adaptation.

The examination of epigenetics in reproduction is relatively recent. Investigation of epigenetic regulation immediately postfertilization is the most mature science with substantial advances and landmark achievements, some of which will be discussed below. Newer to the field is the investigation into epigenetic regulation in the adult and developing brain; here, we give special attention to aspects of this relevant to the physiology of reproduction.

Definitions of Epigenetics

The term *epigenetics* is derived from the Greek use of the prefix *epi* with a root word to indicate relatedness that involves being above, on, over, after, and so on. In this context, it is taken as anything that involves the genome but does not result in changes to the nucleotide sequence of the DNA. Examples of what is considered "epigenetic" can vary from being quite restrictive to fairly broad. Moreover, the definition and function of epigenetic modifications is rapidly changing as research progresses. For purposes of this discussion, we will start with one major distinction—the epigenetic modifications required for permanent differentiation of cells and tissues and which generally follow a program vs the modifications that are responsive to the immediate environment and experience. We define environment and experience in the broadest terms, such as the internal steroid milieu, maternal diet, ambient temperature, psychosocial stress, or exercise. The latter type requires an "epigenerator", a variable that induces the initiation of an epigenetic modification, followed by maintenance of that modification.[10] Regardless of the nature of the epigenerator, epigenetic changes can be further divided into those that will endure into multiple subsequent generations via the germ line, which are therefore called *germline-dependent* epigenetic changes, vs those that will endure for some shorter, variable length of time. These changes may only occur during a portion of the organism's lifetime, or they may even impact the next generation but not beyond; these have been referred to as *context-dependent* epigenetic changes[11] (Figure 52.2).

The two mainstays of epigenetic change are those directed to histones, which modify the structure of chromatin, which surrounds the DNA, or to more specific methylation changes at selected regions of the DNA. Modifications to histones are far more complex because they most commonly involve methylation and/or acetylation, but they can also occur via a number of other processes and combinations thereof. We discuss both forms in considerable detail, including that in either case the ultimate effects of the epigenetic change are consistently

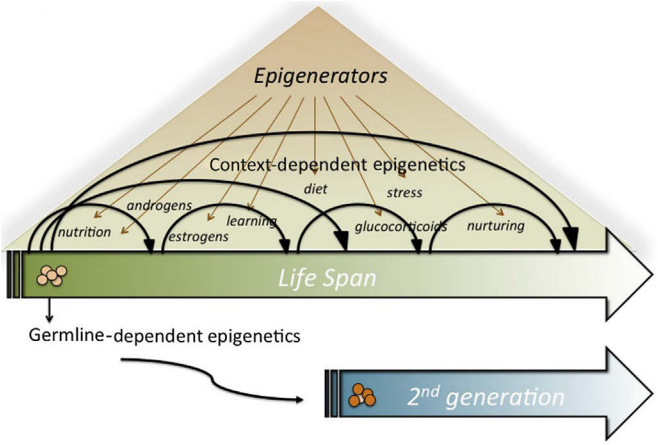

FIGURE 52.2 Epigenetic overview. Epigenetic changes are generated (the epigenerators) by extrinsic or intrinsic variables that activate the enzymes mediating methylation of nucleoside residues in the DNA and modifications to the histones in the surrounding chromatin. Typical epigenerators include gonadal steroids, stress hormones, nutrition, and experiences such as those associated with maternal care or learning. Epigenetic changes can be context dependent and last only a single lifetime, or they can be incorporated by the germ line and therefore be transgenerational. Heritable epigenetic changes are those that endure beyond the F2 generation.

manifested by suppression and/or enhancement of gene expression.

A broader inclusion of mechanisms that produce epigenetic changes includes consideration of the following: so-called microRNAs (miRNAs), which are noncoding RNAs (ncRNAs) such as those involved in inactivation of one X chromosome in every cell in females; parental imprinting, resulting in preferential monoallelic expression; and the appearance of retrotransposons in the DNA, previously thought of as junk but now known to be both a source of and contributor to genetic variation (see below). In addition, it is important to remember that new mechanisms are being and will be discovered; thus, this list is not exhaustive.

Chromatin Remodeling

Chromatin consists of DNA and specialized protein structures that comprise the nucleosome. These specialized protein structures are the histones. Chromatin has multiple functions, including the critical structural aspects of efficient packaging of the DNA and provision of the tensile strength needed for mitosis. In the context of epigenetics, the most important function of chromatin is to regulate gene expression by controlling the access of transcription factors and associated proteins to the DNA. When chromatin is tightly compacted, access to DNA is blocked and transcription is reduced. In contrast, when the chromatin is loosely associated with the DNA, conditions are permissive for transcription because the nucleotide sequence is accessible to the ensemble of transcription factors.

Chromatin comes in two basic varieties, heterochromatin and euchromatin, distinguished initially based on the cytology density of staining, with heterochromatin staining more darkly due to its dense packaging. Heterochromatin represents the vast majority of chromatin and it is not uniform, with different domains distinguished by the degree and nature of epigenetic modifications. The heterochromatin making up the centromeres and telomeres is the most densely packed and immutable, and it is referred to as constitutive heterochromatin, while other regions of heterochromatin can be modified and thereby change the profile of gene expression nearby or in neighboring regions. Euchromatin is the site of active gene expression, although not all genes within a euchromatin segment are capable of being activated. Both types of chromatin are of interest in the epigenetics of reproduction.

Histones and Nucleosomes

The human genome contains approximately 25,000 genes, but their sequence makes up just a small fraction of the over 3 billion base pairs contained in the chromosomes. All this genomic material needs to be compacted to fit inside the cell nucleus; yet, the relevant DNA sequences have to be accessible for transcription. The solution to this dilemma is that condensed DNA is wound around a set of core histone proteins: H2A, H2B, H3 and H4. Approximately 145–147 base pairs of genomic DNA wrap around a set of eight histones, which is considered the basic unit of chromatin, and is referred to as the *nucleosome*. Among the four core histone proteins, the H3 and H4 partner as do the two H2s. Within the nucleosome, each histone is found in duplicate. A fifth histone, H1, serves to link the cores to each other. Thus, the histones are built as octomers and are among the most highly conserved proteins across all species. This condensation and basic architecture is illustrated in Figure 52.3. While the classic "beads on a string" structure is helpful for conceptualizing how DNA is condensed, the more we learn about chromatin structure, the more variations we uncover. Histone variants are relatively common, particularly for H2A and H3. The histone variants are species, and in some cases tissue, specific[12] and mutants have been found associated with disease. Clearly, this is an area poised for further discovery.

Histone Modifications and the "Histone Code"

Not only do the histone proteins serve as a framework for condensation of the chromosomal material, they also facilitate and/or block accessibility of DNA to transcription. About 25% of the mass of the histones is composed of N-terminus, or tail, domains.[13] When the

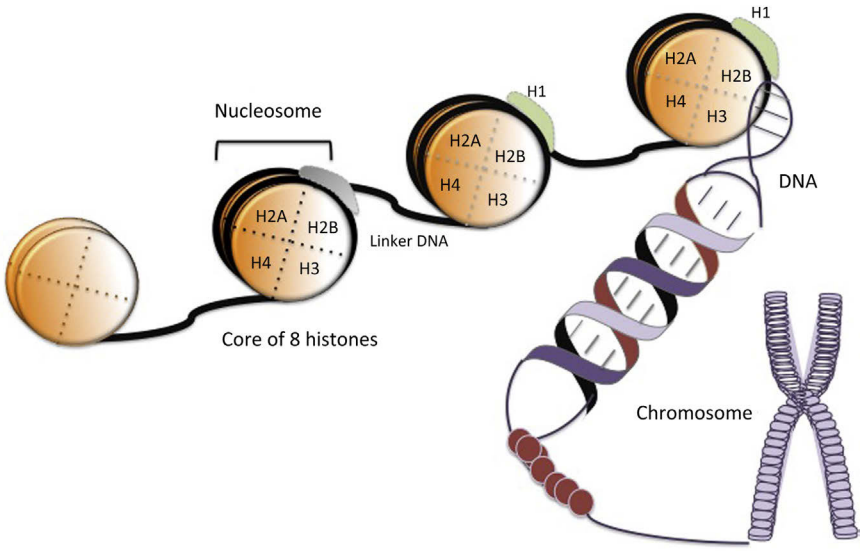

FIGURE 52.3 Histones and nucleosomes. Chromosomes are comprised of DNA and associated proteins, collectively known as chromatin. Condensed DNA is wound around a set of core histone proteins: H2A, H2B, H3, and H4. Approximately 145–147 base pairs of genomic DNA wrap around a set of eight histones, which is considered the basic unit of chromatin and is referred to as the nucleosome. Among the four core histone proteins, the H3 and H4 partner as do the two H2s. Within the nucleosome, each histone is found in duplicate. A fifth histone, H1, serves to link the cores.

tails are exteriorized, they are accessible to a number of enzymes. The histone tails twist inside and outside of the chromatin. These flexible N-terminal tails are fluid in their conformation and can serve to either increase or reduce the density of the chromatin structure. Importantly, nucleosome structure is not uniform. Other structures for the nucleosome have been solved, and these reflect variations in DNA compaction and interactions with histone and nonhistone proteins. At least 60 different residues on histones are known, and this is certainly an underrepresentation. Moreover, many types of histone tail modifications have been identified, and it is likely that this is not exhaustive. The possible histone modifications now include nearly all the known protein modifications: acetylation, methylation, proline isomerization, sumoylation, ubiquitination, phosphorylation, ADP ribosylation, and deamination. These modifications occur primarily on lysine residues,[14] but they can also occur on arginine, tryptophan, and serine residues. In addition to changing access to DNA, histone tails also modify the relationships between the nucleosomes. Seemingly small changes in the primary structure of chromatin can be amplified to affect the shape, stability, and/or protein surfaces of these complexes.

The "histone code" was proposed by Strahl and Allis to take into account the possibility that combinations of posttranslational modifications (PTMs) may interact. Like the genetic code, where certain stretches of amino acids or nucleotides have specific functions, such as stop or start codons, perhaps combinations of enzymatic modifications on H3 lysines formulate specific transcriptional regulatory directions. Moreover, the combined actions of certain modifications may be different from those produced in isolation.[13] The numbers of possible combinations of modifications and their timing all contribute to the complex manner in which DNA transcription is regulated. The histone code postulates that combinations of modifications will have meaningful readouts similar to DNA base pairs. The code may explain why a certain type of modification, such as acetylation, typically enhances transcription the majority of the time; however, under some conditions, when other modifications are present, it may be repressive (Figure 52.4).

Position is also influential. Two PTMs that are in *cis* (on the same histone) may have a different outcome on transcription than the same two PTMs in *trans*, which can occur on the same nucleosome or adjacent nucleosomes. One example of this is on histone 3 (H3). If H3 serine 10 (S10) is phosphorylated, the HP1 chromodomain, an enzyme that "reads" PTMs, cannot bind to the H3 lysine 9 trimethylation (K9me3) site.[15] Another example is the case of the bromodomain, an extraterminal domain family of nuclear proteins. These proteins act as transcription factors and synchronize the activities of two acetylation sites on histone H4.[16,17]

Histone-Modifying Enzymes

One way to consider the enzymes associated with chromatin modification are that they transduce the signals initiated by the epigenerators. Thus, if the organism experiences a change in ambient temperature, social conditions, or dietary conditions, for example, these are interpreted or "read" by epigenetic initiators, such as ncRNAs and DNA binding factors. Then, the new epigenetic status is maintained by histone-modulating enzymes,[18] which are often referred to as "writers" and "erasers". The dynamic aspects of the changing chromatin structure are regulated by modifications on specific amino acids in the N-terminal tails. These amino acids are the sites for enzymatic action. The two best-understood modifications are acetylation and methylation. Acetylation only occurs

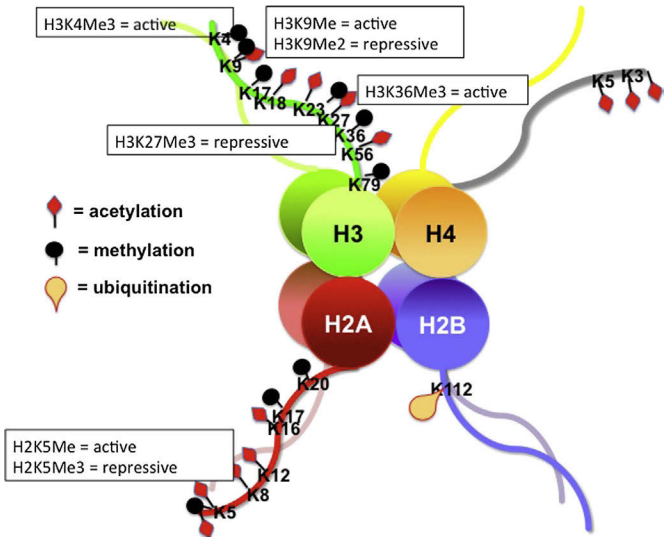

FIGURE 52.4 The histone code. The term "histone code" was proposed by Strahl and Allis and refers to the impact that combinations of modifications to the histones has on gene expression, either repressive or permissive. The type of modification (i.e., acetylation, methylation, phosphorylation etc.), the histone on which it occurs (i.e., H3 vs H4), and its position on the histone tail all impact the final readout regarding transcription. Many modifications occur on lysines (K), but serines are modified as well. Methylation of lysines can be transcriptionally active or repressive depending on the number of methyl groups added. Acetylation of lysines is predominantly activating but the nature of its effects can be changed by alterations to other residues either *cis* or *trans*.

on lysine residues. When positive charge is removed, the interaction of the histone tail with the negatively charged phosphates on DNA is reduced. Thus, euchromatin can be transcribed. The enzymes that regulate this process are histone acetyltransferases (HATs), also known as "writers", which facilitate acetylation. Epigenetic mark removal is conducted by "erasers". The histone deacetyltransferases (HDACs) remove acetyl groups from lysine residues. Specific lysine residues and the HATs that interact with them are shown in Table 52.1. Importantly, HATs and HDACs act as part of multiprotein complexes that recruit other enzymes and proteins to specific sites. This is important to keep in mind because simply measuring HDACs alone is not enough to understand activity levels. If the appropriate DNA complexes are not present, the HATs or HDACs are not recruited to the target sites and will not affect gene expression.

HISTONE ACETYLTRANSFERASES

There are several classes of HATs, based on their functions and their cellular distributions. Type A HATs are nuclear and type B HATs are present in the cytoplasm. We will limit our discussion to type A HATs, which are further refined into five subtypes.[74] One class of type A HATs is related to nuclear receptors and includes steroid receptor coactivators 1 and 3 (SRCs). CREB-binding protein (CBP) is in its own grouping, which is often denoted as CBP/p300 because these two proteins are structurally very similar and may substitute for each other (see Chapter 9). However, separate functions have been discovered, including modifications of different lysine residues.[75] Another type A HAT group is the GNAT family. The first HAT discovered was Gcn5, which can coactivate the estrogen receptor alpha (ERα; p300/CBP-associated factor). The MYST family of enzymes is important for differentiation and development. One example of cross-talk between these groups of HATs is the ability of ERα-CBP/p300 to stimulate histone acetylation.[76] Acetylation has actions in addition to changing the charge of N-terminal tails on histones; for example, acetylated histones serve as docking sites for other proteins that recruit transcription factors. HATs also function in DNA damage detection and repair.

HISTONE DEACETYLTRANSFERASES

Epigenetic mechanisms can be silenced during various stages in development and cellular differentiation. Presently, there are 18 known deacetylating (HDAC) enzymes, which in general act to suppress gene transcription by removing acetyl groups from lysines. These enzymes act in complexes that often include histone methylating or demethylating enzymes. In addition, the HDACs can act on other substrates. HDACs are grouped into five classes based on their sequence similarities to three yeast HDACs. All the classes are somewhat homologous, with the exception of Class III containing the sirtuins, which are dependent on nictotinamide adenine dinucleotide (NAD) and are important for cellular metabolism.

Class I includes HDAC1, 2, 3, and 8, which are found in cells throughout the body in several multiprotein complexes. These nuclear complexes are highly conserved and can associate with two families of histone demethylases. HDAC1 and 2 are part of complexes that generally function in development. In the brain, HDAC1 is mainly present in glia and HDAC2 is expressed primarily in neurons. When either one of these HDACs is knocked out in mouse brain, the mice survive. But when both are deleted, the mice do not survive past a week after birth and brain development is severely abnormal.[77] Both HDAC1 and 2 participate in the Notch cell signaling pathway during embryogenesis.[78] One set of HDAC complexes act primarily in promoter regions and to a lesser extent at transcribed regions. Another HDAC complex, NCoR/SMRT, also including HDAC1 and 2 along with methyl binding domain proteins, is essential for development in many species from flies to mammals. NCoR/SMRT binds with nuclear receptors and together they recruit other proteins to DNA. In conjunction with the repressive element silencing transcription (REST) complex, NCoR is involved

New histone-modifying enzymes are still being discovered and this list is not comprehensive. In addition, nomenclature for these genes may have changed.
L = lysine, R = arginine, S = serine, T = threonine. Enzymes designated in lower case were identified in yeast.

in neural and glial development.[79–81] Not only do these protein complexes have independent actions, but they also work together in many cell types.

Class IIa HDACs include HDAC4, 5, 7, and 9. Unlike the Class I HDACs, these enzymes are more restricted in their distribution, yet they can exist in the cytoplasm as well as the cell nucleus. Class IIa HDAC enzymes are abundant in heart, skeletal muscle, and brain (particularly HDAC4 and 5), and HDAC7 is expressed in a subset of thymocytes. HDAC6 is found in testes and HDAC10 is present in liver, spleen, and kidney.[82] Several lines of evidence suggest roles for Class I HDACs along with HDACs 4 and 5 in learning and memory.[83,84] These two HDACs are highly expressed in the basal ganglia, hippocampus, and cerebellum. Class IV contains only HDAC11, which is widely distributed in the developing brain; after birth, expression increases in specific regions.[85] In particular, HDAC11 is concentrated in adult oligodendrocytes and hippocampal granule neurons.

Deciphering the roles of these important enzymes in the brain is in its early phase. A descriptive study examined co-expression of HDACs and various neuropeptides, including corticotropin-releasing hormone (CRH), oxytocin, vasopressin (AVP), agouti-related peptide (AgRP), pro-opiomelanocortin (POMC), orexin, histamine, dopamine, serotonin, and noradrenaline neurons. Unique co-expression was noted for HDAC4, 8, and 10. HDAC4 was present in neurons producing histamine, CRH, oxytocin, AVP, orexin, serotonin, and noradrenaline. Noradrenaline was in common with HDAC10, which is also present in AgRP, POMC, and dopamine neurons. HDAC8 immunoreactivity was detected in the cytoplasm of almost all histamine neurons.[86] This differential expression of HDACs may provide clues as to their selective roles in neuronal function.

Class III HDACs are unique because they require NAD as a cofactor for their enzymatic activity. These enzymes, also known as the sirtuins (SIRT1-7), are structurally dissimilar to the other HDACs. Sirtuins are implicated in many critical cellular processes, including metabolism and aging.[87] The mammalian sirtuins are located in different subcellular areas. SIRT1, 6, and 7 are found in the nucleus; SIRT3, 4, and 5 are present in mitochondria; and SIRT2 is found in the cytoplasm. SIRT1, which is involved in lipid and glucose metabolism, stress responses, and aging and in the brain, is essential for B-cell lymphoma 6 protein (BCL6)-mediated neurogenesis.[88] One of the many functions of SIRT2 is to regulate transcription of sterol response element binding protein, which promotes cholesterol biosynthesis in neurons and is essential for myelin and steroid formation. In agreement with this fact, SIRT2 is present in particularly high levels in myelin-forming oligodendrocytes.[89] Both SIRT1 and 2 are present in human placenta, with lower levels in the amnion and choridecidua.[90] SIRT3 is expressed in brown but not white adipose tissue, where it interacts with estrogen-related receptor alpha to regulate responses to oxidative stress and calorie restriction. Also found in mitochondria, SIRT4 may be important for insulin downregulation in pancreatic beta cells.[91] SIRT5 is broadly expressed but not well understood. SIRT6 is present in most tissues throughout the body, and SIRT6 knockout (KO) mice die at about 1 month of age.[92] The final nuclear sirtuin, SIRT7, is present in the nucleoli; it interacts with RNA polymerase I and other DNA transcriptional factors. Given the importance of energy and metabolism for reproduction, these are clearly fundamental observations in understanding how the sirtuins are involved in reproductive processes.

HISTONE METHYLTRANSFERASES

Three histone N-terminal residues—lysine, histidine, and arginine—are subject to methylation, which generally leads to decreased access to DNA by transcriptional protein complexes. Histone methylation does not change the charge of histone tails but instead affects hydrophobicity, which influences the affinity of transcription factors for DNA. In addition, the histone methyltransferase (HMT) enzymes are more specific for certain histone modifications than are the enzymes associated with acetylation. Methylation can be graded; one, two, or three methyl modifications can be added to specific lysines, and up to two methyl modifications can be added to arginines. Histidines can only have one methyl modification. Also, methylation can be both activating and repressing, whereas acetylation nearly always enhances transcription.

Three enzyme families, containing over a dozen known specific enzymes, catalyze the addition of methyl groups, which are donated from S-adenosyl methionine (SAM) to histones: (1) enzymes with a highly conserved protein domain (so-called SET domains) found in chromatin regulators; (2) the DOT1-like proteins that methylate lysines; and (3) the members of the protein arginine *N*-methyltransferase family (PRMT), which methylate arginines. The specific enzymes are shown in Table 52.2. Many of these enzymes have targets other than histones and can act on transcription factors, DNA repair, and genome stability. Some of these enzymes can methylate proteins on chromatin other than histones.

HISTONE DEMETHYLTRANSFERASES

Two different enzyme families act to demethylate lysines: amine oxidases and jumonji C-domain containing iron-dependent dioxygenases. The arginine demethylases are less well known. Interestingly, it was only a few years ago that histone demethylation was noted. Previously, methyl groups on histones were thought to be permanent, similar to the situation for DNA methylation, which up until very recently was considered to be irreversible. There are specific DNA sequences that recruit methylation

Enzymes designated in lower case were identified in yeast.

enzymes. The best known are the Polycomb group (PcG) response elements (PRE) and the Trithorax group (TrxG) response elements (TRE). The Polycomb repressive complex 2 targets H3K27, while the TRE directs recruitment of enzymes to the fourth lysine on histone 3 (H3K4). Only PcG has been identified in humans.

Methyl marks may act in concert but also may exclude each other (Figure 52.4). For example, if H3K4 has three methyl moieties (me3), H3R2 cannot undergo dimethylation.[112] In another example, the histone demethylase JHDM1D binds to H3K4me2 or me3; after this is accomplished, it demethylates H3K27me2.[113] H3K4me3 generally enhances transcription, thus demonstrating that methylation is not always repressive. Combinations of methyl marks can have actions that differ from single marks; for example, H3K4me3 is active and H3K27me3 is repressive when they are present alone, but when both are present together, the cell is poised for transcription.[114] The demethylase enzyme for H3K27, KDM6A, can associate with other enzymes that work on the activating mark, H3K4. This may explain the combined actions of these two modifications.[38]

In keeping with the multiple actions of histone methylation enzymes, it is possible that the methyl modifications change the configuration of the chromatin and thus create new interactions by chromosomal looping.[115] Certain patterns of histone modifications are required for transcription factors to bind. Of particular interest is the fact that proteins of at least seven of the X-chromosome genes involved in X-linked mental disabilities have histone modification functions. These include: methyl CpG binding protein 2 (*MeCP2*), alpha thalassemia mental retardation

syndrome X-linked (*ATRX*) a DNA-dependent ATPase, lysine specific demethylase 5C (*KDM5C*, also referred to as *JARID1C*), another histone lysine demethylase PHD finger protein 8 (*PHF8*), the BCL6 corepressor BCOR, which forms complexes with PcG, the PHD finger protein 6, and the bromodomain and WD repeat containing protein 3 (BRWD3). Recently, a patient was diagnosed with both mutations in two of these genes (*MeCP2* and *ATRX*) and severe intellectual disabilities.[116] Clearly, mutations in these genes will have multiple downstream affects via faulty epigenetic maintenance.

Epigenetic Modifications to the DNA

Compared to the varied and multiple associations between histone modifications, proteins, protein complexes, and specific genes, epigenetic changes to the DNA itself are restricted to specific genes, and specifically to cytosine residues proximal to guanines. This is annotated as "CpG" to indicate C-phosphate-G, confirming they are next to each other as opposed to being CG base-pairs across the DNA strand. Because the change involves methylation of the fifth carbon residue of the cytosine, this is also often annotated as 5mC for 5-methylCytosine; it involves the transfer of a methyl group from a donor SAM (Figure 52.5). Cytosines can also be methylated when associated with the other nucleotides, adenine and thymidine, and even another cytosine, but this occurs much less frequently and is currently of unknown significance. However, a report suggests that this occurs more frequently in the brain compared to other tissues and, more importantly, increases as the brain ages.[117] A summary of the enzymes and associated proteins involved in DNA methylation can be found in Table 52.2.

CpG Islands

In the mammalian genome, the frequency of CG as compared with AT occurrences is less than that expected by chance. However, the frequency of CG increases notably in the promoter region of some genes, increasing to above 50%, as opposed to as little as 1% in the reading frame. This leads to the designation of a "CpG island". Cytosines that are methylated can undergo spontaneous deamination and thereby be converted into thymidines. This sequence change is believed to be the source of the evolutionary pressure that keeps CpG frequency so low. However, the addition of a methyl group to cytosines within the 5′ promoter region can also have profound influences on the transcription of the gene, with the canonical effect being gene silencing. This can occur via two different modes: a direct steric hindrance of transcription factor access to the DNA or a secondary recruitment of specific methylated DNA binding proteins, which in turn recruit additional repressor proteins and thereby effectively prevent transcription factor access and gene expression (Figure 52.6). Part and parcel of the ability of changes in CpG islands to regulate gene transcription is that many mammalian gene promoters either reside within or contain CpG islands, although some do not. Moreover, chromatin is often densely packed into nucleosomes, thus precluding gene expression. However, CpG islands are either found outside of nucleosomes or, if found within one, the associated histones contain marks that are conducive to, not repressive of, gene expression.[118]

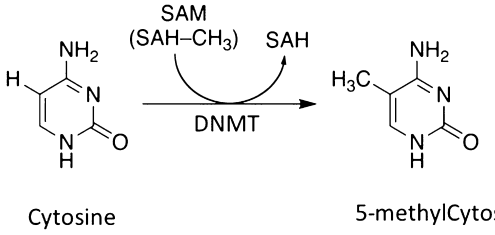

FIGURE 52.5 Methylated cytosine. Cytosines are the principal target of methylation in DNA. The methyl group is transferred to the 5-carbon of the cytosine by DNA methyltransferase (DNMTs) enzymes that use S-adenosyl methionine (SAM) as the methyl donor. Only cytosines found proximal to (not based paired with) a guanine are the target of methylation and this combination is referred to as CpG.

DNA Methylation Enzymes

In some instances, the methylation of CpGs is sufficient to regulate transcriptional activity, but often there is further recruitment of an additional set of proteins that both recognize and bind to highly methylated regions that can thereby further repress gene expression. These are referred to a methyl binding proteins and they come in a variety of forms (see Figure 52.6).

METHYL BINDING DOMAIN PROTEINS

The most famous gene member of the group of methylated DNA binding domain proteins (MBDs) is MeCP2, which was first identified as a critically mutated protein in Rett syndrome, a progressive neurological developmental disorder and the leading cause of intellectual disabilities in females.[119] Its location on the X chromosome is the basis for the sex bias in that males having their one and only copy of MeCP2 mutated rarely survive. MBD1, MBD2, MBD3, MBD4, and Kaiso are common methylated DNA binding proteins that recruit additional transcriptional repressors. These may further recruit DNA methyltransferases (DNMTs), resulting in more DNA methylation.[120,121] Some MBDs are also capable of both binding to specific sequences in nonmethylated DNA and still recruiting transcriptional repressors.[122] MBDs often also provide a platform for recruiting chromatin modifying enzymes that further alter transcriptional profiles (reviewed in Ref. 123).

In the most simplistic sense, methylation within CpG (mCpG) islands is correlated with and believed to be causally responsible for repression of transcription. However, as interest in the role of DNA methylation in

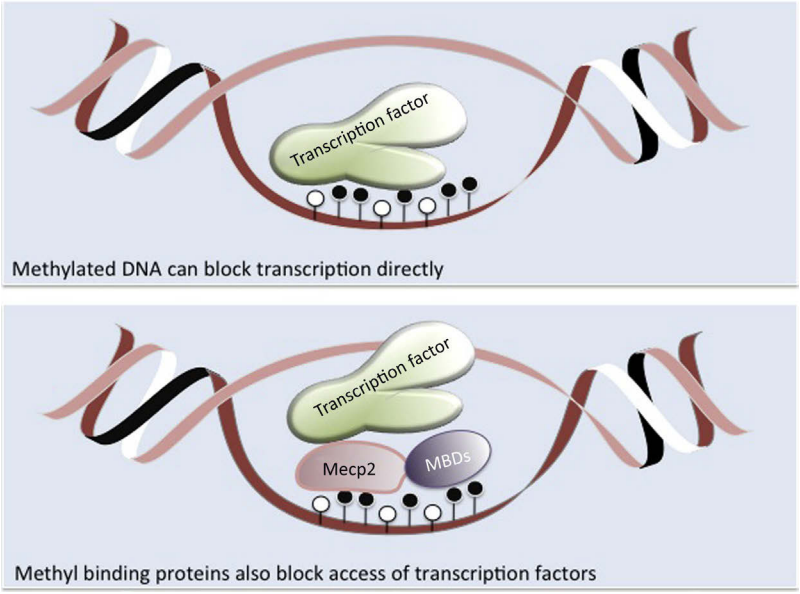

FIGURE 52.6 Impact of DNA methylation. The addition of a methyl group (in black) to cytosines or other residues can modulate transcription either by direct steric hindrance of transcription machinery associated proteins, blocking their access to the DNA, or indirectly by recruiting methyl binding proteins (MBD). One of the most well known is Mecp2, first identified as a critically mutated protein in Rett syndrome.

transcriptional regulation has grown, so has awareness that there is not a perfect correlation between mCpG and gene expression. One issue is that promoters typically have multiple CpG sites, and it is not typically the case that all of the sites are hypo- or hyper-methylated. Using a novel technology called sequence-tagged analysis of methylation patterns, Brenet et al.[124] conducted genome-wide analyses of densely methylated regions in distinct gene cassettes (i.e., transcription start site, first exon, introns and downstream exons). They found a high correlation in the amount of methylation in introns and downstream exons, but this was unrelated to the amount of mCpG in the promoter region. More importantly, the degree of mCpG in the promoter was variably associated with transcriptional regulation, whereas the methylation status of the first exon was more highly predictive, with greater methylation associated with transcriptional repression. In response to this and other discoveries, there is growing awareness of methylation of CpGs within the open reading frame (ORF) or within introns of some genes. Rather than mediators of transcriptional repression, these methylation marks are often more closely associated with past transcriptional history, meaning that after a gene has been transcribed there is an increase in intragene methylation, resulting in an inverse correlation between CpG methylation and gene expression. The amount of CpG methylation changes with aging and interestingly, generally increases in CpG islands but decreases at intragenic sites.[125]

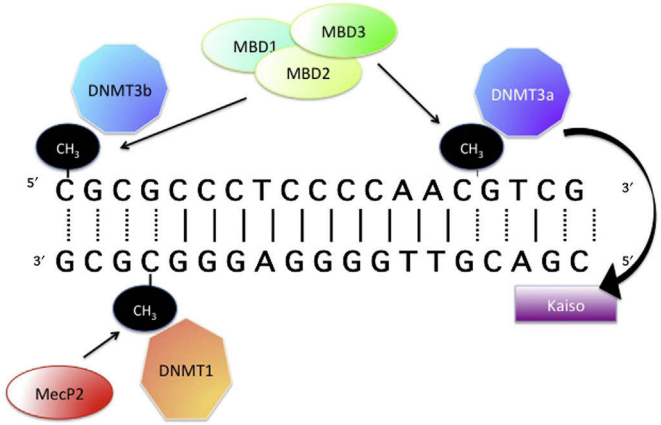

FIGURE 52.7 DNA methyltransferases (DNMTs). Two classes of DNMTs serve two different functions. DNMT1 maintains the previously established methylation pattern during DNA replication due to its ability to use hemimethylated CpGs as a substrate, thereby faithfully repeating the previously established pattern. DNMT3a and 3b are the so-called de novo enzymes as they can create new methylation patterns and their activity is modulated by environmental variables. DNMTs can also facilitate the recruitment of methyl binding proteins (MBD), which include MBD 1–3, Kaiso and MecP2 (which stands for methyl CpG binding protein 2 and is mutated in Rett syndrome). These methyl binding proteins can further recruit additional DNA or histone modifying enzymes, providing for cross-talk between DNA and chromatin.

DNA METHYLTRANSFERASES

The methylation of DNA is accomplished by a group of enzymes named for that function, the DNMTs. DNMTs carry out the addition of a methyl group to the five position of the cytosine pyramidine ring (Figure 52.5). Methylation can also occur on nitrogen of the adenine purine ring, but the functional significance of this is unknown. Mammalian DNMTs fall into three classes—DNMT1, DNTM2, and DNMT3—but only DNMTs 1 and 3 function as DNA-methylating enzymes (Figure 52.7). DNMT2 was misnamed and is not actually a DNMT, but instead methylates tRNA. The most abundant is DNMT1, and it is also

considered the maintenance DNMT. This is because it predominantly methylates hemimethylated CpG di-nucleotides, which are created during the process of DNA replication. Thus, with each cell division, the previous pattern of methylation on the single strand of DNA is matched on the second strand by the actions of DNMT1.[126] However, DNMT1 is also capable of de novo methylation, particularly in some mammalian cancers. De novo methylation is that which occurs outside the context of DNA replication; it is considered to be the form of epigenetic change that is responsive to the environment, hormonal signals, or other external modifiers. Most (if not all) of these methylation marks are removed during the wave of demethylation that occurs in the preimplantation embryo, thereby erasing the pattern of parental methylation. However, it is beginning to emerge that not all DNA methylation patterns are erased and reset at this time, and it has been suggested that novel DNA methylation can be inherited if epigenetic modifications fail to be reprogrammed. This so-called epigenetic inheritance is an active and controversial area of research with many questions remaining to be resolved.

DNMT3a and 3b are the de novo methyltransferases and are also critically important to early embryogenesis. Loss of either one results in severe developmental abnormalities, and the loss of both DNMT3 isoforms is embryonically lethal.[126] The first indication that DNMT3a and 3b serve different functions was in the distinct pattern of abnormalities and timing of mortality when each was mutated. The main difference between DNMT3a vs 3b is tissue distribution, with 3a being ubiquitously distributed and 3b much more restrictive after tissue differentiation, with some reports that it is found only in the testis, thyroid and bone marrow,[118] although others describe its presence in the brain.[127]

DNMT3L is an isoform of the DNMT3s that does not possess catalytic activity on its own but promotes the activity of its family members. It is predominantly expressed during development, being restricted to the testis and thyroid in the adult. However, during development it plays critical roles in the establishment of both maternal and paternal imprinting, inactivation of the X chromosome, and repression of transposable elements. In the nervous system, DNMT3L is expressed in the embryonic brain but is not found postnatally.[118]

DNA DEMETHYLATION

The covalent bond established when a methyl group is added to the 5′ position of cytosine is considered among the strongest in nature and is therefore difficult, if not impossible, to break enzymatically. Moreover, methylation patterns can be preserved during both meiosis and mitosis due to DNMT1-mediated maintenance during replication of the single strand, allowing for heritability of the epigenome marks. These facts contributed to a prevailing view of immutability of DNA methylation patterns. However, divergent and consistent evidence has challenged and modified this view to recognize that DNA methylation can be quite dynamic across the lifespan. In the simplest sense, the number of mCpGs can be passively reduced if there is an absence of active maintenance of methylation by DNMT1 during DNA synthesis. Thus, with each round of cell division, there will be a progressive loss of mCpG, with up to 50% lost for every turn through the cell cycle. As a result, DNA methylation is slowly and passively depleted, as is seen in the removal of methylation from the maternal pronucleus. However, this scenario only holds true for dividing cells and is not relevant to the many terminally differentiated cells, nor is it relevant to the two known naturally occurring waves of global DNA demethylation: one in the fertilized zygote and the other during primordial germ cell (PGC) development, confirming that indeed methylation marks can be removed.

In the zygote, the paternal pronucleus undergoes rapid demethylation shortly after fertilization, and much of this is due to oxidation to 5′-hydroxymethylated-2′-deoxycytodine, referred to as 5hmC (see below and Refs 128,129). PGCs, on the other hand, undergo genome-wide demethylation, erasure of all genomic imprints, and large-scale chromatin remodeling.[130] This restores the totipotency of the germ cell and is achieved within a single day.[131] However, there are also numerous other examples of more specific, focused, and modulated DNA demethylation, with emphasis in two areas: cancer cells and the brain. In the case of cancerous cells, inappropriate removal of suppressive methylation marks in the promoter regions of oncogenes is emerging as a critical event in dysregulation of cell cycle control.[132] By contrast, active demethylation in the brain is associated with normal events, such as learning,[133,134] but has also been implicated in the pathology of severe neuropsychiatric disorders involving major psychosis, such as schizophrenia and bipolar disorder.[135]

In all these instances, active demethylation is achieved in one of two general ways: either through oxidative 5mC demethylation, which is discussed below under ten-eleven translocation (TET)-family proteins, or through DNA repair. There are three separate ways in which DNA repair mechanisms can lead to demethylation: (1) removal of the 5mC and replacement with an unmethylated cytosine in a process called base excision repair (BER), (2) deamination of 5mC followed by BER, or (3) nucleotide excision repair (NER) to remove the 5mC (Figure 52.8). NER is a multistep process involving 20–30 proteins and is invoked when serious DNA damage has occurred, such as in response to ultraviolet irradiation. BER, however, is for small lesions, thousands of which occur daily in every cell

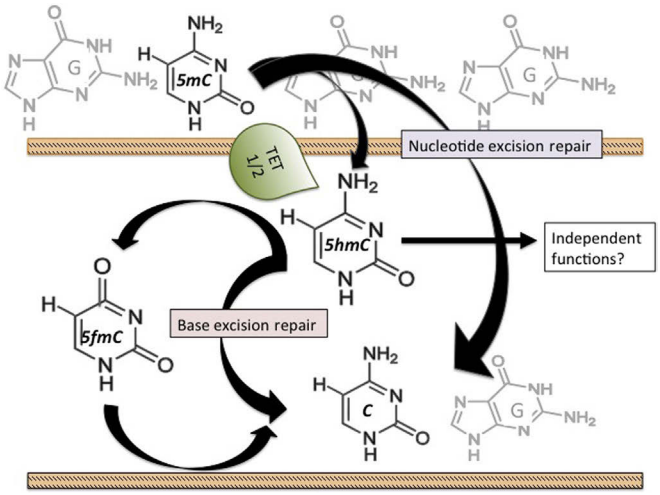

FIGURE 52.8 DNA demethylation. Demethylation of particular nucleotides can occur passively during cell replication due to failure of DNMT1 activity, but this process is generally slow and requires multiple cell divisions to significantly remove epigenetic marks. Active demethylation occurs predominantly as a by-product of DNA repair. The TET (ten-eleven translocation) family of proteins is emerging as major regulators of demethylation, which is achieved by first converting the methylated cytosine (5mC) to hydroxymethylated cytosine (5hmC) via oxidation. This substrate can then be further oxidized to 5-formylcytosine (5fmC) or 5-carboxylcytosine (not shown here). Both of these are then subject to base excision repair (BER) and return to an unmethylated cytosine (C), which can also occur directly from 5hmC. A 5mC can also be removed via the process of nucleotide excision repair (NER), a multistep process involving 20–30 proteins and invoked when serious DNA damage has occurred, such as in response to ultraviolet irradiation. Several intermediate steps in both these processes are excluded here for clarity.

and are induced by metabolic byproducts or exogenous agents. Understanding how these two processes can contribute to regulated demethylation, be it either active or passive, requires knowledge of the associated enzymes.

GROWTH ARREST AND DNA DAMAGE INDUCIBLE 45 As with many components of epigenetic regulation, growth arrest and DNA damage inducible 45 (GADD45) was initially characterized for its role in tumor growth. There are three isoforms of GADD45 (a, b, and g), and they all lack enzymatic activity themselves but induce demethylation by associating with effectors of the cell cycle and carrying out DNA repair. These enzymes are involved in both NER and BER and are responsive to signals that challenge cells such as stress, heat, and nuclear receptor-mediated hormones. One of the major questions regarding GADD45 activity is specificity—that is, how is it targeted to specific genes? Among the co-factors recruited by this protein are nuclear hormone receptors, including ERα, retinoid X receptor α, and retinoic acid receptor, and there is evidence that GADD45A may be involved in either demethylation or direct gene regulation induced by these and other associated nuclear receptors. There is also evidence suggesting that GADD45 interacts directly with DNMT1 and speculation that it may therefore prevent maintenance methylation from occurring during cell replication (reviewed in Ref. 136).

TET PROTEINS A new player has appeared on the scene as a potentially obligatory partner in DNA demethylation, the TET proteins. The emergence of these enzymes as important epigenetic regulators rests on their ability to convert 5mC into 5hmC via oxidation, and this substrate can then be further oxidized to 5fmC (5-formylcytosine) or 5camC (5-carboxylcytosine). Both of these are subject to BER. There are three members of this family in mammals: TET1, TET2, and TET3, all of which show high homology in their C-terminal catalytic domain. The major difference between the isoforms is their temporal expression pattern, tissue distribution, and the presence of a CXXC domain present in TET1 and TET3 but not TET2, which appears to enhance binding to CpG islands. Unlike Gadd45, where the strategy by which the enzyme is localized to sites of DNA methylation is unclear and may be indirect, both TET1 and TET3 are capable of direct association with CpG-rich regions, although controversial and ongoing studies also suggest interactions between the TET family of proteins and the methyl-CPG-binding domain (MBD) proteins, including MeCP2 (reviewed in Ref. 137).

Hints to the importance of TET protein activity are indicated by the differing amounts of 5hmC found across tissues and cell types. Although the level of 5mC is relatively constant across tissues (but varies between species), 5hmC levels vary widely, with the highest levels being found in specific cell types in the brain, such as the Purkinje neurons of the cerebellum.[138] Embryonic stem cells (ESCs) also have notably high levels of 5hmCs, and levels decrease as differentiation proceeds.[139] The elevation of 5hmC early in development with a decline as maturation proceeds was recently expanded to the frontal cortex.[117] A role for TET1 in maintaining the pluripotency of ESCs by maintaining hydroxymethylated DNA that is not recognized by DNMT1 has been proposed, but this notion has also been challenged. Both the TET proteins and 5hmC are found in gene-rich regions and are strongly associated with promoters; however, as with the presence of 5mC, the relationship to gene expression is not straightforward. As many genes appear to be repressed by the presence of TET proteins as are induced, further muddling the role of DNA methylation in gene expression. The differential effects of TET proteins are likely due to associations with repressive complexes such as SIN3A or the polychrome proteins. Ultimately, however, it appears that the high association of 5hmC and TET proteins at transcription start sites serves to maintain DNA methylation fidelity and to

largely keep CpG islands free of methylation and hence repression (reviewed in Ref. 140).

DNA DEMETHYLATION IN THE BRAIN

Several factors have converged to focus attention on the importance of DNA demethylation in the brain. These include a realization that although generally the brain is considered to consist of postmitotic permanently differentiated neurons, there are nonetheless high levels of key enzymes critical to both methylation and demethylation of DNA. When measured, DNA methylation of specific gene promoters is found to be mutable, changing in response to experience, learning, aging, or even hormones.[141–147] This, combined with a growing appreciation for the enduring impact of adverse early life experiences on adult brain and behavior, as well as the relative risk of developing disorders of mental health, suggest that something fundamental is imparted to the developing brain—a form of imprinting that is distinct from the genetic use of the term, although nonetheless a form of "memory". This memory may be the pattern and/or strength of synapses formed within particular brain regions, the rate at which new neurons are born in those select niches in which this process continues in the adult brain, or the expression pattern of key neurotransmitters, their synthetic and degradative enzymes, and the receptors that transduce them into altered neuronal activity. Expression levels of steroid receptors for both the gonadal and adrenal steroid classes are altered in discrete brain regions in response to epigenetic regulation.

The TET family of proteins is gathering interest in the nervous system because the adult mouse brain exhibits the highest levels of 5hmC when compared to other tissues, and this level progressively increases with age in at least three regions examined: the cerebellum, hippocampus[148] and frontal cortex.[117] The MBD protein, MeCP2, is also of interest regarding TET proteins. Assessment of genetically modified mice reveals an inverse correlation between MeCP2 and 5hmC in the cerebellum, suggesting that this so-called intermediate of hydroxymethylated C may actually be a stable mark that contributes to normal neurologic development. TET proteins are expressed in multiple brain regions, but a complete characterization has yet to be realized. A potential role for TET proteins in the evolutionary drive toward an increasingly complex brain seems feasible.[137]

Histone Modifications Interact with DNA Methylation

Although it is common for didactic purposes to separate the discussion of histone modifications from direct epigenetic changes on the DNA, in reality these two modes of modulation are intricately and mutually linked. For instance, members of the PcG place restrictive marks on the chromatin, which subsequently recruit enzymes that methylate DNA. Conversely, methyl CpG-binding-domain proteins bind to the DNA, then recruit chromatin modifying complexes that are usually associated with chromatin compaction and transcriptional repression.[124] Thus, there is coordinated regulation of histone and DNA modifications toward a common goal of either gene repression or expression. One universal principal that has emerged is that HDACs are essential for the recruitment of MBDs to specific genes. In primary neuronal cultures, MeCP2 can be acetylated by p300/CBP or deacetylated by the HDAC SIRT1. When *Sirt1* is removed in a nestin-cre mouse, the amount of brain-derived neurotrophic factor (BDNF), a target of MeCP2, is reduced. This demonstrates that there is a balance between HDAC and MeCP2 in the regulation of at least one gene, BDNF.[149]

As mentioned earlier, KDM5C is a histone demethyltransferase (HDMT) that reduces methyl moieties on H3K4. In addition, this gene resides on the X-chromosome, but it escapes X-inactivation. Thus, XX females have 1.5 times expression levels compared to XY males. The Y-chromosome contains a paralog of KDM5C, KDM5D, yet in male mice expression of this gene fails to completely compensate for the lower levels of KDM5C.[150] Mutations in KDM5C produce intellectual disability in males.[151–153] Recently, blood from a patient population revealed three target genes that might be downstream of KDM5C. The three genes had reduced levels of DNA methylation associated with their promoters, a situation that was not found in any of the 900 normal control samples. This relationship was also noted in patient brain samples.[154] These observations and many others strongly link histone methylation to DNA methylation.

Another intriguing study found that sex determination in the chicken is regulated by epigenetic marks associated with the *Cyp19a1* aromatase enzyme gene.[155] In many birds, exposure to estrogens prehatch can switch development of the genetically male gonad to an ovary. Blockade of estrogens has the reverse effect. In gonads of genetic males, estrogens decrease DNA methylation of the *Cyp19a1* promoter, which increases mRNA and thus enhances estrogen production. In addition, using chromatin immunoprecipitation (ChIP) for both H3K4me3 and H3K27me3, the authors found enhanced association of both modifications at the *Cyp19a1* promoter in male gonads after estrogen treatment.

One instructive way to think about the interactions between histones and DNA methylation is to consider the REST complex, which is implicated in a variety of brain disorders.[156] REST binds to the neuron-restrictive silencer element 1 (RE1) that is present on many neural genes, including genes for ion channels and neurotransmitter receptors. Once bound, REST acts as a scaffold for

other complexes, which in turn can recruit HDACs to the complex and CoRest, which recruits even more proteins, including HDAC1, 2, MeCP2, the HDMT LSD1, and others. Clearly, this complex is a hub of activity and interaction,[156] and in this manner the interrelationships between histones and DNA methylation are revealed.

OTHER EPIGENETIC MECHANISMS

One of the greatest surprises from the sequencing of the human genome was the realization that the number of genes was far less than expected (~25,000 at most), along with the discovery of vast quantities of so-called junk DNA. The central dogma of molecular biology is that DNA codes for mRNA, which codes for protein. However, only 2% of human genetic material functionally codes for proteins. Moreover, the genetic similarity between humans and other closely related primates, such as chimpanzees, is so great (95–98% homology) that it belies the tremendous divergence between the species. Multiple variables contribute to the divergence between such apparently closely related species, including pre- and post-translational processing. However, information encoded outside of canonical genes is also critical to their expression.

Noncoding RNAs

As the name suggests, ncRNAs are transcribed from DNA but are not translated into functional proteins. There are several types of ncRNAs that are grouped based on their size or function. The two main classes are the long ncRNAs (>200 nt) and the short ncRNAs, which includes micro (mi) transfer (t), and short interfering (si) RNAs. Many ncRNAs appear to have functions in housekeeping processes, such as protein trafficking and cellular stability. Another class is the regulatory ncRNAs, which may have discrete actions in certain tissues and/or at selected times in development; these are the ncRNAs involved in chromatin function. Here, we will focus on long ncRNAs and miRNAs because there is more work on these compared to other classes of ncRNAs.

Long ncRNA

The long ncRNAs are greater than 200 nt long and can be from intronic, intergenic, or genomic regions. Like mRNA, the long ncRNAs have a 3′ polyadenylated end and a 5′ cap, and they are transcribed by RNA polymerase II. Moreover, they often display enrichment for H3K4me3 at their promoter sites and H3K36me3 across their coding regions. These two marks denote active gene promoters and actively transcribed regions. The long ncRNAs also display marked differences from mRNA. For example, they are shorter than mRNAs and have fewer exons and introns. They are also less well conserved. The long ncRNAs are tissue specific and typically expressed at low steady-state levels. Because they are not translated into proteins, the long ncRNAs are found throughout the cell.[157]

The major role of long ncRNAs is to regulate transcription by altering enhancers, promoters, or other regulatory regions of the gene. This is accomplished by interactions with chromatin-modifying proteins. The best example of long ncRNAs that affect transcription

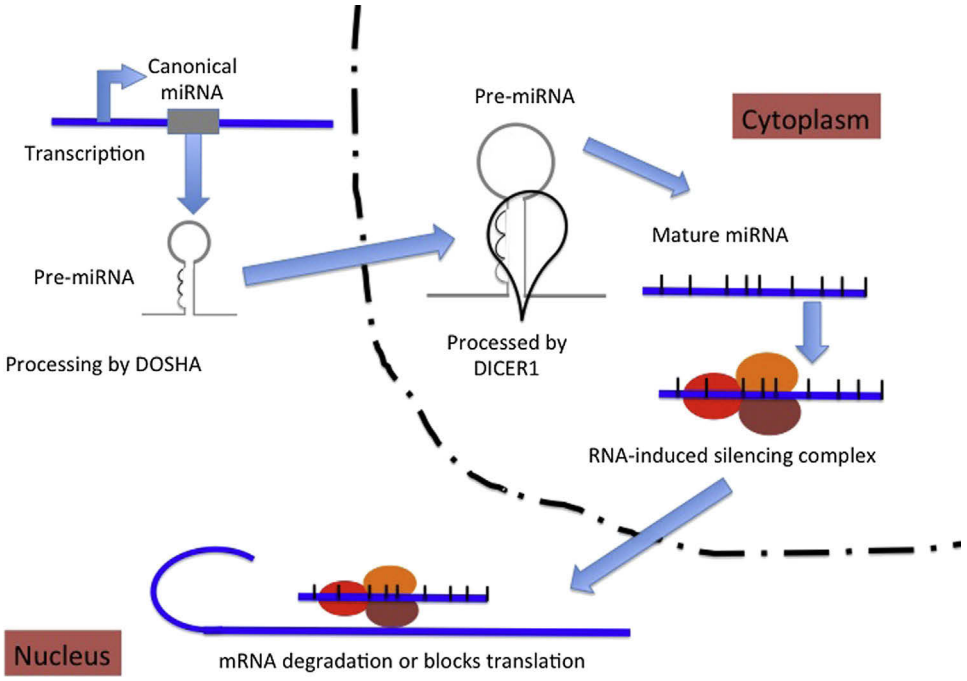

FIGURE 52.9 Processing of microRNAs. Transcription occurs in the cell nucleus where the pre-miRNA (microRNA) is processed by the enzyme Dosha. The pre-miRNA is processed in the cell cytoplasm by the DICER1 enzyme which clips the miRNA. The now linearized mature miRNA can act in a number of ways. As depicted here, it is bound to the RNA-induced silencing complex, then transported back to the nucleus where it binds to mRNA and blocks translation and/or degrades the mRNA.

are found in inactivation of the silenced X-chromosome. This process is detailed below. Essentially, the X-chromosome is silenced by the formation of repressed chromatin. The reverse function, promotion of active chromatin, can also be achieved by long ncRNA.[158] The long ncRNA *HOTTIP* acts with the myeloid/lymphoid (MLL) complex, which contains methytransferases; these then increase methylation of H3K4. Many of the actions of these ncRNAs are done in conjunction with the PRC2 complex.

ncRNAs can also regulate transcription by acting with transcription factors and coregulators. The steroid receptor RNA activator (*SRA*) is a *trans*-acting long ncRNA. *SRA* enhances the actions of liganded steroid receptors on their reporter genes.[159] SRA can associate with most steroid receptors, as well as the DAX-1 and SF-1 orphan receptors in the adrenals and may thus function in sexual differentiation.[157] Interestingly, *SRA* has been shown to produce a protein, SRAP[160]—the function of which is unclear, but it appears to interact with nuclear receptors. Another example of a long ncRNA that acts with steroid receptors is growth arrest specific 5 (*GAS5*). Some of the nucleotide sequence of *GAS5* is close enough to the glucocorticoid receptor (GR) response element that GR will bind.[161] Thus, when levels of *GAS5* are high, it can block the actions of GR. Finally, *CTBP1-AS* acts as an antisense to a corepressor of the androgen receptor (AR).[162] Long ncRNA also interact with and give rise to miRNAs. There are several examples of long ncRNAs that act as "sponges" to antagonize the actions of miRNAs.

Interestingly, brain sex differences in multiple regions can be attributed to Y- and X-chromosome genes.[163,164] Novel female-biased long ncRNAs in brain are associated with regions that surround genes that are known to escape X-inactivation. This observation suggests that sex differences in brain may be at least in part regulated by long ncRNAs.[163]

MicroRNAs

miRNAs are small (21–25 base pair) ncRNAs that regulate gene expression after transcription. These single-stranded RNAs target mRNAs for cleavage or translational repression. Humans have more than 1500 identified miRNAs so far (http://www.mirbase.org). They are produced from imperfect hairpin structures in long ncRNA precursors or from introns of noncoding genes. They are processed and produced in the cell nucleus by interactions between the enzymes DICER and DROSHA (Figure 52.9). In the cytoplasm, miRNAs interact by pairing with mRNA, the translation of which they block. miRNAs complex with ARGONAUTE and other proteins as part of the RNA-induced silencing complex. Hundreds of miRNAs have been identified in the past few years, and their targets include many genes and ncRNAs. They are important during development and interact with NOTCH signaling, *HOX* family genes, and SMAD proteins.[165] They can also regulate DNA methylation in mouse ESCs. In addition to developmental roles, many miRNAs are cell-type specific. The miRNAs interact with both DNA methylation and histone-modifying proteins and enzymes, representing another level of gene transcription regulation.

Multiple lines of evidence suggest that miRNAs are essential for embryonic neural development. Complete KO of *Dicer* is embryonically lethal, but *Dicer* KO in brain,[166] particularly in dopaminergic cells, is not lethal. Using a dopamine receptor-Cre to eliminate *Dicer* in the medium spiny neurons of the striatum leads to reduction of several miRNAs; mice showed reduced stride length and increased astrogliosis, but no increased neuronal death. Many miRNAs are present in brain, and miR-124 accounts for nearly half of all miRNA in brain.[167] MiR-9 is only found in the brain—both in embryos and adults.[168] The distributions of miR-128 and miR-124 are nearly exclusively in neurons.[169] Importantly, the REST complex may regulate brain miRNAs, including miR-9, 124, and 132, and these miRNAs also provide feedback on REST.[170]

In germ cells, X-linked genes are silenced during spermatogenesis, but X-linked miRNAs are not.[171] In addition, there are no known miRNAs associated with the Y-chromosome. In fact, more than one-third of the 77 X-chromosome-linked miRNAs are expressed in a testis-preferential or testis-specific pattern, suggesting that these X-linked miRNAs have functional roles in spermatogenesis.[172] In particular, X-chromosome-linked miR221/222 is essential for development of spermatogonia via its regulation of KIT protein and message.[173] Recently, the Bale laboratory has reported that male mice stressed prior to siring offspring have elevated levels of nine miRs in their sperm.[174] Their offspring were highly stress-reactive, but no data on the profile of miRs in offspring sperm were given. If any of the miRs affected in fathers were also modified in sons, this could suggest a role for miRs in multigenerational inheritance.

It has been demonstrated that overexpression of miR-132, a brain-specific miRNA, increases dendritic spine density and impairs novel object recognition.[175] MiR-124 is involved in normal spatial learning and social interactions.[173,176] Several miRNAs, including miR-132, have been implicated in the regulation of circadian clocks.[177] Variation in miRNA expression has been documented in the hippocampus of 24 different recombinant-inbred mouse strains as well as the parental strains.[178] Greenberg and colleagues[179] demonstrated a role for miRNAs in honeybee social interactions, suggesting that these molecules are important for brain function in multiple species. Clearly, miRs are an important additional level

of transcriptional control, which is only beginning to be described.

Another class of small RNAs is the Piwi-interacting (pi) RNAs; these are 28–33 base pairs and are found in male and female germ cells. PiRNA predominantly silence retrotransposons during embryonic germ cell development, but they are also emerging as regulators of nonretrotransposon sections of DNA and may be important in epigenetic modifications of transcription.[180] There are three known groups of piRNAs in mice, all in germ cells, at different developmental stages. Loss of piRNA function leads to spermatogenic failure.[181] These potent regulatory molecules can be transmitted via the cytoplasm of germ cells (sperm or oocytes) to the next generation and thereby maintain parent of origin epigenetic inheritance.[182,183]

LINEs and Short Interspersed Elements and Alu Elements

Embedded within the putative junk DNA are long stretches of repetitive sequences that Barbara McClintock identified as mobile genetic elements in her Noble prize–winning work on maize in the early 1900s. McClintock was ahead of her time in many ways, including proposing that in addition to being insertional mutagens, transposons might also influence the expression of surrounding genes and thereby serve as controlling elements. The latter view was not generally accepted. Instead, transposons were viewed as parasitic sequences that invaded host genomes for selfish purposes and ultimately did more harm than good. There is still good evidence that most transposons are selected against and purged from the genome,[184] but the interpretation that they are all bad has dramatically changed in recent years. Current thinking looks more toward host organisms exploiting the benefits of transposons as contributors to genetic variability and agents of evolutionary change. Transposed elements, which are distinguished from retro-elements in that they have been rendered incapable of further transposition due to mutation, also contribute as supporters of genome integrity via their role as components of centromeres and telomeres (reviewed in Ref. 185).

The characteristics that define mobile elements are also used to subdivide them into two classes based on size and mode of integration. Class I retrotransposons must first be transcribed into RNA and then integrated into the genome in a copy-and-paste approach; Class II DNA transposons integrate into the genome via a cut-and-paste approach, meaning they induce the breaking of chromosomes and insert themselves. Class I retrotransposons are further subdivided into those containing long terminal repeats (LTR) or non-LTR. Of the non-LTR, the long interspersed nucleotide elements (LINEs) are the most prevalent (reviewed in Ref. 186). DNA transposons, LTRs, and LINEs are 3–7 kb long, while short interspersed nucleotide elements (SINEs) are several hundred base pairs and usually do not exceed 600 bp (reviewed in Ref. 187). Analyses of 18 separate mouse strains categorized over 100,000 polymorphic transposed elements, finding twice the number that functionally altered gene expression as previously believed and determining that the majority of transmission was via the male germ line.[184] These emerging roles for LINEs and SINEs in regulation of gene expression and greater genetic variability also highlight specific roles in reproductive physiology and in the brain (Figure 52.10).

LINEs

LINEs are mobile genetic elements that are amplified via retrotransposition. They are the most widespread class of transposons in mammals, constituting ~20% of mammalian genomic content. LINEs are distinguished from LTRs in that LINEs do not have repeating sequences and are the only active class of non-LTR retroelements in the human genome. Most LINEs are no longer capable of retrotransposition, in large part because important 5′

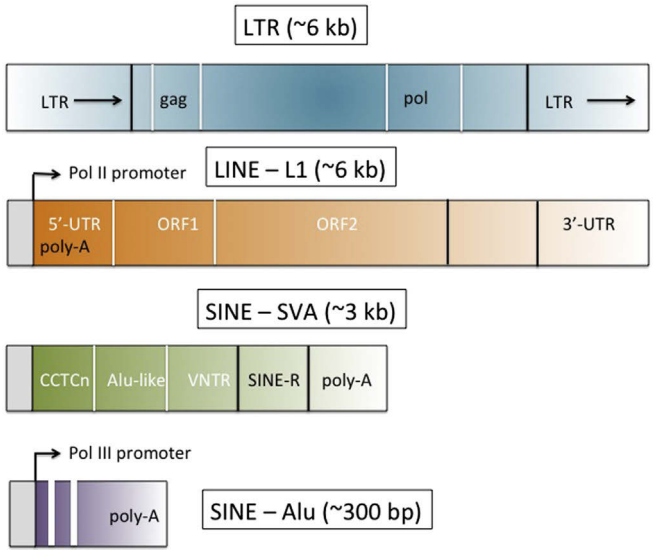

FIGURE 52.10 Transposons: LINEs, SINEs, and Alu Elements. Mobil DNA elements of the retrotransposon class are further subdivided into those containing long terminal repeats (LTR) or non-LTR. The LTRs and LINEs are both 3–7 kb long, while short interspersed nucleotide elements (SINEs) are in the several hundred base pair range and usually do not exceed 600 bp. LTRs are characterized by long terminal repeats at the beginning and ends of the insert. The proteins encoded by gag and pol are closely related to retroviral proteins. L1 is the dominant LINE and still capable of retrotransposition. The SINE category includes SVA, which is a composite of SINE-R, VNTR (variable non-tandem repeat) and Alu-like. Alus are primate specific SINEs and the most abundant in the human genome. LINEs include a polymerase II promoter site, while SINEs have a polymerase III promoter site as well. ORF1 and ORF2 are open reading frames.

regulatory sequences are lost upon insertion; nonetheless, there are almost 150 full-length active LI elements in the human genome and ~3000 potentially mobile LINEs in the mouse genome.[185] The average human genome contains ~80–100 active L1s[188] and up to 100,000 copies of human Line-1 are found in cells of the germ line.[189]

LINEs are considered autonomous because they code for proteins that they need for their own insertion (Figure 52.11). The most well characterized are L1 elements, which at full length are ~6 kb and contain an RNA polymerase II promoter in their 5′-UTR followed by two ORFs, referred to as ORF1 and ORF2. This is followed by a short 3′-UTR that ends in a poly(A) signal and an A-rich tail. ORF1 encodes a nucleic acid chaperone protein and ORF2 encodes an endonuclease and reverse transcriptase, both of which are essential for retrotransposition.[190] The LI RNA associates with the ORF1 protein and is then reverse transcribed by the ORF2 product to generate the cDNA, which is integrated into the genome. These same proteins can be used by the nonautonomous SINEs, as discussed below. When LI inserts, there are target site duplications at each end, and this can lead to the generation of pseudogenes.

L1 insertions occur in both somatic and germ cells. However, it is argued that from an evolutionary standpoint, the only significant transpositions are those occurring in the cells destined for the next generation.[191] In mammals, these include PGCs, which begin extraembryonically in the mesoderm, the germ cells proper, and very early embryos. Confirmation of active LI transpositions was confirmed via immunocytochemical detection of ORF1 protein in the cytoplasm of primitive spermatogonia, followed by Leydig cells in the developing testis, theca cells of the adult ovary, and the syncytiotrophoblast cells of the placenta. The common feature of each cell type is the production of androgens, and this close association was further confirmed by a temporal correlation between androgen production and LI ORF1 expression and a lack of ORF1 in steroidogenic cells of the mouse adrenal gland.[191] The mouse adrenal gland does not produce androgens due to the lack of 17-α-hydroxylase, precluding synthesis of C19 steroids. Most striking is the observed increase in ORF1 in the testicular Leydig cells at embryonic day 17.5, which is the height of the prenatal gonadal surge in androgen production. This is followed by a concomitant fall in both androgen synthesis and ORF1 production in the testes, shortly after birth, with blood levels remaining low until the return of androgen production at puberty. The results of this and other studies indicates that LI is actively expressed in at least five different cell types in the germ line, as well as in somatic cells involved in the production of androgens.

The importance of LINE retrotranspositions in somatic cells is a matter of debate, but the debate is heating up with the observation that the brain is a particular hot spot for these events. Stem cells in the brain are multipotent but limited and are thus referred to as neural progenitor cells, meaning they can become only neurons, astrocytes, or oligodendrocytes, depending on conditions.[192] Human fetal brain stem cells can give rise to neural progenitor cells that support retrotranspositions when transfected with an LI construct known to

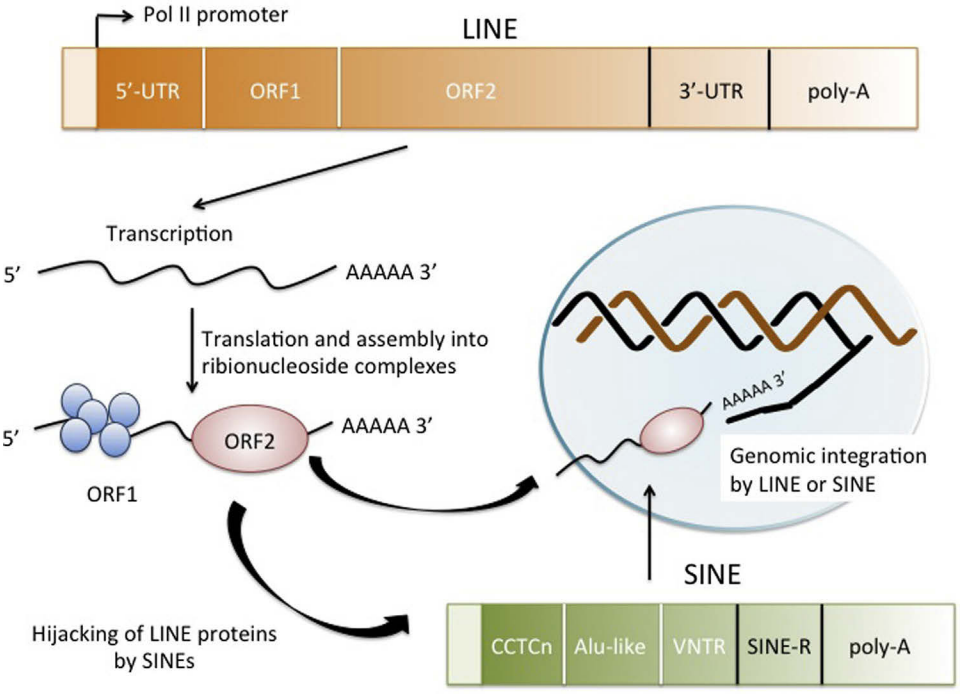

FIGURE 52.11 Retrotransposition. LINEs contain ORF1 and ORF2 (open reading frame 1 and 2), which code for chaperone proteins (ORF1) and an endonuclease and reverse transcriptase. Both sets of proteins are critical for self-replication and insertion as the parent DNA must be nicked and transcribed. LINEs are capable of self replication and insertion; SINEs are not but instead require transactivation by both the nucleic acid chaperone properties of ORF1 and the enzymatic activities of ORF2 in order to achieve successful retrotransposition.

be competent. Moreover, endogenous LI transcripts are detected in cultured human neural progenitors.[188] The activity of the LI promoter peaks during differentiation from stem cell to neural progenitor. The methylation status of the promoter is inversely related to retrotransposition efficiency, and bisulfite sequencing reveals that LI promoters in neural stem cells are far less methylated than those in skin. Further evidence of the predominance of L1 transpositions in brain is found in adults, where ORF2 transcripts are found at significantly higher levels in the hippocampus compared to the heart and liver of the same individuals. A more widespread survey of the brain found marked regional and individual variation in ORF2 copy number; however, regardless of specific region, the brain consistently outranked heart and liver.[188] Unfortunately, this study did not examine the reproductively relevant preoptic area (POA) and hypothalamus.

Hints that LI retrotranspositions might nonetheless be important to reproduction outside the germ line are found in the very few factors that associate with the L1 promoter, which of note includes the SOX family of transcription factors, with SRY being the prototype. SOX genes share a conserved high mobility group (HMG) box domain involved in DNA binding, as well as nuclear export signals that provide for rapid shuttling of SOX proteins in and out of the nucleus in response to dynamic cellular signals, such as calcium and cAMP.[193] A consensus sequence for SOX binding provides convergence for some of the multiple members of this family, with up to 11 different SOX proteins. There are two putative SRY-binding sites in the 5′-UTR of L1, and they are immediately 3′ to the CpG island.[188,189] Electromobility shift assay confirms the binding of the SRY HMG box to the L1 promoter, and luciferase reporter assays indicate a ninefold induction of L1 transcription by SOX11, with a smaller induction by SOX3 and a reversal of L1*luc* expression by SRY in the presence of SOX11. This is consistent with the absence of an activation domain in SRY.[189] SRY and related proteins may further modify LI transcription by associating with the only previously characterized transcription factor connected to the L1 promoter, YY1, and in that capacity contributing to the DNA binding and recruitment of additional regulatory factors. SOX2 associates with the LI promoter in human neural progenitor cells, but less so in mature neurons, consistent with the rate of retrotransposition. MeCP2 also associates with the LI promoter and, along with SOX2, is speculated to modulate L1 activity selectively in different neuronal cell types.[188]

In addition to the effects of SRY on L1 activity, there is evidence for L1 retrotransposition effects on *Sry* duplication and chromosomal translocation. Several rodent species have multiple copies of *Sry*, including the vole *Microtus cabrerae*, which is particularly striking for the presence of multiple polymorphic copies of the *Sry* gene in males and, unexpectedly, also in normal females.[194] In other species in which multiple copies, either polymorphic or monomorphic, of *Sry* are found, they are restricted to the Y chromosome of the male genome. The genus *Microtus* is noted for sex chromosomes of extreme size, so much so that they are called giant chromosomes, which is due to the presence of large blocks of constitutive heterochromatin. In *M. cabrerae*, the entire *p* arm and the proximal portion of the *q* arm of the X chromosome are inactive heterochromatin, while the entire Y chromosome is heterochromatic except for a tiny portion on the *q* arm, which is euchromatic. Embedded within the heterochromatic regions of both the X and Y are multiple clusters of *Sry* genes, with just a few sequences located in the euchromatic region of the Y. To date, all of these *Sry* genes have been found to be nonfunctional pseudogenes possessing internal stop codons, although clearly one functional copy exists on the Y chromosome, as sex differentiation is unremarkable in this species. Evidence of retrotransposon involvement in the remarkable expansion of SRY in this species is the prevalence of L1-mur3, a LINE element, and *Lx6*, an LTR, flanking both the 5′ and 3′ regions of the *Sry* pseudogenes in both X heterochromatin and Y euchromatin. An unanswered question is how *Sry* was transferred from the Y to the X chromosome, but one possibility is via ectopic homologous or nonhomologous recombination between LI elements on the two chromosomes. The high degree of sequence similarity in the *Sry* pseudogenes on the X and Y suggests that the transference was a relatively recent evolutionary event.[194]

SINEs and Alu Elements

SINEs are distinct from LINEs both in their length and by their dependence on the proteins coded for by LINEs that are required to actively transpose (Figure 52.11). In other words, SINEs are not autonomous but instead require transactivation by both the nucleic acid chaperone properties of ORF1 and the enzymatic activities of ORF2 from L1 or, in nonprimate species, other LINE elements. The same is true for other nonautonomous interspersed repeats, which include the primate composite repeat SVA (an acronym of SINE-R, VNTR, and Alu).

The Alu elements are deemed the most successful of all mobile elements, contributing almost 11% of the human genome with a copy number well in excess of 1 million. Alu elements are primate specific and dependent upon the only currently active primate LINE, L1. However, they also code for low levels of RNA that are transcribed by RNA polymerase III (as opposed to the more commonly utilized RNA polymerase II), and these RNAs contribute to retrotransposition. The body of an Alu element is about 280 bases in length, formed from two dimers separated by a short A-rich

region (Figure 52.11). The entire construct is flanked by direct repeats of variable length that are formed during insertion by duplication of the host sequences at that site. There is no terminator sequence for Alu transcription, so transcript size varies depending upon when the polymerase encounters a TTTT terminator sequence in the host genome. This and other variables make each Alu RNA unique, and hence difficult to track. Moreover, the RNA polymerase III activity is weak and dependent upon fortuitously landing near a strong regulator. Even if successful, most Alu transcripts are epigenetically silenced, resulting in very low levels of viable RNA. Nonetheless, some of the variable-sized transcripts coalesce into ribonucleoprotein particles that then associate with ribosomes, and presumably ORF2 protein. The Alu RNAs then utilize the purloined ORF2 to copy themselves at a new genomic site, using a process termed "target-primed reverse transcription". In this scenario, Alu elements do not require ORF1, only ORF2, to successfully transpose. This has important consequences (e.g., in testes, where L1 transcription is high), but almost all the RNA is not full length, mostly due to splicing.[195] However, sufficient ORF2 is made to allow for successful Alu element retrotransposition. Moreover, Alu elements can retrotranspose almost immediately after transcription, whereas LINEs require up to 24 h. These differences between Alu and L1 are speculated to underlie the higher prevalence of Alus in the genome and its greater association with disease states (reviewed in Ref. 196).

Primate-Specific SINEs and Alu Elements

Widely dispersed throughout the human genome, Alu elements modify gene expression via influences on polyadenylation, splicing, and RNA editing.[196] That this may be important evolutionarily is evident in the comparison of humans to our closet primate relative, the chimpanzee. Since humans' divergence about 6 million years ago, there have been ~2400 fixed Alu insertions in chimps compared to ~5000 in humans; in orangutans, there have been only ~250 over twice the length of time (12 million years). Notably, the rate of L1 insertions does not differ between humans, chimps, and orangutans; combined with the observation that Alu elements tend to insert in gene-rich regions and LI insertions are found more often in gene-poor regions, this leads to the impression that Alu elements have played an important role in shaping our genome and perhaps speciation. Younger Alu elements and LI do not display enrichment differences between gene-rich and gene-poor regions, suggesting the LI has been preferentially eliminated from gene-rich regions, possibly due to its longer length thereby subjecting it to more negative selection pressure. There is ongoing Alu element insertion in the human genome, with estimates of one new insertion event per 20 human births, leading to around one in every 1000 new human genetic diseases. The potential for tremendous diversity between individuals is evident when comparing the two completed human genomes, which are polymorphic for approximately 800 Alu elements. The basis of disease production by Alu insertions lies in its ability to disrupt a coding region or splicing signal, and while this is largely random, the X chromosome appears particularly susceptible to disease-causing insertions. While there is much interest in the deleterious consequences of insertions into germline cells, it is also evident that somatic cell insertions can lead to mutations that underlie cancer progression in particular.

Alu elements can regulate genes they land near in a variety of ways, but the effective integration into a gene is a relatively rare event. Alu elements are enriched in CpGs which, unless found in a CpG island, are usually methylated. It is speculated that ~25% of the CpGs in the genome originated as Alu elements, possibly including some CpG islands themselves. Alu elements consist of FRAM and FLAM, standing for *fossil right arm monomer* and *fossil left arm monomer*. They are each about 280 bp long, and these two, nonidentical monomers dimerize in a head-to-tail organization. In between the two is a variable-length, poly-A repeat. There are also transcription binding sites found within the Alu sequences, including the nuclear transcription factor family, of which steroid receptors are a member.

Alu subfamilies are categorized by their age into old, middle aged and younger, with the majority being in the younger category.[197] In the older families, spontaneous mutations have resulted in the creation of HRE's, or hormone binding elements, with the consensus binding site AGGTCA, which is recognized by the nuclear receptor super-family of ligand activated transcription factors including ER, PR, GR and retinoic acid, thyroid hormone and vitamin D receptors. Thus a reasonable approximation of an HRE recognizable by retinoic acid, thyroid hormone, vitamin D, progesterone, estrogen and glucocorticoids exists and these Alu sequences may serve as a cellular sponge, sequestering transcription factors away from viable gene promoters, or in some instances, influencing the regulation of gene transcription (reviewed in Ref. 197).

However, the data are stronger for an impact of Alu elements on posttranscriptional processing via modification of polyadenylation, alternative splicing sites, and changes to RNA editing. Alternative splicing involving Alu elements is referred to as "exonization" and is considered so widespread as to affect hundreds, if not thousands, of human genes. Exonization can produce novel splice variants, and some estimates suggest ~5% of all alternative exons are derived from Alu exonization.[197] One particular form of RNA editing is predominant in brain and involves two complementary Alu elements

forming a hairpin loop. The loop is then modified by double-stranded, RNA-recognizing enzymes, referred to as A-I editing, which results in the inability of the transcript to leave the nucleus, thereby short circuiting translation.[196]

There is an emerging relationship between Alu elements and the ER. The notion of a tightly restricted palindromic DNA sequence constituting an estrogen response element (ERE) and required for ER binding to gene promoters has been substantially revised in light of investigations outside of the chicken vitellogenin gene. Not only is there far more tolerance to imperfections in the ERE sequence than initially believed, there is also substantial interaction of ER with the DNA indirectly via other mediators such as c-Fos, c-Jun and AP-1, and probably others. Screening of ER interactions with human genes in yeast revealed the even more surprising finding that embedded within the estrogen-responsive breast cancer gene, *BRCA-1*, is a new subclass Alu element that diverged away from the original families and that acts as an estrogen receptor enhancer. The estrogen receptor enhancing component does not appear to be widespread, as the consensus sequence was not found in the four main subfamilies of Alu elements.[198] Independent analyses of MCF7 cells also found ER binding to repetitive sequences with Alu elements, in this case in the S subfamily, and that SRC3 was recruited to the same site in an estrogen-dependent manner.[199] Limited evidence suggests AR sensitivity of specific genes relevant to prostate cancer might also have been influenced by retrovirally introduced, LTRs.[200] While relatively modest in score, together these studies suggest that transposed elements may have been important contributors to steroid hormone sensitivity. How and whether this includes steroid signaling in the reproductive system remains to be determined.

Genomic Imprinting

Mendel's initial formulation of genetic inheritance did not include any differences between maternal and paternal alleles. We now know that this is not the case; over 100 genes have been shown to have parent-of-origin effects (Figure 52.12). An early demonstration of genomic imprints comes from attempts to make uniparental mouse embryos from pronuclei, which failed since such embryos do not develop normally and soon die. Interestingly, female-only (gynogenetic) and male-only (androgenetic) embryos fail in distinctly different ways. Gynogenetic embryos live until the 25-somite stage, with very little placental tissue. Androgenetic embryos have the reverse phenotype—well-developed placenta and stunted embryos.

The functions of many of the known imprinted genes are related to embryonic and placental growth; however,

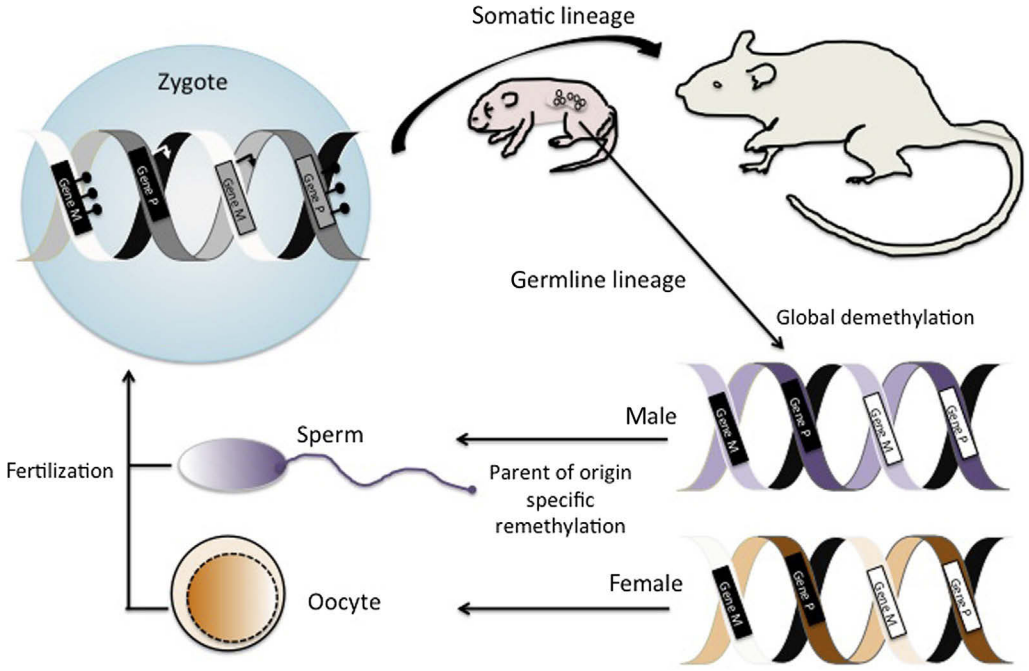

FIGURE 52.12 Genomic imprinting. Multiple genes are subject to the impact of imprinting, meaning the parent of origin determines the level of expression, with one allele being largely silenced systematically throughout the body. This is achieved with differential methylation of the allele on the chromosome from one parent. As illustrated in the figure, fertilization is followed by zygote formation and within the offspring genome maternal vs paternal copies of an imprinted gene may be silenced or expressed. The somatic lineage may not include expression of these genes, but the offspring's germ line will express the imprint during generation of germ cells.

others are involved in physiology, metabolism, and behavior.[201] The first imprinted gene identified was insulin-like growth factor 2 (*IGF2*), which promotes body growth. The receptor, IGF2R, can be thought of as growth-limiting, and its gene is silenced on the sire allele and expressed on the maternal allele.[202] Mutations in the maternal allele, therefore, have no effect since only the paternal copy is expressed. A more recently discovered imprinted gene is on the X-chromosome and encodes for RING finger protein 12 (RNF12), a ubiquitin ligase that acts to increase the dosage of X-inactive specific transcript (*Xist*) in cells with more than one X-chromosome.[203] The paternal copy of *Rnf12* is silenced.[204] In addition to in the embryo, *Rnf12* is also expressed in the mothers' milk-producing alveolar cells. In the few other cases of imprinted genes on the inactivated X-chromosome, including the recent studies showing that this occurs in the mouse brain,[205,206] it is usually the paternal X that is preferentially silenced. In addition to *Rnf12*, several other imprinted genes are involved in feeding. Expressed in the brain, *Peg3*, *Dlk1*, and *Gnasxl* regulate suckling behavior and are imprinted on the paternal allele.[207]

A variety of organisms experience imprinting: ranging from flowering plants to fruit flies to mice and to humans. However in vertebrates only mammals have evolved this mechanism and the genes subject to imprinting may not be conserved. In addition, there is evidence for tissue specific imprinting, as referred to above in embryonic vs placenta tissues. While less than half of imprinted genes have been examined in multiple tissues, of those that have been, only about 30% are specific and imprinted in only one tissue type.[207] Furthermore, some imprinted genes are only expressed at certain stages in the life cycle. The evolution of imprinting is not well understood, although the fact that it is widespread in plants and animals suggests some adaptive significance. The hypothesis put forward by Moore and Haig[208] suggests that the differences in mammalian parental investment affect imprinted genes. In general, maternally imprinted genes increase the size of the tissues that will become the placenta and paternally imprinted genes increase the size of the embryo. This leads to the "parental conflict" hypothesis in which the sire strives to utilize maternal resources and produce large offspring, at the energetic cost of the dam. On the other hand, the maternal genome is best served if the amount of energy provided by the dam is balanced with that provided to the embryo, and thus the imprinted genes regulating milk production and placental growth.

The mechanisms that underlie the process of parental imprinting are reminiscent of those described for X-inactivation, and this process uses many of the same proteins and enzymes. One difference between the two processes is that imprinting has a larger requirement for DNA methylation than does X inactivation. Many imprinted genes are found in clusters that also contain CpG-rich regions and which are only methylated on one of the two parental chromosomes. These clusters may serve as imprinting control regions (ICR), which act as either insulators or promoters for ncRNAs. In some cases, the ncRNAs have high affinity for trithorax proteins, which mediate H3K4 methylation.[209] Primary imprints in germ cells are erased and re-established during gametogenesis, and their differential methylation requires DNMT3a and DNMT3L. How maternal vs paternal ICRs are distinguished is not clear, but it might be related to location because maternal ICRs tend to be within transcriptional units and paternal ICRs are in intergenic regions. The imprinted genes persist during the early embryonic genome-wide demethylation. At this time, MBDs recruit additional silencing factors. The maintenance methyltransferase, DNMT1, is essential at this time, as is STELLA, a maternal factor formerly known as developmental pluripotency-associated 3 (DPPa3). STELLA binds to H3K9me2 to block the activity of TET3, which demethylates the genome globally.[210]

The importance of faithfully replicated, imprinted marks is illustrated by the consequences of when they are not. This can lead to Angelman syndrome or Beckwith–Wiedemann syndrome, with the former characterized by severe developmental delay, aphasia, and seizures and the latter by excessive growth and endocrine disorders. In vitro culture conditions can impact imprinting in preimplantation embryos, thus having consequences for in vitro fertilization (IVF). It has been proposed that children conceived with assisted reproductive technology (ART) are more likely to suffer from imprinting disorders, but other studies dispute this idea (reviewed in Chapter 45).

Keverne and colleagues have described the actions of the paternally imprinted mouse gene, *Peg3*, by using a *Peg3* KO mouse and manipulating the parent of origin of the null allele.[211] Dams pregnant with litters that were heterozygous for the null *Peg3* (from their sires) gained less weight during pregnancy; in addition, their pups were lighter weight and gained less weight than wild-type pups during the lactational period. After weaning, *Peg3*+/− females attained puberty at a later age and at lighter body weights than wild-type control females. Interestingly, when heterozygous dams mated with wild-type males to produce all wild-type litters, the dams gained less weight during pregnancy. Milk letdown was impaired in the dams and the pups were lighter than controls throughout, as well as after the suckling period. Thermoregulation was impaired in pups and dams that were *Peg3*+/−. These data illustrate that when the paternally imprinted Peg3 allele is disrupted, it reduces the size of the pups, and about one third died during the postnatal period. The expression

of *Peg3* in brain and placenta are also influenced by the nutritional state of the dam. After a 24-h fast during midpregnancy, *Peg3* mRNA increased in the hypothalamus but decreased in the placenta. The *Peg3* mutation affects a number of reproductive behaviors. In addition to maternal care, olfactory preferences for urine from estrous females and exploratory behavior are disrupted in males; in one mouse strain, maternal aggression was affected.[212,213] Some of these phenotypes are related to interactions between the oxytocin system, apoptosis, and *Peg3*+/− in mouse brain.[212,214]

X-Inactivation

X-chromosome inactivation is one of the best understood examples of epigenetic regulation of gene expression. In mammals, gonadal sex is determined by the sex chromosomes: XX in females and XY in males. This is the only pair of sexually dimorphic chromosomes. The human X-chromosome contains about 1000 genes, while the Y-chromosome contains only about one tenth of that number. Compensation for the lack of two copies of the X genes in males, as well as the potentially lethal overexpression of X-chromosome genes in the female, is accomplished by random inactivation of one X chromosome in each female cell. Thus, females are mosaic, having one X-chromosome that is euchromatic vs one that is heterochromatic. This essential difference makes females less vulnerable to genetic mutations on the X-chromosome because it is rare that both alleles would be mutated. However, when a female has one mutant copy, she will be mosaic for the expression of the protein it encodes and on a cell-by-cell basis will or will not have a phenotype.

As illustrated in Figure 52.13, the evolution of this system is thought to have started approximately 200 million years ago with the pair of autosomes that contained the *Sox3* gene, the likely predecessor to *Sry* in mammals.[215,216] In fact, this gene can substitute for *Sry* if it is inserted into the *Sry* HMG box and delivered as a transgene to XX mice.[217] The copy of *Sox3* on an autosome, which would become the Y chromosome, experienced mutations that resulted in the male sex-determining gene, *Sry*. Next, the region on the proto-Y gained male-specific functions and the genes nearby took on male-specific functions.[218] In fact, all the genes in this location now function in spermatogenesis. As a result of these modifications, the Y chromosome now passes only from fathers to sons. The pseudoautosomal region(s) (PAR) of the X- and Y-chromosomes are the only sections of the sex chromosomes that experience crossing over, and thus are common to both sexes.

To compensate for the loss of some of the essential genes on the Y-chromosome, the X-chromosome is hypothesized to have increased expression of a subset of genes that have paralogs on Y. These genes are designated as X-escaping genes. In humans, about 15% of the genes on the X-chromosome escape inactivation; in mice, that estimate is about 3%.[219] Other X-chromosome genes, without counterparts on the Y-chromosome, also escape inactivation. Of note, the actual rate of overexpression of these genes in XX females is less than twofold and is typically variable between individuals.[220] The final process in the evolution of the sex chromosomes was X-inactivation because it was essential to decrease expression of X-genes, which in a double dose might lead to lethality or other less deleterious effects. In contrast, it is obvious that overexpression of the escaping X-genes is also important. Turner syndrome is a fairly common (1:2000) aneuploidy condition with a complete or partial deletion of the second X-chromosome. In humans, despite

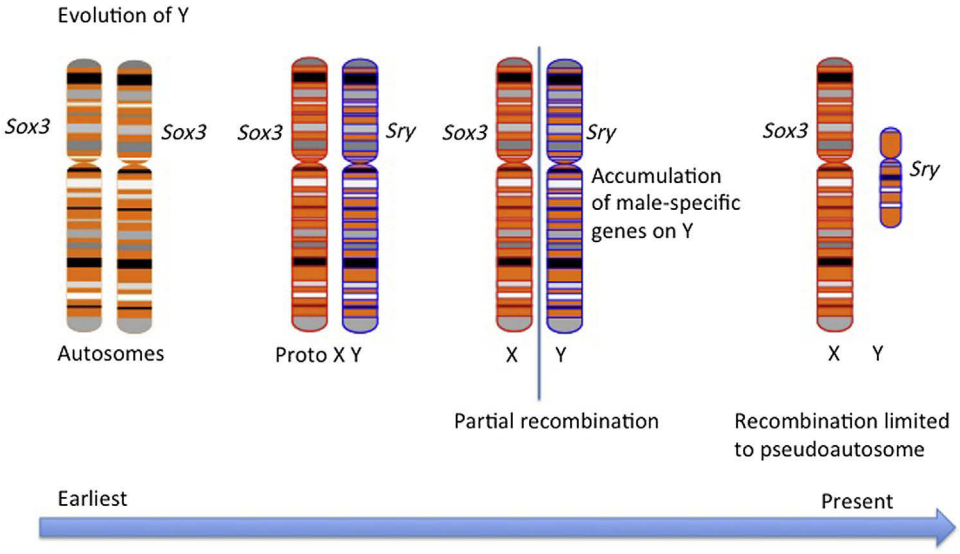

FIGURE 52.13 Evolution of the Sry gene and Y chromosome. Approximately 160–180 million years ago, the *Sox3* gene was located on a pair of autosomes in early mammals. This gene was the sex-determining gene. The next stage in this evolution was the modification of *Sox3* to give rise to the *Sry* gene only on the paternal autosome. Next, this autosome accumulated male-essential genes and a recombination block between the pair of chromosome established the pair as X and Y chromosomes. The number of genes on the Y chromosome was limited to those that had a sex-specific purpose leading to a reduction in the size of the Y chromosome. A portion of the X and Y still undergo limited recombination in the psuedoautosomal region.

the large number of live births, it is estimated that X0 is lethal in 99% of embryos with this mutation.[219]

Mechanisms of X-Inactivation

The long ncRNA, *Xist* (17-kb) spreads in *cis* along the X-chromosome (Figure 52.14). It is likely that LINEs, such as L1, assist in *Xist* spreading by serving an anchoring function.[221,222] In mice, genes that escape X-inactivation do not contain L1 repeats nor do they recruit *Xist*.[223] In addition, binding and propagation of *Xist* may require Yin Yang 1 (YY1), a protein that is suspected to bridge *Xist* RNA to its own locus.[224] The ncRNA *Tsix* is the antisense of *Xist* and spreads along the active X-chromosome, enhancing gene expression and thus maintaining accessibility to these genes. It is thought that *Xist* and *Tsix* are formed from the same RNA strand, which is cleaved by the RNAi enzyme DICER. Finally, *Xce* is an enhancer for *Tsix*. In addition, during random inactivation, both *Xce* and *Tsix* are thought to affect the choice of the inactive X (Xi) vs the active X (Xa). Mutation studies show that *Tsix* activity is required to suppress *Xist* on the Xa.[225] However, in male embryos, *Tsix* mutation is not lethal, suggesting the importance of factors other than *Tsix*. Data from male embryos suggest that the HMT *Eed*, one of the PcG genes, may be one of the other essential factors.[225–227] This enzyme trimethylates H3K27me3, a mark of repressed chromatin.

The PcG includes two repressive complexes: PCR1 and 2. These proteins are essential for targeting genes to be silenced by producing histone modifications. They are also essential for maintaining the silenced X. The essential PCR2 genes include *Eed*, *Ezh2* (also a HMT), *RbAp48* (includes a histone-binding domain), and *Suv12* (interacts with DNA via a zinc finger). All H3K27 methylation (mono, di, and tri) requires the PcG2 proteins. When *Xist* spreads over the Xi, a short ncRNA called *RepA*, within the *Xist* region, is part of the process that recruits PcG2 via *Ezh2*. A series of chromatin modifications result in silencing of nearly all the genes on this chromosome. The silenced chromosome cannot be reversed, and it is stably maintained in a silenced state through mitotic divisions. The first of these histone modifications is the recruitment of the repressive chromatin modification, H3K27me3. Other marks, H3K9me3, and a histone variant, macroH2A1, are also enriched on the Xi. This histone variant and de novo DNA methylation on promoters of Xi genes mediate long-term silencing. It is also likely that *Ehmt*, the euchromatic histone lysine-*N*-methytransferase 2, acts on H3K9 to promote DNA methytransferases, which also result in gene silencing. However, the recent discovery that DNA methylation need not be permanent may shed new light on long term X-inactivation.

Genes that Escape X-Inactivation

Clearly, an important class of epigenetically regulated genes are those on the inactivated X-chromosome (Xi) that escape inactivation. In humans, 15% of the genes on Xi are not inactivated; in the mouse, a study suggests that significantly fewer (3%) of all genes escape inactivation.[228] It is not known why Xi is more complete in mice than in humans. It is possible that the placement of the centromere, in the middle of the human X but at the end of the mouse X-chromosome, could be important. One hypothesis is that the centromeric heterochromatin in the human X may impair *cis*-spreading of *Xist*.[229] The locations of these genes in the human X are in clumps, containing up to 13 Xi-escaping genes, but in mice they are more spread out over the entire chromosome. The ability of the Xi-escaping genes to avoid X-inactivation is intrinsic to the DNA sequence and not dependent on their location on the X-chromosome. This was demonstrated by insertion of bacterial artificial chromosomes containing *Kdm5c* (also known as *Smcx* and *Jarid1c*), a gene that escapes X-inactivation into active locations on

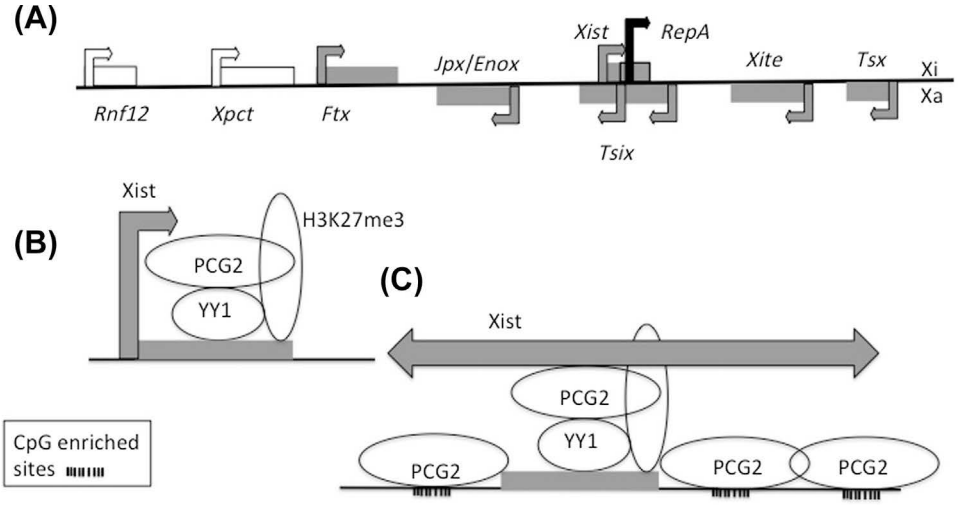

FIGURE 52.14 The control center and initiation of X chromosome inactivation. (A) The X-inactivation center consists of multiple genes (*Rnf12* and *Xpct* in white) and lncRNA, including *Xist*, *RepA*, *Tsix*, *Xite*, *Jpx/Enox*, *Ftx*, and *Tsx* (in gray). Xi = silenced X-chromosome. Xa = active X-chromosome. (B) When X inactivation is initiated, Xist recruits the polycomb group 2 complex (PCG2) and yinyang1 (YY1). YY1 bridges the repressive H3K27me3 modification. (C) As Xist expression spreads over the Xi, the PCG2 targets CpG enriched sites to silence transcription.

the X; in all locations, expression was present.[230] One clump of Xi-escaping genes present in both species is the PAR, which is the only region subject to crossing over between the X- and Y-chromosomes. The genes on the X-PAR have homologs on the Y; in addition, some of the Xi-escaping genes in other regions of X also have Y paralogs. Two such genes are *Kdm5c* and *Kdm6a* (also called *Utx*), and both produce histone demethylases that act at H3K4me3 and H3K27me3. Interestingly, H3K4me3 is an activating mark, whereas H3K27me3 is repressive and is important for X-inactivation. The Xi-escaping genes are devoid of *Xist* and contain nucleosomes with modifications that promote transcription, specifically H3K4me2, total H3, and H4 acetylation. Plus, their CpG islands are not methylated. In addition, the chromatin between active and inactive genes is associated with the CCCTC-binding factor, an insulator protein that prevents the spread of heterochromatin by blocking promoter and enhancer interactions.[231] LTRs are also depleted at Xi-escaping genes that have AT-rich motifs.[232] One aspect of these genes that has not received much attention is whether these genes have some unique function(s) or evolutionary roles that give rise to their escape. Lastly, inactivation of one of the two homotypic sex chromosomes is not universal. In chickens, female sex chromosomes are ZW and male sex chromosomes are ZZ, but the issue of dosage compensation would still be predicted to exist. In contrast to mammals, far fewer genes are subject to inactivation on the Z chromosome than would be expected, with most Z genes being expressed at 40–50% higher rates in males.[233] The presence of CpG islands in the promoters is the best predictor of whether genes are subject to dosage compensation on the Z chromosome, with long interspersed nucleotide elements, or LINEs being the next best predictor.

Early Preimplantation X-Inactivation

There are several reasons to hypothesize that the maternally derived X-chromosome, Xm, and the paternally derived X-chromosome, Xp, are not equal. One indirect piece of evidence is that Xp0 and Xm0 embryos grow at different rates (Xp0 embryos grow slower[234]). In addition, embryos with two Xm chromosomes are lethal.[235,236] However, whether the Xp is predisposed to inactivation, the Xm is resistant to inactivation, or both processes occur is not yet clear.

The process of X inactivation occurs twice during the female (XX) life cycle. The first time is in the early cleavage stage embryo (4–8 cell stages in the mouse). At that time, silencing is not random and only the Xp is inactivated. By the two-cell stage after fertilization, the Xp is expressing *Xist*, which leads to RNA pol II exclusion. Two active marks are suppressed: by the 8-cell stage, H3K9 is deacetylated and H3K4 is demethylated. At this point, X-genes on Xp decrease in expression and the PRC2 complex along with H3K27me3 appear on the Xp. By the 16-cell stage and later, the Xp remains inactive in the tissues that will become the trophoblast, but the Xp is reactivated in the inner cell mass (Figure 52.15). Then, just after implantation in most mammals, in the somatic cells but not in the germ cells, one X-chromosome is randomly inactivated. Marsupials are the exception: at both stages, only the paternal X-chromosome is inactivated. The question of how the Xp and/or Xm are marked such that only the Xp is inactivated at the four-cell stage likely involves the actions of the recently discovered TET enzymes discussed above. TET enzymes demethylate DNA by converting 5mC into 5-hydroxymethyl-cytosine (5hmC), 5-formlycytosine (5fC), and 5-carboxycytosine (5caC). Further evidence for functionally significant differences in the Xp vs Xm is found in individuals with sex chromosome aneuploides. Girls with Turner syndrome (XO) may inherit only one complete X-chromosome, which

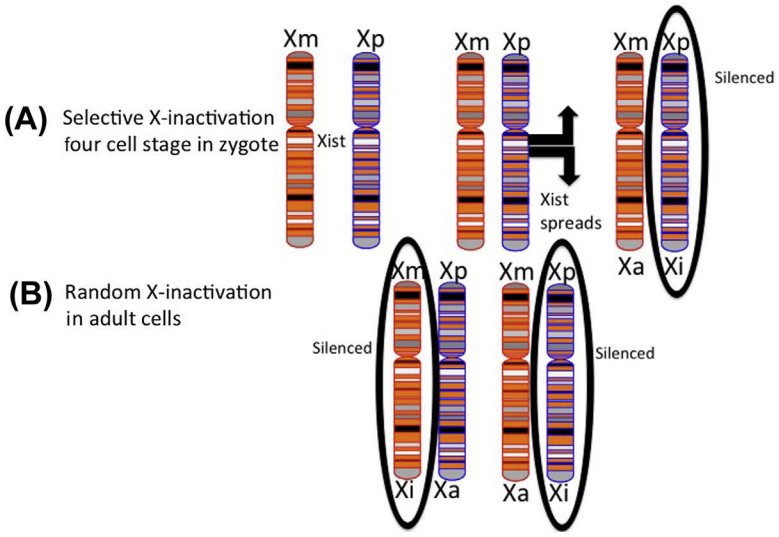

FIGURE 52.15 Selective and random inactivation of the X-chromosome. (A) Shortly after fertilization, the paternal copy of the X chromosome is selectively inactivated in every cell in the zygote and/or developing embryo. (B) In adults, X-inactivation is a random event. Either the maternal or the paternal X chromosome can be silenced. In both cases, the long ncRNA Xist is expressed and this leads to silencing.

can come from either their mother or their father. Skuse explored whether there was a parent-of-origin effect in X-monosomic females. He found better social and cognitive abilities in the females with a paternally derived X-chromosome. Several laboratories have reported brain differences between XO individuals with a paternal vs maternal X, including cortical thickness and regional gray matter volumes.[237,238] In contrast, Klinfelter's syndrome males (XXY) who inherit a second X from their fathers have more severe impairments of motor, speech, and language skills than males with two maternally derived X-chromosomes (reviewed in Ref. 239). These findings speak to the intimate interplay between imprinting and escape from inactivation of select genes on the X-chromosome.

Dosage Compensation

Both vertebrates and invertebrates have evolved systems of dosage compensation to balance expression of sex chromosome genes between the sexes.[229] Birds (ZZ) and mammals (XX) with homogametic sex chromosomes accomplish compensation by inhibiting expression of genes on one of the two identical chromosomes—X or Z for mammals and birds, respectively. In chickens, the Z chromosome is associated with ncRNA recruitment of H4K16ac; this mechanism is also found in the fruit fly, *Drosophila melanogaster*.[233,240,241] In *D. melanogaster*, the number of X chromosomes determines sex. In these animals, amplification of genes on the single X accomplishes dosage compensation. The male specific lethal (*Msl*) ncRNA is part of a larger protein complex (referred to as MSL), which contains recognition sites targeted by the histone acetyl transferase subunit, MOF. MOF is a member of the MYST family of HATs and acetylates H4K16 to enhance gene transcription.[242] In the nematode, *Caenorhabditis elegans*, males have one X-chromosome and hermaphrodites have two, both of which are partially repressed.[243] In placental mammals, not only is one X-chromosome inactivated, there is also upregulation of X-genes. This may be caused by a combination of factors, including: (1) histone acetylation, (2) Pol II enrichment on two activating modifications,[244] and (3) less rapid degradation of transcripts from X.[245] In marsupials, X-inactivation is not a random event. Only the paternal X is inactivated. This occurs without *Xist*. Instead, a different ncRNA, *Rsx*, triggers silencing. These examples demonstrate the variety of ways that different animals have evolved to compensate for dosage differences.

EPIGENETICS AND THE PHYSIOLOGY OF REPRODUCTION

The centrality of epigenetics to reproduction is self-evident in the reprogramming of the single-cell zygote into a fully differentiated individual, which itself is capable of reproduction. Every cell must undergo some degree of epigenetic programming in order to obtain its ultimate phenotype, and much of this is developmentally programmed. But there is also an emerging conceptualization that the early environment, meaning in utero, plays an important programming role in determine adult health and disease and that much of this is coded in epigenetics.[246]

Multiple fields have converged at more or less the same time on the concept of the enduring effects of the gestational environment, with the biggest impact coming from the Barker hypothesis,[6] which proposed that fetal undernutrition and restricted growth leads to increased coronary heart disease in adulthood. However, there is also less-celebrated work showing that prenatal stress impacts adult reproductive behavior in male rodents.[247] More recently, there has been careful attention to the enduring impact of exposure to introduced toxins such as nicotine, alcohol, drugs of abuse, and manmade chemicals such as plasticizers. In the latter case, there is evidence that epigenetic changes in response to so-called endocrine disrupters can manifest in the germ line and be transmitted cross-generationally,[248] a concept that is also emerging in the fields of fetal nutrition and prenatal stress. This topic is covered in detail in Chapter 45.[249] Appreciating how a fetal exposure event can endure across multiple generations requires an understanding of timing and origins of reprogramming of the germ cells, which occurs during fetal development and thus creates a window of opportunity, or vulnerability, for imprinting the environment throughout and beyond an individual's lifespan.

Epigenetics during Germ Cell and Early Embryo Development

As discussed above, there are two life-critical prenatal demethylation events: (1) the reprogramming of PGCs in order to restore totipotency; and (2) the removal of many, but not all, of the epigenetic marks in the newly created zygote (Figure 52.16). For the PGCs, this process occurs during their migration into the genital ridge, which is at ~E10.5 in the mouse, coinciding with the onset of *Sry* expression that will direct the formation of the testis in the male. The reprogramming of the genomic potential of PGCs is considered unique among epigenetic processes, as it is a complete reversal involving extensive remodeling of the chromatin, erasure of all imprinting, and the removal of epigenetic marks, including the active removal of DNA methylation. PGCs are derived from epiblast cells, meaning that they come from cells already embarking down a differentiation pathway, an event in the mouse that occurs at ~E6. This is followed by migration along the genital ridge before taking up residence in the now sex-specific gonad by day 12.5.[250] By embryonic day 13.5, the restricted population of PGCs

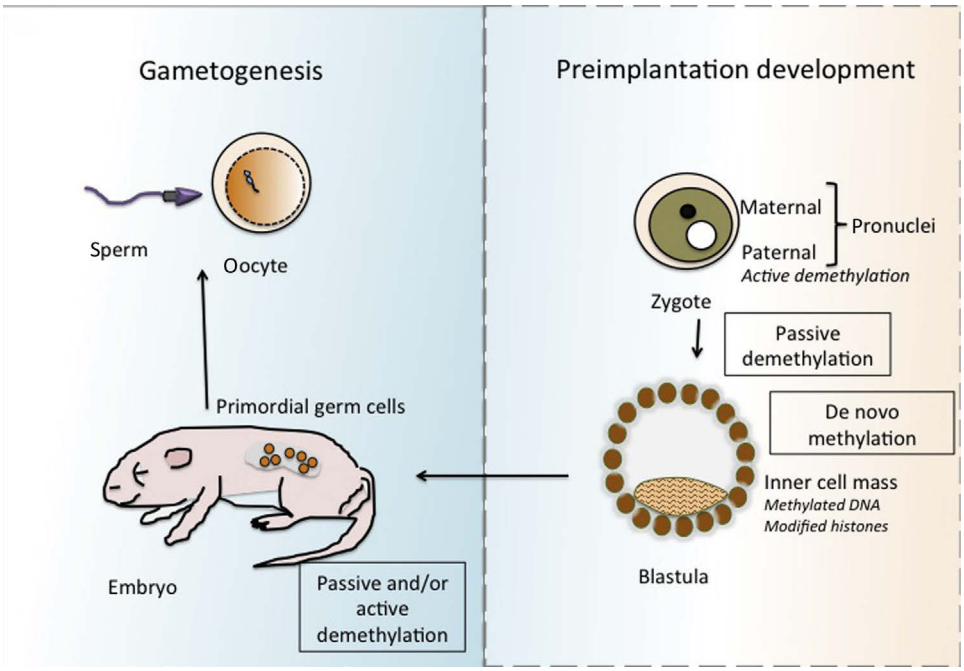

FIGURE 52.16 Two phases of global demethylation. There are two critical prenatal demethylation events, the reprogramming of primordial germ cells (PGCs) during gametogenesis in order to restore totipotency, and the removal of many, but not all, of the epigenetic marks in the newly created zygote. Both involve a combination of passive (secondary to cell division) and active demethylation but the timing and overall contribution of each process varies depending on sex.

either undergoes mitotic arrest in males or meiotic arrest in females; therefore, the deprogramming of the previous cell fate and reprogramming for totipotency, including reactivation of an inactive X chromosome if present, occurs rapidly and is considered the epigenetic nadir of mammalian development. Recently, it has emerged that there are demethylation-resistant genomic compartments that include transposable elements. Moreover, the rate and timing of remethylation differs in male vs female PGCs. Collectively, the results indicate that sex differences are present in methylated CpG islands on autosomes in the PGCs after gonadal sex determination. This occurs largely through increased CpG methylation in male germ cells while the X-linked genes, in both sexes, remain resistant to de novo methylation.[251] The mechanisms by which resistance to both demethylation and de novo methylation are conferred is unknown, but plausibly they involve DNA binding factors that block or recruit specific methylation enzymes.

Given the essential role of DNA demethylation in the PGCs and in the zygote, the presence and activity of TET family proteins during these processes has been of interest. PGCs do not express TET3, but they do express TET1 and 2 and therefore may also increase 5hmC. TET-mediated demethylation is emerging as one component of the global demethylation that occurs in both migrating PGCs and the zygote, but there are clearly other players as well, including the cytidine deaminase pathway and passive demethylation consequent to cell division.

An important question is: What is the function of global demethylation in PGCs—meaning, what purpose does it serve? One initial and primary purpose is to allow for activation of key genes required for PGC development, and these genes are normally tightly silenced by promoter methylation and attendant chromatin changes so as to avoid ectopic expression and possible tumor formation. A second theorized purpose is the removal of so-called epimutations, which are inappropriate epigenetic changes that would be detrimental if inherited by the next generation. Third is related to the expression of transposable elements (discussed in detail above), which are largely considered to be harmful and are therefore usually epigenetically silenced. Global demethylation runs the risk of allowing these harmful elements to awaken and even to propagate by further translocations. Paradoxically, there is evidence that global demethylation allows for additional precise repression of transposable elements, possibly involving small RNAs expressed by the elements themselves.[252]

The pervasive and complete removal of prior epigenetic marks in PGCs is distinguished from the other wave of global demethylation that occurs in the zygote in that the latter retains imprints, some DNA methylation, and polycomb-mediated chromatin modifications. 5mC in the paternal, but not the maternal, pronucleus is oxidized to 5hmC and TET3 is the key enzyme catalyzing 5mC into 5hmC in the paternal genome (i.e., paternal pronuclei) of developing zygotes,[128,129] with that TET3 coming from the maternal genome. The maternal pronucleus appears to be protected from demethylation by STELLA protein,[129,253] which specifically binds to H3K9me2.[210] In this way, a critical differential regulation of DNA methylation of the paternal vs maternal genome is established.

There is emerging consensus that there are mechanistic similarities between the two waves of global

demethylation, but there are distinctions as well—many of which are only recently emerging. One example is the role of TET3, which is the only TET family member expressed in zygotes, and the wave of cytosine demethylation (5mC) is accompanied by an increase in hydroxymethylated cytosine (5hmC). Various pathways exist to replace the 5hmC with an unmethylated C, thereby bypassing the need to invoke DNA synthesis to eliminate the epigenetic methyl mark. These include amidation of the 5hmC to uracil, or conversion to 5fmC (f = furyl), or 5camC (ca = carboxyl), all of which can be returned to C by BER. Loss of TET3 is lethal to the zygote, attesting to the critical importance of this demethylation event. Other aspects of demethylation unique to this global phase include the following: (1) germ cells are eightfold more methylated in males than in females because of methylation of autosomes, not of sex chromosomes; (2) LINE/LTR retrotransposons are resistant to DNA demethylation during germ cell generation; (3) some maternally imprinted genes in oocytes are also resistant to demethylation; and (4) non-CPG methylation occurs only in male germ cells.[191,254,255] This is an emerging area of research, with surely more surprises to come.

Assisted Reproductive Technologies

An important corollary to both germ cell and zygote epigenetic reprogramming converges with the concept of early life programming. It is becoming apparent that changes to epigenetic profiles can occur as an unintended consequence of ARTs, such as IVF or intracytoplasmic sperm injection. Concern was heightened by reports of increased incidence of imprinting disorders due to improper maintenance of the DNA methylation maintaining the bias in maternal vs paternal expression of a limited but vitally important set of genes. Both Beckwith–Wiedemann[256,257] and Angelman syndrome,[258] which are known but rare imprinting disorders, occur at higher rates in children conceived by ART than in the general population (see Chapter 45). In both cases, the severity of the syndrome is greatest when there are deficits in imprinting of the maternal allele, suggesting the epigenetic reprogramming of the oocyte may be more fragile or more vulnerable to perturbation than that of the sperm.[259] Studies using animal models, both rodents and larger species such as farm animals, have confirmed that there is increased risk of epigenetic alterations associated with aspects of ART, but the precise origins and mechanisms of the risk are unclear, in part because the majority of children born following ART are healthy in contrast to the more consistent deleterious effects observed in animal models.[260] Nonetheless, there is a need for increased awareness, more hypothesis-driven research, and greater transparency in the methods and reagents used in ART in order to assure best practices and reduce risk.[256,259]

Parental Influences on Offspring

Barker and colleagues discovered that infant birth weights were correlated with risk for a variety of adult-onset diseases, including diabetes and hypertension.[6–8] The focus of many studies that assess the negative relationship between low birth weight and adult diseases, including obesity, has been the hypothalamic–pituitary–adrenal axis (HPA) as a source of these metabolic abnormalities.[261] Although Barker was not concerned with behavior or reproduction, his work combined with earlier studies on prenatal stress and sexual differentiation[247] laid the groundwork for a new avenue of research, which helped establish the field of behavioral epigenetics and the notion of early life programming. Much of this work was conducted in Meaney's laboratory at McGill University. Meaney and colleagues were examining the role of stress during the neonatal period on changes in the HPA axis with an emphasis on the permanence of these alterations.[262] The breakthrough came with the discovery that variation in maternal behavior of rat dams changed expression of many behaviors related to stress in adult offspring.[9,263–265] The addition of epigenetics expert Moshe Szyf to the team facilitated understanding of the mechanistic bases for the changes in gene expression, which determined adult behaviors.[144] The idea that maternal care so profoundly affected adult behavior captured many scientists', and the public's, imaginations. The work blended developmental psychology and molecular genetics and has had a transformative impact on the field (Figure 52.17).

Since these discoveries by Barker, Meaney, and others, several paradigms have been used to study the relationship between parental environment and/or behavior and the phenotypes of the adult offspring. Much of this exciting work is at the cutting edge of determining epigenetic mechanisms.

Maternal Licking and Grooming Effects on Male Offspring

In many animals, including humans, there is a high degree of variability in maternal care. One type of care, licking and grooming (LG), is essential in rodents: neonates cannot urinate and defecate without this stimulation. Rat dams display a normal "bell curve" distribution in the expression of these behaviors. When adult offspring from dams on the two extremes of this population are observed, many behavioral differences are noted, including differences in anxiety in males. Differential levels of maternal licking and crouching behavior promote changes in expression of several genes in the stress axis. The first one extensively investigated was the GR, *Nr3c1* in the hippocampus. In an elegant series of studies, the relationship of maternal LG behavior during the critical period (the first week of life) to anxiety in

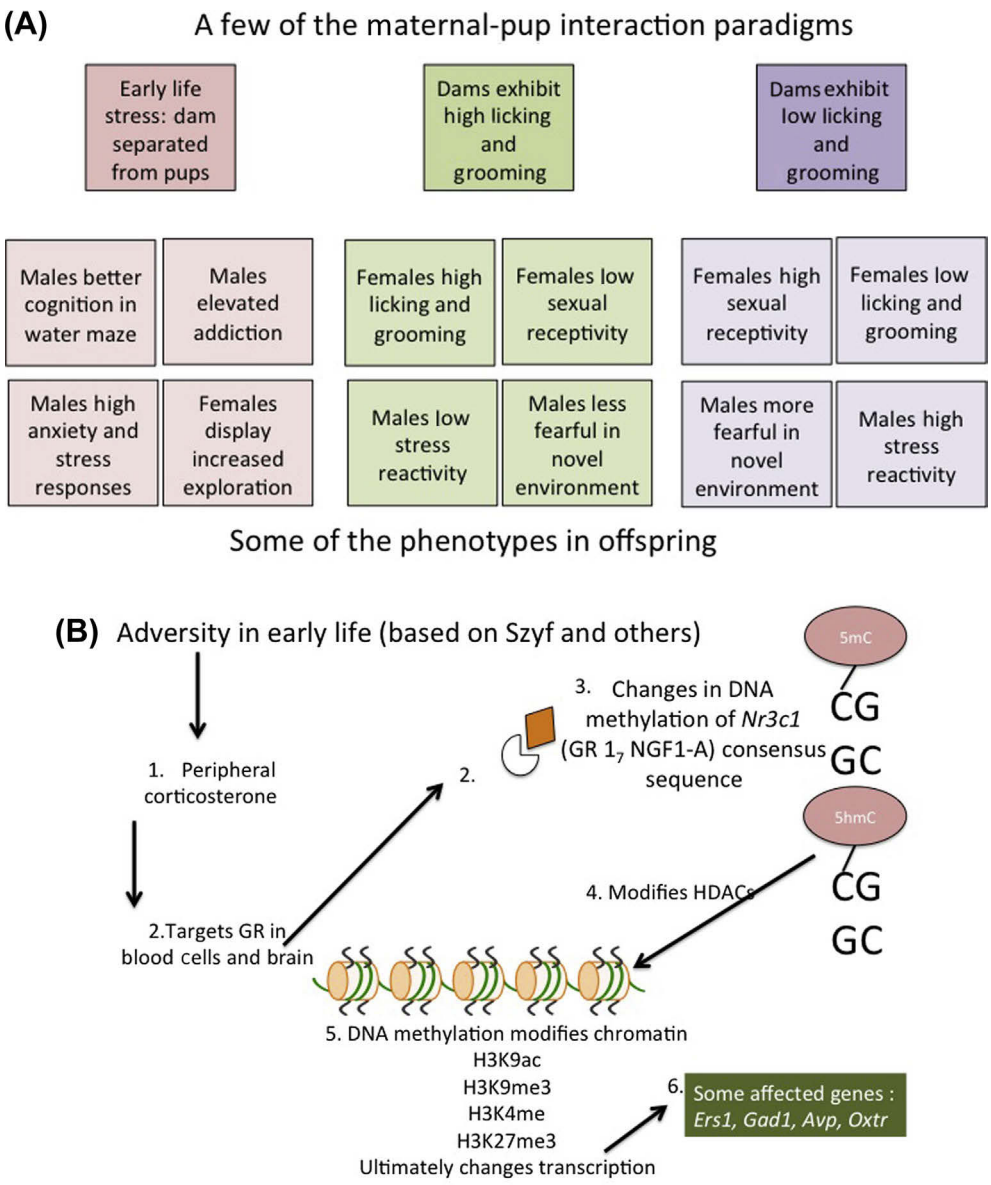

FIGURE 52.17 Maternal behavior impacts brain and behavior. (A) Many paradigms have been used to study how dam-offspring interactions change adult behavior of grown offspring. A sample of behavioral phenotypes associated with early life stress, and natural variation in licking and grooming behaviors are presented. (B) Model for maternal behavioral effects on hormone/epigenetic interactions in pups. Step 1: The behavior directed toward the pup alters the pup's levels of corticosterone. The direction of this change is determined by the amount of maternal care. Step 2: In brain and also in blood cells, the hormone interacts with its receptor. Step 3: Modifications in DNA methylation of Exon 1_7 and NGF1-A consensus site of the GR. Step 4: DNA methylation modifications affect HDAC recruitment. Step 5: HDAC availability affects the amounts and types of chromatin modifications associated with the GR. Step 6: Downstream direct and indirect actions on transcription of other genes. *Nr3c1* = glucocorticosterone receptor, *NGF1-A* = neural growth factor inducible factor A, 5mC = 5-methlycytosine, 5hmC = 5-hydroxymethlycytosine, HDAC = histone deacetyltransferase, *Ers1* = estrogen receptor alpha, *Gad1* = glutamate decarboxylase 1, *Avp* = vasopressin, *Oxtr* = oxytocin receptor.

adult male rats was illustrated (Figure 52.17). The first important aspect of these behaviors is that they are environmentally specified. When pups younger than postnatal day 6 (PN6) from high LG dams are fostered to low LG dams, and vice versa, the behaviors of offspring in adulthood were in accordance with their foster dams, not their biological mothers.[9,266] High maternal LG leads to a decrease in sensitivity to glucocorticoids; thus, as adults, offspring of high LG dams have a reduced stress response.[267] Behavioral differences included decreased startle and burying responses to novel objects, decreased latency to eat, and increased exploration in a novel environment. In addition to *Nr3c1*, high LG offspring had increased mRNA levels of $GABA_A$ and decreased *Crf* in the amygdala.

How could LG of the pups have such a profound effect on their brains and behavior? The initial stimulus for this developmental pathway may be serotonin (5-HT) released in the hippocampus in response to the tactile stimulation of grooming. The serotonin receptor 5-HT7 colocalizes with GR-containing neurons[265]; when 5-HT is present, the protein kinase A pathway is activated and CBP plus another transcriptional activator, nerve growth factor 1A (NGF1-A), bind to the *Nr3c1* promoter.[268] The amount of Ngf1-A at the *Nr3c1* promoter in exon 1_7 is thus differentially expressed: higher in pups that receive more LG stimulation. The percent of DNA methylation on exon 1_7 in turn dictates the amount of *Nr3c1* mRNA. The differences in Ngf1-A were only noted in 6-day-old or younger pups and were not present in the adult brain.[266] This suggested histone acetylation might be required during this critical period to recruit DNMTs to the promoter and change methylation status. To test this hypothesis, ChIP was conducted with hippocampal

tissue using an H3 pan acetylation antibody. More H3 acetylation was associated with the *Nr3c1* exon 1_7 region in pups exposed to low levels of LG as compared to pups receiving high LG. In addition, central infusion of the HDAC inhibitor, trichostatin A (TSA), into brains of pups or diets containing high levels of methyl donors both shifted DNA methylation and resulted in enhanced methylation of the *Nr3c1* promoter.[269] In adults, intracerebral infusion of L-methionine (a methyl donor) reversed the anxiety phenotype in males raised by high LG dams. An exciting aspect of this work is that these epigenetic relationships may also be present in humans. In human suicide victims, a decrease in *NR3C1* mRNA in the hippocampus was associated with increased DNA methylation.[270]

Maternal Behavior and Female Offspring

The same paradigm described above revealed that adult females from low LG dams spend less time on average LG their own pups, and the reverse is true for parturient females from high LG dams.[266] Female reproductive behavior and puberty onset are also affected by maternal care.[271–273] Females that receive low levels of LG as pups attain puberty earlier than females from high LG dams. In paced mating tests, adult females from low LG environments are more receptive to males, receiving more ejaculations (particularly at the beginning of the estrous period) compared with females raised by high LG dams.[274] In group mating tests, adult female offspring from high LG dams received fewer ejaculations initially as compared with offspring of low LG mothers.[275] Over the duration of the test, both types of females received equivalent mating and there were no differences in pregnancy outcomes. Of note, in cross-fostering studies, the offspring of low LG dams displayed receptive behavior like their foster high LG adopted dams. However, the same was not true for the offspring of high LG dams that were fostered. This suggests that a truly genetic mechanism is involved in the lower levels of receptive behavior performed by offspring of high LG dams.

Mechanisms underlying these differences in female reproduction are due to actions on the gene encoding ERα (*Esr1*) and its target genes, such as the receptor for oxytocin.[276,277] High LG dams and their offspring have greater levels of *Esr1* mRNA in the medial POA (MPOA) than do low LG rats. When pups were cross-fostered to the opposite LG type, their *Esr1* mRNA levels in the MPOA corresponded to those of their foster dam. The difference in *Esr1* gene expression can be mapped to methylation of *Esr1* exon 1b, which is greater in the brains of low LG females. One portion of the differentially methylated *Esr1* promoter contains the STAT5 consensus sequence; *Stat5* has been shown to increase expression of *Esr1* via the Jak/Stat signaling pathway. ChIP studies using an antibody to STAT5b have shown that adult female offspring from high LG dams have significantly more STAT associated with *Esr1* promoter as compared with offspring from low LG dams.[276] One gene regulated by ERα that is important for maternal behavior is the oxytocin receptor (*Otxr*). High LG rats have more oxytocin binding in the MPOA than do low LG dams. This is likely due to increased OTR produced by higher levels of *Esr1* in the MPOA of the highly maternal dams. Interestingly, in a different brain region, the amygdala, simulated LG (tactile stimulation) given three times daily prior to 10 days of age enhanced *Esr1* methylation and decreased mRNA in females.[278]

Impaired Maternal Care

One of the more powerful aspects of the studies on maternal LG of pups is that all of the dams behave within the normal range, just at opposite extremes of normal. But what about when maternal care is decidedly abnormal? In other words, can we model parental abuse and neglect in our animal models? Based on the work of Sweatt and colleagues, the answer would be yes. Exploiting the fact that newly parturient rats are distressed by environmental changes, these investigators created an environment in which dams neglected pups, showed little nursing and grooming, frequently stepped on them, and occasionally handled them roughly or dropped them. As a result, there was a dramatic change in the methylation status of the promoter of the *Bdnf* gene, which is implicated in numerous neuropsychiatric disorders but most notably affective disorders, such as depression. Not only was the control of *Bdnf* expression altered in the offspring of abusive dams, it was also altered in their granddaughters (F2), showing multigenerational epigenetic programming. The potential for therapeutic reversal of the deleterious effects of maternal abuse on the epigenome was found in the ability of Zebularine, a DNMT inhibiting enzyme, to reduce the excessive methylation of the BDNF gene promoter and presumably restore normal expression.[279] Unfortunately, behavior was not assessed in this study; however, interestingly, in mice communal nesting increases both maternal care and peer interactions and produces enhanced BDNF protein in the frontal cortex, hypothalamus, and hippocampus.[280] Thus, in addition to pharmacological treatments, social stimulation may modulate BDNF production.

Prenatal (Maternal) Stress Affects Offspring

Prenatal stress has been known for many years to alter behavioral phenotypes in animals, and data suggests it does the same in humans.[281] One classic stress technique in rodents is restraint with simultaneous exposure to a bright light.[282] Offspring of pregnant rats exposed to this paradigm during the last week of gestation have a number of behavioral and neuroendocrine changes. These include changes in sleep/wake cycles, increased

anxiety, decreased learning, and increased immobility in the forced swim test. In general, the male offspring are more vulnerable than the females.[282,283] It is worth noting that several types of enrichments, such as group housing and complex caging with running wheels and objects to explore, have been used to reverse these stress phenotypes.[284,285] One mechanism by which dams' stress is transduced to the embryos is by her glucocorticoids, which are normally inactivated in the placenta by 11β-HSD2. In placenta of chronically stressed embryos, this enzyme is reduced; yet, after an acute stress, 11β-HSD2 is upregulated.[286] Another potential mechanism is via changes in exposure to androgens, which may demasculinize the male central nervous system.[247,287]

An additional source for transducing the impact of gestational stress to the embryos could be the formation of the placenta at the beginning of the pregnancy, which might be susceptible to stress; this could affect nutritional input to the fetus. Indeed, this has been recently demonstrated in hybrid mice. The Bale laboratory has shown that expression of *O*-linked *N*-acetylglucosamine (GlcNAc) transferase (*Ogt*) gene, which is on the X-chromosome, is lower in male than in female placenta. Moreover, when dams experience stress for the first week of their pregnancies, expression of this gene decreases even further in male placenta. These data show profound differences in the sensitivity of males vs females.[288] The role of epigenetics in these processes is beginning to be explored.

Exposing pregnant mice to variable chronic mild stress during the first week of gestation demasculinzines both stress responding in adulthood and brain gene and miRNA expression in the second-generation males. The second generation males from prenatally stressed fathers had a reduced anogenital distance and smaller testis weights compared to offspring of nonprenatally stressed sires, suggesting the behavioral phenotype and stress axis sensitivity may be secondary to reduced testosterone developmentally. However, prenatal stress also reduced brain miRNA levels in four of the seven miRNA assayed in the first generation males and altered the expression of multiple genes relevant to brain development.[289] A shorter period of prenatal stress (gestational days 12–18) consisting of restraint and forced swimming was used to examine the potential role of miRNAs in both maternal and rat pup brains.[290] Frontal cortex and hippocampus from control and stress dams revealed over 300 miRNA that were differentially expressed. In whole pup brains, three miRNAs were enhanced, none of which overlapped with the data set found in mice.

An interesting variation on prenatal stress is "bystander" stress. In this clever paradigm used by Mychasiuk and colleagues, a pregnant rat is housed with another female. To produce indirect stress to the dam and her embryos, the nonpregnant cage-mate is subjected to periodic stress on an elevated platform under a bright light.[291] Exposure to this indirect stress, just during the gestational period, has long-term effects on behavior and brain anatomy of the pups. Young females (9–10 days old) from the pregnant dam subject to bystander stress spent less time pointing upwards on a vertical platform, an indication of disrupted geotaxis, which is an excellent measurement of sensorimotor development. By 3 weeks of age, female offspring of dams exposed to bystander stress weighed less and displayed less locomotor activity in an open field[291] than controls. Histology was conducted to examine the hippocampus and the medial prefrontal cortex. In general, density and dendritic branching in hippocampal neurons are enhanced in 3-week-old male and female pups exposed to bystander stress.[292] Primarily in females, bystander stress also affected numbers of synapses, neurons, and glial cells. Global DNA methylation was higher in the hippocampus and frontal cortex of all rats that experienced this prenatal stress as compared with controls. As expected, gene expression (as assessed by microarray) was depressed in the majority of differentially expressed genes from stressed brains.[291] The array revealed many sex differences as well as effects of stress. One interesting gene that was significantly down regulated in frontal cortex in both sexes exposed to prenatal bystander stress was *Slc6a.1*, which encodes a GABA transporter.

One potential confound with any prenatal stress model is that the dams subjected to stress may provide suboptimal maternal care. Less nursing behavior has been reported in prenatally stressed rat dams as compared with controls.[293] Pups from prenatally stressed dams that were raised by either another stressed or a normal foster rat had normal type 2 GR, dopamine, and glutamate receptors, as determined by receptor binding assays.[294,295] In addition, fostered rats return to basal corticosterone after stress or novelty. This caveat is true for postbirth stress models as well.

Maternal Separation (Early Life Stress)

Yet another way to stress infants and produce alterations in their adult behavior and brains is to remove the dam. Maternal separation is also frequently referred to as early life stress (ELS). ELS paradigms can vary in the length of time the separation lasts, how frequently it occurs, the age of the infants, condition of the infants (if they are left at room temperature or heated), and the distance between the dam and her pups. Neumann and colleagues spearheaded research on ELS using rats and separating pups from dams for 3 h a day for the first 2 weeks of their lives.[296] Males were tested in adulthood and displayed more floating in a forced swim test (an indicator of depression), and higher ACTH and corticosterone after the swim. They also showed more aggression

in a resident intruder test and their *Avp* mRNA and immunoreactivity were higher after the aggressive encounter as compared with normal males. In addition, 5HT immunoreactivity was depressed in the anterior hypothalamus, and this was inversely correlated with aggressive behavior. Using a similar paradigm in mice, ELS increased anxiety in both sexes, decreased attack behavior in the adult male offspring, and decreased maternal aggression in the females. Optical densities of AVP in the paraventricular nucleus (PVN) were elevated by ELS in both sexes, and oxytocin was reduced in females only.[297]

These studies set the stage for more mechanistic work done by Murgatroyd and collaborators.[298] The ELS was conducted with C57BL/6 mice using a 3-h separation for the first 10 days of life. Adult male offspring exhibited many of the same phenotypes as quantified previously.[297] Males exposed to ELS had elevated serum corticosterone, higher *Pomc* mRNA in the PVN, elevated anxiety, and increased motility in the forced swim test. POMC is regulated by CRH and AVP; both genes were examined, and ELS increased *Avp* but not *Crh* mRNA in the PVN. Bisulfite sequencing of CpG sites on the *Avp* enhancer revealed hypomethylation in ELS males between the ages of 6 weeks and 1 year. Interestingly, the number of sites and amount of hypothmethylation declined with age. With a hypothalamic cell line, they went on to show that one particular CpG site was consistently hypomethylated in ELS mice, and this site binds MeCP2 selectively. In vivo, PVN phosphorylated MeCP2 was co-expressed in AVP-containing neurons and in ELS brains. ChIP studies using MeCP2 antibody demonstrated reduced binding to the *Avp* gene promoter. Taken together, the data suggest that the effect of ELS is to increase MeCP2 phosphorylation, thus reducing its binding to the *Avp* gene, which results in decreased methylation and increased gene expression.

This elegant work stands as one of the best examples of the transduction of early life experiences into epigenetic modifications in gene transcripts and changes in behavior. One interesting sidebar is that in C57BL/6 mice, maternal separation for 3 h increased pup retrieval, licking, and/or nursing and nesting while reducing off the nest activity.[299] Thus, in contrast to being raised by a high LG rat dam, mice experiencing ELS show increased anxiety.

Fathers Matter Too

In humans, historical data from Swedish farmers shows that nutritional status of grandfathers (in the late 1800s) had multigenerational effects on a number of metabolic measures in sons and even grandsons.[300,301] These effects can also be seen in mice when the sire experiences a 24 h fast prior to mating. Offspring of both sexes have elevated serum glucose and corticosterone levels.[302] In addition, in mice, dams on high-fat diets prior to and during pregnancy have offspring with reduced insulin sensitivity; when the first-generation males or females are mated, their offspring possess this same trait.[303] In rats, a low-protein diet during gestation produces offspring with hypertension, which can also be transmitted by males or females to the next generation but not to the following (F3) generation, suggesting a multigenerational effect but not a transgenerational effect.[304] The age of the sire can also influence several characteristics; male mice born to very old (120 weeks) sires had lower reproductive success than males with young sires.[305] There are many examples in humans of negative effects of paternal age on various diseases, including autism.[306]

Characteristics of the sire, while less often examined, can also influence the offspring's behavior.[307] In rats, environmental enrichment experienced by the sire for 28 days prior to mating effects both male and female offspring.[308] Counterintuitively, 3-week-old offspring from enriched sires had lighter brain weights, and hippocampus and frontal cortex had less global methylation than found in controls. In males only, offspring (tested on PN10–13 and 15) of enriched sires displayed enhanced activity in an open field. Allowing dams to live in an enriched environment before and during gestation had even greater effects on offspring. Maternal enrichment decreased positive geotaxis in 10-day-old pups and increased activity in the open field in slightly older pups. As was the case for sires from an enriched environment, global DNA methylation was also reduced by enrichment of dams.

Male rats exposed to a brief daily stress on an elevated platform for 27 days prior to mating sired less anxious male pups with a temporary (PN9 but not PN10) impairment in geotaxis shown in both sexes.[309] Global DNA methylation in the hippocampus of both sexes of offspring was increased when sires were stressed. Interestingly, in the prefrontal cortex, no differences were noted in males, while in females stressed sires decreased methylation. It is interesting that prenatal stress to sires vs dams did not have the identical effects on DNA methylation. In the case of maternal prenatal stress, DNA methylation was increased in both the hippocampus and frontal cortical regions.[310] The differences in the frontal cortex may be related to the parental origin of the stress.

When male mice were raised in environmentally and socially enriched conditions, they sired less anxious and heavier pups than males raised in isolation.[311] It is possible that this paradigm may include some bystander effects (see above) because the sires and dams interacted for about 2 weeks—a period that likely encompassed some of the early pregnancy. A study demonstrated a potential contribution of the Y-chromosome to anxiety in female offspring.[312] The authors tend to argue for a

genetic effect, and this may be the case particularly because the PARs of the sex chromosome genes undergo recombination at fertilization. However, the dams and sires were together for at least part of the mating period; thus, the sires' behavior could have had an epigenetic effect on the dams and their pups.

What about Humans?

An exciting aspect of this work is that some of these epigenetic relationships may also be present in humans. The first demonstration of these types of epigenetic changes related to human behavior was work with postmortem suicide victims. In comparison with control brains, suicide victim brains had a decrease in *NR3C1* mRNA in the hippocampus, and this was associated with increased DNA methylation.[270] More recently,[313] brains from suicide victims that did or did not report early abuse were assessed. A specific promoter variant of the *NR3C1* gene was identified in those victims reporting ELS.

To more directly measure the effects of parental stress on offspring gene expression, parents of 15-year-olds rated their stress by self-report for two time periods during the children's early life.[314] DNA samples were collected from more than 100 adolescents. Global methylation was correlated with maternal stress and several genes were also examined for their DNA methylation status in relationship to parental stress, gender of the child, and timing of the stressful period. Questions of causality linger, but taken together these studies demonstrate the potency of early life events, be they adverse or merely variable within the normal range. Epigenetics is poised to transduce environment and experience into semipermanent changes to the brain, thereby optimizing behavioral phenotype in the predicted adult environment.

Transgenerational Epigenetic Inheritance

One of the most exciting—and disturbing—aspects of epigenetics is that it can contribute to inheritance. We typically think about inheritance of genetic traits; however, we now know that different gene alleles, mutations, and copy number variations are not the only way to accomplish inheritance of a behavioral, physical, or reproductive trait in subsequent generations. How epigenetic modifications arise from environmental (nutritional, chemical, or physical) perturbations is the topic of much of this chapter. Inheritance via any of the mechanisms mentioned earlier in the chapter is a whole different aspect that we are just beginning to consider. Before considering the data, we need to introduce a few definitions. As noted previously, in order for the inheritance to be truly transgenerational, the epigenetic (or genetic) changes must manifest in the germ line.[315] To conclude that some trait is going through germline transmission after intrauterine exposure, the trait must be expressed for at least three generations. This is referred to as "germ line" or "transgenerational" inheritance. This three-generation rule is important, as we will explain here.

When a trait is expressed only in the first generation, the terms "social" or "state dependent" are typically used to describe the mode of transmission.[11] One good example is inheritance of maternal style in female rats reared by low vs high LG dams. In each generation, the trait is determined by the pups maternal behavior experience. This is demonstrated by cross-fostering studies in which adult offspring have the maternal style of the dam that reared them, not their biological dam.[316] Thus, the behavioral phenotype is experience dependent.

"Multigenerational" is the best term to describe inheritance in the F1 or the F2 offspring. In several of the cases we have just discussed above, a behavioral or genetic feature was examined in F1 or F2, but it has not been assessed in the F3. One example is the anxiety phenotype in F1 and F2 male mice produced by dams subjected to chronic variable stress for the first 7 days of their pregnancies.[289] This may well be transgenerational, but so far the data only support a multigenerational effect, not genuine epigenetic inheritance. The same descriptions would apply to genetic mutations, which might be caused by exposure of the dam to mutagenic agents that impact embryonic development. In order to be inherited, transgenerational mutations need to be maintained past the F2 generation and into the F3. Importantly, to know if a transgenerational phenotype was genetic or epigenetic in origin, it is necessary to perform DNA sequencing of the essential gene; this would need to include determining which CpG nucleotides were methylated and whether this pattern was faithfully maintained across generations in order to conclude an epigenetic transgenerational effect.

As illustrated in Figure 52.18, when the developing fetus is exposed to an environmental variable (nutritional, chemical, or physical) during gestation, the dam is the F0 generation and the embryos are the F1. There are two periods in development when genome-wide germ cell reprogramming occurs: during fertilization and at the time that germ cells are migrating into the undifferentiated gonad.[252,317] During reprogramming, changes in DNA methylation, histone modification, etc., occur. In the developing F1 embryo, the entire developing body of the fetus, including its germ cells, is exposed to the environmental trigger. Thus, any changes in reproduction or behavior in the F1 may be caused by direct actions of the environment on the developing organism. The F1 animals' offspring are the F2; even at this stage, if the change is maintained, it is not yet clear it is transgenerational because the F2 offspring were F1 germ cells and thus during F1 gestation F2 DNA was exposed directly

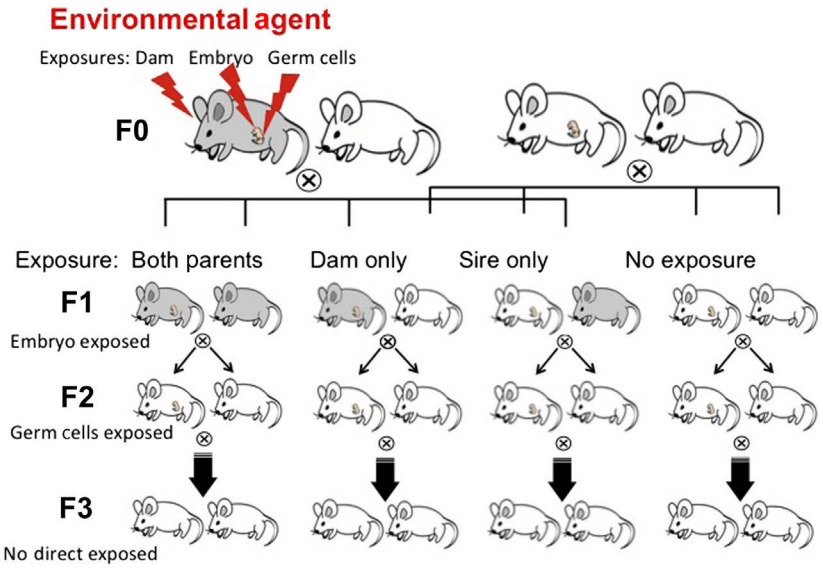

FIGURE 52.18 Transgenerational epigenetic inheritance. To detect transgenerational changes in the epigenome, animals are typically exposed to the environmental agent during pregnancy (F0, gray mouse). Epigenetic remodeling occurs at fertilization and when germ cells migrate to the indifferent gonads; thus, these are optimal times for exposure. The first generation of offspring (F1) will have direct exposure to the environmental agent. These offspring can be mated with similarly exposed or with control partners to create the F2 generation. By pairing exposed dams or sires to control partners, the parent responsible for the inheritance can be determined. The F2 offspring from the exposure line were only exposed to the environmental agent via their germ cells (present in the F1 embryos). Thus, it is likely that phenotypes of F1 and F2 generations will differ. The most important generation for these studies is the F3. If offspring from the exposed vs the control lines have differences in phenotype, they may be due to epigenetic inheritance.

to the environmental trigger. The F3 is the first generation that has had no direct exposure to the environmental trigger. In the case of a postnatal or adult exposure, the F1 germ cells may be affected; thus, the F2 generation needs to be assessed.

One of the other interesting aspects of F1, F2, and F3 (or greater) inheritance is that the phenotype may be different in different generations. For example, the actions of a prenatal exposure to the endocrine disrupting compound (EDC) bisphenol A on F1 behavior may be the opposite of the effects in F2 or F3, and this may be explained by how the compound acts on the developing brain vs the germ cells. We will describe an example below. Another aspect of transgenerational inheritance that we will discuss is the issue of the parent of origin. One dichotomy between the sexes is that male germ cells continue to go through mitosis throughout the lifespan. Female germ cells have partly completed mitosis by birth; within each cycle after puberty a subset of these, the ones destined to ovulate, complete the process as part of preparation for fertilization.

Endocrine Disrupting Compounds

Studies of EDC effects on reproduction were stimulated by two chemicals in particular: 2,2-bis(4-chlorophenyl)-1,1,1-trichloroethane (DDT) and diethylstilbestrol (DES). DDT was developed to help control lice in soldiers during World War II and afterward was widely used as an insecticide. It was banned in the early 1970s in the US after the negative impact of this compound on wildlife was revealed. There is a clear link between breast cancer and prepubertal exposure to DDT.[318] There are also F1 effects of paternal exposure to DDT on other cancers[319–321] and hypertension.[322] DDT can bind to ERs and ARs; it is lipophilic and breaks down very slowly, persisting in the environment long after its use has been discontinued.[323] Despite the ban, DDT is still present in detectable levels in blood samples of pregnant women in Texas and Peru, to name a few locations.[324,325] Studies are underway to determine if F2 effects are evident.

DES was prescribed to pregnant women at risk of miscarriages. The idea was that this treatment would maintain pregnancies; however, it failed to do so and instead produced abnormal reproductive effects. Daughters of women given DES during their pregnancies tended to have more reproductive abnormalities than unexposed women.[326] Dose-response studies in mice showed that doses as low as 0.002 μg/pup resulted in 30% incidence of uterine tumors in adults, and these studies provided evidence of an inverted-U dose–response curve for these effects.[327] Inheritance of these effects in offspring of both sexes has been demonstrated (up to the second generation) in mice[328] and confirmed by recent human data. In a population study of DES-exposed families, sons of DES-exposed mothers had a small, but significant, increase in hypospadias (3.57% as compared to none in unexposed controls). In the next generation (grandsons of DES-exposed mothers), the incidence increased again to 8.2% and none of the control grandsons had hypospadias.[329] The next generation of results will be critical to see if this effect has gone into the germ line. These examples illustrate that the parent of origin (the mother) does not have to be the same sex as the affected offspring.

Not surprisingly, manmade EDCs have received the largest amount of attention regarding their potential transgenerational effects.[330] Starting in 2005, Skinner and colleagues reported transgenerational actions of the antifungal agricultural agent, vinclozolin, and the pesticide, methoxychlor, on fertility in male rats.[331] Pregnant rat dams from gestational days 8–15 (during germ cell

migration) were treated with one of the EDCs, or control injections and the subsequent generations of male offspring were monitored. Starting in the first generation and continuing through F4 males, ancestral lines who had received vinclozolin or methoxychlor had increased cell death in the testes, fewer sperm, and reduced sperm motility. Using outcrossing, they determined that the parent of origin for this effect was the sire. Subsequently, studies focusing on vinclozolin have reported transgenerational incidence of increased tumors; diseased-appearing tissues in kidney, prostate, and testes; and inflammation in many regions.[332] In females, uterine abnormalities that interfered with pregnancy were noted along with increased glomerular abnormalities in kidneys.[333] This work has been extended to behavior. Males in the F3 vinclozolin lineage are less anxious (and/or more active) than controls, while the opposite effect is seen in female rats.[334] Of note, vinclozolin-exposed males (F3) are less attractive than control males when females were tested for partner preferences.[335]

Given the abnormal cell growth produced by vinclozolin, it is important to know whether its actions are directly on DNA (gene mutations) or epigenetic. Skinner has argued that the majority of EDCs, particularly in the doses most humans are exposed to, do not cause DNA mutations, but they can affect the epigenome. He rationalizes that the high frequencies of phenotypes is incompatible with the random nature of DNA mutations, which would affect less than 1% of all genes.[336] Vinclozolin toxicology studies have been conducted in mice, human cells, yeast, bacteria, and cell lines.[337,338] Using relatively high starting concentrations (5 μM or 1 μg/culture or 625 mg/kg body weight in mice), some studies report changes in various indirect markers of genetic mutations, such as chromosomal abnormalities, sister chromosome exchange, cell nuclei numbers, and activity of carcinogenic metabolic enzymes. However, in light of the high concentrations used, the lack of inheritance data, and use of indirect markers, it is not likely that the doses used in vivo by Skinner (e.g., 100 mg/kg body weight) and others are producing DNA mutations.

The Skinner laboratory has examined the impact of a number of other EDCs (in mixtures) in F3 offspring, recently.[339] The combination of phthalates and bisphenol A, at two doses, several dioxins, and jet fuels all accelerated puberty onset in female rats; all these chemicals, plus a mixture of pesticides, reduced the number of follicles in the ovaries. In F3 males, serum testosterone was reduced significantly by all the EDCs except the pesticides. In addition, the effects of vinclozolin exposure in utero on F1 through F3 males and females were assessed in two mouse strains.[340] Sperm cell apoptosis was increased transgenerationally in mice along with disease phenotypes in kidney, prostate, and testes. In females, the numbers of adults with ovarian cysts increased with generation.

Bisphenol A (BPA) has transgenerational actions on fertility in rats. Dams were treated during pregnancy with one of two doses; in subsequent generations, their daughters were mated and resorbed fetuses were noted. In F1, F2, and F3 offspring, reabsorption rates were higher in BPA vs control lineages.[341] In agreement with this observation, litter sizes were reduced. In male offspring, body, epididymis, and prostate weights were increased by BPA exposure in F2 and F3 generations. Sperm counts and motility were also reduced. In rat testes, immunocytochemistry was used to quantify steroid receptors and several co-activators.[341,342] AR, ERβ, SRC1, and NCor, were all lower in BPA males across all generations. BPA also acts on the brain in a transgenerational manner. In mice, dams were fed a low dose of BPA in chow prior to and during pregnancy. Juvenile males and female offspring displayed decreased social interactions in the F1, but more interactions in F2 and F4 generations.[164] In a social recognition test, F1 mice exposed to control diet or low-dose BPA chow in utero displayed normal habituation when the same female was presented over time and dishabituation when a novel female was presented. However, in the F3 mice, the BPA lineage did not dishabituate in this task; yet, olfactory discrimination was normal.[343] This suggests a specific social impairment. In embryos collected at E18.5, whole brains from the F1 and F3 generations had lower expression of *Avp* in F1 and F3. In F3 males, only *Oxt* mRNA was also depressed by BPA.[164]

The effects of gestational exposure to phthalate di-2-ethylhexyl (DEHP) have been examined transgenerationally in mice.[344] Females were fed by gavage once a day during the second week of life with control or DEHP-containing corn oil. Puberty was delayed in all generations (F1–F3) of males, and F3 males had reduced sperm counts, testicular germ cell function, and increased incidence of abnormal seminiferous tubules. These phenotypes were noted in F3 males regardless of the parent of origin. Polychlorinated biphenyls (PCBs) were banned in the 1970s but still persist in the environment and in fatty tissues. Mice received one of four doses in their chow starting on the day of mating, and continuing throughout lactation.[345] Ovary and testes weights were reduced in F1 mice by PCBs in all generations, and males had reduced anogenital distances, but none of these effects were transgenerational. Dioxins (TCDD) are another class of EDCs that are found throughout the world. In mice, exposure of dams to TCDD during pregnancy reduced the number of full-term deliveries in F1 and F3 daughters.[346]

The issue of dose and its relevance to human exposure is central to all studies of EDCs. The work on BPA by Wolstenholme[164] used low doses quantified by high-performance liquid chromatography (HPLC) measurements of blood from treated and untreated mice. The

studies by Salain[341,342] used somewhat higher doses, but no quantification was performed, so it is not clear how relevant these BPA treatments were for humans. The study by Pocar[345] and colleagues was designed to mimic levels of PCB found in breast milk. All the other studies used higher doses that are not likely to be representative of those experienced by most people. It is possible some of these compounds cause DNA mutations at these high doses. Using a comet assay to assess DNA damage in sperm, a study found more damage in males consuming higher than human-relevant doses of BPA as compared with lower dose or no BPA.[347] The group also assessed the "dominant lethal mutation rate" based on calculations of the success in mating, pregnancies, corpora lutea implantations, and live fetuses at E15. A mutation rate of 10% was calculated in males exposed to 4 weeks of daily oral intake.

Another issue to consider is the method of delivery. Most EDCs are ingested but some are inhaled. A few of the studies mentioned used one of those methods, as appropriate. The work done in the Skinner laboratory only used injections, typically intraperitoneal.[334] Many other studies have treated mice and rats orally with EDCs via gavage, which may cause stress that could interact with the actions of the EDCs.[348] A final consideration is the timing of the EDC exposure. There are two prenatal periods when reprogramming occurs; all of the studies cited above except one specifically targeted the midpregnancy period, when PGCs are migrating into the gonads. Wolstenholme placed mice on the BPA-containing diet 10–14 days before pairing and the mice were maintained on those diets for the entire pregnancy; thus, both organizational periods were exposed.[164]

Finally, an additional aspect of EDCs is that they appear to affect gene imprinting status. Over two generations, vinclozolin exposure during pregnancy had a long term (F3) effect on methylation of *Peg3* in sperm.[349] BPA can also disrupt genomic imprinting.[349,350] Using two doses of BPA, both embryonic (E9.5 and E12.5) and placental biallelic expression of several imprinted genes increased. This was accompanied by a reduction in global methylation. Expression of these genes was either enhanced or reduced compared with controls, particularly when the embryos were exposed to the higher of the two BPA doses. Interestingly, this paper reported greater effects of BPA than an earlier study.[351] The major difference was that in the earlier study embryos were only exposed to BPA during germ cell migration, whereas Susiarjo and colleagues fed mice BPA for 2 weeks prior to mating, thus encompassing the fertilization period. If imprinting is influenced by EDCs, it is possible that X-inactivation might also be dysregulated. A summary of environmental toxins demonstrated to have transgenerational effects can be found in Table 52.3.

Paternal Stress

In a series of intriguing studies, the Mansuy laboratory has shown that the combination of stress during pregnancy and maternal separation postpartum creates antisocial behavior in male but not female mice.[356] In a juvenile social encounter, the F1 males from the stress background are not less investigatory of a novel conspecific as the unstressed controls. However, F2 and F3 males from the stressed background were significantly less investigatory than controls. Interestingly, the males produce sons with the same phenotype. Importantly, this effect can be seen in males two generations past the initial stress,[282] making it truly transgenerational. Interestingly, the females that mated with the socially isolated sires had a positive correlation between their nursing frequencies and expression of BDNF mRNA; the opposite relationship was noted for MeCP2 expression.

Potential Mechanisms for Transgenerational Inheritance

In general, epigenetic modifications in gametes are cleared and then reset during two stages in development: fertilization (preimplantation) and during migration of the PGCs to the undifferentiated gonads.[357] However, as is clear from the data presented above, some modifications persist, and these can affect transgenerational changes in gene expression. Details on which mechanisms are involved differ in different species. Zebrafish display asymmetry in remodeling of DNA methylation during these time periods. Only the maternal methylome is remodeled, while the paternal methylome is stably inherited.[358,359] In addition, histones in zebrafish sperm are not associated with protamines and thus are good targets for epigenetic inheritance. In *Drosophila* and *C. elegans*, the chromatin modification H3K9me2/3 and piRNA have been implicated in epigenetic inheritance. Several other chromatin modifications are also important in *C. elegans*.[360] Mutants for the worm homolog for the histone demethylase 1A gene (LSD1/KDM1), which demethylates H3K4me2, have smaller brood sizes; this trend increases over generations.[361] In these animals, the H3K4me2 mark increases in germ cells, leading to sterility over generations.

In mice, most of the work on transgenerational epigenetic inheritance has focused on DNA methylation. This bias is probably due to the long-held view that this epigenetic modification is permanent, although we now know this is not the case.[362] Moreover, during reprogramming in sperm, the protomines were thought to completely replace histones, but we now know this process is not complete, with 5–15% of histones remaining.[363] In known fertile patients, histone retention is found at the promoters of genes important in the embryo, including

TABLE 52.3 Endocrine Disrupting Compounds and Toxins that Impact Epigenetics

EDC	Common Sources	Species	Target for Transgenerational or Epigenetic Action	References

developmental gene promoters, miRNA clusters, and imprinted loci, suggesting that the nucleosome retention is programmatic in nature.[364] In sperm, genes enriched at H3K27me3 are repressed in the early embryo; thus, this modification may contribute to male transmission of epigenetic inheritance. Another source of evidence implicating histones is that the HDAC inhibitor, TSA, given to male mice resulted in a dose-dependent decrease in spermatogenesis and testis weight as well as a decrease in histone deacetylase activity,[365,366] More studies on the role of histone modifications in mammalian epigenetic inheritance are needed.

Much of the epigenetic inheritance data come from work with a variety of EDCs.[164,331,342,344,345] However, only Skinner and colleagues have examined mechanisms. They found that the parent responsible for the transmission of a number of phenotypes is the male and have focused on promoter-wide DNA methylation changes in sperm in F3 lineages exposed originally to vinclozolin vs control in both rats and mice.[331,332] Their techniques include methylation-dependent immunoprecipitation (MeDip) followed by DNA tiling arrays and validation with real-time polymerase chain reaction (PCR). Differentially methylated regions (DMRs) have been noted. Some of the 16 DMRs contain known genes, and one association could be attributed to copy number variations.[340] The genes of interest typically have a low number of CpG repeats. Skinner and

colleagues propose that DMRs in both mouse and rat sperm are similar to imprinting sites. These sites protect the DNA from reprogramming during the epigenetic remodeling periods in development. Using bioinformatics programs, they further suggest several differential methylation motifs (EDMs) that are present within DMR and similar in mice and rats. Direct tests of these ideas will be insightful.

Hypothalamic Control of the Pituitary–Gonadal Axis

At some point in postnatal development in the majority of mammalian females, the surge-release of gonadotropin releasing hormone (GnRH1, subsequently referred to as GnRH) produced in a discrete population of hypothalamic neurons is coordinated with the other aspects of hypothalamic–pituitary–gonadal axis function (see Chapters 26–28 and 30–32). The first time this happens, females move from reproductive immaturity to fertility. Puberty is marked by changes to the neural control of luteinizing hormone (LH) and follicle stimulating hormone (FSH) release, as well as by appropriate changes in behavior, which must be achieved for reproductive success. The neural integration of environmental inputs that affect the timing of puberty and the maintenance of reproductive competence in adults have been recognized for decades. Nutrition, proximity of mates, photoperiod, temperature, and a host of other signals indicate the feasibility of successful reproduction; not surprisingly, all of these modifiers can have epigenetic effects.

GnRH is produced in a small number of neurons that reside in the hypothalamus and project to the median eminence (Figure 52.19) (see Chapter 11). Steroid hormones do not directly regulate the activity of GnRH neurons. However, cell populations in the arcuate nucleus (Arc) and in the anteroventral periventricular nucleus (AVPV) express ERα and AR and are regulated by estrogen and androgen; these cells produce kisspeptin (KISS1).[367] KISS1 can directly regulate GnRH neurons; this neuropeptide and its gene, *KISS1*, are essential for normal puberty.[368] In addition, these cells produce neurokinin B and dynorphin, leading to them being referred to as KNDy neurons in some instances. Other components of the hypothalamic network are substances produced by glia, particularly growth factors. The genes encoding these factors, and others, comprise the GnRH-regulation gene network.[369–371] Thus, all these genes are potential targets of epigenetic modulation.

In rodents, the two main populations of *Kiss1* neurons respond differently to estradiol. In the Arc, estradiol down regulates *Kiss1*, while in the AVPV the steroid has the opposite effect; it is this population of *Kiss1* neurons that controls the ovulatory GnRH surge in these species. Each anatomical region contains a different splice variant of the *Kiss1* gene,[372] and histone modifications play a role in the regulation of the *Kiss1* gene. In a non-*Kiss1* expressing immortalized hypothalamic cell line (N6), treatment with the HDAC inhibitor TSA increased expression of *Kiss1* mRNA.[372] In contrast, the DNA methylation inhibitor, 5-aza-2′-deoxycytidine (5-aza-dC), had no effect on expression of the *Kiss1* gene in this cell line. Using a luciferase construct, a transgenic mouse with

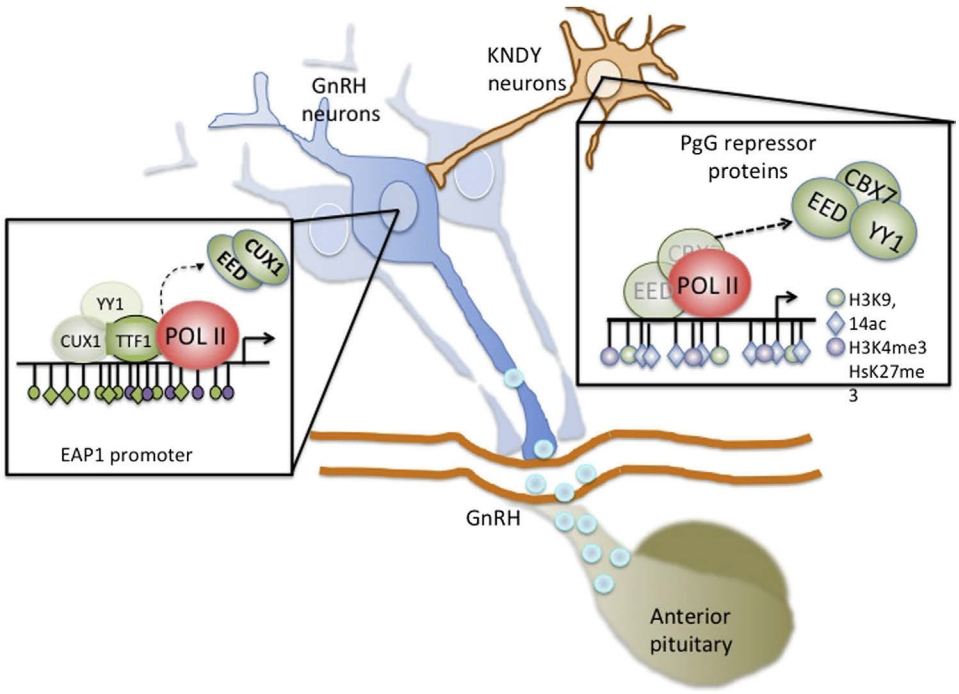

FIGURE 52.19 Epigenetic regulation of GnRH neurons. GnRH release from neurons is regulated in part by kisspeptin (KISS1) produced in KNDy neurons. Expression of the *Kiss1* gene, however, is repressed by polycomb group proteins (EED, CBX7, YY1), as illustrated in the righthand box. Permissive changes to the histones associated with the *Kiss1* promoter release the transcriptionally repressive proteins and allow transcription by RNA polymerase II (Pol II) to proceed. Several of these polycomb group proteins also block *Eap1* (enhanced at puberty 1, left hand box) in GnRH neurons (and perhaps in KISS1 neurons as well). When they are removed from the promoter, GnRH release may proceed.

labeled *Kiss1* neurons was produced and ChIP allowed for examination of hyperacetylation in the two populations of *Kiss1* neurons. Ovariectomized (OVX) mice treated with estradiol, as compared with untreated OVX mice, had higher H3 acetylation in the *Kiss1* promoter from AVPV neurons. This finding was replicated in a comparison of naturally cycling diestrous vs proestrous animals. In contrast, the reverse results were noted in cells from the Arc, suggesting that estradiol acetylated the *Kiss1* promoter in the AVPV but deacetylated the promoter in the Arc.[372] Chromatin confirmation capture performed on AVPV cells showed that estradiol enhances a chromatin loop between the *Kiss1* promoter and the 3′ intergenic region. In the Arc, the 5′ and 3′ regions of the gene were associated with the promoter regardless of the estrogen status of the mouse. Finally, DNA methylation of the *Kiss1* promoter did not differ in either of the subpopulations of kisspeptin neurons, nor in N6 cells and the *Kiss1* expressing cell line, N7.[372]

The expression of at least two PcG genes, embryonic ectoderm development (*Eed*) and chromobox homology 7, decrease prior to the onset of puberty as a result of increased methylation in their promoters, and EED is dislodged from the *Kiss1* promoter (Figure 52.19). This in turn leads to coordinated changes in H3 of the *Kiss1* chromatin that are conducive to gene activation, thereby providing a means for increasing KISS1 protein without changes to the methylation status of the gene.[373]

In contrast to the *Kiss1* population in the Arc, DNA methylation may be important for the sex difference in the AVPV *Kiss1* neurons.[374] Females have more neurons expressing *Kiss1* in this region than do adult males. This sex difference is caused by the actions of early postnatal estrogens derived from aromatization of androgen, which typically only males experience as a product of the normal developmental surge in testicular testosterone (see Chapter 47). When the HDAC inhibitor valproic acid (VPA) was given for 2 days after birth, it reversed the sex difference in the size of the bed nucleus of the stria terminalis (BNSTp).[375] However, this treatment had no effect on the *Kiss1* sex difference. In addition, bisulfite sequencing followed by pyrosequencing of the *Kiss1* gene in the AVPV revealed small differences in percent methylation in four of the seven CpG islands assessed. In all cases, the gene was less methylated in males than females. This finding is counterintuitive and may be caused by a dilution effect because the assessed brain regions contained more than *Kiss1* expressing cells. Alternatively, other sites in the *Kiss1* gene may have sex differences in methylation in the opposite direction. Finally, lower methylation levels in males might allow for more binding of transcriptional repressors—several of which are present on the *Kiss1* gene.[376] In any event, this provides an interesting example of a case where the relationship between DNA methylation and gene expression is not always as predicted.

One recently discovered gene in the GnRH-regulation network is enhanced at puberty (*EAP1*). In a series of studies, Ojeda and colleagues compared RNA and DNA expression profiles from nonhuman primate females selected at a number of times relative to puberty.[377] They also collected human hypothalamic hamartomas associated with early pubertal onset. Bioinformatic analyses revealed a number of genes common to tumors and expressed in postpubertal brains. *Eap1* is a gene encoding for a transcription factor that activates the promoter of the GnRH (*Gnrh1*) gene in neuronal and nonneuronal cell lines.[378] Interestingly, in cell lines, *Eap1* is activated by thyroid transcription factor 1 (*Ttf1*) and repressed by cut-like homeobox (*Cux1*) and yan yang 1 (part of the PcG complex). Both CUX1 and TTF1 are associated with the *Eap1* promoter in pubertal female rat brain.

Several studies support the role of epigenetic modification for expression of *Gnrh1*. The immortalized GnRH cell line GT1-7 displays active histone marks H3ac and H3K4me3, whereas immature GnRH cells (GNII) and non-GnRH cells do not.[379] Two HDAC inhibitors, TSA and VPA, can decrease GnRH expression in GT1-7 cells.[380] This is likely accomplished by repressing *Otx2*, a homolog of the *Drosophila* orthodenticle homeobox 2. When *Otx2* is deleted in mice, this reduces GnRH neuron number, delays puberty, and produces infertility.[381] In parallel with changes to *Gnrh1* gene-associated chromatin, analyses of methylation status of cultured primate GnRH neurons derived from the nasal placode of fetal monkeys revealed a developmental decrease in methylation of the promoter, which parallels increases in intracellular calcium signaling and spontaneous pulsatile GnRH release—clear indicators of maturation.[382]

Mechanisms that regulate puberty are not likely to be restricted to DNA methylation and chromatin modifications. For instance, the onset of vaginal opening in mice was influenced by a LINE element.[383] Thus, there appears to be coordinated epigenetic changes occurring in multiple components of the neural axis governing puberty. A cohesive picture of all the coordinated changes seems nearly within our grasp. However, given how complex and important this function is for evolution, it is likely to be regulated not only by many genes, but by multiple levels of epigenetic modification of these gene players.[384]

Epigenetics and Sexual Differentiation of the Brain and Behavior

The culmination of successful puberty is the production or final maturation of gametes delivered to the reproductive tract, combined with the appropriate motivation to seek out and mate with high-fitness individuals of the opposite sex. Both the strategies and choices regarding

a mate vary between males and females as a function of investment in the offspring. In most mammals, the energetic investment in each embryo is usually large and the female is likely to be the major if not sole provider of food and shelter postpartum. Thus, her reproductive decision making may involve dominance status of the male. In most bird species, the parental investment after egg-laying can be more equitable; thus, mate choice may be more influenced by variables related to territory size, courtship displays, resource provision, etc. In either situation, the brain must be in synch with the gonads so that mating occurs when the female is physiologically ready for insemination and fertilization. To assure this, the brain is preprogrammed developmentally so that an animal possessing male gonads, or testes, will exhibit male reproductive behavior as an adult, while an animal possessing functional ovaries will exhibit female reproductive behavior and all its attendant nuances. This preprogramming is a process called sexual differentiation of the brain[385] (Figure 52.20), to distinguish it from both sex determination (i.e., testes vs ovaries) and sexual differentiation of the secondary sex characteristics. Differentiation of the brain is a direct by-product of sex determination in that a developing male produces large amounts of androgen from the embryonic and neonatal testis, whereas the female ovary is largely quiescent. The gonadal androgens gain access to the brain where they, or estradiol, "differentiate" the male from the female by directing neural development that will favor expression of male sexual behaviors in response to postpubertal androgens and appropriate external stimuli, such as the sights, sounds, and smells of females (see Chapter 47).

A hallmark of this early preprogramming, or sexual differentiation of the brain, is that it occurs during a restricted sensitive period. In the laboratory rat and mouse, this period is the last few days of gestation and the first few days of life. The sensitive period is operationally defined by the onset of gonadal hormonal production in the male and the offset of responsiveness of the female to exogenous hormone administration. Thus, a gonad-intact female can be programmed to have a "male" brain by administering a masculinizing dose of testosterone to her during this perinatal sensitive period. Moreover, in many animals, some of the actions of testosterone on the developing brain are in fact mediated by its aromatized end-product, estradiol, and so administering large doses of estradiol to neonatal females is just as effective at masculinizing many end points as is testosterone. The need for large doses stems from the fact that circulating alpha-fetoprotein binds estrogens in the bloodstream that originated with the dam, so that inadvertent masculinization of female fetuses is avoided. Administrating large doses of estradiol exceeds the binding capacity of the alpha-fetoprotein and allows access to the brain.[386,387]

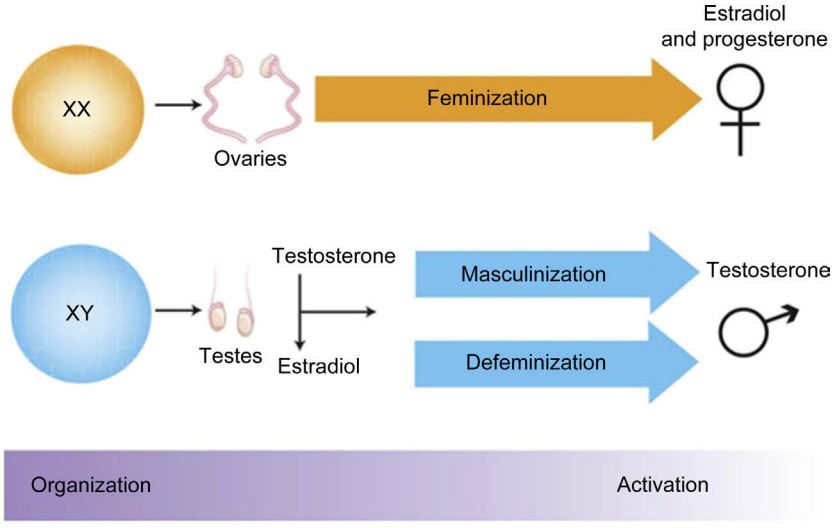

FIGURE 52.20 Sexual differentiation of the brain. Sexual differentiation of the brain begins with the chromosomal complement, which determines gonadal sex. Testosterone synthesized and released by the fetal and neonatal testis can be aromatized to estradiol and both steroid hormones act on the developing brain to both masculinize and defeminize it in males. The female brain develops in the absence of a high level of gonadal hormones during this early sensitive period. Hormone action at this time is referred to as organizational because it sets the stage for adult activational effects, which induce stereotypic behaviors in males and females in response to gonadal steroid production. The organizational effects of steroids are believed to endure at least in part due to epigenetic changes induced during the sensitive period, but there is also evidence for new hormone-dependent epigenetic changes in the adult brain. For the past 50 years, the prevailing view of sexual differentiation of the brain has been a linear model in which chromosomal sex determines gonadal sex, which determines brain sex. This iconic model based on the organizational/activational hypothesis has proved a sturdy framework for elucidating some, but not all, of the aspects of sexual differentiation of the brain. *Source: Reprinted from Ref. 385.*

The actions of gonadal steroids, androgens, and estrogens on the developing brain are termed "organizational" as they are complimented by adult activational effects, such that the hormonal milieu of the adult will now induce the appropriate physiological and behavioral responses. Some are suggesting that this is really more akin to early life programming, only the agent of change is steroids instead of diet or adversity (see Chapter 47). More specifically, in rats, the presence of elevated testosterone in a masculinized brain will regulate pulsatile release of LH from the anterior pituitary with no LH surge, and it will promote male sexual behavior (i.e., mounting the female, intromission, and ejaculation, if capable). Conversely, a feminized brain, in addition to regulating pulsatile release of LH, will respond to sequential estrogen and progesterone exposure with cyclical LH release that includes an ovulation-inducing surge and female sexual behavior (i.e., proceptive solicitation behavior and lordosis in response to appropriate somatosensory stimuli from the male). In both cases, if the adult hormonal milieu does not match that of the developmental exposure, there is a failure of reproductive competence, both behaviorally and physiologically. The requirement for convergence in developmental and adult hormone action is a central tenet of reproductive neuroendocrinology and is referred to as the organizational/activational hypothesis, following an iconic paper in 1959 by Phoenix, Goy, Gerall, and Young.[388]

A critical aspect of the activational component of this two-phase process is that a memory or imprint of the previous organizational component must be accurately and reliably maintained. For many years, this was thought to be accomplished via permanent morphological or structural changes so that differentiated end points such as cell number, axonal projections, and synaptic patterns would be established and then be essentially immutable—a view reflected in our vernacular with the use of words such as the organizational "blueprint" and the "wiring" of the neonatal brain. Although some aspects of this view are no doubt true, we have since gained a greater understanding of the brain's capacity for change and a realization that synapses come and go, cell genesis and cell death are continuous processes even into adulthood (albeit restricted), and that even the strength of axonal projections can change.

Given this high degree of plasticity, an obvious question is how can the earlier hormonally mediated organizational effects be maintained until adulthood when there is an extended intervening period that is largely void of any circulating gonadal steroids? Epigenetics is the likely answer, and indeed steroids are perfectly poised to exert epigenetic influences given that the receptors are nuclear transcription factors that directly interact with the DNA and associate with myriad nuclear proteins, including those with HAT activity, such as Src1 and CBP/p300. Moreover, steroid receptors themselves appear subject to epigenetic regulation as well as indirectly exerting epigenetic influences by modulating key enzymes and other regulatory elements. Although still in the very early phases of discovery, sex differences in brain epigenetics are emerging as key regulators for both establishing and maintaining functional divergence, and perhaps convergence, in males and females.[123,389–391]

Two approaches can be used to explore epigenetics and brain sexual differentiation: (1) determine if there are sex differences in epigenetic parameters in brain regions known to be different in males and females and relevant to reproductive end points and (2) disrupt mechanisms by which epigenetic marks are established and determine if this impacts on the organizational effects of steroids and thereby interferes with or dampens the activational effects. Toward the first approach, sex differences in both histone modifications and DNA methylation of steroid receptors have been identified.

Chromatin Remodeling and Brain Sexual Differentiation

Remembering that hyperacetylated histones H3 and H4 are associated with activated gene transcription while deacetylation results in repression, the levels of these have been measured in various brain regions, including those known to be subject to sexual differentiation. The POA is a key brain region for the expression and regulation of male sexual behavior (see Chapter 49). The activational histone marks H3K9/14ac and H3K9me3 were examined in mouse embryos and neonatal pups; contrary to expectations, there were no sex differences observed in the hypothalamus/POA. However, there were sex differences in the cortex and hippocampus; while the higher levels of H3K9/14ac in males could be attributed to gonadal hormones, the higher levels of H3K9me3 could not, suggesting a role for sex chromosome complement in establishing this particular sex difference.[392] This approach reveals interesting sex differences in epigenetic marks in the brain, but to date does not tell us the functional significance of the differences.

Using the alternative approach of first identifying a sex difference and then determining if there is an epigenetic underpinning to it, Forger and colleagues focused on one sexually dimorphic nucleus, the principle subdivision of the BNSTp. This brain region is characterized by a sex difference in apoptosis, such that males and females start with the same number of neurons but many of them undergo preprogrammed cell death in females, but not in males. Administration of male hormones to females prior to the onset of the critical period for cell death rescues the neurons from dying in females. However, there is a lengthy delay between hormone action and the cell death, leading to the question of whether

steroid-mediated epigenetic programming of the chromatin was involved. Forger and colleagues tested this hypothesis via broadband pharmacological inhibition of HDACs using VPA, which increased H3 acetylation in the BNSTp. Blocking brain HDAC activity in newborn male mice or females treated with a masculinizing dose of testosterone also prevented the neuroprotective effects of both the endogenous (males) and exogenous (females) hormones, resulting in a mature BNSTp that was the same size as that seen in unmanipulated females (i.e., smaller).[375] This is the first demonstration of hormonally mediated epigenetic programming of a structural change in the brain, and it includes changes to vasopressin innervation, not all of which involve the BNSTp. A lack of any effect of VPA treatment on two other brain nuclei speaks to a degree of specificity in the effect, but the genes affected by the chromatin remodeling in males vs females have yet to be identified.

In a combination of the two approaches, Matsuda and colleagues identified candidate genes for epigenetic analyses and used a pharmacological approach to block those changes and correlate them with behavior. Immunoprecipitated chromatin from the POA of embryonic and neonatal male and female rats was assessed for H3 and H4 acetylation in the dominant brain promoter for *Esr1*, promoter 1b, and the brain-specific aromatase promoter, 1f, as well as the gonadal promoter for aromatase, promoter II, which is also active in brain. A varied profile of relative acetylation between the two histones, the two ages, and the two sexes emerged, highlighting the dynamic nature of epigenetic modifications in the brain and hinting but not establishing that these changes are involved in hormonally-mediated differentiation. A more causal connection is found again with the use of a pharmacological inhibitor of HDAC—in this instance, TSA infused directly into the brain on the first 2 days of life. As adults, males showed markedly reduced sexual performance. Most HDAC inhibitors available to date are not specific to subtypes, but antisense oligonucleotide-mediated inhibition indicated both HDAC2 and HDAC4 are required for normal masculinization of behavior. Further support for this view is the observation that both enzymes bound to the *Ers1* promoter, but only HDAC2 was found to be associated with the aromatase II promoter.[393]

Combined, these studies implicate epigenetics as an important component of the organizational, or enduring, aspect of brain sexual differentiation. The information to date is likely only the tip of the iceberg, and this will be an important and exciting area for future research.

Methylation of Steroid Receptor Gene Promoters in Brain

As the primary transducers of steroid action, developmental sex differences in ER and AR would be anticipated in those brain regions most impacted by organizational steroid effects and epigenetic programming as a means to regulate any observed sex differences. There are some modest sex differences in the levels of these steroid receptors, but both the magnitude and consistency are not sufficient to explain masculinization vs feminization of the brain. This is self-evident in the demonstration that giving testosterone (or estradiol) to newborn female rodents will fully masculinize many aspects of brain and behavior, thereby confirming they have the requisite receptors. Nonetheless, there are age, species, and sex differences in the amount of steroid receptors in various brain regions, which presumably underlie some functional outcome. Perhaps the most dynamic range of ER expression is found in the cortex where levels are quite high in the very young brain but decline with advancing age. The change in expression levels is nicely paralleled by changes to the methylation status of the promoter of *Esr1*, which increases with age as receptor expression declines. Both males and females show similar patterns of high to low *Ers1* expression over the course of development.[394–396] A re-emergence of *Ers1* expression following injury in the adult brain also appears to be the result of a removal of the repressive CpG methylations.[397] In contrast to the developmental regulation of ERα, ERβ is epigenetically regulated in the aging brain.[398] The intrinsic signals that direct these divergent patterns are unknown and their identification will be of considerable interest.

Although there are sex differences and developmental changes in ER expression in the POA, they are much more subtle than those in cortical brain regions. Nonetheless, in rats there appears to be at least some degree of epigenetic regulation, as there is a developmental increase in the methylation of a portion of the *Ers1* promoter, with an almost doubling between birth and 3 weeks of age; however, there is no clear decline in receptor expression.[142] Thus, in this instance methylation marks may reflect past transcriptional history as opposed to future expression potential. What was perhaps most striking in this study, however, was the transient nature of observed sex differences in all three steroid receptors examined (ERα, ERβ, and PR), with some disappearing over time and other new ones emerging, suggesting a far higher degree of dynamism than previously anticipated (Figure 52.21). Examination of another portion of the promoter by a different group found good correlation between methylation levels and ERα expression in the POA of 10-day-old rat pups, such that males had higher methylation and lower ER levels and masculinization of females with estradiol treatment on the day of birth mimicked the profile of males.[278,399] A similar correlation is found between promoter methylation and AR expression in the cortex in that males have more AR and less methylation.[400]

Gene of Interest	Brain Region	Postnatal Day 1	Postnatal Day 20	Postnatal Day 60
Estrogen Receptor α 	POA	Site 7: F > M, F+E2 Site 9: F > M, F+E2	No differences	Site 5: F > M, F+E2
	MBH	Site 6: F > M Site 9: F > M	No differences	No differences
	HIPP	--------	No differences	No differences
Estrogen Receptor β 	POA	Site 5: M > F (p=0.07)	Site 6: F+E2 > M	Site 5: M > F, F + E2
	MBH	No differences	Site 6: F < M, F+E2	Site 4: F > M, F+E2 Site 5: F > F+E2 > M
	HIPP	No differences	No differences	Site 4: F+E2 > M, F
Progesterone Receptor 	POA	Site 11: F+E2 > M, F Site 12: F+E2 > F	No differences	No differences
	MBH	Site 13: F+E2 > M, F	Site 11: F < M, F+E2 Site 13: F < M, F+E2 Site 17: F < M, F+E2 Site 27: F+E2 > M, F	Site 27: F+E2 > M, F

FIGURE 52.21 Epigenetic changes to steroid receptors in brain are highly dynamic. Pyrosequencing of bisulfite converted DNA was used to compare the methylation status of a small region of the promoters of the genes encoding for ERα, ERβ, and the progesterone receptor (PR) in male (M) and female (F) rats that were 1 day, 20 days, and 60 days old in three brain regions: preoptic area (POA), mediobasal hypothalamus (MBH), and hippocampus (HIPP). An additional group of females was treated with a masculinizing dose of estradiol (F+E2) to determine if any sex differences in methylation observed were the result of organizational hormone effects. There were significant sex differences and hormonal modulation of the degree of methylation at multiple CpG sites in the newborn animals, but these had largely disappeared by 20 days of age and in some cases were replaced by new sex differences in adulthood. The *PR* gene displayed a number of sex differences in CpG methylation status at 20 days, a period when gonadal steroid levels are low. These results are highly reliable due to the large number of animals per group and the statistical robustness of pyrosequencing, but their physiological significance remains unclear other than to illustrate the degree of plasticity in steroid receptor promoter methylation and the lack of a clear relationship between methylation status and gene expression. *Source: Reprinted from Ref. 141.*

In a merging of epigenetic influences of maternal care and endogenous sex differences, Auger and colleagues took advantage of the well-established fact that rat dams perform more LG on their male pups than the females. Based on work of Meaney and Champagne, reviewed above, this difference in maternal care would be predicted to have an epigenetically mediated functional impact. Simulation of maternal grooming of pups with a paintbrush allowed for standardization of care between males and females, increased the level of methylation in the promoter of the ERα gene, and correspondingly decreased expression levels of the receptor in females to that of males.[278] This nicely demonstrates a convergence between experiential variables, such as maternal care, and endogenous hormones, such as estradiol, to mediate the establishment and perhaps maintenance of sex differences in the brain.

Together, this handful of studies on the methylation status of steroid receptor promoters in the brain reflects two important things: (1) there is not always a clear relationship been methylation status at a particular site and expression levels; and (2) what is true for one developmental time point or brain region may not be true for another. As a third point, these studies reveal how little we know and how poorly we understand epigenetic regulation of steroid receptors in the brain, highlighting the need for further investigation into the multitude of variables that impact on both steroids and their receptors and, in turn, the role epigenetics plays in that impact as well as in responsiveness.

Sex Differences in MBDs in the Brain

An additional approach to elucidating how and where epigenetics impacts the establishment of sex differences in the brain focuses on regulatory factors that have the potential to impact on large numbers of genes. The MBD genes are a primary candidate and

the iconic *Mecp2* is indeed higher in the VMN and amygdala of newborn female rats.[401] These two brain regions are notable for their primary role in the control of female sexual behavior and a panel of social and emotional behaviors, respectively, many of which differ between males and females. One in particular is social play, which is expressed during the juvenile period and is found to occur at a higher rate and with greater intensity in males in a wide range of species, from laboratory rodents to domesticated pets to wild animals, humans and nonhuman primates. One of the more striking aspects of the sex difference in social play (also referred to as rough-and-tumble play) is that it peaks during a phase of life when steroid hormones are at their nadir. Thus, any sex differences that are hormonally determined were organized early in development but do not require activation—a scenario consistent with an epigenetic memory of earlier hormone exposure. Auger and colleagues have demonstrated via manipulation of MeCP2 levels in newborn rats that there is indeed an epigenetic programming of social play by hormones (Figure 52.22), and that the neural mechanism involves changes in vasopressin innervation.[401,402] Vasopressin has emerged as a central neuropeptide in a variety of social behaviors, including pair bonding, social recognition, and intraindividual aggression.[403–405]

Epigenetic regulation is emerging as the interface between the environment, experience, and the internal hormonal and metabolic milieu of the developing brain. Designed to program the brain to match both the reproductive capacity of the body and the anticipated external environment, these powerful changes can have lifelong enduring effects but also can be surprisingly transient and labile. This duality of purpose allows for both long-term anticipatory programming and short-term flexibility for altering course if the circumstances demand—precisely the qualities needed for successful reproduction. Further confirmation of this duality will come from study of additional species beyond the traditional rodent models, as reproductive strategies vary widely across the animal kingdom.

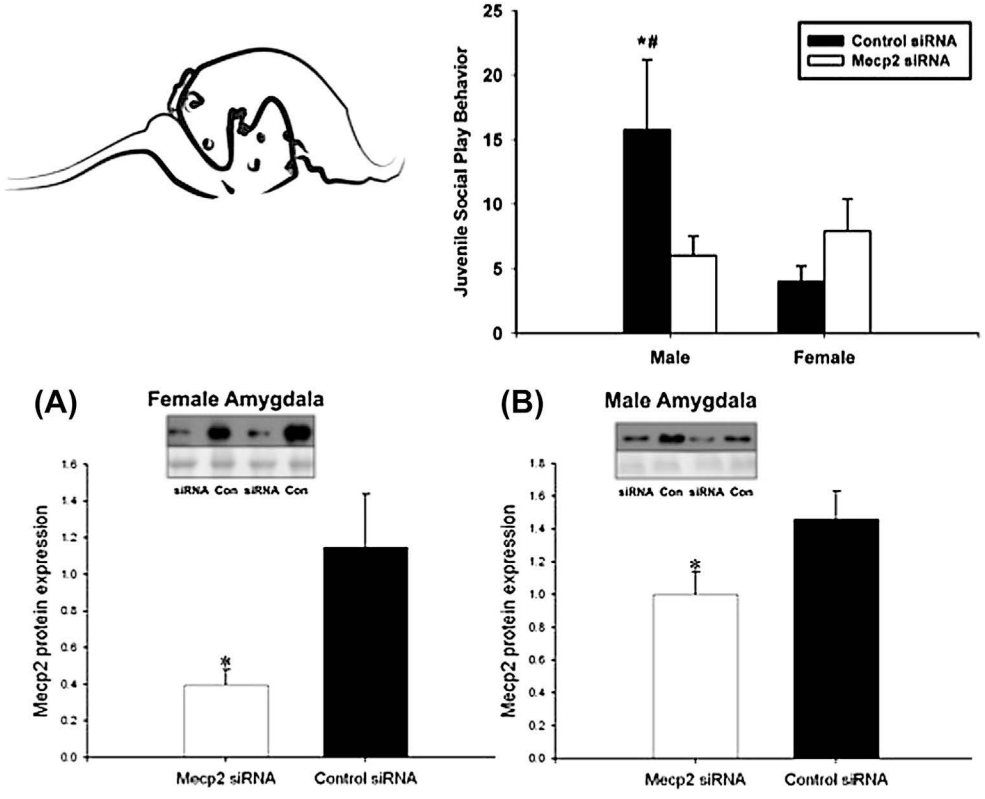

FIGURE 52.22 Epigenetics of social play. Juvenile animals of many species participate in play behavior with conspecifics. In rats, males play for longer duration and at a higher intensity than females, and this difference is determined by the organizing effects of perinatal gonadal steroids. Mecp2 is a methyl binding protein (MBD) originating from a gene on the X chromosome. Auger and colleagues administered a silencing RNA (siRNA) directed against Mecp2 mRNA into the amygdala of juvenile male and female rats. There was no effect on the already low level of play seen in females, but male play was significantly reduced compared to control injected animals (upper panel, *p<0.05 compared to females, #p<0.05 compared to Mecp2 siRNA treated males). The lower panel demonstrates the effectiveness of the siRNA at reducing Mecp2 protein in the amygdala and the lack of a sex difference in control animals (*p<0.05 compared to controls). These data indicate an epigenetic basis to the sex difference in social play but precisely how it is manifest remains unclear. *Source: Reprinted with permission from Ref. 401; drawing of playing rats courtesy of Anthony Auger.*

METHODS IN EPIGENETICS

The tools for studying epigenetics are many and rapidly growing. Because the principle enzymes in both DNA methylation and demethylation have now been identified, they can be pharmacologically inhibited, substrate limited or enhanced, genetically deleted, or overexpressed. Mice with single multiple or partial deletions have been generated for most if not all of the relevant enzymes, and work now is focusing on regional and temporal specific deletions as well as overexpression. This field is moving so rapidly that it is not feasible to review it in any meaningful way that would be of use to the reader. Instead, we will focus on standard methodology that is widely available.

Pharmacology

Most of the advances in drug targeting of either DNA or chromatin modifying enzymes come from cancer biology.[406,407] This has been tremendously beneficial as preclinical studies on toxicity, effectiveness, specificity etc. receive focused attention. Conversely, cancer cells as targets for drug manipulation are not necessarily the best model for the study of germ cells, early embryos, or the postmitotic cells of the brain and pituitary. Nonetheless, there is a reasonably sized tool set available for probing epigenetic questions in animal models, and this is only likely to increase as the promise of this approach in cancer biology and other biomedical disciplines grows.

Chromatin Modification

Inhibitors of HAT activity are not as numerous as inhibitors of HDACs, but this is an area of active investigation. The HAT inhibitors currently in use include several naturally occurring compounds. Polyisoprenylated benzophenone garcinol, a medicinal product isolated from rinds of the *Garcinia indica* fruit, inhibits both PCAF and p300.[408] Moreover, it can block the effect of at least one HDAC inhibitor. A more specific compound is anacardic acid from cashew nut shells. This inhibits p300, but in vivo it cannot penetrate cell membranes.[74] In LNCaP prostate cells, phenolic compounds from allspice can act as a HATi, producing decreased transcription of two AR target genes. AR co-activators are HATs and blockade of their actions may interfere with AR function.[409] Curcumin (diferuloylmethane), a natural polyphenol and popular spice derived from the plant *Curcuma longa*, is a very specific p300/CBP inhibitor and has biological activity in vivo.[410] In cells, curcumin can block the actions of an HDACi.[411] Curcumin also modulates activity of quite a number of miRNAs.[412] Although the mechanisms of action are under investigation, curcumin may target and disrupt Nf-kb signaling.[413]

The first synthetic HATi was a substrate analog for the acetyl CoA enzyme. Lysyl CoA is a p300 HAT-specific inhibitor. One issue with this and related molecules is cell permeability.[74] Compounds with an α-methylene-γ-butyrolactone core structure selectively inhibit GCN5. This drug has been used in cell lines and human tumors and may be useful for some leukemia treatments.[414] Isothiazolones are also able to block HAT activity in tumor cell lines by inhibiting PCAF.

Inhibitors of HDAC targets are being actively explored to treat diseases ranging from cancer to mental illness. In tumor cells, they act on cell death, migration, cell growth, and metastasis.[415] While chromatin modifications are ubiquitous, in fact, current HDACi only alter transcription in 2% of all genes.[416,417] Sodium butyrate is probably the most widely used HDACi. It is a short chain fatty acid that acts on all Class I and some Class II HDACs. In addition, it acetylates high-mobility group proteins and transcription factors and arrests cell proliferation.[418] Thus, off-target actions are an issue with this drug. Advantages of sodium butyrate include that it can be given in drinking water or by injection, making it very versatile.[419] This drug has also been used extensively for studies of epigenetics and brain function.[420] When provided to naïve female mice, sodium butyrate can enhance the onset of spontaneous maternal behavior.[421] In the presence of wild-type ERα, it can also accelerate the onset of receptivity in female mice.[422] A similar compound is VPA, which is currently used to treat epilepsy and bipolar disorders. If taken during pregnancy, it increases the risk of neurobehavioral disorders in children and rats.[423,424] In mice, it alters sexual differentiation of vasopressin in the BNSTp.[375] TSA and suberoylanilide hydroxamic acid inhibit Zn(II)-dependent Class I and II HDACS. Both drugs have been used in vivo and in vitro. For a more in-depth description of HDACi biochemistry, see Ref. 425.

DNMT Inhibitors

The development of inhibitors of DNMTs stemmed directly from the observation that many tumor-suppressing genes became hypermethylated and thereby repressed, allowing for uncontrolled cell growth and division (i.e., cancer). The first to be developed are the so-called substrate analogs because they mimic cytosine residues (Figure 52.23), and first among these were 5-azacytodine and its derivative 5-aza-2′-deoxycytodine.[427]

5-AZA

As cytosine analogs, the 5-Aza compounds are incorporated into the DNA during replication. However, the modified pyrimidine rings of the aza nucleotide block the methyl group transfer reaction and, in

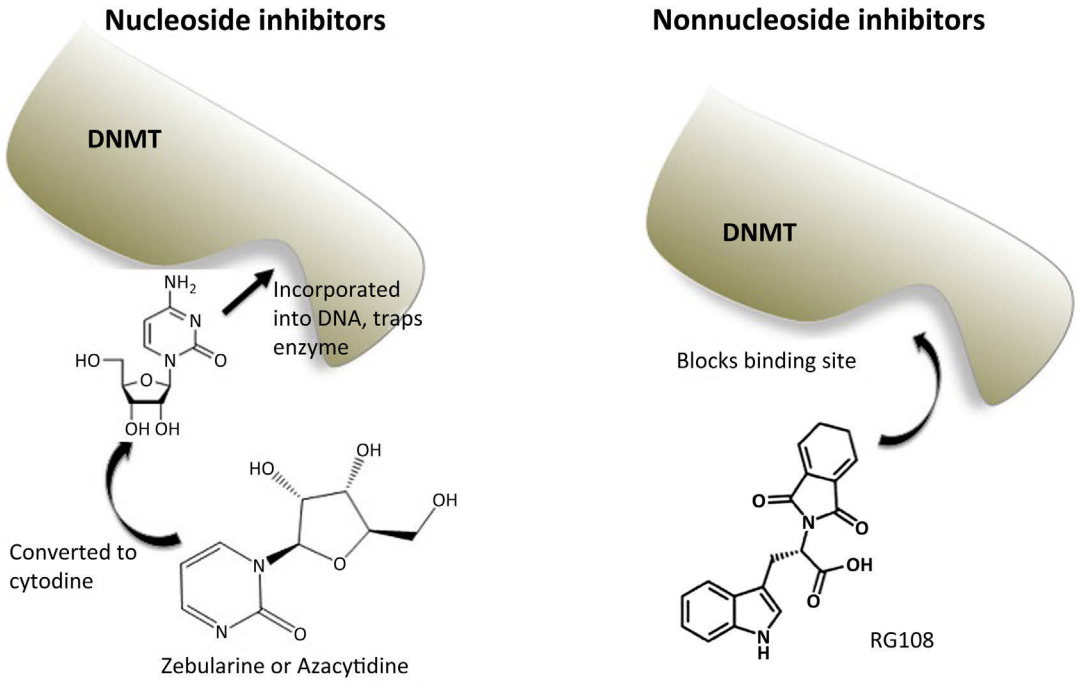

FIGURE 52.23 DNMT Inhibitors. Chemical inhibitors of the DNMTs come in two varieties: those that are nucleoside derivatives metabolized within the cell to a cytosine analog (cytodine) before being incorporated into the DNA (Zebularine and Azacytidine) vs nonnucleoside-based (RG108). Zebularine and azacytidine are ribonucleotide analogs and so-called suicide inhibitors in that they attract and covalently bind the DNMTs, which are then degraded, thereby depleting cellular stores of the enzyme and resulting in demethylation via as-yet unknown mechanisms. Nucleoside-based inhibitors are presumed to require cell division for incorporation into the DNA, but their effectiveness in nonmitotic cells, such as neurons, belies this requirement and suggests other mechanisms may be involved. Nonnucleoside-based inhibitors such as RG108 act in a more classic antagonist fashion and block the methyl binding site of the enzyme with direct involvement of the DNA. *Source: Based on references in Ref. 426.*

the process, trap the DNMT in a covalently bound DNA-protein adduct. This adduct is thought to be a major source of toxicity of the Aza compounds[428]; thus, questions have been raised regarding its specificity. Nonetheless, the 5-Aza compounds are still used experimentally and have been approved by the FDA for clinical trials.

ZEBULARINE

Zebularine (1-Beta-D-Ribofuranosyl-2(1H)-pyrimidinone) is, like Aza, a cytosine analog. However, it was developed to counter the shortcomings of Aza, in particular its cytotoxicity, instability, and short-half life. Zebularine is incorporated into DNA linearly over time; hence, it is attractive for use in rapidly dividing cancer cells.[429] However, this property was considered to make zebularine an unattractive agent in the nervous system, where most cells are postmitotic. Others argue that zebularine might stimulate demethylation via excision base repair mechanisms found in nondividing cells.[279] In cancer cells, continuous treatment for a period of days results in depletion of the DNMT enzymes, with DNMT1 being most sensitive. This is presumed to be due to the enzymes being trapped at the zebularine-containing DNA.[430] Thus, while the mechanism of zebularine action in cancer cells is well worked out, this creates a mystery for how it could also be effective in nonmitotic cells. In addition to its DNMT-inhibiting activities, zebularine blocks cytosine deaminase; in fact, this was the first action identified. This mechanism appears to involve at least in part a competitive inhibition of the enzyme. It is possible a similar action occurs in the brain only in the realm of DNMT activity, and that the unique regulatory control of DNA methylation in the brain may then result in pronounced demethylation, just as is seen in rapidly dividing cancer cells.[431]

RG108

There are still concerns with zebularin in regards to specificity and mechanism of action, which has led to the development of new compounds focused at the DNMT catalytic binding site. This has proven successful in the compound RG108, which is highly specific for DNMTs, has low toxicity, and has demonstrably reduced methylation in tumor cells.[432] The computer-aided drug design focused on DNMT1, but the high degree of homology and >50% amino acid conservation of the catalytic binding site of all of the DMNTs supports broad applicability of this drug.[433]

None of these drugs are thought to effectively cross the blood–brain barrier, which can be a considerable

barrier in empirical research of animal models, although some have had success with peripheral administration (see Ref. 373).

Measuring Histones and Their Modifications

Isolating Histones

Nuclear isolation is the first step in quantification of histones. This can be accomplished by cell lysis under hypotonic conditions. Next, nuclei are extracted in acidic or high-salt conditions. Acidic conditions are the standard, but new modifications might be isolated better with high-salt to protest against acid-induced degradation. In addition, acid-extraction can reduce yields by elimination of "free" histones not incorporated into the chromatin. Further purification can be accomplished with reverse-phase high-performance liquid chromatography.[434] Another method is to use alkaline extraction, which is faster than acidic extraction and may be better for some types of modifications.[435] Most of the methods have been developed with cell lines or yeast cells. In the case of the brain, we have found that homogenization of the brain by gently drawing and ejecting the material through a series of large to small gauge needles is preferable to using a tissue shredder.[392] Other protocols are also available, which use dounce homogenizers.[436]

Visualizing Histones

Histones are positively charged, low-molecular-weight proteins. Their PTMs also affect their charge. The five major histones—H1, H2a, H2b, H3, and H4—can be resolved with standard sodium dodecyl sulfate (SDS) polyacrylamide gels. However, this method is not sensitive enough to reveal modified histones. The best separation method for differentiation of known or novel modifications are triton X-100/acetic acid/urea (TAU)-polyacrylamide gels.[437] This method is more efficient than others providing better separation of histone proteins. However, the detergent in the gel impairs transfer to membranes; to circumvent this problem, an alkaline transfer buffer is used along with SDS, which displaces the TritonX-100.

Quantification of Specific Modifications

After histones are collected and transferred from SDS-polyacrylamide gels to membranes, modifications can be visualized with specific antibodies. Controls typically include total H3 or H4, as the total amounts of histone should be stable. Another good control is the cytosolic fraction, which should be histone-free. Densitometry programs are used to measure the relative amount of the modification.[436] Several companies have started offering kits that detect either total acetylation of methylation of H3 or H4 or specific modifications (BioCat). The authors have no experience with these products.

Associations between Chromatin and Specific Genes

ChIP is the most widely used method to examine protein–histone interactions. This method identifies genes associated with histone modification. The basic method is first to cross-link proteins with DNA using a fixative, typically formaldehyde. This freezes the interaction in time, which can be important in characterizing the dynamics of chromatin interactions. Next, sonication is used to mince the chromatin into pieces of uniform size, as required for the application. An alternative often used with brain tissues is micrococcal nuclease digestion. Then, chromatin is precipitated with selective antibodies bound to magnetic beads. The antibody used depends on the target. This same principle has been applied to DNA methylation using antibodies against 5-methylCytosine. It can also be used for other applications, such as transcription factor binding proteins associated with regulatory elements. Here, we will discuss its application for specific histone modifications. After the antibody-ChIP complexes are captured, they can be used to probe single genes or whole genomes (Figure 52.24). Overall, the major limitation for these techniques is the availability of highly specific antibodies. A comparison of the different ChIP approaches is presented in Figure 52.25.

Optimization of the technique for a specific tissue requires determining how long to fix the tissues, how much material to use, and how much antibody is needed. Positive controls would include samples with the modification of interest. A no-antibody control is required along with a nonreactive antibody (IgG). A portion of the original sample is also required to determine how much starting material was used. The simplest use of ChIP is to ask about interactions between modifications and specific genes. This is done by designing primers for RTqPCR, and then running ChIP or control material with or without (control) primers and examining amplification profiles. Given how little material is needed for RTqPCR, multiple target genes can be assessed in this manner. Another excellent control primer set would target regions of DNA not associated with transcription.

ChIP-on-Chip

This method was favored in the past, but now availability and price of whole-sequence analysis has largely replaced it. However, for animals that do not have a sequenced genome, or for researchers with a small number of candidate genes or interest in only one chromosome, ChIP-on-chip is still useful. In addition, a novel

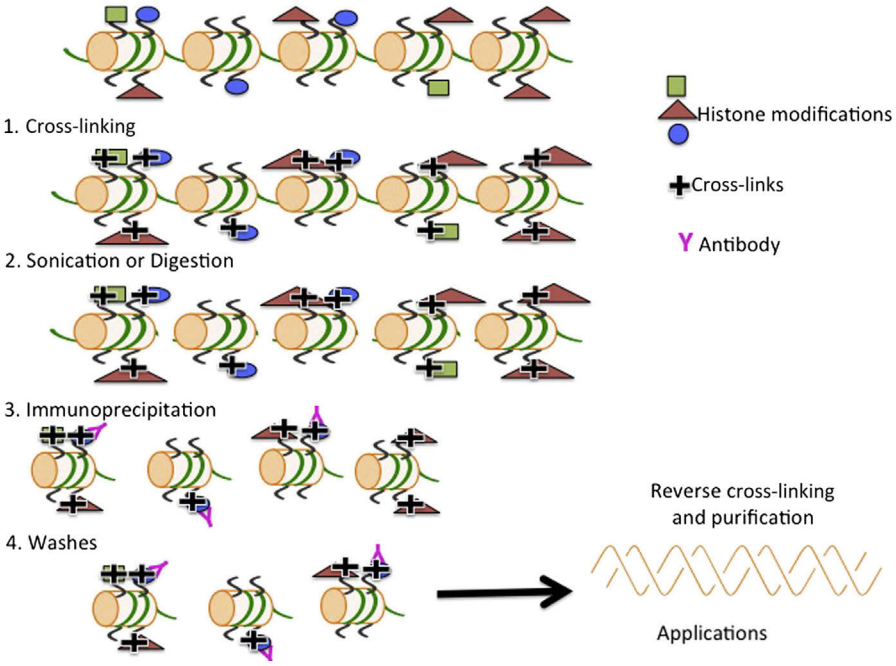

FIGURE 52.24 Chromatin immunoprecipitation (ChIP) methods. To perform ChIP, tissues are collected and rapidly exposed to fixative to cross-link the modifications and/or proteins of interest to the DNA. Next, sonification or enzyme digestion is used to produce uniform sized DNA fragments. Immunoprecipitation with an antibody for the histone modification is conducted, typically over antibody coated magnetic beads. A series of washes to remove fragments that are damaged is followed by confirmation that the material is the correct size. Various histone modifications are shown by circles, triangles, and squares. The cross-linking between the modifications and the DNA are shown with a plus sign. Antibody is designated by a "Y".

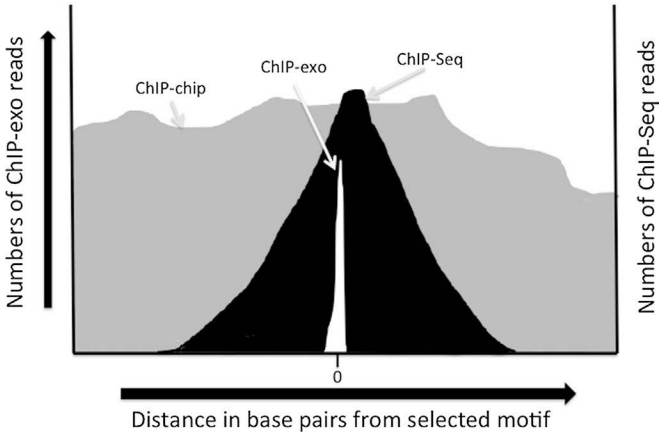

FIGURE 52.25 Comparison of ChIP methods. A theoretical comparison showing the increasing amount of specificity provided by less vs more refined methods for ChIP analyses. ChIP-chip = genome-wide microarray hybridization, Chip-Seq = deep sequencing, ChIP-exo = exonuclease is an extra step to trim the ChIP-DNA a precise number of exons from the linkage site. The technique can be used to target motifs of interest. *Source: Redrawn from Ref. 438.*

application of this technique is to combine it with a tiling array for miRNA promoters.[439] Moreover, this method is less complex than others in terms of data analysis. After ChIP DNA is purified, it can be labeled with different fluorescent colors and hybridized to a DNA microarray (also called tiling arrays). One problem for this technique is that DNA contamination may produce false positives. One solution to this is ChIP-exo. Here, an exonuclease is used to trim the ChIP DNA to a precise distance from the cross-linking site. Excess DNA is degraded.[438] Another downside to ChIP-on-chip is that typically only 10% of the DNA linked to protein is recovered and the amount of starting material (>500,000 cells/10–100 ng DNA) needed is more than it is for other ChIP applications. Amplification during the PCR reaction can always introduce biases. Finally, primer design can be problematic if the region on the gene of interest that interacts with the histone modification is not known.

ChIP Sequencing

Next-generation sequencing in combination with ChIP has become the criterion standard in the field. This method requires fewer steps than ChIP-on-chip, gives better genomic coverage, is more sensitive, and uses less starting material. The novel step as compared with other ChIP methods is the preparation of a genomic DNA library. Sequencing library preparation involves the production of a random collection of adapter-modified DNA fragments, with a specific range of fragment sizes, which are ready to be sequenced. This is accomplished by using blunt ended 5′ phosphorylated fragments to repair DNA fragments. Next, A-tails are added to the 3′ end of the fragmented DNA. The fragments are now able to be adapter ligated and are selected based on their size. PCR is conducted for amplification of the fragments, which are then made into single-stranded DNA. The DNA library is linearized, blocked, subjected to hybridization, and then sequenced. Florescent nucleotides are incorporated into the strand for the sequencing.[440] Many improvements have been made to this basic protocol, including development of nanoChIP sequencing.[441] This protocol only requires 10,000 cells and thus is well-suited for small brain regions and rare patient samples. One of the many improvements is use of custom-made primers that form a

hairpin structure at low temperatures to minimize primer self-annealing. Next, a second custom primer is used for PCR that produces DNA fragments with adapter-like sequences on both ends. The fragments can be ligated directly, thereby reducing the amount of amplifications and material associated with purification over columns. This method, combined with cell selection prior to DNA sonification, could be used to generate sequencing data from small numbers of neurons or other cell types. If florescence activated cell sorting is to be used to select cells of interest, then enzymatic digestion needs to be conducted after cells are dissected from the original material.[441] One common stumbling block, however, is that sequencing generates very large data sets. Bioinformatics programs are available (for a review, see Ref. 442), but for many investigators the optimal situation would be either a core facility specializing in bioinformatics or a collaborator.

DNA Methylation and Histones

Getting back to the idea that histone modifications can interact and that they are required for DNA methylation, we briefly review some techniques designed to interrogate these interactions. Using hierarchical clustering, Linghu et al.[443] identified the 18 most frequently occurring histone modifications in CD4+T human cancer cells. They also found that DNA methylation combined with histone acetylation more often than histone methylation. By labeling different modifications with different florescent dyes and subjecting them to single-molecule fluorescence resonance, energy transfer distances between modifications can be assessed. Thus, nucleosome constructs were methylated with a methytransferase enzyme and the relationship between modifications examined.[444] DNA methylation produced histone compaction and a repressive histone state. An interesting strategy to look at DNA methylation and chromatin cross-talk is sequential ChIP-bisulfite sequencing.[445] This approach can be applied to other histone modification, but the authors developed this to examine H3K27me3 and DNA methylation both of which are important components of the Polycomb repressive complex 1. Using this technique, the authors were able to settle a controversy on if and how often these two processes co-occur. They found abundant overlap between H3K27me3 and DNA methylation genome-wide; however, this was restricted to regions that did not contain dense CpG sites. In brief, they used ChIP for the histone mark DNA. End repair A-tailing and adapter ligation was performed and the material was isolated on agrose gels. Bands were collected based on their size and subjected to bisulfite conversion. Next, PCR amplification was conducted and material was used for sequencing. Several controls were included, such as MethylCap-Seq and in-depth analysis of 300-bp windows in the genomic data set.

Measuring CpG Methylation

Methods for the quantification of DNA methylation vary from those that can be readily performed in any reasonably equipped laboratory to those requiring extensive sequencing and bioinformatics support that only fully equipped centralized core facilities are likely to be capable of reasonably performing. Each has its advantages and disadvantages, and these shift in accordance with the question at hand.

DNMT Enzyme Activity

In the not-too-distant past, measuring DNMT activity was labor intensive, required the used of radioactive compounds, and was only semiquantitative. Fortunately, there are now kits available for measuring DNMT activity, which utilize a 96-well colorimetric based approach. These use an ELISA-based method in which the well is coated with cytosine-rich DNA that serves as a substrate for the enzyme and methyl groups are provided as donors; these are referred to as AdoMet, for SAM, and also referred to as SAM. The ELISA portion involves the use of recombinant MBDs that are His-tagged and attach to the methylated DNA in an amount proportional to the enzyme activity. An HRP-conjugated antibody against polyhistidine then provides a sensitive colorimetric readout, which is quantifiable by spectrophotometry. A sample of purified DNMT is provided as a positive control. A variation on this theme is provision of purified recombinant DNMT, which allows for determination of whether the factor is regulating DNMT1 vs DNMT3a for instance.

Global Methylation Approaches

The same general principle for DNMT activity can also be applied to quantification of DNA methylation without attention to specific sites. In this instance, the 96-well plates are antibody-coated to have a high affinity for DNA. The methylated portion of the DNA is determined by using capture and detection antibody based techniques as above, and the final readout is in optical density units which are proportional to the amount of methylated DNA as compared to a reference sample.

These techniques can be relatively quick and easy for initial analyses, but they are also lacking in details. The most powerful approach is to begin with these sweeping analyses followed by in depth and directed analysis.

Sequence-Specific Methylation Approaches

BISULFITE CONVERSION FOLLOWED BY SEQUENCING

Bisulfite conversion of DNA is an essential first step in most techniques for the detection of methylated cytosines (Figure 52.26). The basic principle is that when incubated in sodium bisulfite for an extended period, cytosines in

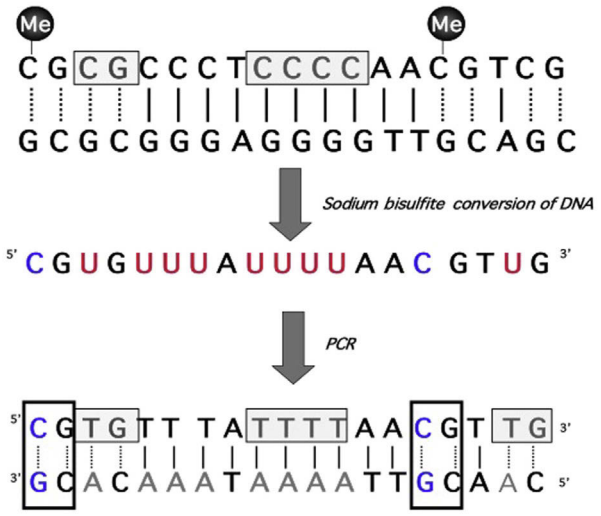

FIGURE 52.26 Bisulfite conversion. The central workhorse of most sequencing methods that detect and quantify 5mC is the conversion of unmethylated cytosines to uracil by bisulfite. Those cytosines that are methylated are protected from conversion. Subsequent PCR will convert the uracils to thymidines but faithfully replicate the previously methylated cytosines, although they lose the methylation during this process. Important limitations to the protocol are achieving a greater than 90% conversion rate and the inability to distinguish 5hmC from 5mC.

single-stranded DNA are deaminated to give uracil unless they possess a methyl group on the 5′ position, in which case they are protected from the deamination reaction. In order to detect which cytosines were protected after bisulfite conversion, the DNA is amplified by PCR and then either subcloned into a vector and multiple clones sequenced, or all the cDNA strands are directly sequenced via pyrosequencing, which is a sequencing by synthesis strategy. The "pyro-" in *pyrosequencing* refers to the release of pyrophosphate (PPi) following the incorporation of each nucleotide. The release of PPi occurs in an equimolar fashion to the number of nucleotides incorporated and is therefore highly quantifiable. The addition of ATP sulfurylase converts the PPi to ATP, which then activates a luciferase reaction and produces light in proportion to the amount of PPi generated. By controlling which of the four nucleotides is added at any given time, the amount of light generated provides a precise read-out of which nucleotide is incorporated, and how many are incorporated as the second DNA strand is synthesized. The disadvantage of pyrosequencing is that it is only effective for relatively short amplicons, 300–500 bp, but this is often sufficient for sequencing of CpG islands, which are rarely over 1000 bp in length. There are also restrictions on the primers that can be used, which may preclude comprehensive coverage of a particular island.

The major shortcoming of bisulfite sequencing is that it only works on single-stranded DNA and thus depends on complete denaturation and a lack of any annealing between the single stands. Thus, when a site is found not to be methylated, it is never completely assured that this is due to an artifact or lack of conversion by the bisulfite. An additional shortcoming of bisulfite sequencing is its inability to recognize hydroxymethylated cytosines, instead mistaking them for unmethylated, and they are deaminated to uracil. In many tissues, this may be a problem that is more apparent than real since presumably the majority of 5hmCs are fated to ultimately be converted to unmethylated cytosines. However, still-evolving views suggest these hydroxylated methyl Cs may be stable moieties conferring more information than previously realized ("the sixth base").

The quest for simple and accessible methods for DNA methylation analysis has spawned a cottage industry of techniques, which can be divided along four general lines: (1) use of restriction enzymes to detect sequence changes following bisulfite conversion, (2) PCR that is either impacted by methylation or builds upon it, (3) modified ChIP, and (4) brute force sequencing.

METHYLATION-SPECIFIC RESTRICTION ENZYME DIGEST

When the gene of interest is known, the promoter is well mapped with clearly identified CpG island(s), and the precise amount of methylation of a specific CpG residue is not necessary, the simplest approach may be the use of methylation specific restriction enzyme digest. This strategy is based on the simple principle that restriction enzymes recognize specific sequences of DNA and that when a CpG is converted to a uracil following bisulfite incubation, that recognition will be lost. Two PCR products, one from the original DNA and one bisulfite converted DNA, are subject to restriction enzyme digest, and the lack of a band produced from the bisulfite converted DNA indicates the CpG within the enzyme cite was methylated. A shortcoming of this approach is that it relies on a negative observation (i.e., no PCR product), and there is no quantification of the percentage of methylation. A modified version of this approach solves both of these problems with the generation of a standard curve that provides semiquantitative assessment of percent methylation and is dependent upon a positive result (i.e., cleavage of the PCR product to indicate either methylation or nonmethylation).[446]

METHYLATION-SPECIFIC PCR

Rather than depending upon sequence-specific restriction enzyme sites, methylation-specific PCR utilizes the specificity of primers which will only anneal to sequences that include methylated CpGs. This approach relies upon comparison to unmethylated PCR products (i.e., bisulfite converted), but avoids the need to sequence the PCR product since the sequence of interest is already

known. This approach is best when the density of methylated CpGs is high because it increases the specificity of the assay. As with restriction enzyme digest, there is no need to sequence the region of interest, but there also is no information provided on the absolute percentage of CpG methylation at a specific site or the degree of methylation of individual CpGs.

A variation on MSP is MethylLight PCR, which uses real-time PCR and therefore provides a quantitative analysis. In this instance, methylated-specific primers are again used, but a methylated-specific fluorescence reporter probe that anneals to the amplified region is included. A methylated reference DNA provides for quantitation. Further specificity can be achieved by also quantifying and subsequently subtracting DNA that was not successfully bisulfate converted using an additional probe, in a process called ConLight-MSP. In essence, this modification prevents detection of false positives. Finally, MSP-amplified DNA can be further assessed using melting curve analysis (Mc-MSP) of the two PCR products produced with methylated- and unmethylated-specific primers. This has been proposed for use in the sensitive detection of low-level methylation.

A further methodological approach based on PCR is referred to as MS-SnuPE, methylation-sensitive single-nucleotide primer extension, which takes advantage of the primer extension method initially designed for analyzing SNPs, or single nucleotide polymorphisms. In this instance, primers are designed to anneal to the sequence up to the base pair immediately before the CpG of interest. The primer is then allowed to extend one base pair into the C, or the T if the unmethylated C was converted to U during bisulfite incubation. The relative ratio of C to T is then determined quantitatively, which can be done using radiolabeled or fluorescently labeled nucleotides, pyrosequencing, and more recently MALDI-TOF and a modification of HPLC.

METHYLATION-DEPENDENT IMMUNOPRECIPITATION

Based on the same principle as ChIP, MeDip differs by using a monoclonal antibody specific to methylated CpGs that binds to the DNA following its sonication into fragments, preferably of 400–600 bp in length. This is followed by the classic immunoprecipitation technique in which magnetic beads conjugated to anti-mouse-IgG are used to bind the anti-5mC antibodies which are bound to the DNA and thereby precipitated. The technique works best when multiple CpG sites are methylated.

The next steps can vary and include MeDip-ChIP, in which a fraction of the input and immunoprecipitated DNA are labeled with fluorescent cytosines (either red or green) and then hybridized to standard DNA microarrays (hence chip) to probe for presence and relative abundance of methylation. As with any microarray, there are limits to the approach, but this can be a useful means by which to compare relative methylation between samples.

METHYL-SEQ

The advent of next-generation sequencing technology is providing for unprecedented levels of genomic information, including detailed unbiased and representative mapping of DNA methylation status that does not require intervening cloning into plasmids.[447] Methyl-seq is deep sequencing combined with bisulfite conversion so that specific methylation sites can be identified. Rather than sequencing the entire methylome, this approach can also be used for a series of candidate genes (economy of scale does not justify these approaches for only one or two genes) in which the CpG islands are identified and reduced to 300–600 bp sections that can then be sequenced. The approach is highly quantitative in that all the sequences in a sample are read, providing accurate and unbiased estimates of methylation.

METHYLCAP-SEQ

MethylCap-Seq is a clever combination of immunoprecipitation and deep sequencing, leveraging the advantages of each. The procedure allows for genome-wide profiling of DNA methylation but first captures highly methylated regions by immunoprecipitating with antibodies for the methyl binding domain of MeCP2. The captured methylated DNA is further enriched by eluting through a salt gradient which stratifies the genome based on different CpG density, thereby allowing for cost-effective deep sequencing of the enriched fraction.[448]

REDUCED REPRESENTATION BISULFITE SEQUENCING

If genome-wide methyl status information is desired but sequencing of the entire genome is not (due to the obvious limitations imposed by expense and large data sets), an additional approach is reduced representation bisulfite sequencing, which is analogous to a shotgun sequencing approach developed for single nucleotide polymorphism, SNP, analyses. The method uses restriction enzyme digestion to provide a "reduced" but random representation of the genome, which can then be compared between samples.[449]

This brief overview is not intended as comprehensive and is likely to be out-of-date as quickly as its written, but hopefully nonetheless provides some semblance of the range and variety of techniques available for studying epigenetic processes.

CONCLUSION

This is an exciting time in the field of epigenetics and reproduction. New discoveries are appearing so quickly we found it a challenge to keep this review up-to-date, and

it will likely be in need of additions by the time of publication. Central to this is the development of new technologies increasing the ease and accessibility of epigenetic assays so that individual laboratories are now capable of exploring in greater detail the realm of epigenetic modifications. The limitations inherent in bisulfite conversion to detect methylation of cytosines and the shortcomings of antibody detection of chromatin modifications are likely to all but disappear in the next few years with emergence of direct detection techniques. These will prompt a reanalysis of much of what has already been done with surely some surprises and refinements. New pharmacologies will further enrich the available toolbox and encourage more research in the field. Moreover costs for some of these techniques continue to come down and will soon be affordable for even modest laboratories. Nonetheless, major advances have been achieved, enough to both provide a level of confidence and detail appropriate for review and enough to inform us of how much we still do not know.

How are epigenetic marks retained in the zygote and/or germ cells to allow for transgenerational inheritance? That some genes are imprinted (meaning expression is preferentially limited to the allele inherited from one parent) has been known for some time, but how this imprint is maintained consistently across the generations is unknown. That it is truly maintained is evident in that the same parent of origin is faithfully propagated across generations, as opposed to it switching randomly between the maternally or paternally derived allele. There are two waves of global demethylation—one in the early zygote stage and one at the formation of the germ cells—but how imprints are maintained is entirely unknown.

How many genes are imprinted and how can the number or pattern of imprinted genes vary by tissue or sex? For many years the number of imprinted genes consisted of a short and well-known list of only a few hundred. Reports exploiting new technologies and the power of mouse genetics suggest there are far more imprinted genes than originally realized and that these can vary by tissue, brain region, or sex, meaning more or fewer imprinted genes in male vs female offspring, and that the degree of imprinting can change across the lifespan. Both how and why there is such plasticity in genetic imprinting is not known.

How does X inactivation switch from being exclusively of the paternally derived to random? There are two periods during the lifespan when X inactivation occurs—one very early in the blastocyst stage when the paternal X is silenced in every cell, followed by a period when they are both active and then random inactivation thereafter. If randomness is lost (i.e., inactivation is skewed in favor of the paternal or maternal X), the individual suffers serious deleterious consequences. How the switch from skewed to random occurs is unknown, and why there is a requirement for random inactivation is equally unknown.

Do epigenetic marks mediate and/or maintain sexual differentiation of the brain? Steroids are poised to mediate epigenetic changes via their activation of nuclear transcription factors which associate with enzymes capable of modifying both the chromatin and the DNA. It has long been a mystery as to how early hormonal exposure of the brain can exert effects that endure into adulthood. The notion of a cellular memory induced by steroids is a reasonable picture, but one for which only the broadest brush strokes have been made.

How do EDCs and other environmental agents affect transgenerational change? Several EDCs have been shown to have long-lasting effects on gonads, germ cells and the brain. In rodents, the only mechanism that has received experimental attention is DNA methylation. Certainly that is part of the process, but studies examining histone modifications, miRNA, and piRNA are lacking despite the fact that in nonmammalian species all of these are involved in transgenerational inheritance.

How are epigenetic marks removed and what determines that? For the emerging field of neuroepigenetics, this is a most fundamental question. That epigenetic changes can be a component of neuroplasticity is anathema to the definition of epigenetics as enduring. Demethylation as a biological process has proven difficult to definitively establish, although the emergence of the TET enzymes is beginning to change that. Major progress can be expected in this area in the next few years.

Are transposons and ncRNAs scientific oddities or major regulators of reproduction? Transposons have contributed to both genetic diversity and the physical structure of chromosomes, but they are still largely viewed as parasitic marauders capable of doing great harm if not contained. Their overrepresentation on the X chromosome and regulation by the SOX family of transcription factors, however, suggests they may be doing much more than realized, perhaps even contributing to the delicate dance that must be coordinated between males and females for reproduction to succeed. The ncRNAs are equally mysterious but again central, playing vital roles in X inactivation and potentially in the germ cell transmission of deleterious life events to the next generation. In the arena of "ones to watch", this class of molecular messengers is front and center.

How do environmental stimuli integrate with the epigenetic control of ovulation in females? That the PcG of repressive markers must be released to allow for kisspeptin expression in the brain nicely established epigenetics as an effector of ovulation, a process that is highly variable and responsive to environmental cues. Establishing how these cues are transduced epigenetically will provide much needed insights into what is contributing to

the still diminishing age of onset of female reproductive development.

Does epigenetics impact male puberty? While we have learned a great deal about the role of epigenetics in the timing of puberty onset in females, the same cannot be said for males. Are the mechanisms the same? Are environmental cues coded in the same way by males or do they carry a distinct salience that is manifest as unique epigenetic changes in males? The lack of a clear external marker of puberty in males that is evident in females (vaginal opening/menarche) makes this a greater challenge, but it is nonetheless approachable.

Does epigenetics play a role in reproductive senescence? Reproductive potential in the human female is typically limited to only three or four decades of her lifespan. While the loss of viable oocytes is central to this phenomenon, there is also a neural component to menopause (see Chapter 37). Is there a loss of important epigenetic repressive or stimulatory marks that precede menopause? If so, which are the brain genes being regulated—those encoding for steroid receptors, kisspeptin, or GnRH? These important questions have not yet been addressed but surely will be in the near future.

Color Plates

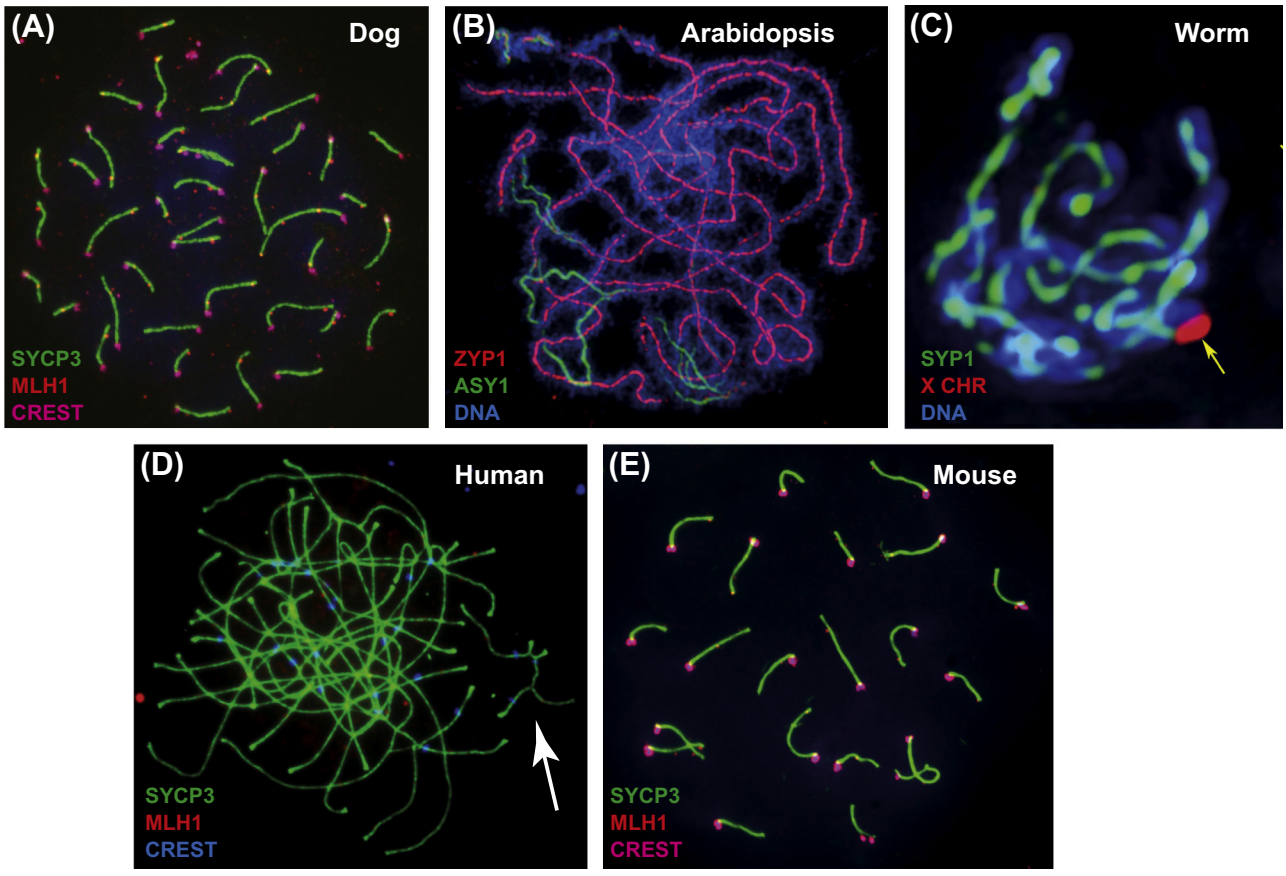

FIGURE 1.2 Comparative meiosis across eukaryotic species. (A) Pachytene cell from an adult dog testis stained with antibodies against SYCP3 (green), MLH1 (red), and CREST (centromeres, pink). (B) Immunolocalization of the *Arabidopsis* synaptonemal complex transverses filament protein ZYP1 (red), polymerizing between the homologous chromosome axes marked by ASY1 (green) and the DNA loops (blue) in a late-zygotene nucleus. The ASY1 signal (green) is reduced in synapsed regions (red), and an interlock is being resolved. (C) A *C. elegans* pachytene nucleus immunostained to show that the synaptonemal complex (green) is normal and that the pairing center ends of the X chromosome are fully paired (red); *(Source: Adapted from Saito et al., PLoS Genet, 2009.)* (D) A trisomic human embryonic oocyte at the pachytene stage stained with antibodies against SYCP3 (green), MLH1 (red), and CREST (centromeres, blue). The three copies of chromosome 21 can be seen attempting to pair (arrow). (E) Mouse pachytene cell stained immunostained with SYCP3 (green), MLH1 (red), and cREST (centromere, pink).

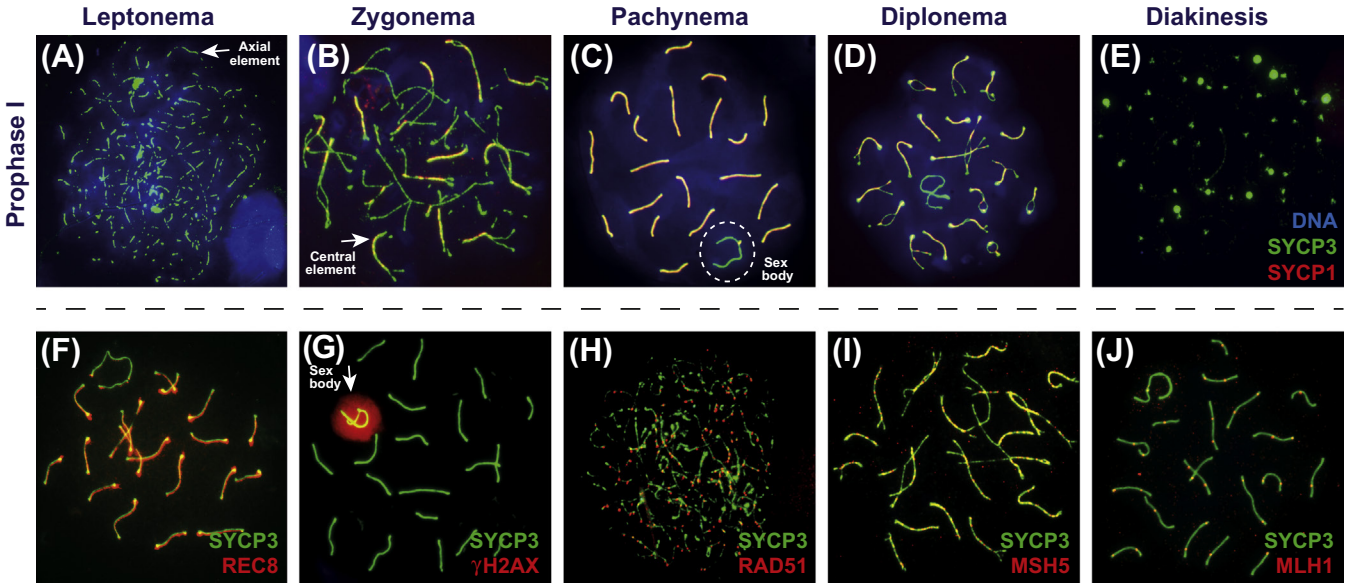

FIGURE 1.7 Immunofluorescent analysis of meiotic prophase I events in mouse spermatocytes. (A–E) Synaptic events in the five substages of prophase I, visualized by staining with antibodies against axial–lateral element protein SYCP3 (green) and central element protein SYCP1 (red), where the overlay between the two appears in yellow. (F–J) Immunolocalization of SYCP3 (green) with key meiotic markers during prophase I; (F) REC8, (G) λH2AX, (H) RAD51, (I) MSH5, and (J) MLH1 all in red, and SYCP3 in green.

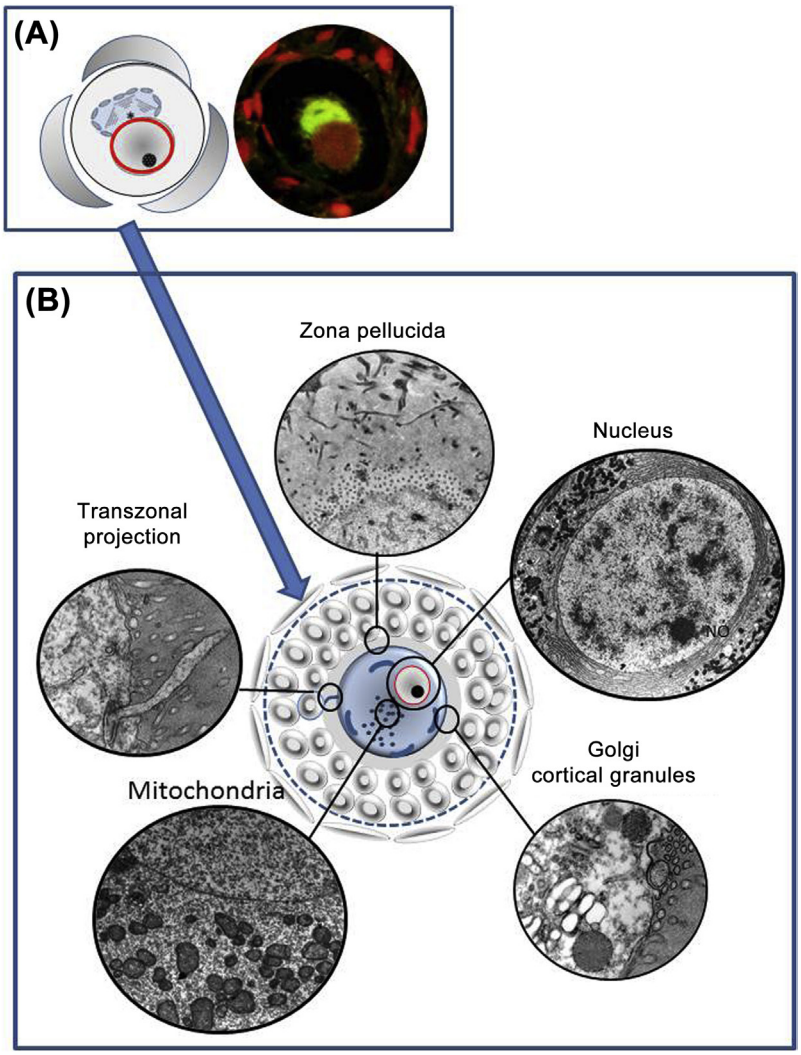

FIGURE 2.1 **Structure of the mammalian oocyte.** (A) depicts the general organization of organelles in a primordial follicle; schematic (left) denotes centrally positioned nucleus and aggregation of organelles known as Balbiani's body (asterisk). Right is an immunofluorescence micrograph illustrating the concentration of the germ cell–specific marker VASA within Balbiani's body (green) located next to the oocyte nucleus (red). *(Image courtesy of Professor Alfredo Vitullo)*. Upon activation, oocytes enter the growth phase of oogenesis (B). (B) summarizes the major ultrastructural features of a growing oocyte within a preantral follicle noting the assembly of the extracellular coat or zona pellucida, the enlarged nucleus or germinal vesicle with prominent nucleoli (NO), subcortical Golgi complexes with associated cortical granules, abundant perinuclear mitochondria, and the elaboration of microvilli on the oocyte plasma membrane interacting with somatic cell projections known as transzonal processes.

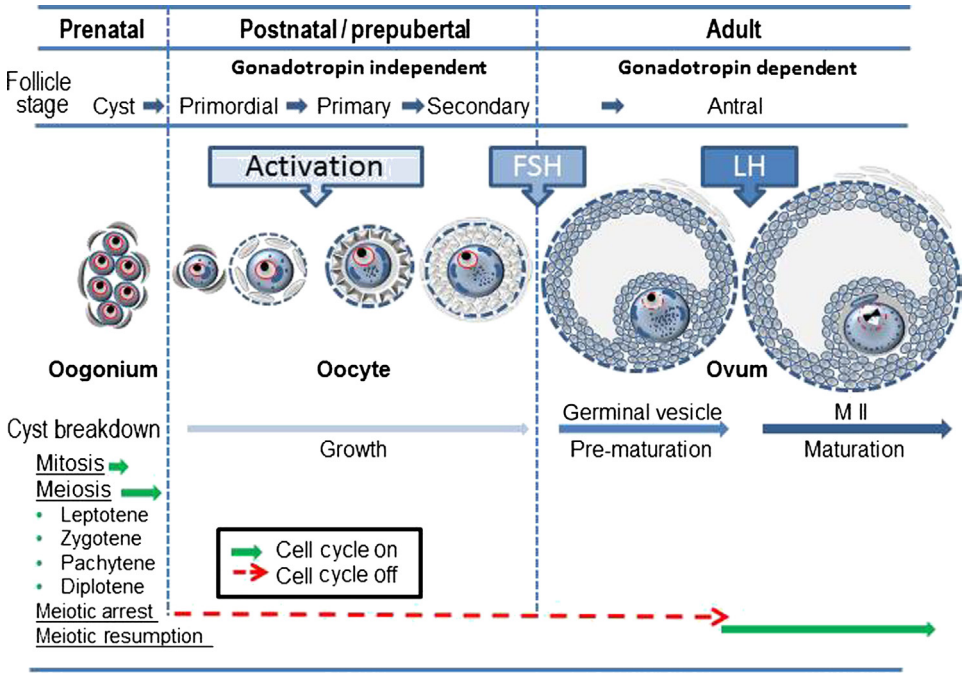

FIGURE 2.2 Stages of oogenesis defined on the basis of the oocyte cell cycle state as it occurs in the mouse. Mitotic proliferation of oogonia occurs in the prenatal gonad and is accompanied by entry into meiotic prophase as follicle formation and cyst breakdown take place. The cell cycle is then turned off for the duration of the growth phase of oogenesis that occurs during the preantral stages of follicle development. While FSH is required to advance follicle development, the oocytes remain in meiotic arrest with a germinal vesicle in the prematuration stage. In response to the LH surge, meiotic arrest is released and the oocyte proceeds through maturation being ovulated at the metaphase two stage of meiosis, which is maintained until the fertilization signal elicits completion of meiosis two. Note that in general the growth phase of oogenesis occurs independent of gonadotropin stimulation, whereas the prematuration and maturation phases require gonadotropin stimulation.

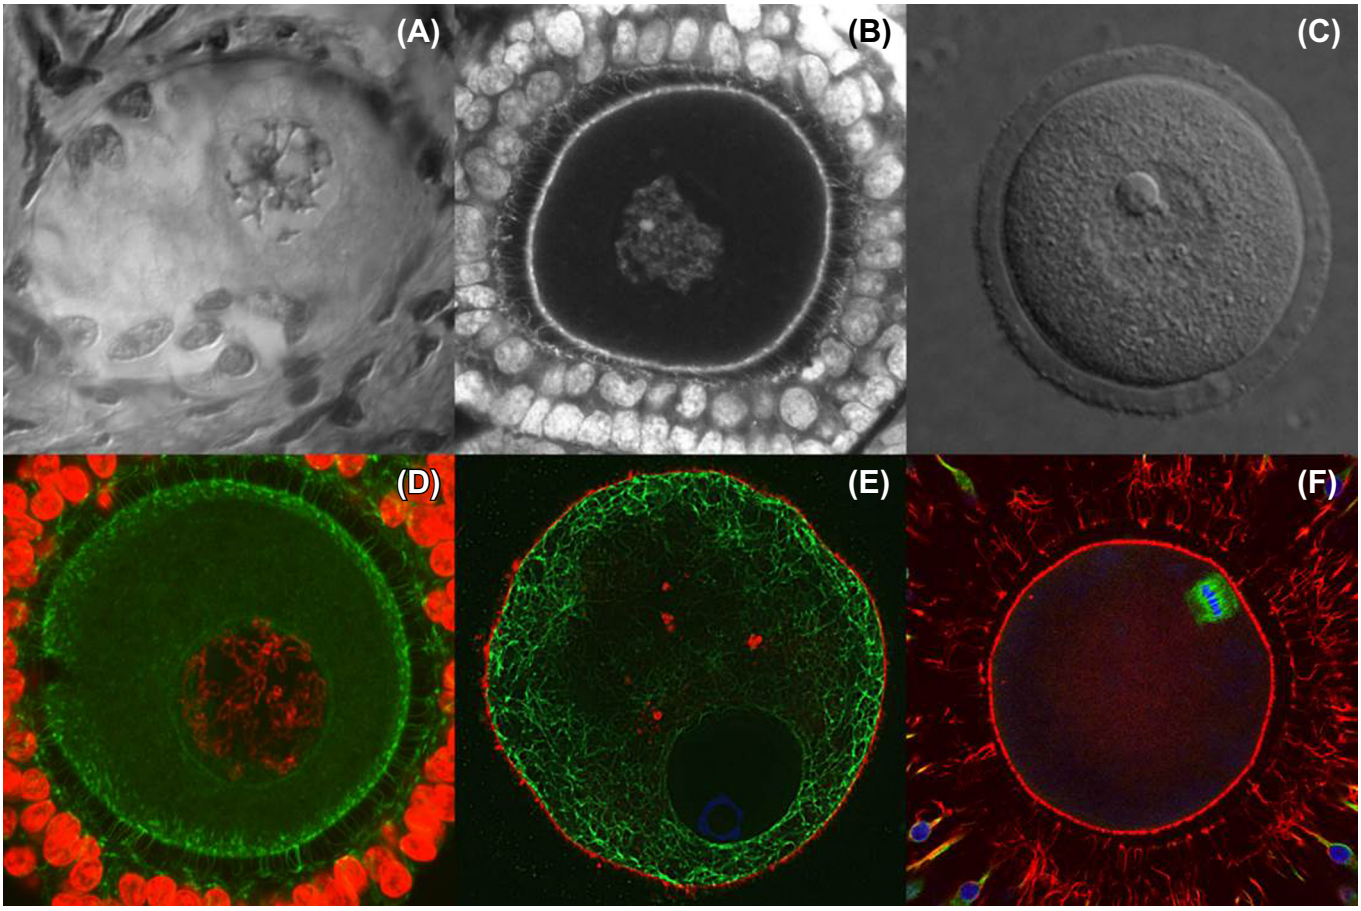

FIGURE 2.3 **Prominent morphological features of the mammalian ovum at various stages of oogenesis in various species.** (A) depicts a resting primordial oocyte within the bovine ovary in which the germinal vesicle chromatin assumes a distinctly fibrillar pattern of organization. (B) represents a primary growing oocyte from the mouse containing a centrally positioned germinal vesicle and illustrating the prominent actin-rich cortex and numerous transzonal projections emanating from surrounding granulosa cells. (C) demonstrates the appearance of a full-grown immature mouse oocyte following isolation from the ovary; note the prominent eccentrically positioned nucleolus within the GV and the cell free zona pellucida. (D) depicts a full-grown immature bovine oocyte isolated from a Graafian follicle; note the clear organization of bivalents in the GV and the presence of numerous foci at the oocyte cell surface, which represent terminal connections with corona TZPs (preparation labels f-actin using rhodamine phalloidin). (E) illustrates an immature GV-stage human oocyte that has been labeled for chromatin and microtubules (fibrillar structures); note that the chromatin is aggregated around the nucleolus of the GV and that a dense network of cytoplasmic microtubules is present in the outer regions of ooplasm. (F) illustrates a mature metaphase two arrested oocyte from a horse following controlled ovarian hyperstimulation; this preparation has been dual-labeled for tubulin (green) that highlights the cortical anchored meiotic spindle and f-actin (red) that labels the prominent corona cell projections or TZPs that appear detached from the oolemma.

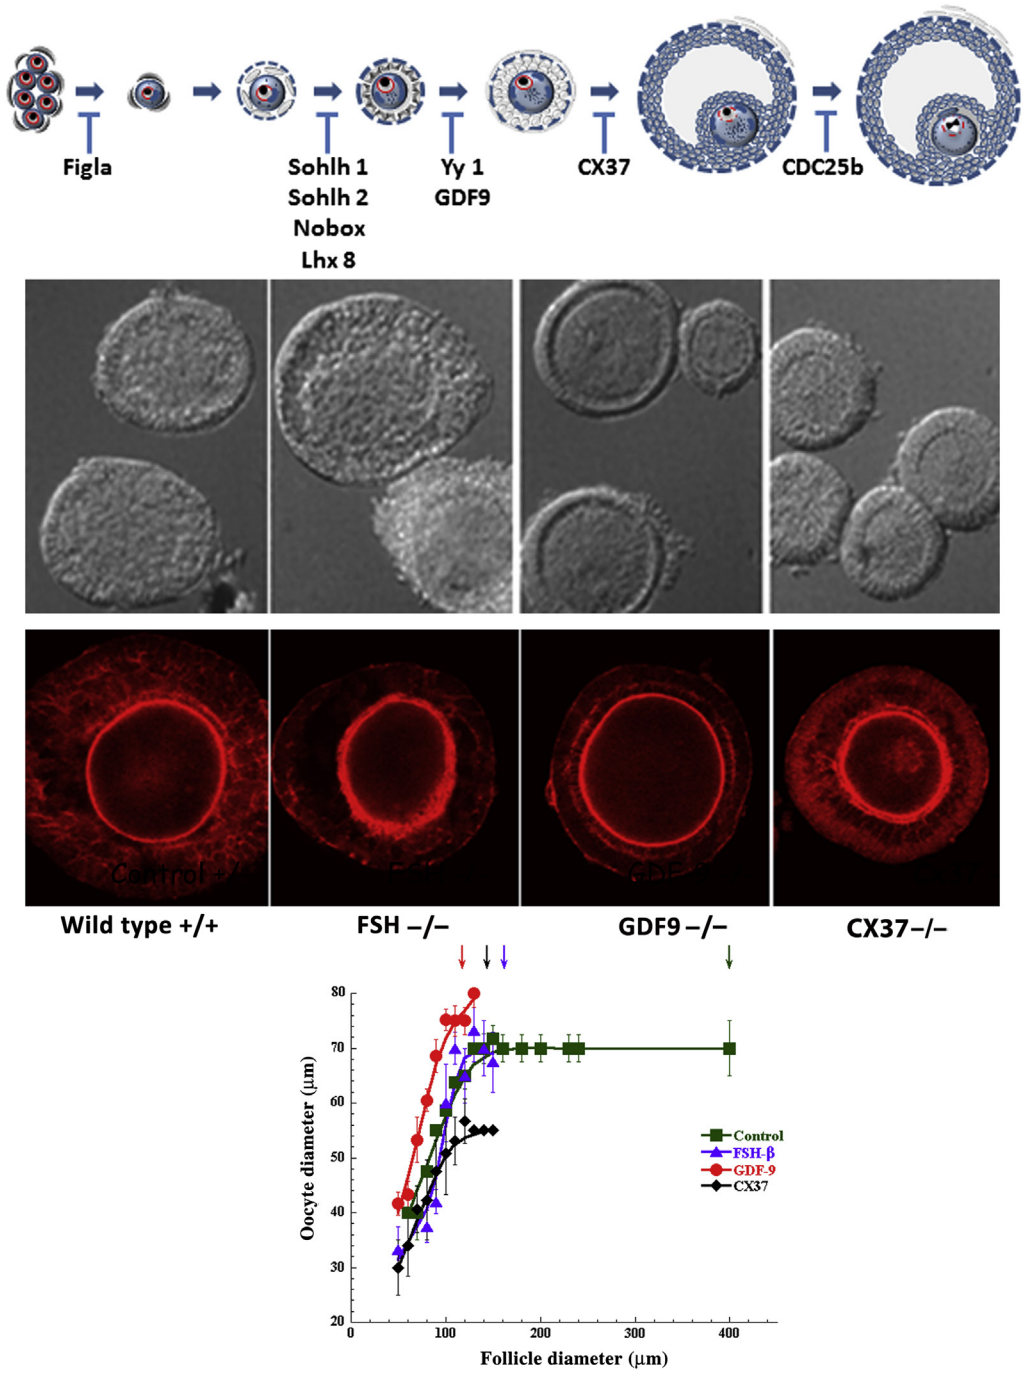

FIGURE 2.10 Mouse knockout phenotypes with distinct defects during the growth phase of oogenesis. Schematic at top shows effects of targeted gene deletion on stage of follicle development. Images show phenotype of wild type (left), GDF9, FSH beta, and CXN 37 in sequence that in the top panel show living follicles, and in the lower panel, the organization of granulosa cell–oocyte interface. Graph (bottom) plots the relationship between follicle and oocyte growth for the same four groups.

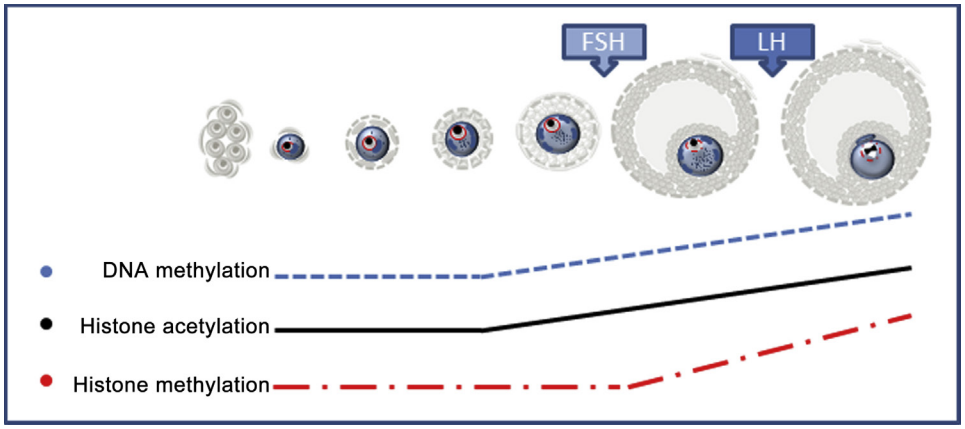

FIGURE 2.11 Epigenetic modifications of chromatin during the course of oogenesis. Genes subject to imprinting show progressive signs of DNA methylation beginning during the growth phase of oogenesis and ending at some point in the preovulatory follicle. Histone acetylation in developing oocytes follows a similar time course as DNA methylation, whereas histone methylation is reported to occur following the growth phase. Data are based primarily on studies in the mouse.

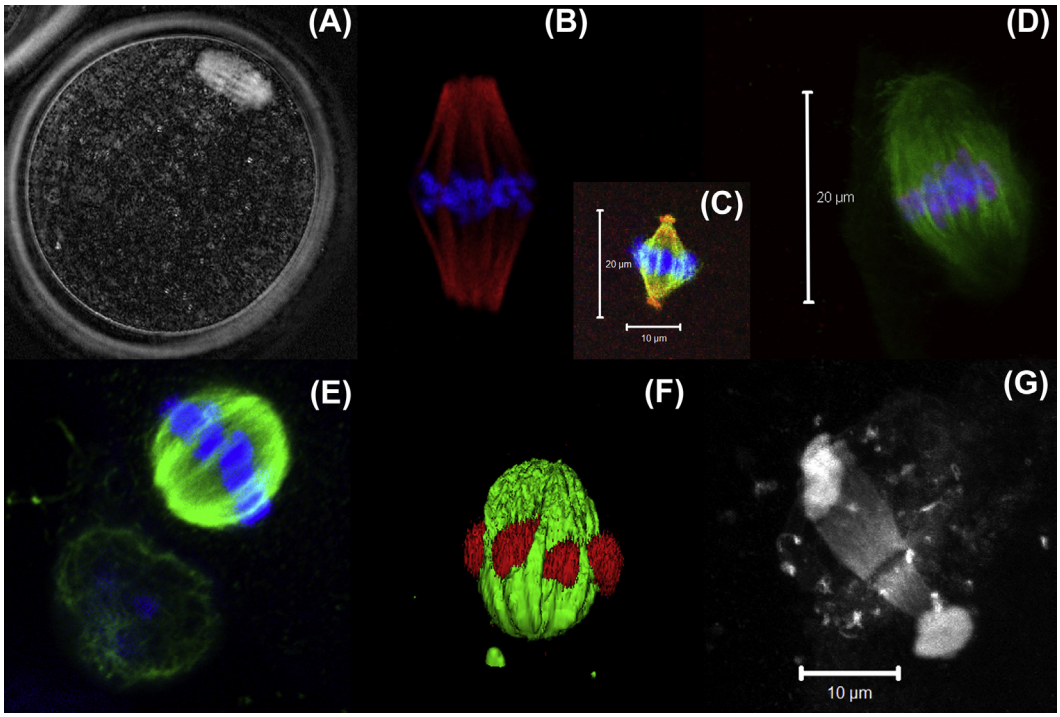

FIGURE 2.15 Meiotic spindles of mammalian oocytes. (A), (B), and (C) depict metaphase two–stage mouse oocytes under polyscope in a living oocyte (A), and after confocal immunofluorescence of tubulin (B, red; C, green); chromosomes aligned on the metaphase plate are rendered blue, and in (C), the poles of the spindle from a naturally ovulated oocyte show gamma-tubulin in red. (D) illustrates kinetochore microtubules as green stripes in a metaphase one horse oocyte that has been stained for chromosomes (blue) and phosphohistone H3 (red). (E), (F), and (G) are human oocytes at metaphase two (E and F, with the latter rendered as a three-dimensional projection); and (G) illustrates a projection of telophase one at the time of polar body extrusion.

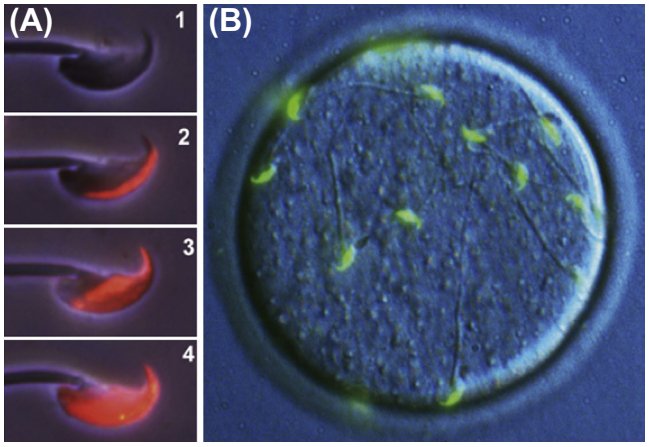

FIGURE 4.7 Gamete fusion-related factor IZUMO1 and localization in sperm. (A) IZUMO1 is an acrosomal membrane protein that is not exposed before the completion of an acrosome reaction (1). Acrosome-reacted sperm can be classified into three major groups by their IZUMO1-staining pattern: acrosomal cap (2), equatorial (3), and whole-head (4). (B) Accumulation of many sperm in the perivitelline space of the eggs recovered from females mated with *Izumo1*$^{-/-}$ males. Sperm in the perivitelline space were labeled with acrosome-reacted sperm-specific monoclonal antibody MN9. *Figure reprinted from Ref. 273 with permission from the* Asian Journal of Andrology. *Courtesy of Dr Masaru Okabe.*

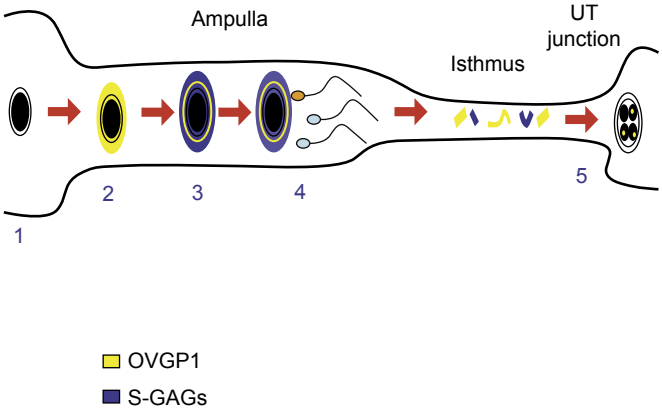

FIGURE 4.8 Depiction of the proposed role of oviductal contents in preventing polyspermy in ungulates. After the egg is shed into the ampulla following ovulation (1), oviduct-specific glycoprotein (OVGP1) surrounds it in a "shell" that renders the zona pellucida (ZP) resistant to proteolysis (2). Other oviduct molecules such as heparin-like glycosaminoglycans (S-GAGs) are thought to aid and strengthen the binding of OVGP1 to the ZP (3), modifying interaction with spermatozoa (4). As the zygote advances to the uterus, the aforementioned factors are shed or absorbed into the egg (5). *Figure reprinted and legend adapted from Ref. 375 with permission from John Wiley & Sons. Courtesy of Dr Pilar Coy.*

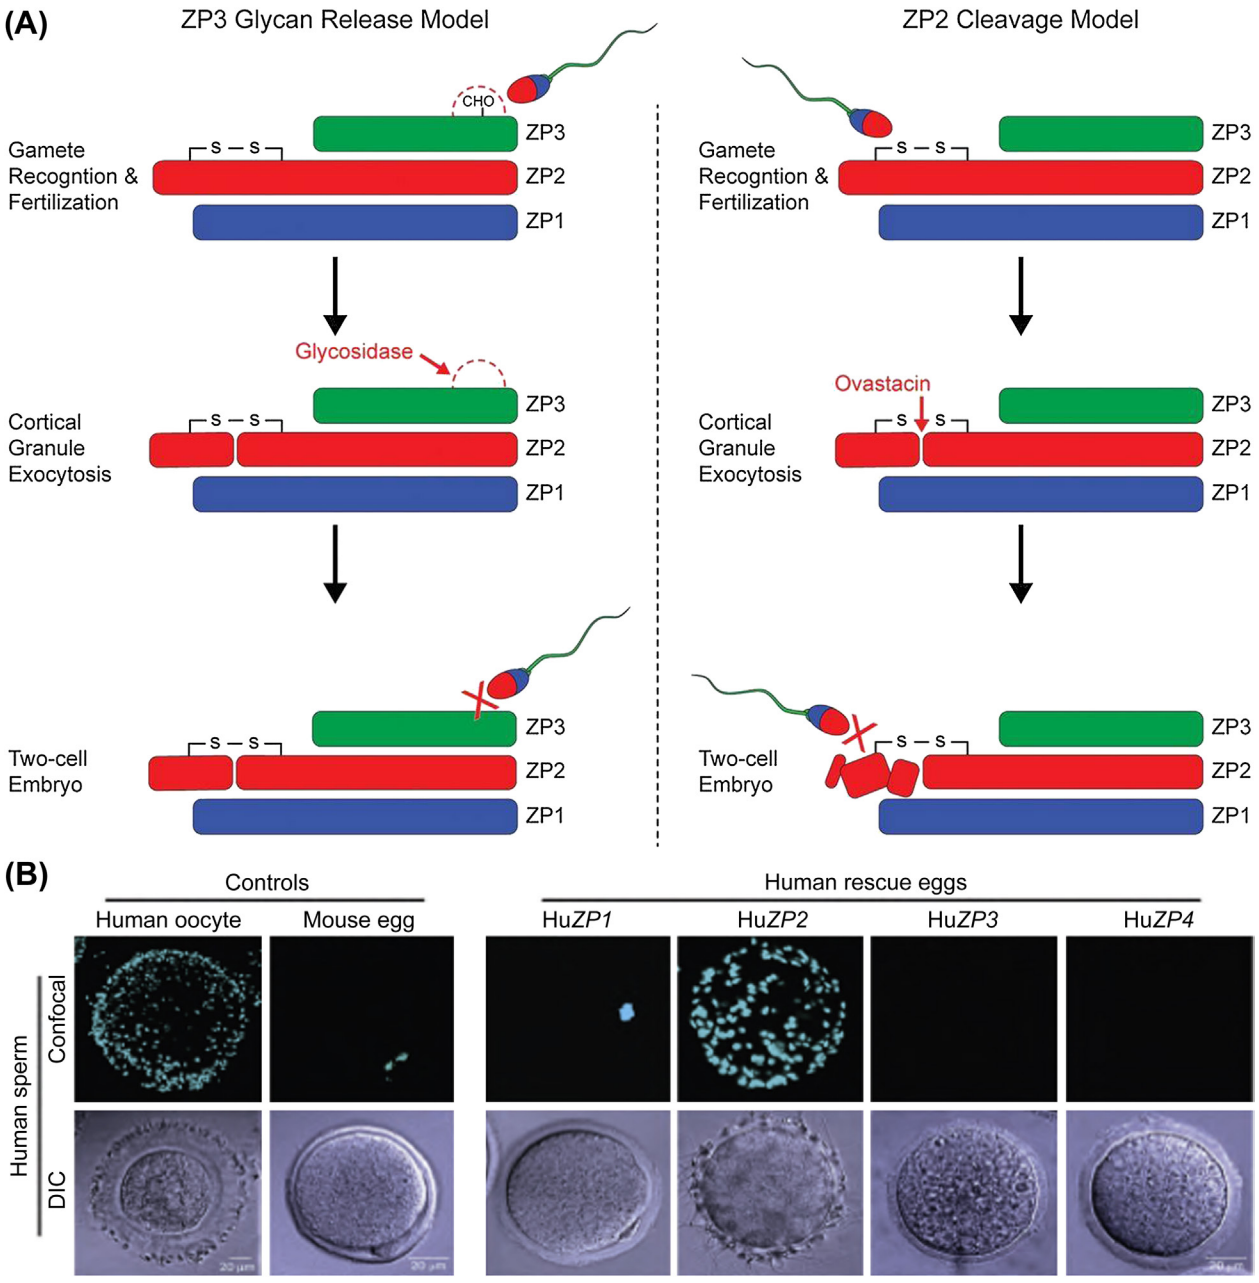

FIGURE 4.9 Models of zona pellucida block to polyspermy. (A) A specific glycan-release model (left panel) proposes that *O*-glycans on ZP3 Ser^{332} and Ser^{334} or possible others act as ligands for a sperm surface receptor. Following fertilization, cortical granules would release a glycosidase that would remove the *O*-glycans and account for the inability of sperm to bind to two-cell embryos. The ZP2 cleavage model (right panel) proposes that sperm bind to an N-terminal domain of ZP2. Following fertilization, ovastacin, a cortical granule metalloendoprotease, is exocytosed and the proteolytic destruction of the ZP2 docking site prevents sperm from binding to two-cell embryos. (B) Human sperm bind to mouse eggs from transgenic strains expressing human ZP2, but not other human ZP proteins, in the ZP. Confocal and differential interference contrast images of capacitated human sperm binding to the ZP of mice expressing human ZP1, human ZP2, human ZP3, or human ZP4, in the absence of the corresponding mouse protein. Human oocytes and mouse eggs served as positive and negative controls, respectively. Specific references and experimental details can be found in the text. *Figure reprinted from Ref. 229 with permission from Oxford Journals. Courtesy of Dr Jurien Dean.*

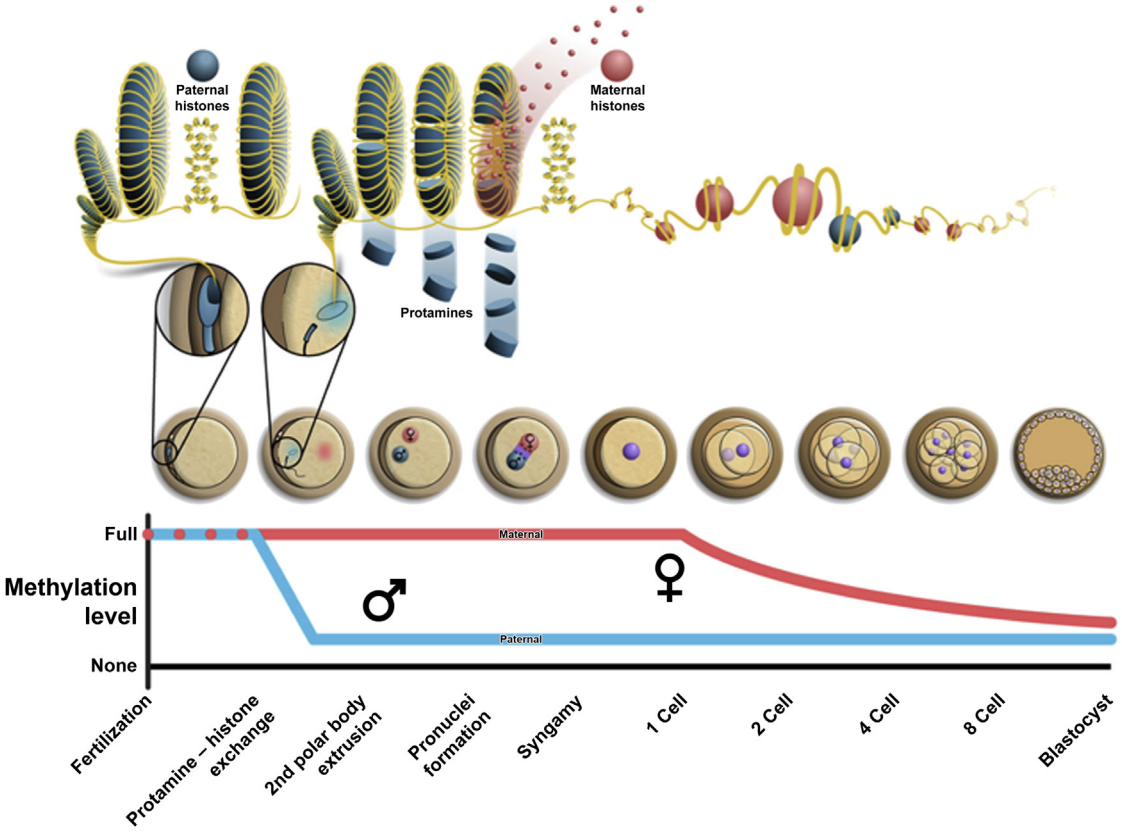

FIGURE 4.13 Reorganization of the male chromatin after fertilization and alterations to the epigenome postfertilization. The top panel illustrates the chromatin structure of the mature sperm immediately following fertilization (highly protaminated with some retention of paternally derived histones). Soon after sperm entry, the protamine to histone transition takes place where maternally derived histones replace protamines resulting in the decondensation of the sperm head. The middle panel illustrates the various stages of early embryonic development. The bottom panel shows the methylation changes that occur over time in the maternal and paternal pronucleus, where the paternal pronucleus undergoes active demethylation and the maternal DNA is demethylated passively in a replication-dependent manner. The approximate chronology of major events in the early embryo is outlined along the bottom of the figure and correlates to the illustrations of embryos above. *Figure reprinted from Ref. 444 with permission from Frontiers. Courtesy of Dr Douglas Carrell.*

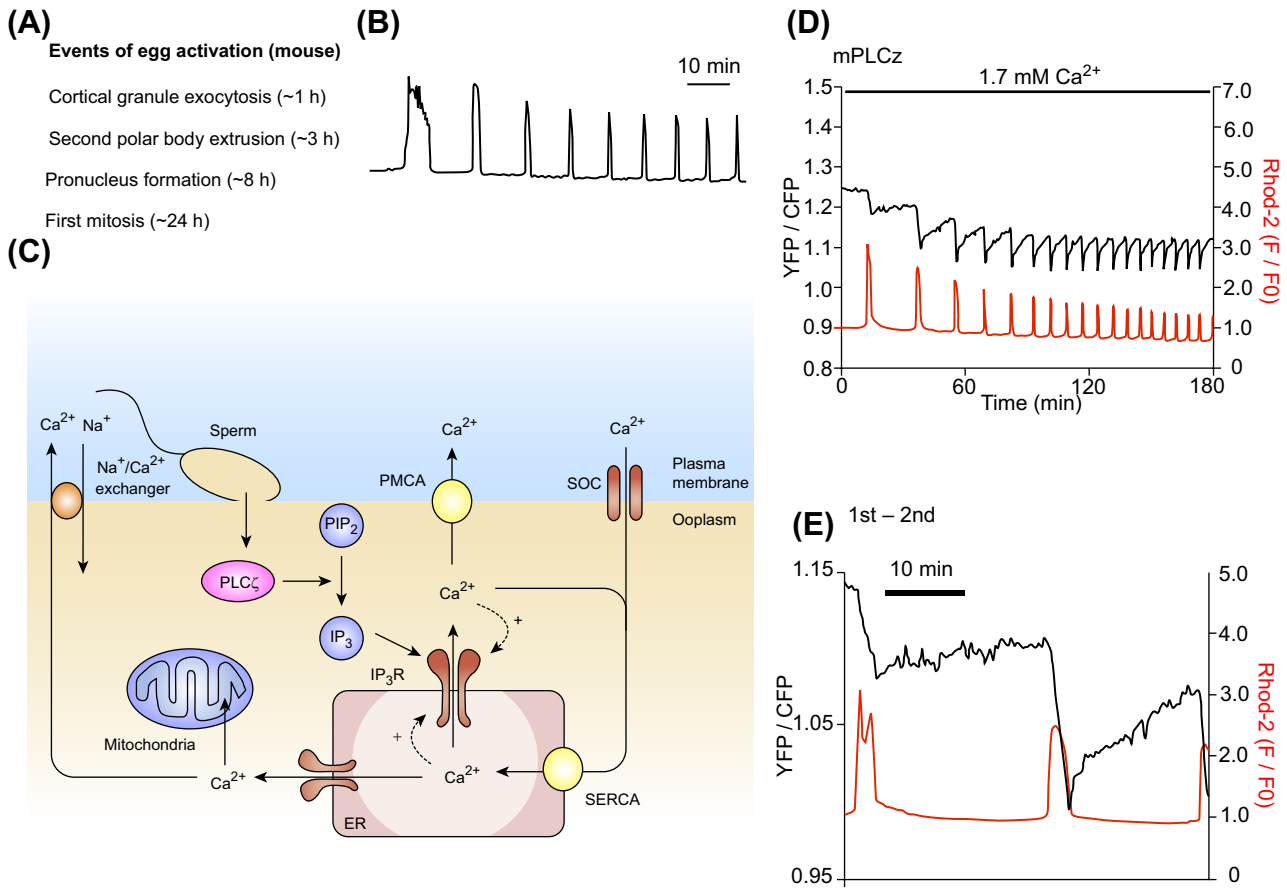

FIGURE 4.14 **Temporal course of activation events in mouse eggs with a characteristic Ca^{2+} response and candidate molecules involved in the initiation oscillations and in Ca^{2+} homeostasis.** (A) Main cellular events of egg activation after sperm entry and approximate time in hours (h) required for their completion. (B) A typical pattern of $Ca^{2+}{}_i$ oscillations associated with fertilization or with injection of PLCζ cRNA. Note that recordings were terminated prematurely. (C) Upon fusion, the sperm is thought to deliver phospholipase C (PLC) ζ, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP2) into inositol 1,4,5-trisphospahte (IP_3) and diacylglycerol (DAG). IP_3 binds its receptor, IP_3R1, causing Ca^{2+} release out of the endoplasmic reticulum (ER). Following Ca^{2+} release, basal $Ca^{2+}{}_i$ levels are regulated by the combined action of the sarcoendoplasmic reticulum Ca^{2+} ATPase (SERCA), plasma membrane Ca^{2+} pump (PMCA), Na/Ca^{2+} exchanger, and mitochondria. Store operated Ca^{2+} channels (SOC) or other Ca^{2+} channels are proposed to mediate Ca^{2+} influx, which is required to fill the ER and maintain oscillations. Broken lines suggest feedback action of Ca^{2+} on IP_3R1. *(Adapted from Ref. 507 with permission of CSHLP.)* (D) $Ca^{2+}{}_{ER}$ and $Ca^{2+}{}_i$ undergo simultaneous but opposite changes in concentration during oscillations in mouse MII eggs. $Ca^{2+}{}_i$ responses were induced by injection of 0.05 µg/µl mouse PLCζ cRNA into MII eggs. In vitro transcribed D1ER cRNA was injected into eggs 5 h before the initiation of $Ca^{2+}{}_i$ measurements. The emission ratio of D1ER (YFP/CFP) was used to estimate relative changes in $[Ca^{2+}]_{ER}$ (left axis, black trace). $[Ca^{2+}]_i$ (right axis, red trace) was recorded using Rhod-2. (E) The first and second $Ca^{2+}{}_i$ rises do elicit significant refilling of the ER, but subsequent rises, especially after ~ the sixth rise (D). *Adapted from Ref. 508 with permission from The Company of Biologists.*

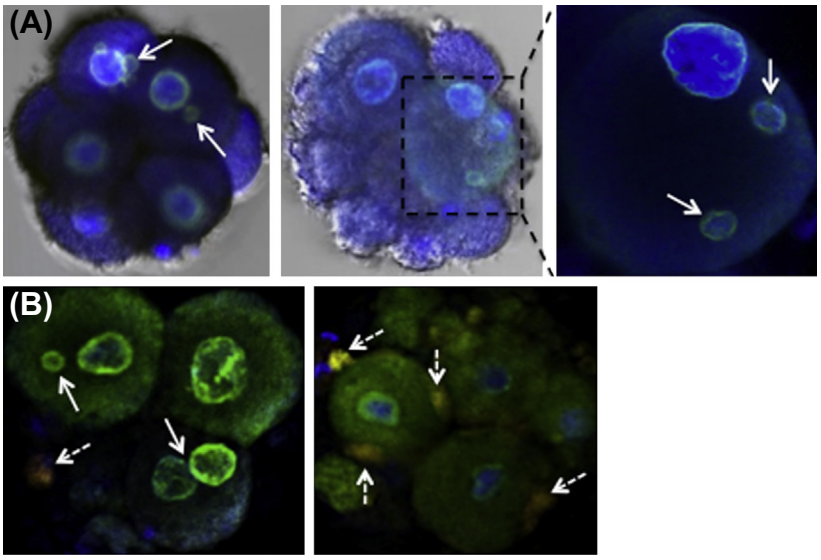

FIGURE 6.4 Detection of embryonic micronuclei in cleavage-stage human embryos. (A) Expression of the nuclear envelope marker, LAMIN-B1 (green), in 4′,6-diamidino-2-phenylindole (DAPI)-stained (blue) cleavage-stage human embryos visualized by immunofluorescent confocal microscopy and differential interference contrast (DIC) imaging at 20× (left and middle) and 40× (right) reveals the presence of several embryonic micronuclei (indicated by white solid arrows) distinct from primary nuclei in human blastomeres. (B) Similarly evaluated additional cleavage-stage human embryos with low (left) and high (right) fragmentation also immunostained for centromere protein E (CENP-E; orange) in the absence of DIC imaging identifies multiple missing chromosomes in cellular fragments (indicated by white dashed arrows) adjacent to blastomeres at this stage of development. *Source: Adapted from Ref. 16.*

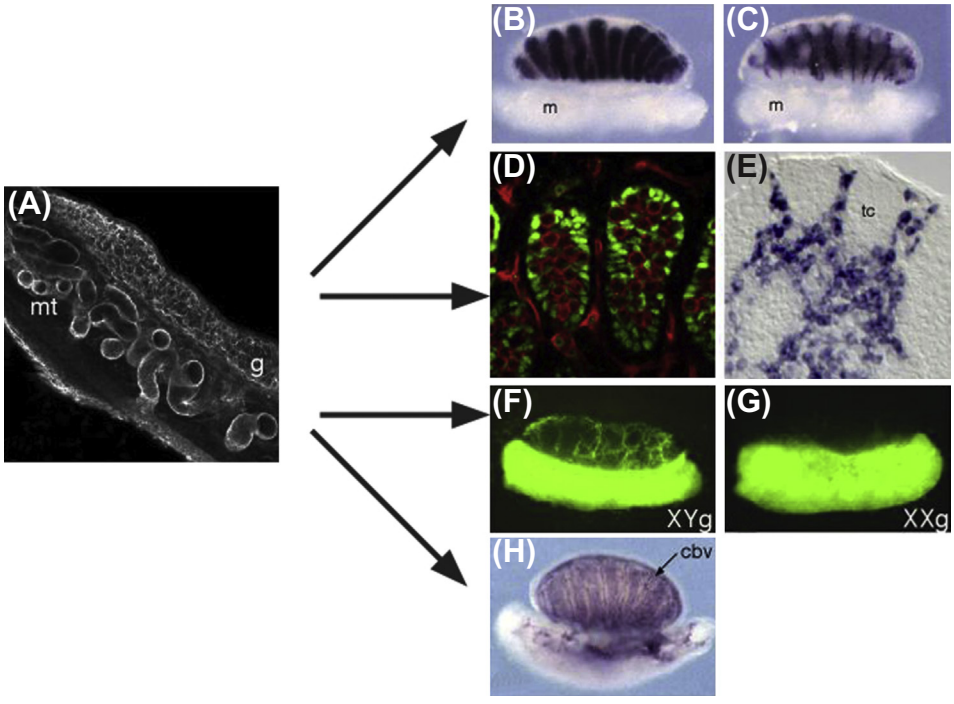

FIGURE 7.6 Differentiation of the embryonic testis from a bipotential precursor. (A) Confocal image of a gonad and mesonephros stained with an antibody to laminin at a stage before morphological changes take place (E11.5). (B–H) Morphology of the embryonic testis. (B, C) The Sertoli and Leydig cells of the E13.5 gonad are marked by whole-mount in situ hybridization for the expression of the Sertoli cell marker AMH (B) and the Leydig cell marker *Cyp11a1* (C). The structure of the testicular cords is seen in the confocal image of an E12.5 gonad that was stained with an antibody against SOX9 in green (D). Germ cells are found within the testicular cords as marked by the antibody stain for PECAM in red (D). In the interstitium, epithelial cells, as marked by the antibody stain for PECAM in red (D), and Leydig cells, as marked by the section of the whole mount in situ hybridization on a gonad from a E14 embryo for the expression of *Cyp11a1* (E), are found. (F, G) Mesonephric cell migration is observed in the XY (F) but not the XX (G) gonad, as shown by organ culture samples where the mesonephros but not the gonad is derived from transgenic mice that express GFP ubiquitously. (H) The formation of male-specific vasculature as shown by a whole-mount antibody stain to PECAM, which marks endothelial cells, of gonad and mesonephros from an E14 embryo. mt, mesonephric tubules; g, gonad; m, mesonephros; tc, testis cord; cbv, coelomic blood vessel. *Source: Adapted from Ref. 252; confocal image (D) courtesy of Blanche Capel.*

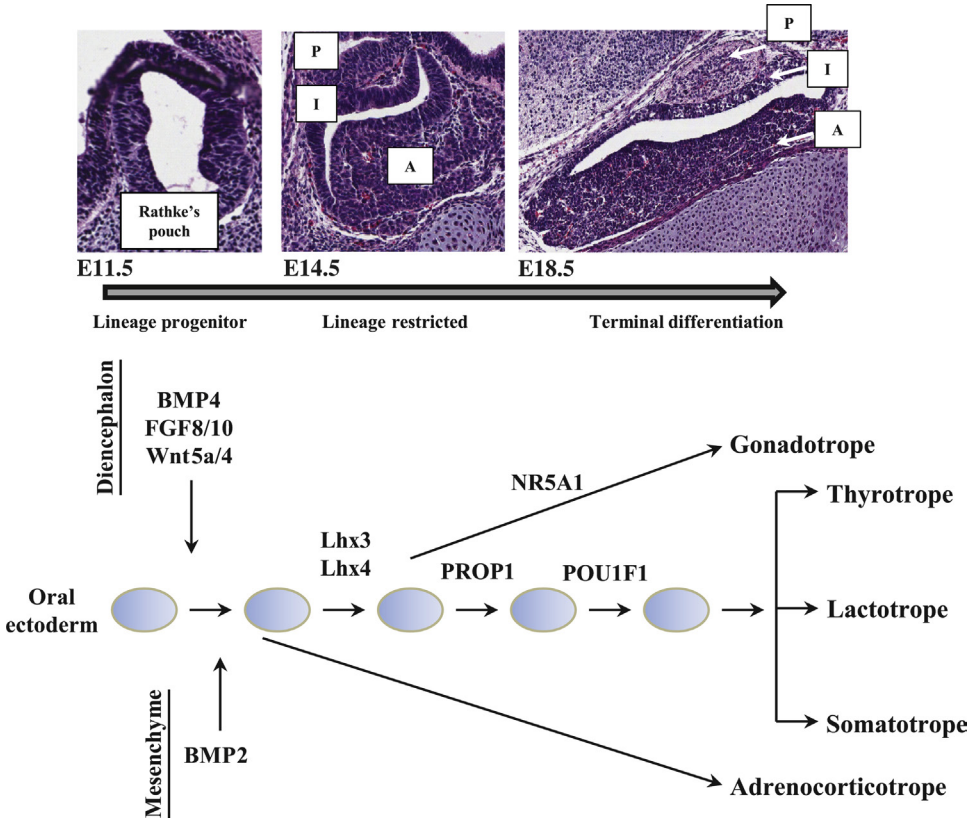

FIGURE 10.1 **Pituitary development.** The pituitary gland emerges from important interactions between the oral and neural ectoderm (diencephalon). Early expansion of the oral ectoderm appears to be functionally related to paracrine signals (such as bone morphogenic proteins (BMPs) and fibroblast growth factors (FGFs)) originating from the neural ectoderm and affecting proliferation and early differentiation of the oral ectoderm. The resulting expansion of tissue forms Rathke's pouch, the anlagen of the presumptive lineage progenitors of the anterior and intermediate lobes of the gland. In addition to signals emerging from the diencephalon, the surrounding mesenchyme provides additional paracrine signaling from BMPs, further restricting lineage identity. Differentiation of the five endocrine cell types within the anterior lobe of the pituitary is controlled by concise expression of a series of transcription factors that serve to restrict cell identity and drive terminal differentiation of the anterior pituitary. For specification of the gonadotrope cell lineage, early expression of Lhx3 (controlled by FGF signaling) and later expression of NR5A1 are central. Interestingly, Lhx3 and NR5A1 play central roles in the regulation of the four gonadotrope signature genes that define gonadotrope function in the adult animal. Sagittal tissue sections shown are from the mouse (unpublished data from M.S. Roberson and A.M. Navratil; e11.5 represents embryonic age in days post conception; P: posterior; I: intermediate; A: anterior).

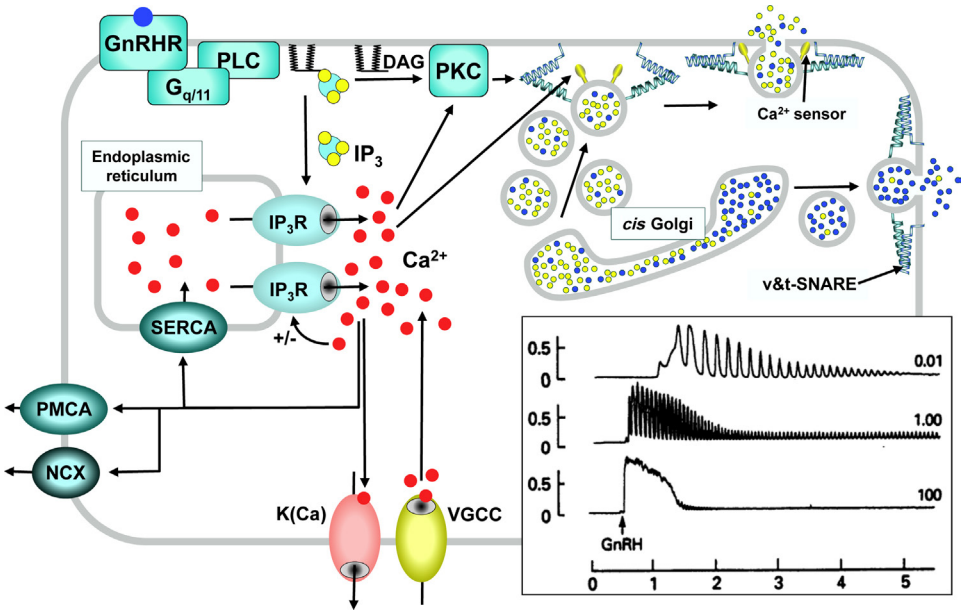

FIGURE 10.2 Acute effects of GnRH on Ca^{2+} and gonadotropin secretion. GnRH acts via Gq/11 coupled GPCRs to activate PLC, with consequent IP_3-mediated Ca^{2+} mobilization and Ca^{2+}–DAG-mediated activation of PKC. The interplay of Ca^{2+} mobilization from intracellular stores and Ca^{2+} entry across the plasma membrane increases $[Ca^{2+}]_i$. This response may be oscillatory or more sustained, often with a spike–plateau-type profile. The response elicited by GnRH varies according to cell type and stimulus intensity but is also variable from cell to cell, even within isogenic cell populations. The GnRHR-mediated increase in $[Ca^{2+}]_i$ drives the secretion of LH and FSH by regulated exocytosis, a process likely involving interaction of a vSNARE (i.e., synaptobrevin) and a t-SNARE (i.e., syntaxin) as well as regulation by a Ca^{2+} sensor (i.e., synaptotagmin). PKC can also stimulate gonadotropin secretion, acting as a positive modulator of Ca^{2+}-driven exocytosis. In addition to regulated exocytosis, gonadotropins may be secreted via the constitutive pathway. The proportion of FSH (blue circles) secreted constitutively is higher than that of LH (yellow circles), and this could reflect sorting into distinct secretory vesicles formed at the Golgi. This principle is illustrated here by the presence of a Ca^{2+} sensor on LH-enriched vesicles but not on FSH-enriched vesicles. The inset shows μM $[Ca^{2+}]_i$ in individual cells stimulated with the indicated concentration of GnRH (plotted against time in min) and is adapted from Ref. 258.

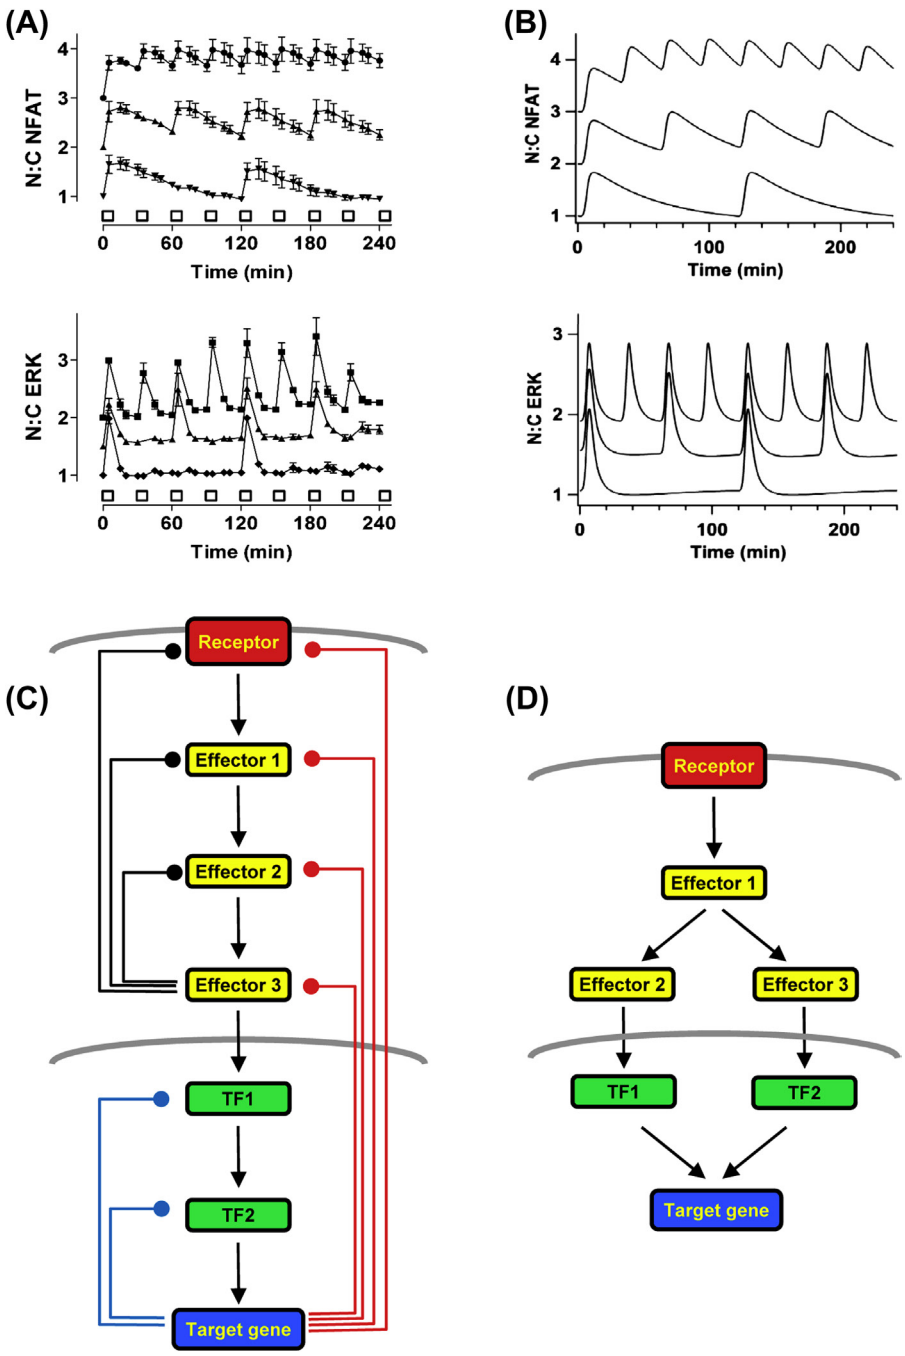

FIGURE 10.7 **GnRH pulse frequency decoding, part I.** Panel (A) shows the effects of pulsatile GnRH (1 nM pulses of 5 min duration and varied intervals) on the nuclear:cytoplasmic ratio (N:C) of NFAT2–EFP (upper chart) or ERK2–GFP (lower chart). In each case, the data are normalized to the prestimulation value and are offset on the vertical axis for clarity. Note that neither of the responses shows desensitization from pulse to pulse and that NFAT–EFP shows a cumulative sawtoothed response at the highest pulse frequency, whereas the ERK2–GFP response is not sawtoothed at any frequency (because it is rapidly reversed on removal of GnRH). Panel (B) shows data from an ordinary differential equation–based mathematical model that mirrors the empirical data for NFAT–EFP and ERK2–GFP translocation. Panel (C) shows a schematic signal transduction cascade in which a receptor in the plasma membrane causes sequential activation of three cytoplasmic proteins (effectors 1–3), and the last of these drives sequential activation of two transcription factors (TF1 and TF2) within the nucleus, which are upstream of a target gene. Also illustrated are multiple negative-feedback loops that could be restricted to the cytoplasm (black) or could involve transcription-dependent feedback to cytoplasmic proteins (red) or nuclear proteins (blue). Panel (D) shows a schematic network in which the receptor activates a bifurcating signal transduction pathway involving three cytoplasmic effectors and two nuclear transcription factors and where these transcription factors converge on the target gene. The empirical and modeled data in panels (A) and (B) suggest that the signal passing from the cytoplasm to the nucleus does not desensitize with pulsatile GnRH, arguing against the upstream negative-feedback pathways shown in black or red in panel (C). *Source: The data in panels (A) and (B) are adapted from Refs 618,620,621.*

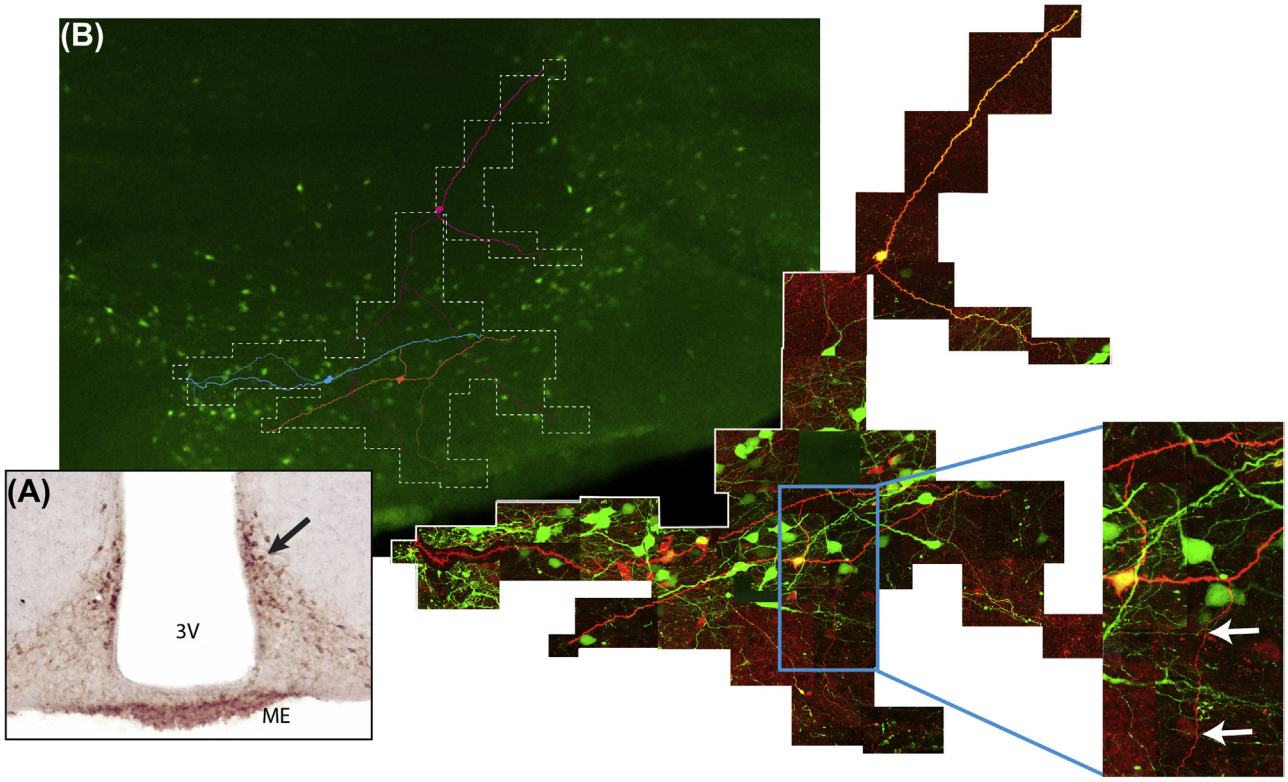

FIGURE 12.3 Neuroanatomy of the TIDA neurons. Panel A shows a coronal section through the mouse hypothalamus, with TIDA neurons identified by tyrosine hydroxylase (TH) immunoreactivity (3V: third ventricle; ME: median eminence). Note the cell bodies in the dorsomedial arcuate nucleus (arrow), as well as strong staining in the nerve terminals in the external zone of the median eminence. Panel B shows a low-power sagittal view of the hypothalamus from a mouse in which green fluorescent protein is expressed under the control of the TH promoter (green). These neurons were visualized in a brain slice, and then three individual TH-positive neurons were filled with neurobiotin (red; but pseudocolored pink, blue and orange in the low power view), allowing visualization of the full extent of the nerve processes. The montage (right) is constructed from multiple high-power views obtained using a laser confocal microscope, illustrating the dentritic tree of three filled cells extending a long distance throughout the nucleus. In the enlargement (right), note the major dendrites coming off the cell body, identified by a wide diameter and multiple spiny processes. The thin, smooth axon (arrow) arises off a primary dendrite and projects down toward the median eminence in the base of the hypothalamus. *Source: Images provided by Drs Michel Herde and Allan Herbison, based on work published in Ref. 86.*

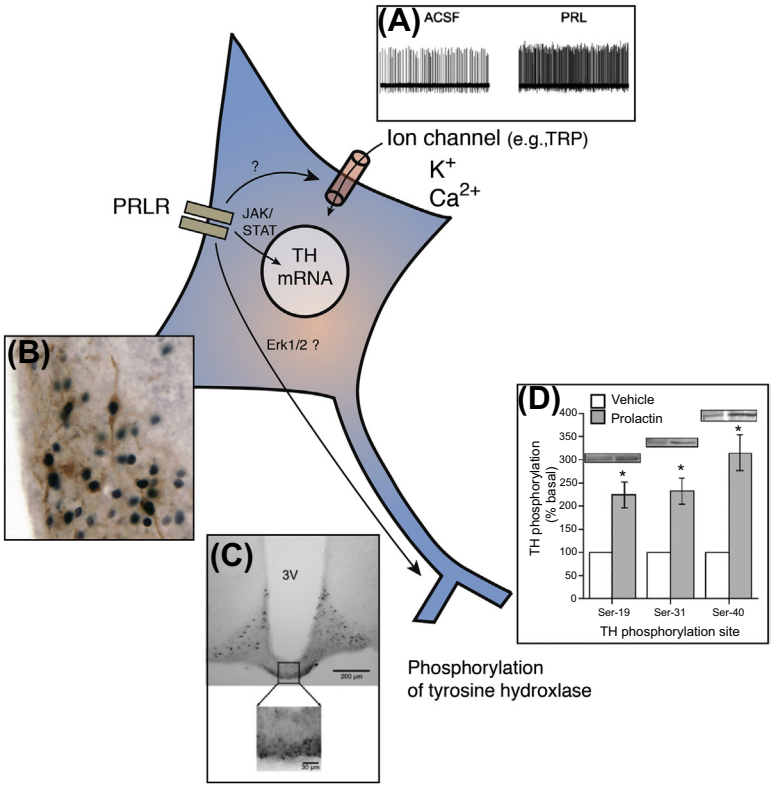

FIGURE 12.4 Diagrammatic representation of the multiple levels of prolactin feedback on NEDA neurons. Prolactin binds to prolactin receptors on NEDA neurons and then acutely (within 5 min) increases the firing rate of those neurons. Inset (A) shows prolactin-induced increase in the firing rate of a TIDA neuron.[92] Prolactin also increases the phosphorylation of STAT5 in TIDA neurons (approximately 15–20 min), inducing a transcriptional response. Inset (B) shows prolactin-induced STAT5 immunoreactivity (black) co-localized with immunoreactivity for tyrosine hydroxylase (TH) (brown), demonstrating direct prolactin action in these cells.[91] Finally, prolactin induces the phosphorylation of TH (approximately 15–30 min) both within the cell body and, more particularly, in the nerve terminals within the median eminence. Inset (C) shows prolactin-induced serine 40 phospho-TH immunoreactivity in the arcuate nucleus and median eminence (unpublished data); inset (D) shows prolactin-induced phosphorylation of TH at serines 19, 31, and 40 in mediobasal hypothalamic cultures.[102] ? indicates an uncertain mechanism; **P* <0.05.

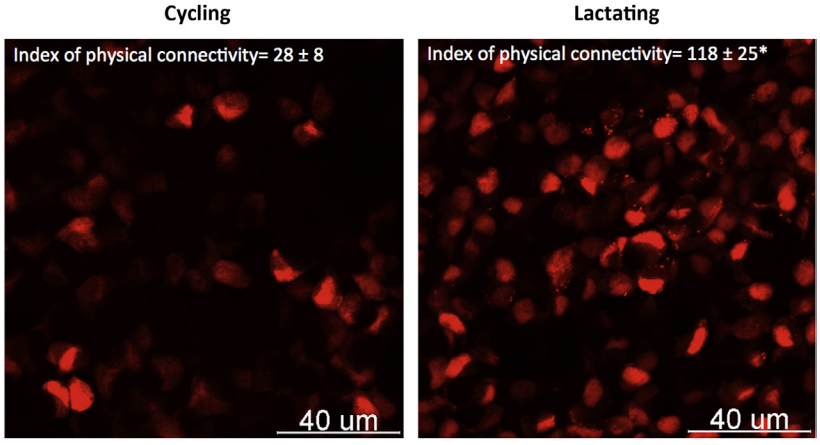

FIGURE 12.5 Biphoton imaging of pituitaries from virgin (left panel) and lactating (right panel) mice with transgenic expression of DsRedExpress fluorescent protein identifying lactotroph cells. In the virgin pituitary, lactotrophs are organized into a network of honeycomb-like structures. In the lactating pituitary, these honeycomb structures become more pronounced, and there is an overall increase in the proportion of lactotrophs with homotypic contacts. The "index of physical connectivity" is generated by three-dimensional reconstructions of the fluorescent label and reflects the degree of structural connections of lactotrophs with other lactotrophs. ? indicates an uncertain mechanism; **P* <0.05. *Source: Image courtesy of Chrystel Lafont, Taoufik El Yandouzi, and Patrice Mollard, Montpellier, France, based on work published in Refs 327,340.*

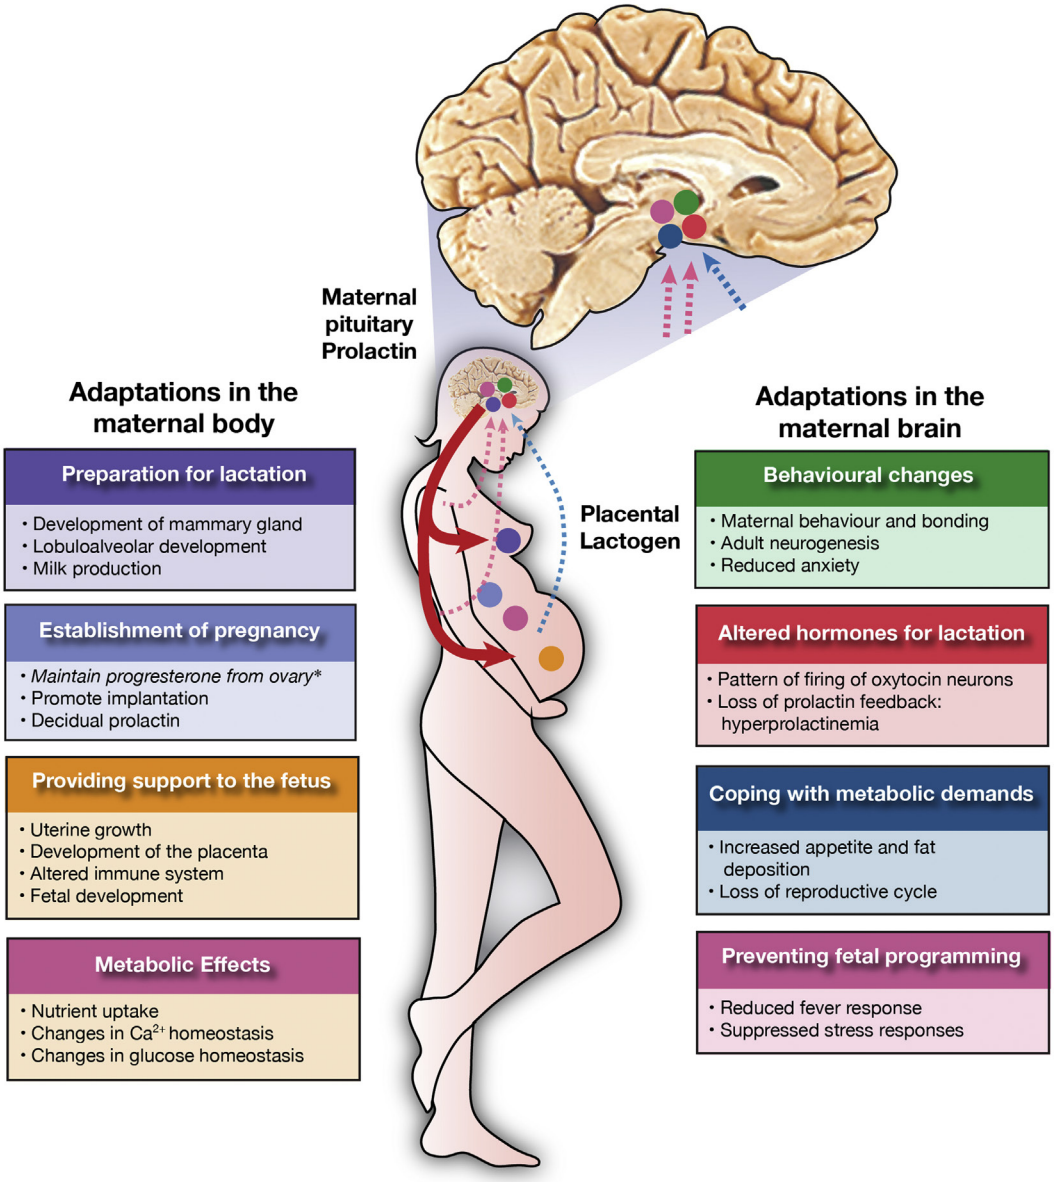

FIGURE 12.8 **Summary of adaptive responses in the pregnant female that may be induced or regulated by prolactin and/or placental lactogen.** Note that while this figure shows a human pregnancy, most of the data are based on experimental data from laboratory animals, and some have not yet been confirmed in women. *Those shown in italics are known to occur only in rodents.

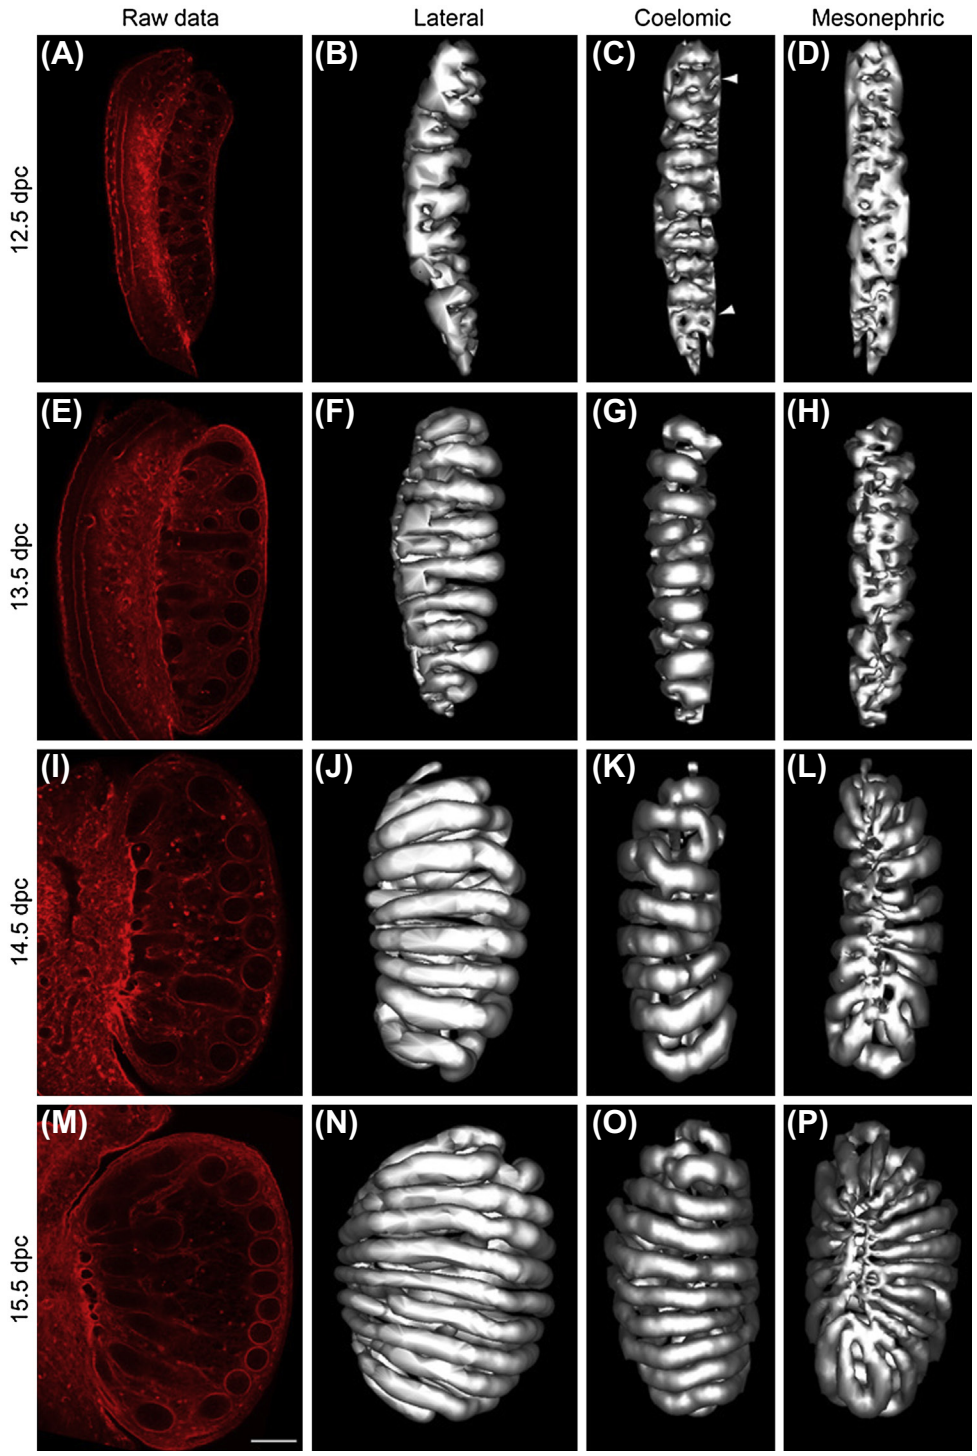

FIGURE 14.2 Modeling of testicular cord development in the mouse. This figure is taken from Ref. 9 and shows lateral (B, F, J, N), coelomic (C, G, K, O), and mesonephric (D, H, L, P) views of models generated from testis cord outlines prepared from whole mount testis. The left panel in each row (A, E, I, M) is a representative image from the data set used to compile the models. The results show that cords initially form as a network of irregular cell clusters that are subsequently remodeled to form regular parallel loops, joined by a flattened plexus at the mesonephric side. Branched, fused, and internalized cords are commonly observed. Parts A–D, E–H, I–L and M–P show models of testicular development at 12.5, 13.5, 14.5 and 15.5 dpc, respectively. Scale bar, 100 μm. *Source: Modified from Ref. 9.*

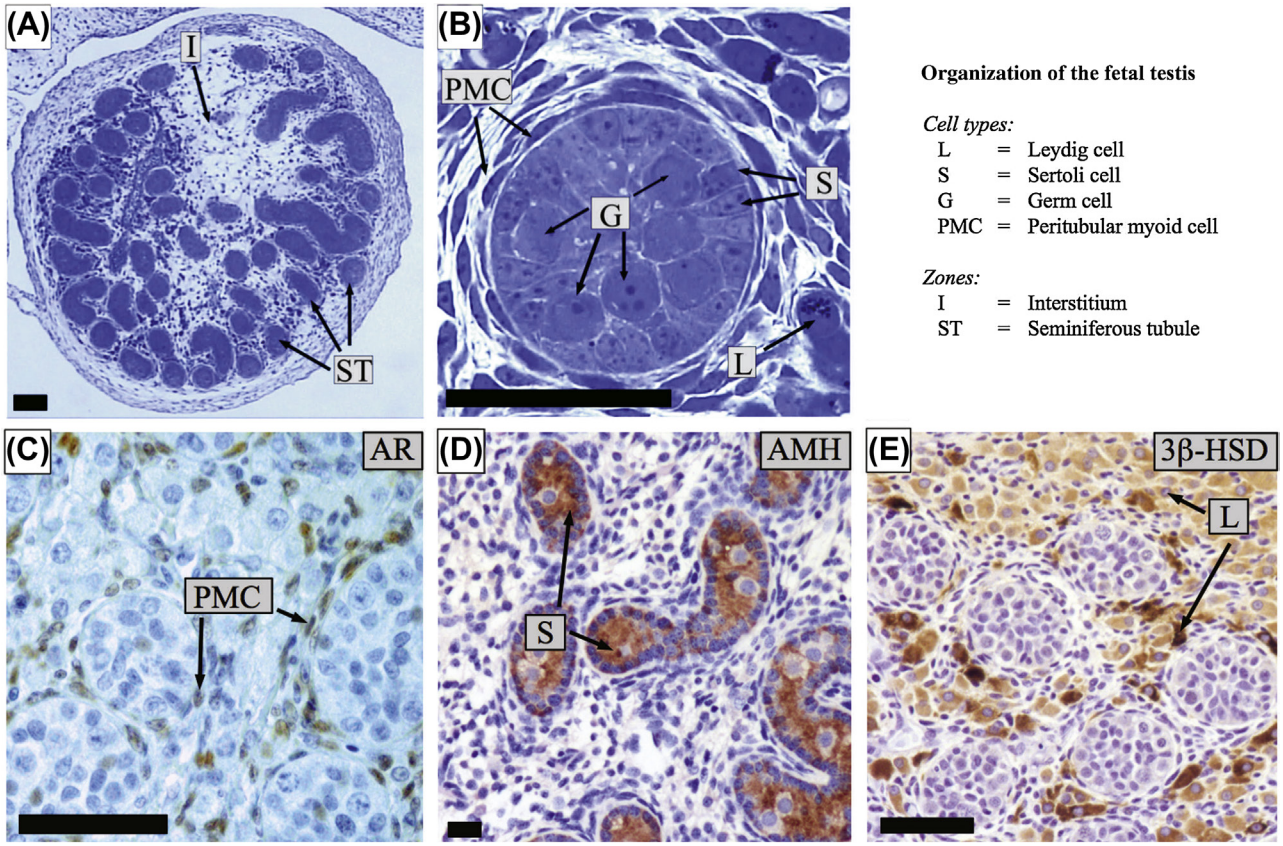

FIGURE 14.3 Histology of the fetal testis. (A) Fetal mouse: low magnification of a semi-thin section showing seminiferous tubules and interstitial tissue (I). (B) Fetal mouse: higher magnification of (A) showing gonocytes (G) in the central part of the sex cord with the Sertoli cells (S) around the periphery. The peritubular myoid cells (PMC) form a concentric layer around the cord, and Leydig cells (L) are present within the interstitium. (C) Fetal human: immunohistochemically labeled for the androgen receptor (AR), which is clearly expressed in PMC and in some interstitial cells. (D) Fetal sheep: immunohistochemically labeled for anti-Mullerian hormone (AMH), which is strongly expressed in fetal Sertoli cells. (E) Fetal human: immunohistochemically labeled for 3β-hydroxysteroid dehydrogenase (HSD3B), which is localized exclusively in the Leydig cells. In all photomicrographs, the bar represents 50 μm. *Source: Reproduced from Ref. 11. © Society for Reproduction and Fertility (2011). Reproduced by permission.*

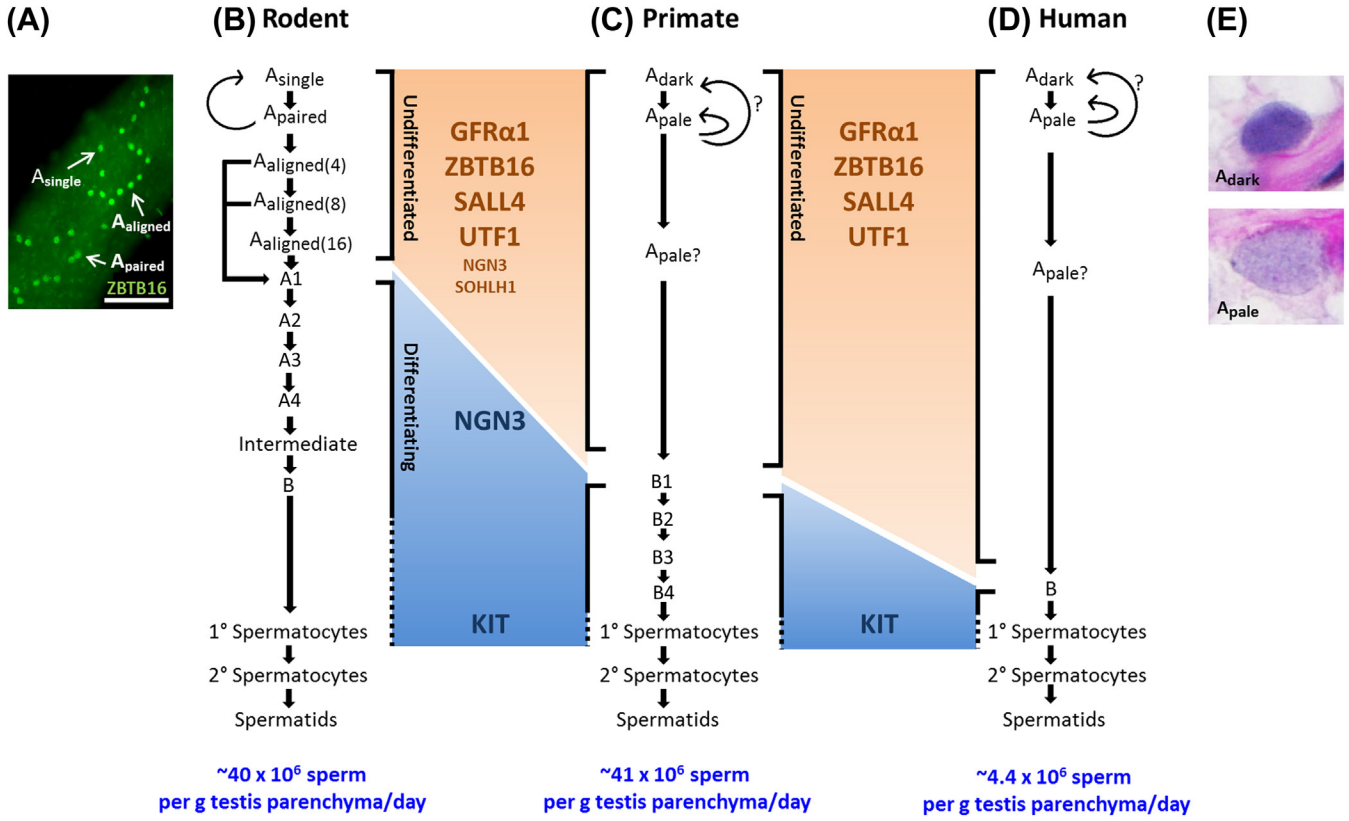

FIGURE 15.2 Current model of rodent, nonhuman primate, and human spermatogenesis. (A) Whole-mount immunohistochemistry staining for ZBTB16 in adult mouse seminiferous tubules. ZBTB16^{+} spermatogonia are identified as A_{single}, A_{paired} or $A_{aligned}$. Scale bar = 100 μm. (B) Rodent undifferentiated spermatogonia, including the SSC pool, is comprised of A_{single} and some A_{paired} spermatogonia and based on whole-mount staining analysis their phenotype is of GFRα1^{+}, ZBTB16^{+}, SALL4^{+}, UTF1^{+}, NGN3$^{+/-}$, and KIT^{-}. Transit amplifying progenitors include some A_{paired} spermatogonia and $A_{aligned}$ spermatogonia (chains of 4–16 cells), with a phenotype of GFRα1^{+}, ZBTB16^{+}, SALL4^{+}, UTF1^{+}, NGN3$^{+/-}$, and KIT$^{+/-}$. The differentiating spermatogonia that are made up of A1–A4, intermediate, and B spermatognia have a phenotype of GFRα1^{-}, ZBTB16^{-}, SALL4^{-}, UTF1^{-}, NGN3$^{+/-}$, and KIT^{+}. (C and D) In nonhuman primate and human testis, the undifferentiated spermatogonia are the type A spermatogonia that are designated A_{dark} and A_{pale} based on nuclear staining intensity with hematoxylin. The B spermatogonia are considered to be the differentiating spermatogonia and in nonhuman primates; they go through four divisions before producing primary spermatocytes, whereas in human there is only one division of B spermatogonia. (E) Sections of human testis stained using periodic acid-Shiff method and counterstained with hematoxylin to show nuclear morphology. ZBTB16, zinc finger and BTB domain containing 16; GFRα1, GDNF family receptor alpha-1; UTF1, undifferentiated embryonic cell transcription factor 1; SALL4, Sal-like 4; NGN3, neurogenin 3; SOHLH1, spermatogenesis and oogenesis specific helix-loop-helix 1. *Adapted from Ref. 75.*

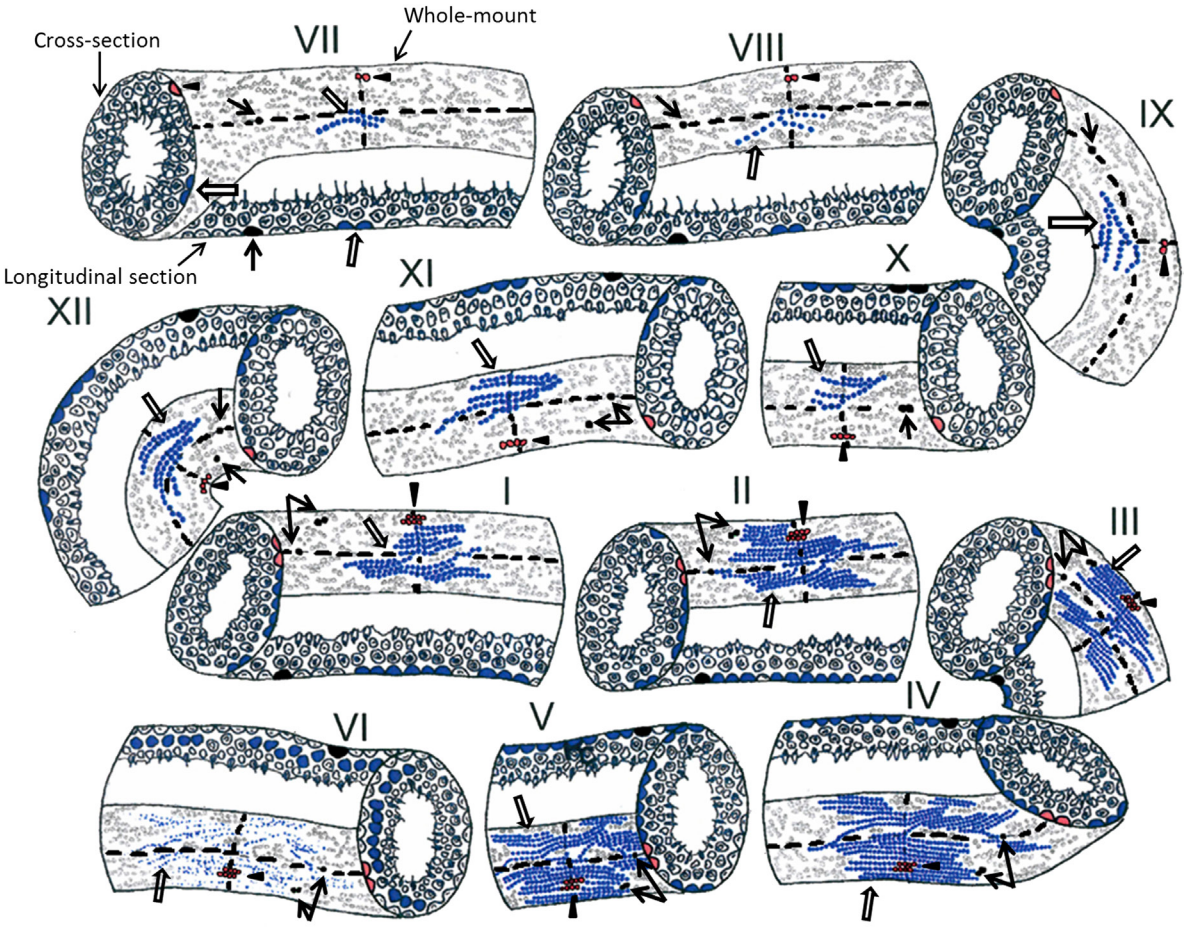

FIGURE 15.3 Schematic of mouse spermatogenic clone development by stage. The seminiferous epithelial cycle of the mouse contains 12 stages (I-XII). Each stage is shown in cross-sectional, longitudinal, and whole-mount perspectives (labeled in stage VII). Three putative spermatogonial clones are highlighted in blue (open arrow), red (arrowhead), and black (black arrow). These clones are only representative examples and do not imply A_{single} spermatogonia divide only in stages X and I. A_{single} and A_{paired} spermatogonia are present in all stages of the seminiferous epithelium and tend to divide more frequently in early and late stages than middle stages. The dotted lines in the whole-mount perspective indicate planes of the cross-section and longitudinal section views. Cells that lie on the focal plane in the whole mount appear in the corresponding cross-section and longitudinal section views; this is indicated by matching color or arrows (arrows shown for stage VII only). For example, in stage VII, the red cell (arrowhead) is in the vertical line and therefore appears in the cross-sectional view. A black cell (black arrow) is in the horizontal line, so it is observed in the longitudinal section view. The development of three putative clones (blue/open arrow, red/arrowhead and black/black arrow) through one cycle of the seminiferous epithelium is shown. Stage VII: $A_{al\text{-}16}$ (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage VIII: A1 (clone of 16) (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage IX: A2 (clone of 32) (blue/open arrow); A_{pair} (red/arrowhead); A_{single} (black/black arrow); stage X: A2 (clone of 32) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{pair} (black/black arrow); stage XI: A3 (clone of 64) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{single} (x2) (black/black arrow); stage XII: A3 (clone of 64) (blue/open arrow); $A_{al\text{-}4}$ (red/arrowhead); A_{single} (x2) (black/black arrow); stage I: A4 (clone of 128) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage II: intermediate spermatogonia (clone of 256) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage III: intermediate spermatogonia (clone of 256) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage IV: Type B spermatogonia (clone of 512) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage V: Type B spermatogonia (clone of 512) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow); stage VI: primary spermatocytes (lifting off the basement membrane) (blue/open arrow); $A_{al\text{-}8}$ (red/arrowhead); A_{single} and A_{pair} (black/black arrow). *Reproduced with permission from Ref. 28.*

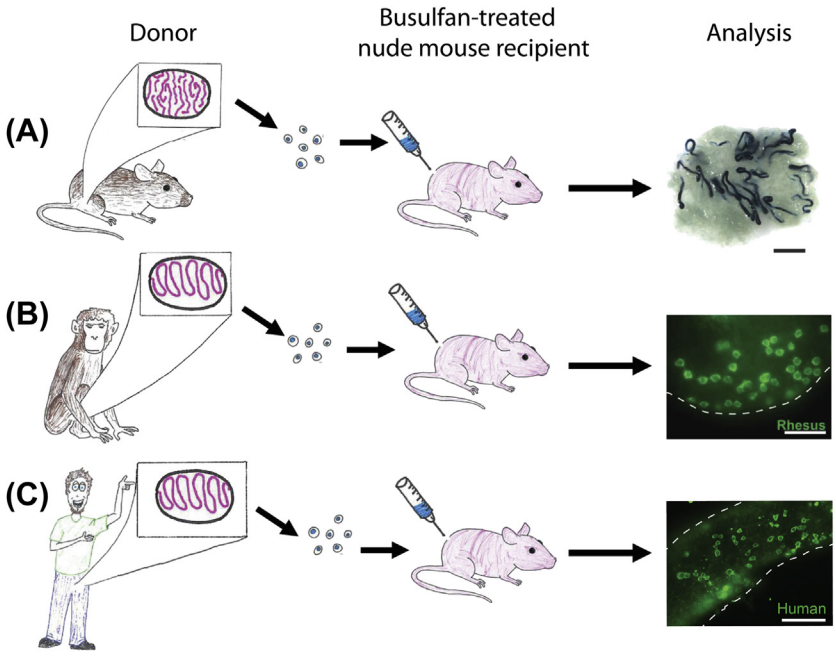

FIGURE 15.6 Spermatogonial stem cell (SSC) transplantation assay. The only way to definitively identify SSCs is to analyze SSC function. (A) In this case, a testicular cell suspension is produced from a *lacZ* donor mouse. The cells are injected into the testis of an infertile recipient mouse and the results are analyzed two to three months after transplantation for *lacZ* expressing donor spermatogenesis (dark colonies). Scale bar = 2 μm. (B, C) Xenotransplantation of nonhuman primate (B) and human (C) testicular cells into busulfan treated nude mouse can be used as an assay to identify SSCs by their ability to initiate the early steps of spermatogenesis in the mouse testis. The colonies of spermatogonia are identified by staining with anti-primate antibody that only recognizes primate cells. The colonies of SSCs are identified by the following criteria—they are located on the basement membrane of the seminiferous tubules, they have four or more cells, and the cells are within 100 μm of each other. Scale bars = 100 μm. In the B and C analysis panel, broken lines indicate the borders of seminiferous tubules.

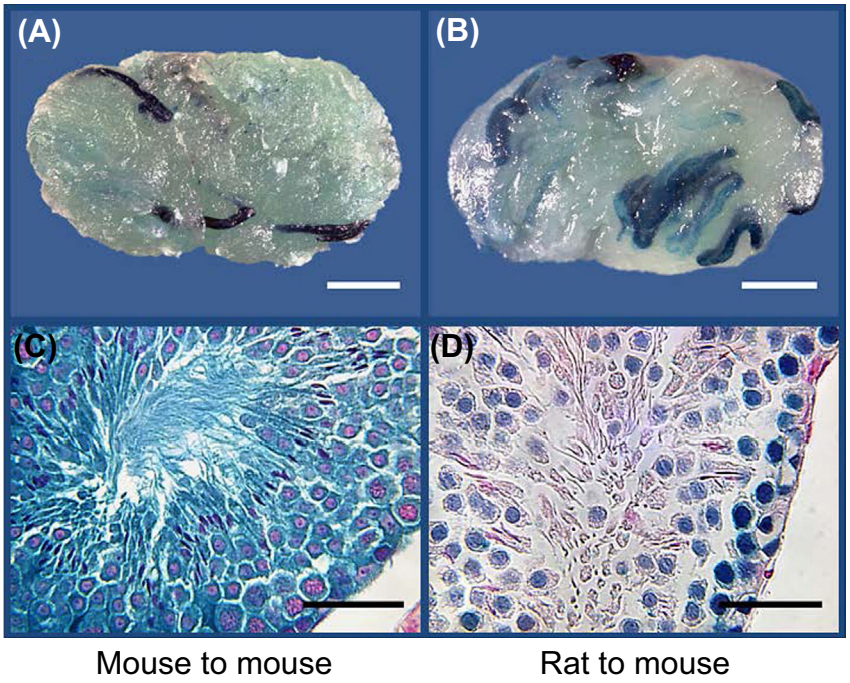

FIGURE 15.7 Macroscopic and histologic appearance of recipient testes transplanted with mouse and rat adult donor testis cells expressing *lacZ*. NCr nude (spontaneous mutant T cell deficient mice) recipient mouse testes were stained with X-gal 3 months after transplantation to visualize mouse (A and C) and rat (B and D) donor-derived spermatogenic colonies. Both mouse and rat donor testis cells generated complete spermatogenesis, characterized by multiple germ cell layers and mature spermatozoa, in recipient testes. Note that the lacZ stain is localized in the cytoplasm of ROSA26 mouse testis cells (C) and the nucleus of MT-lacZ rat testis cells (D). Nuclear fast red counterstain (C and D). Bar = 1 mm (A and B), 40 μm (C and D). *Reproduced with permission from Ref. 134.*

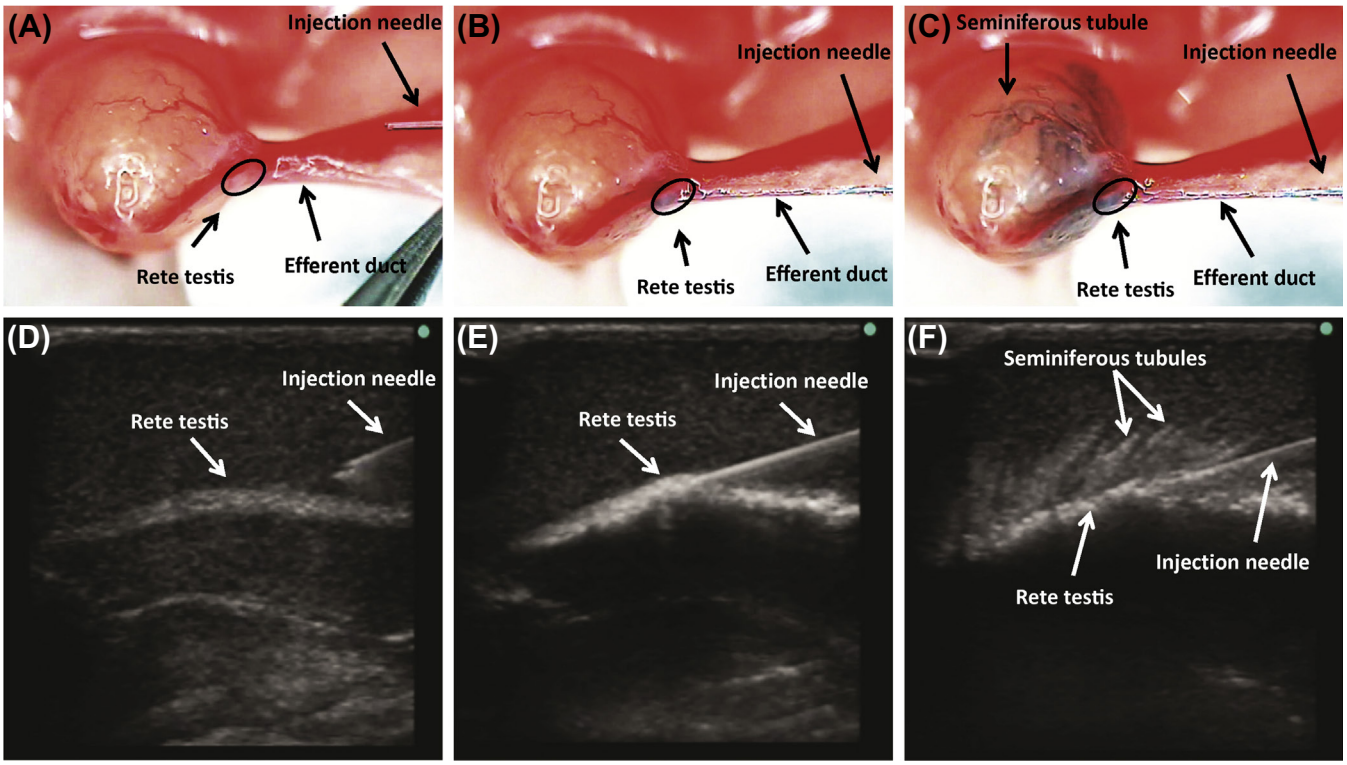

FIGURE 15.8 Testicular cell transplantation. (A–C) In rodents, the testicular cells are injected via the efferent ducts into the rete testis space, which can be visualized on the surface of the testis and is contiguous with all seminiferous tubules. (C) Trypan blue is injected with the testicular cells to visualize the filling of the seminiferous tubules. (D–F) Testis anatomy in large animals is different than rodents, with the rete testis being more centrally localized and therefore more difficult to visualize and access. Therefore, ultrasound is used to guide injections. (D) Rete testis (echo-dense structure) is visible on ultrasound. The injection needle is inserted under ultrasound guidance through the scrotal skin into the rete testis space, which is continuous with the seminiferous tubules. (E) Positive pressure is applied to the needle, so the cells are slowly injected into the rete testis and seminiferous tubules. (F) The filling of the seminiferous tubules is observed using microbubbles.

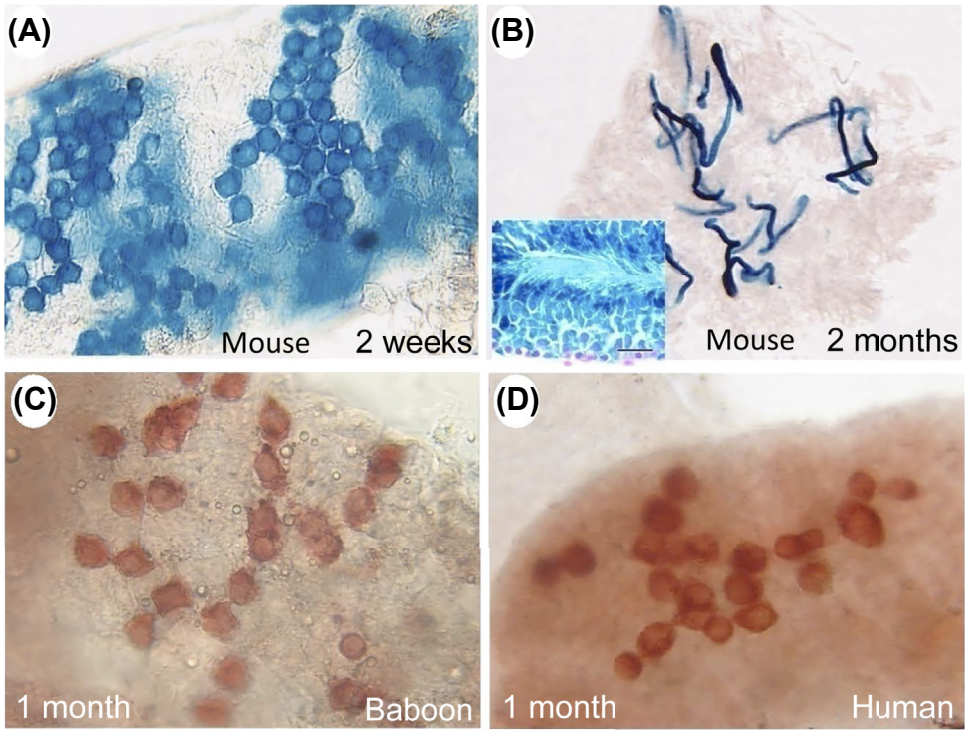

FIGURE 15.9 Colonization of recipient testis. (A) Two weeks after transplantation of transgenic mouse donor cells (stained blue) into a recipient mouse seminiferous tubules, small groups of cells can be seen at low magnification. (B) Two months after the transplantation of mouse donor cells, the blue areas are dark in the center, indicating multiple layers of germ cells and development of spermatogenesis. (B inset) Cross-section of a transplanted mouse seminiferous tubule 2 months after transplant. Scale bar = 30 μm. (C and D) Detection of baboon and human germ cells transplanted into the seminiferous tubules of recipient mouse, using an antibody raised against baboon testis cells. One month after the transplant, clusters of baboon (C) and human (D) germ cells are located on the basement membrane of mouse tubules and exhibit characteristics of undifferentiated spermatogonia. The clusters are similar to the ones seen in mouse 2 weeks after the transplant. *Modified with permission from Refs 104 and 149.*

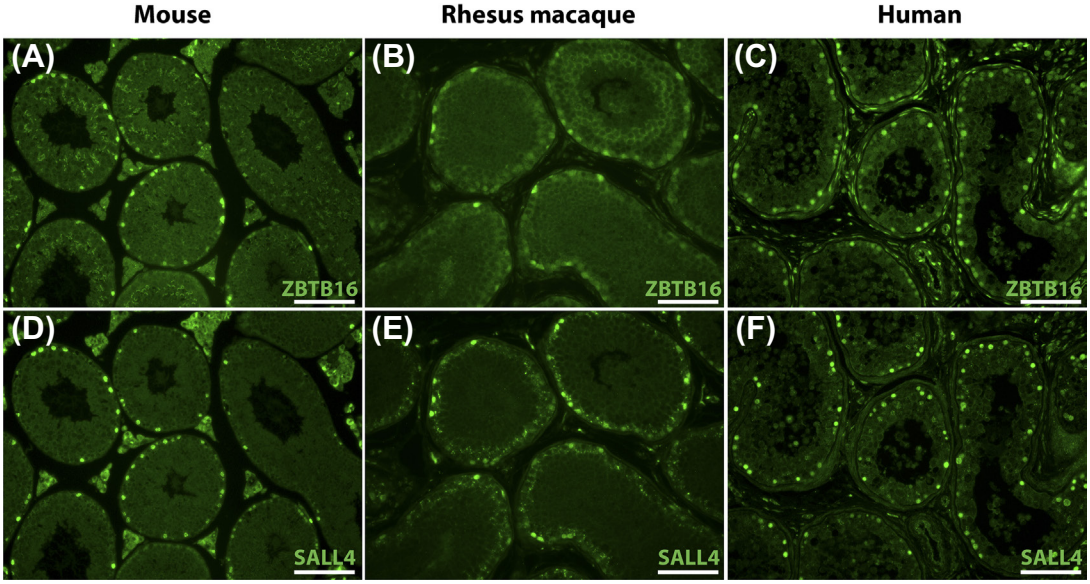

FIGURE 15.10 Conservation of stem and progenitor markers ZBTB16 and SALL4 from mouse to human. ZBTB16 (A–C) and SALL4 (D–F) staining in cross-sections of seminiferous tubules from mouse, rhesus macaque, and human testes shows expression of these transcription factors on the basement membrane of the tubule. Both ZBTB16 and SALL4 are conserved markers from mouse to rhesus macaque to human. Scale bar = 100 μm. ZBTB16, zinc finger, and BTB domain containing 16; SALL4, Sal-like 4.

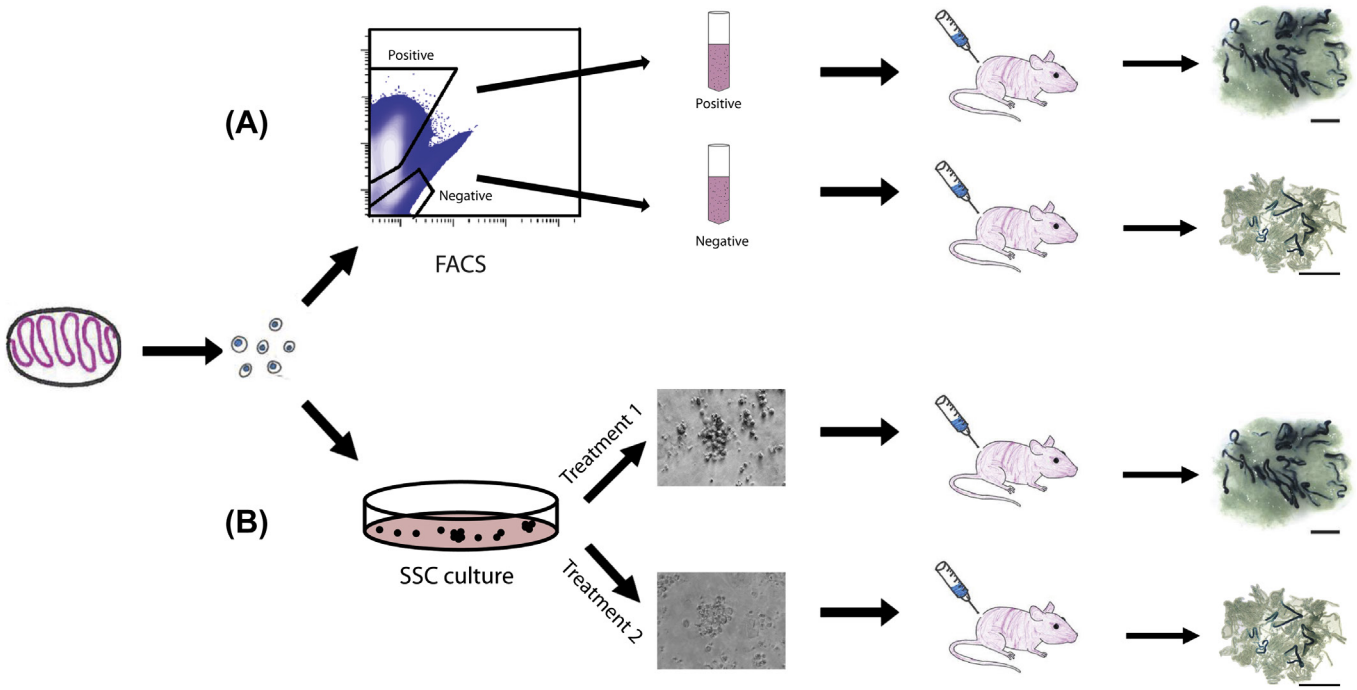

FIGURE 15.11 Experimental designs to study seprmatogonial stem cells. SSC transplantation is used to analyze the effectivness of (A) fluorecsence-activated cell sorting (FACS) for a cell-surface protein or (B) a treatment of SSC culture. (A) FACS is used to fractionate the testicular cell population stained with an antibody against a cell-surface protein, based on marker$^+$ and marker$^-$ status. The sorted fractions can then be transplanted into infertile nude mice to determine which fraction contains the SSCs. (B) SSC cultures are used to identify factors important for SSC self-renewal and maintenance or for SSC differentiation. For example, GDNF can be removed from the culture media to determine whether or not it has an effect on SSC self-renewal and/or maintenance. The cells cultured with or without GDNF are then transplanted into testis of infertile recipient mice and, 2 months later, the testis are analyzed for colony formation. FACS, fluorescence activated cell sorting; SSC, spermatogonial stem cell; GDNF, glial cell-derived neurotrophic factor.

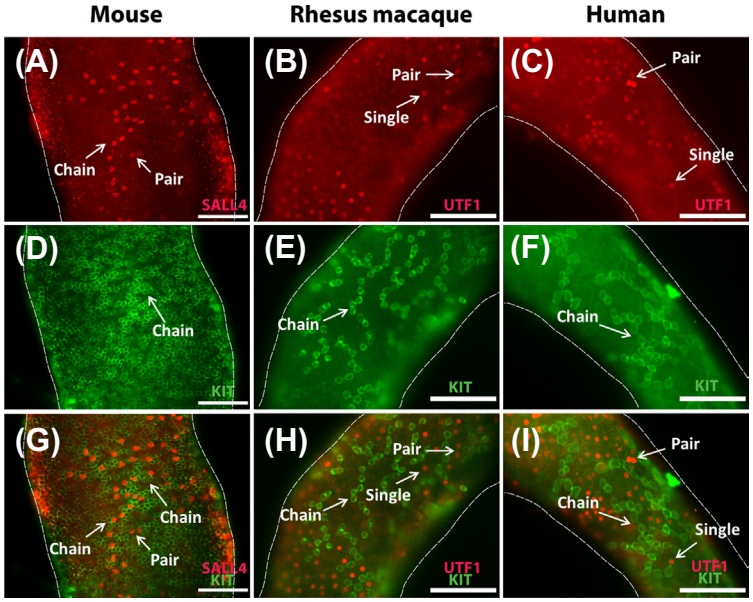

FIGURE 15.12 Whole-mount immunohistochemistry of seminiferous tubules from mouse, rhesus macaque, and human testes. Whole-mount immunofluorescence analysis of the undifferentiated spermatogonia marker, SALL4 (A), differentiating spermatogonia marker, KIT (D) and co-staining of SALL4 and KIT (G) in mouse. Whole-mount immunofluorescence analysis of undifferentiated spermatogonia marker UTF1 (B, C), differentiating spermatogonia marker KIT (E, F), and co-staining of UTF1 and KIT (H, I) in the rhesus macaque (B, E, H) and human (C, F, I). Arrows indicate spermatogonia arranged as single cells, pairs, and larger chains for each species. Scale bar = 100 μm. SALL4, Sal-like 4; UTF1, undifferentiated embryonic cell transcription factor 1.

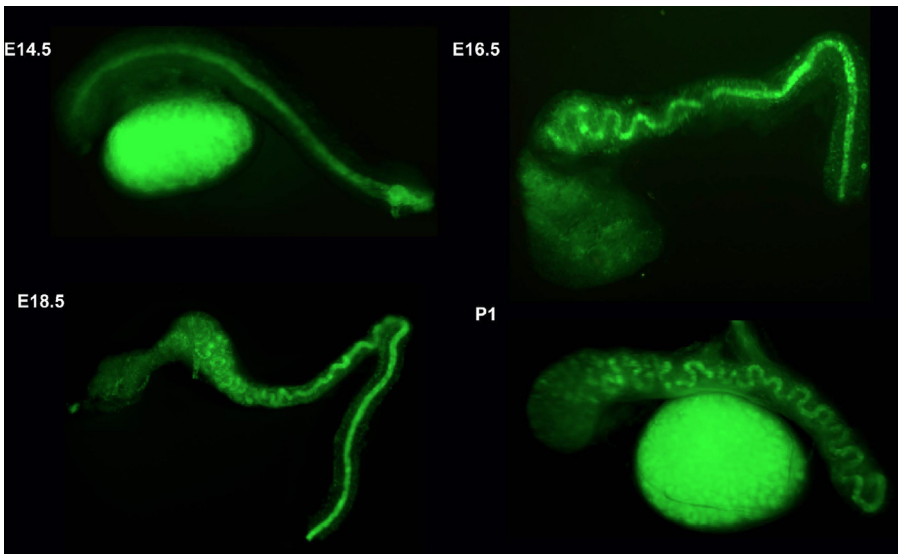

FIGURE 17.2 Wolffian ducts collected from hoxb7-gfp mice at different developmental stages, embryonic (E) days 14.5, 16.5, 18.5 and postnatal (P) day 1. Note how the coiling proceeds from proximal to distal with three-dimensional coiling beginning around 18.5. *Source: Image from Ref. 60.*

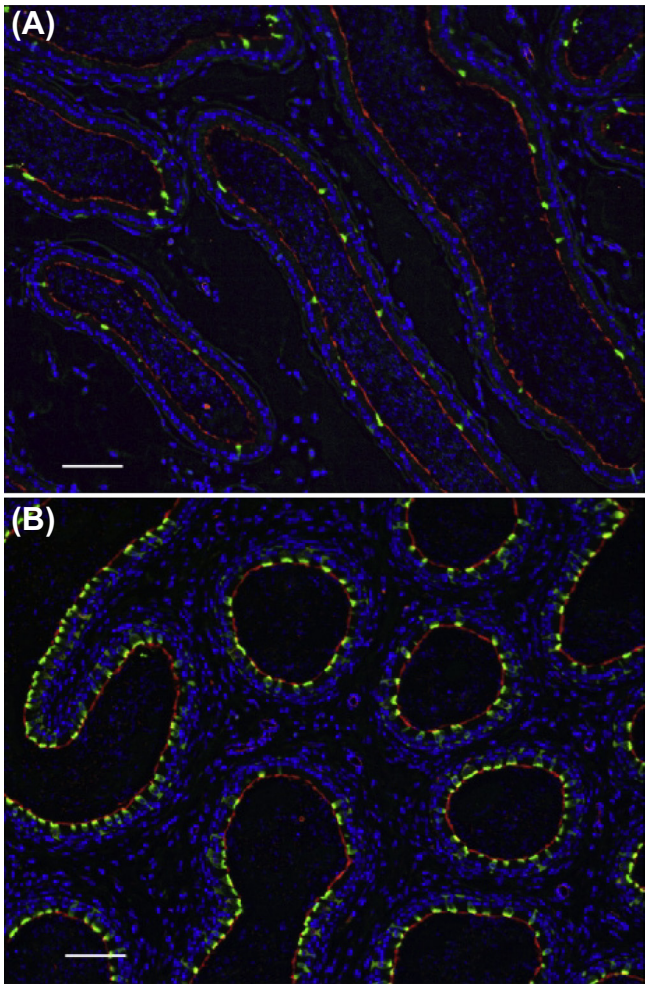

FIGURE 17.8 Relative numbers of clear cells in the rat caput (A) versus cauda (B) epididymidis. Rat epididymis was stained for the V-ATPase B1 subunit (green) to label clear cells, and NHERF1 (red). Nuclei and spermatozoa were stained with DAPI (blue). NHERF1 is located in the apical membrane of both principal cells and clear cells. Clear cells positive for the subunit B-1 or V-ATPase are much more numerous in the cauda (B) than in the caput (A) epididymidis. Scale bars, 50 μm. *Source: Reproduced with permission from Ref. 164.*

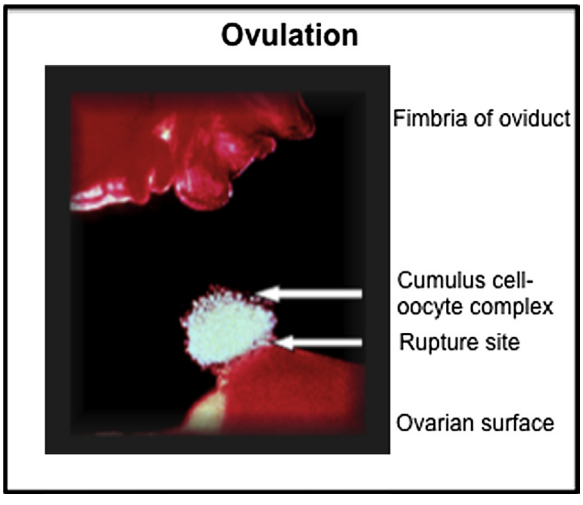

FIGURE 22.1 Moment of rupture of a rabbit follicle. Ovulation of a fertilizable oocyte involves disintegration of the ovarian surface epithelium and extrusion of the expanded cumulus cell–oocyte complex (COC) through the ovulation pore. This is followed by retrieval of the COC by the ciliated cells of the oviduct and its subsequent transport down the oviduct where fertilization occurs. (See text.) *Source: Ref. 3.*

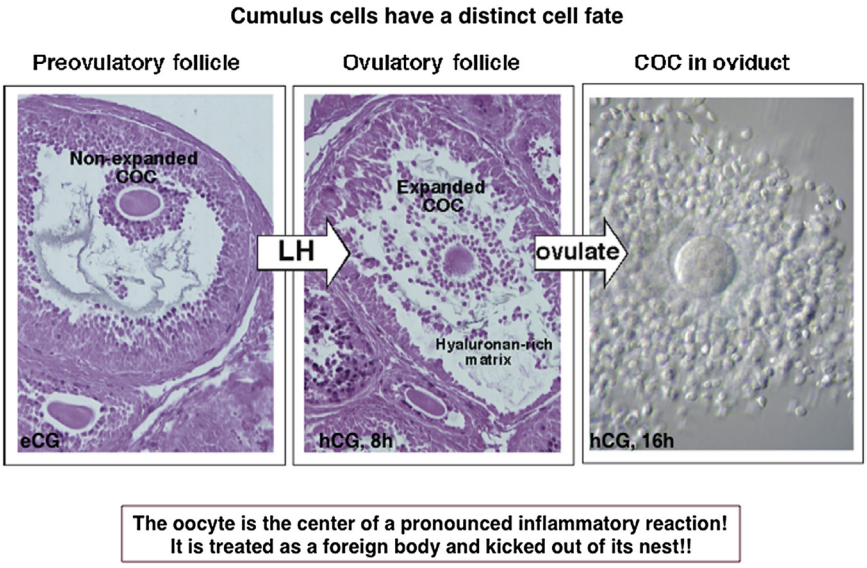

FIGURE 22.3 **The LH surge induces expansion of the cumulus cell-oocyte complex (COC).** Expansion is dependent on the biosynthesis of long polymers of hyaluronan by HAS2. The hyaluronan polymers are stabilized by specific hyaluronan-binding factors including the proteoglycan versican and inflammatory-related factors such as TNFAIP6, IαI, and PTX3. COC expansion is obligatory for release of the enclosed oocyte from the surface of the ovary into the oviduct. (See text.)

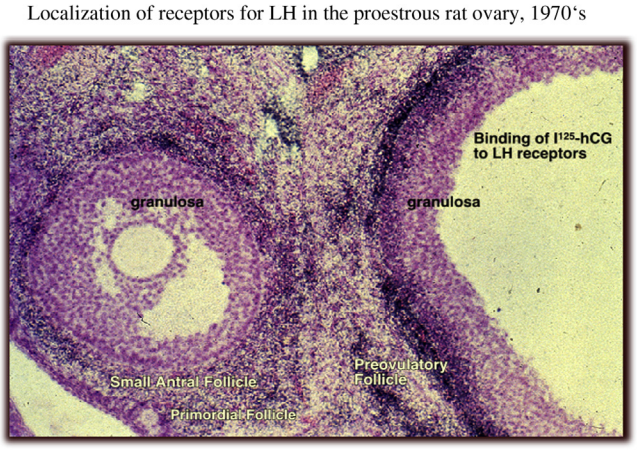

FIGURE 22.5 **Induction of LH receptors (LHR; LHCGR) in granulosa cells is the key distinguishing hallmark of preovulatory follicles.** The presence of LHR in granulosa cells of preovulatory follicles permits them (but not small follicles lacking LHR in granulosa cells) to respond to the LH surge and initiate the molecular programs required for ovulation, COC expansion, resumption of meiosis, and luteinization. This image shows the uptake of radiolabeled hCG (LH) into the theca cells and mural granulosa cells of a preovulatory follicle (right) but only in theca cells of small follicles (left). Primordial follicles do not exhibit detectable uptake of the hormone. Uptake reflects the presence of receptors.

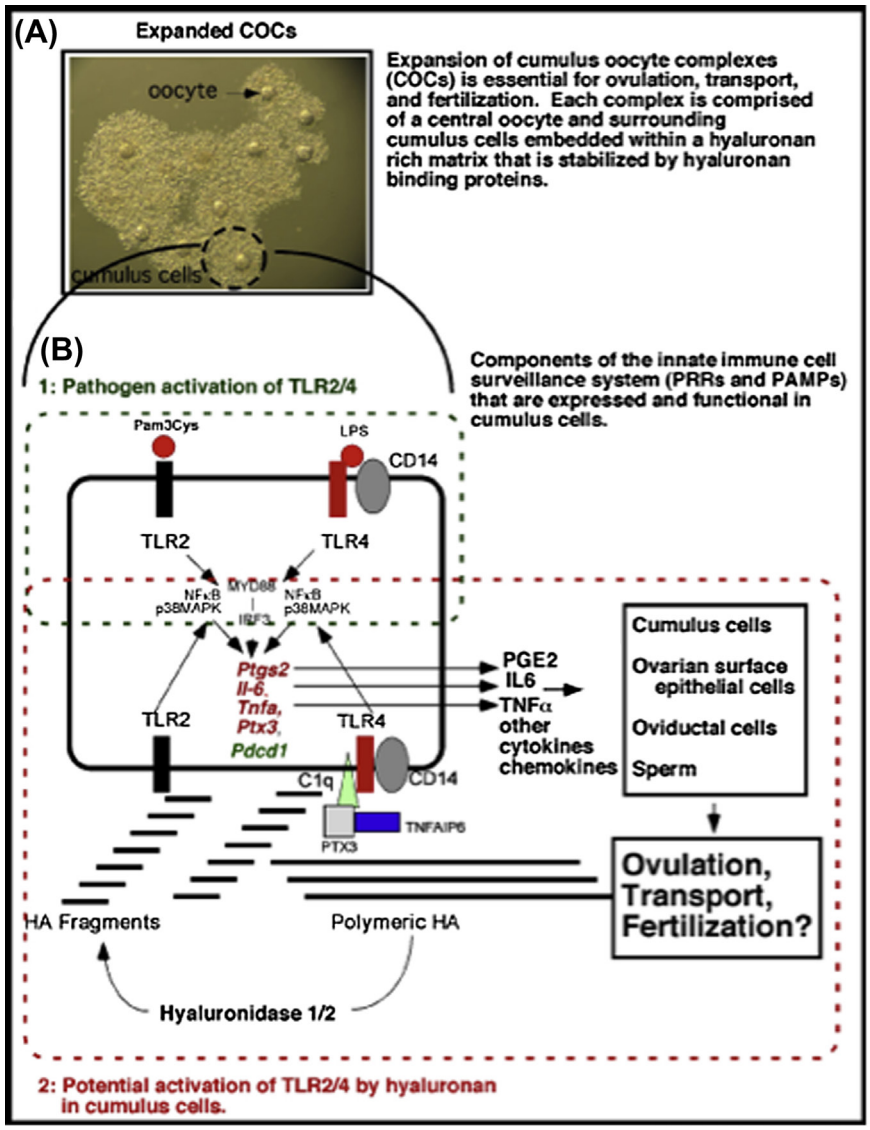

FIGURE 22.12 Schematic of TLR pathway activation and functions in cumulus cells during COC expansion, ovulation, transport and fertilization. (A) In response to the ovulatory surge of LH, cumulus cell–oocyte complexes (COCs) undergo expansion. This process requires the synthesis of a hyaluronan (HA)-rich matrix and factors that bind HA to stabilize the matrix. This process is critical for ovulation. (B) Cumulus cells express members of the Toll-like receptor (TLR) superfamily and can respond to specific ligands (1: pathogen-derived or 2: matrix-derived), leading to the induction of inflammation- and innate immune-related genes. These include: *Ptgs2, Il6, Tnfaip6, Tnfa*, and *Pdcd1*. Prostaglandins (PGE2) synthesized by PTGS2, IL6, and TNFα, as well as other cytokines and chemokines, are released from cumulus cells and can impact the function not only of the cumulus cells but also oviductal cells during transport and sperm during fertilization. The degradation of polymeric HA by hyaluronidases is presumed to lead to the generation of HA fragments that activate TLR2 and TLR4. *Source: Ref.160.*

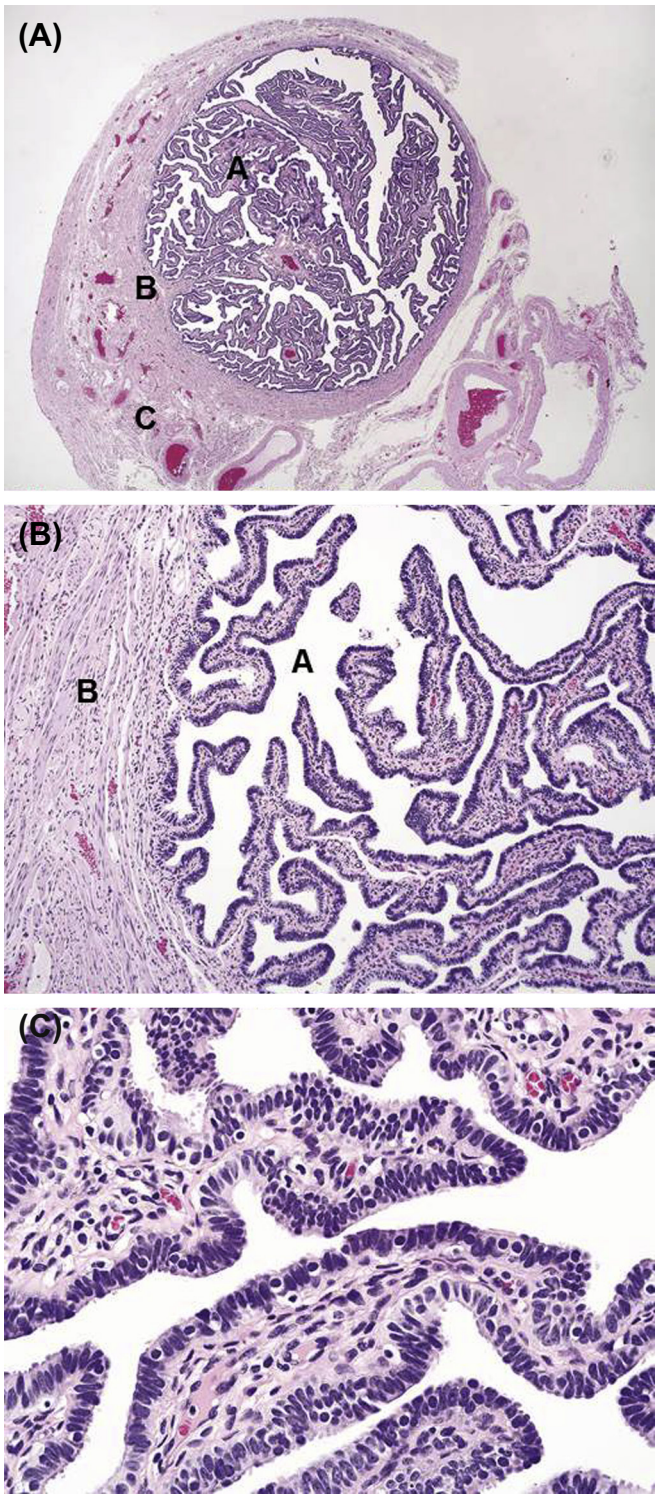

FIGURE 24.2 Cross-section of human fallopian tube, ampulla. Inner mucosa (A) is arranged in longitudinal folds within the middle muscularis (B) and outer serosa (C). The mucosa is lined by a single layer of epithelium (lower panel) composed of ciliated and secretory (nonciliated) cell types. Hematoxylin and eosin (H & E) stain, magnification 20–400×. *Source: Images courtesy of Ramya Massand and Jason Moss.*

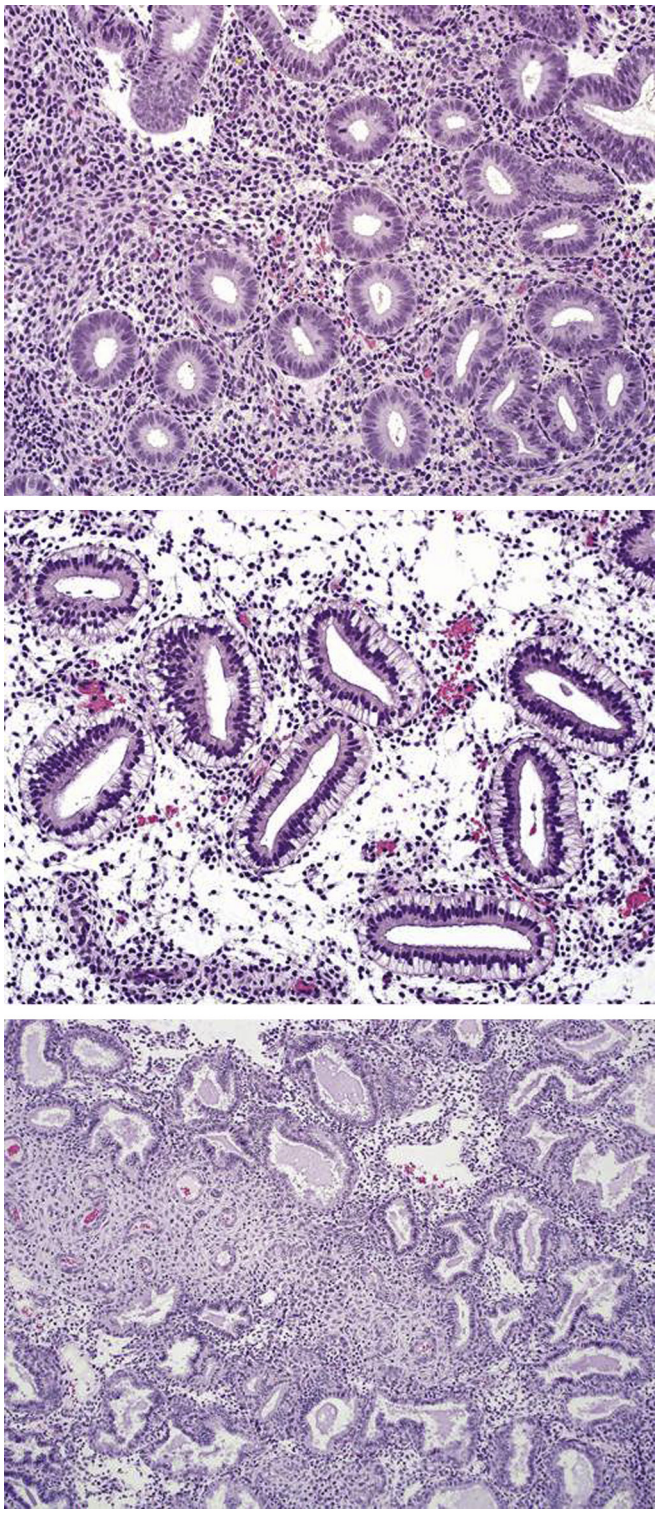

FIGURE 24.4 Human endometrium from proliferative (upper), early-secretory (middle), and late-secretory phases (lower). Note the wide spacing between simple-appearing glands (proliferative), apically displaced nuclei in the glandular epithelium due to glycogen accumulation (middle), and tortuous glands with secretions and a decidualized stroma with abundant pale cytoplasm (lower). H&E stain, magnification 100–200× (Images courtesy of Ramya Massand and Jason Moss).

Color Plates

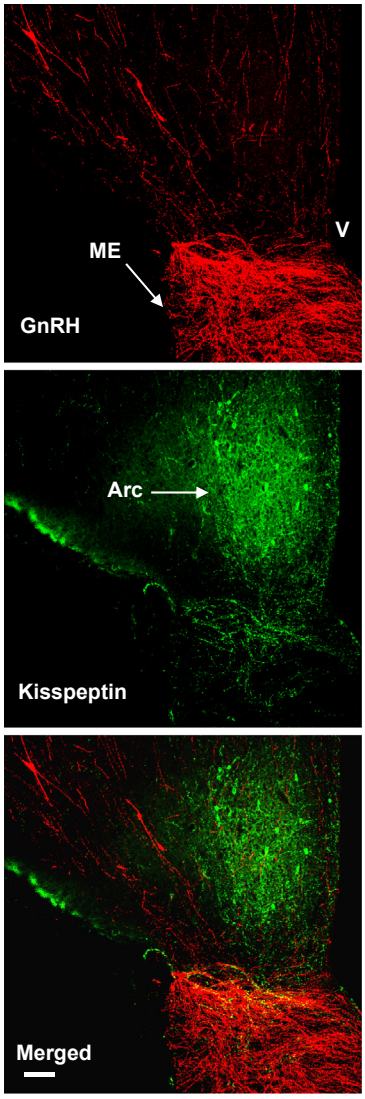

FIGURE 28.3 **A hemi-coronal section through the mediobasal hypothalamus of a castrated rhesus monkey at the level of the arcuate nucleus (Arc), the posited site of the gonadotropin-releasing hormone (GnRH) pulse generator.** The section was doubled labeled by immunofluorescence for GnRH and kisspeptin. Top panel, a confocal image of the distribution of GnRH cell bodies and fibers; middle panel, also a confocal image of the same section showing the corresponding distribution of kisspeptin cell bodies and fibers. The lower panel shows the merged image. Castration results in an upregulation of kisspeptin expression that is associated with robust GnRH pulse generator activity. Note that GnRH cell bodies at this level of the hypothalamus are found lateral to the kisspeptin perikarya in Arc: both sets of neurons send projections to the median eminence (ME) where they closely intermingle. The ependymal lining of the third ventricle (V) may be seen on the right-hand side of the section. Scale bar 100 μm. *Source: Rearranged from Ref. 57, with permission, Copyright 2008, The Endocrine Society.*

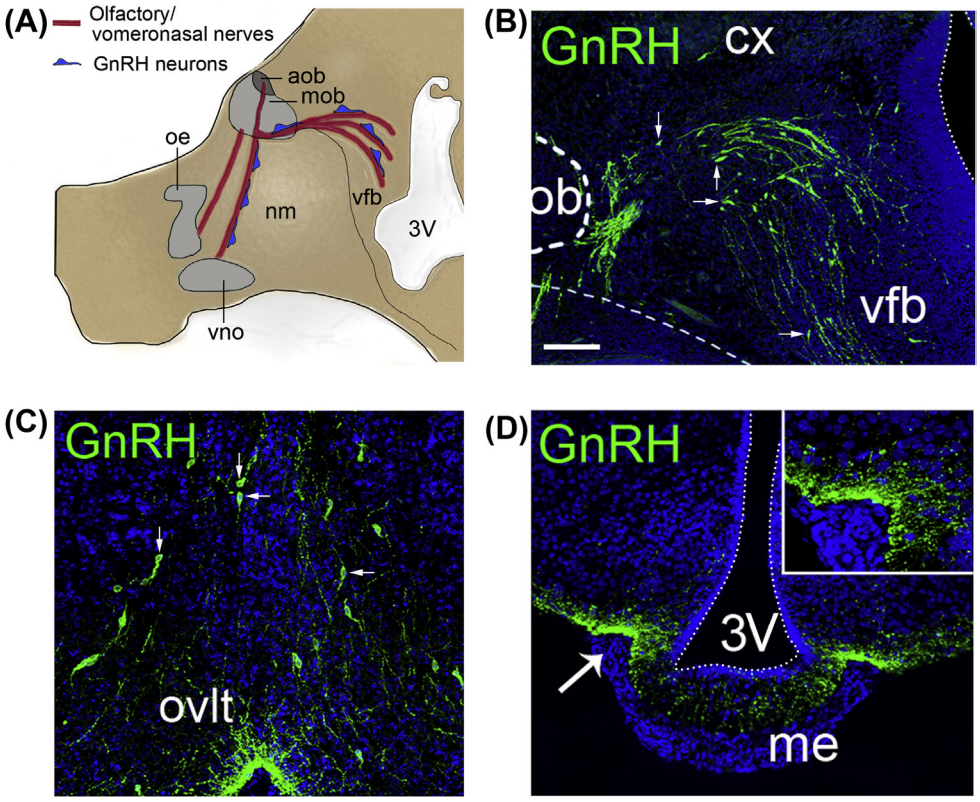

FIGURE 30.1 (A) Schematic representation of the head of a mouse embryo at E14.5, showing the scaffold of vomeronasal/terminal nerve fibers (thick lines) along which GnRH cells (neuron-like shapes) migrate from the nose to the brain. (B) Sagittal section of the rostral and ventral forebrain regions at E14.5, immunolabeled for GnRH. Arrows show GnRH neuronal cell bodies. (C, D) Coronal section of the preoptic region showing GnRH neuroendocrine cells (arrows, C) and their nerve terminals in the median eminence (me, D) in newborn (P0) mice. In D, the inset shows a higher magnification of the area identified by the arrow in the main panel. Abbreviations: oe, olfactory epithelium; vno, vomeronasal organ; nm, frontonasal mesenchyme; mob, main olfactory bulb; aob, accessory olfactory bulb; vfb, ventral forebrain; cx, cerebral cortex; ovlt, organum vasculosum of the lamina terminalis; 3V, third ventricle. Scale bar: 100 μm (50 μm in inset).

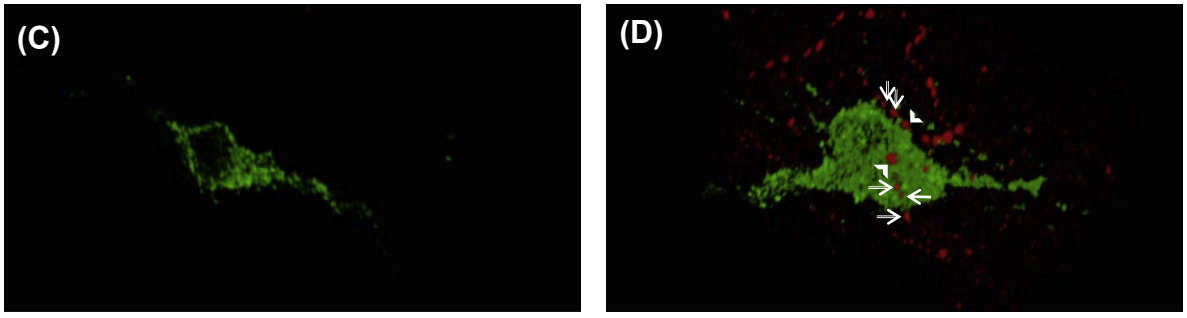

FIGURE 31.8 Changes in LH pulse frequency and kisspeptin during pubertal development. *Panel A*: LH pulse frequency in prepubertal and postpubertal female lambs that were either gonad-intact (Intact) or ovariectomized (OVX). Postpubertal intact lambs were in the early follicular phase. LH pulse frequency was higher in intact postpubertal female lambs than in intact prepubertal female lambs and rose following ovariectomy in the prepubertal, but not postpubertal, lambs. *Panel B*: Kisspeptin-immunopositive cell numbers were greater in postpubertal intact females than prepubertal intact females and increased with ovariectomy in the prepubertal, but not postpubertal, lambs. *Panels C and D*: GnRH neuron from a prepubertal female (panel C) and postpubertal female (panel D). Heavy arrows indicate point of contact between kisspeptin-containing varicosities and the GnRH neuron. Lighter arrows depict kisspeptin-positive nerve fibers. *Panels E and F*: The percentage of GnRH neurons exhibiting at least one kisspeptin close contact (panel E) was greater in intact postpubertal females than intact prepubertal females. This percentage increased with ovariectomy in the prepubertal, but not postpubertal, group. Numbers of contacts per GnRH neuron (panel F) did not differ among groups. *Redrawn from Ref. 72, with permission.*

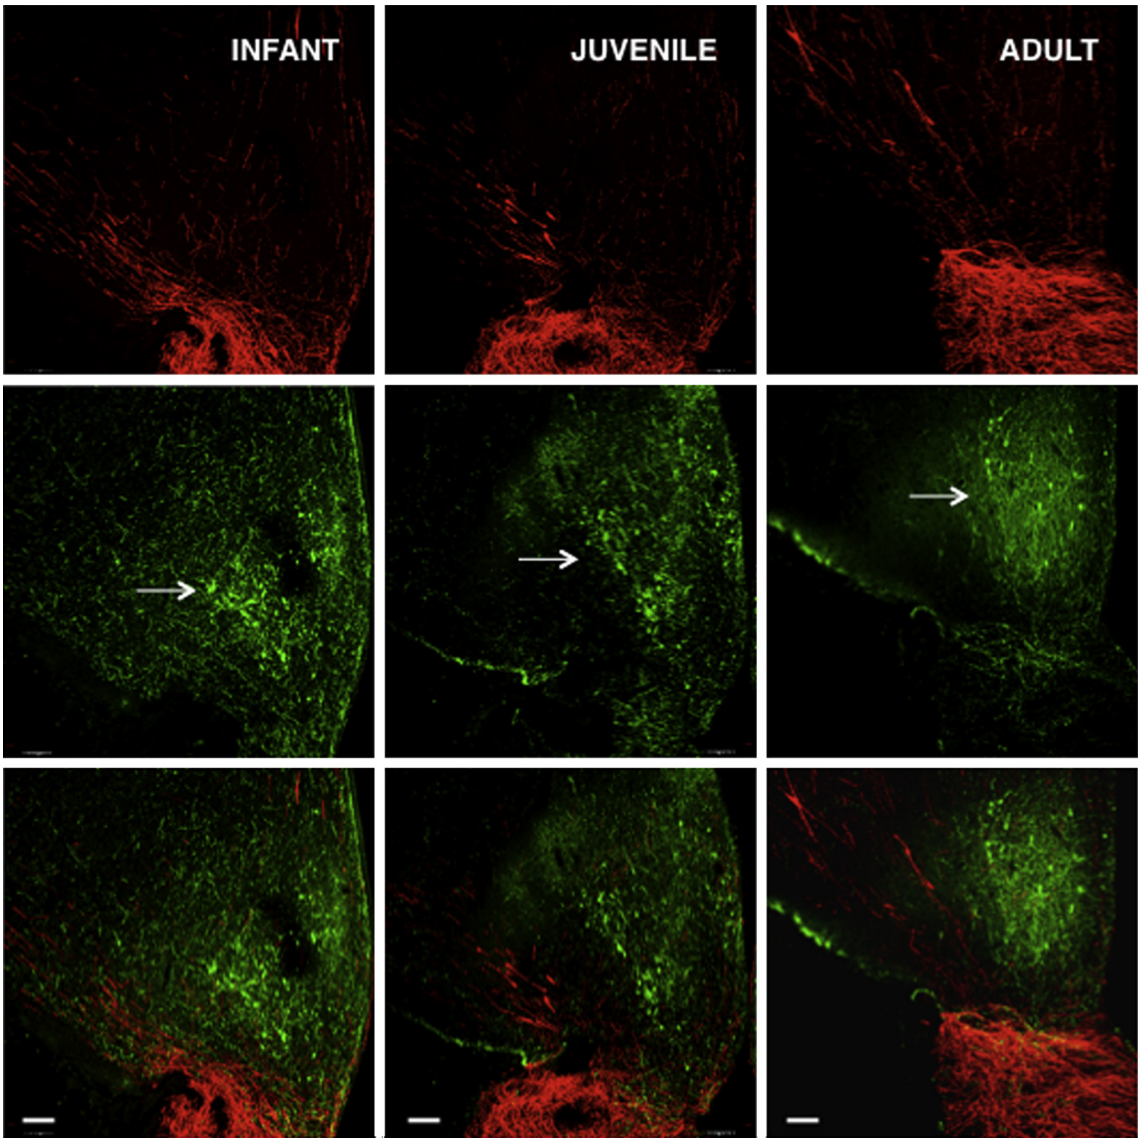

FIGURE 32.6 Confocal images illustrating developmental changes in GnRH (top panels) and kisspeptin (middle panels) neurons (immunopositive perikarya and fibers) in the MBH at the mid-tuberal level during postnatal development in the agonadal male rhesus monkey. The lower panels show the merged images. A hemi-hypothalamic section is shown for an infant (left-hand panels), juvenile (center panels), and adult (right-hand panels) animal; stages of postnatal development corresponding to the on-off-on pattern of GnRH pulse generator activity in primates. Note that kisspeptin immunoactivity is reduced in the juvenile MBH at a time when GnRH pulsatility is arrested but GnRH immunoactivity in the median eminence is maintained during this phase of development. In most cases the ependymal lining of the third ventricle is visible on the right-hand boundary of each hemi-section. *Arrow* indicates kisspeptin neurons in the arcuate nucleus. Scale bar, 100 μm. *Source: Parts of this montage have been reprinted with permission from Refs 170,266.*

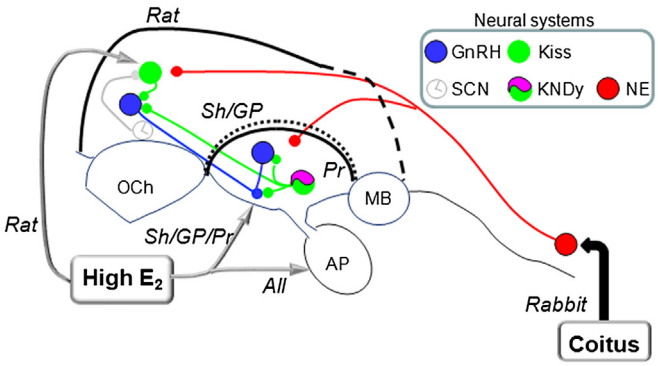

FIGURE 33.8 Schematic of parasagittal section of the hypothalamo–hypophysial unit illustrating the anatomical areas and neural systems participating in the preovulatory GnRH surge and sites of E_2 positive feedback in various species. All structures are required in rabbits; in other species, solid lines depict knife cuts that had no effect on the surge. Dotted lines are cuts that only decreased the amplitude of the LH surge, and the dashed line illustrates that NE input is normally required for the surge in rats but can be compensated for under some circumstances. See the text for more details. AP: anterior pituitary; GP: guinea pig; MB: mammillary body; OCh: optic chiasm; Pr: primate; Sh: sheep.

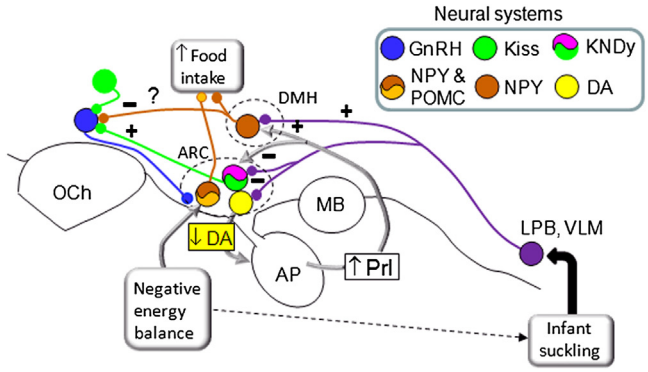

FIGURE 33.12 Neural systems stimulating food intake and inhibiting GnRH secretion during lactation in the rat. The suckling stimulus is transmitted to the hypothalamus via neurons in the lateral parabrachial nucleus (LPB) and ventrolateral medulla (VLM), inhibits DA release from tuberoinfundibular dopaminergic (TIDA) neurons and kisspeptin release from KNDy neurons, and stimulates NPY neural activity in the DMH. The fall in DA allows prolactin secretion to increase, which further inhibits KNDy kisspeptin and stimulates NPY from the DMH. The latter increases food intake, while the former inhibits GnRH secretion. At the same time, the negative energy balance in the mother induced by the demands of the offspring acts via the metabolic homeostatic circuitry in the ARC (increased NPY–AgRP and decreased POMC–CART), which also acts to stimulate food intake and may inhibit GnRH secretion. Note that this circuitry is depicted by a single neural element (NPY and POMC) for simplicity. Similarly, orexogenic neurons in the LHA and anorexogenic CRH neurons in the PVN are not illustrated.

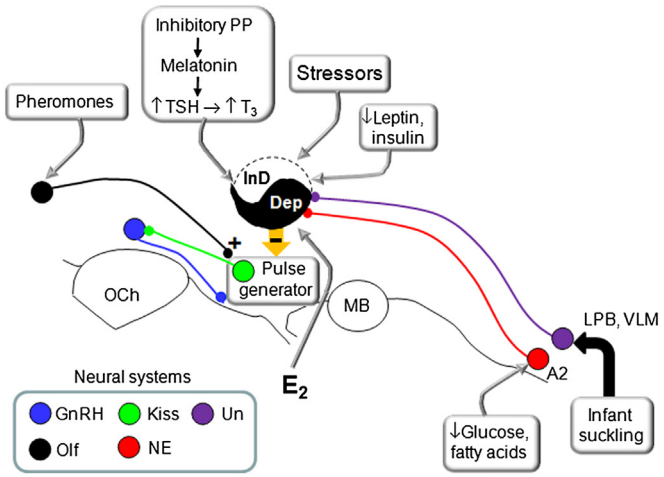

FIGURE 33.13 Schematic of parasagittal section of the hypothalamus illustrating mechanisms by which different external factors alter episodic GnRH secretion. Note that neural inputs are conceptual and do not represent monosynaptic pathways. See the text for more details. Dep: steroid-dependent mechanisms; InD: steroid-independent mechanisms; Kiss: kisspeptin; NE: norepinephrine; Olf: olfactory epithelium; Un: unknown neurotransmitter.

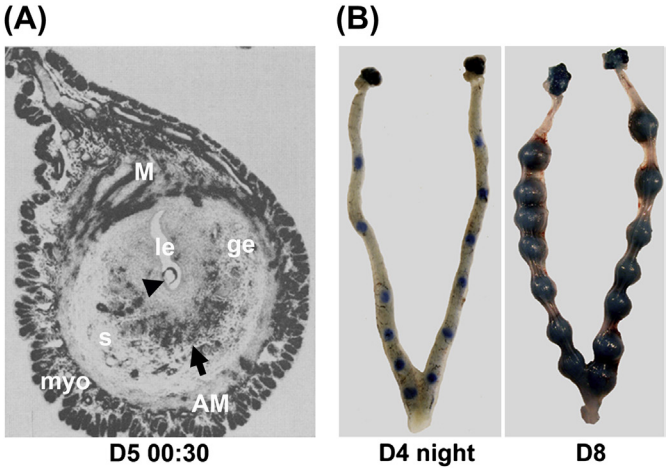

FIGURE 38.1 Increased endometrial vascular permeability upon attachment and implantation in the mouse. (A) Transverse section of uterus on day 5 (D5) early morning (00:30) of pregnancy showing implantation at the antimesometrial pole within a crypt (arrowhead). This section also shows weak alkaline phosphatase activity in the uterine stroma (black, arrow). Note the edema in the outer areas of the mucosa, contrasting with the closely packed cells around the uterine lumen (presumptive primary decidual zone). Le, luminal epithelium; ge, glandular epithelium; s, stroma; myo, myometrium; M, mesometrial pole; AM, antimesometrial pole. *(Source: Reprinted with permission from Ref. 2.)* (B) Increased vascular permeability at the sites of blastocyst attachment with the uterine luminal epithelium was detected after an intravenous injection of a blue dye (Chicago Blue B6) solution in mice at midnight of day 4 (D4) and day 8 (D8) of pregnancy. On day 4, distinct blue bands (dark bands in this picture) indicate that the attachment process has been initiated.

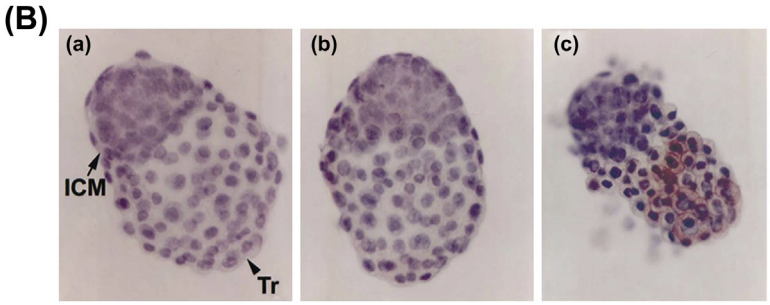

FIGURE 38.4 Molecular markers for blastocyst dormancy and activation. (B) Dormant blastocysts recovered from P_4-primed delayed-implanting mice on day 7 were cultured for 24 h in Whitten's medium, in the presence of (a) vehicle; (b) E_2; or (c) 4-OH-E_2. Blastocysts were processed for immunostaining and counterstained with hematoxylin. Red deposits indicate the sites of immunoreactive COX2. ICM, inner cell mass; Tr, trophectoderm. *Source: Reprinted with permission from Refs 67,137.*

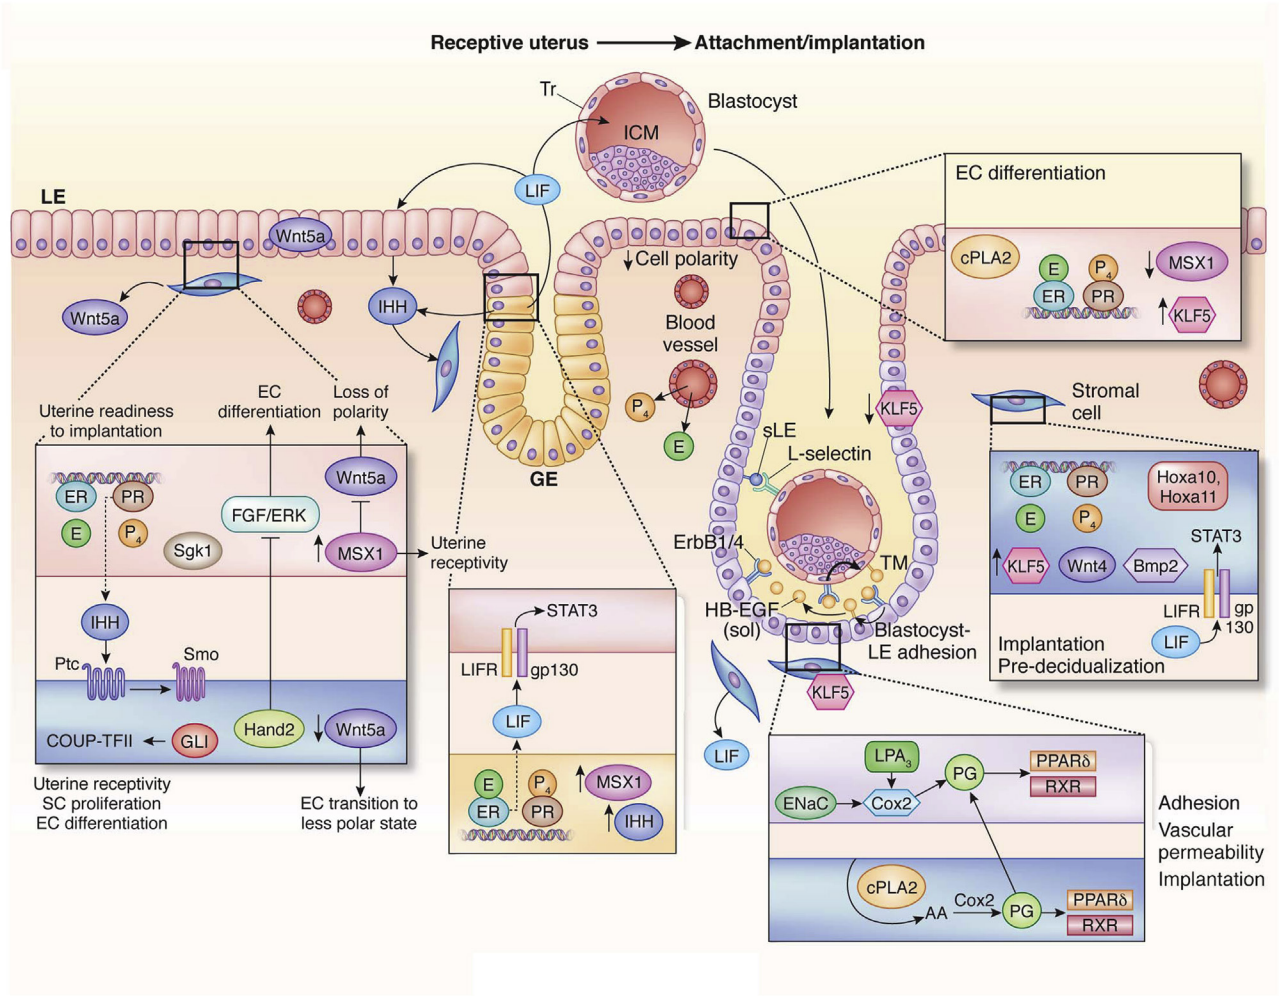

FIGURE 38.5 Signaling network for uterine receptivity and implantation. This is a hybrid cartoon, based on mouse and human studies, portraying compartment- and cell type–specific expression of molecules and their potential functions necessary for uterine receptivity, implantation, and decidualization. Interplay of ovarian P_4- and/or E_2-dependent and P_4- and/or E_2-independent factors in the pregnant uterus in specific compartments contributes to the success of implantation in a juxtacrine–paracrine–autocrine manner. During attachment, interactions between the blastocyst and luminal epithelium (LE) involve ErbB1/4 (blue) and both transmembrane (TM) and soluble (Sol) forms of HB-EGF, as well as L-selectin ligands (sLE) expressed by the luminal epithelium to L-selectin receptors on the blastocyst. The other key signaling pathways for uterine receptivity and implantation are also shown. AA, arachidonic acid; BMP2, bone morphogenetic protein 2; cPLA2α, cytosolic phospholipase A2α; COUP-TFII, chicken ovalbumin upstream promoter transcription factor 2; Cox2, cyclooxygenase 2; E, estrogens; EC, epithelial cell (luminal and glandular epithelia); ENaC, epithelium sodium channel; ER, estrogen receptor; ErbB1/4; epidermal growth factor receptor 1/4; ERK, extracellular signal–regulated kinase; FGF, fibroblast growth factor; GE, glandular epithelium; gp130, glycoprotein 130; Hand2, heart- and neural crest derivatives–expressed protein 2; HB-EGF, heparin-binding epidermal growth factor-like growth factor; Hoxa10/11, homeobox A10/11; ICM, inner cell mass; IHH, Indian hedgehog; KLF5, Kruppel-like factor 5; LIF, leukemia inhibitory factor; LIFR, LIF receptor; LPA3, lysophosphatidic acid receptor 3; MSX1, muscle segment homeobox 1; P_4, progesterone; PG, prostaglandin; PPAR-δ; peroxisome proliferator-activating receptor δ; PR, progesterone receptor; Ptc, Patched; RXR, retinoid X receptor; SC, stromal cell; SGK1, serum- and glucocorticoid-inducible kinase 1; Smo, Smoothened; STAT3, signal transducer and activator of transcription 3; Tr, trophectoderm; Wnt4/5a, Wingless-type MMTV integration site family members 4/5a. Compartment colors: blue, stroma; pink, luminal epithelium; orange, glandular epithelium; purple, epithelium at the attachment site. *Source: Reprinted with permission from Ref. 153.*

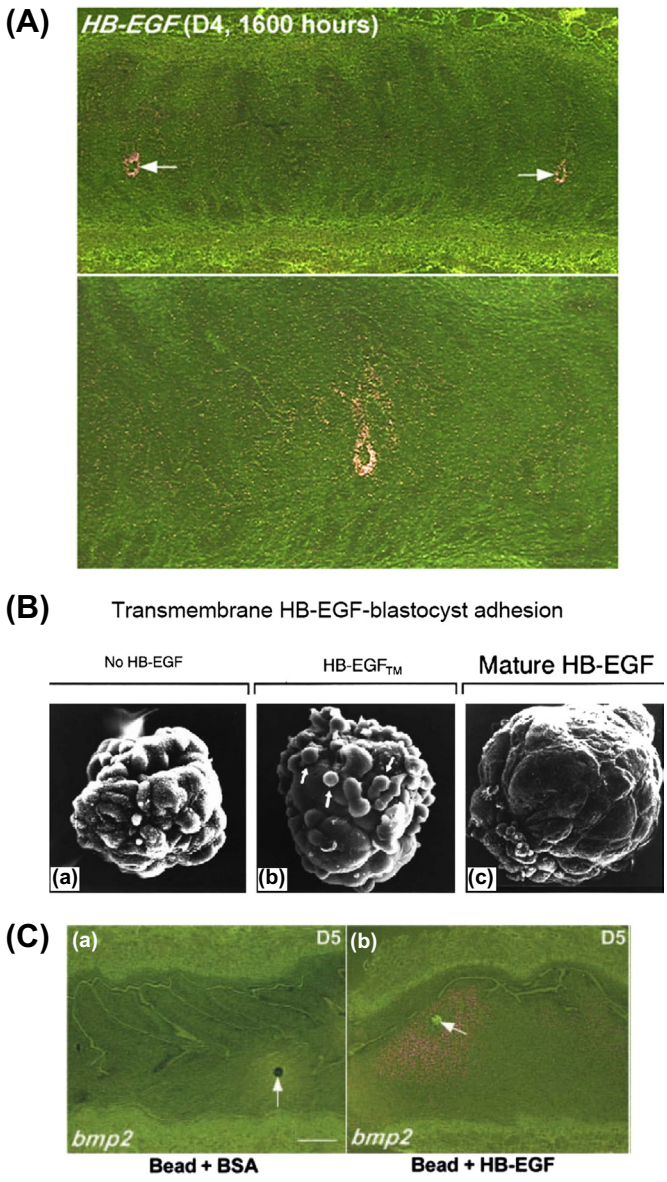

FIGURE 38.6 HB-EGF serves as a reciprocal mediator between the luminal epithelium and activated blastocyst during attachment reaction. (A) In situ hybridization of HB-EGF mRNA (dark-field) in the mouse uterus at 1600 h on day 4 of pregnancy. Note distinct hybridization signals in luminal epithelial cells surrounding two blastocysts in a longitudinal section. Arrows demarcate location of blastocysts. (B) Scanning electron microscopy of blastocysts co-cultured with 32D cells (a murine myeloid cell line). Zona-free day 4 (0900 h) mouse blastocysts were co-cultured with (a) parental 32D cells, (b) 32D cells displaying transmembrane form of HB-EGF^{TM}, or (c) 32D cells synthesizing soluble form of HB-EGF for 36 h. After extensive washing to remove loosely adhering cells, blastocysts were fixed and examined by scanning electron microscopy; magnification 800×. Arrows point to 32D cells. (C) *Bmp2* gene expression in response to beads preloaded with HB-EGF. Beads (7 beads/horn) preabsorbed either in BSA (control) or HB-EGF (100 ng/ml) were transferred into uterine lumens of day 4 pseudopregnant mice. Mice were killed on day 5 to examine *Bmp2* expression at the sites of beads. Arrows indicate the locations of the beads. Note localized stromal expression of *Bmp2* at the sites of beads preabsorbed with HB-EGF. Bar: 75 mm. *Source: Reprinted with permission from Refs 9,135,220.*

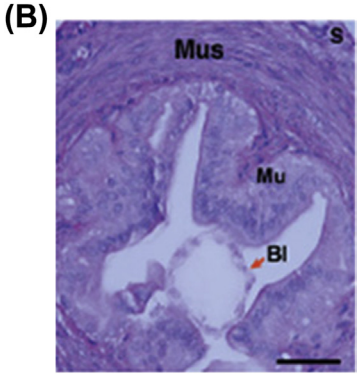

FIGURE 38.7 Impaired oviductal embryo transport causes pregnancy loss in *Cnr1*$^{-/-}$ but not *Cnr2*$^{-/-}$ mice. (B) A representative histological section of a day 7 pregnant *Cnr1*$^{-/-}$ oviduct showing an entrapped blastocyst (Bl, arrow) at the isthmus. Mus, muscularis; S, serosa; Mu, mucosa. Bar, 100 μm. *Source: Reprinted with permission from Ref. 394.*

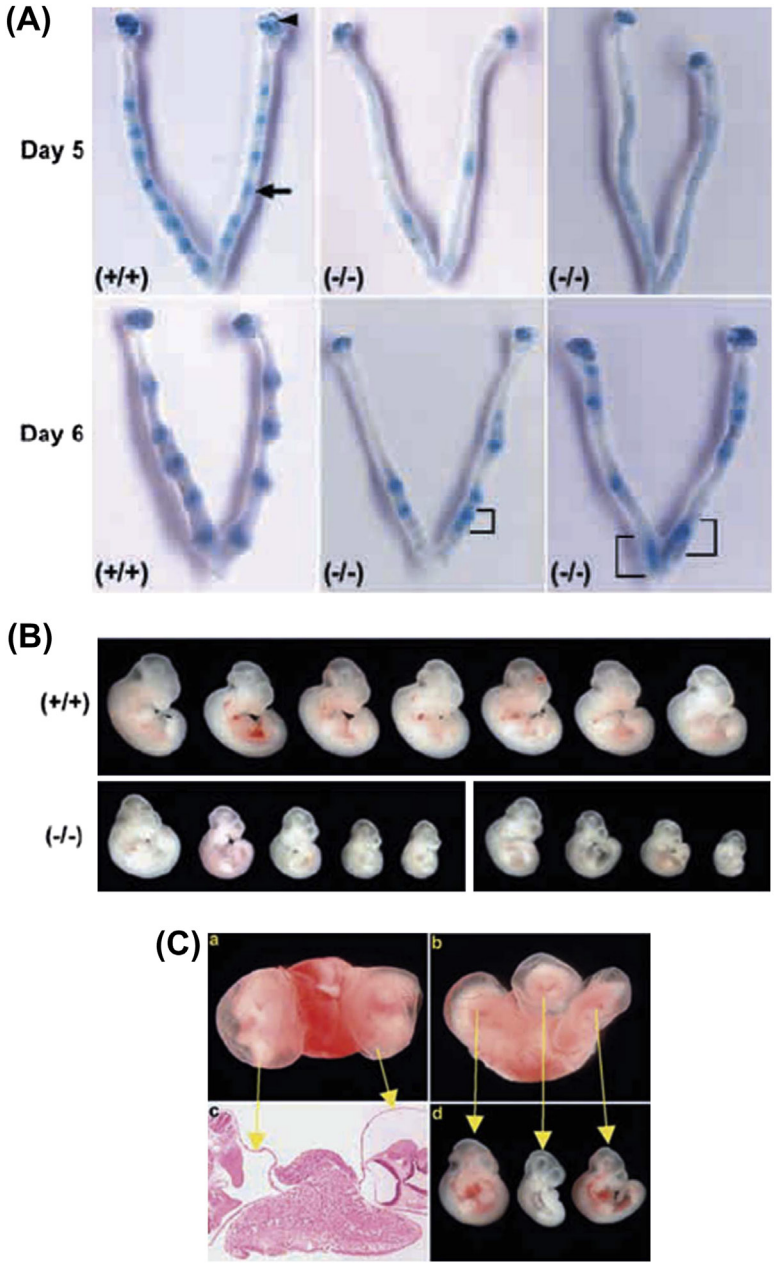

FIGURE 38.8 **Defective postimplantation development in *Pla2g4a*$^{-/-}$ mice.** (A) Representative photographs of uteri with implantation sites (blue bands) on days 5 and 6. Note very few or no implantation sites on day 5, but unevenly spaced implantation sites on day 6 in *Pla2g4a*$^{-/-}$ mice. Arrowhead and arrow indicate ovary and implantation site, respectively. Brackets indicate crowding of implantation sites. (B) Photographs of embryos isolated from implantation sites of one representative wild-type and two *Pla2g4a*$^{-/-}$ mice on day 12. Note retarded and asynchronous development of embryos in *Pla2g4a*$^{-/-}$ mice. (C) Representative photographs of conjoined embryos in a placenta (a, c) and three embryos in the same decidual envelope (b, d) from *Pla2g4a*$^{-/-}$ mice on day 12. (c) A histological section of (a) with two embryos; embryos shown in (d) are from (b). Yellow arrows indicate the source of the embryos from the decidual envelope. *Source: Reprinted with permission from Ref. 47.*

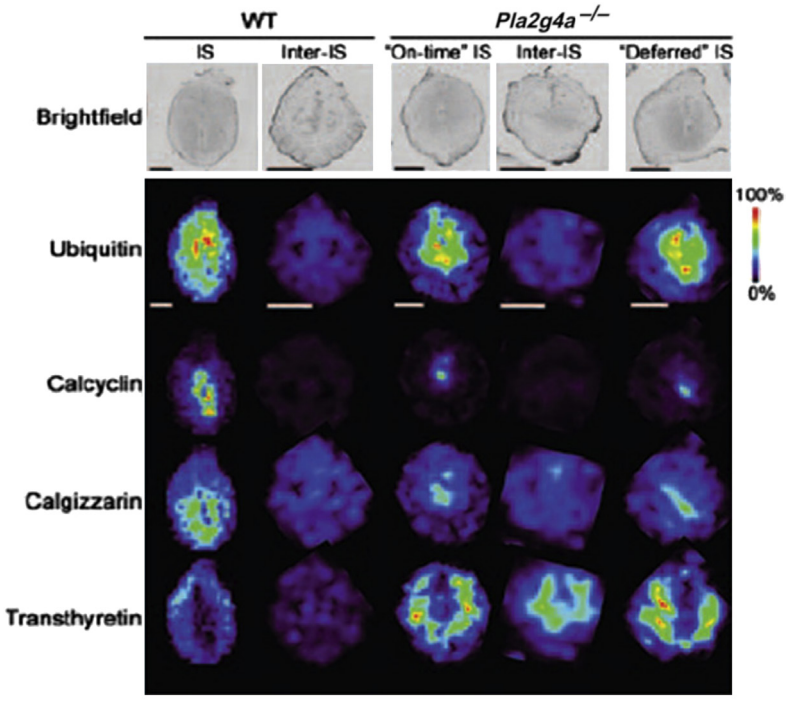

FIGURE 38.9 **Proteome profiles differ between WT and *Pla2g4a*$^{-/-}$ uteri on day 6 of pregnancy, regardless of implantation timing.** Optical images of a WT implantation site (IS) and interimplantation site (inter-IS) and *Pla2g4a*$^{-/-}$ deferred and on-time IS (*upper panel*). Bar, 670 μm. Ion intensity maps are shown below their respective bright-field images. *Source: Reprinted with permission from Ref. 480.*

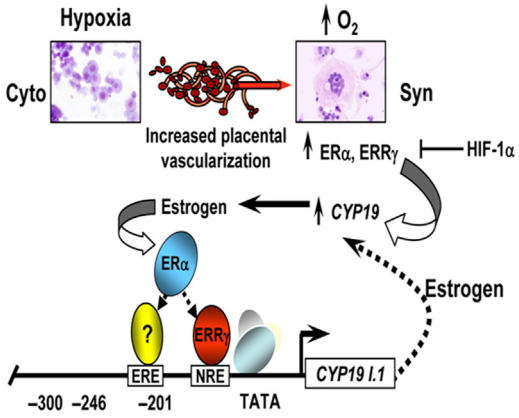

FIGURE 40.12 Model of hCYP19 regulation in human trophoblasts. Early in gestation, the placenta is relatively hypoxic; the elevated levels of HIF-1α inhibit ERRγ transcription via interaction with a response element (HRE) in the ERRγ promoter. This, together with hypoxia-mediated induction of basic helix–loop–helix factors ASCL2 and USF1/2, blocks syncytiotrophoblast differentiation and hCYP19 gene expression. After the ninth week of gestation, increased placental vascularization results in increased oxygen availability to the trophoblast cells. The consequent decrease in HIF-1α levels and the expression of other inhibitory transcription factors cause upregulation of ERRγ and induction of hCYP191.1 transcription. The increased estrogens produced, in turn, activate ERα, which may functionally interact with ERRγ and other activating transcription factors to further upregulate hCYP19 expression. *Source: Reprinted with permission from Ref. 360.*

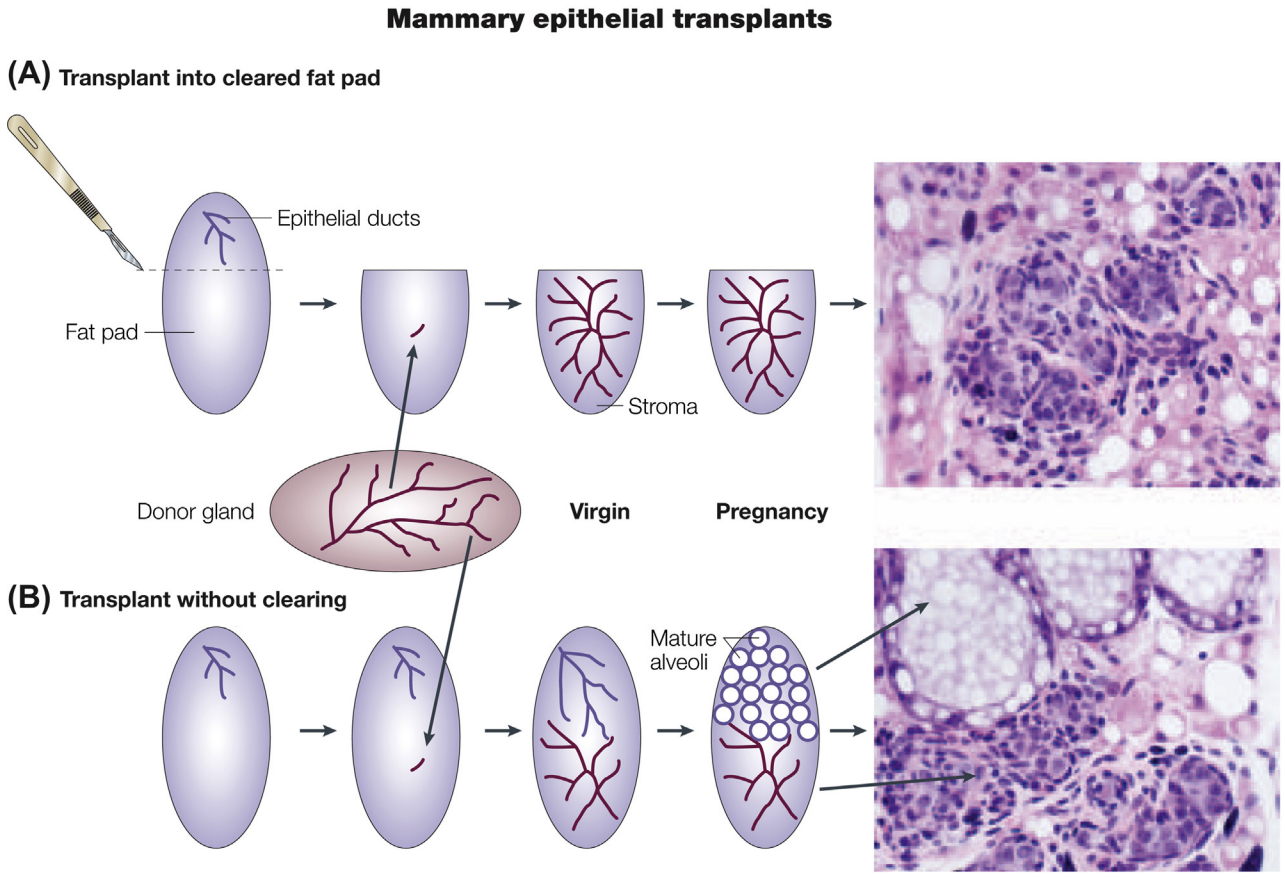

FIGURE 46.2 Use of mammary gland transplantation to assess developmental potential. (A) The area containing the ductal anlage (purple) in a 3-week-old mouse is surgically removed to generate a "cleared fat pad" into which donor tissue (dark pink) is transplanted. The development of the transplanted tissue is monitored at intervals posttransplant by either whole mount or standard histological analysis. (B) An alternative approach involves direct transplantation into a non-cleared mammary gland. Transplanted cells are frequently marked with either immune-fluorescent markers, genetic markers, or infected with viruses expressing detectable markers. *Source: Used by permission from Macmillan Publishing Company; Ref. 14.*

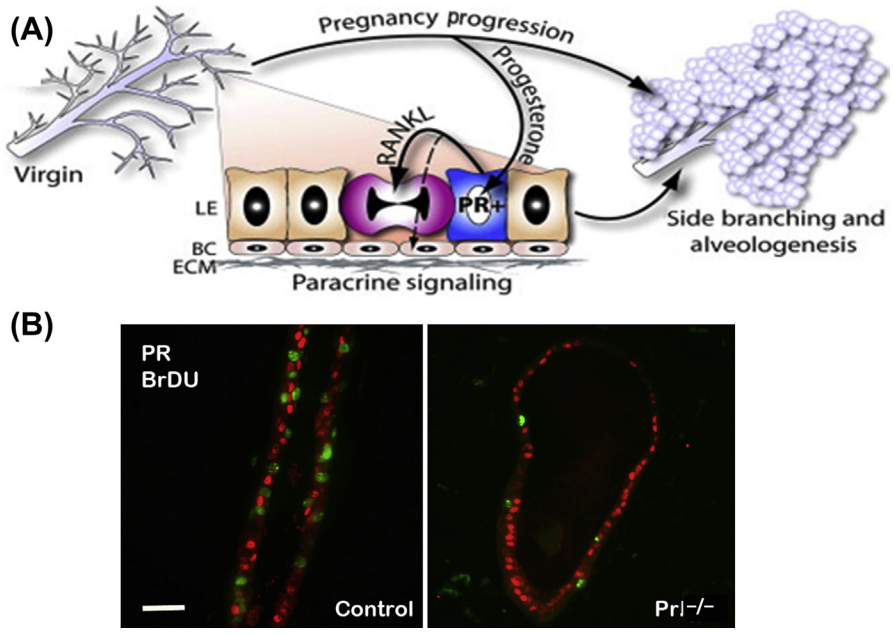

FIGURE 46.4 Role of paracrine signaling in alveologenesis. (A) As pregnancy progresses side branches develop at discreet intervals along the ducts; cells in these side branches proliferate to form alveoli. The progesterone receptor (PR) is expressed in a subset of alveolar cells that are stimulated by increasing P4 from the ovaries to secrete RANKL. This paracrine factor acts on neighboring cells to promote proliferation. (B) Expression of PR and proliferating cells after 2 days of treatment with E2 and P4 in wild-type (control) and PRL-null mice. Proliferating cells (BrDU labeled, green) and PR positive cells (red) are generally not coincident. Note that the number of proliferating cells is reduced in the absence of PRL. Scale bar, 50 μm. *Source: (A) Used by permission from Ref. 93. (B) Original figure from Ref. 64.*

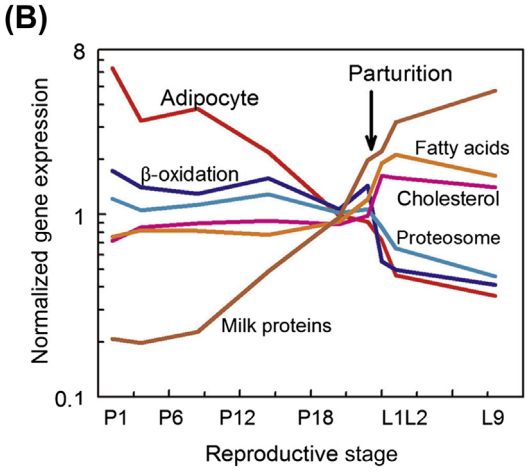

FIGURE 46.5 Changes in the differentiated activity of the mammary gland in pregnancy and lactation. (B) Changes in gene expression of different categories of genes in the mouse mammary gland from microarray studies. Expression of adipocyte-specific genes and collagens (not shown) decreases six- to eightfold during pregnancy and another twofold at parturition, whereas the genes for fatty acid degradation and many components of the proteosome are level during pregnancy and decrease about twofold at parturition. Milk protein genes, on average, increase about fivefold during pregnancy and another threefold around parturition, whereas the genes for fatty acid and cholesterol synthetic enzymes increase about twofold just after parturition. Normalized data for each class were averaged to produce the lines on this graph. *Source: (B) From Ref. 11.*

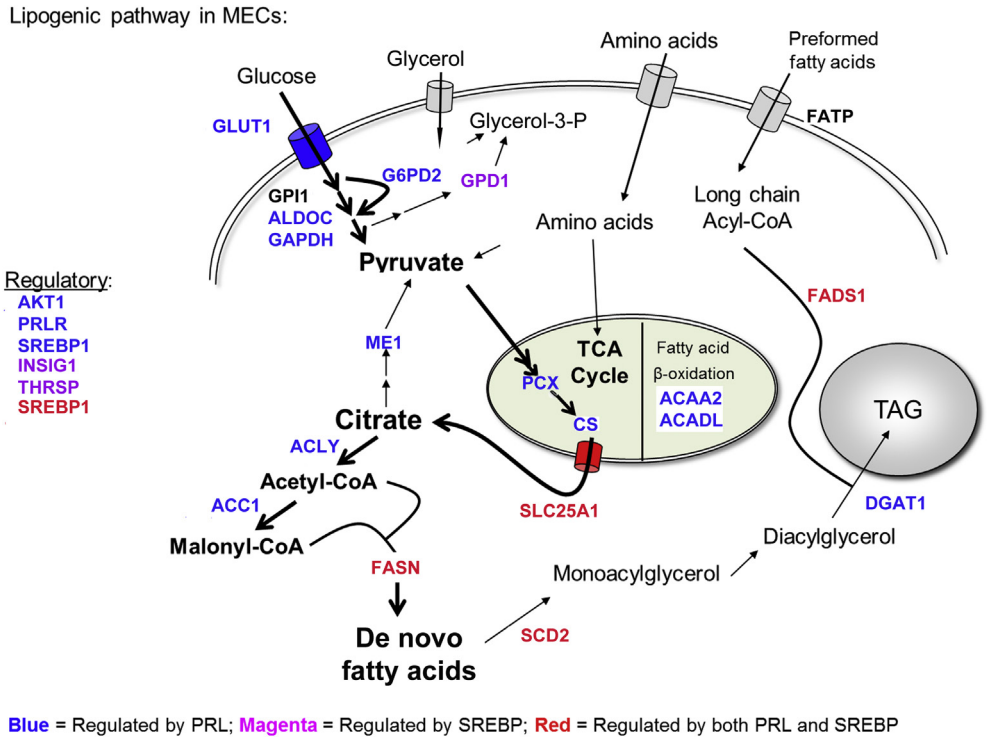

FIGURE 46.7 **Lipid synthesis pathways in mammary epithelial cells during lactation.** Substrates for lipid synthesis enter the cells via the glucose transporter (GLUT1), a glycerol transporter, as amino acids, or as preformed fatty acids via a fatty acid transport protein (FATP). Glycolysis leads to the production of both glycerol-3-phosphate and pyruvate from glucose. The genes for several enzymes in this pathway, fructose bis-phosphate aldolase (ALDOC) and glycerol-3-phosphate dehydrogenase (GAPDH), as well as glycose-6-phosphate dehydrogenase (G6PD2 in the mammary gland) are all upregulated by prolactin along with mitochondrial genes for pyruvate carboxylase (PCX) and citrate synthase (CS). Glycerol-3-phosphate is formed from dihydroxyacetone phosphate, a product of glycolysis, by glycerol-3-phosphate dehydrogenase (GPD1) to be used as a backbone for triacylglyceride (TAG) synthesis. GPD1 is regulated by SREBP. Amino acids are transformed into pyruvate and other substrates that enter the mitochondria to be transformed into citrate, which is exported via the tricarboxylic acid transporter, SLC25A1. Citrate is the major substrate for de novo synthesis of fatty acids in species other than ruminants, which utilize acetate for this purpose. Citrate is transformed into acetyl-CoA by ATP citrate lyase (ACLY), then to malonyl CoA by acetyl-CoA carboxylase (ACC1), and finally to saturated fatty acids with 8–16 carbons (C:8–C:16) by fatty acid synthase (FASN). Cytosolic malic enzyme (ME1) and the enzymes of the pentose phosphate shunt both provide the necessary reducing molecule NADPH that is required for activity of FASN. C:16 fatty acids can be desaturated by stearoyl-CoA desaturase (SCD2) prior to being esterified into monoacylglycerol, then diacylglycerol, and finally into triacylglycerols, with subsequent integration of the fatty acids derived from preformed sources. The final step in the TAG synthesis pathway is catalyzed by diglyceride acyltransferase (DGAT1). The TAG coalesce into lipid droplets. Both prolactin and SREBP have been shown to regulate the genes for FASN, SLC25A1, SCD2, and FADS1. *Source: Diagram derived from data in Refs 19,20.*

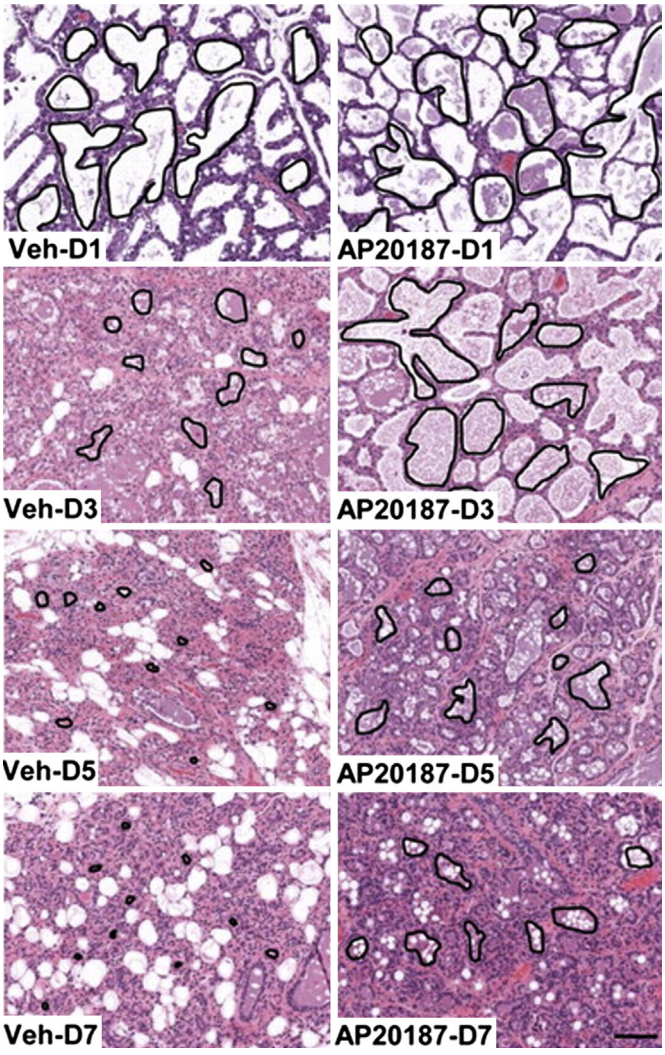

FIGURE 46.9 The role of macrophages in mouse mammary gland involution; histological analysis. Glands from Mafia mice were analyzed on days 1, 3, 5, and 7 after pup removal from a 10-day lactating mouse suckling five to six pups. Three days prior to pup withdrawal experimental dams were given a dose of AP20187, which depletes macrophages in this strain. Left-hand images, vehicle only (macrophages present); right-hand images, AP20187 (macrophages depleted). In both control and experimental mice marked luminal expansion is evident 1 day after removal of pups (some lumens outlined in black for illustration). In vehicle-only mice a marked decrease in lumen size by day three is observed as milk is resorbed. Very small lumens remain on day 7, however significant numbers of lipid filled adipocytes are evident between the alveoli starting on day three and increasing to day 7. These changes occur much more slowly in the glands of AP20197-treated mice, providing evidence that macrophages are required for several aspects of normal involution. *Source: Reproduced by permission from Ref. 183; link at Development:* dev.biologists.org.

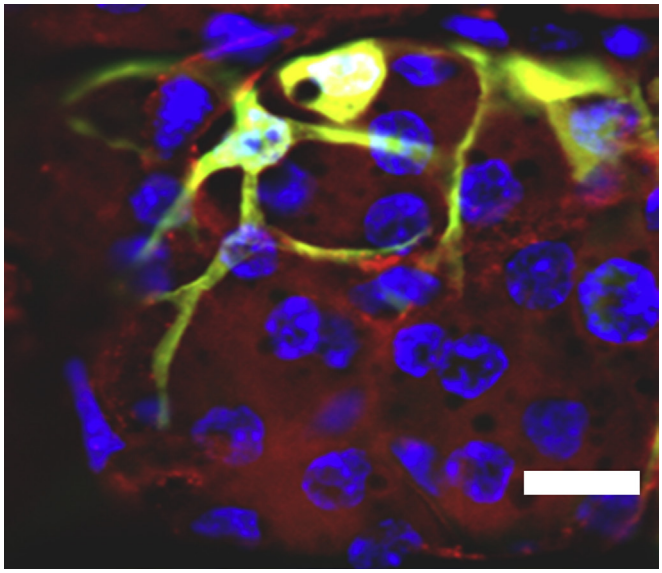

FIGURE 46.19 Myoepithelial cell in the mammary gland of a lactating mouse. The cell has been transduced with adenoviral GFP (yellow) showing processes embracing the luminal epithelial cells (red). Nuclei stained with DAPI (blue). Scale bar 10 μm. *Source: From Russell T, Fischer A, Beeman N, Freed E, Neville MC, Schaack J. FIGURE 47.7 Four ways that sex chromosomes could affect gene expression. Four possible classes of primary sex-determining factors are recognized. Class I comprises Y genes that have a male-specific effect on one or more tissues. Class II is X genes that are expressed at a higher level in females than males by virtue of the 2:1 ratio in the number of X chromosomes. Class III is X genes that receive a parental imprint. The X chromosome receiving a maternal imprint (Xm, yellow) is active in half of XX cells and all of XY cells, whereas the X chromosome receiving a paternal imprint (Xp, blue) is active in half of XX cells and no XY cells. Class IV comprises proposed regions of the sex chromosome heterochromatin (the heterochromatic inactive X (Xi) is illustrated here) that act as sex-specific sinks for factors (red dots) that regulate the amount of euchromatin–heterochromatin at interphase and therefore affect gene expression throughout the genome. To date, specific members of only Class I have been identified (*Sry* and spermatogenesis genes). Although evidence indicates that the number of X chromosomes leads to some sex differences in phenotype, the specific genes or chromosome regions that explain these X effects have not been identified. Class IV is particularly speculative at present because it is based on a limited number of studies. Future studies are likely to expand the importance of Classes II–IV. *Source: Adapted with permission of Elsevier from Ref. 58.*

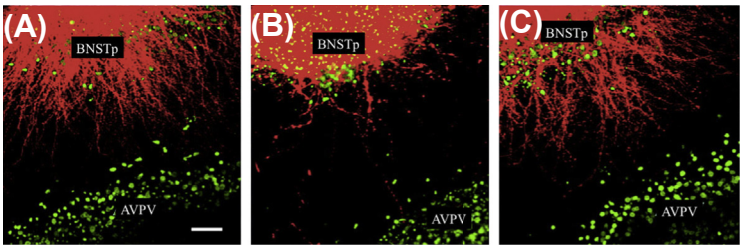

FIGURE 47.10 Target-dependent induction of neurite outgrowth in co-cultures of the principal nucleus of the bed nucleus of the stria terminalis (BNSTp) and anteroventral periventricular nucleus (AVPV). Confocal images of BNSTp-AVPV co-cultures show DiI labeling of neuritis (pseudo-colored red) that extend from the BSTp toward the AVPV. The BSTp explant was derived from a male rat on postnatal day 5 (PN5) and co-cultured with an AVPV explant (pseudo-colored green) derived from a PN9 (A) male, (B) female, or (C) androgenized female. A marked difference in the density of neurites between the co-cultures explants was observed, with many more neuritis seen when the AVPV explant was derived from a male (A) versus a female (B) rat. Treatment of neonatal female rats with testosterone during the first 9 days of life in vivo masculinized (i.e., increased) neurite outgrowth from BSTp explants (C), suggesting that the target-dependent formation of neuritis extending from the BSTp to AVPV is determined by exposure to sex steroid hormones during the neonatal period. Scale bar: 15 μm. *Source: Adapted with the permission from Ref. 217.*

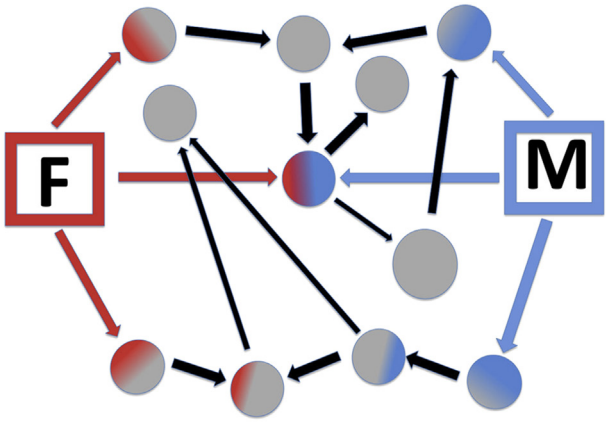

FIGURE 47.21 Schematic view of the sexome. Male- and female-biasing factors (chromosomes, hormonal profiles, etc.) are represented by the M and F boxes, respectively. These factors act on specific nodes in the gene network causing male and female bias in gene expression represented by differently colored shading. Sex bias can be propagated to other nodes, thereby increasing or decreasing gene expression and in some cases canceling out sex-biasing effects. Arnold and Lusis define the sexome as the total of all sex-biasing actions within the network.[404] Although they focus on sex bias in gene products,[404] the circles and arrows in this figure may just as well represent interactions between different organ systems. *Source: Adapted from Ref. 404.*

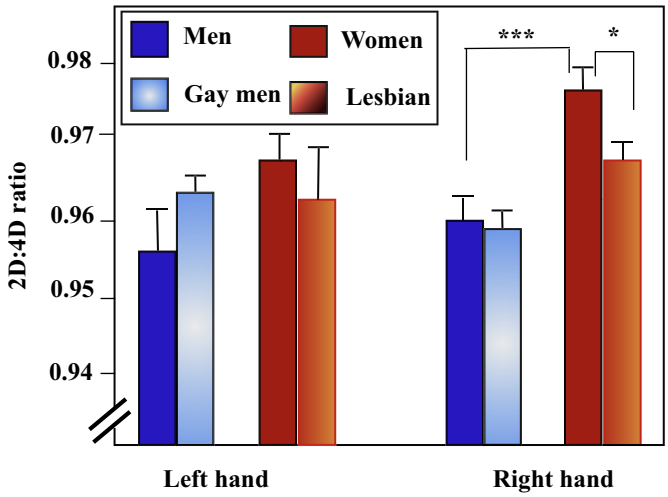

FIGURE 48.7 **Ratio of lengths of the index (2D) and ring finger (4D) as a function of sex and sexual orientation.** The 2D:4D ratio is greater in women than in men, probably due to in utero exposure to testosterone of male embryos. It is close to the male level in homosexual women, suggesting that they have been exposed to abnormally high levels of testosterone during a part of their embryonic life. For unknown reasons, these differences are more pronounced in the right hand. * = $p < 0.05$, *** = $p < 0.001$. *Source: Redrawn from Ref. 117.*

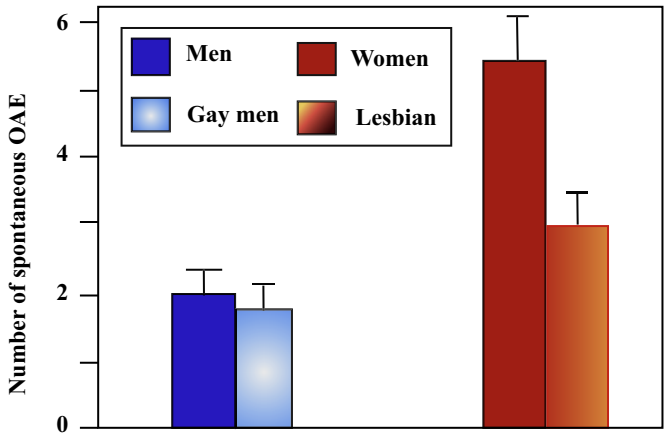

FIGURE 48.9 **Frequency of oto-acoustic emissions (OAE) evoked by click sounds measured in the right ear in men and women as a function of sexual orientation.** OAE are sexually differentiated and significantly masculinized in homosexual females. *Source: Redrawn from data in Refs 124,127.*

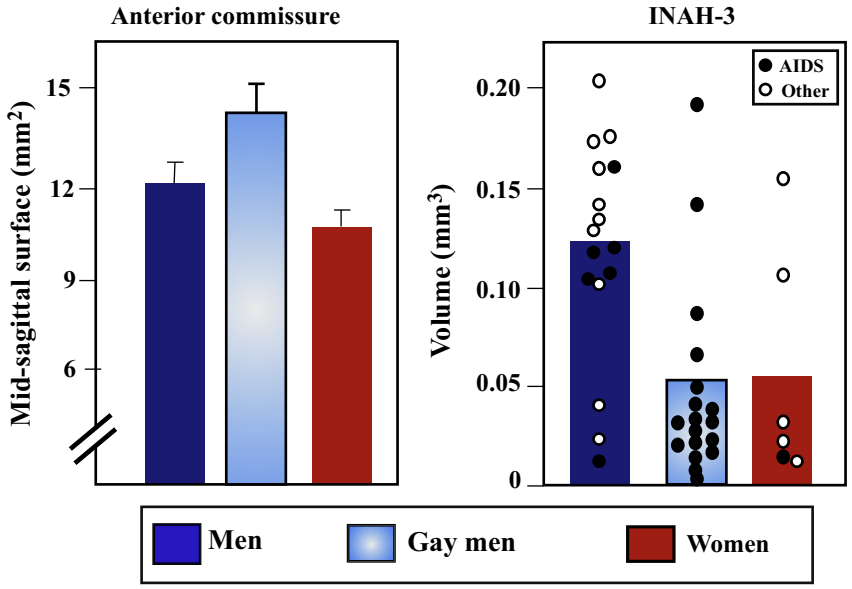

FIGURE 48.11 **Average size of the anterior commissure as estimated by its surface in the mid-sagittal plane (left) and volume of the 3rd interstitial nucleus of the anterior hypothalamus (INA-3) (right) in men, gay men, and women.** Data for the anterior commissure are presented as means ± SEM, whereas for INAH-3 the average value in each group, as well as all individual data points, are shown to clearly illustrate the partial overlap between groups despite the significant differences between men and women and between men and gay men. Individual data points are filled in subjects who died from AIDS and open in subjects who died from other causes. The smaller average size of INAH-3 in gay men cannot be accounted for by the fact that all subjects included in the study had died from AIDS since in the control group, the INAH-3 of men who died from AIDS is not smaller than in men who died from other causes. *Source: Redrawn from data in Refs 140,141.*

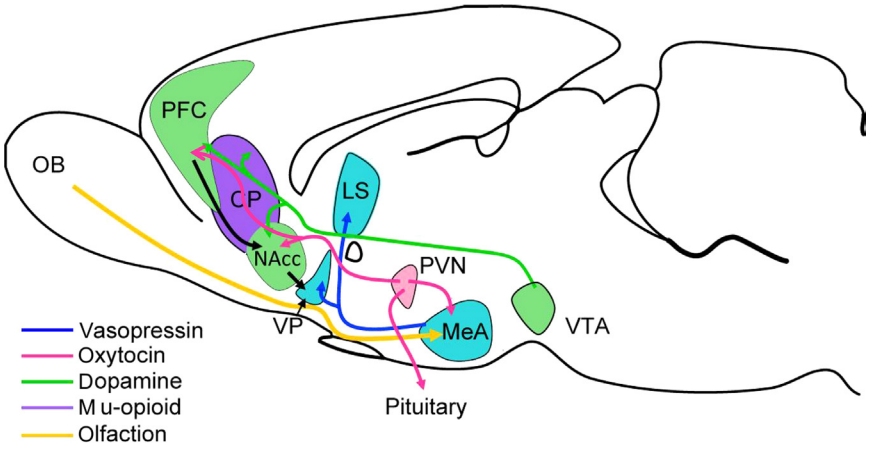

FIGURE 48.21 A schematic of the proposed neural circuitry of pair bond formation in prairie voles. Mating stimulates the release of oxytocin from neurons in the paraventricular nucleus of the hypothalamus (PVN) into the nucleus accumbens (NAcc) and prefrontal cortex (PFC) in females, and the release of vasopressin from neurons in the medial amygdala (MeA) into the ventral pallidum (VP) and lateral septum (LS) in males. Mating also stimulates the release of dopamine from neurons in the ventral tegmental area (VTA) into the NAcc and PFC. The MeA receives olfactory input from the partner and conveys the neural encoding of the olfactory signature of the partner to the striatum and LS. Mu-opioid receptors in the CP stimulate the rewarding aspects of mating. OT and AVP facilitate the processing of the olfactory signatures of the mate, and dopamine facilitates an association between the neural encoding of the social cues of the partner and the opioid-based reward and reinforcement. The actions of these neurochemicals in these circuits lead to a conditioned partner preference. *Source: Adapted from Refs 271,334.*

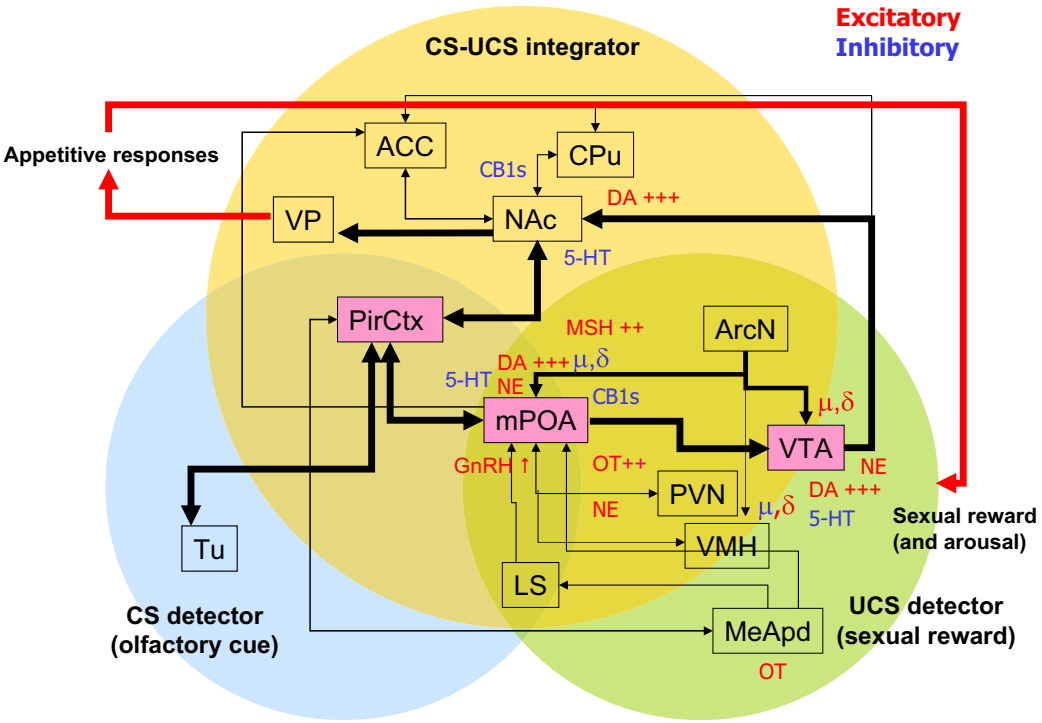

FIGURE 50.28 **Neural systems critical for the display of sexual behavior in the rat.** Appetitive behaviors made toward unconditioned or conditioned sexual incentive stimuli lead to sexual reward that is processed by three interactive systems. Two systems process olfactory stimuli and sexual reward relatively independently, whereas a third, mesolimbic DA system, acts to integrate both the conditioned olfactory cue and its rewarding sexual outcome. Three common regions, the piriform cortex, mPOA, and VTA, are activated in male and female rats by conditioned olfactory stimuli. Opioid actions in the VTA potentiate mesolimbic DA activation, whereas opioid actions in the mPOA inhibit sexual arousal and desire. Neurotransmitter systems or their receptors in red are excitatory for sexual motivation whereas those in blue are inhibitory. Black pathways signify major inputs and outputs of the system. Note that opioids can be excitatory in the VTA, inhibitory in the mPOA, or either in the VMH (depending on the receptor type). A similar system is activated in humans.[63] Abbreviations: ACC, anterior cingulate cortex; ArcN, arcuate nucleus of the hypothalamus; CB1, cannabinoid Type 1 receptor; CPu, caudate-putamen (striatum); DA, dopamine; δ, delta opioid receptors; GnRH, gonadotropin releasing hormone; LS, lateral septum; MeApd, posterior-dorsal nucleus of the medial amygdala; mPOA, medial preoptic area; MSH, melanocyte stimulating hormone; μ, mu opioid receptors; NAc, nucleus accumbens; NE, norepinephrine OT, oxytocin; PirCtx, piriform cortex; PVN, paraventricular nucleus of the hypothalamus; Tu, olfactory tubercle; VMH, ventromedial nucleus of the hypothalamus; VP, ventral pallidum; VTA, ventral tegmental area; 5-HT, serotonin. *Source: Adapted from Pfaus et al.*[683]

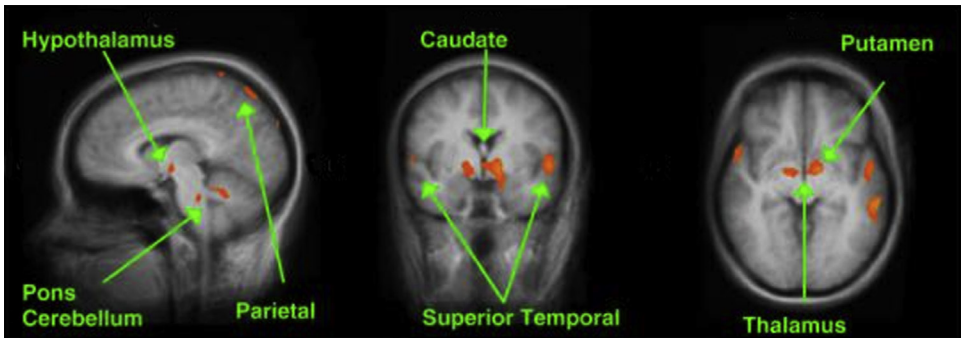

FIGURE 51.20 Sites of the maternal brain where fMRI activity was higher (indicated by red) in mothers who delivered vaginally compared to via Caesarean section while listening to their own infant crying. *Source: Modified from Swain et al., 2008.*[98]

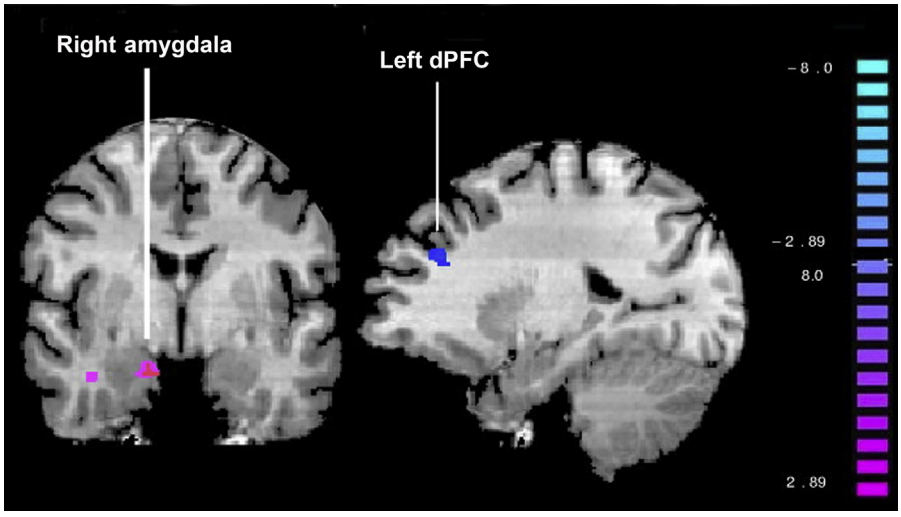

FIGURE 51.21 Sites in the parental brain where mothers (left) or fathers (right) showed greater fMRI activity in response to their own infant video compared to viewing an unfamiliar infant. Mothers showed greater activity in the right amygdala and temporal, occipital, and parietal cortices compared to fathers, while fathers had greater activity in the dorsal prefrontal cortex (dPFC). *Source: Modified from Atzil et al., 2012.*[711]
